Several limitations warrant mention. First, the retrospective training data and the lack of universally available confirmatory tests for CVA may introduce selection bias and label noise. We mitigated these by strict adherence to ERS guidelines and temporal validation. However, future multicenter prospective cohorts are needed. Second, our temporal and external validation cohorts were relatively small due to the strict pulmonary testing criteria. The limited cohort sizes may reduce the precision of performance estimates and constrain generalizability, as also reflected by the corresponding confidence intervals. Larger multicenter prospective studies are needed to further validate these findings. Third, the full 54-variable model includes coagulation profiles that are not routinely tested in primary care. To address this, our feature pruning analysis (Table S5 in

XSL•FO
RenderX

Multimedia Appendix 1) confirmed that a strictly routine 49-variable model still achieves high sensitivity (88.6%). This enables a practical 2-tier approach—using the 49-variable model for initial screening in primary care and reserving the full 54-variable model for further specialist evaluation in specialized centers [31]. Nevertheless, the pruned 49-variable model showed a marked drop in specificity to 55.8% in external validation, implying that approximately half of patients with non-CVA could be unnecessarily referred for further confirmatory testing. This high false-positive rate may compromise the cost-effectiveness of this primary-care screening strategy and warrants careful consideration in future implementation studies. Fourth, variables such as APTT had moderate missing rates. In real-world practice, this missingness is often informative (missing not at random) because doctors order specific coagulation tests based on suspected disease severity. TabPFN natively processes raw missing values to capture this clinical intuition. However, traditional benchmarks like XGBoost were evaluated on KNN-imputed data. This was due to upstream pipeline locks and the strict complete-case requirements of downstream validation frameworks. Although comparing TabPFN against an imputed baseline introduces a methodological discrepancy, it accurately reflects the real-world deployment constraints of traditional clinical algorithms. Finally, missing outpatient medication records introduce a potential confounding risk from drugs like proton pump inhibitors, diuretics, or anticoagulants. This bias was largely minimized by requiring complete PFT, which naturally excluded classic gastroesophageal reflux cough patients who are typically treated empirically without undergoing such evaluations. Additionally, TabPFN relies on high-dimensional interactions across 54 variables rather than isolated single-marker thresholds, providing resilience against localized drug-induced fluctuations. Future prospective studies with tracked medication registries remain necessary to completely decouple true biological signatures from treatment effects.

Future Directions

Two main areas require further research. First, experimental studies are needed to establish the precise biological mechanisms linking electrolyte imbalances and coagulation dysfunction to CVA. Second, prospective implementation studies in primary care settings are recommended to integrate this model into EHRs and evaluate its real-world impact on diagnostic efficiency.

Conclusions

This study prospectively validated an interpretable TabPFN model for CVA screening using routine laboratory data. TabPFN demonstrated robust performance across prospective validation cohorts and showed favorable threshold-dependent classification characteristics at the fixed cutoff. However, model comparisons were metric dependent; TabPFN achieved higher AUCs than XGBoost in the internal testing and temporal validation cohorts, whereas XGBoost achieved a higher AUC in the external validation cohort. These findings support TabPFN as a promising and accessible screening approach for CVA while avoiding claims of uniform superiority over conventional machine-learning models.

Acknowledgments

We would like to thank all the patients who participated in this study and the medical staff at the Department of Respiratory and Critical Care Medicine of Renmin Hospital of Wuhan University and Zhongnan Hospital of Wuhan University for their assistance in data collection. The authors acknowledge the use of generative AI tools (ChatGPT) for language editing and grammatical polishing of the manuscript. The authors take full responsibility for the scientific content, analyses, and conclusions of the work.

Data Availability

The datasets generated and analyzed during this study are not publicly available due to ethical restrictions and patient privacy concerns (the data contain potentially identifying information). However, the de-identified participant dataset, study protocol, and statistical analysis code are available from the corresponding author upon reasonable request, subject to approval from the institutional ethics committee. The Python implementation code for the TabPFN and benchmark models is also available from the corresponding author upon reasonable request.

Funding

This work was supported by the National Natural Science Foundation of China (No. 82370031). The funders of the study had no role in study design, data collection, data analysis, data interpretation, or writing of the report.

Abstract

Background: Acute kidney injury (AKI) is a common, life-threatening complication among hospitalized patients. Timely prediction is crucial for prevention, while accurate prognosis following onset is essential for guiding care. Although electronic health records (EHRs) provide rich longitudinal data, their high dimensionality, heterogeneity, and temporal complexity pose challenges for traditional machine learning.

Objective: The aim of this study was to develop and evaluate a transformer-based model for generalizable AKI prediction and prognosis by modeling long-range temporal dependencies and complex relationships in heterogeneous EHR data and to examine its interpretability.

Methods: We developed the Biomarker-Aware Transformer for AKI (BAT-AKI), which integrates multidimensional embeddings capturing temporal dynamics, textual descriptions, hierarchical ontology structures, and semantic relationships in EHRs. To enhance sensitivity to AKI-related biomarker fluctuations, BAT-AKI combines masked language modeling with a novel biomarker abnormality-aware pretraining task. The model was pretrained and fine-tuned for 4 tasks: AKI onset, early reversal, recovery at discharge, and 90-day post-AKI mortality. Pretraining and internal validation used data from the National Patient-Centered Clinical Research Network (PCORnet) site, with external validation across 3 additional sites.

Results: BAT-AKI achieved the strongest overall discrimination, outperforming baseline models in area under the receiver operating characteristic curve (AUROC) and area under the precision-recall curve (AUPRC) on most tasks. For AKI onset prediction, it achieved an AUROC of 0.8549 (95% CI 0.8433-0.8658) and an AUPRC of 0.6041 (95% CI 0.5786-0.6292), exceeding the second-best baseline by 2.8% in AUROC and 8.1% in AUPRC. Across prognostic tasks, BAT-AKI achieved AUROCs of 0.6006 (95% CI 0.5703-0.6318), 0.6080 (95% CI 0.5745-0.6397), and 0.8017 (95% CI 0.7708-0.8311) and AUPRCs of 0.7036 (95% CI 0.6690-0.7388), 0.7417 (95% CI 0.7082-0.7765), and 0.5063 (95% CI 0.4422-0.5684) for early reversal, recovery at discharge, and 90-day post-AKI mortality, respectively, corresponding to relative gains of 2.4% to 6% in AUROC and 3.7% to 4.1% in AUPRC over the second-best baseline. Performance remained stable across external cohorts, with AKI onset AUROCs ranging from 0.7754 (95% CI 0.7677-0.7827) to 0.7989 (95% CI 0.7885-0.8092) and AUPRCs ranging from 0.4777 (95% CI 0.4631-0.4924) to 0.5687 (95% CI 0.5495-0.5871), corresponding to relative improvements of 3.7% to 5.3% in AUROC

XSL•FO
RenderX

and 16.8% to 25.3% in AUPRC over the transformer baseline. In a low-resource setting using only 2% of the fine-tuning data, BAT-AKI achieved an AUROC of 0.7898 (95% CI 0.7759-0.8036) and an AUPRC of 0.4903 (95% CI 0.4640-0.5178) for AKI onset prediction, exceeding the second-best baseline by 4.2% in AUROC and 10.9% in AUPRC. Visualization of embeddings, attention patterns, and integrated-gradient feature attributions highlighted clinically meaningful relationships and patient-specific trajectories.

Conclusions: BAT-AKI provides generalizable AKI prediction and prognosis with consistent discrimination across institutions, while offering interpretability insights into its predictions, supporting its potential for early warning and AKI care optimization.

Introduction

Acute kidney injury (AKI) is a frequent and serious complication of hospitalization, affecting approximately 1 in 5 adult inpatients and nearly half of patients admitted to intensive care units [1]. AKI is associated with substantial short- and long-term morbidity and mortality, including in-hospital mortality rates of 10% to 20%, progression to chronic kidney disease (CKD) in up to 25% of survivors within 3 years, and increased risk of recurrent or persistent kidney dysfunction and cardiovascular complications after discharge [1,2]. Given its high prevalence and severe clinical consequences, timely prediction of AKI is essential for prevention, while accurate prognosis after AKI onset is critical for guiding post-AKI management and mitigating downstream morbidity [3].

The widespread implementation of electronic health record (EHR) systems has enabled new opportunities for data-driven AKI risk stratification [4]. EHRs capture rich, longitudinal, and multidimensional information on patients—including demographics, vital signs, diagnoses, procedures, laboratory measurements, and medications—providing a detailed view of each patient's evolving clinical trajectory that offers a solid foundation for personalized AKI prediction and prognostic modeling [5].

However, most existing AKI prediction studies rely on traditional machine learning methods that represent EHR data as cross-sectional features aggregated over fixed time windows [6-12]. Such representations obscure temporal dependencies and dynamic biomarker patterns that are central to AKI pathophysiology. To better model longitudinal data, deep learning models have increasingly been applied. Recurrent neural networks, including long short-term memory networks and gated recurrent units, have shown improved performance for AKI-related prediction tasks [13-15] but struggle to capture long-range dependencies in heterogeneous patient trajectories and provide limited token-level (ie, individual clinical events) interpretability, which is important for clinical reasoning and trust.

Transformer-based architectures overcome many of these limitations [16]. Originally developed for natural language processing and later adapted to computer vision, transformers enable flexible modeling of long-range temporal dependencies through self-attention mechanisms and support pretraining on large-scale unlabeled data followed by fine-tuning for task-specific prediction. This paradigm is particularly well suited for EHR data, where labeled outcomes may be limited but longitudinal records are abundant. Recent transformer-based models such as BEHRT [17], G-BERT [18], and DeepJ [19] treat medical codes as tokens in patient sequences, enabling models to learn contextual relationships among clinical events and supporting a range of downstream clinical prediction tasks such as mortality, length of stay, and readmission.

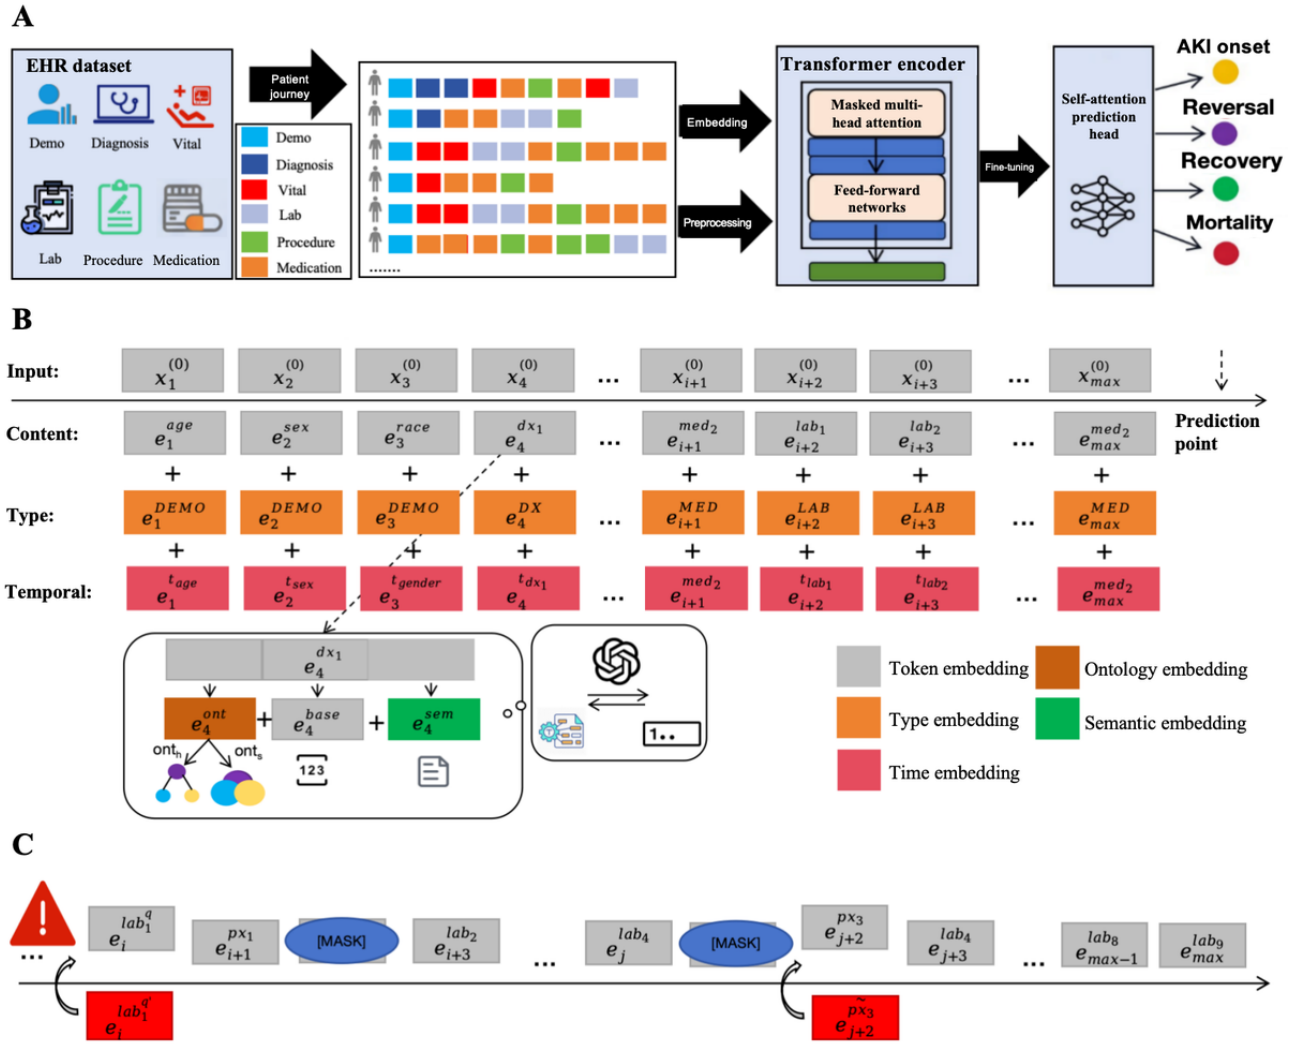
Despite these advances, existing transformer-based clinical prediction models remain limited in several aspects. First, many employ generic transformer architectures with simplified embedding schemes and standard pretraining objectives that insufficiently leverage the structured nature of EHRs and the clinical context of AKI. For example, at the embedding level, each medical code inherently corresponds to a clinically meaningful event with associated textual descriptions and ontology relationships, offering richer semantics than a simple unique identifier. Different code types (eg, diagnoses vs procedures) also exhibit distinct temporal and cooccurrence patterns that reflect underlying disease processes. Second, commonly used pretraining objectives adapted from natural language modeling treat all tokens uniformly and do not explicitly emphasize the temporal dynamics of biomarker changes that are critical for AKI development and progression. Third, most prior studies focus on predicting a single AKI-related outcome (eg, onset or a specific postonset event) in isolation, rather than learning a shared pretrained representation that can be adapted through task-specific fine-tuning to multiple AKI-related outcomes spanning early warning and postonset prognosis, which would support more comprehensive risk assessment for clinical decision-making.

To address these gaps, we propose the Biomarker-Aware Transformer for AKI (BAT-AKI), a transformer-based framework tailored to the clinical characteristics of AKI and pretrained on structured EHR data. Our contributions are threefold:

- Multisource embeddings that integrate medical code types, ontology hierarchies, textual descriptions, and temporal positions of tokens to construct semantically enriched token representations capturing contextual, semantic, and temporal relationships among clinical events.
- Biomarker abnormality-aware pretraining that explicitly models AKI-related token occurrences and biomarker fluctuation patterns, strengthening the model's ability to

XSL•FO
RenderX

learn physiological dynamics preceding onset and characterize AKI progression.



- Comprehensive evaluations across multiple AKI prediction and prognosis tasks, including AKI onset, early reversal, recovery at discharge, and 90-day post-AKI mortality, assessing predictive performance, robustness under limited fine-tuning sample sizes, cross-site generalizability, and interpretability insights derived from embedding visualization, attention analysis, and integrated-gradient attribution.

Methods

Overview of the Framework

At a high level, BAT-AKI follows the traditional pretraining-fine-tuning paradigm to model sequences of structured EHR data derived from patients' longitudinal health care journeys (Figure 1A). The framework aims to capture temporal dependencies and semantic relationships among heterogeneous clinical events to predict various outcomes.

Figure 1. Key components of the Biomarker-Aware Transformer for AKI (BAT-AKI) framework. (A) Overall architecture illustrating patient electronic health record (EHR) sequence construction, transformer-based pretraining, and fine-tuning on 4 prediction tasks. (B) Multisource embedding structure integrating content, type, temporal, ontology, and semantic representations of medical codes to form transformer inputs. (C) Pretraining includes masked language modeling and biomarker abnormality-aware pretraining to learn acute kidney injury (AKI)–related clinical patterns from structured EHR sequences through masking and perturbing tokens, with the red exclamation mark highlighting clinically abnormal biomarker perturbations.

Specifically, BAT-AKI is designed to support both AKI onset prediction and post-AKI prognosis, encompassing the following four prediction tasks: (1) AKI onset, defined as the first occurrence of AKI during hospitalization; (2) AKI early reversal, defined as reversal based on serum creatinine (SCr) falling back below the AKI threshold and remaining stable for at least 24 hours, occurring within 7 days after onset; (3) AKI recovery, defined among patients discharged alive as kidney function recovery at discharge, indicated by the final SCr level returning toward the pre-AKI baseline [20]; and (4) 90-day post-AKI mortality, defined as all-cause death within 90 days following AKI onset. These outcomes were defined according to the Kidney Disease: Improving Global Outcomes criteria [21] and established clinical guidelines [22]. Detailed descriptions are provided in Method S1 in Multimedia Appendix 1.

Building on this design, BAT-AKI comprises three major components corresponding to different stages of the modeling pipeline: (1) multisource embedding—embedding enrichment integrating multisource clinical information to construct semantically rich clinical event sequences (Figure 1B), (2)

XSL•FO
RenderX

biomarker abnormality-aware pretraining—extending the standard masked language modeling (MLM) objective with a biomarker abnormality-aware pretraining (BAP) task to explicitly model AKI-related token occurrences and physiological fluctuations (Figure 1C), and (3) model fine-tuning with task-specific prediction heads for downstream evaluation.

Data Resources and Processing

This study leveraged EHR data from 4 academic health systems within 2 PCORnet clinical research networks—the Greater Plains Collaborative (GPC) and PaTH [23,24]—for model pretraining, internal validation, and external validation. BAT-AKI was pretrained and fine-tuned using University of Kansas Medical Center (KUMC) data from 2009 to 2020 and evaluated on a temporally distinct 2021 KUMC cohort and 3 external PCORnet sites from the same year: the University of Iowa, the University of Texas Southwestern Medical Center, and the University of Pittsburgh.

The study population included adult patients (aged ≥18 years) with at least 2 SCr measurements during hospitalization. To ensure sufficient observation time for AKI development, encounters with a length of stay of less than 2 days were excluded. Additional exclusions were (1) AKI occurring on the day of admission, to focus on hospital-acquired AKI; and (2) patients with prior CKD diagnoses but without available SCr measurements within the preceding year to reliably determine baseline SCr. All eligible encounters were treated as independent visits to maximize data use while ensuring that encounters from the same patient did not appear in both the training and test sets.

We used a unified data-observation window across all downstream tasks. Model inputs included the patient's complete diagnosis history before the index admission together with clinical events recorded during the index hospitalization. For AKI patients, model inputs comprised clinical events recorded during the index hospitalization through 24 hours before AKI onset; for non-AKI patients, index hospitalization events up to 24 hours before the last SCr measurement were used. Sharing a single preonset window across tasks, rather than tailoring the input to each outcome, enables assessment of how much of the AKI course—onset and the trajectory that follows it—is captured in the representation formed before onset, while producing risk and prognosis together from a single clinically actionable decision point.

Six EHR data categories were used: demographics, diagnoses, procedures, laboratory tests, medications, and vital signs. Data were standardized using *ICD* (*International Classification of Diseases*), Current Procedural Terminology (CPT), Logical Observation Identifiers Names and Codes (LOINC), Anatomical Therapeutic Chemical Classification System (ATC), and RxNorm, with textual, ontological, and semantic information obtained from the coding systems and Unified Medical Language System (UMLS) [25]. Continuous laboratory and vital-sign measurements were discretized into quantile-based categorical tokens. Detailed preprocessing procedures are provided in Method S2 in Multimedia Appendix 1.

Preliminary on EHR Data

Throughout, we use "clinical event" to refer to a recorded observation (eg, a laboratory measurement, diagnosis, medication, or procedure), "code" to refer to its standardized identifier, and "token" to refer to the discrete unit derived from it that serves as model input. In this study, each hospital patient encounter is represented as a temporally ordered sequence of discrete medical codes corresponding to individual clinical events. Each medical code is defined as a tuple (c_i, d_i, t_i), where $c_i \in C$, $di \in D$, and $t_i \in T$. Here, c_i denotes a unique medical code that belongs to the overall code vocabulary C; d_i indicates the event type of D, belonging to 1 of the 6 categories of EHR data types described above; and t_i is the corresponding timestamp from the event time set T. Formally, a patient visit can be expressed as , where m is the number of events in the sequence, limited by the maximum length M. For downstream prediction tasks, each patient visit v is associated with a binary labeled outcome vector $y_{ft,s} \in \{0,1\}$, where $s = 1, \ldots, S$ and S is the total number of downstream tasks.

Embedding Construction

We transform each triplet (c_i, d_i, t_i) into a set of embedding vectors , encoding the code's content, type, and temporal position. These embeddings are then summed to form the overall code embedding:  where "+" denotes element-wise vector addition.

First, we initialize a base embedding  as a randomly initialized unique identifier for the clinical event c_i. Next, we obtain a semantic embedding  that captures the textual meaning of the event. Specifically, the official text description of each code is retrieved from the corresponding terminology [26-28] and encoded using a pretrained Sentence-BERT model [29].

We then incorporate hierarchical ontology information by identifying the ancestor concepts of the clinical event c_i within its respective coding hierarchy and obtaining their embeddings, denoted as . For example, the *ICD-9* code 250 (diabetes mellitus) belongs to the higher-level category "Endocrine, Nutritional and Metabolic Diseases, and Immunity Disorders," and its hierarchical ontology embedding is derived accordingly. In parallel, we extract semantic relations from the UMLS by retrieving the semantic type of c_i and encoding it as . For instance, the LOINC code 6037-8 (base deficit in blood) is classified in UMLS as "Finding," a semantic type it shares with diagnostic concepts such as *ICD-9* code 276 (disorders of fluid, electrolyte, and acid-base balance). Unlike the category-based hierarchical structure, the semantic ontology captures cross-terminology relationships that mirror real-world clinical associations. Finally, we define the overall code embedding for the clinical event as the concatenation of these 4 components:

where "||" denotes vector concatenation.

XSL•FO
RenderX

To ensure consistent embedding dimensionality across all tokens, placeholder vectors are assigned when certain subembeddings are unavailable. Further implementation details, including the specific transformations and class definitions used for the semantic and ontology embeddings, are provided in Method S3 in Multimedia Appendix 1.

Sequence Encoding by Transformer Layers

The resulting embeddings $E = [e_1, e_2, \ldots e_m]$ undergo dropout regularization and are then fed into a transformer encoder [16] as the initial hidden representation $H^{(0)}$, which models temporal dependencies and interevent interactions across the entire patient visit sequence. Each encoder layer $l = 1, \ldots, L$ consists of a multihead self-attention (MHSA) module [16] followed by a position-wise feed-forward network (FFN), both equipped with residual connections, dropout, and layer normalization (LN):

After L stacked layers, the encoder outputs contextualized hidden representations:

where each hidden state  corresponds to the i-th token at the L-th layer in the visit sequence and captures its clinical and temporal context by attending to all other tokens within the same encounter.

Pretraining Objectives

During pretraining, a composite learning objective is adopted. The first component is MLM, following the approach introduced by Devlin et al [30], where a prediction head uses the hidden representations of the unmasked tokens to infer the identity of the masked tokens. Specifically, a proportion ρ_{MLM} of the tokens in each v are randomly masked, resulting in prediction pairs . The loss is defined as:

where I denotes the set of masked positions in a patient token sequence v, e_i is the original token at masked position I, $v_{\backslash I}$ represents the same sequence with tokens in I replaced by the special [MASK] token, and θ represents the transformer model parameters.

The second component is the BAP objective. Inspired by previous studies leveraging both perturbation-based pretraining [30,31] and replacement-based discriminative objectives [32,33], we propose a novel BAP pretraining objective to enhance the model's semantic understanding and enable it to capture temporal relationships among different AKI-relevant clinical events. These events were identified by a label-informed selection procedure using encounter-level token-frequency differences with a Mann-Whitney U test, then filtered according to prior clinical evidence [12,34,35], forming an AKI-related lexicon V_{aki} (eg, diagnosis code of "CKD," laboratory measurement code of "blood urea nitrogen," and laboratory measurement code of "anion gap"). The detailed composition of V_{aki} is provided in Method S4 in Multimedia Appendix 1.

For each patient visit sequence v, a proportion ρ_{BAP} of tokens belonging to the AKI-related lexicon V_{aki} are perturbed according to the following rules:

Each quantitative token $e^q \in V_{aki}$ has a probability ρ_{BAP} of being perturbed by applying 1 of 3 quantile-based perturbation rules: (1) symmetric inversion: $e^{q'}$, where $q' = Q + 1 - q$ (eg, when Q=6, quantile $6 \leftrightarrow 1$, $5 \leftrightarrow 2$, $4 \leftrightarrow 3$); (2) random substitution: q' is randomly sampled from $Q\backslash\{q\}$; (3) cyclic shift: $q' = ((q + 1) \bmod Q) + 1$ (eg, $1 \rightarrow 3$, $2 \rightarrow 4$, $3 \rightarrow 5$)

Each categorical token $e^d \in V_{aki}$ with code type $d \in D$, has a probability ρ_{BAP} of being perturbed with its replacement $e^{\sim d}$, randomly drawn from the same code-type subset in V_{aki}.

Each sequence is assigned a binary supervision label vector $y_{bap} = \{y_{bap,1}, y_{bap,2}, \ldots, y_{bap,m}\}$, where $y_{bap,i} = 1$ indicates that the token at timestamp i has been perturbed and $y_{bap,i} = 0$ otherwise. Accordingly, the BAP loss is formulated as a cross-entropy loss, defined as:

where $\hat{y}_{bap,i}$ denotes the predicted probability, obtained from a prediction head applied to the hidden representation of the token at i.

Finally, the overall pretraining objective is defined as a weighted sum of the 2 components:

where λ is a weighting coefficient that balances the 2 loss components.

Patient Representation and Fine-Tuning

After pretraining, each patient sequence v is encoded by the transformer encoder into a contextualized hidden representation: $H^{(L)} = [h_1^{(L)}, h_2^{(L)}, \ldots, h_m^{(L)}]$. These representations can be aggregated by self-attention pooling during the fine-tuning process, which is defined as follows:

where ω is a learnable vector of weights, and α_i are the normalized attention weights assigned to the i-th patient token within the patient sequence v.

Finally, the patient-level representation x is fed into a simple FFN prediction head, $\hat{y}_{ft,s} = FFN(x)$, to predict each of the S downstream outcomes. For the imbalanced AKI onset and 90-day post-AKI mortality tasks, class weighting was applied using $w_{pos} = N_{neg}/N_{pos}$, with the negative class weight fixed to 1. Equal class weighting ($w_{pos} = 1$) was used for AKI early reversal and recovery based on validation performance. Model selection and early stopping were based on validation performance, and final performance was evaluated on the test set. F_1-scores were calculated using a fixed probability threshold of .5.

XSL•FO
RenderX

Model Evaluation

BAT-AKI was evaluated along the following three axes: (1) performance on multiple AKI prediction and prognosis tasks; (2) robustness in low-resource settings by fine-tuning with varying training sizes; and (3) cross-site generalizability in external cohorts. For the primary evaluation, BAT-AKI was compared with 5 baseline models on all 4 downstream tasks using the largest available fine-tuning dataset. To ensure temporal consistency, a fixed 2021 temporal split was used as the test set across all sites. In the low-resource experiments, subsets were drawn from the fixed fine-tuning set by stratified random sampling with respect to the AKI onset label, while the fixed temporal test set was used for evaluation throughout. For each model and task, performance is reported with 95% CIs obtained from 5000 bootstrap resamples of the test set. Models were compared using a paired bootstrap test on the same resamples, with 2-sided *P* values reported [36,37]. We additionally evaluated AKI onset performance within demographic subgroups on the internal temporal test set, stratified by race into White, Black, and other groups and by age into strata of individuals aged younger than 65 years, 65 to 79 years, and 80 years or older, with the transformer baseline as comparator. The other race group included Asian, Native American, and unknown race categories.

We used 5 baseline models. Four are widely benchmarked for AKI and EHR prediction—the vanilla transformer [16], long short-term memory [38], and extreme gradient boosting (XGBoost) [39], and the general-purpose EHR model, Reverse Time Attention (RETAIN) [40]—and the fifth is a recent heterogeneous relation-aware transformer (HEART) [33] pretrained on EHR data. Like BAT-AKI, HEART was pretrained and then fine-tuned on the downstream tasks. The design of the XGBoost baseline is further detailed in Method S5 in Multimedia Appendix 1. All models were evaluated on the same temporal test set using the area under the receiver operating characteristic curve (AUROC), the area under the precision-recall curve (AUPRC), and the F_1-score calculated at a fixed probability threshold of .5.

To evaluate model generalizability, we compared BAT-AKI with a structurally equivalent transformer baseline. Both were developed on the KUMC dataset—BAT-AKI was pretrained and then fine-tuned, whereas the transformer baseline was trained from scratch—and then applied directly to the external sites. Performance was assessed across all 4 downstream prediction tasks.

To ensure fair comparison, all baseline models were implemented under a consistent training framework with aligned input dimensions, optimization strategies, and early stopping criteria while allowing task- and model-specific hyperparameter tuning. Key training configurations, hyperparameter settings, and the computational environment are provided in Table S1 and Method S5 in Multimedia Appendix 1.

Model interpretability was evaluated using 3 approaches. First, t-distributed stochastic neighbor embedding (t-SNE) [41] was applied to visualize static token embeddings in 2D. In parallel, patient-level representations were derived from the demographic-token hidden states of the pretrained BAT-AKI encoder. These representations were reduced with principal component analysis, clustered into subgroups by spectral clustering, and visualized in two dimensions with t-SNE, after which cluster-level AKI incidence was summarized to characterize the subgroups. Second, interpretability was examined through a case study by analyzing token-level attention weights from the transformer encoder to assess temporal patterns in laboratory representations. Third, we applied integrated gradients [42] to quantify feature importance for AKI onset prediction, complementing the case study. Detailed procedures are provided in Method S6 in Multimedia Appendix 1.

Ethical Considerations

This work constitutes a retrospective secondary analysis of routinely collected clinical records. The institutional review board (IRB) at the University of Florida reviewed the study (IRB202400190) and determined it to be exempt on the basis that it involved only preexisting, deidentified patient records. The records analyzed were generated in the course of routine clinical care, and no participant was recruited, contacted, or observed prospectively for this work. With respect to confidentiality, every record was rendered anonymous under the Safe Harbor provisions of HIPAA (Health Insurance Portability and Accountability Act) before it reached the investigators, and access was granted after review by the GPC and PaTH Data Request Oversight Committee, under executed data use agreements with the GPC and PaTH networks that bar reidentification and prohibit release of record-level data beyond the study team. No compensation arises, as the study entailed no participant contact. Finally, neither the manuscript nor the supplementary materials reproduce any image or other material through which an individual could be recognized.

Results

Cohort Description

The study included 247,658 adult encounters from 129,731 unique patients at KUMC (2009-2021), with a mean of 1.9 (SD 2.2) encounters per patient, for model pretraining and internal evaluation along with 3 external validation cohorts from 2021. Within the KUMC cohort, 198,885 encounters were used for pretraining. The fine-tuning cohort comprised 37,909 encounters, including 33,115 training and 4794 validation encounters, while 10,864 encounters constituted the fixed internal temporal test set. The 3 external sites were used entirely as external testing cohorts. In accordance with the applicable data use agreements, the external institutions are reported anonymously as site A, site B, and site C throughout the manuscript. As summarized in Table 1, sex distribution was balanced (male 49.7%-51.9%), mean age ranged from 58.0 (SD 17.3) to 64.7 (SD 17.0) years, baseline SCr values ranged from 0.86 to 0.94 mg/dL, and AKI incidence ranged from 12.9% to 15.6% across sites. Detailed code-based definitions for each comorbidity are provided in Table S2 in Multimedia Appendix 1.

[g]CKD: chronic kidney disease.

Model Performance on AKI Outcomes

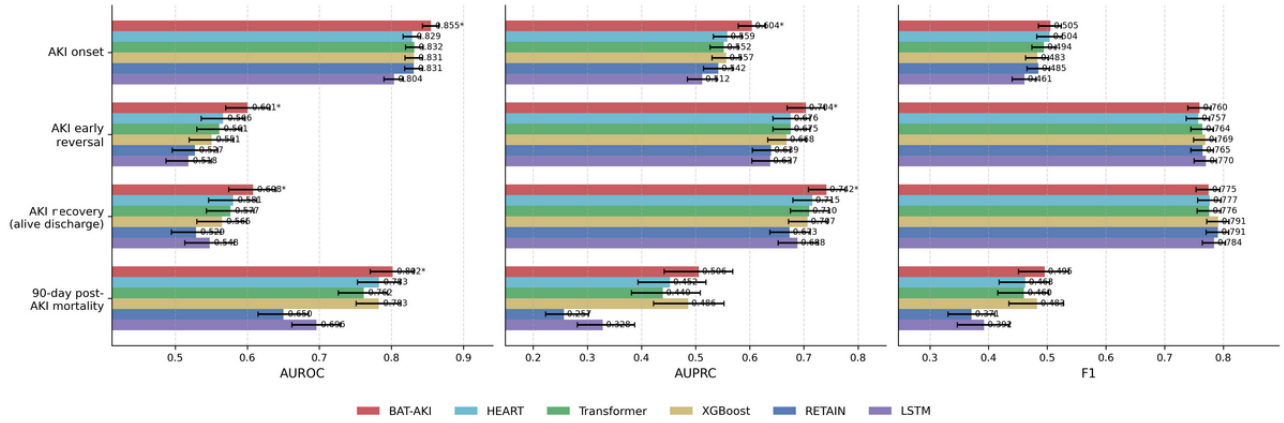
As shown in Figure 2, BAT-AKI achieved superior discrimination on most tasks. For AKI onset prediction, BAT-AKI outperformed the second-best model by 2.8% in AUROC, 8.1% in AUPRC, and 0.3% in F_1-score. For 90-day post-AKI mortality, it yielded improvements of 2.4% in AUROC, 4.1% in AUPRC, and 2.7% in F_1-score over the second-best model. For AKI early reversal and recovery, BAT-AKI improved AUROC by 6% and 4.7%, and AUPRC by 4.1% and 3.7%, respectively. However, at the fixed probability threshold of .5, its F_1-scores were 1.4% and 2.1% lower than those of the best-performing model for early reversal (P=.04) and recovery (P=.003), respectively. Detailed numerical results and statistical comparisons of each baseline against BAT-AKI are provided in Table S3 in Multimedia Appendix 1.

Furthermore, we evaluated the performance of BAT-AKI and baseline models on the primary task of AKI onset prediction in a low-resource setting, that is, under different fractions of the full fine-tuning dataset (1%, 2%, 5%, 15%, 25%, 50%, 75%, and 100%) to examine how performance scales with increasing training data. As shown in Figure 3, BAT-AKI achieved favorable AUROC and AUPRC beginning at 2% of the full

XSL•FO
RenderX

dataset, consistently outperforming all baselines, while the transformer and XGBoost models required approximately 25% of the data to reach comparable performance. HEART, included as a pretrained EHR model benchmark, outperformed the conventional baselines in the low-resource regime but stayed below BAT-AKI at all sample sizes. With more fine-tuning data, HEART, Transformer, and XGBoost improved substantially and converged, yet still trailed BAT-AKI in both AUROC and AUPRC.

Figure 2. Performance of Biomarker-Aware Transformer for AKI (BAT-AKI) and baseline models on downstream tasks. Error bars denote 95% bootstrap CIs on the fixed internal test set after full fine-tuning. Asterisks indicate significant paired bootstrap comparisons between the best-performing and the second-best model for each task and metric (transformer for acute kidney injury [AKI] onset area under the receiver operating characteristic curve [AUROC] and heterogeneous relation-aware transformer [HEART] for all other starred comparisons; $P<.05$); they do not indicate significance against all baseline models. AUPRC: area under the precision-recall curve; F1: F1-score; LSTM: long short-term memory; RETAIN: Reverse Time Attention; XGBoost: extreme gradient boosting.



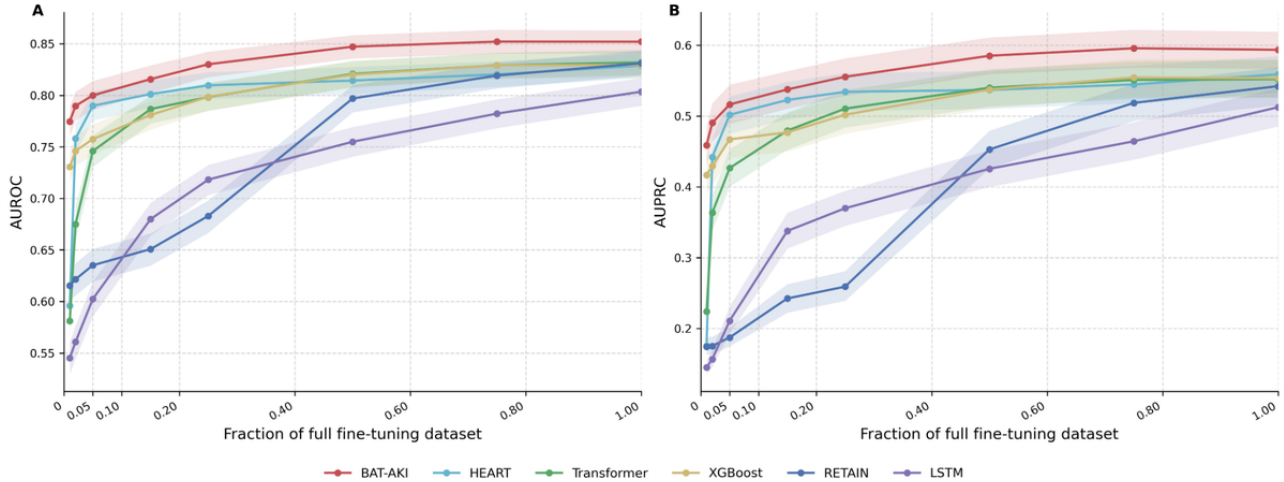


Figure 3. Performance scaling with increasing fine-tuning sample size for the acute kidney injury (AKI) onset prediction task. Results are evaluated on the fixed internal test set after fine-tuning with increasing fractions of the full fine-tuning pool. Error bars denote 95% CIs. Biomarker-Aware Transformer for AKI (BAT-AKI) significantly outperformed the second-best model at each sample size for both (A) area under the receiver operating characteristic curve (AUROC) and (B) area under the precision-recall curve (AUPRC) based on paired bootstrap testing. HEART: heterogeneous relation-aware transformer; LSTM: long short-term memory; RETAIN: Reverse Time Attention; XGBoost: extreme gradient boosting.

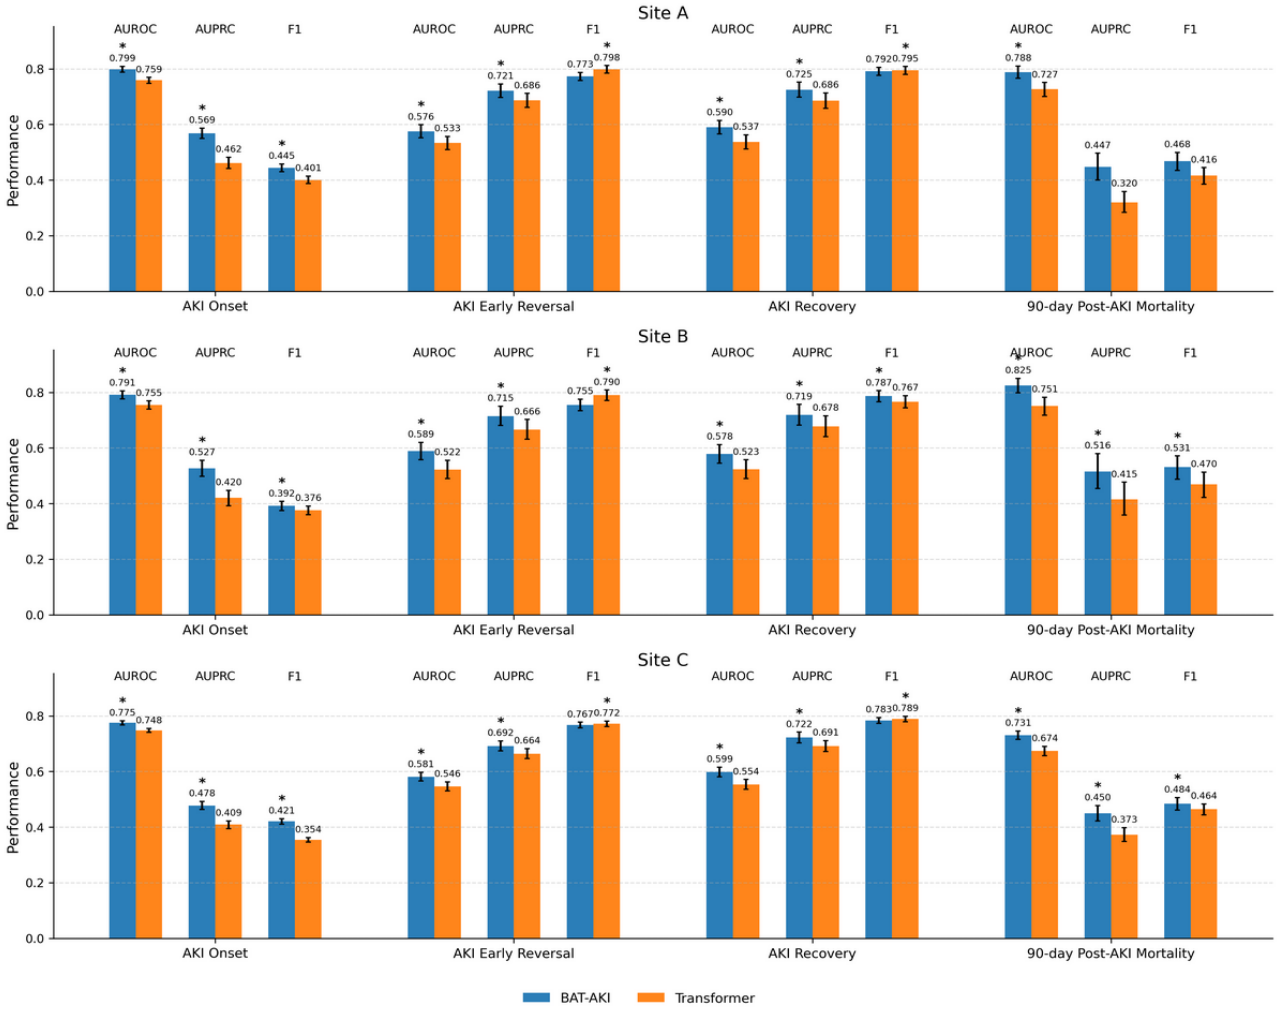
In low-resource settings (<5%), BAT-AKI achieved relative improvements of 4.2% to 6.1% in AUROC and 10.1% to 10.9% in AUPRC over the second-best model. In the moderate-scale setting (5%-25%), the relative improvements were 1.3% to 2.5% in AUROC and 2.8% to 4% in AUPRC. In high-resource settings (≥25%), BAT-AKI maintained relative improvements of 2.4% to 3.2% in AUROC and 6.2% to 8.4% in AUPRC, consistently ranking as the best-performing model across all dataset sizes.

Additional ablation studies were performed to evaluate the contribution of each embedding component and the BAP pretraining task (Method S7 in Multimedia Appendix 1). During pretraining, semantic, temporal, and ontological embeddings consistently improved overall token prediction accuracy, whereas the BAP module yielded substantially larger gains in modeling AKI-related token abnormalities and fluctuation patterns. For the primary AKI onset prediction task, all components, including the BAP module, contributed meaningfully, as removing any component resulted in significant performance degradation (Tables S4 and S5 in Multimedia Appendix 1). Sensitivity analyses comparing 3 BAP strategies—symmetric inversion, random substitution, and cyclic shift—revealed distinct effects on token-level fluctuation accuracy and downstream AKI onset performance (Method S8 and Figure S1 in Multimedia Appendix 1). Based on these



XSL•FO
RenderX

results, symmetric inversion was selected as the final strategy, with additional analyses performed under varying MLM and BAP ratios (Figure S2 in Multimedia Appendix 1). We also evaluated AKI onset performance across demographic subgroups, stratified by race and age (Tables S6 and S7 in Multimedia Appendix 1). Performance differed across subgroups, with wider CIs in the smaller subgroups. The AUROC advantage was significant in the White (P<.001) and other (P=.04) subgroups but not in the Black subgroup (0.8084 vs 0.8048; P=.73) and was significant across all age strata. AKI incidence was 16.1% in the Black subgroup and 12.2% in the White subgroup. We further evaluated the preadmission acute kidney failure diagnosis code through sensitivity analyses (Tables S11 and S12 in Multimedia Appendix 1) and compared class weighting with equal weighting for AKI early reversal and recovery (Table S13 in Multimedia Appendix 1).

Model Generalizability Across Multiple Clinical Datasets

As shown in Figure 4, we further compared the generalizability of BAT-AKI and the transformer baseline across different clinical datasets. For the AKI onset prediction task, BAT-AKI achieved consistent improvements over the baseline model, with AUROC gains of 2.8 to 4.0 percentage points, AUPRC gains of 6.9 to 10.7 percentage points, and F_1-score gains of 1.6 to 6.6 percentage points across the 3 external validation sites. For the AKI early reversal and AKI recovery prediction tasks, the model achieved AUROC improvements of 3.5 to 6.7 percentage points and 4.5 to 5.5 percentage points, respectively, and AUPRC improvements of 2.8 to 4.9 percentage points and 3.1 to 4.1 percentage points. In the 90-day post-AKI mortality prediction task, BAT-AKI achieved AUROC improvements of 5.7 to 7.4 percentage points, AUPRC improvements of 7.7 to 12.7 percentage points, and F_1-score gains of 2.0 to 6.2 percentage points across all external sites. The corresponding numerical results are summarized in Table S8 in Multimedia Appendix 1.

Figure 4. Generalizability comparison of Biomarker-Aware Transformer for AKI (BAT-AKI) and the transformer on downstream acute kidney injury (AKI) prediction tasks across multiple clinical datasets. Error bars denote 95% bootstrap CIs. Asterisks indicate significant paired bootstrap comparisons between BAT-AKI and the transformer for each metric, placed above the model with the higher value (P<.05). AUPRC: area under the precision-recall curve; AUROC: area under the receiver operating characteristic curve; F1: F1-score; LSTM: long short-term memory; RETAIN: Reverse Time Attention; XGBoost: extreme gradient boosting.

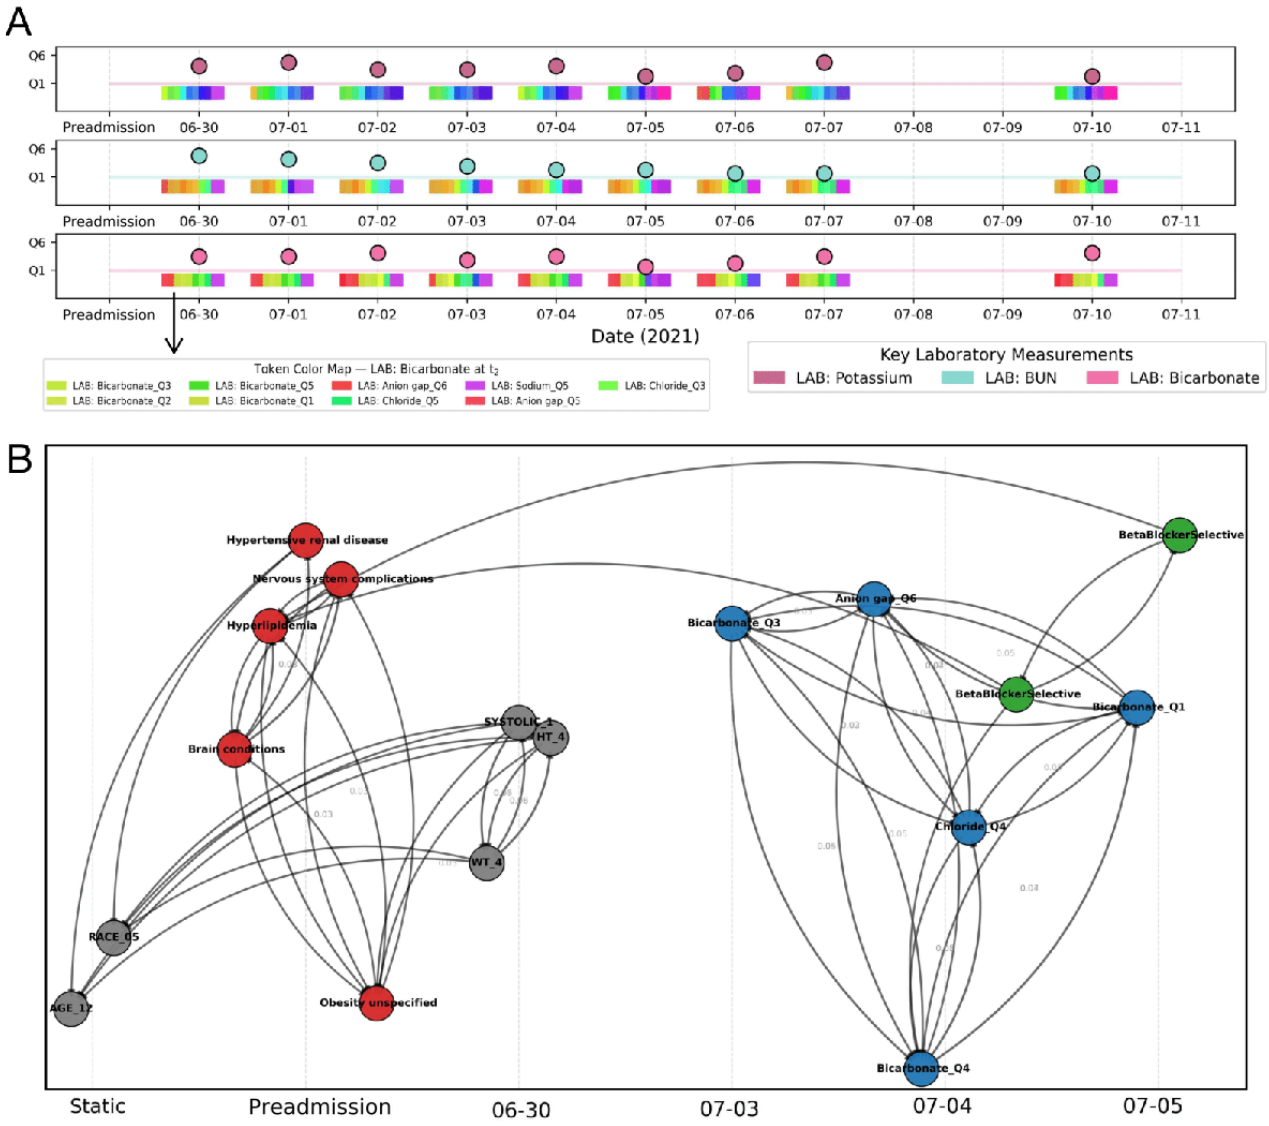
Visualization of Pretraining Representations

To characterize the representation structure learned during pretraining, we visualized token-level embeddings and patient-level representations from BAT-AKI in Figure 5.

Figure 5A shows that tokens from broad clinical categories formed distinct clusters in the latent space; for example, diagnosis events were primarily distributed in the lower-central region, with finer-grained subcategories such as circulatory system diseases (*ICD-9* 390-459) forming compact clusters. Figures 5B and C display patient-level representations derived from demographic tokens, revealing 6 major patient subgroups with distinct AKI incidence rates. Cluster 2 represents a small high-risk group comprising 1.1% of the cohort with 93.3% AKI incidence, consisting of older patients with a mean age of 67.0 (SD 14.4) years whose SCr rose from a mean baseline of 0.929 (SD 0.15) mg/dL to a mean of 1.90 (SD 0.61) mg/dL at AKI onset, with 48.3% reaching stage 2 or above; clusters 4, 5, and 6 correspond to low-risk groups with AKI incidence rates of 5.7%, 7.7%, and 7.2%, respectively.

Figure 5. Visualization of learned embeddings and patient representations from the pretrained Biomarker-Aware Transformer for AKI (BAT-AKI) model. (A) Static token embeddings from the pretrained BAT-AKI model visualized by t-distributed stochastic neighbor embedding (t-SNE), colored according to hierarchical ontology groups. (B) Patient subgroups clustered from demographic-token hidden states of the pretrained BAT-AKI encoder visualized by t-SNE. (C) AKI incidence rates within each patient cluster, with the red dashed line indicating the average incidence rate across all patient subgroups.

Case Study of Attention Mechanisms



We further visualized the model's attention on a representative case (subject ID 2648, male, age 62 years) with a cardio-metabolic-renal profile, including essential hypertension, hypertensive CKD, and obesity, as shown in Figure 6. His clinical trajectory comprised 475 events over a 13-day hospitalization.

Figure 6A illustrates which earlier events the model relied on most when tracking each biomarker, showing temporal trends in potassium, blood urea nitrogen, and bicarbonate together with the top 10 most-related events for each. Potassium exhibited intermittent increases between June 30 and July 10; blood urea nitrogen showed an overall downward trend; and bicarbonate rose steadily from July 5 to July 10. For bicarbonate, on June 30, attention was driven primarily by events related to bicarbonate, anion gap, and chloride. By July 2, the pattern broadened to include sodium- and chloride-related events. By July 10, additional contributions emerged from sodium, chloride, and events linked to electrolyte and fluid disorders.

Figure 6B shows the sequential attention flow across demographic, vital sign, diagnostic, medication, and laboratory events for the same patient during the first week of hospitalization, tracing how the model connects earlier clinical events to the abnormal biomarker events that precede AKI onset. Demographic and vital events such as age, race, height, and weight directed attention toward obesity and hypertensive renal disease. As one such pathway, the medication event "Beta Blocker Selective" attended to cardio-metabolic disorder events. Laboratory measurements such as bicarbonate, chloride, and anion gap exhibited attention connections within and across time steps. Beyond these event-level attention signals, we further quantified the importance of each concept to the AKI onset prediction for this case using integrated gradients (Figure S4 in Multimedia Appendix 1). Among the highest-ranked concepts were renal-function and hemodynamic measures (SCr, blood urea nitrogen, estimated glomerular filtration rate, and diastolic blood pressure), alongside procedure and medication concepts that also ranked highly.

RenderX

Figure 6. Visualization of attention patterns from the pretrained Biomarker-Aware Transformer for AKI (BAT-AKI) model on a representative case (subject ID 2648). (A) Temporal trends of 3 laboratory measurements and the top-10 events most related to each. For each measurement, these are the earlier events the model linked to it most strongly. The detailed color assignments for all events are provided in Figure S3 in Multimedia Appendix 1. (B) Visualization of the most-attended events identified by the model across multiple time steps during the first week of hospitalization. Each point is a clinical event, and events are arranged left-to-right along the hospital timeline, so the chain can be followed as the hospitalization unfolds. Each arrow connects a pair of events that the model linked through attention, running from the attending event to the event it attends to. Colors indicate the type of event. Only arrows with attention scores greater than 0.001 are displayed, and those with scores greater than 0.02 are annotated with their score. BUN: blood urea nitrogen.

Discussion

Main Findings

In this study, we developed BAT-AKI, a transformer-based framework that couples multisource embeddings with a BAP objective, and showed that a single pretrained model can be fine-tuned across the AKI course—from onset prediction to postonset prognosis—while providing token- and patient-level interpretability insights.

Our results highlight the importance of both multisource embedding design and the BAP pretraining objective. As shown in Figure 1B, incorporating ontology information improved the hierarchical structure of token representations (Figure 5A), strengthening token-level (ie, individual clinical event) attention patterns, while textual embeddings enriched semantic context and improved pretraining performance and downstream AKI onset prediction (Table S4 in Multimedia Appendix 1). The BAP objective increased model sensitivity to AKI-related fluctuations and improved abnormal-token detection accuracy from 0.7595 to 0.9178, a 21% relative improvement, leading to consistently better performance across all 4 downstream tasks compared with models pretrained without BAP (Table S5 in Multimedia Appendix 1). These findings underscore the value of incorporating task-relevant signals into pretraining for EHR modeling.

Across downstream prediction tasks, BAT-AKI demonstrated strong performance and adaptability, consistently outperforming baseline models in AUROC and AUPRC with simple fine-tuning (Figure 2; Table S3 in Multimedia Appendix 1), with the largest relative gains on the lower-prevalence postonset prognostic tasks. However, improvements in AUROC and AUPRC did not

XSL•FO
RenderX

uniformly translate into higher F_1-scores at the fixed probability threshold of .5, underscoring that F_1-score performance depends on the selected classification threshold. In low-resource settings, BAT-AKI reached, with only 2% of the fine-tuning data, a level of performance that HEART required 5% and the transformer and XGBoost approximately 25% of the data to match (Figure 3). These findings suggest that pretraining provides a robust initialization that enables efficient adaptation to diverse AKI-related prediction tasks, particularly when labeled data are limited.

BAT-AKI also demonstrated superior cross-site generalizability compared with the transformer baseline. As shown in Figure 4 and summarized in Table S8 in Multimedia Appendix 1, across the external validation sites, BAT-AKI consistently achieved higher AUROC and AUPRC, indicating improved robustness to site-level heterogeneity. This suggests that large-scale pretraining enables learning of transferable and domain-invariant representations, whereas models trained solely on site-specific fine-tuning data may be more susceptible to performance degradation in external settings.

Finally, to understand how BAT-AKI encodes clinical knowledge, we examined its embedding space and attention patterns through pretraining visualizations and a case study. Token embeddings formed coherent clusters reflecting the hierarchical ontology structure (Figure 5A), and ablation confirmed that removing any embedding component reduced token-prediction accuracy and degraded AKI onset performance (Method S7 and Table S4 in Multimedia Appendix 1), indicating that the embedding layer captures semantic and structural relationships beyond token identity. Demographic-based representations alone separated patients into subgroups with distinct AKI incidence (Figures 5B and C), while attention shifted across related laboratory tokens to track temporal biomarker patterns (Figure 6A) and integrated information across demographics, laboratory tests, diagnoses, and medications within a patient's trajectory (Figure 6B). Consistent with these attention patterns, integrated-gradient attributions highlighted clinically relevant renal, physiologic, and treatment-context concepts—including SCr, blood urea nitrogen, and blood-pressure measurements at the case level, with medication-exposure concepts more prominent at the cohort level (Figure S5 in Multimedia Appendix 1). Together with the attention analysis, these results indicate that, after task-specific fine-tuning, the pretrained model bases its AKI onset predictions on clinically interpretable features.

Limitations

Despite these promising results, some limitations warrant consideration. First, the AKI onset definition relies entirely on SCr changes, and the official urine output criteria were omitted because urine output was not consistently captured in the EHR across sites; as a result, a subset of AKI cases may not have been captured. Second, mortality data were obtained by linking patient records to the Social Security Administration's Death Master File; while this source captures all reported deaths, delayed or incomplete reporting and limited follow-up remain possible, potentially leading to some deceased patients being misclassified as survivors. Third, some laboratory input tokens, including race-adjusted estimated glomerular filtration rate, reflect measurements as they were historically recorded in the retrospective EHR data and may carry biases from prior clinical practice. Fourth, the statistical selection of the BAP lexicon was performed without correction for multiple comparisons. The impact of this choice was limited because retained concepts were subsequently filtered against prior clinical evidence and used only to define perturbation targets during pretraining rather than model input features. Fifth, the XGBoost baseline encodes the presence of clinical events across the observation window but not their temporal ordering, and richer temporal feature engineering could narrow the gap. Sixth, HEART was fine-tuned using its native pretrained-model configuration rather than the validation-based tuning used for BAT-AKI and the conventional baselines, which may have disadvantaged HEART in the comparison. Seventh, the cross-site analysis was limited to BAT-AKI and the structurally equivalent transformer baseline and did not include HEART, limiting the generalizability conclusions to this comparison. Eighth, the discrimination for the early reversal and recovery tasks remains modest, reflecting the inherent difficulty of predicting these post-AKI trajectories from preonset information alone, which could be improved by incorporating postonset information as the hospitalization evolves. Ninth, our interpretability analyses rely on embedding visualization, attention weights, and integrated-gradient attributions, which provide useful but indirect evidence of model behavior. Tenth, this study is based on retrospective EHR data and does not yet evaluate prospective clinical deployment or real-time decision support. As an initial assessment of clinical applicability, we report calibration and decision-curve analyses for the AKI onset task in Figures S6 and S7 in Multimedia Appendix 1, where net benefit was positive only after Platt recalibration; realizing this in practice will require further prospective validation and clinical implementation. After recalibration, differences in net benefit between BAT-AKI and the benchmark models were on the order of 0.005 to 0.01. Platt scaling was fitted and evaluated within the internal cohort only, and site-specific recalibration would be required prior to any deployment. Eleventh, BAT-AKI's advantage over the transformer was reduced in the Black subgroup, where the AUROC difference was not significant. Absolute AUROC values are not directly comparable across subgroups given the differences in AKI incidence and subgroup size, and subgroup-specific evaluation would be needed before clinical use. Ensuring fairness across demographic and socioeconomic groups is an important direction for future work, which may benefit from more extensive adaptation methods to address the performance differences observed across subgroups. Future work will focus on prospective validation, updated outcome definitions incorporating urine output, fairness analyses across patient subgroups, and richer temporal and postonset modeling of post-AKI trajectories to more comprehensively assess and improve the model's real-world utility.

Conclusions

In conclusion, BAT-AKI is a pretraining-fine-tuning framework for AKI prediction and prognosis that demonstrates competitive predictive performance, cross-institution generalizability, and interpretability insights into its predictions. By leveraging

XSL•FO
RenderX

transformer-based representations tailored to longitudinal EHR data, a single pretrained model supports multiple AKI-related tasks spanning early prediction and postonset prognosis. These findings suggest that BAT-AKI provides a scalable and generalizable foundation for EHR-based AKI risk modeling, with potential to support early warning, patient stratification, and downstream clinical decision-making in real-world health care settings.

Acknowledgments

This work includes data that were originally funded through the Patient-Centered Outcomes Research Institute (PCORI). The PaTH clinical research network was funded through PCORI Award RI-PITT-01-PS1 (PaTH), and the Greater Plains Collaborative (GPC) was funded through PCORI Award RI-MISSOURI-01-PS1.

During the preparation of this manuscript, the authors used ChatGPT (OpenAI; GPT-5.5) and Claude (Anthropic; Opus 4.8) for language editing, phrasing refinement, and improving the clarity of selected passages. The authors reviewed and edited all AI-assisted outputs and take full responsibility for the content of the manuscript.

Data Availability

The data used in this study were deidentified EHRs from the GPC and PaTH networks within the National Patient-Centered Clinical Research Network (PCORnet), supported by PCORI. Due to data-use agreement (DUA) restrictions governing the use and sharing of these data, the authors are unable to share individual-level data outside of the study team.

Qualified researchers may request access to GPC data by submitting a formal application through the GPC Query and Data Request Form. All data requests are reviewed by the GPC Data Request Oversight Committee (DROC), the Research Opportunity Assessment (ROA) Committee, and local institutional representatives to ensure compliance with governance, IRB, and data-use policies. Similarly, access to PaTH data is available to qualified researchers through the PaTH data request and governance process, subject to approval by the PaTH network and participating institutions in accordance with applicable IRB and data-use requirements.

Detailed information about the GPC and PaTH networks is available on their respective websites [43,44]. Additional information about PCORnet is available on its website [45].

Detailed implementation and source code for this study are available at GitHub [46].

Funding

This project was supported by grants 244404 from the National Science Foundation (NSF) Smart and Connected Health program and R01DK137881 from NIDDK. The funders had no role in the design and conduct of the study; collection, management, analysis, or interpretation of the data; preparation, review, or approval of the manuscript; or the decision to submit the manuscript for publication.

Authors' Contributions

ML initiated the project and the collaboration and obtained funding. ML, ZX, and DL designed the overall study and experiments. ASLY, RM, and DYF contributed their clinical expertise to the study design. ZX extracted the study cohort, and DL and QX contributed to data processing. ZX performed all experiments and result analysis. ZX, DL, QX, and ML drafted and revised the manuscript with critical advice provided by ASLY, RM, DYF, EAC, LGC, and KMM. ZX, DL, QX, and ML verified the underlying data reported in the manuscript.

Conflicts of Interest

ASLY has served as a consultant or on advisory boards for Regulus, Calico, Janssen, and Sarepta, none of which are related to the current work. KMM has led and participated in research studies funded by Pfizer, Amgen, and Eli Lilly, all unrelated to the present work. RM received research grants from NIDDK and Vantive Inc, consulting fees from Vantive Inc, Baxter Inc, AM Pharma Inc, Bioporto Inc, La Jolla Inc, Novartis Inc, and Fresenius Medical Inc, unrelated to this study. LGC is Chief Scientific Officer of OncoSeer Diagnostics, not related to this work.

Multimedia Appendix 1

Additional methods, tables, and figures for the development, evaluation, sensitivity analyses, and interpretability analyses of the Biomarker-Aware Transformer for Acute Kidney Injury (BAT-AKI).

Abstract

Background: Early-stage pulmonary sarcoidosis with serum angiotensin-converting enzyme (sACE) activity within the normal range is difficult to distinguish from other pulmonary diseases with similar radiographic characteristics.

Objective: This study aimed to develop and validate machine learning (ML)–based diagnostic models for differentiating early-stage pulmonary sarcoidosis using indices from routine peripheral blood tests.

Methods: From May 2014 to May 2021, a total of 1142 patients with atypical initial pulmonary imaging findings were enrolled. After applying strict inclusion and exclusion criteria, 420 cases were divided into sarcoidosis and nonsarcoidosis groups (including mediastinal lymph node tuberculosis [MLNT], lung cancer, lymphoma, and pneumoconiosis), then stratified by sex and randomly split (7:3) into training and validation sets. Features were selected via univariate analysis (P<.10), the Boruta algorithm, and least absolute shrinkage and selection operator regression. Six ML algorithms—logistic regression (LR), random forest, support vector machine (SVM), extreme gradient boosting, k-nearest neighbor, and naïve Bayes—were compared using area under the curve (AUC), accuracy, sensitivity, specificity, F_1-score, Brier score, calibration assessment, and decision curve analysis. Shapley Additive Explanations was used for interpretability. The selected models were deployed as an interactive Shiny web application.

Results: After stratification, the male group comprised 224 cases (sarcoidosis n=42; MLNT: n=39; lung cancer: n=106; lymphoma: n=9; pneumoconiosis: n=28), and the female group comprised 196 cases (sarcoidosis: n=100; MLNT: n=39; lung cancer: n=49; lymphoma: n=4; pneumoconiosis: n=4). Models were selected based on comprehensive evaluation of multiple performance metrics, including AUC, accuracy, specificity, F_1-score, and Brier score. The selected model for the male group was SVM, incorporating the following indices: age, lymphocyte count (Lym#), red cell distribution width standard deviation, D-dimer, sACE, cluster of differentiation 4-positive T cells to cluster of differentiation 8-positive T cells ratio ($CD4^+/CD8^+$), erythrocyte sedimentation rate, triglyceride to high-density lipoprotein cholesterol ratio (TG/HDLC), basophil count, and total protein. The selected model for the female group was LR, using Lym#, sACE, total cholesterol, TG/HDLC, glucose, $CD3^+$%, and $CD8^+$%. The validation set results showed AUCs of 0.896 (95% CI 0.746-1.000) and 0.762 (95% CI 0.632-0.892), sensitivities

XSL•FO
RenderX

of 0.700 (95% CI 0.397-0.892) and 0.679 (95% CI 0.493-0.821), and specificities of 0.942 (95% CI 0.844-0.980) and 0.815 (95% CI 0.633-0.918), respectively.

Conclusions: Based on sex-stratified strategies, the models demonstrated preliminary discriminative ability for differentiating early-stage pulmonary sarcoidosis with normal sACE from other pulmonary diseases. However, the wide CIs preclude definitive conclusions about clinical performance, and external validation in larger cohorts is needed.

KEYWORDS

pulmonary sarcoidosis; machine learning; diagnostic model; serum angiotensin-converting enzyme; sex stratification

Introduction

Sarcoidosis is a systemic granulomatous disease characterized by the formation of noncaseating epithelioid cell granulomas with unknown etiology. It can affect multiple organs throughout the body, with the lungs being the most frequently involved site [1-3]. According to the Scadding staging system [4], sarcoidosis is classified into 5 stages (0 through IV). The radiological findings in stages 0, I, and II are atypical, often with bilateral hilar or/and mediastinal lymphadenopathy with (stage II) or without (stages 0 and I) infiltration in lungs, which are also presentations of pulmonary diseases like lung cancer, smear-negative mediastinal lymph node tuberculosis (MLNT) [5], pneumoconiosis, and lymphoma, making diagnosis challenging [1,6]. Without timely intervention, approximately 25% of patients may progress to chronic or progressive disease [7], even to advanced irreversibly fibrotic stage IV, with increased mortality due to respiratory failure, infection, vital organ involvement, or comorbidities [8-10]. Therefore, early diagnosis and treatment of pulmonary sarcoidosis are of paramount importance.

The diagnosis of sarcoidosis remains one of exclusion. The World Association of Sarcoidosis and Other Granulomatous Disorders first established diagnostic criteria for sarcoidosis in 1999 [11] and updated its organ assessment tool in 2014 [12]. Based on this tool, Bickett et al [5] developed 2 sarcoidosis diagnostic scores (SDS): clinical and biopsy scores. The SDS clinical score (with a threshold of ≥3) demonstrated a sensitivity of 90.6% and a specificity of 88.5% [5]. However, a subsequent multinational, multicenter validation study revealed its limited discriminatory power in distinguishing noninfectious granulomatous diseases, with an area under the curve (AUC) of 0.684 (95% CI 0.602-0.766). Furthermore, as the patient evaluation process lacks standardization, there is heterogeneity in the evaluation results among different physicians [13].

Serum angiotensin-converting enzyme (sACE) activity is often elevated in sarcoidosis and is regarded as a potential biomarker for evaluation of activity and diagnosis of sarcoidosis. However, it was reported that 24%-60% of patients with sarcoidosis do not present with elevated sACE levels [14-16]. These false-negative sACE results substantially increase diagnostic complexity.

In recent years, machine learning (ML) has been widely adopted in clinical research due to its strengths in handling complex data patterns [17-19]. Developing reliable ML diagnosis models for sarcoidosis could potentially become one of the approaches to addressing the pain points in clinical diagnosis, as recommended by the American Thoracic Society [20].

Previous studies [21,22] have reported significant sex differences in the incidence of sarcoidosis, with a higher incidence rate in the female group than in the male group. The peak age at diagnosis is 50 years and older for the female group and approximately 40 years for the male group. Accordingly, we adopted a sex-stratified approach in our ML modeling.

The purpose of this study was to construct an interpretable ML-based differential diagnosis model for pulmonary sarcoidosis using peripheral blood indicators and a sex-stratified strategy. By applying the Shapley Additive Explanations (SHAP) method to interpret the model and visualize the contribution of individual variables to diagnostic outcomes [23], we aimed to develop a clinical assessment tool that supports early diagnosis and intervention of pulmonary sarcoidosis, particularly for patients with sACE levels within the normal range.

Methods

Study Population

This study used data from the electronic medical record system of Shanghai Pulmonary Hospital, a tertiary Grade A hospital. We enrolled patients with pulmonary sarcoidosis (stage I and II) and nonsarcoidosis diagnoses (including MLNT, lung cancer, pneumoconiosis, and lymphoma) hospitalized between May 2014 and May 2021, all exhibiting atypical imaging features upon their first admission.

Data Collection and Processing

Data Collection

Patient demographic characteristics (age and sex), clinical diagnoses, pathological diagnoses, and initial peripheral blood test data from the first admission were extracted from the hospital's electronic medical record system. The peripheral blood indicators included a complete blood count (red blood cells, neutrophils, and lymphocytes), humoral immunity markers (immunoglobulin G, immunoglobulin M, and immunoglobulin A), biochemical tests (total protein [TP] and albumin), cellular immunity markers (cluster of differentiation [CD]3^+% and $CD4^+/CD8^+$ ratio), lipid profile (total cholesterol [TC], triglycerides, apolipoprotein A, and apolipoprotein E), and coagulation parameters (prothrombin time, activated partial thromboplastin time, antithrombin III, thrombin time, and fibrinogen). All variables and their reference ranges are detailed

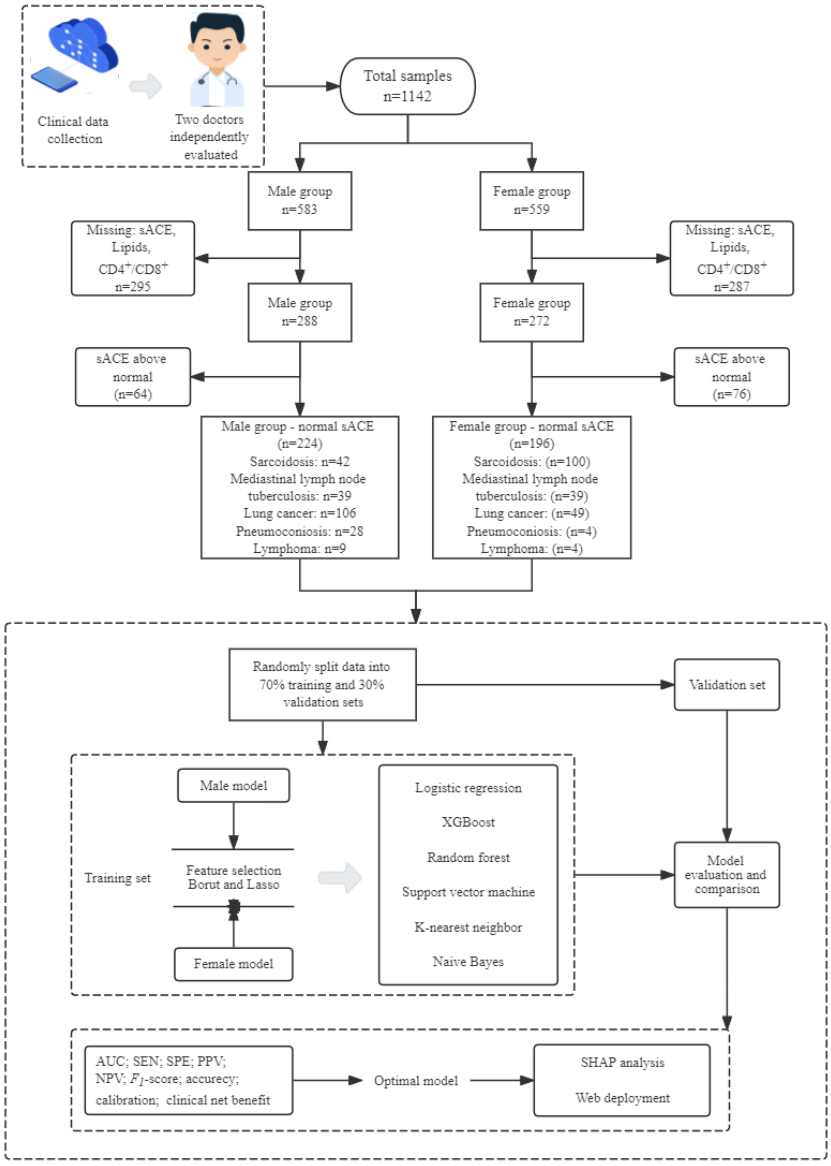
XSL•FO
RenderX

in Table S1 in Multimedia Appendix 1. Additional characteristics included symptoms, computed tomography (CT) findings, and comorbidities.

Inclusion and Exclusion Criteria

All cases presented with atypical imaging findings of the diagnosed diseases (no definitive diagnosis) at initial assessment were independently assessed by 2 senior physicians (JM and QL) from the departments of tuberculosis and respiratory medicine. Only those with consistent judgments from both physicians were selected according to the disease-specific criteria:

- Criteria for MLNT case selection: Cases in pathological stages I and II, which present with atypical features on CT, were selected [24]. While extensively calcified lymph nodes were easily distinguishable, those with partial calcification pose a diagnostic challenge. This study specifically enrolled cases with partial calcification who tested negative for *Mycobacterium tuberculosis* on smear and molecular tests (*M tuberculosis* DNA or RNA) at initial admission but subsequently tested positive on *M tuberculosis* culture or had 3 consecutive positive smears with *M tuberculosis* species identification after at least 1 month of follow-up.
- Criteria for pulmonary sarcoidosis case selection: Stage I and II cases that met international consensus diagnostic criteria with atypical manifestations were chosen. These included cases demonstrating amorphous or partial calcification in lymph nodes.
- Criteria for pneumoconiosis case selection: Given the inherent difficulty in differentiating pneumoconiosis from other diseases based solely on imaging, the study enrolled cases without a definitive preadmission occupational disease diagnosis. All cases received a confirmed diagnosis of pneumoconiosis during follow-up.
- Criteria for lung cancer case selection: The selected cases exhibited extensive pulmonary infiltrates and significant lymph node involvement, with a pathologically confirmed diagnosis during the follow-up period.
- Criteria for lymphoma (particularly Hodgkin lymphoma and non-Hodgkin lymphoma) case selection: The selected cases demonstrated mild to moderate homogeneous enhancement and minimal confluence on imaging, with evidence of pulmonary lymphangitic infiltration on contrast-enhanced CT, and with confirmation of lymphoma diagnosis by histopathology during follow-up.



Exclusion criteria (meeting any of the following):

- Treatment interference: Patients who had received antituberculosis therapy, antitumor therapy, and corticosteroid treatment; who had a confirmed diagnosis before admission; or who had used antibiotics (other than cephalosporins) or angiotensin-converting enzyme inhibitors within 2 weeks prior to admission.
- Abnormal sACE: sACE levels exceeding the normal (>70 IU/L in this study).
- As the lipid variables and the $CD4^+/CD8^+$ have demonstrated considerable value in sarcoidosis diagnosis [25-27], cases with missing records for either lipid variables or the $CD4^+/CD8^+$ ratio were excluded.
- Comorbidities: Concurrent diagnosis with any other disease included in the study groups.
- Cases with other diseases, such as aspergillosis or chronic beryllium disease, that have similar imaging presentations and can be easily diagnosed with characteristic laboratory tests were also excluded.

Based on the inclusion and exclusion criteria, the study included a total of 224 male cases (pulmonary sarcoidosis: n=42, MLNT: n=39, lung cancer: n=106, lymphoma: n=9, and pneumoconiosis: n=28) and 196 female cases (pulmonary sarcoidosis: n=100, MLNT: n=39, lung cancer: n=49, lymphoma: n=4, and pneumoconiosis: n=4). A flowchart outlining the study process is provided in Figure 1.

Model Development and Comparison

The dataset was randomly split into a training set and a validation set in a 7:3 ratio. The parameters for the data preprocessing steps on the validation set (including missing value imputation and standardization) were all derived from the training set to prevent data leakage and ensure an unbiased evaluation of the validation results. Feature selection was performed on the training set. The standardized formula was:

where min(X) denoted the minimum value of the data and max(X) denoted the maximum value of the data. Model variable selection was performed solely on the training set, and the selected features were fixed before any validation set evaluation, following the process: first, univariate analysis was performed to identify variables with a significance level of P<.10. These variables were then subjected to importance analysis using the Boruta algorithm, which rigorously identifies features that are genuinely associated with the target variable by iteratively comparing the importance of original features with that of randomly permuted shadow features. This allows us to retain variables that are statistically relevant to sarcoidosis while filtering out noise, providing a reliable initial feature set [28]. The variables obtained from the Boruta algorithm were subjected to feature compression via least absolute shrinkage and selection operator (LASSO) regression (implemented via the *glmnet* package). LASSO applies L1 regularization to further shrink the coefficient vector. Building on the Boruta output, LASSO eliminates redundant or multicollinear variables, resulting in a more parsimonious model.

The selected feature set from the training set was used to develop models using 6 ML algorithms: logistic regression (LR), random forest (RF), support vector machine (SVM), extreme gradient boosting (XGBoost), naïve Bayes (NB), and k-nearest neighbors (KNNs). To counteract the class imbalance issue in the male

XSL•FO
RenderX

data (sarcoidosis cases: 42/224, 18.7%), we used a model weighting approach when modeling the male subgroup. The weight calculation formula is:

where n is the total sample size, and n_i is the sample size for group i.

LR was implemented using the *stats* package, RF models were implemented using the *randomForest* package for the male cohort and the *ranger* package for the female cohort, SVM and NB using the *e1071* package, XGBoost using the *xgboost* package, and KNN using the *kknn* package. In the male group modeling, weight parameters were incorporated into the code. Specifically, the core of the KNN algorithm lies in its distance-weighted classification: for each test sample, the KNNs are identified based on Euclidean distance, and different weights are assigned according to their distances—closer neighbors receive higher weights. The final predicted class was determined by weighted voting. For the NB algorithm, weighting was achieved by adjusting the prior probabilities. Under class imbalance, setting prior probabilities inversely proportional to the class proportions enhances the algorithm's ability to recognize the minority class. The validation set was reserved for model evaluation. To achieve optimal model performance while minimizing the risk of overfitting, hyperparameter tuning was performed using nested cross-validation and grid search.

Each model was comprehensively evaluated for its discrimination, calibration, and clinical net benefit (using decision curve analysis [DCA]). The discriminatory ability of the 6 models was assessed using the AUC, sensitivity, specificity, positive predictive value, negative predictive value, F_1-score, and accuracy, while the DCA evaluated the practical utility and clinical application value of each model.

Model Stability Analysis

We performed 10-fold cross-validation on the training set using the best model to demonstrate the model's stability during training. Then, we additionally assessed the robustness and generalizability of the model in the validation cohort by evaluating its discriminative performance between sarcoidosis and each individual disease separately.

Model Explanation and Web Deployment

SHAP is a method that ranks feature importance and interprets model outputs. It provides both global and local explanations for a model. Globally, it reveals overall feature-disease associations, while locally, it illustrates the reasoning behind individual predictions [17,23]. To facilitate clinical adoption and enhance understanding for clinicians, the final models were deployed as an interactive Shiny web application. By inputting a patient's corresponding metric values, the application provides the probability score of the patient being diagnosed with pulmonary sarcoidosis and generates an individual force plot for case-specific interpretation.

Statistical Analysis

Two independent data entry clerks performed double entry and proofreading to ensure accuracy and reliability. Except for lipid variables and the $CD4^+/CD8^+$ ratio, all other variables with missing values were imputed using the median method [29]. Specifically, the median calculated from the training set was used to impute missing values in the training set, and the same median value was then applied to the validation set to prevent data leakage. Categorical variables are presented as percentages and compared using the chi-square test. Normally distributed continuous data are expressed as mean (SD) and analyzed with the 2-sided t test, while nonnormally distributed data are summarized as median (IQR) and compared using the Mann-Whitney U test. The optimal cutoff value was established by maximizing the Youden index (sensitivity+specificity–1). Statistical significance was defined as a 2-sided P value <.05. All analyses, including ML model construction and SHAP value analysis, were performed using the R software (version 4.5.1; R Foundation for Statistical Computing). The R code used for the correlation analyses is provided in Multimedia Appendix 2 to facilitate reproducibility.

Ethical Considerations

This study was conducted in accordance with the amended Declaration of Helsinki and the ethical guidelines of the institutional review board of Tongji University (project 221 approval K18-142). Clinical data were anonymized.

Results

Baseline Characteristics

The entire dataset included 224 male cases and 196 female cases. After the data were divided into training and validation sets, the male and female groups consisted of 162 cases and 141 cases in the training set, and 62 cases and 55 cases in the validation set, respectively. Among male patients with pulmonary sarcoidosis, the median age was 44.0 (IQR 39.0-49.8) years; among female patients, the median age was 53.0 (IQR 48.0-60.0) years. In nonsarcoidosis cases, the median age was 59.0 (IQR 46.0-66.0) years for the male group and 55.5 (IQR 45.0-64.2) years for the female group. A higher proportion of bilateral hilar lymphadenopathy was observed in patients with pulmonary sarcoidosis compared to patients without sarcoidosis in both male and female groups. Table 1 describes the demographic information for male and female groups in the entire dataset, as well as the variables included in the models. Tables S2 and S3 in Multimedia Appendix 1 summarize the missing value patterns, while Tables S4 and S5 in Multimedia Appendix 1 present the statistical results for all variables.

Model Development and Performance Comparison

Table 2 lists the detailed parameters for each model after tuning. Figure S1 in Multimedia Appendix 1 illustrates the variable selection process for the 2 models. In the female model, features corresponding to the minimum lambda value were selected, including lymphocyte count (Lym#), sACE, TC, triglyceride to high-density lipoprotein cholesterol ratio (TG/HDLC), glucose, $CD3^+$, and $CD8^+$. The features incorporated into the male model were age, Lym#, red cell distribution width standard deviation (RDW-SD), D-dimer, sACE, $CD4^+/CD8^+$, erythrocyte sedimentation rate (ESR), TG/HDLC, absolute basophil count (BASO#), and TP.

When evaluating the overall performance of the 6 ML models based on multiple performance metrics, including AUC, accuracy, specificity, F_1-score, and Brier score, SVM performed best among the male models (training set: AUC 0.989, 95% CI 0.975-1.000; validation set: AUC 0.896, 95% CI 0.746-1.000), while LR performed best among the female models (training set: AUC 0.848, 95% CI 0.781-0.915; validation set: AUC 0.762, 95% CI 0.632-0.892). Figure 2 presents the receiver operating characteristic curves, calibration curves, and DCA curves for all 6 ML algorithms in the validation set. The corresponding results for the training set are provided in Figure S2 in Multimedia Appendix 1. The discrimination metrics for each model are detailed in Table 3 and Table S6 in Multimedia Appendix 1.

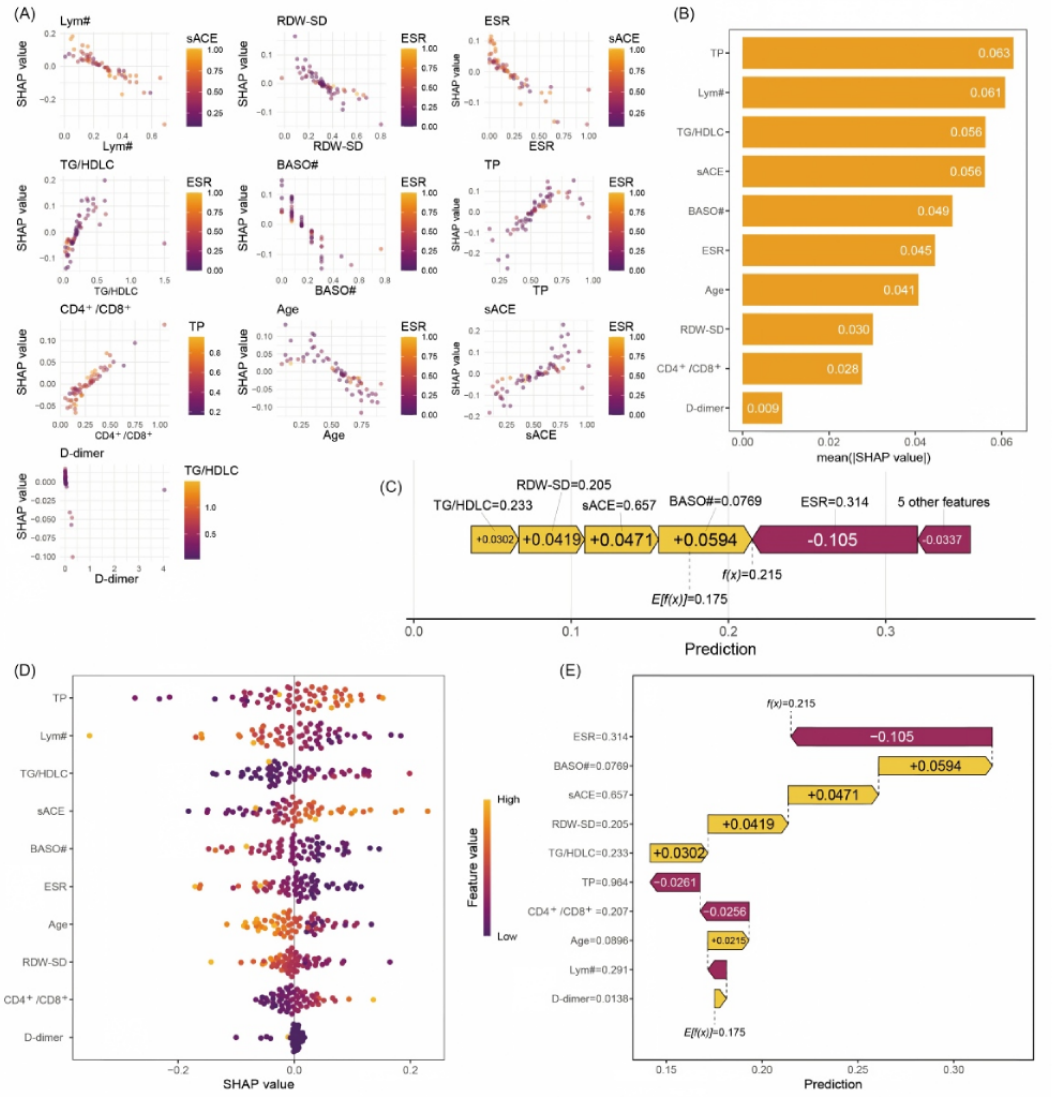
Model Stability Analysis

Figure S3 in Multimedia Appendix 1 presents the detailed results of the 10-fold cross-validation. The selected models, SVM for the male group and LR for the female group, achieved a 10-fold cross-validation AUC of 0.922 (SD 0.079) and 0.825 (SD 0.110) within the training sets, respectively. Table S7 in Multimedia Appendix 1 shows the cross-validation results as well as the discriminative performance for sarcoidosis versus each specific comparator disease.

Model Explanation



The SHAP method explains the final model's output by calculating the contribution of each variable to the prediction, aiding clinicians in understanding and trusting the diagnostic model. The global interpretation, depicted in the SHAP summary

XSL•FO
RenderX

plot (Figure 3B), illustrates the collective impact and importance of all features. The mean SHAP value was used to assess each feature's overall contribution to the model. In the male model, Lym# and TP were the most important features. In the female model, the most significant predictor was sACE, followed by the TG/HDLC (Figure S4 in Multimedia Appendix 1).

SHAP dependence plots help visualize how a single feature influences the model's output across its range of values, showing the relationship between the feature value and its SHAP value (Figure 3A). A SHAP value greater than 0 corresponds to the positive class in the model's prediction, which, in this study, indicates the pulmonary sarcoidosis class. Figure 3D is a beeswarm plot. Each point represents one sample, and the x axis indicates the SHAP value of the corresponding feature for that sample. A positive SHAP value means the feature increases the model's output (eg, the predicted probability of sarcoidosis), while a negative SHAP value means it decreases the output. The color of each point represents the original value of that feature in the sample. By examining the distribution of points and the color gradient, one can infer the relationship between the feature value and its SHAP contribution. For example, if high feature values cluster in the positive SHAP region, higher values of that feature tend to push the prediction toward the positive class; conversely, if high values cluster in the negative SHAP region, higher values are associated with a negative prediction. Force plots (or waterfall plots) detail the prediction for an individual sample, demonstrating how each feature value contributes to pushing the model's base value toward the final prediction output for that specific case (Figure 3C and E).

Figure 3. The feature importance and interpretation of the male model (based on the support vector machine algorithm). (A) SHAP dependence plot: association between each feature and its SHAP value. Point color represents the interaction effect between 2 features. (B) SHAP summary bar plot: ranking the importance of features. (C) SHAP force plot. (D) SHAP summary dot plot: relationship between feature values and SHAP values. The probability of pulmonary sarcoidosis classification increases with the SHAP value of a feature. (E) Waterfall plot: feature contributions to an individual prediction. The impact of a feature increases with the magnitude of its SHAP value. BASO#: basophil count; CD: cluster of differentiation; ESR: erythrocyte sedimentation rate; Lym#: lymphocyte count; RDW-SD: red cell distribution width standard deviation; sACE: serum angiotensin-converting enzyme; SHAP: Shapley Additive Explanations; TG/HDLC: triglyceride to high-density lipoprotein cholesterol ratio; TP: total protein.

Web Accessibility

The final predictive model was implemented in a web-based application to enhance its utility in clinical practice, as illustrated in Figure 4 and Figure S5 in Multimedia Appendix 1. Upon entering the required feature values, the application automatically generates a diagnostic output. Additionally, an individualized force plot is displayed for each patient, indicating which features contributed to the sarcoidosis prediction: features on the right in red push the diagnosis toward "nonsarcoidosis," while those on the left in yellow support a "pulmonary sarcoidosis" classification. The web applications for the male and female models are publicly accessible for research and demonstration purposes [30,31].

Figure 4. A convenient online clinical practice application featuring SHAP (female). CD: cluster of differentiation; GLU: glucose; Lym#: lymphocyte count; sACE: serum angiotensin-converting enzyme; SHAP: Shapley Additive Explanations; TC: total cholesterol; TG/HDLC: triglyceride to high-density lipoprotein cholesterol ratio.

Discussion

Principal Findings

This study developed diagnostic models to differentiate early-stage pulmonary sarcoidosis with normal sACE activities from cases of other atypical pulmonary diseases. To our knowledge, this is the first ML-based diagnostic model for pulmonary sarcoidosis. Our study indicated that, although sarcoidosis itself is a highly heterogeneous disease, sex-stratified ML models may provide useful discrimination between pulmonary sarcoidosis and other similar diseases, with relatively better performance observed in the male group.

The model for male patients incorporated the following indices: age, Lym#, RDW-SD, sACE, $CD4^+/CD8^+$, ESR, TG/HDLC, BASO#, TP, and D-dimer. The model for female patients used Lym#, sACE, TC, TG/HDLC, glucose, $CD3^+$%, and $CD8^+$%. We developed a web-based tool using the selected ML algorithms—the SVM model for male group (training set: AUC 0.989, 95% CI 0.975-1.000; validation set: AUC 0.896, 95% CI 0.746-1.000) and the LR model for female group (training set: AUC 0.848, 95% CI 0.781-0.915; validation set: AUC 0.762, 95% CI 0.632-0.892)—to facilitate the clinical application of this early pulmonary sarcoidosis differential diagnosis model. Additionally, we visualized the model using the SHAP method to enhance clinicians' understanding.

Our model showed promising performance across internal cross-validation and analyses of individual diseases, although further validation in independent cohorts is needed to confirm its generalizability. This study fully considered sex differences in sarcoidosis and adopted a sex-stratified modeling strategy. The National Institutes of Health policy on Sex as a Biological Variable, issued in 2015 [32], calls for the inclusion of sex as a biological factor in biomedical research. Multiple studies have shown that there are significant immunological, clinical, and genetic differences between male and female patients with sarcoidosis [33-35]. A study on the pulmonary functional phenotype of sarcoidosis found that there are differences in pulmonary functional phenotypes between the sexes [36]. In addition, the association between certain human leukocyte antigen markers and sarcoidosis also shows sex differences [34], suggesting that immune pathways play different roles in the male and female groups. In this study, the selected model was SVM for the male group and LR for the female group, a difference that can be attributed to distinct intrinsic data

XSL•FO
RenderX

characteristics between the 2 groups. The indices included in the male model may exhibit nonlinear relationships or threshold effects with pulmonary sarcoidosis. SVM can effectively capture complex nonlinear relationships among variables without requiring predefined functional assumptions. They are particularly suitable for small-to-moderate sample sizes and high-dimensional datasets and have demonstrated strong robustness and favorable generalization performance in various classification tasks. The female group had a smaller sample size and fewer features; LR is suitable for small-sample data and is less prone to overfitting, and its low-variance property makes it more robust. Moreover, the sets of included indices differ slightly between sexes (eg, D-dimer, RDW-SD, and BASO# in the male group; TC, glucose, and $CD3^+$% in the female group), suggesting that sex-specific modeling helps remove confounding bias and improve predictive performance.

To address the class imbalance in the male data, we applied sample weighting during model development, which effectively increased the influence of the minority class (sarcoidosis). As a result, the model showed preliminary discriminative ability on the validation set (male SVM: AUC=0.896; sensitivity=0.700; specificity=0.942). The male model showed relatively better performance across several evaluation metrics than the female model, although the differences should be interpreted cautiously, given the limited sample size and wide CIs. Studies have suggested that estrogen exposure may contribute to the delayed onset of sarcoidosis in the female group by influencing the Th1/Th2 balance [37,38]. In this study, estrogen levels in the female patients fluctuate considerably with the menstrual cycle and age. This may result in greater heterogeneity or atypical patterns in immune-related biomarkers among female patients, leading to a more ambiguous and noisier relationship between features and outcomes, thereby reducing the predictive power of the model. Additionally, the male group in this study had a slightly larger sample size (n=224 cases) than the female group (n=196 cases), and the male model included more features (n=10) than the female model (n=7). These factors may also partly explain the more stable performance of the male model.

It should be noted that although the RF algorithm uses bootstrap sampling and ensemble learning (bagging) to mitigate overfitting, the AUC on the training set in this study still reached 1.000. This suggests that the current hyperparameter tuning range (eg, tree depth, minimum node size, and regularization parameters) may still be insufficient to adequately penalize model complexity, or alternatively, the combination of a small sample size and a high-dimensional feature space may have allowed the model to easily memorize noise in the training data. Specifically, while bootstrap sampling reduces variance, when there are many features or strong discriminative predictors in the data, individual trees can still achieve near-perfect splits on the training samples; after aggregating multiple trees, the predictions on the training set become highly consistent, resulting in an AUC of 1. The relatively limited sample size in this study further exacerbates this issue. Future research should adopt stricter regularization strategies (eg, limiting tree depth, reducing the number of features, and increasing pruning strength) alongside larger sample sizes to enhance model generalizability.

All indices incorporated in our model are routinely available in clinical practice, including complete blood count, inflammatory markers, T-cell subsets, biochemical tests, and lipid profiles, offering good operability and generalizability. Moreover, these indices collectively reflect multiple pathophysiological dimensions—immune activation, chronic inflammation, metabolic disturbance, and nutritional status—closely aligning with the complex mechanisms of pulmonary nodular granulomatous disease. Traditional approaches relying on a single index or manually exploring combinations of indices have often been inefficient and difficult to translate into clinical use. To address this, we used the Boruta algorithm combined with LASSO regression for feature selection, efficiently identifying the above representative and jointly effective indices.

Both models included sACE and T-cell subset indices, which are the most common biomarkers for sarcoidosis. In this research, despite sACE levels of all the cases being within the normal ranges, sACE ranked fourth in importance in the male model but first in the female model, possibly due to the higher prevalence of pneumoconiosis—which also elevates sACE—among the male group [39]. However, sACE activity has been found to be associated with population characteristics. In certain populations, sACE levels fall within the high end of the normal range, which is associated with the angiotensin-converting enzyme gene insertion/deletion polymorphism (ACE I/D) [40]. Research by Csongrádi et al [41] found that combining sACE activity testing with ACE I/D genotyping improved the specificity of sarcoidosis diagnosis to 100%, albeit with a relatively low sensitivity of 42.5%. Both male and female groups showed a reduction in Lym# in peripheral blood, which may be associated with more impaired cellular immune function, for example, dysregulation of T cell subsets, in sarcoidosis than in other differentiated diseases [42]. Elevated $CD4^+/CD8^+$ ratios in bronchoalveolar lavage fluid have been demonstrated in multiple studies to hold diagnostic value for sarcoidosis [43]. Nevertheless, the invasive risk for bronchoalveolar lavage fluid sampling limits its clinical applicability. Our study demonstrated that the peripheral blood $CD4^+/CD8^+$ ratio in male, and percentages of $CD8^+$ and $CD3^+$ in female, when combined with other readily available indicators, can yield a well-performing diagnostic model for sarcoidosis.

Patients with sarcoidosis exhibit dyslipidemia. An integrative observational and Mendelian randomization study on blood lipids and sarcoidosis confirmed that high-density lipoprotein cholesterol and TC are closely associated with the disease [26], which may be attributed to abnormal lipid metabolism in macrophages during sarcoidosis pathogenesis [44]. Consistently, in this study, 2 indices reflecting lipid metabolic status [45], TC and TG/HDLC ratio, were selected. Currently, the TG/HDLC ratio has been extensively studied in metabolic and cardiovascular diseases [46,47]; its relationship pattern with sarcoidosis warrants further investigation. Our model, leveraging easily obtainable samples and providing rapid results, offers a promising solution for the early differential diagnosis of

XSL•FO
RenderX

pulmonary sarcoidosis. In addition, the web-based applications developed in this study are research prototypes intended solely for demonstration and peer review purposes. Translation into clinical practice would require implementation of the following security measures: (1) deploy the application within the hospital's internal network and enforce user authentication or authorization via Lightweight Directory Access Protocol or Shiny Proxy; (2) use HTTPS to encrypt all data transmission; (3) do not store any patient identifiable information; input data are used only for the current prediction and are not persisted; (4) maintain audit logs (timestamp, user, and deidentified input values) for traceability; (5) establish model version control and an approval workflow for updates; and (6) include a clear disclaimer that the tool is for decision support only, and the final diagnosis must be made by a clinician.

Limitations and Future Directions

This study has several limitations. First, the single-center nature of our study represents a key limitation, as it introduces potential selection bias and may restrict the model's generalizability to other demographic and clinical environments. Although internal cross-validation was robust, this constraint necessitates future external validation. Multicenter collaborations are needed to test, refine, and ultimately ensure the broad clinical applicability of the model. Second, although we split an independent validation set and performed robustness analyses, the inherent limitation of sample size remains, which reduces the reliability of the DCA and calibration curves. Future studies with larger sample sizes and external validation are needed to further confirm the robustness and generalizability of the models. Third, class imbalance exists in the male data. Although we applied sample weighting during modeling and acceptable predictive capacity on the validation set, increasing the male sample size and using other methods to address class imbalance are still necessary in the future to enhance model performance and generalizability. Fourth, the cohort splitting strategy was performed using random sampling rather than stratified sampling. Although the distributions of disease categories were comparable between the training and validation cohorts in the present study, future multicenter studies with larger cohorts should consider stratified sampling based on disease categories and external validation to further assess the robustness, clinical applicability, and generalizability of the proposed model. Fifth, although both models demonstrated acceptable discriminative ability, the CIs for sensitivity remained relatively wide. This is partly due to the small sample size and partly because some features of sarcoidosis (eg, elevated sACE and decreased lymphocytes) may also be present in other diseases. Future studies should adopt larger sample sizes and explore novel blood biomarkers. Sixth, the data incorporated into our model consisted of peripheral blood biomarkers, which are subject to inherent variability. However, all blood samples were collected as fasting morning draws, and we excluded patients with a history of medication use (eg, corticosteroids) prior to admission to minimize confounding factors. Seventh, we included patients who had used cephalosporins within 2 weeks, because these drugs are commonly used as empirical antibiotics in clinical practice. To preserve sample size and reflect real-world clinical scenarios, we retained such cases; moreover, short-term use of cephalosporins has a minimal impact on blood parameters [48] (eg, the half-life of ceftriaxone is approximately 1.5-2 hours) [49]. Nevertheless, we acknowledge that incomplete control of antibiotic exposure remains a potential confounder. We suggest that future studies with stricter inclusion criteria or prospective designs may further address this issue. Eighth, although we performed robustness and generalizability analyses for sarcoidosis versus each single comparator disease, the sample sizes for some diseases were too small to allow meaningful statistical analysis. Therefore, the model's generalizability to rare diseases such as lymphoma remains unclear. Future multicenter studies with larger sample sizes are needed to comprehensively validate the model's generalizability across all comparator diseases. Ninth, while the webpage is flexible and user-friendly, it must undergo prospective validation and obtain ethics approval before being implemented in clinical practice.

Conclusions

This study developed an interpretable model for the differential diagnosis of early pulmonary sarcoidosis versus other radiologically atypical pulmonary diseases with normal sACE levels using conventional peripheral blood markers. Given the wide CIs reflecting limited sample size, these findings are preliminary and require validation in larger independent cohorts. If successfully validated, the model holds promise to support clinical decision-making, facilitate the management of early-stage pulmonary sarcoidosis, and provide a scientific basis for clinicians when considering invasive diagnostic examinations.

Acknowledgments

The authors extend their gratitude to Professor Kaixin Ai for his valuable support throughout this project. Generative AI tools were used for language editing and improving the clarity of expression during manuscript preparation.

Funding

This study was supported by grants from the National Natural Science Foundation of China (81771692, 81971558, and 82000068), the Natural Science Foundation of Shanghai Municipality (20ZR1446800), and the Guizhou Provincial Science and Technology Projects (Qiankehe Support Program 2023 General 233).

Abstract

Background: With the rapid expansion of health care data, multiple international standardized terminology systems have been developed and refined to ensure semantic interoperability, which is a crucial factor in facilitating collaborative use.

Objective: This study aimed to evaluate the real-world use and applicability of standardized terminology systems by mapping clinical terms from routine cancer care and to propose guidelines that optimize mapping.

Methods: Clinical terms generated during cancer care at the National Cancer Center Korea were extracted and mapped to multiple target terminology systems: the Korean Standard Classification of Diseases; *International Classification of Diseases, 9th Revision, Clinical Modification*; Logical Observation Identifiers Names and Codes; RxNorm; Anatomical Therapeutic Chemical classification; and Systematized Nomenclature of Medicine Clinical Terms (SNOMED CT). A multidisciplinary working group of health care information managers, data experts, and oncologists verified the mapping outcomes, calculated the cross-verification discordance rate, and compared the coverage across systems.

Results: A total of 3472 source terms were identified across 7 domains: chief complaint, diagnosis, laboratory test, imaging test, surgery/procedure, medication, and radiation therapy. With postcoordination and predefined mapping guidelines, SNOMED CT achieved high overall mapping rates (98.3% - 100%) across domains. Applying postcoordination as needed substantially improved exact semantic match rates, which exceeded 90% in most domains. However, more than 40% of source terms were broadly mapped in the imaging test and radiation therapy domains because procedural details such as imaging technique and radiation field configuration could not be represented in SNOMED CT. The cross-verification discordance rate between mappers, defined as the proportion of source terms with disagreement, remained low (0.3% - 1.3%). RxNorm and Logical Observation Identifiers Names and Codes showed complementary strengths within their specialized domains, adding detail or specificity where SNOMED CT was less complete.

Conclusions: Standardized terminology systems are feasible and effective in encoding clinical terms for cancer care. SNOMED CT was the most comprehensive, and predefined mapping guidelines provide a structured framework for mapping and consensus resolution. Domain-specific systems should be used alongside SNOMED CT, and all systems should be updated regularly to reflect evolving clinical practice.

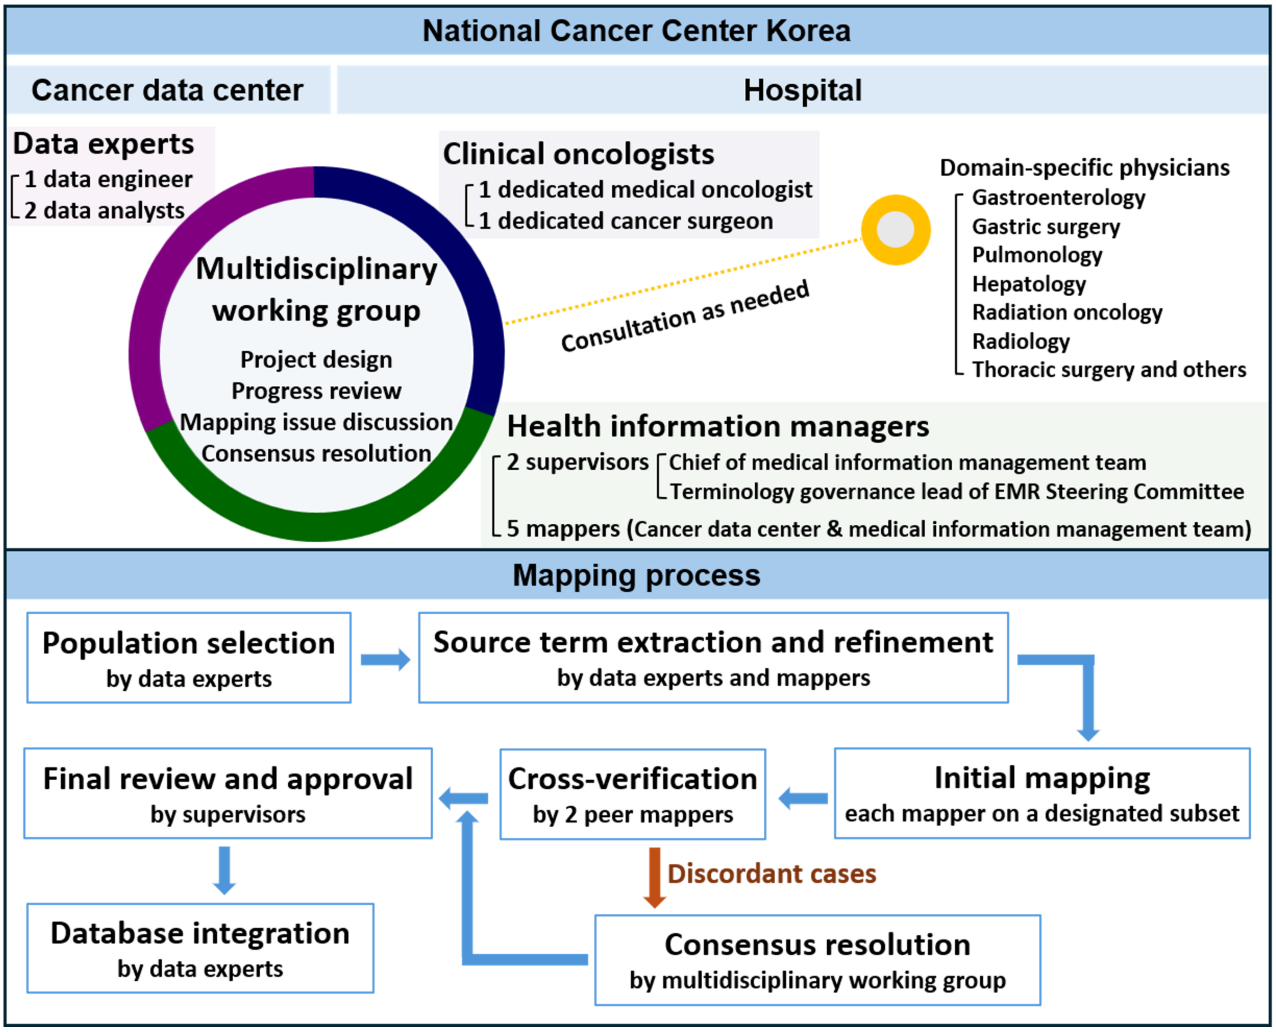
Introduction

With advances in IT and precision medicine, health care data volumes have expanded exponentially [1]. The growth of multicenter research and federated analyses has increased the complexity of data exchange. Unlike other big data, health care data originates from diverse sources, many of which are unstructured, creating interoperability challenges when integrating real-world data for clinical research [2]. Effective exchange requires 4 levels of interoperability: foundational, structural, semantic, and organizational. Semantic interoperability, enabling different systems to interpret information with the same meaning, is critical for complex, large-scale health care data [3,4].

Standardized terminology systems that define and organize medical terms have been developed to achieve semantic interoperability. In the 1940s, the World Health Organization (WHO) introduced the *International Classification of Diseases* (*ICD*) for morbidity and mortality statistics, the current version of which is the *ICD-11*. With advances in oncology, more specialized systems have been established, such as the *International Classification of Diseases for Oncology* (*ICD-O*), which codes neoplasms by tumor site (topography) and histology (morphology) [5]. Additional domain-specific systems include the *ICD-10*-Procedure Coding System (*ICD-10*-PCS) for surgical procedures and treatments, Logical Observation Identifiers Names and Codes (LOINC) for laboratory tests, and RxNorm for medications [6-8]. Systematized Nomenclature of Medicine Clinical Terms (SNOMED CT), originating from the College of American Pathologists' Systematized Nomenclature of Pathology and later merged with the United Kingdom's Read Codes, is the most widely adopted standardized medical terminology system [9].

Despite substantial progress in terminology development, gaps remain in real-world clinical application. High-quality research requires minimizing information loss during terminology mapping. However, the application of multiple standardized terminology systems to original real-world clinical terms containing detailed, unaltered information has not been widely examined, and potential intermapper discrepancies have not been fully evaluated. Moreover, few studies have addressed the unique complexities of patients with cancer, who undergo more diverse and intricate diagnostic and treatment processes than general patients. In this study, a multidisciplinary team mapped clinical terms from routine cancer care to multiple standardized terminology systems to assess their applicability, identify challenges, and propose guidelines for optimizing real-world clinical terminology mapping.



Methods

Working Group

The Cancer Data Center of the National Cancer Center Korea (NCCK), South Korea's National Cancer Data Center, establishes the data infrastructure and utilization environment required to promote nationwide cancer data research. As part of these efforts, a clinical term-to-standard terminology mapping project was initiated. A multidisciplinary working group of 3 data experts, 7 health information managers, and 2 clinical oncologists was convened. Data experts, who are responsible for building and maintaining the National Cancer Data Center research database and NCCK Clinical Research Data Warehouse (CRDW), conducted source term extraction, integration of the mapping outputs into the database, and quality control to ensure data integrity and operational suitability for standardization and reuse. Five health information managers, with expertise in electronic medical record (EMR) data management, multicenter data standardization, and standard terminology mapping, served as primary mappers. Two senior health information managers (the Chief of Medical Information Management Team and the Terminology Governance Lead of the EMR Steering Committee) supervised the overall mapping process and performed final review and approval of all mapping outputs. The 2 dedicated clinical oncologists, 1 medical oncologist and 1 cancer surgeon, contributed domain expertise in cancer care to review whether the clinical meaning of the source terms was preserved during mapping. When specialized clinical interpretation was required, additional consultation was obtained from relevant physicians within the institution. The working group held regular monthly meetings and biweekly written discussions for project design, progress review, mapping issue discussion, and consensus resolution (Figure 1).

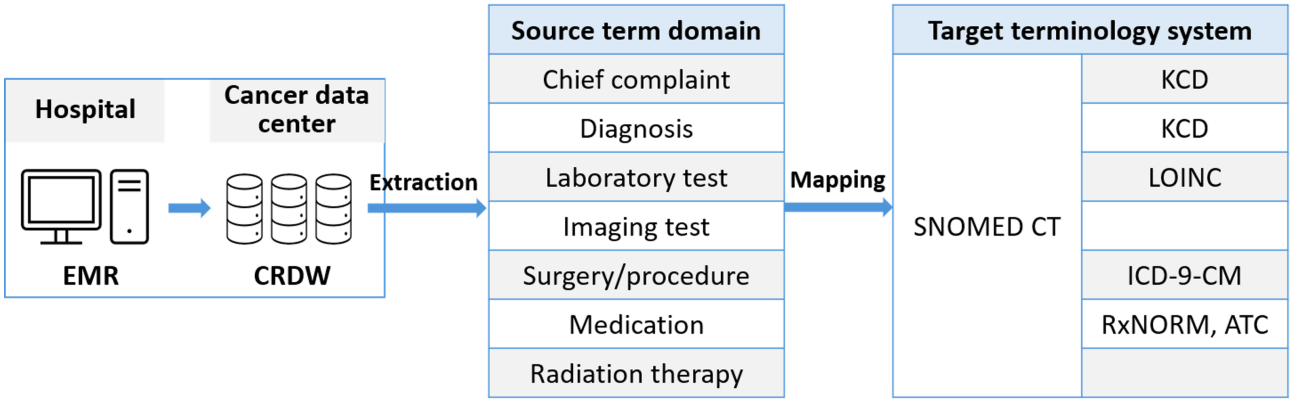
RenderX

Figure 1. Structure of the multidisciplinary working group and workflow of the standard terminology mapping process. The National Cancer Center Korea established a multidisciplinary working group comprising data experts, certified health information managers, and clinical oncologists, with domain-specific physicians consulted as needed. Each step of the mapping process was carried out by the designated members of the working group, as indicated. EMR: electronic medical record.

Study Population and Source Terms



Candidate source terms were identified from clinical data in the CRDW, which collects comprehensive information from the EMR system and houses deidentified data for research. Patients diagnosed with one of 6 primary cancers (stomach, breast, liver, colorectal, pancreatic, or lung) at the NCCK between 2010 and 2023 were included. Inclusion was based on *ICD*-O-3 codes: C16 (stomach), C50 (breast), C18/C19/C20 (colorectal), C22 (liver), C25 (pancreas), and C33/C34 (lung). Patients with intrahepatic bile duct cancer (C22.1) and islet cell tumors of the pancreas (C25.4) were excluded. Clinical data were extracted and classified into 7 domains: chief complaint, diagnosis, laboratory test, imaging test, surgery/procedure, medication, and radiation therapy. The source terms underwent minimal refinement to preserve their original clinical meaning: correction of typographical errors and spacing, expansion of abbreviations, removal of duplicates, and splitting of multivalued terms. Electronic data interchange (EDI) reimbursement codes for Korean National Health Insurance (NHI) claims and their effective dates were extracted from the CRDW for reference during mapping.

Mapping

Each source term was mapped to relevant standardized terminology systems according to its clinical domain. Domain-specific mappings included the Korean Standard Classification of Diseases (KCD), LOINC, *International Classification of Diseases, 9th Revision, Clinical Modification* (*ICD-9-CM*) Volume 3, RxNorm, and the Anatomical Therapeutic Chemical (ATC); all terms, regardless of domain, were mapped to SNOMED CT (Figure 2). Although newer procedure classifications such as *ICD-10*-PCS have been developed, *ICD-9-CM* Volume 3 has been used by many countries and remains in use across several Asian countries because of its established role within national coding infrastructures and the operational complexity of migration [10-14]. In South Korea, *ICD-9-CM* continues to serve as the procedure classification reference for national health statistics, and clinical terms are generated and managed on this basis [15,16]. Therefore, *ICD-9-CM* Volume 3 was selected for the surgery/procedure domain to reflect the source data context.

XSL•FO
RenderX

Figure 2. Mapping of clinical source terms to domain-specific standard terminology systems. Clinical terms were extracted from the clinical research data warehouse (CRDW), which contains deidentified data sourced from the hospital's electronic medical records (EMR) system. Source terms from 7 clinical domains—chief complaint, diagnosis, laboratory test, imaging test, surgery/procedure, medication, and radiation therapy—were mapped to appropriate standardized terminology systems. ATC: Anatomical Therapeutic Chemical; *ICD-9-CM*: *International Classification of Diseases, 9th Revision, Clinical Modification*; KCD: Korean Standard Classification of Diseases; LOINC: Logical Observation Identifiers Names and Codes; RxNorm: normalized naming system for generic and branded drugs.

All mappings followed the commonly recognized rules for each terminology system. For SNOMED CT, mappings adhered to the SNOMED CT Editorial Guide, compositional grammar, and concept model principles [17,18]. For postcoordination, focus concepts, attributes, and attribute values were selected in accordance with the permitted attributes and value ranges defined in the Machine Readable Concept Model (MRCM) [19]. The working group established and shared predefined guidelines with all mappers to specify mapping priorities and ensure consistency when multiple MRCM-compliant mapping options were available within the SNOMED CT framework. SNOMED CT mapping was categorized as "exact" when the target concept matched the source term in meaning, "broad" when the target concept was broader than the source, "narrow" when the target concept was narrower than the source, and "not-mapped" when no suitable target existed. Given the potential loss of semantic specificity and reduced fidelity to the original clinical meaning, narrow mappings were not counted as successful mappings, and grouped with "not-mapped" category as "narrow/not-mapped" in the final mapping performance analysis. Information that the SNOMED CT Editorial Guide identifies as outside the scope of the SNOMED CT International Edition—such as brand names in the medicinal product [20] and administrative or reimbursement-related procedure descriptions, including procedure counts or procedure order [21,22]—was not classified as a broad mapping when absent from the target concept. In contrast, the clinical meaning of the source term itself was considered essential to the mapping and had to be represented in the target concept for the mapping to be classified as exact.

Following initial mapping by 5 mappers each assigned to a designated subset of source terms, 2 peer mappers cross-reviewed each other's mapping results and recorded agreement or disagreement. Any disagreement was escalated to the multidisciplinary working group for consensus resolution. Clinical oncologists verified that the clinical meaning of each source term was accurately preserved, while data experts and supervising health information managers assessed whether the mapping was operationally appropriate and not overly specific in a way that would compromise standardization and reuse. Final decisions were made by prioritizing (1) accurate preservation of the original clinical meaning and (2) consistent application of predefined mapping principles. Cross-verification results were summarized using the cross-verification discordance rate, defined as the proportion of source terms for which disagreement was identified during cross-verification.

Ethical Considerations

This study analyzed a terminology dataset of clinical source terms extracted from the institutional deidentified data warehouse and their mapping results, rather than individual-level clinical records. The unit of analysis was the terminology concept rather than the individual patient, and the analytic dataset contained no identifiable personal information or patient-level linkage. Accordingly, this study was granted exemption by the Institutional Review Board of NCCK (No. 2026 - 0204), with a waiver of informed consent. The study was conducted in accordance with the principles of the Declaration of Helsinki.

Results

Identification of Source Terms

Among the 468,193 patients registered in the CRDW by 2023, 66,380 who were diagnosed with primary stomach, breast, liver, colorectal, pancreatic, or lung cancer between 2010 and 2023 were included. Following extraction, source terms underwent a refinement process, including typographical correction, expansion of abbreviations, duplicate removal, and splitting of multivalued terms (Supplementary Material S1 in Multimedia Appendix 1). No semantic modification or simplification was allowed. A total of 3472 clinical terms were finalized as source terms (Supplementary Material S2 in Multimedia Appendix 1). For the chief complaint domain, the 200 most frequent terms were extracted to prioritize the terms most relevant to routine clinical use. For the medication domain, information on drugs related to cancer prevention and treatment was extracted. All available clinical terms were extracted for the remaining domains.

RenderX

Predefined Mapping Guidelines

While all mappings followed the official guidance of each terminology system, the working group established predefined guidelines incorporating oncology-specific considerations to better preserve the original clinical context of source terms and improve consistency across mappers when multiple clinically plausible and terminology-compliant mapping options were available. The predefined guidelines were as follows.

To map chief complaint and diagnosis terms to KCD, if the source term is semantically identical to a subterm of the KCD target term, it should be mapped to that subterm; otherwise, it should be mapped to the main term, which is the primary identifier for the KCD code. In the surgery/procedure domain, if a single-source term contains multiple surgeries or procedures, each surgery or procedure should be mapped individually. The Korean Standard Terminology of Medicine can be used as a supplementary reference for mapping to the *ICD-9-CM* [23]. Although the EDI codes for NHI claims may be considered when available, priority should be given to the meaning of the source term from the CRDW.

For SNOMED CT, each source term should typically be mapped to the relevant hierarchy; however, if a chief complaint indicates the purpose of admission (eg, “for endoscopic variceal ligation”), it should be mapped to the procedure hierarchy. In the medication domain, information outside the scope of SNOMED CT, such as brand name or clinical indication (eg, transcatheter arterial chemoembolization), should be excluded. When the focus concept lacks dose form or strength information, postcoordination should be used. In the radiation therapy domain, if the meaning of a source term is ambiguous, it should be clarified by referencing the EDI codes for NHI claims before mapping. Narrow mappings that might distort the original meaning of the source term should be avoided, and exact mappings should be prioritized over broad mappings. When multiple postcoordinated representations are possible within SNOMED CT Editorial Guide and MRCM-defined attribute constraints, focus concepts, attributes, and attribute values should be selected according to the priority rules summarized in Table 1.

Table . Systematized Nomenclature of Medicine Clinical Terms (SNOMED CT) postcoordination priorities by clinical domains.

Domain and focus concept	Attribute-value (semantic tag)
Chief complaint	
Symptom	
Select the focus concept corresponding to the main symptom	Postcoordinate "Site (body structure)," if applicable
Reason for admission	
Select "304566005 |Admission for treatment (procedure)|" as the focus concept	Apply postcoordination in the following priority order: ① Treatment name (procedure, regimen/therapy) ② Causative procedure (procedure)
Select "76464004 |Hospital admission, for observation (procedure)|" as the focus concept	Postcoordinate "Test name (procedure)," if applicable
Complications	
Select the focus concept corresponding to the main symptom	Postcoordinate "Causative procedure or surgery (procedure)," if applicable
Diagnosis	
Select the focus concept that best captures the following information, in priority order: ① Behavior + morphology + site ② Morphology + site ③ Behavior + site ④ Behavior + morphology ⑤ Morphology ⑥ Behavior	Postcoordinate additional information not captured by the focus concept in the following priority order: ① Detailed site or laterality (body structure) ② Detailed morphology (morphologic abnormality) ③ Other information (disorder, observable entity, qualifier value, procedure)
Laboratory test	
Select the focus concept that best captures the following information, in priority order: ① Test name + sample type ② Test name	Postcoordinate additional information not captured by the focus concept in the following priority order: ① Test substance (substance, cell) ② (Detailed) sample type (specimen) ③ Test method (procedure) ④ Quantitative/qualitative (qualifier value) ⑤ Other information (qualifier value, physical object, person)
Imaging test	
In-house imaging study	
Select the focus concept that best captures the following information, in priority order: ① Modality + site + position ② Modality + site + injected agents ③ Modality + site ④ Modality + injected agents ⑤ Modality	Postcoordinate additional information not captured by the focus concept in the following priority order: ① (Detailed) site or laterality (body structure) ② Injected agents (substance, procedure) ③ Test method (procedure) ④ Purpose of test (procedure) ⑤ Using device (physical object, physical force) ⑥ Other information (disorder, finding, qualifier value, physical force, person)
Review of outside imaging	
Select "28191001 |Consultation and report by radiologist (procedure)|" as the focus concept	Apply postcoordination in the following priority order: ① Modality + site + injected agents (procedure) ② Modality + site (procedure) ③ (Detailed) site (body structure)
Surgery/procedure	
No additional priority rules	No additional priority rules
Medication	

XSL•FO
RenderX

Domain and focus concept	Attribute-value (semantic tag)
Select the focus concept that best captures the following information, in priority order: ① Ingredient + dose form + strength ② Ingredient + dose form	Postcoordinate additional information not captured by the focus concept in the following priority order: ① Detailed dose form (dose form) ② Detailed dose form unit (unit of presentation) ③ Numerator value (qualifier value) ④ Numerator unit (qualifier value) ⑤ Denominator value (qualifier value) ⑥ Denominator unit (qualifier value)
Radiation therapy	
No additional priority rules needed	No additional priority rules needed

All mappings followed the SNOMED CT Editorial Guide and MRCM. The priorities listed below were applied additionally, only when multiple valid mapping options existed within these rules.

SNOMED CT concepts are displayed in the format "concept identifier |term|." The numeric identifier represents the SNOMED CT concept ID, and the term enclosed by vertical bars ("| |") is the human-readable SNOMED CT term [18]. Numbered items (①, ②, ③, etc) indicate the priority order used in this study for selecting focus concepts or postcoordination attributes when a source term contained multiple mappable elements.

Mapping Results

Table 2 provides examples of how source terms were mapped to the corresponding target terminology systems in each clinical domain and how the SNOMED CT postcoordination priorities described in Table 1 were applied. Supplementary Material S3 in Multimedia Appendix 1 provides further details on the selection of SNOMED CT postcoordination attributes. For instance, in the case of "Carcinosarcoma, connective and soft tissue, unspecified" in the diagnosis domain, no single target term representing both "① behavior + morphology + site" and "② morphology + site" could be identified. Therefore, the focus concepts "448274000 |Malignant neoplasm of connective tissue (disorder)|" and "269469005 |Malignant neoplasm of soft tissue (disorder)|" were used to capture the "③ behavior (malignant) and the sites (connective and soft tissue)" in a 1:N relationship. The remaining information, morphology, was captured using a postcoordinated expression: "116676008 |Associated morphology(attribute)| = 63264007 |Carcinosarcoma(morphologic abnormality)|." In the laboratory test domain, following the priority order of "① Test name + sample type," no single concept capturing both elements was available for "Anti-HCV, immunoassay." The second priority, test name, was mapped to the focus concept "64411004 | Hepatitis C antibody measurement (procedure)|." The remaining details were represented through postcoordination by specifying the "② (Detailed) sample type (specimen)," and "③ Test method (procedure)" as follows: "116686009 |Has specimen(attribute)| = 119364003 |Serum specimen (specimen)|" and "370129005 |Measurement method (attribute)| = 104417008 |Immunoassay, qualitative, multiple step method (procedure)|," respectively.

After mapping all the source terms, we examined how each term was represented across multiple target terminology systems to identify system-specific characteristics (Table 3). In the chief complaint and diagnosis domains, KCD could not fully represent certain terms, such as purposes of admission (eg, “for transplantation work-up”) or morphological detail in

XSL•FO
RenderX

"adenocarcinoma of sigmoid colon," whereas SNOMED CT captured these terms via postcoordination. In the surgery/procedure domain, behavioral characteristics (eg, malignancy) could not be included in *ICD-9-CM* procedure codes, whereas SNOMED CT allowed behavior to be represented as attributes in addition to the procedure focus. In the laboratory test domain, LOINC supports the specification of the unit of measure (eg, mg/dL for phosphate) through recommended units, whereas SNOMED CT lacks this level of unit specificity. Conversely, LOINC could not capture additional contextual information, such as "(em)" denoting an emergency procedure, whereas SNOMED CT could via postcoordination. In the medication domain, RxNorm generally represented detailed medication information most completely; for example, it captured ingredient, dose form, strength, and brand name for "Avastin 400 mg injection (bevacizumab)." In contrast, SNOMED CT represented ingredient, dose form, and strength but typically did not include brand name and often expressed strength per unit (eg, 25 mg per 1 mL) rather than total dose. The ATC classification included only ingredient-level information. Although RxNorm was usually the most complete, exceptions existed; for example, for "Mitomycin-C Kyowa," SNOMED CT provided more complete information than RxNorm.

Cross-Verification and Consensus Resolution

The initial mapping performed by the assigned mapper was additionally reviewed by 2 peer mappers, who recorded their agreement or disagreement with each mapping result. A mapping was considered discordant if either reviewer disagreed with the initial mapping result, and such cases were referred to the multidisciplinary working group for consensus resolution. There were no major discrepancies in the chief complaint, imaging test, or medication domains; the remaining domains showed cross-verification discordance rates of 0.3% to 1.3%. In the diagnosis domain, the cross-verification discordance rate was 0.3%, primarily involving source terms containing more than 1 anatomical site. This was resolved by adding a rule specifying that if multiple sites in a source term belong to the same parent

XSL•FO
RenderX

concept, the term should be mapped to that parent concept rather than mapped 1:N to each child concept. For example, "Neoplasm of uncertain or unknown behavior of liver, gallbladder, and bile ducts" should be mapped to "liver and/or biliary passages," not separately to "liver," "gallbladder," and "bile duct." The surgery/procedure domain showed a 1.0% cross-verification discordance rate, largely from inconsistent handling of parenthetical details; this was addressed by mapping to target terms that incorporate the parenthetical meaning whenever possible (eg, retaining "malignant" in targets for "excision of retroperitoneal tumor (malignant)"). A 1.3% cross-verification discordance rate in the radiation therapy domain was mostly attributable to limited familiarity with the SNOMED CT relationship groups. Even when the meaning of a source term is not entirely reflected in the fully specified name of a focus concept, relationship group attributes may convey the necessary details, negating additional postcoordination. For example, "external irradiation–high energy radiotherapy" should map to the SNOMED CT concept "high energy beam therapy," which includes a device attribute in its relationship group that represents external beam delivery, eliminating the need to encode "external irradiation" and "high energy." Through this process of cross-verification and consensus discussion within the multidisciplinary working group, final mappings were confirmed; as examples, the mapping results for the 20% most frequent terms per each clinical domain are provided in Multimedia Appendix 2.

Mapping Rates by Standardized Terminology System

Overall mapping rates were high across most domain-system pairs, with the chief complaint domain showing the lowest rates at 97.7% for KCD and 98.3% for SNOMED CT (Supplementary Material S5 in Multimedia Appendix 1). The narrow/not-mapped terms in the chief complaint domain were primarily attributable to ambiguity or insufficient specificity in the source terms, such as "oozing," "prolapse," "malfunction," and "for admission," for which a semantically appropriate SNOMED CT target could not be reliably selected. In the diagnosis domain, KCD achieved a 100% mapping rate, whereas SNOMED CT achieved 99.9% because a small number of source terms that could only be narrowly mapped (eg, malignant neoplasm of overlapping lesion of other and ill-defined sites) were treated as narrow/not mapped. Outside these two domains, all source terms were successfully mapped to SNOMED CT. In the medication domain, 1.2% of the terms were not mapped to RxNorm owing to the absence of codes for drugs approved only in specific countries (eg, TS-1). All source terms were successfully mapped to other systems (LOINC, *ICD-9-CM* Volume 3, and ATC) within their respective domains.

The detailed SNOMED CT mapping results are presented in Table 4. Among the exact mappings, precoordination predominated in chief complaint (64.7%), diagnosis (79.1%), imaging test (58.9%), surgery/procedure (63.1%), medication (90.1%), and radiation therapy (70.7%), whereas postcoordination was more frequent in laboratory tests (80.2%). In laboratory tests, postcoordination captures additional information such as quantitative/qualitative details and test methods beyond the focus concept. Broad mappings occurred most frequently in the imaging test (43.3%) and radiation therapy domains (40.7%). In the imaging test domain, broad mappings arose mainly because information on view and projection (eg, pelvic inlet and outlet), patient position (eg, decubitus, supine, and erect), and other acquisition techniques (eg, 3D reconstruction and low-dose protocols) could not be represented in the target concepts. In the radiation therapy domain, source terms in the treatment prescription subdomain showed a high broad mapping rate (61.3%), while source terms in the treatment site subdomain achieved a 100% exact mapping rate. Specifically, most broad mappings resulted from incomplete representation of the number of ports (eg, 3 ports) and field arrangement (eg, parallel-opposed 2 fields), whereas information on the preparation processes (eg, simulation and treatment planning), modalities (eg, tomotherapy), and radiation types (eg, proton therapy) was precisely represented in the target concepts.

XSL•FO
RenderX

Table . Systematized Nomenclature of Medicine Clinical Terms (SNOMED CT) mapping results[a].

Mapping type[b]	Chief complaint (%)	Diagnosis (%)	Laboratory test (%)	Imaging test (%)	Surgery/procedure (%)	Medication (%)	Radiation therapy (%)[c]
Exact	97.1	97.8	98.3	56.7	89.3	100	59.3
PRE	64.7	79.1	19.8	58.9	63.1	90.1	70.7
POST	34.1	20.2	75.9	39.7	30.6	9.9	29.3
PRE + POST	1.2	0.7	4.3	1.4	6.2	0.0	0.0
Broad[d]	1.2	2.2	1.7	43.3	10.7	0.0	40.7
PRE	0.0	91.2	0.0	89.6	63.8	0.0	83.8
POST	100	8.8	100	10.4	30.4	0.0	16.2
PRE + POST	0.0	0.0	0.0	0.0	5.8	0.0	0.0
Narrow/not-mapped[e]	1.7	0.1	0.0	0.0	0.0	0.0	0.0

[a]PRE, precoordinated concept (when an existing SNOMED CT concept fully represented the source term); POST, postcoordinated expression (when a single pre-coordinated concept did not fully capture clinically meaningful details).

[b]Absence of information outside the scope of the SNOMED CT International Edition (eg, brand names, reimbursement-related information) was not classified as a broad mapping.

[c]By subdomain, mapping results were as follows: Treatment prescription, Exact 38.7% (PRE 32.6%, POST 67.4%), Broad 61.3% (PRE 83.8%, POST 16.2%), and Narrow/not-mapped 0.0%; Treatment site, Exact 100% (PRE 100%, POST 0.0%), Broad 0.0%, and Narrow/not-mapped 0.0%.

[d]Examples of broad mapping for each clinical domain are provided in Supplementary Material S6 in Multimedia Appendix 1.

[e]All narrow/not-mapped cases with detailed rationale are summarized in Supplementary Material S7 in Multimedia Appendix 1. These cases were attributable to ambiguity or insufficient specificity of the source terms, which prevented reliable selection of a semantically appropriate SNOMED CT target, rather than to the absence of relevant concepts in SNOMED CT.

Discussion

We mapped 3472 clinical source terms from real-world records of patients with 6 cancers to multiple standardized terminology systems. Several studies have mapped clinical terms to standardized systems; however, few have documented detailed, real-world mapping experiences. For example, a South Korean study introduced a 9-step process to map local EMR terms to SNOMED CT [4], and a Hungarian group mapped 4661 national procedural codes from 2 university hospitals to SNOMED CT [24]. Although these studies covered a wide range of clinical terms and offered valuable insights, they limited their source terms to specific domains (eg, procedures), restricted their targets to SNOMED CT, and reported ~60% exact mapping rates because postcoordination was not used. In contrast, we focused on patients with cancer, whose care is particularly complex, to better understand the standardization of clinical terms in oncology, where multicenter research demand is high. We included terms across the continuum of cancer care and mapped them not only to SNOMED CT but also to other standardized systems, depending on the clinical domain. We also conducted exhaustive cross-verification for all mappings, whereas previous studies omitted or only partially applied cross-verification.

In our study, SNOMED CT achieved high overall mapping rates, ranging from 98.3% to 100% across all domains, confirming its broad applicability as one of the most comprehensive standardized terminology systems. Applying postcoordination as needed substantially improved exact semantic match rates, which exceeded 90% in most domains. Prior studies have noted lower exact mapping rates in certain domains [25-28]. For instance, Sung [25] et al reported that only 1574/4,111 (38.2%) EDI codes for NHI claims mapped in the laboratory test domain, and Kang et al [28] found a 398/2500 (31.9%) match for therapeutic/surgical procedures; Jung [27] et al showed 11,453/22,610 (50.6%) for medications. However, these rates reflect a reliance on precoordinated concepts. After applying postcoordination, Sung et al [25] and Kang et al [28] improved to 90.4% and 63.6%, respectively. Similarly, our precoordinated match in laboratory tests was 19.8%, rising to 98.3% with postcoordination. SNOMED CT postcoordination also captured details not represented by LOINC attributes, underscoring its role in fully representing the original clinical data and enabling precise use across domains [29,30].

However, even when postcoordination was used, exact semantic match rates remained relatively low in the imaging test and radiation therapy domains, with broad mappings accounting for more than 40% of source terms in each domain. In the imaging test domain, imaging adjustments related to view or projection, patient position, and technique were not permitted in postcoordination, although such information was considered clinically important for the correct acquisition and interpretation of images [31]. Similarly, in the radiation therapy domain, the number of ports and field arrangement could not be represented in SNOMED CT International Edition, despite their relevance to treatment configuration and dosimetric evaluation. Although these limitations reflect the scope and modeling principle of the SNOMED CT International Edition, which does not include certain protocol- or configuration-level details to maintain standardized representation of clinical procedures, our findings suggest that this approach may reduce the semantic fidelity of

XSL•FO
RenderX

complex imaging and radiation therapy data that are crucial to cancer care and research. To improve semantic representation, frequently used details could be represented through SNOMED CT national extensions and organized through implementation-specific reference sets. In addition, acquisition parameters and radiation therapy protocol details could be captured using complementary domain-specific terminologies and standards such as Radiology Lexicon and Digital Imaging and Communications in Medicine, including its radiotherapy extension (Digital Imaging and Communications in Medicine – Radiation Therapy) [32-34]. Such a combined approach may help preserve detailed procedural information and improve semantic interoperability in real-world oncology data.

Despite the breadth of SNOMED CT, the complementary use of domain-specific systems is necessary to capture the full characteristics of source terms. For example, although SNOMED CT aligns with the Identification of Medicinal Products, an international standard for dose forms and clinically appropriate strengths, it has limitations with respect to brand names, packaging, and country-specific details (eg, drug codes and reimbursement/insurance status) [35-37]. In contrast, RxNorm represents drug information in greater detail, including multi-ingredient combinations, brand names, exact strengths, and national drug codes. In our study, with precoordination alone, coverage for ingredients, dose form, and strength was same for SNOMED CT (90.1%) and RxNorm (90.1%), but RxNorm more precisely represented the dosage by explicitly encoding the total dose. Although postcoordination can improve SNOMED CT coverage, encoding dosage through postcoordination increases structural complexity, which is a practical limitation. Such country-specific details can also be addressed through a national extension of SNOMED CT, which allows member countries to add concepts and reference sets to meet national requirements while retaining interoperability with the international core [38]. In the United Kingdom, for example, the NHS dictionary of medicines and devices, implemented as the SNOMED CT UK Drug Extension, represents brand names, packaging, and reimbursement-related information using SNOMED CT-compatible identifiers [39]. As South Korea joined SNOMED International in 2020 and is currently developing a national extension, such administrative or policy-related details could also be represented in addition to internationally standardized clinical concepts.

For laboratory tests, LOINC provides a more specialized representation than SNOMED CT via its six-axis model, namely component, property, time, system, scale, and method [40,41]. In our study, precoordinated SNOMED CT concepts alone accounted for only 19.8% of exact SNOMED CT mappings in the laboratory test domain, whereas the remaining 80.2% of exact mappings required postcoordination. Although SNOMED CT postcoordination enabled high mapping rates and captured additional contexts not represented by LOINC (eg, urgent testing status), this limited precoordinated coverage explains the widespread adoption of LOINC-based coding system for laboratory test data in many institutions. These findings support the complementary use of domain-specific terminology systems alongside SNOMED CT. Beyond using these systems in parallel, the recently released LOINC Ontology, a LOINC and SNOMED CT interoperability solution jointly developed by Regenstrief Institute and SNOMED International, may offer a more integrated approach [42,43]. By representing LOINC content within a SNOMED CT concept model, it is expected to enhance LOINC's computability and improve interoperability between LOINC-coded laboratory observations and broader SNOMED CT-based clinical concepts. Such integrated approaches, rather than the independent use of separate domain-specific terminology systems, may further enhance the semantic interoperability and reusability of real-world clinical data.

To broaden the adoption of SNOMED CT, whose strengths are detailed semantics and wide applicability, the complexity of postcoordination must be addressed [44]. Postcoordination was necessary for 9.9% to 80.2% of the exact mappings in our study. However, SNOMED CT's flexibility, supporting various precoordinated and postcoordinated expressions, can yield inconsistent code usage across mappers, challenging standardization, because multiple concepts with similar meanings may exist and several valid combinations of focus concepts, attributes, and attribute values may exist [30,45]. In this study, the use of predefined mapping priorities in addition to SNOMED CT Editorial Guide and MRCM supported high consistency in postcoordination decisions (cross-verification discordance rate, 0.3% - 1.3%). To maintain consistency without sacrificing the flexibility of SNOMED CT, it is necessary to incorporate structured mapper training in both clinical domain knowledge and terminology systems, predefined priority rules on selecting focus concepts and attributes, standardized postcoordination templates or reusable expression libraries for recurrent source-term patterns, and cross-verification with regular consensus review. In addition, SNOMED CT content should be periodically updated through the review of frequently used postcoordinated expressions in routine clinical practice, which may be considered as candidates for precoordinated concepts or national extensions.

This study has the limitation in that mappings were developed at a single institution without multicenter validation. Because standard terminology mapping can be influenced by institution-specific workflows, local code management practices, and information system environments, whether the present results can be applied identically to other institutions remains uncertain. Nevertheless, interinstitutional heterogeneity in South Korea might be relatively less pronounced than in health care systems with more fragmented insurance and coding structures. South Korea operates a single-payer NHI system, and medical services are documented and managed using national-level classification systems. In addition, recent government-led initiatives have continued to promote the standardization of health data across institutions, through the establishment of multicenter common clinical data infrastructures (eg, the Data-Driven Hospital Project and the Korea-Clinical Data Utilization Network for Research Excellence), as well as national standards for health data elements terminology (eg, the Korea Core Data for Interoperability) [46,47]. Accordingly, source terms linked to nationally standardized coding systems, such as KCD, LOINC, and EDI claims codes for NHI, are less likely to show large interinstitutional variation and may therefore be more consistently applicable across other institutions. In

XSL•FO
RenderX

contrast, locally maintained terms, such as institution-specific names for procedures, surgeries, laboratory tests, and imaging studies, or free-text entries in chief complaints, may yield different mapping results across institutions. Further multicenter validation should focus on these locally maintained terms to determine whether our mapping results remain reproducible across institutions and to identify which source-term categories require local adaptation before broader implementation.

Another limitation concerns the choice of procedure classification system. *ICD-9-CM* Volume 3 was selected for the surgery/procedure domain, considering the Korean clinical coding context in which *ICD-9-CM*–based procedure classification continues to serve as a reference classification for national health statistics [15]. However, this may limit the international applicability of the mapped data. Procedure and intervention classification remains highly heterogeneous across countries. Although the WHO introduced International Classification of Procedures in Medicine in 1978, it was not subsequently maintained, and many countries developed their own procedure classification systems with different structures and purposes, limiting international comparability of intervention data [48-50]. In response to the need for more harmonized frameworks, the WHO has developed the International Classification of Health Interventions to provide a common structure to which codes in national classifications can be mapped for compiling international data [51]. Further studies will be needed to extend the mapping of local clinical terms beyond *ICD-9-CM* toward emerging global standards, thereby enhancing the international interoperability of real-world clinical data.

To the best of our knowledge, this is the first large-scale investigation to compare the strengths and limitations of multiple standardized terminology systems by mapping real-world clinical terms across a full continuum of cancer care. Our study demonstrates the feasibility of applying standardized terminology systems to real-world oncology terms. SNOMED CT is the most comprehensive and universally applicable system, whereas domain-specific systems play essential roles in capturing more specialized aspects of clinical data. Clear mapping priorities in addition to the official guidance for each terminology system, together with cross-verification and consensus review, provided a practical framework for resolving mapping disagreement while maintaining flexibility. Regular updates of standardized terminology systems to accommodate newly emerging clinical terms, together with ongoing mapper education, are important to maintain mapping consistency. Future work may enhance the interoperability of real-world cancer data and contribute to the standardization of research data for the development of clinical decision support systems, health care information exchange, and multicenter research facilitation.

Acknowledgments

Generative AI, OpenAI ChatGPT, was used for language refinement and editing of text originally drafted by the authors. It was not used to analyze data, interpret results, generate figures, or collect references. The authors reviewed and revised all AI-assisted suggestions and take full responsibility for the final manuscript.

Funding

This work was supported by the National Cancer Center Korea [2310850 - 3]. The funding source had no role in the study design, data collection, data analysis, interpretation of results, manuscript preparation, or the decision to submit the manuscript for publication.

Data Availability

The dataset used in this research contains original clinical information extracted from an electronic medical record system and, therefore, cannot be made publicly available. Deidentified data may be shared by the corresponding author upon reasonable request for academic research purposes.

Abstract

Background: The development of structured optical character recognition (OCR) systems for Korean medical documents is hindered by strict privacy regulations that limit access to real clinical data. Existing synthetic document frameworks are primarily designed for generic layouts and Western languages, and fail to capture the complex formatting, bilingual terminology, and hierarchical field semantics required for clinical OCR and document-understanding tasks in hospital environments.

Objective: This study aimed to develop and validate a privacy-preserving, template-driven pipeline for generating realistic synthetic Korean medical documents with structured XML annotations, enabling OCR and document-understanding model training in settings where access to real clinical data is restricted.

Methods: We designed MedDocSynth, a 7-stage synthetic document generation pipeline that reconstructs authentic medical document layouts from publicly available references, incorporates clinician-guided template selection, and uses a structured placeholder system encoding 17 medical data types. Human-curated templates were populated with exemplar content and tagged using a delimiter-based scheme, after which GPT-4o-mini generated diverse synthetic values for each field. The pipeline produced 1000 fully synthetic DOCX documents with corresponding XML annotations encoding hierarchical structure, title-answer relationships, and datatype metadata. We evaluated text fidelity, lexical diversity (type-token ratio, measure of textual lexical diversity [MTLD], n-grams, and Pareto), and compared the system with existing synthetic document pipelines. A Qwen2.5-VL model was fine-tuned exclusively on the synthetic dataset and evaluated on 50 real-world Korean clinical documents to assess OCR accuracy, information extraction, and table reconstruction.

Results: The pipeline achieved 100% placeholder coverage, 99.68% format correctness, and 91.56% semantic accuracy. Lexical diversity analysis demonstrated high variability in free-text fields (MTLD≈456) and expected repetitiveness in structured datatypes. Compared with existing pipelines (SynthText, SynthTiger, and DocSynth), the proposed system uniquely supports complex clinical forms, bilingual content, and structured XML annotations. When trained solely on the synthetic data, Qwen2.5-VL achieved the highest real-world performance, with a character accuracy of 86.01%, word accuracy of 78.25%, field accuracy of 67.18%, datatype accuracy of 64.14%, and table reconstruction tree-edit-distance similarity score of 71.09%. Models without fine-tuning performed substantially worse, including GPT-5-mini.

Conclusions: We present the first synthetic data generation pipeline specifically tailored to Korean medical documents, enabling the creation of realistic, richly annotated datasets for structured OCR without exposing patient information. The synthetic data significantly improves OCR performance on real clinical documents, demonstrating the pipeline's potential utility for hospital deployment and its potential extensibility to other languages and health care systems.

Introduction

Background

Optical character recognition (OCR) systems play a central role in digitizing hospital documents by converting scanned images into machine-readable text, enabling downstream structured data extraction and database integration. However, their development is constrained by strict privacy regulations that restrict access to real patient records [1], particularly in languages such as Korean, where institutional formats, complex layouts, and writing conventions differ markedly from those in English-language datasets. As a result, existing clinical OCR systems often exhibit limited generalizability and weak performance in real-world hospital environments [2].

In hospitals, paper-based medical records are routinely scanned and archived as image files within electronic medical record (EMR) systems. While this approach preserves document content, the images remain nonsearchable and nonextractable. When clinicians need to access specific information—particularly in time-critical settings, such as emergency departments—they must manually locate and transcribe data from scanned images, a process that is both inefficient and error-prone. Structured OCR systems, capable of automatically extracting and organizing text from diverse Korean medical documents, would significantly improve clinical workflow efficiency and patient safety.

Structured OCR addresses these limitations by automatically recognizing content and structure from scanned medical documents and organizing them into XML-annotated, EMR-compatible formats. This approach enables (1) automated extraction of structured clinical fields (patient demographics, medication lists, allergy records, and laboratory results) from individual documents; (2) EMR-compatible output that preserves field-level semantics (title-answer relationships and datatypes) for direct database integration; (3) elimination of manual transcription, reducing errors, and clinician cognitive load [3,4]; and (4) a foundation for downstream applications, such as cross-document search and longitudinal patient data aggregation once integrated into hospital information systems.

Synthetic data generation provides a promising solution by enabling the creation of realistic training corpora without exposing sensitive information [5]. However, existing frameworks—including SynthText [6], SynthTiger [7], and DocSynth (DS) [8]—are designed for generic document structures and Western languages, while Korean OCR benchmarks, such as AI Hub OCR [9], CLOVA OCR [10], and KAIST Scene Text [11], lack the hierarchical layout modeling, semantic field pairing, and domain-specific medical terminology required for clinical documents. Crucially, this limitation is not unique to Korean; no published pipeline for Japan, Taiwan, or any other non-English health care system addresses the combined challenge of full-page clinical form image synthesis, intradocument bilingual content, and structured field-level annotation for OCR training [12-14]. Recent layout analysis datasets [15-17] rely on weak supervision from digital sources and fail to capture the irregular formatting, mixed-language text, and scanning artifacts typical of hospital records.

These limitations motivate a specialized, privacy-preserving pipeline capable of generating realistic Korean medical documents for clinical OCR and document-understanding tasks. To our knowledge, no equivalent pipeline exists for non-English clinical environments. Existing non-English work falls into two distinct categories, neither of which meets this need: (1) synthetic clinical text generation for natural language processing tasks (such as named entity recognition or deidentification), which produces no document images, no form layouts, and no field-level annotations [12,13,18-20]; and (2) generic multilingual document image synthesis pipelines, which cover multiple languages but apply no domain-specific clinical content, no bilingual medical form templates, and no datatype-aware semantic annotation [21,22]. This gap is particularly acute in health care systems where clinical documents routinely mix 2 languages within a single form—a challenge documented for Korean and, notably, for Taiwanese medical records, yet unaddressed by any existing document synthesis pipeline. We address this gap by developing MedDocSynth, a modular, template-driven synthetic document generation pipeline that integrates curated document structures with AI-assisted text generation. Datatype-aware placeholders ensure consistent, medically plausible bilingual (Korean-English) content, while paired XML annotations capture title-answer relationships and fine-grained structural metadata, enabling OCR and document-understanding model training without exposing real clinical data.

Objectives

This study aims to develop a privacy-conscious, template-driven pipeline for synthesizing realistic Korean medical documents with structured XML annotations (title-answer and datatype) across diverse document classes. We further aim to quantify textual realism and variability using lexical diversity metrics (type-token ratio [TTR], measure of textual lexical diversity [MTLD], n-grams, and Pareto) and establish baseline comparisons against existing synthetic pipelines. Importantly, we validate the utility of the pipeline by evaluating OCR and document understanding performance on real clinical documents, comparing a fine-tuned Qwen 2.5 VL model against both its GPT-5-mini and Qwen 2.5 VL baseline model, to demonstrate that the generated data are usable in real-world scenarios.

Main Contribution

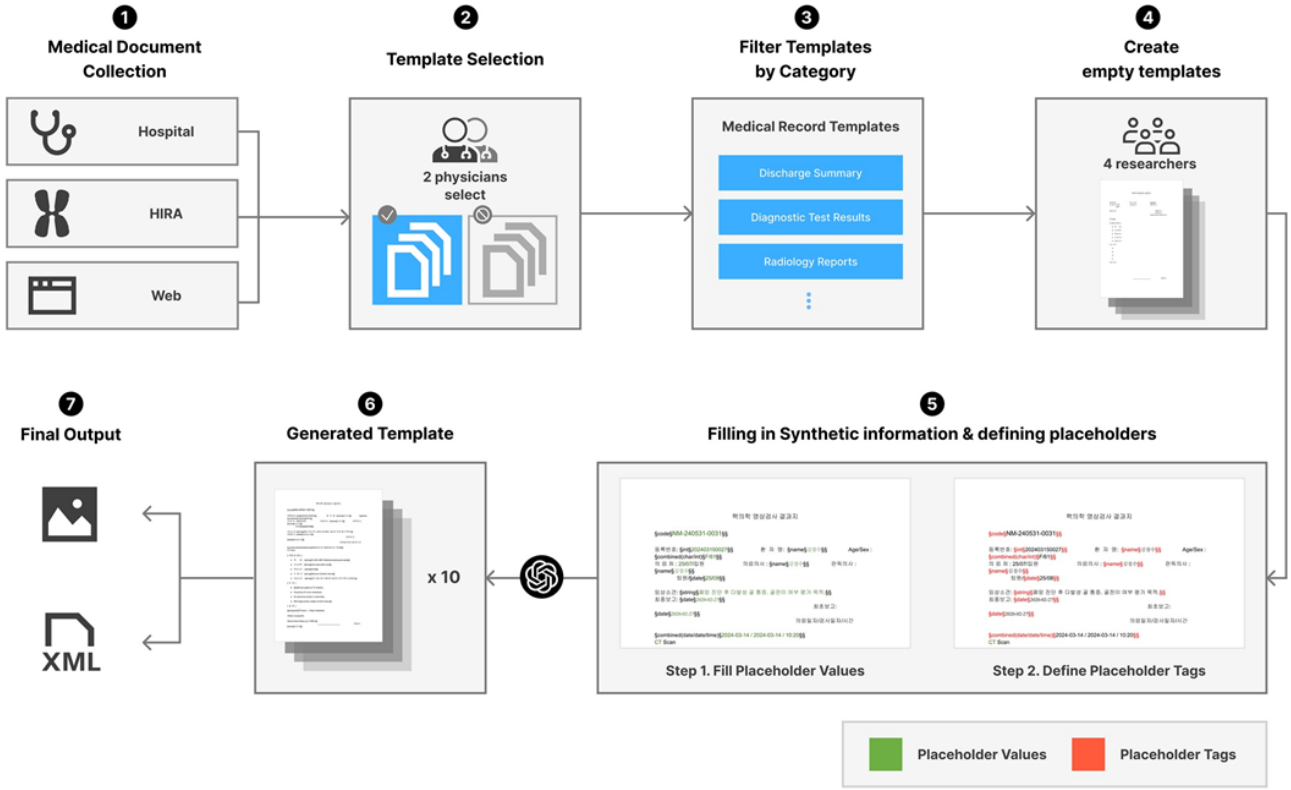
Our key contributions are:

- We introduce the first synthetic data generation pipeline tailored specifically for Korean medical documents, capturing realistic clinical layouts, bilingual content, and domain-specific terminology.
- We design a template-driven system capable of producing full-page documents with complex structured elements, including tables, form fields, multicolumn layouts, and standardized clinical formatting.
- We propose a new XML-based annotation schema, inspired by DocTags [23], that encodes hierarchical document structure, datatype metadata, and semantic title-answer relationships for downstream OCR and document understanding tasks.

XSL•FO
RenderX

- We provide a scalable, extensible framework that supports diverse clinical document types and enables privacy-preserving, reproducible training, and benchmarking of OCR models in health care settings.
- We validate the pipeline using real clinical documents, demonstrating that models fine-tuned on the synthetic data (Qwen 2.5 VL) outperform non–fine-tuned and baseline language models such as GPT-5-mini, confirming the practical utility of our approach.

Methods



Overview

To address the scarcity of publicly available Korean medical document datasets and privacy constraints, we developed a synthetic data generation pipeline to create realistic, privacy-safe OCR training corpora. The pipeline reconstructs representative document templates and populates them with AI-generated, medically plausible bilingual (Korean-English) content. Each generated document is paired with a structured XML annotation capturing hierarchical title-answer relationships and semantic datatypes.

MedDocSynth: Synthetic Document Generation Pipeline

Figure 1 illustrates the end-to-end workflow used to construct our synthetic Korean medical document dataset. MedDocSynth consists of 7 sequential stages, beginning with template sourcing and expert selection and ending with the production of fully populated documents and their corresponding structured annotations. This approach allows the creation of complex layout synthetic document generation. Each of the following sections is aligned with each of the steps referenced in Figure 1.

Figure 1. Overview of the MedDocSynth pipeline for synthetic dataset generation, divided into 7 steps. Step 1: medical documents are collected from three sources (hospital, Health Insurance Review and Assessment Service, and web-based repositories). Step 2: two physicians review and filter the documents based on relevance, structural differences, and other quality criteria. Step 3: the selected documents are categorized to guide template creation. Step 4: using the filtered documents, empty templates are constructed to mimic the structure and layout of the real documents. Step 5: in a two-stage process, these templates are filled with human-generated placeholder content, after which tags are assigned to each content element. Step 6: using these tags and placeholders, GPT-4o-mini generates synthetic data by replacing the tagged elements, producing 10 synthetic records per template. Step 7: finally, document images and corresponding XML files are exported to form the final dataset.

Medical Document Collection

The step 1 of the pipeline as seen in Figure 1 begins with the compilation of real-world medical document samples that serve mainly as structural references. We aggregated publicly accessible materials from the following three sources: (1) hospital-issued forms and publicly released examples, (2) Health Insurance Review and Assessment Service (HIRA) documents, and (3) medical document samples available on official or educational websites. No patient information or protected health data were included; mainly the layout, structure, and formatting style of these documents were used. These references form the foundation from which empty, fully synthetic templates are later manually constructed by human labelers.

Template Selection by Clinical Experts

To ensure that the dataset covers the most clinically representative and structurally diverse document types, 2 licensed physicians conducted an expert-driven template selection process. They reviewed all collected document

XSL•FO
RenderX

structures and identified those considered high-priority for clinical relevance, frequency of use, and structural diversity. Only templates approved by both clinicians were retained, ensuring that downstream synthetic documents reflect real hospital documentation practices while remaining fully privacy-preserving.

Filtering Templates by Category

The curated set of candidate documents was next organized into medical record categories based on expert opinion of 2 clinicians. Categorization serves the following two purposes: (1) ensuring balanced coverage across distinct document classes, and (2) enabling class-specific generation strategies for documents with unique structural characteristics (eg, narrative-heavy summaries vs table-dominated test results). This stage produces a structured taxonomy that guides all subsequent template construction and synthetic data generation.

We identified 12 core document classes that represent the most clinically relevant and structurally diverse types of hospital records—discharge summaries, diagnostic test results, medical imaging results, pathology results, surgical records, emergency records, consultation records, inpatient initial assessment records, physician's orders, transfer records, discharge transfer records, and medication records.

Creation of Empty Document Templates

A team of 4 researchers then reconstructed each selected document type as an empty DOCX template, replicating only the layout, formatting, section structure, and tabular arrangements from the reference examples. All content fields were left blank to avoid any leakage of real patient information. These templates capture intraclass variability by incorporating natural differences in formatting, table organization, headings, and field arrangements. The output of this stage is a high-quality library of layout-accurate but fully deidentified 100 medical document templates, which will serve as the seed of the synthetic document generation. This step provides us with the capability of tailor-making a highly complex structure dataset for any desired scenario.

Defining Placeholders and Filling Synthetic Information

Overview

To enable automated content generation, each empty template was populated with a structured placeholder system. We adopted the section symbol (§) as the delimiter, as it does not conflict with typical medical characters. Each placeholder follows the syntax §<datatype>§<example_value>§§, where the first and second § delimit the datatype identifier (eg, name, date, and code) and the second § and closing §§ delimit the representative example value. For instance, §name§Kim Jiyoon§§ encodes a name-type field with "Kim Jiyoon" as the exemplar. The system supports 17 datatypes covering the diversity of medical records; full definitions and examples are provided in Table S2 in Multimedia Appendix 1. The templates were processed in 2 steps—placeholder value generation and placeholder tag definition.

Placeholder Value Generation

As addressed in Figure 1 step 5, first, a team of four trained labelers manually filled every template instance with realistic synthetic example text following the datatype constraints. This process produced 100 fully populated, human-curated template documents containing both natural linguistic variation and correct field-level structure.

Placeholder Tag Definition

Second, the same labelers then inserted placeholder tags around each example value using the delimiter notation described above, thereby specifying the datatype and semantic role anticipated for automated generation.

Among the 17 datatypes, the select type requires distinct handling because it represents categorical choices rather than free-text generation. The system first identifies selection markers in the placeholder text—including circle (○/●) and square (□/■) styles—extracts each option regardless of its initial state, randomly selects between 1 and 3 options, and reassigns the selected/unselected symbols accordingly. For example: Input: ◦ Diabetes • Hypertension ◦ None

Output: • Diabetes ◦ Hypertension • None

For placeholders without visual markers, delimiter-separated options (eg, M/F or Yes|No) are parsed and one option is randomly selected. Unlike other datatypes, select placeholders are processed locally without API calls.

Together, these steps produce a set of 100 labeled, example-filled templates that serve as ground truth specifications for the generation stage. In the subsequent phase of the pipeline, each template is automatically instantiated ten times, expanding the initial 100 human-created documents into 1000 fully synthetic, consistently annotated records.

Generation of Synthetic Documents

Overview

With all templates and placeholders defined, the pipeline automatically generates the final synthetic documents. This stage comprises 2 parallel processes—content generation, which populates each placeholder with new synthetic values, and annotation generation, which produces a structured XML file encoding the document's semantic and structural metadata.

Content Generation

For each template, the GPT-4o-mini model replaces every placeholder with newly generated synthetic content, adhering to the datatype, structure, and formatting constraints encoded during the template creation stage. Each placeholder is processed via an independent API call with temperature=0.7 to balance diversity and plausibility, and max_tokens=10,000 to accommodate long free-text fields such as radiology findings, surgical descriptions, and clinical progress notes, which may span multiple sentences or paragraphs.

During content generation, the pipeline processes DOCX documents by iterating through the document body in sequential order, distinguishing between paragraph elements and table elements. In Korean medical documents, single-column tables

XSL•FO
RenderX

are frequently used as layout containers rather than data structures—for instance, to frame narrative sections or group related content within bordered regions. The pipeline detects single-column tables and processes their cell contents as regular text elements rather than tabular structures, preventing downstream models from misinterpreting layout-only tables as data tables.

Annotation Generation

Each generated document instance is paired with a structured XML annotation file. The annotation format uses a simplified XML schema inspired by DocTags [23], with 2 primary elements: <text> for textual content and <table> for structured tabular data, subdivided into <row>, <hcel> (header cell), and <ncel> (normal cell).

Content originating from placeholder substitution receives class="answer" along with a datatype attribute specifying the field type, while all non-placeholder text—such as field labels, section headings, and static form content—is automatically assigned class="title." For example:

<text class="title">Patient Name</text>

<text class="answer" datatype="name">Park Minjae</text>

For combined datatypes (eg, entries such as "58/M"), an additional subtype attribute records the constituent types:

<text class="answer" datatype="combined" subtype="int/gender">58/M</text>

Tabular content follows a hierarchical<table>→<row>→ cell structure. For merged cells, the span attribute records the number of columns spanned. An example annotation for a diagnostic test result table is:

<table>

<row>

<hcel class="title">Test Name</hcel>

<hcel class="title">Result</hcel>

<hcel class="title">Reference</hcel>

</row>

<row>

<ncel class="title">Hemoglobin</ncel>

<ncel class="answer" datatype="float">13.2</ncel>

<ncel class="answer" datatype="range">

12.0 - -16.0</ncel>

</row>

</table>

The full XML schema with tag definitions and attribute descriptions is provided in Table S1 in Multimedia Appendix 1.

Final Output

Overview

This process yields 1000 fully synthetic documents, each consisting of (1) a DOCX file containing realistic synthetic medical content and (2) a parallel XML annotation encoding hierarchical structure, title-answer relationships, and datatype metadata. Examples of generated documents with their corresponding templates and XML annotations can be seen in Figure S1 in Multimedia Appendix 2. Together with the placeholder definitions in Table S2 in Multimedia Appendix 1, these materials provide sufficient detail to reproduce the core pipeline.

Synthetic Data Evaluation

Overview

The goal of our evaluation is to determine whether the proposed pipeline can generate synthetic documents that are realistic, diverse, and semantically reliable. To this end, we conducted 3 complementary experiments assessing textual correctness, linguistic variability, and overall pipeline performance.

We conducted the following three experiments to assess the pipeline: (1) text fidelity, (2) lexical diversity, and (3) pipeline comparison.

Text Fidelity

The objective of this experiment is to determine whether the pipeline produces realistic and semantically reliable placeholders. To evaluate the quality of synthetically generated documents, we adopt a placeholder-level evaluation strategy rather than holistic document-level scoring [24]. Each generated placeholder was evaluated for presence, format correctness, and semantic accuracy. Validation included checking datatype constraints (eg, numeric ranges and date formats), verifying structured dependencies such as combined fields, and allowing naturalistic variation including multiple date styles and flexible spacing patterns. All placeholders across synthetic documents were first reviewed solely by a licensed nurse, who served as the primary labeler. Subsequently, the nurse (labeler), a biomedical specialist, and 2 computer science engineers jointly re-examined the placeholders—the nurse and biomedical specialist for semantic accuracy and medical realism, and the engineers for datatype constraint validation

Lexical Diversity

To measure linguistic variability in the generated documents, we computed TTR and MTLD. TTR reflects the proportion of unique tokens relative to the total number of tokens, formally defined as "TTR"=V/N where V is the vocabulary size and N is the total token count; a higher TTR indicates greater lexical richness, although it is known to decrease as document length grows [25]. MTLD addresses this length sensitivity by computing the mean length of sequential token runs. We also analyzed n-gram frequency distributions to capture repetition at the level of multitoken sequences, and applied Pareto analysis to identify the proportion of n-gram types accounting for 80% of total token mass—a low type coverage at this threshold indicates high repetition and low generative diversity [26].

XSL•FO
RenderX

Pipeline Comparison

We compared our system with SynthText, SynthDoc, SynthTiger, and DS. The comparison focused on layout coverage, the use of domain-specific terminology, handling of bilingual content, and the quality of structured annotation produced by each system. The aim is to demonstrate that our pipeline supports document types and linguistic structures that are not adequately covered by existing approaches.

Real-World Validation (Model Training and Fine-Tuning)

We fine-tuned the Qwen2.5-VL visual language model (VLM) on our synthetic dataset using a train-in-synthetic, test-on-real (TSTR) paradigm with 1000 synthetically generated samples. The model simultaneously predicts (1) recognized text, (2) title and answer classification, (3) semantic datatypes, and (4) table structures.

Training details include:

- Precision: bf16
- Hardware: 8× NVIDIA A100 80 GB GPUs
- Epochs: 4
- Learning rate: 1×10^{-5}
- Batch size: 1 (gradient accumulation 16)
- Parallelization: DeepSpeed ZeRO Stage 3

Post training, the model was quantized using activation-aware weight quantization (AWQ) to create Qwen2.5-VLFinetuned-AWQ for efficient inference.

Evaluation Dataset and Metrics

An independent real-world test set of 50 clinical document images spanning 11 document categories was constructed to evaluate generalization under realistic conditions. The dataset includes documents originating from 10 tertiary hospitals in South Korea, and more than 25 documents, between primary and secondary hospitals capturing substantial interinstitutional variation in document formats and styles.

Unlike curated benchmark datasets, the images reflect real-world acquisition conditions. The dataset includes both scanned documents and photographs captured using mobile devices, exhibiting diverse artifacts such as shadows, perspective distortion, motion blur, compression noise, partial occlusion, and document wear (eg, folds and faded text).

We intentionally prioritize diversity and realism over scale, as variability in clinical document acquisition conditions is a primary challenge for deployment. This heterogeneity introduces significant visual and structural variability, making the dataset a challenging and realistic test bed for clinical document understanding systems.

Test set samples differ from the training samples in several important ways. The training data consists of clean captures of synthetically generated documents, without blur or additional augmentation. In contrast, the test set contains documents affected by a wide range of real-world noise and artifacts. Only 3 documents in the test set originate from the same institution as the templates used to generate the training data. However, even in these limited cases, the documents remain distinct and independent; all remaining documents come from previously unseen institutions. While the layouts belong to the same general families defined during data generation, they are structurally and textually distinct from those observed in the training set.

Although limited to 50 documents, the dataset contains a large number of structured elements (fields, key-value pairs, and table cells), enabling fine-grained evaluation beyond document-level accuracy. In total, the evaluation covers 2377 structured elements (1011 text fields and 1366 annotated values) across all documents. The test set was constructed independently from the template generation process, and no exact document layouts or images were reused during synthetic data creation. Given the limited number of documents, results should be interpreted with consideration of dataset size, although the large number of structured evaluation elements provides additional robustness. Detailed statistics are provided in Table S3 in Multimedia Appendix 1.

Annotation Protocol and Interannotator Agreement

Ground truth annotations were produced by 4 annotators with complementary expertise (1 clinical nurse, 1 biomedical specialist, and 2 engineers), ensuring both clinical validity and technical consistency. Annotation was performed at the level of individual XML lines, where each unit corresponds to a structured element (eg, text blocks, table cells, or rows). All 50 documents were annotated to establish the reference standard.

To assess annotation reliability, a representative subset of documents was independently annotated by multiple annotators, covering diverse layouts such as free-text entries, tables, and mixed-format clinical forms. This subset comprised 1274 annotated units used for agreement analysis.

Interannotator agreement was measured using Cohen κ at the line level. Prior to computation, annotations were normalized to reduce the impact of XML alignment discrepancies (eg, line shifts due to missing or merged elements), which would otherwise artificially penalize agreement. Minor variations, such as spacing or small spelling differences were retained.

The overall Cohen κ was 0.73, indicating substantial agreement. Lower agreement was primarily observed in structurally complex cases (eg, nested tables or ambiguous layouts), where disagreements were typically due to representational differences rather than true semantic inconsistencies.

All disagreements were resolved through consensus-based adjudication, where annotators jointly reviewed conflicting cases and agreed on a final annotation. These adjudicated labels were used as the definitive ground truth for all reported evaluations.

Metrics include:

- OCR accuracy: character error rate (CER) and word error rate (WER), measuring transcription quality at the character and word levels.
- Information extraction: field accuracy, datatype accuracy, and F_1-scores (macro, weighted, and per-datatype), evaluating how well the model identifies each field,

XSL•FO
RenderX

classifies its semantic type, and extracts its corresponding value.
- Table structure: tree-edit-distance similarity (TEDS), assessing structural correctness of predicted tables, including row and cell organization and alignment of text to its intended cell.

Comparisons were made between: Qwen2.5-VL-Finetuned, Qwen2.5-VL-Finetuned-AWQ, Base Qwen2.5-VL, GPT-5Mini (zero-shot), GPT-5-Mini (3-shot), and GPT-5-Mini (5-shot).

To provide a fair comparison, we include both zero-shot and few-shot prompting baselines for GPT-5-Mini. In the few-shot setting, 3-shot and 5-shot prompts were constructed by providing annotated examples from the training set; prompt examples have been added in Table S6 in Multimedia Appendix 1.

To assess the statistical robustness of our results given the limited test set size, we performed bootstrap resampling over the 50 test documents. For each metric, 5000 resamples with replacement were drawn at the document level, and 95% CIs were computed as the 2.5th and 97.5th percentiles of the resulting distribution. Aggregation followed the same pooling logic as the primary evaluation, corpus-level pooling for CER and WER, and element-level pooling for field and datatype accuracy, ensuring that bootstrap means exactly reproduce the observed values. All reported results include these intervals.

Ethical Considerations

This study was reviewed by the Institutional Review Board of Samsung Medical Center and granted a waiver of full ethics review under expedited procedures (IRB case SMC 2026-05-119). All synthetic documents were generated from publicly available structural references and contain no patient information. Real-world clinical document images used for validation were fully deidentified prior to use. No patient-identifiable data was collected, accessed, or stored at any stage of this study. This study complies with *Journal of Medical Internet Research* (*JMIR*) policy and Committee on Publication Ethics (COPE) guidelines regarding ethics reporting.

Results

Text Fidelity

Overview

We evaluated text fidelity to assess how accurately each placeholder was instantiated according to its intended datatype and exemplar format. For every placeholder occurrence, we measured 3 aspects—presence consistency, format correctness, and semantic accuracy. Table 1 summarizes results across all datatypes.

Table . Text fidelity evaluation across datatypes. The table is separated in upper part being clinical information datatype and lower part other datatypes making reference to lexical datatypes useful for information extraction. The table describes high accuracy in both format correctness with a 99.68% correctness and semantic accuracy with 91.56%.

Datatype	Total occurrences, n	Format correctness, n (%)	Semantic accuracy, n (%)
Name	291	290 (99.66)	291 (100)
Date	331	329 (99.4)	331 (100)
Time	145	145 (100)	145 (100)
Phone number	20	20 (100)	20 (100)
Gender	13	13 (100)	13 (100)
Address	12	12 (100)	12 (100)
Code	102	102 (100)	92 (90.2)
Amount	69	69 (100)	69 (100)
Unit	20	20 (100)	13 (65)
Other string	840	839 (99.88)	684 (81.43)
Other int	210	210 (100)	210 (100)
Other float	205	205 (100)	205 (100)
Arrow	45	45 (100)	43 (95.56)
Symbol	25	25 (100)	4 (16)
Range	14	14 (100)	14 (100)
Combined	33	33 (100)	32 (96.97)
Select	112	108 (96.43)	99 (88.39)
Total	2487	2479 (99.68)	2277 (91.56)

The system achieved 100% presence consistency, indicating no placeholders were omitted. Format correctness remained high at 99.68%, confirming the generator effectively replicated expected syntactic patterns. Semantic accuracy averaged 91.56%, demonstrating strong contextual reliability while highlighting areas for refinement.

XSL•FO
RenderX

Detailed inspection revealed 4 main failure patterns. The observed errors can be further categorized according to their origin, which falls into two primary sources: (1) VLM's inherent limitations and (2) suboptimal synthetic training data.

Field Label–Answer Misalignment

It occurred primarily in string fields, where content belonged to the wrong information category. This is attributable to the synthetic training data, in which all field values were represented under a generic "string" type without semantic distinction, allowing heterogeneous content to be assigned to any field indiscriminately.

Entity Plausibility Failures

It includes structurally correct but fictitious entities, such as nonexistent medications ("sky medicine") or implausible departments ("Department of Neuroscience"). These are predominantly attributable to VLM hallucination, arising when sufficient grounding information is absent rather than from noise in the training corpus.

Logical Consistency Violations

It includes impossible dates or unit–value mismatches (eg, temperature recorded as "500 mg"). These are attributed to suboptimal synthetic training data. Critically, table structures in the synthetic data often had ambiguous spatial layouts between adjacent cells. This caused a systematic table-offset error, where the model misidentified the target cell for a given value. This is a known limitation of the cell-localization algorithm rather than a failure of the pipeline's semantic understanding; the extracted value itself was semantically valid, but was mapped to an adjacent field due to layout ambiguity.

Selection Incompleteness

This includes occasional failures in choosing among multiple options (eg, checkboxes or categorical values), mainly in symbol, arrow, or combined types. These errors arose from both VLM limitations — where selection markers (eg, filled circles) were misrecognized as visually similar characters — and inconsistent rendering of selection elements in synthetic documents.

Overall, the pipeline maintains high syntactic precision and strong semantic reliability. The most clinically salient errors, such as unit-field mismatches, stem from table spatial ambiguity in training data rather than semantic misinterpretation, and are addressed by the guardrails described in the Discussion section.

Lexical Diversity and Patterns

To characterize linguistic variability across datatypes, we analyzed TTR, the MTLD, and representative *n*-gram patterns. Table 2 summarizes results for both single-word and multiword fields.

Across multiword fields, the string datatype demonstrated the greatest lexical richness, with an MTLD of approximately 456 and a moderate TTR (0.22). This reflects sustained vocabulary variety and the broad semantic space typical of free-text clinical entries. In contrast, other multiword datatypes such as address and combined fields showed substantially lower

MTLD values (3-28) despite comparable or higher TTR values, indicating that their multitoken sequences are structurally repetitive rather than lexically diverse.

Patterns in single-word fields further highlight differences in constraint. Highly variable identifiers—notably code (TTR=0.70) and phone number (TTR=0.66)—exhibited strong diversity due to large pools of unique alphanumeric or numeric values. More formatted fields, including float, time, and amount, showed markedly lower diversity (TTR<0.15), consistent with tightly constrained token spaces. The lowest variation occurred in gender (TTR=0.075), reflecting an inherently small categorical vocabulary.

XSL•FO
RenderX

Table . TTR[a] and MTLD[b] values show that free-text fields (eg, other string) exhibit substantially higher lexical variability, while structured or categorical fields display lower diversity due to their formulaic structure—although some categorical datatypes with larger value spaces (eg, code and phone number) remain comparatively more varied than highly constrained ones such as gender or combined.

Datatype	Samples, n	TTR	MTLD
Single-word fields			
Name	1690	0.2399	—[c]
Date	2050	0.1579	—
Time	350	0.1229	—
Phone number	170	0.6647	—
Gender	80	0.0750	—
Code	680	0.6986	—
Amount	670	0.1444	—
Unit	200	0.4000	—
Other Int	1400	0.2238	—
Other Float	1890	0.1384	—
Multiword fields			
Other string	4930	0.2187	456.1820
Address	80	0.3129	28.1390
Combined (gender/int)	70	0.1800	7.1795
Combined (int/gender)	10	0.2000	3.3333
Combined (name/string)	10	0.4359 1	10.1250

[a]TTR: type-token ratio.

[b]MTLD: measure of textual lexical diversity.

[c]Not applicable.

N-Grams and Pareto Analysis

As presented in Table 3, the *n*-gram distribution patterns corroborate these trends. Free-text fields (other strings) produced diverse bigrams and trigrams due to their low formulaic nature and showing some moderate occurrence encompassing medical routines and dosage expressions (eg, “once daily” and “ibuprofen mg”) suggesting their common usage, therefore, showcasing high MTLD and broad linguistic coverage. In contrast, structured fields such as address displayed highly repetitive, template-driven geographic sequences (eg, “Seoul City, Gangnam-gu”), consistent with narrow semantic roles and their comparatively low MTLD. The original table in Korean is added in Table S4 in Multimedia Appendix 1.

Pareto frequency curves exhibit similar distinctions; free-text fields showed flatter accumulation profiles as seen in Figure 2B plot blue curve, indicating less dominance by a small set of high-frequency tokens, while structured or categorical fields exhibited steep curves characteristic of repetitive patterns. Combined fields, with limited sample size and predefined compositional templates, showed the strongest frequency concentration and correspondingly low MTLD values.

Overall, the lexical diversity, *n*-gram, and Pareto analyses provide a coherent picture—open-text fields maintain substantial variability and semantic breadth, whereas numeric, categorical, and structured fields are intentionally constrained, yielding predictable and repetitive patterns. These differences reflect meaningful datatype-specific characteristics rather than artifacts of the synthetic data generation process showcasing realistic data generation diversity.

XSL•FO
RenderX

Table . Top bigrams and trigrams by datatype. Free-text entries show broad n-gram variety but also a small number of moderately frequent, clinically relevant phrases (eg, "once daily"—78 occurrences out of 4930), which is expected and mirrors real-world clinical usage; these repeated patterns contribute to high measure of textual lexical diversity without indicating excessive templating. In contrast, structured fields such as addresses produce template-like geographic sequences (eg, repeated "gangnam-gu" tokens), reflecting both narrow semantic roles and a dataset-specific geographic bias.

Datatype and top bigrams (2 grams)	Top trigrams (3 grams)
String (4930 samples)	
• "once daily" (n=78) • "per day" (n=65) • "q h" (every h; n=64) • "ibuprofen mg" (n=63) • "in progress" (n=59)	• "mg if needed" (n=33) • "U A EDTA" (n=30) • "mg per day" (n=30) • "every evening dose" (n=30) • "once before meal" (n=30)
Address (80 samples)	
• "Seoul City, Gangnam-gu" (n=21) • "Gangnam-gu, Teheran-ro" (n=19) • "Building/Room" (n=13) • "Seoul, Gangnam-gu" (n=11) • "Busan, Haeundae-gu" (n=9)	• "Seoul, Gangnam-gu, Teheran-ro" (n=10) • "Seoul City, Gangnam-gu, Teheran-ro" (n=9) • "Seoul City, Gangnam-gu, Samsung-ro" (n=7) • "Seoul, Songpa-gu, Jamsil-dong" (n=6) • "Busan Metropolitan City, Haeundae-gu, Jung-dong" (n=3)
Combined name+string (10 samples)	
• "Dermatologist specialist" (n=3) • "Younghee Lee, Dermatologist" (n=2) • "Psychology professor" (n=2) • "Younghee Lee, Pediatrician" (n=2) • "Pediatrician" (n=2)	• "Younghee Lee, Dermatologist specialist" (n=2) • "Younghee Lee, Pediatrician" (n=2) • "Minsu Lee, Psychology professor" (n=1) • "Minjae Lee, Psychology professor" (n=1) • "Minji Lee, Psychology researcher" (n=1)

XSL•FO
RenderX

Figure 2. (A) Single-word fields show steep curves for structured categories (eg, gender, unit, and code) and flatter curves for more variable fields such as names and dates. (B) Multi-word fields reveal strong contrasts: free-text fields (string) exhibit the flattest, most diverse profiles, while structured fields (address) and combined fields display steep, highly repetitive distributions. These patterns align with the n-gram and measure of textual lexical diversity analyses, reflecting the inherent variability of open-text fields vs the constrained nature of structured datatypes.

RenderX

Comparison With Other Data Generation Pipelines

Table 4 displays a comparison among different pipelines. Data generation pipelines for document and text synthesis vary widely in their design objectives and capabilities. Early pipelines such as SynthText (ST), TextRenderer (TR), TextRecognitionDataGenerator (TRDG), and SynthTiger (STi) focus primarily on text line image generation. These systems are effective at producing high-quality text in multiple fonts, languages, and formats, but their outputs are limited to simple text lines. They cannot generate complex document structures, handle tables or forms, or incorporate domain-specific content, making them unsuitable for applications such as medical document generation.

Pipelines such as DocCreator (DC) and DS extend this functionality to full-page document synthesis. DC generates documents by extracting layout and style information from a given template, while DS allows the creation of academic paper–style documents following user-defined layouts. While these approaches enable some structured document generation, they are restricted in scope; DC is mainly limited to paragraph-based layouts, and DS focuses on academic formatting. Neither system adequately supports the complex forms, tables, headers, footers, or domain-specific content typical of medical documents.

Our pipeline MedDocSynth addresses these limitations by providing template-driven generation of Korean medical documents, supporting diverse document types and layouts. It enables the creation of structured content including complex tables, forms, headers, and footers, while incorporating domain-specific medical terminology. This combination of layout flexibility, structured content, and domain relevance allows MedDocSynth to generate realistic synthetic medical documents suitable for training and evaluating OCR and document understanding systems.

The comparison in Table 4 highlights the differences between existing pipelines and our approach. It shows that while SynthText, TextRenderer, TextRecognitionDataGenerator, and SynthTiger excel at basic text rendering, and DC and DS allow limited structured document generation, only MedDocSynth supports comprehensive structured document synthesis with domain-specific content, multiple layouts, and complex forms and tables.

XSL•FO
RenderX

Table . Comparison of synthetic document generation pipelines. Earlier systems (SynthText, TextRenderer, TextRecognitionDataGenerator, and SynthTiger) primarily support text-line rendering and lack structured document capabilities, while DocCreator and DocSynth provide limited page-level layout synthesis without domain adaptation. In contrast, our pipeline MedDocSynth uniquely supports template-driven Korean medical documents with complex forms, tables, multilayout structures, AI-generated clinical content, and fully structured XML annotations—enabling end-to-end generation of realistic medical documents for OCR[a] and document understanding research.

Real-World Model Evaluation

Overview

We evaluated 4 models on 50 real-world document images across 11 categories—Qwen2.5-VL-Finetuned, its quantized variant AWQ, the base nonfinetuned Qwen2.5-VL, zero-shot GPT-5-Mini, 3-shot GPT-5-Mini, and 5-shot GPT-5-Mini. Metrics included OCR accuracy (CER or WER), field and datatype classification, and table reconstruction (TEDS).

Overall Performance

As described in Table 5, the fine-tuned model achieved the highest performance, that is, character accuracy 86.01% (CER=13.99%), word accuracy 78.25% (WER=21.75%), field accuracy 67.18%, and datatype accuracy 64.14%.

In comparison, GPT-5-Mini in the zero-shot setting lagged significantly (word accuracy 65.23% and field accuracy 43.95%). Introducing few-shot prompting improved performance across most metrics; 3-shot prompting increased word accuracy to 67.07% and field accuracy to 46.36%, while 5-shot prompting showed similar performance (word accuracy 66.86% and field accuracy 46.3%). These results indicate that in-context examples help mitigate schema unfamiliarity and improve structured extraction.

However, even with few-shot prompting, GPT-5-Mini remained substantially below the fine-tuned model across all evaluation dimensions, particularly in structured outputs, such as datatype prediction and table reconstruction. Improvements from 3-shot to 5-shot prompting were limited, suggesting diminishing returns from additional in-context examples.

The AWQ variant showed moderate degradation (WER 26.8% and datatype accuracy 51.72%), demonstrating deployable efficiency with minimal loss. To evaluate this efficiency, a speed benchmark was conducted on a DGX Sparks using Qwen-2.5-VL-Finetuned and Qwen-2.5-VL-Finetuned-AWQ. Inference was performed on all 50 images in the test set, and the mean inference time and SD (in seconds) were recorded. The baseline model achieved 123.5 (SD 79.6) seconds, whereas the AWQ variant achieved 53.4 (SD 34.4) seconds.

XSL•FO
RenderX

The nonoverlapping CIs across all primary metrics confirm that performance differences between the fine-tuned model and all baselines are statistically robust despite the limited test set size.

Table . Comprehensive evaluation of OCR[a] quality, information extraction accuracy, and table reconstruction fidelity. Metrics include character or word error rates (CER[b] or WER[c]), character- and word-level recognition accuracy, field and datatype prediction accuracy, and table structure alignment measured via TEDS[d]. Each value reports the observed mean followed by the 95% bootstrap confidence interval in parentheses, estimated via 5000 resamples over the 50-document test set. Bold denotes the best result per metric.

Model	OCR accuracy				Information extraction accuracy		Table accuracy
	CER (%) ↓mean (95% CI)	WER (%) ↓mean (95% CI)	r accuracy (%) ↑mean (95% CI)	Word accuracy (%) ↑mean (95% CI)	Field accuracy (%) ↑mean (95% CI)	Datatype accuracy (%) ↑mean (95% CI)	TEDS average (%) ↑mean (95% CI)
Qwen2.5-VL-Finetuned	13.99 (9.84-18.76)	21.75 (16.21-27.94)	86.01 (81.24-90.16)	78.25 (72.06-83.79)	67.18 (59.77-74.77)	64.14 (55.16-72.07)	71.09 (57.16-85.10)
Qwen2.5-VL-Finetuned-AWQ	17.26 (11.89-23.56)	26.80 (21.04-33.06)	82.74 (76.44-88.11)	73.20 (66.94-78.96)	56.89 (48.79-65.25)	51.72 (43.26-60.44)	55.68 (37.84-75.13)
GPT-5-Mini	19.92 (15.47-24.62)	34.77 (29.33-40.44)	80.08 (75.38-85.53)	65.23 (59.56-70.97)	43.95 (38.83-49.55)	40.34 (32.86-47.80)	18.13 (13.20-29.10)
GPT-5-Mini-3-shot	19.27 (14.21-24.85)	32.93 (26.70-39.29)	80.73 (75.15-86.79)	67.07 (60.71-73.30)	46.36 (39.29-53.67)	47.81 (38.82-55.70)	42.71 (25.90-60.99)
GPT-5-Mini-5-shot	18.49 (13.75-23.58)	33.14 (26.96-39.65)	81.51 (76.42-86.25)	66.86 (60.35-73.04)	46.30 (39.47-53.03)	44.93 (37.12-52.15)	41.28 (22.66-61.27)
Qwen2.5-VL	73.70 (66.88-80.02)	82.15 (76.11-88.48)	26.30 (20.32-33.25)	17.85 (12.56-24.76)	39.41 (32.11-47.51)	31.38 (24.22-38.13)	3.98 (1.12-8.74)

[b]CER: character error rate.

[c]WER: word error rate.

[d]TEDS: tree-edit-distance similarity.

Field and Datatype Classification

The fine-tuned model as presented in Table 6 achieved macro-F_1=0.8020 and weighted-F_1=0.8051 for answer-title classification, outperforming all baselines.

Few-shot prompting improved GPT-5-Mini performance over the zero-shot setting (macro-F_1 increasing from 0.6172 to 0.6423 for 3-shot), but remained well below the fine-tuned model. Gains were primarily observed in title classification, while answer extraction recall remained limited, indicating challenges in consistently identifying structured content fields.

Table . Precision, recall, and F_1-score for classifying metadata (title) and content (answer) fields extracted by our optical character recognition system. Titles correspond to metadata labels defined in the XML ground truth, while answers represent the content associated with those labels. Accurate classification of these fields is essential for enabling structured information retrieval.

Model	Answer			Title			Macro-F_1-score	Weighted-F_1-score
	Precision	Recall	F_1-score	Precision	Recall	F_1-score		
Qwen2.5-VL-Finetuned	0.859	0.7892	0.8226	0.7164	0.8595	0.7815	0.802	0.8051
Qwen2.5-VL-Finetuned-AWQ	0.8416	0.6574	0.7382	0.6227	0.8309	0.7119	0.725	0.727
GPT-5-Mini	0.7719	0.451	0.5693	0.8653	0.5401	0.665	0.6172	0.61
GPT-5-Mini-3-shot	0.8	0.4383	0.5663	0.8885	0.6028	0.7183	0.6423	0.6305
GPT-5-Mini-5-shot	0.7978	0.4288	0.5578	0.8818	0.617	0.726	0.6419	0.6288
Qwen2.5-VL	0.7849	0.4729	0.5902	0.6727	0.4411	0.5329	0.5615	0.5658

Per-datatype performance for the fine-tuned model was highest for structured fields (date 0.8493, phone 0.8333, code 0.8095,

XSL•FO
RenderX

and address 0.8000) and lowest for rare or ambiguous types (amount and gender). Quantized AWQ performance remained competitive for some low-frequency fields.

Additionally, datatype extraction accuracy can be seen in Table S5 in Multimedia Appendix 1.

Table Structure Reconstruction

For TEDS, as presented in Table 5, the fine-tuned model achieved an average of 71.09%, with a maximum TEDS of 100%, indicating perfect table reconstruction for at least 1 complex example.

GPT-5-Mini performed poorly in the zero-shot setting (18.13%), but improved substantially with few-shot prompting (42.71% for 3-shot and 41.28% for 5-shot). This highlights that providing structural examples helps the model better approximate table layouts. However, performance remained significantly below the fine-tuned model, indicating persistent difficulty in capturing precise hierarchical and spatial relationships.

The base Qwen2.5-VL model performed poorly (3.98%), highlighting the importance of domain-specific adaptation.

Overall, results suggest that while few-shot prompting improves performance, it remains challenging to achieve high accuracy on schema-based, layout-intensive document understanding tasks without task-specific fine-tuning.

Additionally, to better characterize table reconstruction performance, we conducted an analysis of TEDS scores across document types and error modes. The proposed model achieved an average TEDS score of 71.7%, with multiple instances of perfect structural reconstruction (TEDS=1.0), indicating strong performance on well-structured tables. Class-wise analysis revealed substantial variability depending on document complexity; near-perfect performance was observed in outpatient, surgical, and pulmonary reports (TEDS≥0.93), while lower performance was observed in diagnostic and medical imaging documents (TEDS=0.31 and 0.54, respectively), which typically contain more irregular layouts.

Error analysis showed that the predominant failure mode was row mismatch, where the model over- or undersegmented table rows, particularly in dense or structurally complex tables. In contrast, column mismatches and general structural misalignment were less frequent. Notably, identical scores between structure-only and full TEDS indicate that errors are primarily structural rather than related to content recognition or text alignment. Additionally, a subset of documents did not contain explicit tabular structures and were therefore excluded from TEDS evaluation, highlighting the dependency of this metric on the presence of detectable tables. Representative failure cases are provided to illustrate these challenges.

Summary of Results

Across all metrics, fine-tuning on synthetic data significantly improved OCR and document understanding. Largest gains were observed in structured information extraction and table reconstruction (improvements of 13 - 55 percentage points). The AWQ variant confirms efficient inference is feasible without major performance loss. These results validate the effectiveness of our synthetic Korean medical document pipeline for training VLMs for its potential for real-world scenarios. Additionally, training on clean (noise-free) synthetic data proved effective for generalization to noisy real-world inputs. While the underlying cause cannot be definitively established, we hypothesize that it was already Qwen-2.5-VL's native capability, which likely enables it to handle noise and visual variability even when fine-tuned on clean data.

Discussion

Principal Findings

This study presents the first comprehensive synthetic data generation pipeline specifically designed for Korean medical documents, addressing a critical gap in OCR research for clinical applications. Rather than targeting immediate clinical deployment, this work addresses a foundational prerequisite, that is, enabling the development of structured OCR systems in settings where strict privacy regulations have historically made real clinical data inaccessible for training. Our template-driven approach successfully generates 1000 diverse medical documents across 12 distinct clinical document classes, demonstrating both the feasibility and effectiveness of AI-powered synthetic data generation in the medical domain.

The lexical diversity analysis reveals important insights about the nature of medical document content, with free-text fields (strings) exhibiting exceptionally high lexical diversity (MTLD>450 for strings), while structured fields demonstrate expected patterns of repetition that accurately reflect standardized medical formatting conventions.

MedDocSynth introduces several methodological innovations that distinguish it from existing synthetic data generation approaches. The placeholder-based system using section symbols (§) as delimiters provides robust content generation control, while AI-powered generation using GPT-4o-mini produces medically plausible content reflecting authentic clinical terminology and mixed-language patterns. The XML-based annotation format, inspired by DocTags but simplified for medical documents, provides rich metadata enabling downstream models to understand semantic roles and context. The comparative analysis reveals our approach's unique positioning, while traditional pipelines like SynthText excel at basic text rendering, and advanced systems like DC support some structured generation, only MedDocSynth combines template-driven Korean medical layouts, AI-filled clinical content, and structured XML output for comprehensive medical document synthesis.

While the pipeline comprises multiple components—including template design, placeholder-based content generation, and structured XML annotation—not all contribute equally to downstream performance. Based on our observations during development, the most critical factor is the supervision signal defined by the labeling guidelines and XML schema. In particular, consistent annotation of title-answer relationships and datatype labels proved essential, as small inconsistencies in labeling led to substantial variability in model behavior. In contrast, factors such as visual realism (eg, noise or blur) and

XSL•FO
RenderX

exact layout fidelity had a comparatively smaller impact, as the model demonstrated strong robustness to diverse document structures. The placeholder-based system and synthetic content generation played a complementary role by reinforcing semantic consistency, but were secondary to the clarity and consistency of the annotation framework. These findings suggest that the primary contribution of our pipeline lies in its structured, datatype-aware supervision design rather than in photorealistic document synthesis.

An additional methodological strength arises from our separation of model versions during development and validation. Synthetic data were generated using GPT-4o-mini, while evaluation leveraged GPT-5-Mini, ensuring that observed performance gains are not artifacts of model memorization or self-consistency bias. This design provides a conservative yet realistic assessment of how synthetic documents support downstream OCR and document-understanding tasks, highlighting that strong results stem from the quality of the template-driven generation rather than the intrinsic knowledge of any single LLM.

The clinical relevance of this work extends beyond technical OCR performance by addressing critical challenges in Korean health care digitization, where strict data protection laws have historically impeded effective OCR solution development. By providing a privacy-compliant, on-premise deployable dataset covering diverse document types from discharge summaries to laboratory reports, our work enables hospitals to develop OCR systems without compromising patient confidentiality. The practical utility demonstrated here through real-world validation represents a necessary first step toward clinical integration, with deployment studies, clinician evaluations, and workflow assessments constituting important and clearly identified directions for future work. This template-driven approach offers a generalizable framework that could be adapted for other languages and medical systems, contributing to global health care digitization efforts while maintaining the clinical realism essential for robust OCR model training.

From a governance and ethical perspective, even when using fully synthetic medical data, responsible use remains essential. Risks related to potential reidentification, unintended memorization, and scope creep must be carefully managed through clear usage boundaries, institutional oversight, and adherence to applicable privacy regulations [27].

Beyond data governance, safe deployment of clinical document understanding systems requires explicit safeguards against downstream extraction errors. To this end, we propose a layered postprocessing guardrail framework integrated downstream of the model. This includes (1) rule-based schema validation to enforce datatype and format constraints, (2) controlled vocabulary matching for closed-domain entities (eg, medications and specimen types), (3) cross-field logical consistency checks to detect violations across related fields (eg, temporal inconsistencies), and (4) human-in-the-loop review for ambiguous or high-risk cases. Such guardrails are particularly important in mitigating silent failure modes (eg, structurally valid but semantically incorrect outputs) and provide a practical pathway toward safe real-world deployment.

Limitations

This study has some limitations that should be considered when interpreting the results. First, we adopted a TSTR evaluation strategy to assess whether fully synthetic medical documents can support OCR and document-understanding model training under strict privacy constraints. This choice reflects realistic deployment conditions in which access to real clinical data is severely limited. While alternative training strategies—such as hybrid synthetic-real setups or iterative retraining schemes—may further improve performance, the TSTR configuration used in this study is sufficient to demonstrate the feasibility and practical utility of the proposed approach.

Second, the evaluation was conducted using a vision-language model with integrated OCR capabilities rather than a standalone OCR engine. As a result, observed performance gains primarily reflect improvements in layout understanding, structured extraction, and multimodal reasoning, and are influenced by the underlying capabilities of the base model.

Nevertheless, this choice aligns with current trends in document understanding, where end-to-end multimodal models are increasingly favored for complex, structured documents such as medical records.

Third, in regard to speed, deployability could be largely enhanced. While AWQ quantization helped compress the model in an efficient way, we acknowledge that our doctag tagging is computationally expensive due to the amount of tagging required. However, speed and efficiency could be easily enhanced by shortening the tag names such as <table> tag becoming <t>, <text>becoming <t>, class="title" becoming cl="t," and similar variations. This would drastically reduce the amount of tokens required and speed up the model's inference time.

Finally, real-world validation relied on a limited set of publicly available document images that broadly matched the document categories used during synthetic data generation. To partially mitigate this limitation, we performed bootstrap resampling analysis which confirmed that the observed performance gaps between the fine-tuned model and all baselines are consistent and nonoverlapping across CIs, supporting the reliability of our conclusions within the available data. Although the sample size and sourcing reflect the practical difficulty of obtaining real clinical data, the evaluation shows clear cross-domain generalization and confirms that models trained exclusively on synthetic data can perform effectively on real-world medical documents.

Taken together, these considerations highlight opportunities for incremental refinement. In practice, insights from real-world deployment, such as institution-specific document layouts or information extraction requirement schemas, can be fed back into template design, placeholder definitions, and document class selection. This iterative process allows MedDocSynth to be adapted to specific institutional contexts while preserving its core objective of enabling privacy-preserving training for structured OCR and document-understanding systems.

XSL•FO
RenderX

Conclusion

We presented a privacy-conscious, template-driven pipeline for generating realistic Korean medical documents with AI-filled content and structured XML annotations, addressing a key gap for clinical OCR. The resulting dataset spans diverse document classes and preserves domain-specific language and layout complexity, while lexical diversity analyses confirm rich free-text variability alongside expected regularity in structured fields. Together, these elements provide a practical foundation for training and evaluating OCR systems in hospital settings, enabling on-premise development without exposing patient data and offering a reusable framework that can be extended across institutions and tasks. Clinical deployment, including workflow integration and prospective evaluation, remains an important next step and a clear direction for future work building on this pipeline.

Acknowledgments

The authors declare the use of generative AI (GenAI) in the research and writing process. According to the GAIDeT taxonomy (2025), the following tasks were delegated to GenAI tools under full human supervision: code generation, creation of algorithms for data analysis, text generation, proofreading and editing, summarizing text, and reformatting. The GenAI tool used was ChatGPT-5 (OpenAI). Responsibility for the final manuscript lies entirely with the authors. GenAI tools are not listed as authors and do not bear responsibility for the final outcomes.

Abstract

Background: Primary care in Thailand often uses mixed Thai-English free-text documentation for diagnoses and clinical problems, limiting standardization, interoperability, and secondary data use. Clinical terminologies like Systematized Nomenclature of Medicine Clinical Terms (SNOMED CT), a comprehensive reference terminology, can bridge this gap through the use of structured clinical data. Developing and mapping a local user interface terminology (UIT) is one of the key strategies for implementing SNOMED CT in real-world clinical settings.

Objective: This study aimed to develop a Thai UIT derived from frequently used terms in real-world primary care practice, map these terms to SNOMED CT concepts, and evaluate the extent of concept coverage.

Methods: Frequently used clinical terms were extracted from outpatient medical records from the family, emergency, and internal medicine departments using a customized tokenization method, N-gram analysis, and expert review. This process yielded 2054 Thai-specific terms. All terms were normalized and mapped to SNOMED CT through manual expert-driven and semiautomated tools. Unmapped terms were subsequently analyzed to identify mapping barriers and solutions.

Results: Of the 2054 Thai-specific terms, 2012 were successfully mapped to 2041 (97.98%) SNOMED CT concepts, including 1781 (85.50%) fully, 123 (5.90%) broader, 56 (2.69%) narrower, 81 (3.89%) inexact mappings, and 42 (2.02%) remained unmapped. Most mappings were one-to-one (1984), with 28 terms mapped to multiple concepts (57), covering 1486 unique SNOMED CT concepts. The remaining 42 unmapped terms were mostly due to culturally specific expressions or concepts not yet represented in SNOMED CT. These were categorized for potential postcoordination, exclusion, or national extension development.

Conclusions: This study demonstrates the feasibility of developing a Thai UIT mapped to SNOMED CT and describes mapping challenges. The resulting UIT enhances semantic clarity in clinical documentation and supports better interoperability, clinical decision-making, and health data analytics within Thailand's health care system.

Introduction

Health care provision is a knowledge-intensive industry, but the quality and accessibility of health care data often fail to adequately meet these needs [1]. This is partly due to the data collection process, which commonly takes place in a fast-paced, high-pressure point-of-care environment [2], leading to the generation of data sufficient to meet the immediate clinical tasks but often lacking the completeness, standardization, and structure necessary for secondary use, for example, research, that drives health care improvement [3,4]. This limitation may compromise patient safety, care quality, and the ability to generate actionable insights [2,5]. To harness the full potential of health care data, it is essential to prioritize structured data collection that supports timely and effective use across the health care ecosystem [3,4]. Standardized clinical terminology, structured representations of clinical concepts understandable to both humans and computer systems, is an essential technology improvement required for developing reusable data that enables interoperable health care delivery [6].

Because clinical terminology must be comprehensive and support multilingual use, the Systematized Nomenclature of Medicine Clinical Terms (SNOMED CT) has been widely adopted internationally as a reference terminology standard that is indispensable for standardized information exchange across clinical care and research settings [7]. SNOMED CT adopts a concept-oriented structure; each unique clinical idea is represented by a concept identified by a language-independent, machine-readable unique identifier.

SNOMED CT consists of 3 core components, including concepts, descriptions, and relationships. Concepts represent the underlying clinical meaning; descriptions provide human-readable terms in multiple languages; and relationships define how concepts are linked within the ontology. A single concept can have multiple descriptions, enabling flexible, precise, and multilingual representation of clinical ideas. Relationships form a poly-hierarchical graph structure to express, distinguish, and connect each clinical concept, maximizing practicality while minimizing ambiguity [8]. For example, the concept “Nodule of lung (disorder)” can be described by multiple terms across languages (eg, English, French, and Swedish), and its meaning is defined through relationships as the child of both “Lesion of lung (disorder)” and “Lung mass (finding),” the associated morphology “Nodule (morphologic abnormality),” and the finding site “Lung structure (body structure).” This structure enables consistent clinical data representation and supports semantic interoperability. Successfully implementing SNOMED CT not only improves data quality and standardization of clinical data but also enhances the quality of health care through more efficient data use for both clinical and research applications [9,10]. While SNOMED CT offers a robust, language-independent conceptual framework, it does not automatically capture the variability of clinical expressions used in routine practice, particularly in multilingual or mixed-language documentation environments.

User interface terminology (UIT) refers to the set of terms clinicians use during routine clinical documentation. It consists of user-friendly and context-specific expressions that reflect the natural phrasing and cognitive patterns of clinical practice [11]. UITs are typically designed to be used by a defined user group and certain settings, prioritizing efficiency and usability [12]. Within the Open Medical Record System (OpenMRS; OpenMRS Inc) ecosystem, many implementations rely on Columbia International eHealth Laboratory (CIEL), an openly maintained UIT that serves as a common starting point for clinical data capture in OpenMRS deployments [13]. CIEL supports user-friendly clinical data capture while providing mappings to international reference terminologies (including SNOMED CT) [14], enabling the harmonization of locally meaningful data for use with global standards, facilitating secondary data use, interoperability, and research usability [3,4]. Combining the advantages of both terminologies leverages their complementary strengths, enhancing communication accuracy, data quality, and adoption among clinicians, while providing semantic precision, computability, and cross-system interoperability [10,11]. Together, they facilitate the standardization of a clinical narrative into more structured data [15,16].

Despite its advantages, implementing SNOMED CT presents challenges, particularly in non–English-speaking contexts [7,10,17]. Studies investigating the performance of SNOMED CT in multilingual contexts report 2 important indicators. Concept coverage refers to the proportion of source clinical ideas that can be represented by a concept, while term coverage refers to the proportion of source terms included in the SNOMED CT description, reflecting comprehensiveness of concept and the usability of descriptions, respectively [18]. For example, European-based studies demonstrate varying degrees of success in translation and implementation efforts. A fully translated Swedish version of SNOMED CT achieved good concept coverage (87%) but lower term coverage (47%), reflecting limited alignment with real-world clinical language [19]. In contrast, a German UIT without the use of SNOMED CT reached comparable term coverage (46%) despite the lack of codes in some key semantic areas, such as procedures, devices, or genes [16,19]. These findings suggest that constructing or adopting language-specific UITs, linked to SNOMED CT’s richer semantics and logical structure, is urgently needed and more effective than simply relying on direct translation [10,15].

Thailand became a member of SNOMED International in 2022, signaling a national commitment to adopt SNOMED CT as the reference terminology for addressing the country’s interoperability and health care data quality challenges [20]. Since joining, SNOMED CT codes have been incorporated into the national reporting and reimbursement datasets for diagnostic data. In clinical practice, a few health care institutes have begun integrating SNOMED CT’s abundant descriptions into their diagnosis entry systems. This approach complements the previous process, in which physicians manually selected *International Classification of Diseases (ICD)* codes. However, the potential benefits of adopting SNOMED CT (eg, improved data granularity, semantic interoperability, and enhanced secondary data use) have yet to be fully realized across the country [9,10]. A prior study in Thailand attempted to auto-map

XSL•FO
RenderX

Thai discharge summary terms to *ICD* codes through SNOMED CT descriptions but excluded all non-English characters, limiting its ability to interpret locally used abbreviations and mixed-language expressions common in Thai clinical documentation [21].

This study was conducted with the following 3 main objectives. First, to develop a Thai-language UIT derived from real-world clinical practice. Using a dynamic corpus of clinical texts, we apply a term collection methodology that integrates clinical expertise with natural language processing (NLP) techniques. The resulting UIT is expected to facilitate and support standardized data entry, enhance data quality, and improve user acceptance of SNOMED CT within Thailand's health care system.

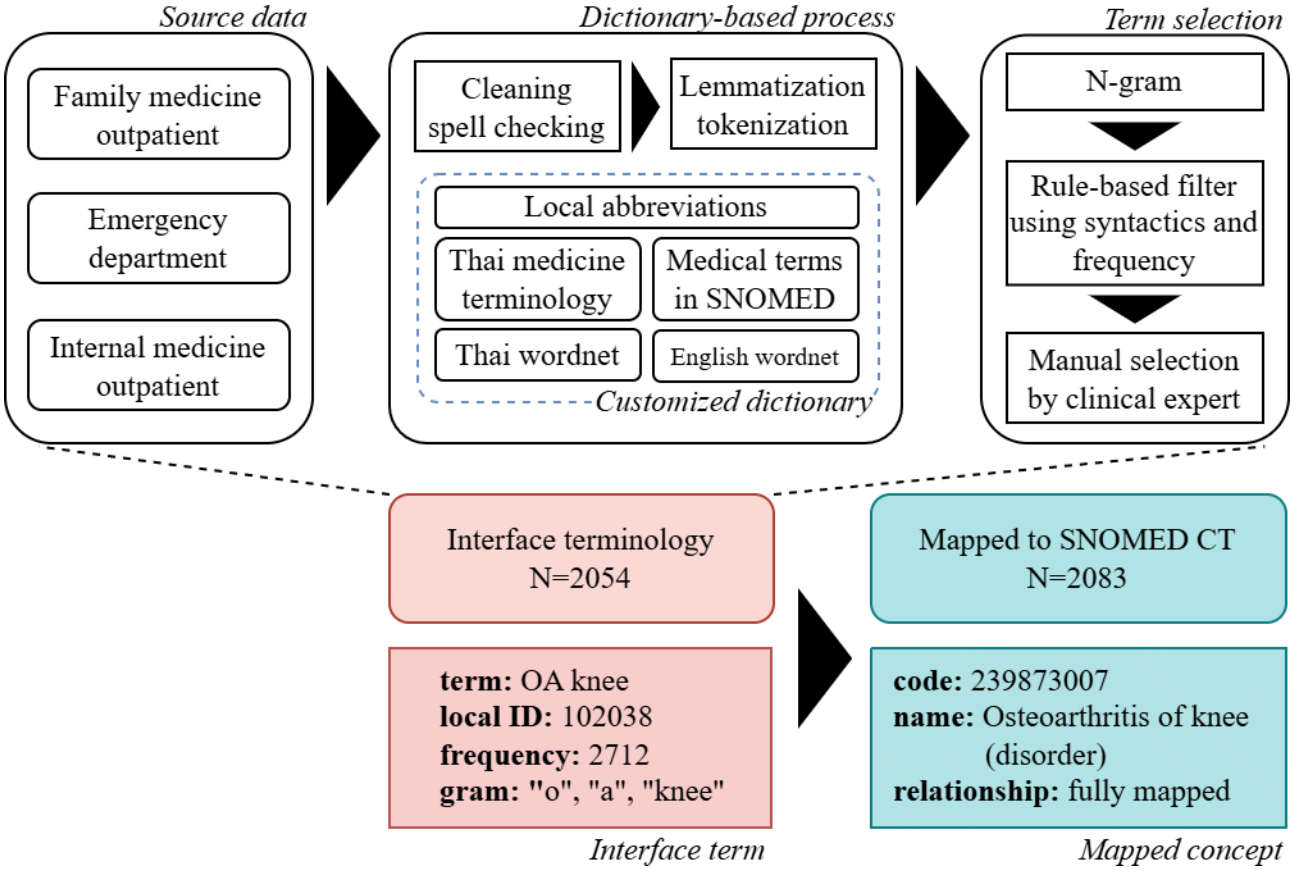
Second, to evaluate the content coverage of SNOMED CT, defined as the proportion of clinical ideas in the Thai context that can be represented through international reference terminology.

Third, to perform mapping analysis of partially mapped and unmapped terms in order to identify potential areas where SNOMED CT or the Thai national extension may need further refinement to better represent Thai health care data.

Methods

Data Source

Data used for the development of the UIT were retrospectively retrieved from the chief complaint and present illness sections of electronic medical records (EMRs) at Chakri Naruebodindra Medical Institute, Ramathibodi Hospital, Mahidol University, covering the period from January 2019 to April 2023. Data were obtained from outpatient clinics in the family medicine (FM) and emergency departments, representing primary care settings. To enhance lexical diversity and coverage, additional data were obtained from the high-volume internal medicine (IM) department. Records lacking both the chief complaint and present illness sections were excluded from the study.



UIT

In this study, UIT was defined as a set of clinically relevant terms used by clinicians to express their clinical ideas within the EMRs. These terms can be presented in either the semistructured or unstructured free-text entries. To qualify as UIT, the terms must contain adequate meaning, clarity, and clinical specificity to support accurate documentation and enable secondary uses, as assessed by medical doctors (eg, " " [chest pain], " " [vomiting blood], " " [ischemic heart disease]), whereas terms that were vague or noninformative (eg, "1 pta" [1 month prior to admission] or "without evidence of") were not considered UIT.

The content of the UIT was harvested from the free-text documents produced during actual patient encounters. Clinician-entered free-text data (chief complaint and present illness) from the EMRs were preprocessed and transformed into clinical terms using NLP techniques, including cleaning, tokenization using our customized method, and N-gram generation. Term frequencies were then calculated, and terms meeting predefined threshold criteria were included in the UIT. The overall process is illustrated as follows (see Figure 1):

XSL•FO
RenderX

Figure 1. Summary overview of the mapping process. Collecting data from all sources (left upper box). Turning free text to N-gram using a customized dictionary from 5 sources (middle upper box). Interface terms selected by term frequency and experts (right upper box). Indexing the interface terms (pink). Mapping to the semantically equivalent SNOMED CT concept (blue). OA: osteoarthritis; SNOMED CT: Systematized Nomenclature of Medicine Clinical Terms.

Text Preprocessing and Tokenization

Free-text data were preprocessed using the Python library for Thai NLP (ie, PyThaiNLP version 4.0.2) [22], which normalized texts by applying case normalization, correcting misplaced Thai tone marks and vowels, removing punctuation, and eliminating duplicate entries (eg, repeated sentences from prior visits). This process removed approximately 11.4% of the total characters, improving data consistency and validity. The code used for implementing text preprocessing and tokenization is provided in the GitHub repository [23].

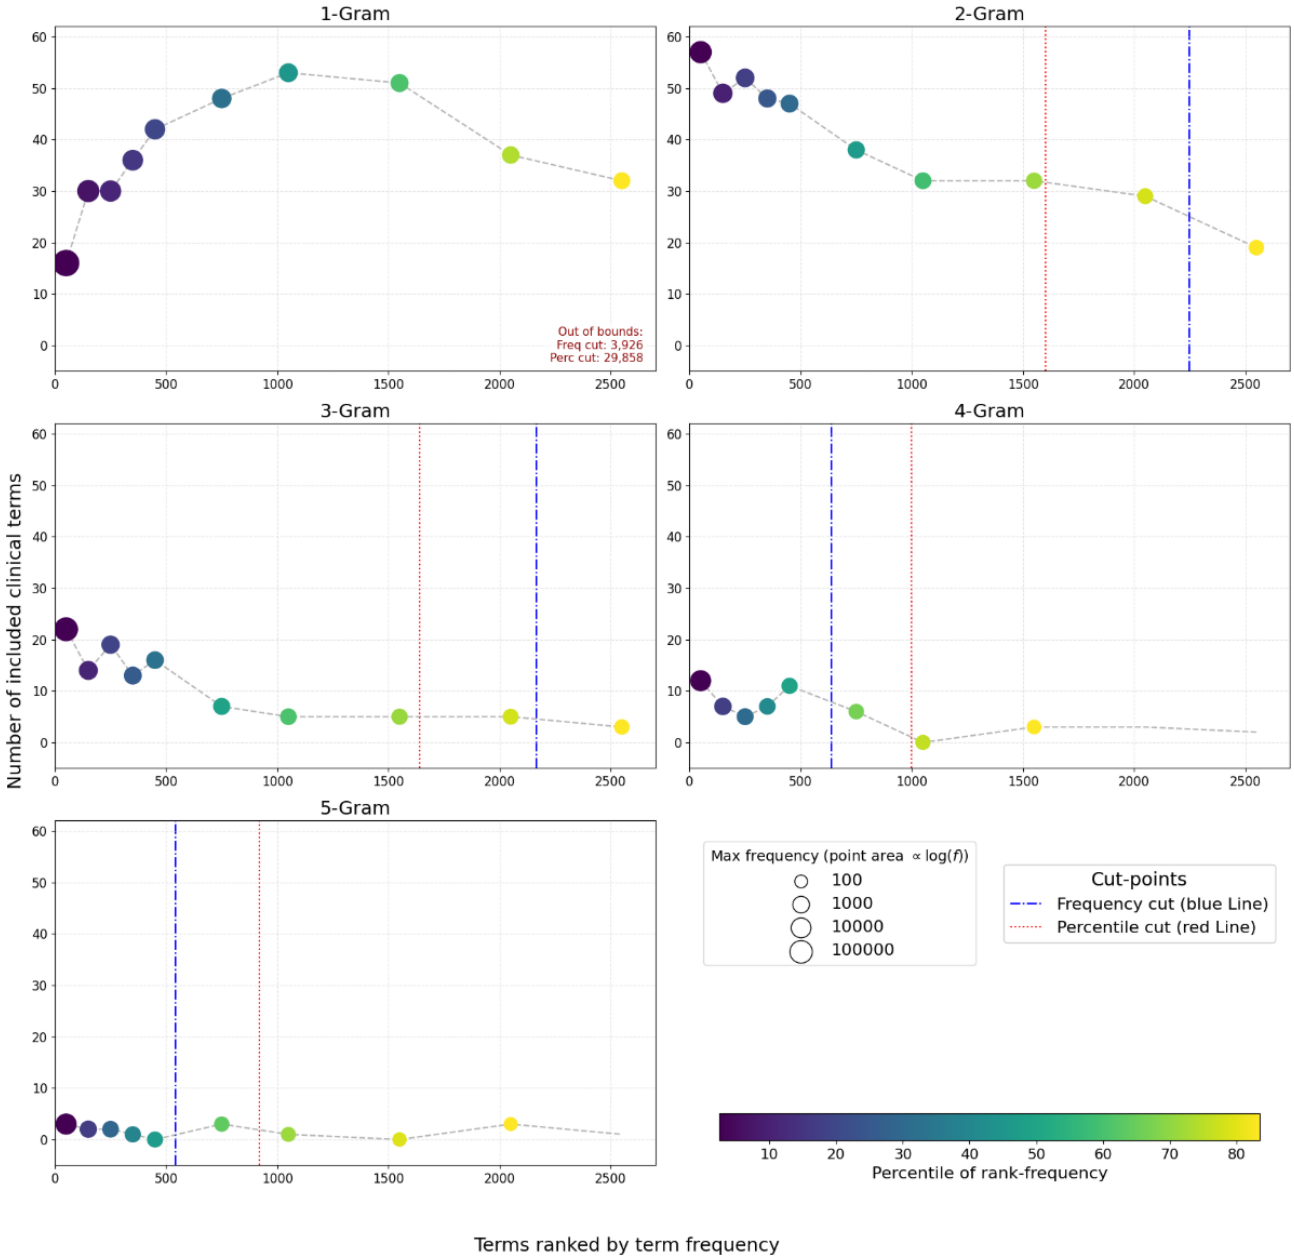
Because Thai is a continuous-script language, which has no word and sentence boundaries (eg, “ ” [ischemic heart disease] consists of 4 lexical units: “ ”(disease), “ ”(heart), “ ”(deficiency), “ ”(blood)), standard Thai tokenizers trained on general Thai corpora perform poorly, particularly for medical text [24]. We therefore used a customized maximum matching algorithm, a greedy approach that segments text by repeatedly choosing the longest possible valid term from a dictionary that matches the current position. The dictionary was expanded to include medical jargon, drug names, and local abbreviations to optimize tokenization accuracy for clinical narratives.

Formally, given an input string S and a dictionary D, at each position j, the algorithm identifies all candidate substrings of S beginning at j that appear in D, and selects the candidate with the maximum length. This substring is then appended to the output sequence of tokens, and the process continues from the next unmatched character until the entire string is segmented.

This left-to-right longest-match strategy enables more accurate tokenization of Thai medical terms.

The custom dictionary D integrated five sources (Figure 1) (1) English WordNet; (2) Thai WordNet; (3) SNOMED CT descriptions (providing English clinical terms and medical jargon); (4) Thai medicine terminology (the national medicine database contains drug ingredients, generic names, trade names, and herbal medicine); and (5) a manually curated abbreviation dictionary (Multimedia Appendix 1), comprising abbreviations with ≥2 capital letters occurring >100 times in the dataset. These abbreviations were reviewed by physicians, validated using 5 random samples of medical records, and mapped to SNOMED CT. This custom dictionary was also used to spell-check before tokenization, ensuring that incorrect or nonstandard spellings were corrected before segmentation (Figure 1).

The N-grams of length 1 - 5, representing continuous sequences of N tokens (or grams), were generated to identify meaningful patterns and construct candidate terms or phrases.



For example, words contained unigram to 5-grams were: “ ” (fever) for unigram, “ ” (abdominal pain) for bigram, “ ” (oral cavity wound) for trigram, “ ” (both legs are swelled) for 4-gram, and “ ” (abnormal bleeding from vagina) for 5-gram. Syntactically irrelevant N-grams (ie, those containing >50% stop words, punctuation,

XSL•FO
RenderX

or numbers; or terms beginning or ending with stop words or prepositions) were excluded. The remaining N-grams were ranked by frequency and carefully reviewed by experienced clinicians. Clinically relevant terms were defined as those that conveyed sufficient meaning for documenting patient conditions.

In the first round, medical doctors reviewed intervals of ranked lists (Multimedia Appendix 1), marked the terms that are clinically meaningful and appropriate for representing as structured data, and selected the terms by applying the following inclusion criteria: (1) frequency rank within the top 70th percentile or (2) absolute frequency ≥300 occurrences, thresholds that reflected diminishing returns in identifying clinically relevant terms (Figure 2). After the second round, 2054 terms were selected from the pool of 10,260 candidate terms for inclusion in the interface terminology, representing commonly used clinical expressions across EMRs.

Figure 2. Numbers of included clinical terms per interval of rank-frequency categorized by the N of N-gram. Blue vertical lines indicate the cut point where term frequency was 300. Red vertical lines indicate the cut point where the percentile of rank-frequency reaches 70.

Mapping to SNOMED CT

Each UIT term was mapped to a semantically equivalent SNOMED CT concept using Snap2SNOMED, an open-source, publicly available mapping tool developed and maintained by SNOMED International. The tool provides key functionalities, including a built-in SNOMED CT browser, versioning, and automated lexical mapping (applicable to English-language terms only). Because automated mapping requires English input, 946 Thai terms were translated into English using Google Translate (Google LLC), and these translated terms were used as source terms for mapping. The automated mapping results were manually reviewed and validated by 2 clinical domain experts (NT and JS). To ensure semantic equivalency to the original Thai terms, 5 clinical usage contexts were supplied to the mappers for each term, selected at random from different patients. Manual mappings were guided by semantic equivalence

XSL•FO
RenderX

criteria recommended in the Snap2SNOMED User Guide, prioritizing alignment for meaning, clinical intent, and hierarchical appropriateness. Disagreements between mappers were resolved through iterative discussion and consensus-based remapping.

Mapping results were classified into three categories, as illustrated in Figure 1: (1) fully mapped: SNOMED CT concepts that fully captured the semantics of the source term (eg, "valvular heart disease" mapped to "Heart valve disorder [disorder]"); (2) partially mapped: SNOMED CT concepts that were close but not fully semantically equivalent to the source term (eg, "home SBP" mapped to the narrower concept "Average home systolic blood pressure [observable entity]"); and (3) unmapped: source terms that lacked sufficient representation in existing SNOMED CT concepts.

A single source term could be potentially mapped to multiple SNOMED CT concepts (referred to as one-to-many mapping), resulting in more mapping pairs than source terms. This arose from one of two scenarios (1) homonyms, terms carried multiple distinct meanings, each represented by different SNOMED CT concepts following guidelines from SNOMED CT managing conventions and (2) ambiguous terms explicitly excluded from SNOMED CT due to insufficient contextual specificity (eg, "fundus" referring to either a hollow organ apex or the eye's interior surface). These ambiguous terms were conservatively classified as unmapped to preserve terminological clarity and precision.

Partially mapped pairs were further classified into broader, narrower, and inexact relationships to quantify mapping quality. The broader referred to the SNOMED CT concept, which encompasses the meaning of the source term. Narrower referred to when the SNOMED CT concept represented only part of the source term's meaning. In cases where semantic equivalence required postcoordination with multiple SNOMED CT concepts, we selected a single precoordinated concept in the same hierarchy as the narrower one. For example, "nodule at right upper lung" was mapped to the broader concept "Nodule of lung (disorder)" rather than combining a finding with "Upper lobe of right lung (body structure)." Inexact referred to mappings where the best available SNOMED CT concept differed in lexical and semantic characteristics but provided a clinically relevant approximation. For example, "over-the-counter drug use" was inexactly mapped to "Patient on self-medication (finding)."

Mapping Analysis

Terms unable to be mapped by mappers were discussed and categorized into either partially mapped or unmapped terms, including ambiguous terms and terms for which no semantic equivalency was found in SNOMED CT. For the terms that can be represented using postcoordination of 2 or more concepts from the same hierarchy, for example, " " (sweating and palpitation), we decided to categorize them as unmapped terms for further analysis. Partially mapped and unmapped terms were analyzed to assess their potential for practical implementation within our research team. Specifically, the analysis examined whether these terms could be adequately represented through SNOMED CT postcoordination or should be proposed for inclusion in an updated national edition of SNOMED CT. This evaluation helped identify specific content areas where concept expansion would better align the terminology with local clinical practice and ensure comprehensive coverage in the national edition.

Ethical Considerations

The study protocol was reviewed and approved by the Ramathibodi Human Research Ethics Committee (Approval number COA.MURA2023/469). The informed consent was waived due to the retrospective nature of the dataset and minimal risk to participants. All personally identifiable information (eg, names, surnames, dates of birth, addresses, hospital numbers, and visit dates) was removed from the dataset prior to analysis to ensure privacy and confidentiality.

Results

Dataset Characteristics

A total of 1,88,468 documents were initially retrieved from the EMRs during the study period. After excluding records with missing data, 1,83,557 documents from 53,142 patients were included in the analysis to develop the interface terminology. Characteristics of the 53,142 patients are described in Table 1. IM patients were the oldest (mean 59.3, SD 16.9), followed by FM (mean 54.4, SD 15.2), and emergency department (mean 43.4, SD 28.0). The percentage of males was highest in emergency (44.3%), followed by IM (39.7%) and FM (36.94%).

At the document level, the IM department contributed the largest volume (1,18,382/1,83,557, 64.5%), followed by the emergency (34,829/1,83,557, 19.0%) and FM departments (30,346/1,83,557, 16.5%). The median number of documents per patient (IQR) was 2 (1-5) for IM, 1 (1-2) for emergency, and 1 (1-3) for FM (Table 1).

Text-level analysis of 1,83,557 documents yielded 14,946,559 total words. IM contributed the majority (10,471,768/14,946,559, 70.1%), followed by emergency (2,750,896/14,946,559, 18.4%) and FM (1,723,895/14,946,559, 11.5%). Median (IQR) words per document were 107 (62-175) for IM, 74 (44-125) for ER, and 60 (38-99) for FM. Thai words were varied by department. Emergency department documents had the highest proportion of Thai words (1,752,756/2,750,896, 63.7%), followed by FM (1,016,914/1,723,895, 59.0%), while IM contained the lowest proportion (4,154,255/10,471,768, 39.7%).

[a]FM: family medicine.

[b]ER: emergency room.

[c]IM: internal medicine.

Coverage

A total of 2054 frequently used clinical source terms met the inclusion criteria and were integrated into the interface terminology. Of these, 2012 terms were successfully mapped to 2041 SNOMED CT concepts. Most terms were mapped one-to-one (1984 terms), while 28 terms were mapped to 57 multiconcepts through one-to-many mappings, yielding a total of 2083 entries while covering 1486 unique SNOMED CT codes. The final mappings are provided in Multimedia Appendix 2. Mapping characteristics are as follows:

- Language: English (1140 out of 2083 terms [54.73%]) and Thai (943 out of 2083 terms [45.27%]).
- N-gram: unigrams (1098 terms), bigrams (741 terms), trigrams (189 terms), 4-grams (45 terms), and 5-grams (10 terms).
- Equivalency: 1781 (85.50%) fully mapped terms, 123 (5.90%) mapped to broader concepts, 56 (2.69%) mapped to narrower concepts, and 81 (3.89%) inexactly mapped terms (Table 2). The remaining 42 terms (2.02%) could not be mapped due to culturally specific expressions or clinical concepts not yet represented in any SNOMED CT concept.
- Overall, the concept coverage was 85.50%. Combining fully and partially mapped terms yielded an overall concept coverage of 97.98%.

Term coverage is defined as the percentage of local clinical terms that can be accurately mapped to an existing SNOMED CT description. Among 1140 English terms, 656 terms (31.49%) had direct lexical matches with English SNOMED CT descriptions, including simple variations of writing, for example, “wound dressing” versus “Dressing wound.” The remaining 484 English terms (23.24%) did not have an exact lexical match and were still mappable through contextual interpretation, such as local abbreviations (eg, “f/u” → “Follow-up visit [procedure]”), or variation in writing style (eg, “contact tb” → “Exposure to tuberculosis [situation]”). As expected, no Thai terms were considered direct lexical matches because SNOMED CT descriptions are not yet translated into Thai.

Table . Concept coverage of Systematized Nomenclature of Medicine Clinical Terms (SNOMED CT) for Thai interface terminology.

Concept equivalency	English	Thai	Total
Fully mapped, n (%)	973 (46.71)	808 (38.79)	1781 (85.50)
Partially mapped, n (%)	140 (6.72)	120 (5.75)	260 (14.48)
Broader	65 (3.12)	58 (2.78)	123 (5.90)
Narrower	38 (1.82)	18(0.86)	56 (2.69)
Inexact	37 (1.78)	44 (2.11)	81 (3.89)
Unmapped, n (%)	27 (1.30)	15 (0.72)	42 (2.02)
Total, n (%)	1140 (54.73)	943 (45.27)	2083 (100)

XSL•FO
RenderX

Mapping Analysis

Mapping analysis of the 260 partially mapped terms revealed linguistic and semantic challenges. All 123 broader (5.90%) and 56 narrower (2.69%) pairs comprised of concepts differed in granularity, where terms belonged to the same semantic domain, but they were at different levels of clinical detail or abstraction. On the other hand, inexact terms arose when clinical intention aligned, but lexical or cultural expression differed. For example, “ ” (sleep with multiple pillows) was used to indicate the situation when a patient cannot sleep lying down due to shortness of breath; it was inexactly mapped to “Orthopnea (finding)” and “ (taking medicine regularly)” and its variations were the patient-reported concept “Drug compliance good (finding).”

We also observed that culture and linguistic characteristics contributed to mismatches. Some Thai expressions convey complex clinical scenarios through idiomatic phrasing, complicating alignment with SNOMED CT. For example, “over-the-counter drug use” in the Thai context often implies access to medications that would require prescriptions in many other countries. After deliberation in our team, although this was mapped to “Patient on self-medication (finding),” this concept does not fully capture its implications within Thailand’s health care system.

Forty-two unmapped terms (2.02%) were further categorized into 3 categories based on their characteristics (see Table 3).

Ambiguous terms (23/42, 54.76%) violated SNOMED CT naming conventions and required additional contexts for appropriate representation (eg, “lobe,” “node,” and “septum”).

Multiple clinical concepts (10/42, 23.81%) represented multiple distinct findings or events (eg, “s1 s2” [heart sounds], “ ” [sweating and palpitation], “ ” [fall and head collision]). Many terms reflect Thai-specific linguistic constructions and could potentially be addressed through postcoordination.

Clinically meaningful terms without SNOMED CT equivalents (9/42, 21.43%). Some terms were (locally) nationally specific (eg, “ ” [fear of heights or a feeling of butterflies in the stomach]) while others were universally applicable but absent from SNOMED CT (eg, “ ” [antipyretic medicine] and “DOI” [date of infection]). The terms were exhaustively searched using both lexical and graph properties of SNOMED CT through the use of SNOMED CT Expression Constraint Language.

Table . Categories for unmapped concepts.

Characteristics	Ambiguous terms	Multiconcept terms	No concept terms
Value, n (%)	23 (54.76)	10 (23.81)	9 (21.43)
Further intervention	Exclusion from terminology or addition of contextual information	Postcoordination or separation to multiple distinct concepts	Creation of new concept
Examples	• Lobe • Node • Septum	• S1S2 (Heart sounds) • (sweating and palpitation) • (fall and head collision)	• DOI (Date of Infection) • (Antipyretic medicine) • (fear of heights or a feeling of butterflies in the stomach)

Discussion

Principal Findings

This study developed a multilingual UIT derived from real-world clinical documents across the FM, emergency, and IM departments and evaluated its alignment with SNOMED CT. The resulting UIT reflects a nearly balanced linguistic composition (54.49% English terms and 45.51% Thai terms). Consistent with the bilingual nature of Thai medical records. SNOMED CT demonstrated strong concept coverage with 85.50% full and 97.98% full plus partial coverage, confirming its suitability as a reference terminology even in the setting where nearly half of the source terms are non-English. However, term coverage remained modest (31.49%) because SNOMED CT descriptions have not yet been translated into Thai, making exact lexical matches possible only for English-language terms.

The source data also showed different patterns in clinical documentation practices. For instance, IM generated the highest volume of text but had the lowest proportion of Thai words, consistent with its more technical and specialty-oriented clinical activities. In contrast, emergency and FM documents contained more Thai narrative language, which may reflect more direct patient-provider interaction, brief encounters, and patient-reported symptoms. These differences emphasize the need for UITs that can accommodate both biomedical language and colloquial Thai expressions.

We also found that only a small proportion of terms remained unmapped (2.02%), underscoring that the majority of local expressions can be integrated into SNOMED CT without major structural changes. These relatively small, unmapped concepts may help identify where efforts should be strategically concentrated at the national level. Moreover, the moderate-term coverage (31.49%), driven entirely by English lexical matches, reinforces the need for localized terminology tools and translation strategies if Thailand aims to scale SNOMED CT adoption nationwide.

Comparison With Previous Work

Despite differences in term extraction methods, particularly our focus on commonly used clinical terms and the use of a more recent SNOMED CT release, our findings generally align with previous evaluations of SNOMED CT concept coverage. Prior studies have reported a strong preference for high coverage in

XSL•FO
RenderX

the English-language international edition (86% fully mapped and 92% partially mapped) and similar strong performance in the fully translated Swedish edition when applied to Swedish clinical datasets (87% fully mapped and 92% partially mapped) [19]. In comparison, our findings showed 85.50% full and 97.98% full plus partial coverage, demonstrating that SNOMED CT remains robust even in bilingual and partially non-English documentation environments.

Comparable evidence has also been observed in low- and middle-income country settings. For example, an evaluation from Argentina reported 83% coverage based on user feedback during real-world implementation [12]. Other specific domains targeting nationwide data collection and surveillance objectives have very high coverage, 99% precoordinated and 100% postcoordinated concept coverage for AIDS-defining illnesses in Kenya [25], and high correspondence for tuberculosis-related terminology, although the latter did not include a formal concept coverage analysis [14].

In Thailand, a prior study mapped Thai discharge summary notes to SNOMED CT but removed non-English content and did not report concept coverage [21]. Our study extends this work by incorporating both English and Thai clinical terms from 3 departments, performing concept coverage, term coverage, and mapping analysis, and examining implications for national UIT development. This provides a more comprehensive and representative assessment of SNOMED CT's applicability for Thai primary care and hospital settings.

Partially mapped terms frequently reflect homonyms (eg, " " meaning both abdominal colic and a cigarette unit), mismatches in granularity (eg, "hypoglycemic symptom" mapped to hypoglycemia [disorder]), or culturally shaped usage patterns. These challenges are consistent with those reported in other multilingual SNOMED CT mapping studies [10,26]. In the Thai language, many biomedical concepts and terms are not readily expressed in Thai. Unlike languages that share linguistic roots (eg, English, French, and Swedish), Thai lacks direct lexical equivalents for some medical terms, creating communication barriers between clinicians, patients, and even health care providers. To ensure mutual understanding, clinicians need to phrase simple questions that patients can comprehend, allowing information to be collected accurately. For example, "compliance" is simply conveyed as "taking medicine regularly" or "never miss a dose," which is reflected in how these terms appeared in the EMRs. This observation has also been reported in other languages, not from the same roots as the English language [27].

Term coverage in our dataset was modest (31.49%), driven entirely by English lexical matches. The observed term coverage is comparable with countries whose SNOMED CT editions are only partially translated, for example, Dutch (35%) and French (39%) [19]. A considerable proportion of our Thai clinical terms were synonymous with globally common English medical jargon, reflecting Thailand's long-standing integration of English terminology in medical education and clinical communication. As shown in Table 1, Thai language use was more prevalent in primary care departments (FM and emergency), while IM documents contained more specialized English terminology, consistent with previous reports [28].

Challenges in Expressing Clinical Concepts in the Thai Context

Our mapping analysis of partially mapped terms highlighted several challenges in representing Thai clinical concepts within SNOMED CT. Many partially mapped terms require determining whether they should (1) be represented through postcoordination with existing SNOMED CT concepts (thereby supporting international interoperability) or (2) be introduced as new concepts in the Thai national extension to preserve locally specific meaning.

Postcoordination can be beneficial for international interoperability but may lose nuanced local semantics. Conversely, creating new concepts preserves the locally used expression but introduces a long-term maintenance burden and requires clear criteria for inclusion. No standardized national guidelines currently exist; decisions must consider clinical relevance, documentation frequency, clinical importance, and anticipated use cases within Thailand's EMR ecosystem. A representative example from our study is "over-the-counter drug use," which frequently appeared in our dataset and reflects a long-standing public health challenge in unsupervised medication access in Thailand [29], which contributes to national issues such as antimicrobial resistance and drug misuse [30]. While "Patient on self-medication (finding)" is the most relevant concept in SNOMED CT, it does not fully represent Thailand's regulatory distinctions and safety concerns. If more granular differentiation is required in Thailand for surveillance or policy purposes, a new child concept under "Patient on self-medication (finding)" may be warranted.

The analysis of unmapped terms also highlighted the role of language-specific and culturally specific expressions that are not directly translatable into English (see Table 3). In our data, 20.93% of unmapped terms reflected culturally unique, ambiguous, or context-dependent meanings. These findings suggested three key strategies for terminology management and strengthening (1) exclude ambiguous terms or add contextual information to the context-dependent terms. For example, the Thai term " " has multiple meanings (fear of heights or a feeling of butterflies in the stomach). Instead of mapping it directly, adding the more specific term " " (giddiness in the heart) mapped to "Palpitations (finding)" can ensure clarity and avoid misclassification. (2) Use postcoordination for multiconcept or idiomatic expressions. This pattern was also found in the English context, for example, the concept "Nausea and vomiting (finding)," which exists as a precoordinated concept within the international edition of SNOMED CT. However, since separated distinct concepts are presented, we suggest mapping to separate entities to preserve legacy information and also interoperability with the international context. (3) Recommend new concepts for national extension or international inclusion for globally relevant but unsupported terms. This should be done with a well-established concept with clear practical implications. One example we found was a local abbreviation, "DOI (Date of Infection)," which we believe has seen an increase in occurrences during the pandemic, particularly

XSL•FO
RenderX

in cases where infectious history has been thoroughly collected. Additionally, some of these represent global clinically relevant concepts insufficiently addressed by SNOMED CT, indicating areas for future expansion [7].

Overall, these challenges highlight the need for national governance structures, clearly defined criteria for new concept creation, and a systematic strategy for translation and localization to ensure accurate, consistent, and interoperable representation of Thai clinical terminology. Regional guidance from the Asia eHealth Information Network (AeHIN) similarly emphasizes that successful and sustainable interoperability depends not only on the technical standards but also on governance, architecture, workforce capacity, and institutional processes [31]. Centralized governance through a national health data dictionary and terminology services, as described in many interoperability architectures, like Open Health Information Exchange (OpenHIE; Linux Foundation Public Health), can standardize terminological assets and reduce fragmentation across implementation sites [32]. Such services can support the controlled use of postcoordination and governed concept creation and enable local expressiveness while preserving semantic consistency and international interoperability. Importantly, these functions are best managed at the terminology service level rather than within individual EMR implementations, thereby reducing duplication and implementation burden. In addition, mappings between shared UITs and reference terminologies or classification systems (eg, the *ICD* family) should be centrally maintained, versioned, and routinely updated. For example, the OpenMRS ecosystem also adopts the similar implementation pattern, where many deployments rely on the CIEL interface terminology, centrally managed and distributed via Open Concept Lab, supporting reuse and reducing divergence across implementations [13].

Strengths and Limitations

To our knowledge, this is the first study in Thailand—and among the few resource-limited countries—to develop a UIT and evaluate both concept- and term-level coverage of SNOMED CT in a real-world clinical setting. A key strength of this study lies in its data source, free-text entries from actual clinical encounters, which ensures that the extracted terms are grounded in real-world usage. Moreover, the terminology development process integrated clinical expertise with NLP techniques in a resource-limited setting, offering valuable insights for similar environments. The final UIT is composed of the commonly used clinical term. Although it is small in numbers, we believe this terminology to be generally applicable for use within Thailand. Although SNOMED CT concept coverage has been examined in a few resource-limited country settings, evidence remains scarce. This study extends the discussion to Southeast Asia by evaluating Thai-language primary care data, constructing a UIT mapped to SNOMED CT, and reporting concept coverage.

Several limitations should be acknowledged. First, source data were collected from a single hospital, which may limit the generalizability of the developed UIT. Consequently, the developed UIT may not fully capture the diversity of expression terms used across Thailand's broader health care system, particularly in regions where distinct dialects or documentation styles prevail. Nevertheless, this study achieved its goal of constructing a realistic UIT to inform national implementation strategies and evaluate the feasibility of adopting SNOMED CT as a national standard. As new clinical terms and concepts emerge, the UTI can be continuously expanded through routine monitoring, domain-expert review, and integration of automated extraction tools to ensure incremental improvement over time. Second, although the mapping and term extraction processes were performed by clinically trained physicians, the subjective nature of manual mapping introduces the potential for interpretation bias or human error. An interannotator agreement score was not assessed due to constraints in available personnel and resources; consequently, only one mapper and one reviewer contributed to the final mapping. Third, the coverage results may be overestimated compared to those reported in previous studies because our term list was developed from commonly used clinical expressions and mapped to a more recent SNOMED CT release. At the same time, the mapping tool Snap2SNOMED does not support postcoordination at the time of this writing, which may lead to a potential underestimation of full SNOMED CT content coverage. However, since postcoordination has not been generally performed in previous studies, the results remain broadly comparable with existing evidence [19].

Recommendation for Future Research

Future research should expand the evaluation of concept and term coverage across hospitals of varying sizes and settings, including northern, northeastern, and southern regions of Thailand, where specific dialects may influence clinical documentation practices. Extending these methods beyond a single institution will help determine the generalizability of the UIT and support efforts toward national standardization.

Automated methods should also be explored. Advanced NLP techniques and large language models may substantially improve the efficiency and accuracy of term extraction, disambiguation, and SNOMED CT mapping, particularly as our team is already beginning to implement these tools in parallel methodological work. Additional studies should examine how postcoordination can be operationalized in real-world EMRs, with the goal of identifying best practices that maintain semantic precision without burdening clinicians during documentation.

Finally, future research should include more diverse document types (eg, operative notes, procedure reports, and specialty consults) and a broader population. Doing such improves characterization of locally used clinical concepts, strengthens coverage estimates, and supports the development of a more comprehensive national UIT that accurately reflects the linguistic and clinical diversity of Thailand's health care system.

Conclusions

In conclusion, SNOMED CT represents most common clinical concepts but lacks sufficient local language coverage. With the interpretation of local clinical terms, a Thai UIT mapped to SNOMED CT can serve as a comprehensive standard for clinical documentation. This hybrid approach can enhance data quality, promote interoperability, and facilitate better use of health care

data, contributing to improved patient care and creating opportunities for international collaboration.

Abstract

Background: Psychiatric disorders are diagnostically challenging and often rely on subjective clinical judgment, particularly in resource-limited settings. Large language models (LLMs) have demonstrated potential in supporting psychiatric diagnosis; however, robust evidence from large-scale, real-world clinical data remains limited.

Objective: This study aimed to evaluate and compare the diagnostic performance of multiple LLMs for psychiatric disorders using multicenter real-world electronic health records (EHRs).

Methods: We retrospectively analyzed 9923 inpatient EHRs collected from 6 psychiatric centers across China, encompassing all ICD-10 (International Statistical Classification of Diseases, Tenth Revision) psychiatric categories. In total, 3 LLMs—GPT-4.0 (OpenAI), GPT-3.5 (OpenAI), and GLM-4-Plus (Zhipu AI)—were evaluated against physician-confirmed discharge diagnoses. Diagnostic performance was assessed using strict accuracy criteria and lenient classification metrics, with subgroup analyses conducted across diagnostic categories and age groups.

Results: GPT-4.0 achieved the highest overall strict diagnostic accuracy (71.7%) and the highest weighted F1-score under lenient evaluation (0.881), particularly for high-prevalence disorders, such as mood disorders and schizophrenia spectrum disorders. Diagnostic performance varied across age groups, with the highest accuracy observed in older adult patients (up to 79.5%) and lower accuracy in adolescents. Across centers, model performance remained stable, with no significant intercenter differences.

Conclusions: LLMs—especially GPT-4.0—demonstrate promising capability in supporting psychiatric diagnosis using real-world EHRs. However, diagnostic performance varies by age group and disorder category. LLMs should be regarded as assistive tools rather than replacements for clinical judgment, and further validation is needed before routine clinical implementation.

Introduction

Mental disorders are a significant public health concern worldwide; they have high prevalence rates, which are continuously increasing each year [1]. About 20% of the global population is estimated to experience mental illness in their lifetime, placing a substantial burden on both society and health care systems [2]. However, there is an acute scarcity of psychiatric professionals. Many countries have fewer than 5 psychiatrists per 100,000 individuals; this results in delays in providing timely, high-quality diagnostic and therapeutic services for patients with mental health disorders, particularly in resource-limited regions, including China [3]. This medical resource shortage further underscores the urgent need to increase the accuracy and efficiency of psychiatric diagnoses. In addition, psychiatric diagnoses are inherently complex and challenging. Complex etiologies and high symptom heterogeneity characterize mental disorders. The symptom descriptions of patients often depend on subjective expression, with physicians' medical records and clinical diagnoses also based on their subjective experience [4]. This subjectivity makes diagnoses susceptible to variation among physicians, leading to inconsistent diagnostic outcomes. Therefore, in psychiatry, there is a crucial need to use modern technologies to increase diagnostic efficiency and accuracy [5].

Recently, the widespread adoption of electronic health records (EHRs) has provided a wealth of unstructured data to support the application of artificial intelligence technologies in medical diagnostics, offering new opportunities for diagnosing psychiatric disorders [6]. Large language models (LLMs), including the GPT series, exhibit powerful capabilities in natural language processing and semantic understanding. They can efficiently process unstructured text and have shown great potential in medical diagnostic assistance [7-10].

At present, studies on the application of LLMs in other medical fields have further confirmed their clinical potential. For example, Hasani et al [11] assessed the performance of GPT-4.0 (OpenAI) in standardizing radiology reports; they reported that it generates high-quality standardized radiology reports and significantly improves the efficiency of report generation and data analysis capabilities. Liu et al [12] compared GPT-4.0 with senior neurosurgeons and reported that the performance of GPT-4.0 in complex medical tasks is comparable with that of experienced experts, demonstrating its value in facilitating the diagnosis of complex cases. In addition, Horiuchi et al [13] reported that GPT-4.0 has demonstrated superior diagnostic accuracy in challenging neuroradiology cases, suggesting that generative artificial intelligence technologies can serve as important supplements to physician cognition in complex diagnostic scenarios. Overall, these studies demonstrate the potential application of GPT-4.0 in multidomain diagnostic tasks.

In psychiatry, LLMs have also begun to garner attention. Because psychiatric diagnoses heavily depend on textual descriptions of patient complaints and medical history, LLMs naturally possess significant application advantages in this field. Previous studies have revealed that ChatGPT-4 (OpenAI) can achieve an accuracy rate of 96.1% in the diagnosis of obsessive-compulsive disorder, significantly outperforming that of clinical psychologists (81.5%) and primary care physicians (49.5%) [14]. In 1 study, researchers used the UTH-BERT model and reported that its diagnostic accuracy for medical history in EHRs (74.3%) surpassed that of psychiatrists with intermediate experience (71.5%) [15]. Despite these advances, prior studies on LLM-based psychiatric diagnosis have several limitations. First, the scope of diseases in previous LLM research has often been narrow, with most studies focusing on a single or a small subset of psychiatric disorders (eg, major depressive disorder and obsessive-compulsive disorder) [16]. In contrast, our study simultaneously included all major *ICD-10* (*International Statistical Classification of Diseases, Tenth Revision*) psychiatric categories (F00-F99), thereby providing broader coverage than previous studies. Nevertheless, our analysis was conducted at the level of primary diagnoses within each category, without explicitly addressing comorbidity patterns, which remains an important direction for future research. Second, data sources are often single and lack validation in real-world clinical settings. Current studies rely primarily on simulated cases or data from a single institution [17], making it challenging to capture patient characteristics across diverse regions and health care practices. In the Chinese context, several studies have begun to explore the use of LLMs for psychiatric diagnosis and Chinese-language medical records; however, comprehensive, large-scale validation in real-world psychiatric EHRs—especially with direct comparisons between international and Chinese models—remains limited. Third, the diagnostic performance across age groups has not been thoroughly investigated, with most studies focusing solely on overall accuracy without examining differences in diagnostic performance across age groups (eg, adolescents and older adult patients). Symptoms, disease progression, and treatment plans for psychiatric disorders significantly differ across different age groups. Whether LLMs can adapt to these differences remains unexplored.

To address the aforementioned issues, this study optimized 3 key aspects: data sources, disease coverage, and population segmentation. First, we incorporated real-world EHR data from 6 representative provincial and municipal psychiatric centers across different regions of China. By directly using clinical records to evaluate the model, this approach is better aligned with real-world medical settings, filling the gap left by previous studies that lacked real-world data validation in the Chinese language. Second, we covered all psychiatric disorders listed in the *ICD-10* classification (F0-F9), overcoming the limitations of previous studies, which focused primarily on a single or a few disease types. This design allowed us to evaluate the model's generalization ability across a broad range of clinical diagnostic tasks. In addition, we conducted fine-grained age stratification, systematically comparing the model's diagnostic performance across 4 age groups: adolescents, young adults, middle-aged individuals, and older adult patients. This allowed the identification of the model's adaptation differences across different age groups. In summary, our study, based on large-scale, multicenter real-world data, is the first to comprehensively evaluate the clinical potential of LLMs for psychiatric diagnosis in China.

Methods

Research Design and Data Sources

The study data were sourced from 6 provincial and municipal psychiatric centers in China. These centers are located in Sichuan, Gansu, Shanxi, Guangdong, Jiangxi, and other regions, covering Southwest China, Northwest China, North China, South China, and East China, thereby ensuring good regional representation. The dataset included the EHRs of psychiatric inpatients between July 2017 and July 2024. In total, 12,819 cases were initially screened. Among them, 2896 cases were excluded owing to incomplete records or unclear diagnoses. Therefore, 9923 eligible cases were included. The EHR data used in this study consisted exclusively of unstructured narrative text fields, including chief complaints, history of present illness, and psychiatric examination notes. Structured data, such as laboratory test results, medication prescriptions, vital signs, nursing notes, and imaging reports, were not included, as psychiatric diagnosis primarily depends on descriptive symptomatology and mental status examination rather than auxiliary tests. All records included in the model were noted down by attending psychiatrists at the time of admission only. Clinical notes taken during hospitalization were not included, ensuring that the model received only information available at the initial diagnostic encounter and preventing potential temporal information leakage.

Ethical Considerations

The Ethics Committee of the Sichuan Provincial Mental Health Center approved this study (approval 202460). Considering the retrospective nature of the study, the Ethics Committee exempted the need for informed consent from the patients. All EHR data were fully deidentified in accordance with the Health Insurance Portability and Accountability Act safe harbor method (45 CFR 164.514(b)), with direct identifiers (eg, names, addresses, contact details, and hospital IDs) removed before analysis. In addition, because narrative clinical text can contain residual indirect identifiers, a stratified manual audit of 500 randomly sampled EHR narratives (approximately 5% of the dataset) was conducted to further minimize reidentification risk. Among these 500 records, 7 (1.4%) instances of potential indirect identifiers were identified and corrected before model inference. No direct identifiers were detected in the sampled records.

Model queries were transmitted through encrypted API calls (HTTPS/TLS) rather than public chat interfaces. Although no formal data processing agreement was established with the external provider, the institutional review board explicitly approved the use of deidentified clinical narratives for inference on external LLM servers. It was assured that the procedure complied with local data governance regulations and did not include identifiable personal information. Only deidentified free text—without metadata, patient identifiers, or institutional information—was transmitted, and no protected health information left the institution.

The study adhered to relevant international and domestic privacy frameworks, including General Data Protection Regulation Article 46 for cross-border data transfer, China's Personal Information Protection Law, and ISO/IEC 27018 guidelines for the protection of personal data in public cloud environments. Nevertheless, we acknowledge that narrative EHR text has inherent deidentification limitations, and we minimized data transmission to mitigate privacy risks.

Data Preprocessing

To closely replicate real-world clinical settings, the admission diagnosis names were removed from the medical history; no other data were modified, thereby preserving the integrity of the original data [18]. The diagnoses were classified into 11 categories by extracting only the first letter and the 10-digit *ICD-10* codes from Chapter V (Mental and Behavioral Disorders; F0-F9) and other related codes. Specifically, F0 includes organic mental disorders such as dementia; F1 includes substance-related disorders such as alcohol addiction; F2 includes schizophrenia and associated psychotic conditions; F3 includes mood disorders such as depression; F4 includes anxiety and stress-related disorders; F5 includes disorders associated with physiological conditions, such as eating disorders; F6 includes personality and behavioral disorders in adults; F7 includes intellectual disabilities; F8 includes developmental disorders such as autism; and F9 includes behavioral and emotional conditions beginning in childhood, including attention-deficit or hyperactivity disorders [19]. For subgroup analysis, patients were stratified into 4 age groups: adolescents (≤17 years), young adults (18-35 years), middle-aged adults (36-59 years), and older adult individuals (≥60 years). The thresholds at 18 and 60 years follow established conventions in psychiatric and geriatric research [20]. The adult group was further subdivided into young and middle-aged categories to capture differences in onset age, symptom presentation, and comorbidity patterns of major psychiatric disorders across life stages.

Research Tools and Model Setup

In total, 3 LLMs were selected for evaluation: GPT-4.0 and GPT-3.5 (OpenAI) and GLM-4-Plus (Zhipu AI). GPT-3.5 was chosen as a widely used baseline model because of its broad accessibility and extensive application in previous medical natural language processing tasks, providing a reference point for evaluation [21]. GPT-4.0, a more advanced successor in the GPT series, was included to assess performance improvements driven by enhanced semantic understanding and reasoning capabilities [22]. GLM-4-Plus is one of the most advanced Chinese-optimized LLMs [23]. It was selected to examine the adaptability and potential of domestic LLMs in psychiatric diagnosis using Chinese-language EHRs and to compare their performance with that of international mainstream models under localized application scenarios.

In addition, a unified prompt was used: "请根据以下患者信息给出最可能的诊断。" ("Please provide the most likely diagnosis based on the following patient information"). Because the clinical input consisted of Chinese-language EHR narratives, the instruction prompt was also written in Chinese to maintain monolingual consistency and avoid potential cross-lingual prompting effects. This prompt was intentionally selected to ensure methodological consistency and fair comparability across all LLMs, as varying prompt strategies may introduce

XSL•FO
RenderX

model-specific advantages. Zero-shot prompts also reflect a realistic clinical scenario in which clinicians typically expect the model to provide a diagnostic impression directly without additional examples. No English prompt or mixed-language prompt was used at any stage. No prompt engineering or chain-of-thought prompting was applied, as the study aimed to evaluate each model's baseline diagnostic capability under identical input conditions. The preprocessed data included the patient's sex, age, chief complaints, medical history, and psychiatric examination results. The psychiatric examination results included narrative descriptions of key mental status domains, such as appearance and behavior, mood and affect, thought process and content, cognitive function, and insight, which were documented in a standardized format across all participating centers to ensure structural consistency and data comparability. These inputs were provided to the model to generate diagnostic results. All diagnostic analyses by the LLMs were completed between January 1 and January 31, 2025. The discharge diagnosis served as the reference standard and was confirmed by a senior associate chief physician with over 10 years of clinical experience.

Model outputs were evaluated using a 0-2 point scoring system: 2 points for a completely correct diagnosis (exact *ICD-10* match), 1 point for a partially correct diagnosis, and 0 points for an incorrect diagnosis. "Partially correct" was operationally defined as cases in which the predicted diagnosis was clinically close to, but not an exact, *ICD-10* match. Examples included (1) misclassification within the schizophrenia spectrum (eg, schizotypal disorder scored as schizophrenia), (2) assigning a broader category within mood disorders without specifying the exact episode (eg, manic episode scored as mood disorder), or (3) capturing the correct diagnostic domain at a broader level of granularity (eg, generalized anxiety disorder scored as anxiety disorder). Predictions that did not meet these criteria were considered incorrect.

To ensure reliability and minimize bias, multiple 2-rater groups were formed, each comprising 2 attending psychiatrists with more than 5 years of independent clinical experience. Both raters independently scored each case after the model outputs were anonymized and randomized, which blinded them to the source model. Disagreements were resolved by consensus with a senior psychiatrist. Interrater reliability was assessed using Cohen κ coefficient, which demonstrated substantial agreement (Cohen κ=0.82).

Data Analysis

Statistical analyses were conducted using SPSS Statistics (version 27.0; IBM Corp). Descriptive statistics were used to present the demographic characteristics and distributions of disease categories. Model performance was evaluated by comparing the predicted diagnoses with the discharge diagnoses, which served as the reference standard. Accuracy was calculated as the proportion of correct predictions (score=2). In this study, strict evaluation criteria were used as the primary analytic framework. Under this explicit definition, only exact matches between the model-predicted *ICD-10* diagnosis and the discharge diagnosis (score=2) were considered correct, whereas partially correct predictions (score=1) were treated as incorrect.

For the classification performance metrics—namely, precision, recall, and F_1-score—we also applied a lenient evaluation. Under this lenient definition, both exact matches (score=2) and partially correct predictions (score=1) were treated as correct and counted as true positives (TPs). In this framework, TPs were predictions that were exactly or partially consistent with the true diagnosis (score=2 or score=1); false positives (FPs) were predictions for a class when the true diagnosis belonged to another class; and false negatives (FNs) were cases in which the true diagnosis belonged to a class, but the model prediction did not. Predictions with score=0 were always treated as incorrect. These lenient metrics were used exclusively for the classification performance results and are clearly labeled as such. All other analyses throughout the manuscript relied solely on the strict evaluation criteria. In addition, performance metrics, including precision, recall, and F_1-score, were computed under a strict definition: only exact matches between the model-predicted *ICD-10* diagnosis and the discharge diagnosis were considered correct. In this framework, TPs are cases where the prediction exactly matches the true diagnosis; FPs are predictions for a class when the true diagnosis belongs to another class; and FNs are cases where the true diagnosis belongs to a class, but the model prediction does not. Partially correct outputs (score=1) were treated as incorrect predictions and classified as FPs or FNs depending on the prediction-reference mismatch; only score=2 outputs were counted as TPs.

The macro- and weighted-average F_1-scores were calculated to measure overall performance. Because the F8 category contained only 8 cases (0.1% of the dataset), macroaverage F_1-scores were additionally reported, both including and excluding this extremely rare category, to provide a more stable estimate of overall performance. Tests of normality and homogeneity of variance were conducted. The Shapiro-Wilk test indicated that the score data significantly deviated from normality across all model groups, and the Levene test confirmed unequal variances (Table S1 in Multimedia Appendix 1). Therefore, nonparametric rank-sum tests were applied for intergroup comparisons. In addition, Kruskal-Wallis tests were used to examine whether diagnostic accuracy differed across the 6 centers for each model (Table S2 in Multimedia Appendix 1). A P value of <.05 indicated significance. To further compare diagnostic performance across LLMs, an ordinal logistic regression analysis was conducted. Because the diagnostic outcome was an ordered 0-2 score (0=incorrect, 1=partially correct, and 2=correct), a proportional odds model was applied to estimate the likelihood of achieving a higher diagnostic score for each model. GPT-3.5 served as the reference category. Odds ratios (ORs) and 95% CIs were calculated to quantify differences in diagnostic performance. The results of this analysis are presented in Table S3 in Multimedia Appendix 1.

Results

Demographic Characteristics and Disease Category Distribution

In total, 9923 patients (3665, 36.93% males and 6258, 63.07% females) were included in this study. Across age groups, 1881 (18.96%) were adolescents (≤17 years), 2468 (24.87%) were

XSL•FO
RenderX

young adults (18-35 years), 3695 (37.24%) were middle-aged adults (36-59 years), and 1879 (18.94%) were older adults (≥60 years). The disease categories were distributed as follows (Table 1): mood disorders (F3) were the most common, accounting for 36.7% (3646/9923) of the cases, followed by schizophrenia, schizotypal, and delusional disorders (F2, 2470/9923, 24.9%), and neurotic disorders (F4, 1991/9923, 20.1%). The distribution of other disorders was relatively low.

Table 1. Demographic data and clinical characteristics.

Characteristics	Value
Sex, n (%)	
Male	3665 (36.93)
Female	6258 (63.07)
Age (y), mean (SD)	40.5 (20.03)
Age category, n (%)	
Adolescent (≤17 y)	1881 (19)
Young adult (18-35 y)	2468 (24.9)
Middle-aged (36-59 y)	3695 (37.2)
Older adult (≥60 y)	1879 (18.9)
Disorder category, n (%)	
F0 (Organic disorders)	597 (6)
F1 (Substance use disorders)	243 (2)
F2 (Schizophrenia, schizotypal, and delusional disorders)	2470 (24.9)
F3 (Mood disorders)	3646 (36.7)
F4 (Neurotic disorders)	1991 (20.1)
F5 (Eating disorders, etc)	70 (0.7)
F6 (Personality disorders)	86 (0.9)
F7 (Mental retardation)	177 (1.8)
F8 (Autism, etc)	8 (0.1)
F9 (Behavioral disorders)	635 (6.4)

Diagnostic Accuracy of the 3 Models

Overall, GPT-4.0 achieved an overall accuracy of 71.7%, outperforming GLM-4-Plus (69.3%) and GPT-3.5 (68.8%). In terms of category-specific performance, GPT-4.0 exhibited higher overall accuracy than the other models in the F1, F3, and F6 categories. However, in the F2 and F4 categories, the diagnostic accuracy rates of the 3 models were similar, with no significant differences. Among the different age groups, diagnostic accuracy was higher in the older adult group (with an overall accuracy rate of 74.3%-79.5%). Additional analysis using the rank-sum test revealed significant differences between adolescents and middle-aged adults, adolescents and older adults, young adults and middle-aged adults, and young adults and older adults (P<.001). The results are summarized in Tables 2 and 3, and the category-level diagnostic score patterns across the 3 models are visualized in Figure 1.

RenderX

Figure 1. Heatmap of the diagnostic scores. The color intensity indicates the model's diagnostic score (on a 2-point scale), with darker colors indicating higher scores. This reflects the diagnostic accuracy of the models in each category.

Center-Level Diagnostic Performance

To evaluate whether model performance varied across institutions, a supplementary center-level analysis was conducted. The diagnostic accuracies of all 3 models demonstrated only minor numerical fluctuations across the 6 centers. Importantly, the Kruskal-Wallis test indicated no statistically significant differences for any of the models (GPT-4.0: P=.52; GPT-3.5: P=.47; and GLM-4-Plus: P=.61). The detailed results for each center are provided in Table S2 in Multimedia Appendix 1.

Analysis of Differences in Scoring Distribution of 3 Models

The rank-sum test was used to compare differences in the scoring distributions of GPT-4.0, GPT-3.5, and GLM-4-Plus across various *ICD-10* categories. We observed that GPT-4.0 had higher scores than GPT-3.5 in the F0 (P<.001), F6 (P<.001), and F7 (P<.001) categories. Furthermore, GLM-4-Plus exhibited differences in its scoring distribution compared with GPT-3.5 in the F0 (P<.001) and F7 (P<.001) categories. Overall, the score distribution of GPT-4.0 was superior to that of both GPT-3.5 (P<.001) and GLM-4-Plus (P<.001). However, the difference in the scoring distribution between GPT-3.5 and GLM-4-Plus was not statistically significant (P=.09). Table 4 summarizes the results.

XSL•FO

F9	.65	.72	.42
Total	<.001	<.001	.09

Comparison of the Classification Performance of 3 Models

Table 5 summarizes the precision, recall, and F_1-scores of the GPT-4.0, GPT-3.5, and GLM-4-Plus models across various *ICD-10* disease categories. To enhance interpretability, these classification metrics were computed using a lenient evaluation framework, in which both exact matches (score=2) and partially correct predictions (score=1) were treated as correct. GPT-4.0 achieved the highest F_1-scores in the F0 (0.915), F1 (0.926), and F2 (0.929) categories. GLM-4-Plus achieved the highest precision in the F2 category (0.951), whereas GPT-4.0 had a superior recall rate (0.959). Small-sample categories exhibited significant fluctuations, including the F8 category, where GPT-4.0's recall rate reached 1.00, while its precision was only 0.308. This phenomenon reflects class imbalance and overprediction in rare categories. The macroaverage F_1-scores (including F8) were 0.655, 0.410, and 0.712 for GPT-4.0, GPT-3.5, and GLM-4-Plus, respectively. The weighted average F_1-score of GPT-4.0 (0.881) was superior to that of both GPT-3.5 (0.849) and GLM-4-Plus (0.873). To mitigate the instability caused by the extremely small F8 category, macroaverage F_1-scores were also calculated after excluding F8. The exclusion yielded more stable macrolevel estimates: 0.821 for GPT-4.0, 0.745 for GPT-3.5, and 0.806 for GLM-4-Plus.

To further complement this evaluation, we also performed an ordinal logistic regression analysis using the 0-2 scoring system (0=incorrect, 1=partially correct, and 2=correct) as the outcome variable, accounting for its ordinal nature. The results were consistent with the overall performance patterns observed in the main analysis. GPT-4.0 was significantly more likely to achieve a higher diagnostic score compared with GPT-3.5 (OR 1.18, 95% CI 1.11-1.25; *P*<.001). In contrast, GLM-4-Plus showed slightly lower odds of achieving a higher score relative to GPT-3.5 (OR 0.95, 95% CI 0.90-1.01). Although this difference did not reach statistical significance (*P*=.09; Table S3 in Multimedia Appendix 1).

Discussion

Principal Findings

This multicenter real-world study is the first to systematically evaluate the diagnostic performance of 3 LLMs—GPT-4.0, GPT-3.5, and GLM-4-Plus—across the full spectrum of *ICD-10* psychiatric categories via Chinese psychiatric EHRs. The results demonstrate that GPT-4.0 achieved the highest overall strict diagnostic accuracy (71.7%), followed by GLM-4-Plus (69.3%) and GPT-3.5 (68.8%), showing a clear performance gradient across model generations. In addition to strict accuracy, GPT-4.0 also achieved a higher lenient F_1-score (0.881), indicating performance when partially correct predictions are counted as correct. These complementary metrics highlight different aspects of diagnostic ability under distinct evaluation frameworks.

Consistent with these findings, the ordinal logistic regression provided a quantitative estimate of these differences: GPT-4.0 was significantly more likely to achieve a higher diagnostic score compared with GPT-3.5 (OR 1.18, 95% CI 1.11-1.25; P<.001). In contrast, GLM-4-Plus demonstrated ORs comparable with those of GPT-3.5 (OR 0.95, 95% CI 0.90-1.01), indicating no statistically significant difference in performance between the 2 models. These results further support the interpretation that GPT-4.0 provides a measurable performance advantage, whereas GLM-4-Plus and GPT-3.5 exhibit broadly similar diagnostic capability.

Significant differences were observed across most age groups, with diagnostic accuracy generally increasing with age. Older adult patients exhibited notably better diagnostic performance than adolescents and young adults. For GPT-4.0 and GLM-4-Plus, all pairwise adjacent age-group comparisons were statistically significant (all P<.001). For GPT-3.5, accuracy also increased with age overall; however, the comparison between middle-aged and older adult patients did not reach statistical significance (P=.15). This trend likely reflects several clinical and documentation-related factors: older adults typically present with more stable symptom trajectories, longer disease histories, and more structured and complete EHR documentation, whereas younger patients often exhibit heterogeneous and fluctuating emotional and behavioral symptoms, which increase diagnostic uncertainty.

Across diagnostic categories, GPT-4.0 consistently showed stronger contextual reasoning ability and more accurate extraction of relevant diagnostic cues. It performed particularly well in mood disorders (F3), personality disorders (F6), and several neurotic and stress-related disorders (F4). GLM-4-Plus demonstrated strong performance in schizophrenia spectrum disorders (F2), suggesting an advantage in identifying disorders with clearly structured symptom patterns. GPT-3.5 exhibited the highest rate of misclassification, particularly between disorders with overlapping emotional or behavioral symptoms.

In low-prevalence categories, such as pervasive developmental disorders (F8), all 3 models showed instability in performance. GPT-4.0 achieved perfect recall but exhibited low precision, suggesting overidentification in categories with limited diagnostic cues. These patterns highlight the ongoing challenge

XSL•FO
RenderX

for general-purpose LLMs in identifying rare psychiatric conditions.

Beyond model comparison, this study demonstrates the overall feasibility of applying large-scale language models to real-world psychiatric EHRs covering all *ICD-10* categories. The results indicate that GPT-4.0 can extract diagnostically relevant information efficiently and generate multidimensional diagnostic suggestions, thereby supporting initial clinical screening, reducing physician workload, and improving efficiency in high-volume psychiatric settings. However, LLM-based diagnosis remains dependent on the quality of EHRs, symptom clarity, and physician interpretation, and cannot be used as a substitute for clinical expertise or individualized assessment.

Overall, GPT-4.0 demonstrated the strongest, most stable, and most clinically meaningful diagnostic performance across age groups and psychiatric categories, supporting its potential value as a diagnostic assistance tool within real-world psychiatric workflows.

Center-Level Consistency and Its Implications

Although the 6 centers differed in documentation habits, patient demographics, and narrative styles, all 3 LLMs demonstrated stable diagnostic performance across sites. This consistency suggests that the models rely primarily on core clinical symptom patterns rather than center-specific narrative conventions, which may explain their robustness in real-world settings. The absence of center-level variability also indicates that LLM-based diagnostic support may generalize well across institutions with heterogeneous clinical workflows—a critical requirement for real-world deployment. From an implementation perspective, these findings imply that LLM-assisted diagnostic tools may not require site-specific retraining or local optimization, substantially reducing the technical and operational burden associated with clinical adoption. Collectively, these observations highlight the scalability and practical utility of LLMs in psychiatric diagnostic workflows.

Misclassification Patterns in the F8 Category

The extreme imbalance between recall and precision in the F8 category warrants further clinical interpretation. Although GPT-4.0 successfully identified all true F8 cases, its low precision indicates a substantial number of FP predictions. Upon reviewing these cases, we found that most FPs originated from F9 (behavioral and attention-deficit/hyperactivity disorder–related disorders), with a smaller proportion from F7 (intellectual disabilities). These diagnostic groups share overlapping behavioral and neurodevelopmental characteristics with F8—including impulsivity, irritability, social dysfunction, and developmental impairment—which may lead the model to rely on broad behavioral descriptors when more specific differentiating features are not explicitly documented in the narrative EHR. This overdiagnosis pattern suggests that GPT-4.0 is sensitive to general behavioral dysregulation but is less effective in distinguishing between rare neurodevelopmental disorders with partially overlapping phenotypes. Understanding this tendency toward misclassification is essential for evaluating the model's safety profile when applied to clinically rare categories.

Comparison With Previous Work

The superior diagnostic performance of GPT-4.0 observed in this study is consistent with previous evaluations, which report that newer-generation LLMs outperform earlier versions in clinical reasoning tasks [24-26]. This performance advantage has been attributed to the enhanced ability of GPT-4.0 to capture semantic associations and long-range contextual patterns in complex textual inputs [27]. Previous studies have demonstrated that GPT-4.0 provides higher diagnostic accuracy, better contextual understanding, and more stable reasoning patterns than does GPT-3.5 across diverse clinical applications. Our findings extend this body of evidence to the domain of psychiatric diagnosis via Chinese-language EHRs in real-world settings.

A major distinction between our study and earlier work is the use of multicenter real-world psychiatric EHR narratives rather than simulated vignettes or single-institution datasets. The complexity and variability of real-world clinical documentation allow for a more realistic assessment of LLM behavior in routine psychiatric practice, thereby providing stronger ecological validity.

Consistent with the broader literature, earlier-generation models, such as the GPT-3.5, tend to perform less reliably in disorders characterized by overlapping emotional or behavioral symptoms [24-26]. In our study, this general pattern was reflected in GPT-3.5's tendency to misclassify personality disorders (F6) as mood disorders (F3), likely due to the similarity and ambiguity of symptom descriptions in these categories within real-world psychiatric EHRs. This observation aligns with the known challenges faced by earlier LLMs in distinguishing clinically overlapping symptom domains. In contrast, GLM-4-Plus demonstrated strong performance in schizophrenia spectrum disorders (F2), suggesting that models trained on Chinese corpus characteristics may perform well in categories with clear and structured symptom patterns.

Beyond diagnostic accuracy, prior studies have highlighted the potential role of LLMs as clinical decision support tools capable of improving workflow efficiency and reducing clinician workload in real-world health care settings [28]. In psychiatry, recent evaluations have summarized the diagnostic accuracy of LLMs and emphasized their potential utility in assisting clinicians with complex diagnostic decisions [29]. More broadly, advances in deep learning–based electronic health record analytics have demonstrated the feasibility of extracting clinically meaningful information from narrative EHRs to support timely screening and downstream decision-making processes [30].

Taken together, our findings reinforce the performance advantages of GPT-4.0 observed in previous work and highlight the importance of evaluating both international and domestic LLMs in localized, real-world psychiatric contexts.

Limitations

This study has several limitations. First, although we used multicenter real-world psychiatric EHRs, differences in documentation style—including variability in narrative structure, terminology, completeness of information, and implicit

XSL•FO
RenderX

diagnostic cues—may have influenced model performance. These inconsistencies can alter the prominence, clarity, and temporal linkage of symptom descriptions, potentially affecting diagnostic outputs. Broader validation in institutions with diverse linguistic and cultural backgrounds is needed to assess cross-system and cross-national generalizability more fully [31].

Second, this study adopted a single unified prompting strategy to ensure consistent comparability across models. However, previous research has shown that more advanced prompting techniques can improve diagnostic reasoning. For example, Savage et al [32] reported that diagnostic reasoning prompts enhance LLMs' ability to emulate stepwise clinical reasoning compared with standard prompts. In our setting, a small exploratory pilot study using chain-of-thought prompts on 200 randomly selected cases suggested a modest improvement in exact-match accuracy (about 2-3 percentage points), particularly for mood and anxiety disorder categories. Although this was not a full comparative experiment, the results suggest that the prompting strategy may influence diagnostic performance. Future studies should systematically evaluate zero-shot, few-shot, and chain-of-thought prompt approaches across diagnostic categories and age groups.

Third, the study used a single-label classification framework based on primary discharge diagnoses. While this reflects routine clinical practice, it does not capture psychiatric comorbidities, which are common and clinically important. Multilabel diagnostic frameworks may be necessary to better reflect the real-world complexity of diagnosis.

Fourth, our analysis relied on static EHR text and did not incorporate longitudinal or multimodal clinical information. Real-world psychiatric care involves dynamic symptom progression and treatment trajectories, which cannot be fully captured in static narratives. Integrating time series EHR data, imaging, or laboratory results may increase the diagnostic robustness of LLMs [33].

Fifth, the dataset did not include key socioeconomic variables—such as education level, employment or income status, or urban versus rural residence—which limited our ability to examine potential algorithmic bias or fairness across different social strata. These factors can shape health care access, diagnostic pathways, and linguistic characteristics of clinical documentation, and their absence prevented a systematic assessment of whether model performance varied across sociodemographic groups. Future studies incorporating richer socioeconomic status–related demographic information will be essential for evaluating equity in LLM-assisted diagnostic workflows.

Sixth, although admission diagnoses were removed from model inputs, sections, such as the history of present illness, may still include implicit diagnostic tendencies embedded within physicians' narrative styles. To address this concern, we manually reviewed a subset of correctly and incorrectly classified cases to determine whether the model relied on "giveaway" phrases or diagnosis-specific linguistic cues. We did not identify consistent or systematic patterns—such as psychopharmacological keywords, standardized phrasing, or clinician-specific formulations—that uniquely pointed to a specific diagnosis. When such terms occurred (eg, references to antidepressants or antipsychotics), they were typically nonspecific and appeared across multiple diagnostic categories.

However, certain unmasked psychotropic medications—particularly lithium and clozapine, which function as strong diagnostic proxies—may have allowed the models to infer diagnoses through medication extraction rather than full clinical reasoning, potentially inflating accuracy in specific categories. These observations suggest that while soft leakage cannot be entirely eliminated in narrative EHRs, its impact on model performance in this dataset was likely limited. Future studies should consider masking medication names or evaluating model behavior under medication-removed conditions to better isolate true diagnostic reasoning.

In addition, this study has privacy-related limitations. Although all EHR narratives were deidentified before transmission to external LLM servers, narrative clinical text carries inherent challenges for complete anonymization. Despite multiple safeguards, the possibility of residual identifiers cannot be entirely eliminated, and future research should prioritize on-premise or institution-governed LLM deployment to avoid external data transmission fully. Moreover, because the manual deidentification audit was conducted on a sampled subset of 500 records rather than the full dataset, a small risk of undetected residual identifiers cannot be completely excluded.

Furthermore, the study did not include a human benchmark for comparison, such as the diagnostic accuracy of junior clinicians, admitting psychiatrists, or structured admission diagnoses. Without this comparative context, it is difficult to ascertain whether the observed strict accuracy of 71.7% represents a clinically meaningful performance threshold. Future research should incorporate human-model comparison frameworks or prospective reader studies to more clearly establish the clinical utility of LLM-assisted diagnostic workflows.

Finally, although multicenter data improved external validity, further validation through prospective observational designs or randomized controlled trials is necessary to robustly establish the real-world clinical utility of LLMs in psychiatric diagnostic workflows [31].

Future Directions

Future research should expand the diversity of data sources to evaluate the generalizability of LLMs across different health care systems, linguistic environments, and cultural contexts. The incorporation of longitudinal EHR data, time series symptom trajectories, and multimodal clinical information—such as laboratory tests and imaging—may further enhance the ability of LLMs to capture dynamic clinical changes and improve diagnostic robustness.

Furthermore, more sophisticated strategies warrant systematic investigation. Comparative evaluations of zero-shot, few-shot, and chain-of-thought prompts across different psychiatric categories and age groups may help optimize the integration of LLMs into clinical workflows. Future studies should also explore multilabel diagnostic frameworks to capture psychiatric comorbidities better and reflect the complexity of real-world clinical presentations.

XSL•FO
RenderX

Finally, prospective validation—particularly through observational studies or randomized controlled trials—will be essential for establishing the real-world clinical utility, reliability, and safety of LLM-assisted diagnostic tools in psychiatric practice.

Conclusions

This multicenter real-world study systematically evaluated the diagnostic performance of the GPT-4.0, GPT-3.5, and GLM-4-Plus across all *ICD-10* psychiatric categories using Chinese psychiatric EHRs. GPT-4.0 demonstrated the strongest and most stable diagnostic performance in this study across age groups and diagnostic categories and showed clear advantages in interpreting complex psychiatric narratives. All models performed less reliably in low-prevalence categories, and diagnostic accuracy varied substantially across age groups, with lower accuracy observed in adolescents and young adults.

These findings confirm the feasibility of applying LLMs to real-world psychiatric EHRs and highlight the potential value of GPT-4.0 as a diagnostic support tool. However, the diagnostic outputs of LLMs remain constrained by the quality of documentation, symptom clarity, and the limitations of the models. LLMs should therefore be viewed as complementary tools that can assist clinicians but cannot replace clinical expertise, individualized assessment, or professional decision-making in psychiatric practice.

Abstract

Background: Although individually uncommon, rare diseases (RDs) collectively affect an estimated 329-624 million people worldwide. There are over 6500 known RDs, 85% of which affect fewer than 1 person per million. Consequently, the critical amount of data necessary to improve knowledge, care, and treatment can only be achieved through cumulative data collection across countries. However, RDs remain underrepresented in medical terminologies and classification systems, hindering data sharing, interoperability, and public health monitoring.

Objective: This paper presents the Orphanet Nomenclature and Classification of RDs detailing its content, production and update methodology, and mappings to other semantic resources. It also provides an up-to-date count of RDs based on the consensus operational definition describing their distribution by medical domain.

Methods: The Orphanet Nomenclature of RDs is a multilingual standardized system composed of clinical entities, each defined by a unique and time-stable ORPHAcode, a preferred term, synonyms, a classification level, and a textual definition. This nomenclature is structured into 3 classification levels organized within a multihierarchical and multiparental classification system by medical domain. Its production, updates, and mappings to major biomedical resources rely on standardized and published procedures, continuous literature review, manual curation, and expert validation, reflecting advancements in RDs knowledge and clinical practice. Presented data metrics were computed using the Orphanet July 2025 release to quantitatively characterize the content, structure, classification, and semantic alignments of the Orphanet Nomenclature and Classification system.

Results: As of July 2025, the Orphanet Nomenclature of RDs includes a total of 9784 active clinical entities, including 6527 disorders (corresponding to the RDs definition), 1084 subtypes of disorders, and 2173 groups of disorders. Disorders are multiclassified into 29 classification hierarchies, each corresponding to a distinct medical domain, accurately representing the complex multisystemic nature of RDs. Extensive qualified mappings ensure semantic interoperability: 97.4% (6355/6527) of disorders are mapped to at least 1 *ICD-10* (*International Statistical Classification of Diseases, Tenth Revision*) code (415/6527, 6.4% with an exact proximity relationship), 71.8% (4683/6527) are mapped to at least 1 *ICD-11* (*International Classification of Diseases, Eleventh Revision*) Mortality and Morbidity Statistics code (958/6527, 14.7% with an exact relationship) and 94.8% (6191/6527) are mapped to Systematized Nomenclature of Medicine Clinical Terms (all with an exact relationship). Genetic disorders represent 72.2% (4715/6527) of all RDs, and 63.4% (4141/6527) are mapped to at least 1 phenotypic Online Mendelian Inheritance in Man number.

XSL•FO
RenderX

Conclusions: The Orphanet Nomenclature and Classification of RDs is the only RDs-specific interoperable medical terminology meeting the needs of health care, research, and public health systems. By addressing the underrepresentation of RDs in medical terminologies, it enables accurate RDs identification, coding, and monitoring, supporting cross-border data interoperability, and contributing to improved knowledge, policymaking, and ultimately better care for people living with an RD.

Introduction

Although rare diseases (RDs) are individually uncommon, with over 6500 different known RDs, they collectively affect an estimated 329-624 million people worldwide [1,2]. Despite this significant global burden, available data indicate that 85% of RDs affect less than 1 person per million [1]. As a result, the critical amount of data necessary to improve knowledge, care, and treatment can only be achieved through cumulative data collection across different countries in a standardized manner [3,4]. Cross-border data collection, sharing, and exploitation to support evidence-based policymaking, health care, and research are therefore essential in the field of RDs, as underscored by numerous international and European initiatives [5].

Over the past decades, numerous definitions of RDs have been proposed, reflecting local legislations and public health priorities [4,6-11], most of which use point prevalence as the common epidemiological indicator. However, the threshold for rarity varies geographically, ranging from less than 1 per 2500 in Japan [12] to no more than 50 per 100,000 in Europe [13], or no more than 200,000 persons in the United States [14]. Furthermore, definitions can differ clinically, sometimes including restrictions such as “life-threatening” or “chronically debilitating” [6,13,15]. To address these inconsistencies, Rare Diseases International (RDI), in collaboration with a global panel of experts and the World Health Organization (WHO), has developed an operational description of rare diseases, defining an RD as a “medical condition with a specific pattern of clinical signs, symptoms, and findings that affect fewer than or equal to 1 in 2000 persons living in any WHO-defined region of the world” [16]. Despite these efforts, the lack of harmonization among countries continues to impact RDs research, diagnosis, and health care planning [3,5,8].

To take public health action on RDs, it is fundamental to measure how many people are affected by these diseases in a defined population (prevalence), how these conditions impact those affected, and how to monitor their medical and societal consequences. [1,4,17]. In this regard, the United Nations resolution on people living with an RD “encourages Member States and relevant United Nations agencies to collect, analyze, and disseminate disaggregated data on persons living with a rare disease... to assess progress towards the improvement of the status of persons living with a rare disease.” This further highlights that adequate coding of data of patients with RD within health information systems is a prerequisite for an effective response to this global public health priority [18].

However, RDs are underrepresented in medical terminologies and classification systems used within health systems, with only a small fraction of RDs possessing specific and unambiguous codes [19-22]. This limitation makes it difficult to trace patients with RD in health information systems, preventing a robust understanding of the actual number of people living with RD. Only a small proportion of RDs have a specific code in the *ICD-10* (*International Statistical Classification of Diseases, Tenth Revision*) [20-22], the most widely used codification system worldwide; the representation of RDs has increased in the *ICD-11* (*International Classification of Diseases, Eleventh Revision*) [21,23] and the Systematized Nomenclature of Medicine Clinical Terms (SNOMED CT) [24], though it still remains below the number of known RDs. Moreover, RDs cannot be easily identified in these reference systems, as they do not explicitly include any indication of the rarity of a disease. Finally, different regions use diverse semantic resources in their coding systems (eg, *ICD-10* or SNOMED CT), or diverse versions of the same resource (*ICD* [*International Classification of Diseases*] local extensions or different *ICD* versions), hampering data sharing and interoperability. Given the already scarce nature of RDs data, this barrier to data collection requires dedicated efforts to make RDs recognizable in health information systems [25-27].

To tackle the challenges of RDs codification and interoperability, Orphanet has developed and maintained an inventory of RDs since 1997 and a nomenclature and classification of RDs since 2007 [20,28]. Over time, adoption of the Orphanet Nomenclature of RDs for RDs codification within national health systems has been supported and endorsed by European and international policy initiatives aimed at improving RDs identification and monitoring and RDs cross-border data sharing. The Orphanet Nomenclature and Classification of RDs is now recognized as the reference resource to support standardized RDs codification across health care and research settings.

The aim of this paper is to present the Orphanet Nomenclature and Classification of RDs, detailing its content as well as its production and update methodology, and an overview of its mappings to other medical terminologies and classification systems. Additionally, it provides a clear and up-to-date count of RDs based on the above-mentioned consensus definition, and their distribution by medical domain. Finally, it discusses the importance of maintaining and adopting a standardized and reliable RDs nomenclature and classification system to support clinical coding, research, health care interoperability, and policymaking.

Methods

Structural Description of the Orphanet Nomenclature and Classification of RDs

The Core Elements of the Orphanet Nomenclature and Classification of RDs

The Orphanet Nomenclature of RDs is a unique and multilingual standardized system aimed at providing a specific reference standard for RDs, which is organized in a classification system, a multihierarchical and polyparental structure organized by medical domain according to diagnostic and therapeutic relevance. The Orphanet Nomenclature of RDs is composed of clinical entities (a generic technical term used to describe the clinical items included in the nomenclature), each of which includes several elements to ensure precise and unambiguous representation of RDs concepts (Textbox 1) [29]:

- ORPHAcode: a unique and time-stable numerical identifier automatically assigned in ascending order to every entry registered in the Orphanet Nomenclature.
- Preferred term (or main name): the most widely accepted name for the diagnosis in the literature and/or in the medical community.
- Synonyms: additional terms, including acronyms, fully equivalent to the preferred term, as many as necessary according to the information found in the literature.
- Classification level: indicates the level of precision of the clinical entity, among 3 possible granularity levels (group of disorders, disorder, or subtype of disorder).
- Definition: a brief description of the major clinical characteristics that define the diagnosis and differentiate it from other related clinical entities.

Textbox 1. Technical elements composing the Orphanet Nomenclature of rare diseases. Example of a clinical entity in the Orphanet Nomenclature of Rare Diseases, defined by an ORPHAcode, a preferred term, as many synonyms as needed, a classification level, and a textual definition.

ORPHAcode

- ORPHA:2134

Preferred term

- Atypical hemolytic uremic syndrome

Synonyms

- Atypical HUS; aHUS

Classification level

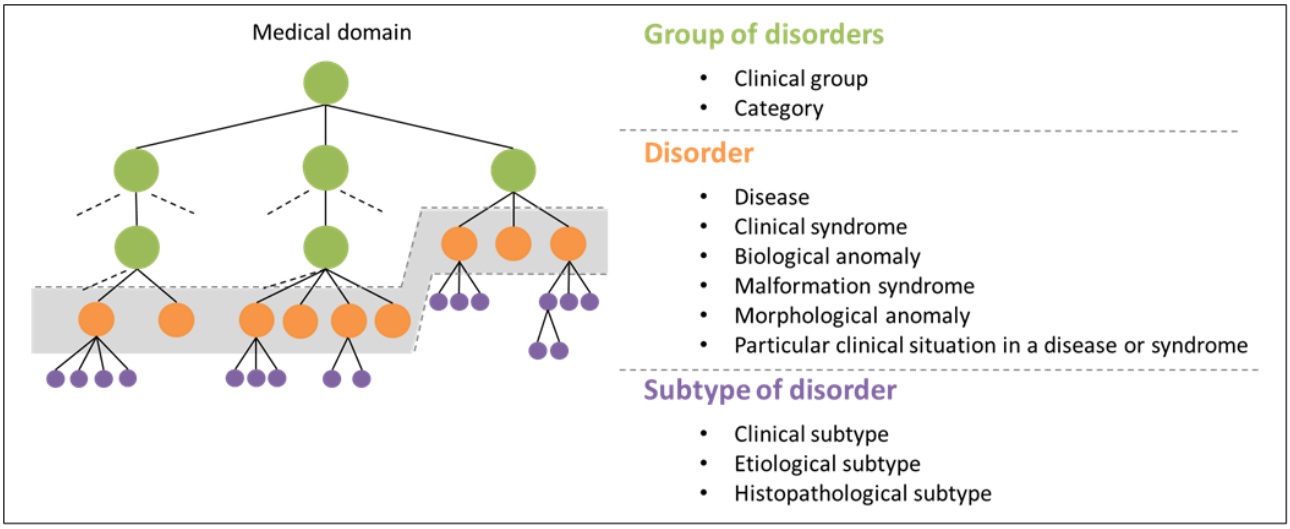
- Disorder

Definition

- A rare, genetic thrombotic microangiopathy due to dysregulation of the alternative complement pathway and characterized by the triad of hemolytic anemia, thrombocytopenia, and acute renal dysfunction.

Naming Rules and Multilingual Translation of the Orphanet Nomenclature of RDs

In the absence of an international consensus on how to name diseases, preferred terms and synonyms are assigned according to standard naming rules developed by Orphanet to create a comprehensive RDs nomenclature that aligns with current knowledge and clinical practice [30]. These rules ensure consistency across different disorder groups and medical domains, facilitating better integration and use of RDs-related clinical information in databases and health care systems. The Orphanet Nomenclature of RDs is produced in English and entirely translated into 8 languages: French, German, Spanish, Italian, Dutch, Portuguese, Polish, and Czech, by translation teams located in member countries of the Orphanet Network. All translations are validated by RDs expert medical doctors in each country. The English nomenclature serves as the basis for the translation of concepts; however, the translation process considers the particularities and local practices specific to every language, in particular with regard to the number of synonyms [31].



Classification Levels and Typology

The Orphanet classification system is composed of the 3 above-mentioned classification levels, namely group of disorders, disorder, and subtype of disorder (Figure 1). The classification level serves as the basis for parent-child relationships between related clinical entities. These relationships structure the Orphanet classification according to successive criteria that are relevant in the clinical setting [29]. Additionally, each clinical entity is attributed a typology, a characteristic that, within the classification level, conveys the nosological definition of the clinical entity. For a group of disorders, typologies include clinical group and category; for disorders, they include disease, clinical syndrome, biological anomaly, malformation syndrome, morphological anomaly, and particular clinical situation in a disease or syndrome; and for subtype of disorder, they include clinical subtype, etiological subtype, and histopathological subtype (Figure 1; definitions in Multimedia Appendix 1) [29]. Of note, while generally used interchangeably to accommodate the widespread use of the term “rare diseases,” the terms “disease” and “disorder” designate different concepts within the Orphanet Nomenclature of RDs.

XSL•FO
RenderX

The term “disorder” is used to refer to the classification level that includes the 6 different typologies mentioned above, while the term “disease” represents a specific typology and a narrower clinical concept within the “disorder” classification level (Figure 1; Multimedia Appendix 1) [29]. In the Orphanet Nomenclature and Classification system, the “disorder” level corresponds to the WHO-RDI consensus definition of “rare disease” [16].

Figure 1. Classification levels and typologies of the Orphanet Nomenclature and Classification of rare diseases. Every clinical entity in the Orphanet Nomenclature and Classification of rare diseases is associated with a classification level conveying the precision of the diagnosis (group of disorder, disorder, or subtype of disorder), and a unique typology within the classification level.

Production and Update Process of the Orphanet Nomenclature and Classification of RDs

Curation and Update Procedure of the Orphanet Nomenclature and Classification of RDs

The Orphanet Nomenclature and Classification of RDs is produced and updated according to a standardized and published procedure, in order to maintain an optimal quality of information, by a scientific team of information scientists at the Institut national de la santé et de la recherche médicale (INSERM) US14 service unit, Paris, France. The information provided in the Orphanet Nomenclature is sourced from up-to-date scientific and medical literature (more than 2000 papers are consulted yearly), manually curated, reviewed, and validated by Orphanet information scientists and RDs medical experts [29,32].

The maintenance of the Orphanet Nomenclature of RDs is ensured through 3 main types of actions:

- Inclusion of a new clinical entity: to be included in the Orphanet Nomenclature, a disorder-level clinical entity must correspond to a well-delineated clinical presentation, have a prevalence of fewer than or equal to 1 in 2000 persons, and be described in at least 2 unrelated individuals in the literature, or 2 individuals from the same family when there is a clear genetic cause identified. Groups of disorders and subtypes of disorders are included according to established clinical practice and evolving medical knowledge. Before inclusion, the clinical entity is compared with existing entities to avoid overlaps and ensure classification consistency.
- Modification of an existing entity: a clinical entity in the Orphanet Nomenclature of RDs can be modified to improve or update its information, including the preferred term, synonyms, classification level, typology, or definition. Clinical entities described before the genetic era, and lacking publications since then, are labeled as “historic” and are kept in the Orphanet Nomenclature because their initial descriptions are still available and carry a potential for further characterization.
- Inactivation of a clinical entity: a clinical entity in Orphanet can be inactivated due to deprecation (it is now included in another concept), obsolescence (it has no valid reason to exist, such as being an imprecise or duplicate concept), or for no longer meeting the rare disorder prevalence criteria.

Management of Inactivation, Reactivation, and Replacement of ORPHAcodes

An ORPHAcode is permanently linked to the same clinical concept and is never deleted or reused for a different entity, even if the original entity becomes inactive. In rare instances, an inactive clinical entity may be reactivated after reexamination with updated knowledge and reintroduced into the Orphanet Nomenclature and Classification with all relevant scientific information. To ensure continuity of information, especially in patient records and coding systems, Orphanet provides a replacement active clinical entity for deprecated and obsolete entities. This replacement code, or target code, must be used instead of the corresponding deprecated clinical entity, as it aligns with the evolution of knowledge in the literature. For obsolete entities, the target often refers to a group of disorders, guiding users to explore the relevant classification to identify the most appropriate replacement code based on the patient’s diagnosis. Entities inactivated as nonrare in Europe are not given a replacement code, as they no longer fall under the RDs scope.

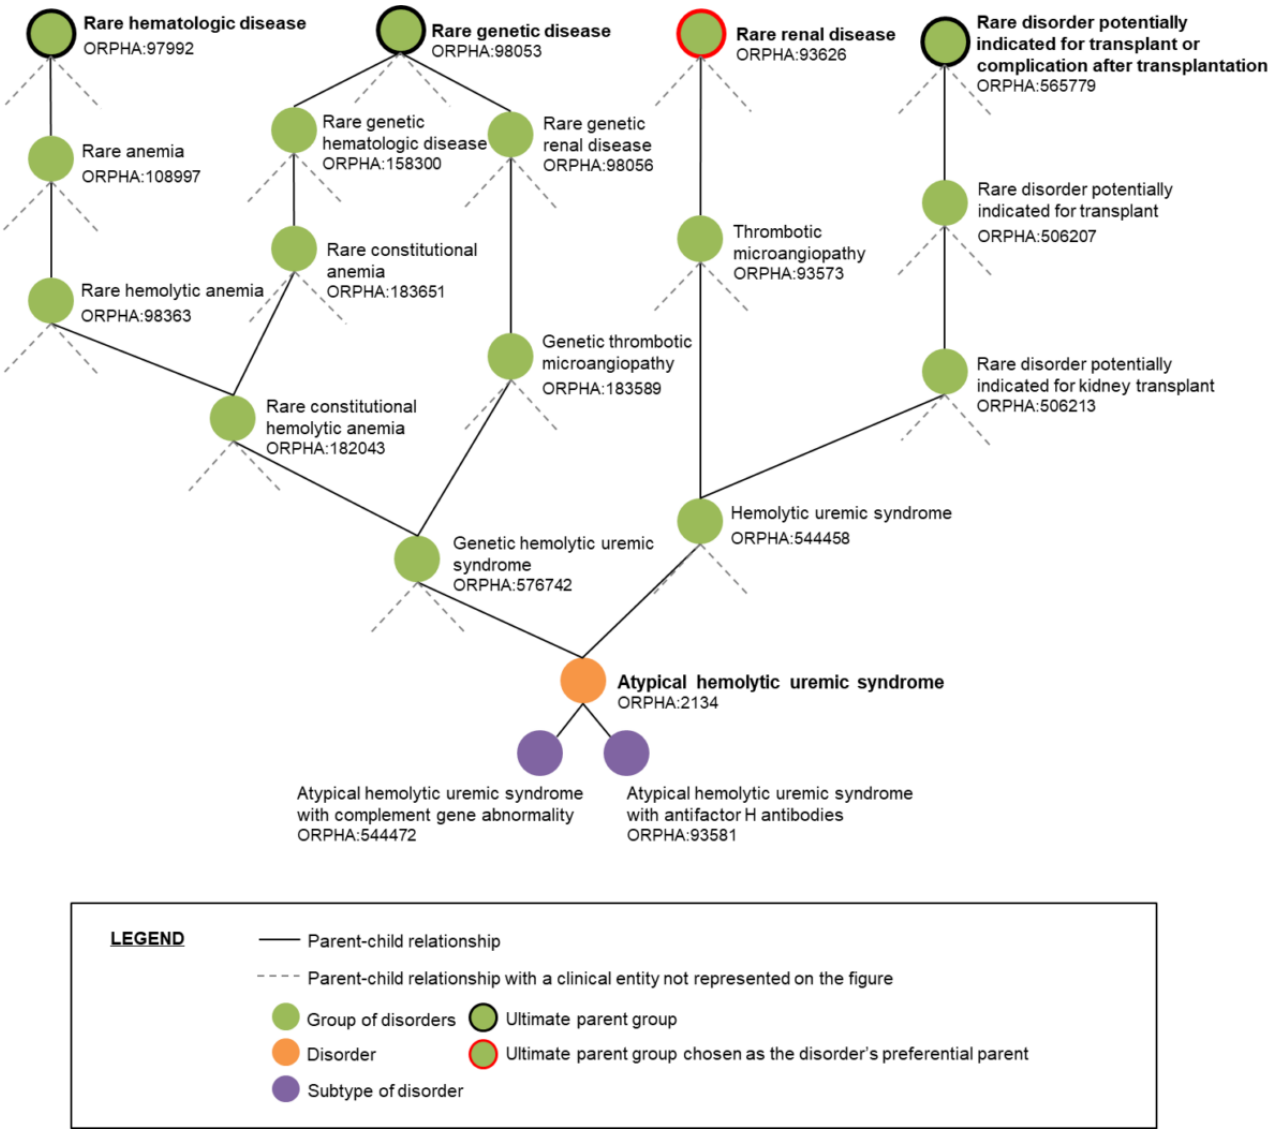
XSL•FO
RenderX

Classification of RDs by Medical Domain

The Orphanet Classification Hierarchies

The Orphanet classification is structured in 34 major classification groups, individually referred to as the classification hierarchy. Of these, 29 represent a distinct medical domain and are listed in Multimedia Appendix 2. The remaining 5 hierarchies are ad hoc classifications designed primarily for organizational purposes:

- Rare genetic diseases: this classification does not represent a distinct medical domain but is rather a derived genetic version that mirrors all the other clinical classification hierarchies.
- Rare systemic and rheumatological diseases of childhood: this classification is fully included in the Orphanet classification of rare systemic or rheumatologic disorders.
- Rare transplant-related diseases: this classification does not represent a medical domain but is used to classify disorders according to an intervention.
- Rare teratologic disorders: this classification is fully included in the Orphanet classification of rare developmental anomalies during embryogenesis.
- Rare disorder without a determined diagnosis after full investigation: this classification does not represent a medical domain and is used to classify a single disorder, ORPHA:616874 rare disorder, without a determined diagnosis after full investigation [33]. This is a code that does not conceptually fall under any of the other Orphanet classification hierarchies, as it allows for the identification in health care information systems of patients who remain undiagnosed after a full investigation.



Every classification consists of a tree structure starting with a unique ultimate parent group at the top representing the broadest clinical concept/medical domain (head of classification), then branching out into as many intermediate groups as necessary with increasing precision of clinical concepts, until reaching the first level of the confirmed diagnosis, the disorder. For any given disorder, subtypes can be added when this level of precision is required in clinical practice for appropriate management and follow-up.

Multihierarchical Classification and Linearization

Every clinical entity in the Orphanet Nomenclature of RDs is introduced in as many classification hierarchies as necessary according to major medical domains involved in the management of the disorder. This results in a multihierarchical and multiparental classification structure that reflects the multidimensionality and complexity of RDs (Figure 2). However, only 1 ultimate parent group is chosen as the entity's preferential classification (preferential parent), according to the most severely affected body system, the most determining involvement for the prognosis, and/or the medical domain that will most likely be relied on for the management of the disorder. This process, named linearization, enables coherent statistical analysis. For a substantial number of RDs, no firm scientific basis exists to support assignment to a single medical domain, making preferential parent selection inherently complex. Linearization in these situations is a conventional framework guided by a set of published rules aimed at limiting arbitrariness and ensuring consistent application [34].

XSL•FO
RenderX

Figure 2. Representation of a disorder in the Orphanet classification system. The disorder Atypical hemolytic syndrome (ORPHA:2134) is classified into 4 classification hierarchies. It has 2 direct parent groups, each with broader parent groups, culminating at the top of the hierarchy, where each ultimate parent group represents a medical domain. The rare renal disorder group (ORPHA:93626) was designated as the preferential parent of the disorder Atypical hemolytic syndrome (ORPHA:2134). Note that all groups in the figure have additional child entities not shown here.

Mappings to Other Semantic Resources

The Orphanet Nomenclature of RDs is mapped to other international terminologies, classification systems, controlled vocabularies, knowledge bases, and ontologies according to a standardized and published procedure, to enable interoperability between different information systems [35]. Target standards include the WHO classification systems *ICD-10* [36] and *ICD-11*, both Mortality and Morbidity Statistics (MMS) and Foundation [37], the clinical terminology SNOMED CT [38,39], the Online Mendelian Inheritance in Man (OMIM) knowledge base [40], the metathesaurus Unified Medical Language System (UMLS) [41], the controlled vocabularies Medical Subject Headings (MeSH) [42] and Medical Dictionary for Regulatory Activities (MedDRA) [43], the NIH (National Institutes of Health), the Genetic and Rare Diseases Information Center (GARD) knowledge base [44], and the Mondo Disease Ontology (Mondo) [45].

The mapping cardinality always goes from the ORPHAcode to a code of the target resource. All mappings are qualified by a proximity relationship that defines the nature of the correspondence between the two concepts. The adopted proximity relationships are as follows:

- Exact: the Orphanet entity designated by an ORPHAcode and the target code have the same range of application; they describe the same pathological entity.
- Broader term to narrow term: the Orphanet entity designated by an ORPHAcode has a broader range than the target code.
- Narrow term to broader term: the Orphanet entity designated by an ORPHAcode has a narrower range than the target code.

Mappings are generally validated at the Orphanet disorder and subtype levels; however, when an exact corresponding concept exists in the target resource, mappings may also be retained at the group level. For *ICD-10*, *ICD-11*, and OMIM, mappings are maintained with all 3 possible proximity relationships,

XSL•FO
RenderX

whereas for SNOMED CT, UMLS, MeSH, MedDRA, GARD, and Mondo, only exact matches are retained.

The mappings with the WHO *ICD-10* and *ICD-11* are further characterized by a specificity relationship, describing how the equivalent clinical concept is represented in *ICD* [35]. The relationships are defined as follows:

- Specific code: the clinical concept represented by the ORPHAcode corresponds to a code in the *ICD-10* tabular list/*ICD-11* MMS exclusively denoting the concept.
- Index term: the clinical concept represented by the ORPHAcode is listed as an entry term in the *ICD-10* alphabetical index or in the *ICD-11* Foundation, without being assigned a dedicated tabular list/MMS code.
- Inclusion term (*ICD-10* only): the clinical concept represented by the ORPHAcode appears as an inclusion term under an *ICD-10* term in the tabular list without a distinct code.
- Attributed code: in the absence of an explicit corresponding term in *ICD-10* or *ICD-11* for the clinical concept represented by the ORPHAcode, an *ICD* code is attributed by Orphanet as the closest available clinical concept.

All mappings are manually curated and validated by an Orphanet information scientist and a medical doctor before publication, unless explicitly marked as *Not yet validated* to indicate pending medical review. Mappings with SNOMED CT concepts result from a collaborative process with SNOMED International, in which Orphanet disorder concepts are first evaluated for inclusion in SNOMED CT by a SNOMED International terminologist, and the resulting exact mappings are subsequently validated jointly by SNOMED International and Orphanet before publication. Notably, only mappings to *ICD-10*, *ICD-11*, and OMIM are distributed together with the official Orphanet Nomenclature files for coding, while the entirety of the mappings is distributed through Orphadata Science.

Data Extraction and Analysis

Datasets Description

Data metrics were computed using the Orphanet Scientific Knowledge Files delivered on the Orphadata Science website [46]. These datasets, structured in an XML file format and in JSON format, are released in July every year at the same time as the official Orphanet Nomenclature files for coding (Nomenclature Pack) [47]. For this study, we analyzed the following datasets of the July 2025 release:

- the “rare diseases and alignments with terminologies and databases” dataset (<iso>_product1.xml) in English, Czech, Dutch, French, German, Italian, Polish, Portuguese, and Spanish languages; version 1.3.42/4.1.8 [3] released 24 Jun 2025.
- the “linearization of rare diseases” English dataset (en_product7.xml); version 1.3.42/4.1.8 [3] released 24 Jun 2025.
- the “genes associated with rare diseases” English dataset (en_product6.xml); version 1.3.42/4.1.8 [3] released 24 Jun 2025.
- The “classifications of rare diseases” English datasets (en_product3_<x>.xml); version 1.3.42/4.1.8 [3] released 24 Jun 2025.

Moreover, the differential files of the Orphanet Nomenclature packs for coding (ORPHAnomenclature_diff_en.xlsx) released from 2020 to 2025 were used to manually retrieve the annual inclusion and inactivation of disorders, and the human-readable Orphanet-SNOMED CT mapping file (ORPHA-SNOMEDCT_Mapping_File_production.xlsx), July 2025 version, released in October 2025, was used to report on the Orphanet-SNOMED CT mappings.

Metrics Calculation

Metrics were computed using Python 3.8 scripts made available as dedicated Jupyter Notebooks (.ipynb files) in a Binder/Github-ready repository [48]. This repository provides a publicly accessible, reproducible, and interactive computational environment that enables on-demand calculation of metrics using Orphadata files. A total of 8 scripts were developed to calculate the necessary metrics and were annotated to document the calculation methodology. Metrics not computable via scripting were calculated manually, as detailed below.

The distribution of active clinical entities by classification level and typology was calculated using the script “1_number_of_Orphanet_clinical_entities.” This script uses the “rare diseases and alignments with terminologies and databases” dataset in English, filters active and inactive clinical entities, and subsequently counts them by classification level and typology. The same dataset was used to manually calculate the number of historical clinical entities by filtering for the “historical entity” annotation.

The distribution of synonyms by classification level in English, as well as the number of adapted synonyms in Czech, Dutch, French, German, Italian, Polish, Portuguese, and Spanish, was calculated with the script “2_production_of_the_-Orphanet_RD_terminology_in_english_and_other_language.” This script uses the “rare diseases and alignments with terminologies and databases” dataset in all target languages and sequentially filters and counts annotations for active clinical entities, and retrieves and counts their synonyms, grouping them by classification level.

The number of translated preferred terms in Czech, Dutch, French, German, Italian, Polish, Portuguese, and Spanish was calculated manually by comparing the preferred terms of active clinical entities in each target language with the corresponding English preferred terms in the “rare diseases and alignments with terminologies and databases.” Terms differing from the corresponding English term were considered translated; terms identical to the corresponding English term were considered untranslated, with the exception of acronyms and Latin terms, which were considered translated.

The coverage of definitions at the disorder level in each language was calculated using the script “8_number_of_Orphanet_RD_with_definition_in_all_languages.” This script uses the “rare diseases and alignments with terminologies and databases” dataset in all target languages,

XSL•FO
RenderX

filters active clinical entities at the disorder classification level, and retrieves and counts the corresponding definitions.

The annual disorder inclusions and inactivations for the period 2020-2025 were manually retrieved from the differential files of the Orphanet Nomenclature packs for coding released between 2020 and 2025.

The number of disorders classified in more than one classification hierarchy vs those classified in a single classification hierarchy was calculated using the script "4_number_of_Orphanet_RD_monoclassified_vs_multiclassified" which uses the "classifications of rare diseases" datasets to select disorders and assess their inclusion in one or multiple hierarchies. The same datasets are exploited by the script "5_distribution_of_Orphanet_RD_in_Orphanet_classifications" to retrieve and count the number of disorders included in each classification hierarchy. Of the 34 classification hierarchies in the Orphanet classification system, only 29 were included in the analysis. The previously described 5 hierarchies not corresponding to distinct medical domains or representing organizational or nonclinical groupings were excluded. The distribution of disorders by preferential parent was calculated using the script "6_distribution_of_Orphanet_RD_by_preferential_parent." This script selects all active disorders from the "rare diseases and alignments with terminologies and databases" dataset and uses the "linearization of rare diseases" dataset to retrieve their preferential parent, subsequently counting the total number of disorders linearized for each classification hierarchy.

The proportion of genetic disorders was calculated using the script "3_proportion_of_genetic_versus_non_genetic_Orphanet_RD." This script retrieves all active disorders from the "rare diseases and alignments with terminologies and databases" dataset and assesses their inclusion in the "genes associated with rare diseases" dataset and the "classifications of rare diseases-rare genetic diseases classification" dataset. Inclusion in either dataset was considered indicative of a genetic disorder.

Mappings to other semantic standards were retrieved using the script "7_alignment_between_Orphanet_RD_and_international_terminologies" for *ICD-10*, *ICD-11*, and OMIM, and manually for UMLS, MeSH, MedDRA, GARD, and Mondo. In both cases, the "rare diseases and alignments with terminologies and databases" dataset was filtered by the target standard to retrieve mappings at the Orphanet disorder level and their relationships. Orphanet-SNOMED CT mappings were retrieved manually by filtering the human-readable Orphanet-SNOMED CT mapping file for mappings at the disorder level.

Ethical Considerations

This study did not involve human participants, patient-level data, or identifiable personal information. The analyses were conducted exclusively using data derived from published literature and publicly available sources curated within Orphanet. Consequently, approval from an institutional review board or equivalent ethics committee was not required, and informed consent was not applicable.

Results

Quantitative Characterization of the Orphanet Nomenclature and Classification of RDs

Counting and Distribution of Active Clinical Entities in the Orphanet Nomenclature and Classification of RDs by Classification Level and Typology

As of July 2025, the Orphanet Nomenclature of RDs contains a total of 9784 active clinical entities, including 6527 disorders corresponding to the consensus definition of "rare disease" [16] (among which is a specific disorder code for undiagnosed patients after full investigation [33]), 1084 subtypes of disorders, and 2173 groups of disorders. Among all active entities, 3.3% (325 disorders and 1 subtype) are considered historic, with no publications over the past 25 years. The distribution of all active clinical entities by their classification level and their typology is presented in Table 1 and in Multimedia Appendix 3. Definitions of each typology are provided in Multimedia Appendix 1.

XSL•FO
RenderX

Table 1. Distribution of active clinical entities in the Orphanet Nomenclature of Rare Diseases by classification level and typology.

Classification levels	Active clinical entities, n (%)[a]
Disorders	6527 (66.7)
Diseases	4172 (63.9)
Clinical syndromes	50 (0.8)
Malformation syndromes	1788 (27.4)
Morphological anomalies	446 (6.8)
Biological anomalies	11 (0.2)
Particular clinical situations in a disease or syndrome	60 (0.9)
Subtypes of disorders	1084 (11.1)
Clinical subtypes	839 (77.4)
Etiological subtypes	195 (18)
Histopathological subtypes	50 (4.6)
Groups of disorders	2173 (22.2)
Clinical groups	450 (20.7)
Categories	1723 (79.3)

[a]Percentages for top-level classification categories (Disorders, Subtypes of disorders, and Groups of disorders) are calculated relative to the total number of active clinical entities. Percentages for subordinate classifications are calculated relative to the total number within their respective parent category.

Counting and Distribution of English Synonyms Across Active Clinical Entities in the Orphanet Nomenclature of RDs

Of the 9784 active clinical entities in the Orphanet Nomenclature of RDs, 6311 (64.5%) carry at least 1 synonym in English, while the remaining 3473 (35.5%) are not associated with any synonym. Of the 6527 disorders, 4805 (73.6%) carry at least 1 synonym in English, with a total number of synonyms at the disorder level amounting to 10,547. The minimum number of synonyms associated with a disorder is 1, and the maximum is 15, with a mean of 2.2 (SD 1.6) synonyms for disorders with at least 1 synonym. The complete distribution of synonyms by classification level is reported in Multimedia Appendix 4.

Counting and Distribution of Translated Preferred Terms and Synonyms Across Translation Languages

All preferred terms associated with active clinical entities registered in the Orphanet Nomenclature of RDs are translated into the following languages: French, German, Spanish, Italian, Dutch, Portuguese, Polish, and Czech. Table 2 shows the rate of translation of preferred terms for every language. The very minor delay in translation is due to the different timings and frequencies at which translations are processed by every translation team. Nontranslated preferred terms are nevertheless included in English, pending translation. Synonyms can be adapted in all translated languages according to the medical practice in the target language; the number of adapted synonyms for every translation language is shown in Table 2. The complete distribution of synonyms by classification level in all translated languages is reported in Multimedia Appendix 4. Additional translations are also available in Chinese (9158 translated preferred terms, last update June 2020), Turkish (9168 translated preferred terms, last update September 2021), and Ukrainian (9612 translated preferred terms, last update July 2024), and are provided in separate files in the “rare diseases and alignment with terminologies and databases” section of Orphadata Science [46].

Table 2. Number of active clinical entities with translated preferred term and adapted synonyms by language.

Language	Translated preferred terms (n=9784), n (%)	Adapted synonyms, n
French	9784 (100)	13,000
German	9778 (99.9)	12,854
Spanish	9784 (100)	12,912
Italian	9569 (97.8)	11,234
Dutch	9777 (99.9)	14,546
Portuguese	9576 (97.9)	5858
Polish	9605 (98.2)	12,804
Czech	9628 (98.4)	14,298

Coverage and Distribution of Disorder Definitions Across Languages

Disorder definitions are produced in English for all disorders included in the Orphanet Nomenclature of RDs and are subsequently translated into the 8 translation languages: French, German, Spanish, Italian, Dutch, Portuguese, Polish, and Czech. Table 3 presents the coverage of disorder definitions at the disorder level in each language. Currently, 94% (6116/6527) of rare disorders have a definition in English, while the rate of coverage in other languages depends on the priorities defined by each translating country.

Table 3. Number of disorders with available definitions per language.

Language	Disorders with a definition (n=6527), n (%)
English	6116 (93.7)
French	5941 (91)
German	4572 (70.1)
Spanish	6095 (93.4)
Italian	4592 (70.4)
Dutch	6068 (92.9)
Portuguese	1186 (18.2)
Polish	1372 (21)
Czech	17 (0.26)

Annual Inclusion and Inactivation of Disorders in the Orphanet Nomenclature of RDs Over the Past 6 Years (2020-2025)

Since 2020, an average of 123 (SD 72) new disorders per year have been added to the Orphanet Nomenclature, while an average of 44 (SD 18) disorders per year have been inactivated. A detailed report of the number of newly included, obsoleted, deprecated, and nonrare disorders for each year from 2020 to 2025 is provided in Table 4.

Table 4. Yearly overview of newly included and inactivated disorders in the Orphanet Nomenclature of Rare Diseases (2020-2025).

	Newly included disorders, n	Obsoleted disorders, n	Deprecated disorders, n	Nonrare disorders, n
2020	74	35	24	5
2021	53	8	16	1
2022	92	29	5	4
2023	114	21	8	5
2024	253	38	22	9
2025	152	13	19	2

Distribution of Rare Disorders by Medical Domain in the Orphanet Classification of RDs

The Orphanet classification of RDs has a multiparental structure: 4415 (67.7%) disorders are classified in more than one classification hierarchy, while 2106 (32.3%) are classified in just one classification, independently of the number of parents that they have in this same hierarchy. Figure 3 illustrates this multiparental structure by comparing the number of disorders linearized to each medical domain and therefore counted once (gray bars), with the number of disorders classified in one or more medical domains and therefore counted as many times as they appear in each classification (white bars). As an example, while 1096 disorders are primarily classified as neurological disorders, a total of 2492 disorders present a major neurological involvement. Based on the linearization rules, the majority of rare disorders fall into the rare developmental defect during embryogenesis classification (n=2109, 32.3% disorders), closely followed by the rare neurologic disorders classification (n=1096, 16.8% disorders), amounting to almost 50% of all rare disorders. The following most-represented classifications are the rare neoplastic disorders at 7.6% (497/6527), the rare inborn errors of metabolism at 6.1% (395/6527), the rare skin disorders at 6% (391/6527), the rare bone disorders at 5.4% (352/6527), the rare ophthalmic disorders at 3.7% (243/6527), the rare immune disorders at 3.2% (208/6527), the rare endocrine disorders at 3% (196/6527), the rare hematologic disorders at 2.8% (184/6527), the rare infectious disorders at 2.7% (177/6527), and the rare systemic or rheumatologic diseases at 2.5% (164/6527). The remaining classifications each include fewer than 100 linearized disorders each, collectively representing the residual 8% (515/6527) of rare disorders (Figure 3 gray bars; Multimedia Appendix 5).

XSL•FO
RenderX

Figure 3. Distribution of rare disorders by medical domain according to their classification. Gray bars represent the number of disorders linearized according to their preferential parent classification, while white bars indicate the distribution of multiclassified disorders, counted as many times as they appear in the relevant classification hierarchies. Classifications containing fewer than 100 disorders are annotated with exact counts to enhance readability. The analysis includes 29 classification hierarchies corresponding to distinct medical domains; 5 hierarchies representing organizational or nonclinical groupings were excluded, as described in the Methods section. Six disorders were excluded from this analysis because they correspond to biological anomalies without clinical manifestations or were linearized under the classifications of rare genetic disorders or rare transplant-related disorders. ORPHA:616874 rare disorder without a determined diagnosis after full investigation was also excluded.

A similar pattern is observed when considering multiclassified disorders, where the largest numbers are again found in the rare developmental defect during embryogenesis classification (2793 disorders) and the rare neurologic disorders classification (2492 disorders). The following classifications, however, contain considerably fewer multiclassified disorders and are, in descending order: rare ophthalmic disorders (868 disorders), rare skin disorders (835 disorders), rare bone disorders (793 disorders), rare neoplastic disorders (743 disorders), and rare inborn errors of metabolism (704 disorders). All remaining hierarchies contain fewer than 500 multiclassified disorders each, with only 3 hierarchies containing fewer than 100 (Figure 3 white bars; Multimedia Appendix 5).

Coverage and Proximity of the Mappings Between the Orphanet Nomenclature of RDs and Other Semantic Resources

Of the 6527 active disorders registered in Orphanet, 6355 (97.4%) are aligned to at least one code *ICD-10*, with only 415 (6.4% of all disorders) having an exact proximity relationship. The remaining aligned codes are either present in the *ICD-10* alphabetical index/are included in the tabulated list under the *ICD-10* code (655 disorders), or they have been attributed by Orphanet to the *ICD-10* code that corresponds to the closest entity according to Orphanet's rules (Table 5). The work on *ICD-11* mapping has not been completed yet; however, as of July 2025, a total of 4683 (71.8%) disorders were mapped to at least one code in the *ICD-11* MMS, with 958 (14.7% of all disorders) characterized by an exact proximity relationship and 3013 (46.2%) present in the *ICD-11* Foundation with an exact Unique Resource Identifier. The remaining mappings have been attributed by Orphanet to the *ICD-11* code corresponding to the closest entity (Table 5).

Table 5. Number of active disorders mapped to other semantic resources.

	Active disorders with at least 1 mapping (n=6527), n (%)	Active disorders with an exact proximity relationship (n=6527), n (%)
ICD-10 [a]	6355[b] (97.4)	415 (6.4)
ICD-11 [c]	4683[b] (71.8)	958 (14.7)
SNOMED CT[d]	6191 (94.8)	6191 (94.8)
OMIM[e]	4141 (63.4)	3319 (50.9)
UMLS[f]	6501 (99.6)	6501 (99.6)
MeSH[g]	2735 (41.9)	2735 (41.9)
MedDRA[h]	1455 (22.3)	1455 (22.3)
GARD[i]	3279 (50.2)	3279 (50.2)
Mondo[j]	6194 (94.9)	6194 (94.9)

[a]ICD-10: International Statistical Classification of Diseases, Tenth Revision.

[b]Counts include mappings attributed by Orphanet when the rare disorder concept was not present in the target resource.

[c]ICD-11: International Classification of Diseases, Eleventh Revision.

[d]SNOMED CT: Systematized Nomenclature of Medicine Clinical Terms.

[e]OMIM: Online Mendelian Inheritance in Man.

[f]UMLS: Unified Medical Language System.

[g]MeSH: Medical Subject Headings.

[h]MedDRA: Medical Dictionary for Regulatory Activities.

[i]GARD: Genetic and Rare Diseases Information Center.

[j]Mondo: Mondo Disease Ontology.

According to the October 2025 release of the Orphanet-SNOMED CT mapping, 6191 (94.8%) active Orphanet disorders are mapped to 1 SNOMED CT code, all with an exact proximity relationship (Table 5).

Among all active disorders present in the Orphanet Nomenclature, 72.2% (n=4715) are genetic disorders. A total of 4141 Orphanet disorders are mapped to at least 1 phenotypic OMIM number, and 3319 mapped disorders have an exact proximity relationship with the corresponding phenotypic OMIM number (Table 5).

In addition, exact mappings to external semantic resources are distributed as follows: 6501 (99.6%) for the UMLS Metathesaurus, 2735 (41.9%) for MeSH, 1455 (22.3%) for MedDRA, 3279 (50.2%) for GARD, and 6194 (94.9%) for Mondo. Of note, only mappings to *ICD-10*, *ICD-11*, and OMIM are distributed together with the official Orphanet Nomenclature files for coding, while the entirety of the mappings is distributed through Orphadata Science.

Discussion

Understanding the Necessity of an RD-Specific Terminology

While collectively common, RDs are numerous, clinically heterogeneous, and share challenges directly related to their individual rarity: persons living with each RD are few and dispersed, knowledge about each RD is limited and often inaccessible to nonspecialist health professionals, and expertise is scarce and dispersed as well. RDs are hard to identify in medical records since most are absent from medical terminologies in use in hospitals or are not labeled as rare, rendering them invisible in health systems. This lack of identification results in inequalities in accessing a timely diagnosis and appropriate care, hinders data collection on RDs natural history and their individual and societal burdens, and complicates patient recruitment for clinical research and therapy development [4,8,17,49].

The availability of adequate codes for each RD is a well-recognized need at the international level [25]. Improved codification for RDs has been cited as a priority in the 2009 EU (European Union) Council Recommendation on an action in the field of RDs [27], and more recently by the Rare2030 recommendations [50]. Having codes for each RD would help international, European, national, and local health authorities obtain better knowledge of health care pathways and of the impact of RDs on both specialized (such as centers of expertise) and general health care services, while also supporting budget planning for health and social services [8,25,27]. Adequate coding is also necessary for identifying patients for clinical trials at both national and transnational levels. Finally, a large proportion of patients with RD remain undiagnosed despite undergoing a full investigation, but this particular situation cannot be captured by the codification systems in use.

RDs codification requires a nomenclature and classification system that meets the requirements of a standard medical terminology to ensure implementation in health information systems and in systematic research collections, such as patient

XSL•FO
RenderX

registries. A trustworthy and reliable medical terminology must meet strict quality requirements: univocity and unambiguity of coded concepts, unrestricted management of synonyms, consistency of semantic relationships between concepts, multilingual support, accuracy of translations, correctness of semantic alignments, and relevant coverage of identified use cases. Additionally, terminology standards must adhere to rigorous and essential quality procedures, ensure sustainability and scalability to support the rapid development of knowledge, and guarantee long-term stability, preservation of the meaning of concepts from previous versions, and traceability of changes [51].

A key prerequisite for an RD terminology is to adopt a clear and operational definition of RDs. Orphanet adopts a clinical definition that encompasses all RDs, regardless of whether the etiology is known or not. This core concept ensures a terminology that can be adapted to different use cases, that is, health systems with diverse diagnostic capabilities or different stages of the patient's diagnostic journey. An RD in Orphanet is therefore defined as a clinical entity characterized by a set of well-delineated phenotypic abnormalities, described in at least 2 independent cases in the medical literature, and a consistent evolution, allowing for a definitive clinical diagnosis. The rarity of a disease is defined according to the European prevalence threshold (not more than 1 in 2000 persons in the European population). This choice was made for historical reasons, as Orphanet was developed in Europe and cofunded by the European Commission (EC). However, this definition is consistent with those used in other geographical areas, which adopt either a similar or more restrictive cutoff, with the exception of the United States, where diseases with a higher prevalence are included [1,14]. Another limitation of this definition is that it includes infectious diseases that are rare in Europe, even if they are common in other parts of the world. To address this, some countries having adopted the Orphanet Nomenclature of RDs outside the European space, like Argentina, have adapted this chapter to exclude infectious diseases that are common in their countries [52]. These limitations underline the need for consensus around a global operational definition of RDs, a goal the WHO has worked toward in collaboration with RDI, with the participation of a multistakeholder, international group of experts, including an Orphanet representative (AR) [16]. The results of this work support Orphanet's adoption of a clinical definition of RDs and may lead in the future to adaptations of the Orphanet RDs lists for the different WHO regions. In the meantime, Orphanet collaborates with non-European countries to help adapt the Orphanet Nomenclature of RDs to local needs, improving global RDs interoperability.

Implications of the Orphanet Terminology Structure, Mappings, and Updates

The Orphanet Nomenclature and Classification of RDs is, to the best of our knowledge, the only RDs terminology clearly defining 3 levels of granularity: group of disorders, disorder, and subtype of disorders, with the disorder level complying with the internationally agreed-upon definition of RDs. This distinction has essential implications.

A first implication is that it allows for unambiguously counting the number of existing RDs (ie, the disorder classification level), preventing overcounting due to the aggregation of heterogeneous granularity levels. As of today, many enumerations of RDs circulate, some derived from semiautomated integration of different databases and ontologies (most frequently Orphanet and OMIM), sometimes resulting in estimates exceeding 10,000 RDs [8,53,54]. However, these methods aggregate different levels of granularity without clearly stating which RDs definition is adopted, rather reflecting the growing knowledge of disease mechanisms or treatable genetic variants than an actual increase in the number of RDs. While this overall figure aligns closely with Orphanet's total active clinical entities (9784 as per the July 2025 release), it is essential to recognize that superimposing different levels of granularity and/or different etiologies of the same RDs can lead to counting the same disease multiple times. Using this broader count in public health discussions without clarification can lead to misinterpretations, potentially affecting policy decisions, budget allocation, and health care planning. For epidemiological and public health purposes, the count of clinically defined RDs (6527 according to the Orphanet July 2025 release) provides an appropriate common denominator for comparing countries and health care systems with varying technological and diagnostic capacities. It also permits to follow the evolution of therapy development and of health care resource allocation, including assessment of how many RDs benefit from these measures over time and across geographies. Conversely, for precision medicine or molecular diagnosis, a more granular approach, including subtypes (1084 in the July 2025 release) or information on genetic variants collected in patient records, may be needed.

A second implication is that defining the disorder granularity level allows the prevalence of RDs to be established accurately and facilitates comparability across countries and continents. A clear RDs definition, therefore, results in accuracy in counting RDs and, consequently, in counting patients, which is essential for assessing the magnitude of RDs as a public health issue. Furthermore, while allowing patient coding at the lowest granularity level (ie, subtypes of disorder), the classification hierarchies also allow data aggregation at the disorder level, thereby permitting to unambiguously establish the prevalence of RDs. Notably, the Orphanet Nomenclature of RDs is the only system that provides a code for undiagnosed patients with RD who underwent all available diagnostic possibilities. This population with RD has been estimated to represent up to 50% of all patients with RD, based on the experience of RDs expert centers [33]. Being able to code these patients at the disorder level makes it possible to include them in research pathways and undiagnosed programs, as recommended by the International Rare Diseases Research Consortium's goal #1 [55-57], and to include them in future global RDs point prevalence estimations.

The 3-level classification structure of the Orphanet Nomenclature and Classification of RDs supports consistent semantic relationships between concepts, enabling effective use across various use cases and settings. While the disorder level serves as the primary reference level for data sharing among systems and countries, and for epidemiological purposes, groups of disorders allow data aggregation for use cases analysis, that

XSL•FO
RenderX

is, for public health decision-making, such as health care organizations (eg, designation of centers of expertise by RDs area). Meanwhile, subtypes of disorders allow for fine-tuning of RDs codification at the clinical, etiological, and histopathological level, and can be used for applications in genetics, precision medicine, and other research and innovation purposes [58-64].

The Orphanet classification system is also able to capture the multisystemic nature of RDs, as clinical entities are organized into 29 distinct medical domains and classified as many times as needed according to their relevant domain of care. This is reflected in the distribution of RDs across classification hierarchies: the majority of RDs fall within the rare developmental defect during embryogenesis and rare neurologic disease classifications, together accounting for nearly 50% of all RDs. However, almost 70% of RDs are classified in more than one classification, reflecting their multisystem involvement. This approach ensures a more accurate representation of the complex nature of RDs and of their linked resources, allowing for better orientation of patients and medical doctors toward appropriate information and specialized care [58-60]. At the same time, the distribution of entities across preferential parent classifications is uneven, with some domains encompassing a large proportion of RDs and others including comparatively fewer entities. This distribution has implications for statistical analysis and data representation, as domains with fewer entities may appear less represented when preferential parent classifications are used for data aggregation. However, the multihierarchical structure allows flexible aggregation strategies that can be tailored to specific epidemiological or public health questions.

The field of RDs is a rapidly evolving one: with the continuous advancement in genetic knowledge and the growing interest in personalized medicine, new RDs are described each month. Additionally, the scope of previously identified RDs can be refined, with medical concepts being either merged or divided based on new discoveries or the examination of larger numbers of patients. To ensure that the Orphanet Nomenclature and Classification of RDs remain up to date with current scientific knowledge, Orphanet conducts a monthly systematized review of the literature and continuously collaborates with medical experts, particularly from the European Reference Networks and international RDs learned societies [32,65]. Decisions on modifications to ORPHAcodes are made after an extensive review of the literature, and are validated by the Orphanet medical and scientific committee, following published standardized procedures [29]. Between 2020 and 2025, a total of 738 new RDs were included in the Orphanet Nomenclature of RDs, averaging about 120 RDs per year. This number reflects not only newly described RDs, but also the outcomes of numerous time-effective collaborative projects with experts, aimed at restructuring and updating the classification to incorporate revised medical concepts. At the same time, Orphanet also applies a strict inactivation policy to preserve the stability and univocity of ORPHAcodes. Inactivated codes are never reused for other entities, and a substitution code is always suggested to maintain traceability. While unusual, it is possible to reintroduce an inactivated ORPHAcode when new evidence emerges that justifies a reconsideration [29]. This has occurred in cases such as systemic lupus erythematosus ORPHA:536 and immunoglobulin A nephropathy ORPHA:34145, which did not initially meet RDs prevalence criteria and are now considered RDs. Taken together, the integration of new RDs and the number of inactivated ones contribute to a small and relatively stable annual increase in the total number of RDs, averaging fewer than 80 RDs per year. A small proportion of active clinical entities are identified as historic, corresponding to RDs for which no new patients have been reported in the medical literature for 25 years. These entities are retained in the nomenclature to preserve diagnoses that could potentially reemerge and to support retrospective analyses, while their specific status limits the risk of confusion.

To further ensure the univocity and accessibility of concepts, Orphanet implements an unrestricted management of synonyms. Synonyms must cover the exact scope of the concept and are added as needed, without limitations in number [29]. This approach maximizes semantic coverage across different usages and data sources. Additionally, Orphanet provides a standardized, medically validated definition for each RD included in the Orphanet Nomenclature. These definitions consist of short texts describing the clinical features to unambiguously delineate the entity and distinguish it from other RDs, and are intended to support health care professionals in assigning the correct ORPHAcode to a patient [29,66]. To further ensure international interoperability, the Orphanet Nomenclature and Classification of RDs is also a multilingual resource. Translations are performed according to established procedures that include a final manual medical validation [31]. The different translations also include an unlimited number of synonyms that are tailored according to the relevance for each language. Taken together, these elements ensure semantic consistency and facilitate ORPHAcode integration into health and research information systems.

RDs is a field in which the boundaries between diagnosis, health care, and research are often blurred; maintaining semantic interoperability between health and research sectors is essential. The multiplicity of reference semantic standards used in health care, research, and regulatory science reflects the fact that each serves a distinct purpose, adopting diverse levels of granularity and encoding clinical concepts according to its own organizing principles. For example, *ICD* classifications are optimized for morbidity and mortality statistics, billing and reimbursement, and administrative reporting, which often results in broad disease groupings. In contrast, research-oriented resources such as OMIM organize information around gene-phenotype relationships, frequently splitting a single clinically defined disease into multiple molecular entries or, on the contrary, merging distinct clinical disorders related to the same gene. Consequently, semantic alignments between terminologies entail inherent complexity and need domain expertise, and must not be represented as simple one-to-one correspondences, but rather as structured relationships, as described in studies investigating RDs terminology harmonization and mapping processes [67]. Mapping strategies must therefore explicitly document mapping cardinality and capture varying degrees of conceptual proximity and specificity, in order to preserve meaning across contexts

XSL•FO
RenderX

and avoid misinterpretation. In addition, while automated approaches may assist in identifying candidate correspondences, the validation of RDs mappings requires expert medical review to ensure that assigned relationships accurately reflect clinical meaning. This is reflected in the way ORPHAcodes are mapped to different resources, with defined relationships and medical validation. As of July 2025, Orphanet has aligned 97.4% (6355/6527) of its active rare disorders to at least 1 *ICD-10* code, with only 6.4% (415/6527) of all RDs being exactly represented. The work on *ICD-11* mapping is ongoing, but by July 2025, 71.8% (4683/6527) of Orphanet's RDs were mapped to at least 1 *ICD-11* MMS code, with 14.7% (958/6527) of all RDs being exactly represented. Additionally, the October 2025 release of the Orphanet-SNOMED CT mapping shows that 94.8% (6191/6527) of Orphanet's active RDs are mapped to SNOMED CT, with all exhibiting an exact proximity relationship. Regarding genetic diseases, Orphanet classifies 4715 (72.2% of active disorders) RDs as genetic (defined as either caused by a known gene or having a clear familial inheritance pattern), with 4141 RDs mapped to one or more phenotypic OMIM numbers. It is interesting to note that many genetic RDs are mapped to multiple OMIM numbers, reflecting the fact that Orphanet adopts a clinical definition of disease, whereas OMIM organizes entries around individual gene-phenotype relationships.

Orphanet is currently the only primary producer of a scientifically validated nomenclature and classification of RDs. Other terminologies are increasingly integrating Orphanet concepts as a source of RDs information, acknowledging the critical scientific contribution Orphanet makes to the RDs community. Outstanding collaborations between Orphanet, SNOMED International, and WHO ensure that the RDs content of SNOMED CT and the *ICD-11* continue to be improved by the inclusion of RDs concepts as defined by Orphanet [23,24].

In parallel with mappings to major reference standards, the alignment of ORPHAcodes with other semantic resources, including UMLS, MeSH, MedDRA, GARD, and Mondo, supports a range of use cases such as literature indexing, pharmacovigilance, regulatory reporting, and knowledge integration. Overall, this extensive and accurate mapping system ensures consistency of transcoding across multiple platforms, further enhancing the use of the Orphanet Nomenclature of RDs in clinical, research, and regulatory contexts [61-64,68,69].

Recognition and Adoption of the Orphanet Nomenclature of RDs

Since 1997, Orphanet has maintained through its publicly available website an inventory of RDs to provide information on RDs and their dedicated services across Europe [28]. This has evolved over time into a nomenclature and classification system of RDs, which is today the only RDs-specific standard meeting the high-quality requirements of a medical terminology [20].

In 2014, the EC Expert Group on Rare Diseases adopted a recommendation on improving RDs codification [25]. In this document, EU Member States are encouraged to assess the feasibility of implementing ORPHAcodes at a national level and to include RDs codification into their national RDs plans/strategies. In 2017, the EC Steering Group on Promotion and Prevention recognized ORPHAcodes as a best practice [70]. Since then, ORPHAcodes have been included in the set of common data elements for Rare Diseases Registration, released by the EU RDs platform on RDs registration to enhance interoperability between registries [71]. The Orphanet Nomenclature of RDs has also played a key role in implementing the EU 2011 Cross-Border Healthcare Directive in regard to RDs. As a result, ORPHAcodes have been recommended for tracking RDs diagnoses in the European Common Semantic Strategy (2019) [72] and the Guidelines on Patient Summary (release 3.2, March 2022, and release 3.4, November 2024) [73], and have been integrated into the code systems used in the Master Value Sets Catalogue—My Health@EU—eHealth Digital Service Infrastructure [74,75]. The functional specifications developed by the X-eHealth project were instrumental for including ORPHAcodes in the minimum dataset required for the electronic patient summary [73,76]. Finally, the World Health Assembly resolution "Rare diseases: a global health priority for equity and inclusion," adopted on May 24, 2025, urges member states to commit to "considering the implementation of *ICD-11*, and where appropriate, interoperable codification systems for RDs such as the Orphanet Nomenclature of RDs, at their earliest possibility, and in accordance with their available resources, in order to enable the recording, reporting and monitoring of rare diseases at the national and international levels" [77].

To support the effective and sustainable implementation in health and research information systems, the Orphanet Nomenclature of RDs (ORPHAcodes) is distributed under an open license (CC-BY 4.0) on different platforms depending on use: Orphadata Science for structured datasets intended for large-scale analyses [46], and the Orphacode.org platform [78] for coding resources for health information systems [47]. Each annual release (in July of each year) is versioned and accompanied by differential files to ensure traceability of changes and continuity of coding, as per the recommendation of the RD-ACTION working group for routine maintenance of codification [79]. In addition, a suite of technical tools is provided to facilitate implementation into diverse systems, promote accurate patient codification, and ensure continuous support by the community. Finally, the implementation of ORPHAcodes within information systems should be guided by established and evolving guidelines and best-practice recommendations, including those developed within the RD-CODE and the OD4RD/OD4RD2 project [33,80-82]. This supporting infrastructure ecosystem is essential to ensure evolution over time and respond to emerging use cases in a rapidly evolving field.

Establishing a seamless data ecosystem for RDs based on the Orphanet Nomenclature and Classification of RDs is a key step toward increasing the knowledge in a field that has long remained largely invisible within health systems, and ultimately improving the lives of people living with RD [50]. Indeed, accurate codification of patients with RD enables the production of data for both primary and secondary use. Primary use includes, among others: recognition of the RDs condition by nonexpert health professionals, ensuring best care practices at

XSL•FO
RenderX

all stages of the patient's care pathway, and recognition of undiagnosed patients with RD who might benefit from new discoveries, potentially leading to establishing a diagnosis. Secondary use of RDs data includes accurately measuring the prevalence of the entire population with RD and monitoring public health interventions to inform evidence-based decision-making, producing real-world evidence for research and therapeutic development, and facilitating recruitment for clinical research.

Conclusions

The Orphanet Nomenclature and Classification of RDs is the only RD-specific, high-quality standard, interoperable medical terminology meeting the needs of health care, research, and public health systems. By providing a clinically based and scientifically validated framework, it helps close the RDs visibility gap in health and research information systems, enabling consistent RDs identification and monitoring. Its wide adoption will support cross-border and cross-sectoral data interoperability, contributing to improved knowledge, policymaking, and ultimately better care for people living with a RD.

Acknowledgments

We would like to thank the Orphanet translating members for their essential contribution to the translation of the Orphanet Nomenclature of RDs, as well as the European Reference Networks and the Filières de santé maladies rares for their continued involvement in nomenclature and classification revisions, and in the production of textual content.

Data Availability

The datasets supporting the conclusions of this study are publicly available. Orphanet provides open access to rare disease nomenclature, classification, genetic data, and mappings to other terminologies [28]. Structured datasets for large-scale analysis are distributed via the Orphadata Science platform [46], and all previous versions are archived in a dedicated GitHub repository [83]. Additional resources include the Orphanet Nomenclature files for coding (Nomenclature Pack) distributed on the ORPHAcodes platform [78] and the Orphanet Rare Disease Ontology [84]. All formats are maintained and updated annually or biannually to ensure accuracy and accessibility.

Funding

The Orphanet Nomenclature and Classification system has been developed and maintained thanks to INSERM support since 2007, as well as European support since 2009. Funding was provided through the following grants and initiatives: RDs-PORTAL (S12305098-2006119), RDs-PORTAL2 (S12324970-20091215), ORPHANET EUROPE Joint Action (20102206), EUCERD Joint Action (20112201), ORPHANET Operating Grant (20133305), RD-ACTION Joint Action (677024), ORPHANETWORK Direct Grant (831390), RD-CODE (826607), OD4RD (101070531), and OD4RD2 (101110100). The funders had no role in study design, data collection and analysis, decision to publish, or preparation of the manuscript.

Abstract

Background: The implementation of Clinical Data Interchange Standards Consortium (CDISC) standards is essential for accelerating clinical research and is mandated for new drug applications in Japan. However, the current status of their implementation and associated challenges in Japanese academic medical centers has not been comprehensively investigated.

Objectives: This study aimed to comprehensively clarify the current status, challenges, and opportunities associated with implementing CDISC standards in Japanese academic medical centers.

Methods: We conducted a questionnaire survey targeting 91 academic medical centers (83 university hospitals, 7 national centers for advanced and specialized medical care, and 1 national hospital organization) from June to August 2024. The survey assessed experience with contracted CDISC data creation, implementation status, barriers, and available resources. We performed Mann-Whitney *U* tests to assess the association between the number of data managers or biostatisticians and CDISC implementation status.

Results: Responses were received from 84 institutions (response rate: 92%). While 29% (26/91) had experience with contracted CDISC standards data creation, 22% (20/91) had implemented CDISC standards. The most frequently cited barrier to CDISC standards implementation was “significant human and financial effort and resource shortages” (62%, 56/91). A significant “supply and demand” gap was identified: while 66% (60/91) of institutions expected support (eg, materials, workshops) from other organizations, only 5% (5/91) were capable of providing such resources. Furthermore, 66% (60/91) of institutions had not yet decided on a future policy regarding CDISC compliance. Notably, institutions that had implemented CDISC standards had significantly higher numbers of data managers (P<.001) and biostatisticians (P<.001) compared to those that had not.

Conclusions: The implementation of CDISC standards in Japanese academia is limited, primarily due to resource shortages and a lack of specialized personnel. However, the discrepancy between the high demand for support and limited supply highlights a significant opportunity. Experienced academic research organizations, in cooperation with pharmaceutical companies and contract research organizations, can drive nationwide adoption by taking a strategic leadership role in providing educational resources and training, thereby addressing the critical shortage of specialized personnel and know-how.

(JMIR Med Inform 2026;14:e83774) doi:10.2196/83774

KEYWORDS

Clinical Data Interchange Standards Consortium; CDISC standards; academic research organization; ARO; Clinical Data Acquisition Standards Harmonization; CDASH; Study Data Tabulation Model; SDTM; Analysis Data Model; ADaM

Introduction

The Clinical Data Interchange Standards Consortium (CDISC) is a nonprofit organization dedicated to developing global electronic standards for clinical trial data. The “CDISC standards” refer to the set of standards developed by this consortium. Implementing these standards entails a series of technical activities throughout the clinical data lifecycle. Specifically, it involves designing case report forms based on Clinical Data Acquisition Standards Harmonization (CDASH), mapping collected raw data to Study Data Tabulation Model (SDTM) domains, and creating analysis-ready datasets according to Analysis Data Model (ADaM). These processes require writing programming scripts for data transformation, generating

XSL•FO
RenderX

metadata files such as define.xml, and rigorously validating the datasets and their conformance to the standards. In Japan, the Pharmaceuticals and Medical Devices Agency (PMDA) has been accepting electronic clinical trial data submissions compliant with CDISC standards for new drug marketing approval applications since October 2016 [1]. Furthermore, the Japan Agency for Medical Research and Development has expressed the view that compliance with CDISC standards from the planning and execution stages will become essential in academia-led clinical research and trials in the future [2].

Additionally, global data sharing platforms promote the sharing and reuse of clinical trial data [3-9], and several of these advance data standardization in collaboration with the CDISC [3-6,8].

The sharing of clinical trial data is expected to promote advancements in medicine and science [10,11]. Moreover, since July 1, 2018, the International Committee of Medical Journal Editors has mandated the inclusion of a data-sharing statement in manuscripts reporting the results of clinical trials submitted to International Committee of Medical Journal Editors member journals [12].

In 2017 in Japan, the University Hospital Medical Information Network Center and Japan Agency for Medical Research and Development cohosted the "CDISC Public Symposium" [2]. Furthermore, in 2018, University Hospital Medical Information Network, PMDA, and CDISC cohosted the "Workshop on CDISC Utilization in Academia" [13]. These activities aim to promote the dissemination of CDISC standards in Japanese academia.

The implementation of CDISC standards is expected to accelerate clinical research [14]. In particular, researchers and related institutions are beginning to recognize the importance of planning research and preparing case report forms based on the premise of electronic submissions compliant with CDISC standards throughout the processes of data collection, data management, and statistical analysis. These initiatives are expected to help reduce costs and workloads while maintaining data quality [15].

A previous study investigated the current status and challenges associated with the implementation of CDISC standards in Japanese academic medical centers [16]. However, in that study, the definition of "academia" was ambiguous.

Therefore, the present study aimed to comprehensively clarify the current status and challenges associated with implementing CDISC standards in Japanese academic medical centers.

Methods

Ethical Considerations

This study was a questionnaire survey targeting administrative personnel at academic medical centers regarding the operational status of CDISC standards. The study did not involve interventions on human participants or the collection of sensitive personal health information from patients. Therefore, an ethics review board assessment was not sought, in accordance with the ethical guidelines for medical and health research involving human subjects in Japan.

The purpose of the study was clearly explained in the invitation to the online questionnaire, and the completion and submission of the questionnaire were regarded as implied consent to participate. Participation was voluntary, and respondents could withdraw at any time by not submitting their responses.

To protect the privacy and confidentiality of the respondents, the collected data were stored securely and accessed only by the research team. The data were aggregated for analysis, and no personally identifiable information was reported. No compensation was provided to the participants for this study. This manuscript and the supplementary materials do not contain any images or data that could identify individual participants.

Participants and Survey Administration

In this study, "academia" is defined as institutions in Japan legally mandated to conduct research as part of their official duties. Based on this definition, the following 91 academic medical centers (hereinafter referred to as "institutions") were selected as survey targets: 83 university hospitals (43 national university hospitals, 8 public university hospitals, 31 private university hospitals, and 1 ministry-affiliated university hospital), 7 national centers for advanced and specialized medical care, and 1 national hospital organization. We contacted these institutions by email, requested their cooperation in the questionnaire survey, and sent them the questionnaire.

The survey period was from June 12 to August 16, 2024. The questionnaire survey was conducted online using Google Forms. As a general rule, 1 response per institution was accepted. No duplicate responses were received from any single institution; therefore, all submitted responses were included in the final analysis.

The survey was primarily distributed to the directors of clinical research centers or heads of data centers at each institution. In cases where direct contact information for these roles was unavailable, we identified the appropriate respondents through personal professional networks. For institutions where no direct contact could be established, the request was sent to the general administrative office of the Clinical Research Support Center, with instructions to forward the questionnaire to the staff member most knowledgeable about CDISC standards.

Questionnaire Items

The main questionnaire items were as follows:

Experience with contracted CDISC standards data creation

Implementation status of CDISC standards

Barriers to CDISC standards implementation

Future policies regarding CDISC standards-compliant data creation

Availability of CDISC standards-related documents and training

Ability to provide CDISC standards-related documents and training

Expectations for pharmaceutical companies, contract research organizations (CROs), and other academic research organizations (AROs)

XSL•FO
RenderX

Ability to provide to pharmaceutical companies, CROs, and other AROs

Number of data managers and biostatisticians

In this study, "implementation" was defined as CDISC data creation conducted internally, jointly with external partners, or externally with acceptance reviews performed by internal CDISC experts. "Experience with contracted CDISC standards data creation" was defined more broadly to encompass these implementation categories as well as external data creation performed without such internal expert-led acceptance procedures.

Further details regarding the questionnaire items are presented in Multimedia Appendix 1.

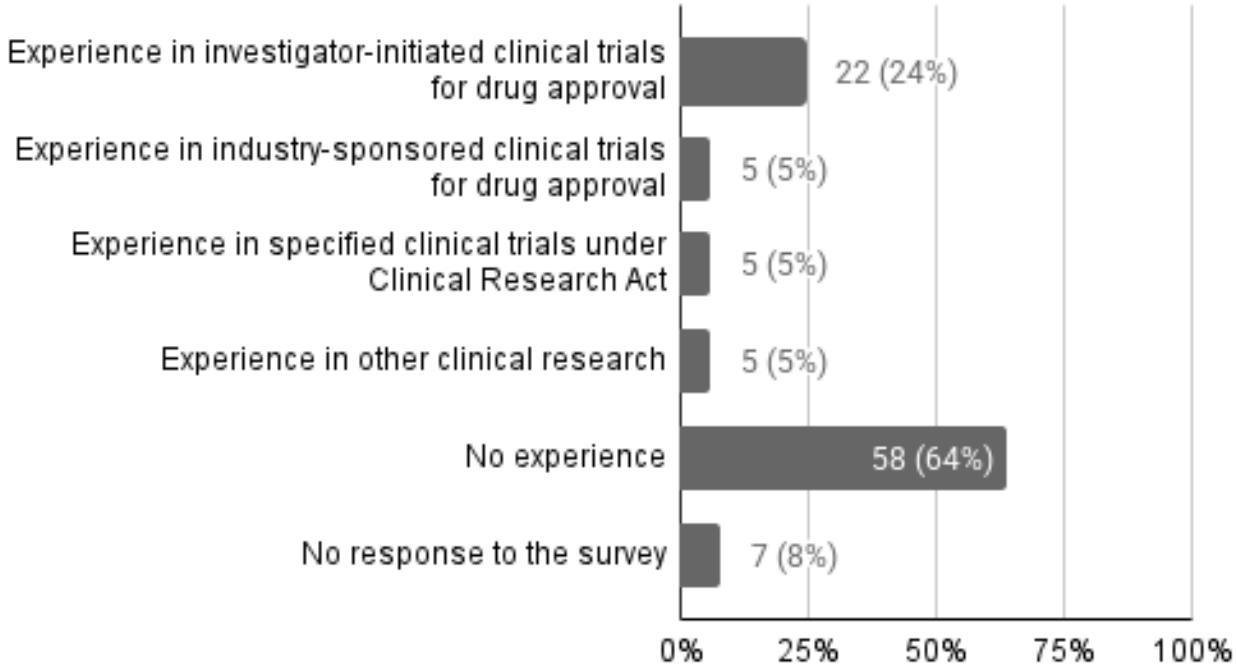
Statistical Analysis

Descriptive statistics were calculated using the total number of targeted institutions (n=91) as the denominator. This approach was adopted to establish a consistent baseline for future longitudinal surveys targeting the same population. Furthermore, using the total population as the denominator prevents the overestimation of implementation rates caused by selection bias—where institutions with greater interest in CDISC standards are more likely to respond—and ensures the results accurately reflect the status across all defined Japanese institutions. Categorical variables are presented as numbers and percentages. To assess the association of the number of data managers and biostatisticians with the CDISC implementation status, we performed the Mann-Whitney *U* test. In this analysis, the number of staff was treated as a continuous variable. Although staffing levels were categorized (0‐3, 4‐10, and ≥11) for visualization purposes, the statistical hypothesis testing was based on the continuous data. To examine potential confounders, we also analyzed the association between institution type (public/national vs private) and CDISC implementation using Fisher exact test. A *P* value <.05 was considered statistically significant. All statistical analyses were performed using R statistical software (version 4.4.1; R Foundation for Statistical Computing).

Results

Response Rate and Participant Characteristics

In this study, 91 institutions were targeted, among which responses were received from 84 (response rate: 92%). Of these, 7 (8%) institutions did not respond. The breakdown of the responding institutions was as follows: 42 national university hospitals, 27 private university hospitals, 7 public university hospitals, 7 national centers for advanced and specialized medical care, and 1 national hospital organization. No responses were received from ministry-affiliated university hospitals. The breakdown of respondents by job title is shown in Multimedia Appendix 2.



The percentages in these results were calculated with the total number of targeted institutions (N=91) as the denominator and rounded to the nearest integer, unless otherwise specified.

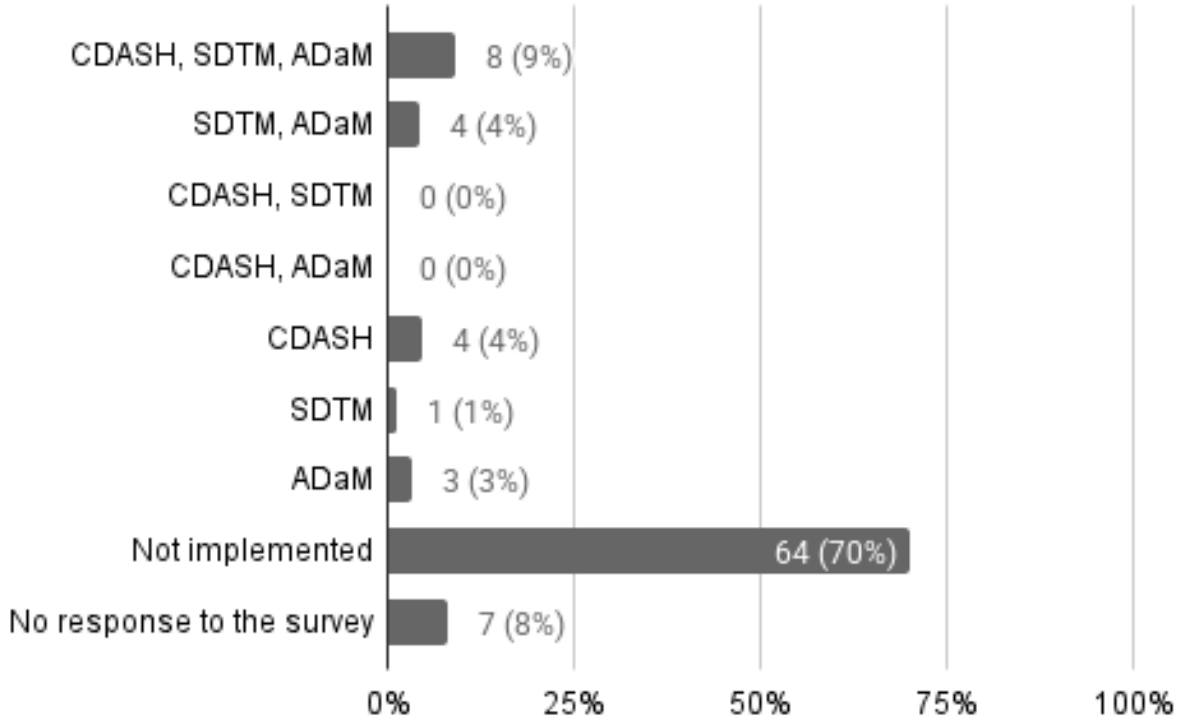
Experience With Contracted CDISC Standards Data Creation

Experience with contracted CDISC standards data creation refers to the track record of accepting projects for CDISC data creation. This includes cases where the actual data creation was outsourced to a third party. Regarding experience with contracted data creation using CDISC standards, 26 (29%) institutions reported having such experience, while 58 (64%) did not; 7 (8%) institutions did not respond to this question. Among the types of trials for which institutions had experience (multiple answers allowed), investigator-initiated clinical trials for drug approval were the most common, at 22 (24%), followed by industry-sponsored clinical trials for drug approval (n=5, 5%), specified clinical trials under Japan's Clinical Research Act [17] (n=5, 5%), and other clinical research (n=5, 5%) (Figure 1).

XSL•FO
RenderX

Figure 1. Experience with contracted Clinical Data Interchange Standards Consortium standards data creation (multiple responses allowed) (N=91).

These results indicate that slightly less than 30% (26/91) of the institutions had experience with contracted data creation using CDISC standards. Notably, this experience extends beyond trials for drug approval to include specified clinical trials and other clinical research.



Implementation Status of CDISC Standards

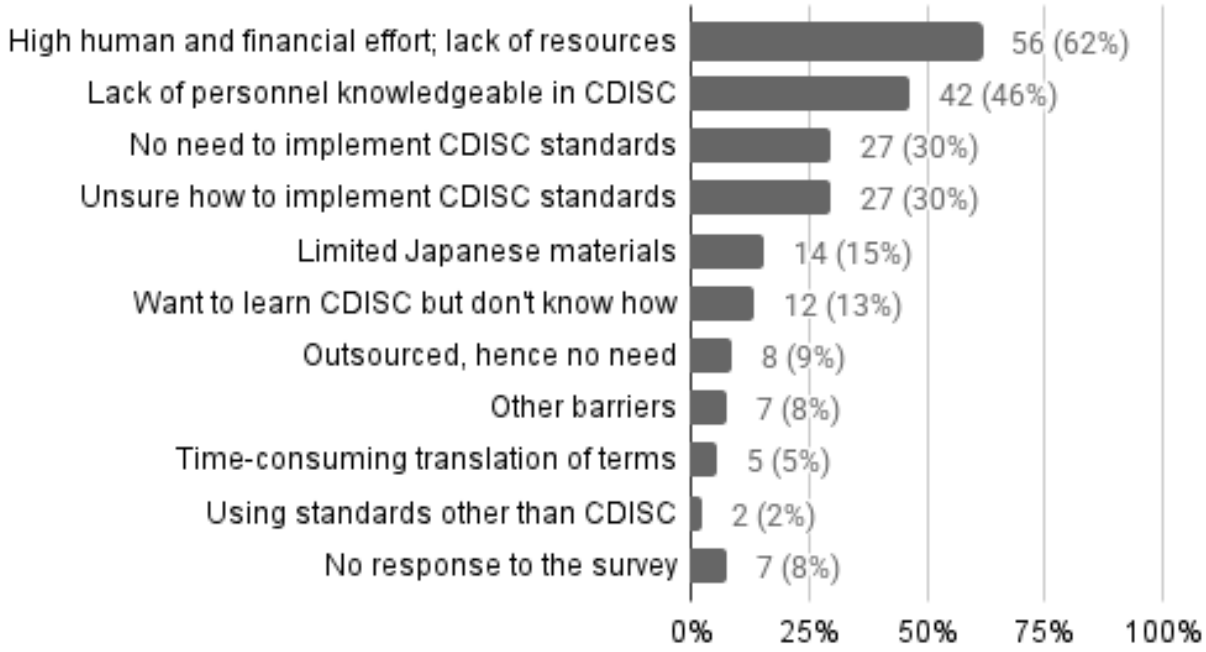
Implementation of CDISC standards refers to creating CDISC data using internal resources or, in the case of outsourcing, conducting acceptance work by CDISC experts. Regarding the implementation status of CDISC standards, 20 institutions (22%) reported having implemented them, whereas 64 institutions (70%) reported not having implemented them; seven institutions (8%) did not respond.

Among the 20 institutions that had implemented CDISC standards, the most common combination of standards (multiple answers allowed) was the implementation of all three—CDASH, the SDTM, and the ADaM—reported by eight institutions (9% of the 91 institutions). This was followed by institutions implementing SDTM and ADaM (n=4, 4%), CDASH only (n=4, 4%), ADaM only (n=3, 3%), and SDTM only (n=1, 1%) (Figure 2).

XSL•FO
RenderX

Figure 2. Implementation status of the Clinical Data Interchange Standards Consortium standards (N=91). ADaM: Analysis Data Model; CDASH: Clinical Data Acquisition Standards Harmonization; SDTM: Study Data Tabulation Model.

Regarding individual standards, ADaM was implemented by 15 (16%) institutions, SDTM by 13 (14%), and CDASH by 12 (13%).



These results indicate that while only 22% (20/91) of all institutions had implemented CDISC standards, many of these implementing institutions use multiple standards (CDASH, SDTM, and ADaM) in combination.

Barriers to CDISC Standards Implementation

Barriers with CDISC implementation refer to the obstacles or challenges that institutions face when attempting to adopt or maintain CDISC standards. Institutions cited the following items as barriers to CDISC standards implementation (multiple answers allowed). The most frequently cited barrier was “high human and financial effort and lack of resources” (n=56, 62%), followed by “lack of personnel knowledgeable in CDISC” (n=42, 46%), “no need to implement CDISC standards” (n=27, 30%), and “unsure how to implement CDISC standards” (n=27, 30%) (Figure 3).

XSL•FO
RenderX

Figure 3. Barriers to CDISC standards implementation (multiple responses allowed). Note: Percentages were calculated based on the total number of survey targets (N=91). "No response to the survey" indicates institutions that did not answer this survey entirely. CDISC: Clinical Data Interchange Standards Consortium.

These results indicate that the main barriers to CDISC standards implementation are the significant human and financial effort required, resource shortages, and a lack of personnel knowledgeable about CDISC.

Future Policies Regarding CDISC Standards-Compliant Data Creation

Regarding future policies for CDISC standards-compliant data creation (single answer), the most common response, reported by 60 (66%) institutions, was "no decision made," followed by "will not undertake" (n=7, 8%), "will undertake, and external experts will perform the work with internal involvement" (n=6, 7%), "will undertake, and both internal and external personnel will perform the work" (n=5, 5%), "will undertake, but only external experts will perform the work without internal involvement" (n=5, 5%), and "will undertake, and the work will be performed internally" (n=1, 1%) (Table 1). These results indicated that 66% (60/91) of the institutions had not yet decided on their future policy; only 19% (17/91) had a clear policy for undertaking such work.

Table . Future policies regarding CDISC[a] standards-compliant data creation (N=91).[b]

Future policy regarding CDISC compliance	All institutions (N=91), n (%)	Currently implemented (n=20), n (%)	Currently not implemented (n=64), n (%)
Internal execution	1 (1)	1 (5)	0 (0)
Joint internal and external execution	5 (5)	3 (15)	2 (3)
External execution with internal involvement	6 (7)	5 (25)	1 (2)
External execution without internal involvement	5 (5)	1 (5)	4 (6)
Will not undertake	7 (8)	2 (10)	5 (8)
No decision made	60 (66)	8 (40)	52 (81)
No response to the survey	7 (8)	—[c]	—

[a]CDISC: Clinical Data Interchange Standards Consortium.

[b]Note: All values are n (%); percentages are calculated based on the total number of survey targets (N=91). "Implemented" and "not implemented" columns represent the current status at the time of the survey, where "implementation" is defined as internal CDISC data creation or expert-led acceptance work for outsourced tasks. "No response to the survey" refers to institutions that did not return the questionnaire.

[c]Not available.

The association between current implementation status and future policies is detailed in Table 1. Among the 20 institutions that had already implemented the standards, fewer than half (9 institutions, 45%) intended to continue "implementation"

XSL•FO
RenderX

(defined as work involving internal resources or internal expert-led acceptance). A similar lack of interest was observed among the 64 nonimplementing institutions, with only 3 (5%) planning for future implementation.

CDISC Standards Implementation Resources: Availability and Ability to Provide

Among all, 15 (16%) institutions reported having documents or training related to implementing CDISC standards. A breakdown of these resources (multiple answers allowed) indicated that “beginner-level training” was the most common, reported by 12 (13%) institutions, followed by “Japanese-language educational materials” (n=9, 10%), “documents on implementation know-how” (n=8, 9%), and “tools supporting CDISC” (n=8, 9%) (Table 2).

Table . Availability of and ability to provide CDISC[a] standards-related documents and training (multiple responses allowed) (N=91).[b]

Item	Availability, n (%)	Ability to provide, n (%)
Japanese-language educational materials on CDISC standards	9 (10)	4 (4)
Documents on implementation know-how for CDISC standards	8 (9)	4 (4)
Tools supporting CDISC standards implementation	8 (9)	4 (4)
Beginner-level training on CDISC standards	12 (13)	5 (5)
No response to the survey	7 (8)	7 (8)

[a]CDISC: Clinical Data Interchange Standards Consortium.

[b]Note: Percentages were calculated based on the total number of survey targets (N=91). "No response to the survey" indicates institutions that did not answer this survey entirely.

Next, regarding the question of whether these documents and training could be provided to other institutions, 5 (5%) institutions responded that they “could provide” them. A breakdown of providable resources is shown in Table 2.

These results indicate that while 16% (15/91) of institutions had CDISC standards implementation resources available, only 5% (5/91) were able to provide these resources to other institutions.

Support Expected From and Providable to Pharmaceutical Companies, CROs, and Other AROs

Regarding expectations for pharmaceutical companies, CROs, and other AROs (multiple answers allowed), 60 (66%) institutions responded that they had “some expectations.” Among these 60 institutions, the most desired item was “materials and information on CDISC” (n=53, 58%), followed by “training sessions (seminars, workshops, etc) on CDISC” (n=45, 49%) and “on-the-job training related to CDISC” (n=33, 36%) (Table 3).

Table . Expectations for and ability to provide support to pharmaceutical companies, contract research organizations, and other academic research organizations (multiple responses allowed) (N=91).[a]

Item	Expectations, n (%)	Ability to provide, n (%)
Training sessions (seminars, workshops, etc) on CDISC[b]	45 (49)	2 (2)
On-the-job training related to CDISC	33 (36)	2 (2)
Materials and information on CDISC	53 (58)	4 (4)
No response to the survey	7 (8)	7 (8)

[a]Note: Percentages were calculated based on the total number of survey targets (N=91). "No response to the survey" indicates institutions that did not answer this survey entirely.

[b]CDISC: Clinical Data Interchange Standards Consortium.

Next, regarding support that could be provided to pharmaceutical companies, CROs, and other AROs (multiple answers allowed), 5 (5%) institutions responded that they “could provide” some support. A breakdown is shown in Table 3.

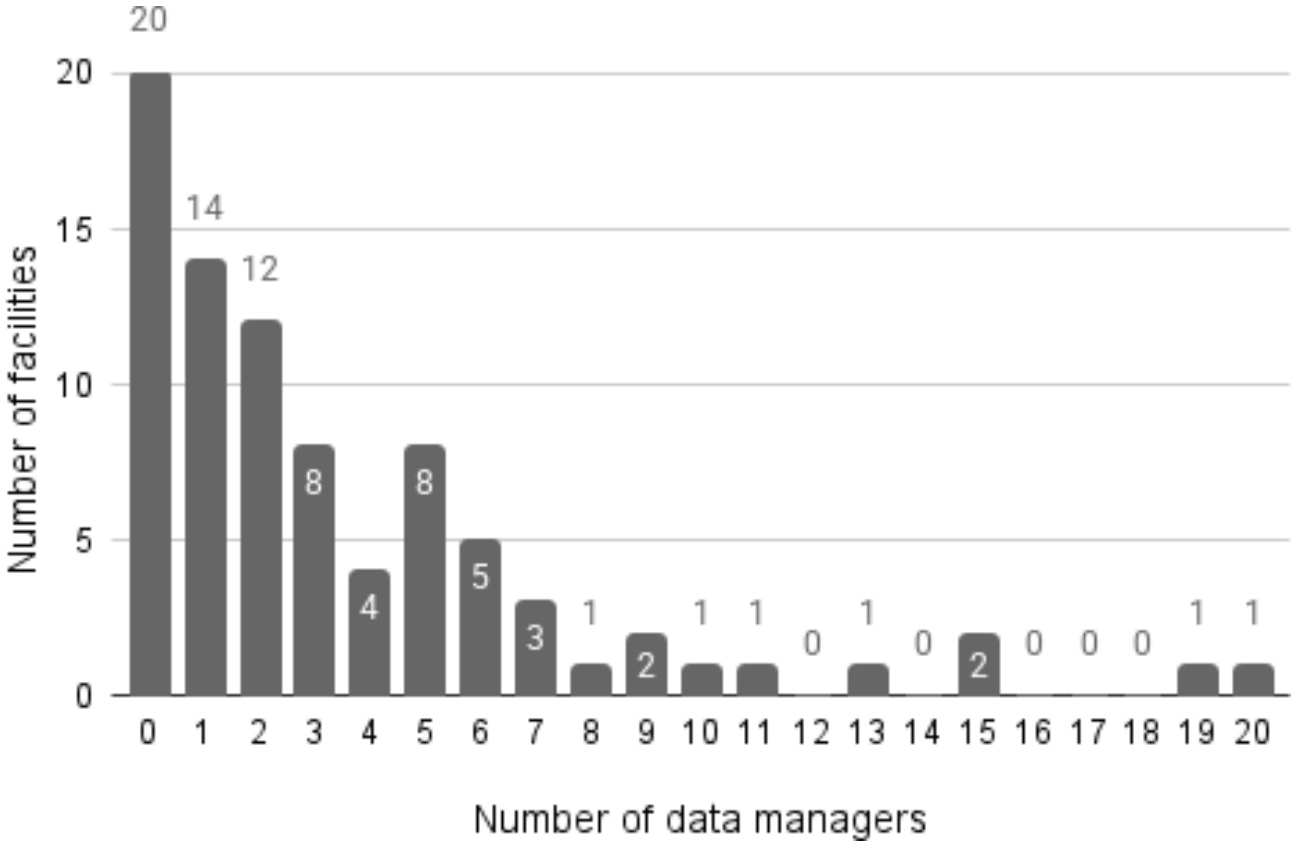
These findings revealed that 66% (60/91) of the institutions expected CDISC-related material provision, information sharing, and workshop hosting from pharmaceutical companies, CROs, and other AROs. On the other hand, only 5% (5/91) of the institutions were able to provide such support, indicating a limited capacity.

Number of Data Managers and Biostatisticians

Among the 84 responding institutions, the median number of data managers was 2 (mode: 0; range: 0‐20) (Figure 4). Similarly, the median number of biostatisticians was 2 (mode: 1, range: 0‐13) (Figure 5).

XSL•FO
RenderX

Figure 4. Number of data managers at responding facilities (n=84). Note: Analysis excluded the 7 institutions that did not respond to the survey.



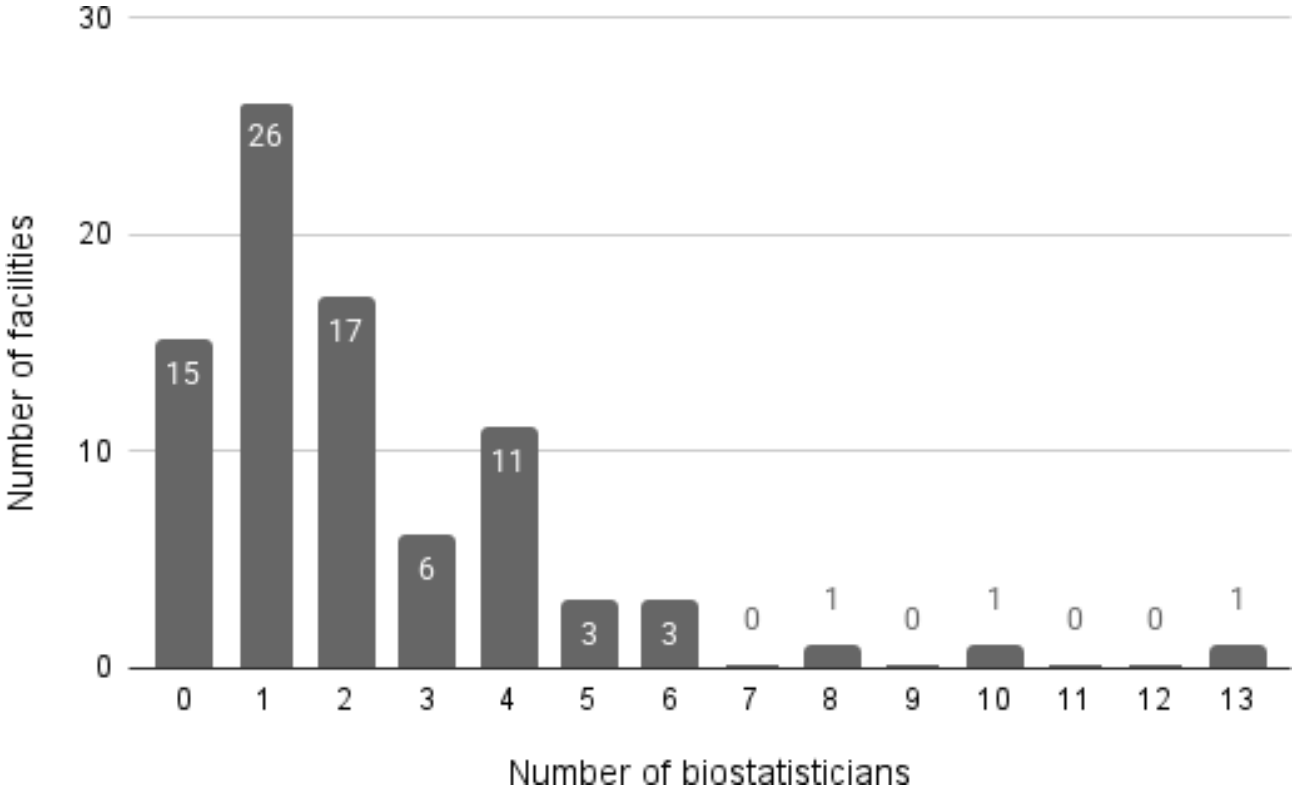


Figure 5. Number of biostatisticians at responding facilities (n=84). Note: Analysis excluded the 7 institutions that did not respond to the survey.

Association Between Staffing Levels and CDISC Standards Implementation Status

An analysis of the relationship between staffing levels and CDISC implementation showed that institutions with more data managers tended to be more advanced in their implementation (median 5, IQR 2 - 9.25 vs median 2, IQR 0 - 4; *P*<.001) (Figure 6). A similar trend was observed for biostatisticians (median 3.5, IQR 1.75 - 5 vs median 1, IQR 1-2; *P*<.001) (Figure 7).

XSL•FO
RenderX

Figure 6. Number of data managers and status of Clinical Data Interchange Standards Consortium standards implementation (n=84). Note: Analysis excluded the 7 institutions that did not respond to the survey. Data were categorized for visualization purposes, while the Mann-Whitney *U* test was performed on continuous variables (*P*<.001).

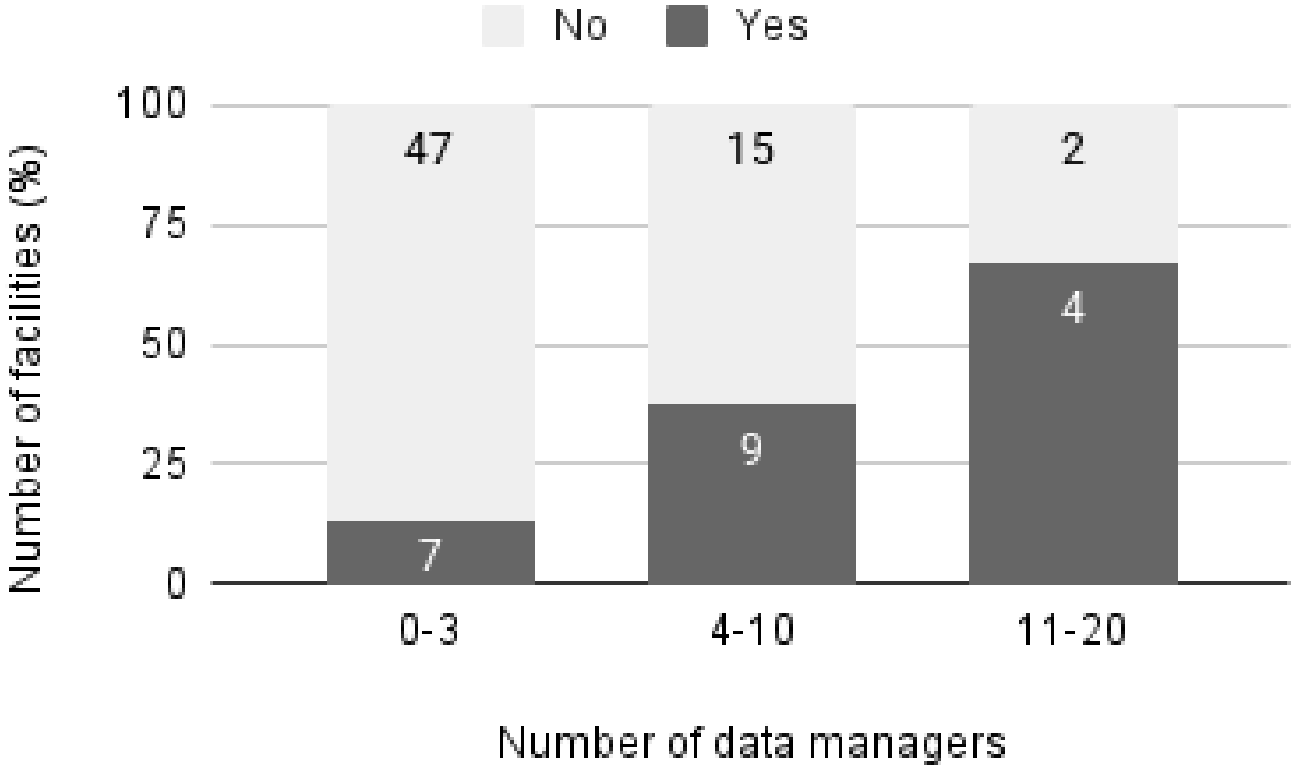

Figure 7. Number of biostatisticians and status of Clinical Data Interchange Standards Consortium standards implementation (n=84). Note: Analysis excluded the 7 institutions that did not respond to the survey. Data were categorized for visualization purposes, while the Mann-Whitney *U* test was performed on continuous variables (*P*<.001).

These findings suggest that institutions with more data managers and biostatisticians tend to be further along in implementing CDISC standards.

In addition to staffing levels, we evaluated the association between institution type and CDISC implementation. Implementation rates were 28.1% (16/57) in Public/National

XSL•FO
RenderX

institutions and 14.8% (4/27) in private institutions; however, no significant difference was observed (Fisher exact test, *P*=.27).

Discussion

Current Status and Significance of CDISC Standards Implementation

In a questionnaire survey conducted in 2020 to clarify the current status of and challenges associated with CDISC standards implementation in Japanese academic medical centers [16], the definition of "academia" was ambiguous, which posed challenges in interpreting the results and tracking changes over time. Therefore, in the present study, "academia" was more strictly defined to ensure the accuracy of longitudinal comparisons. By selecting institutions based on this clear definition, the present study could assess the current status and challenges associated with implementing CDISC standards more accurately, thereby providing foundational data to promote future adoption.

In a questionnaire survey conducted in 2020 to clarify the current status of and challenges associated with CDISC standards implementation in Japanese academic medical centers [16], the definition of "academia" was ambiguous, which posed challenges in interpreting the results and tracking changes over time. Therefore, in the present study, "academia" was more strictly defined to ensure the accuracy of longitudinal comparisons. By selecting institutions based on this clear definition, the present study could assess the current status and challenges associated with implementing CDISC standards more accurately, thereby providing foundational data to promote future adoption.

The findings revealed that only 29% (26/91) of institutions had experience with contracted CDISC standards data creation. Furthermore, institutions with experience in contracted data creation most frequently undertook investigator-initiated clinical trials for drug approval. This finding suggests that the application of CDISC standards in Japan, particularly that centered around investigator-initiated clinical trials for drug approval, is progressing. On the other hand, the present findings also confirmed that institutions had some experience in contracted CDISC standards data creation for specified clinical trials under the Clinical Research Act and other clinical research not intended for marketing approval applications. These findings suggest that CDISC standards are being used not only for regulatory submissions but also for standardizing and improving the efficiency of overall clinical research operations. In addition, it has been reported internationally that CDISC standards are also being used for Real-World Data [18]. We believe that clarifying the significance of standardization and efficiency and sharing practical case studies could lead to the promotion of CDISC standards implementation.

Regarding the implementation status of CDISC standards, the present study found that only 22% (20/91) of institutions had implemented them, indicating limited adoption. Notably, this study confirmed that while a high proportion of implementing institutions adopt multiple CDISC standards in combination, a certain number of institutions implement only individual standards. These results suggest that varying needs and resource situations at each institution may influence the form of CDISC standards implementation.

Barriers to CDISC Standards Implementation

Regarding implementation barriers, this study confirmed that "human and financial effort and resource shortages" remains the greatest challenge, followed by "a lack of personnel knowledgeable about CDISC." This finding suggests that securing human and financial resources and developing CDISC specialist personnel within institutions are crucial for promoting CDISC standards implementation. The findings also revealed that only 16% (15/91) of institutions possess documents or training related to CDISC standards, and furthermore, only 5% (5/91) of institutions can provide these resources to other institutions, which suggests that the expansion of CDISC-related educational resources within the country remains a challenge. We hypothesize that this discrepancy may stem from proprietary restrictions, copyright issues, or the lack of generalized templates that can be easily shared across institutions. In AROs in other countries as well, there is a demand not only for formal training by experts but also for open-source resources and "bite-sized" educational materials that are easily accessible online, such as the W3Schools model, as suggested by Jentoft et al [19]. Therefore, developing similar practical and accessible educational resources may serve as an important strategy for addressing the shortage of training materials in Japan.

Regarding barriers to implementation, 27 (30%) institutions cited "no need to implement CDISC standards." Within this group, some respondents cited "outsourced, hence no need." Furthermore, our detailed analysis revealed that the majority of these 27 (81%, 22/27) institutions selected "will not undertake" or "no decision made" regarding their future policies on CDISC standards-compliant data creation. The primary reason for these responses is likely that the PMDA requires CDISC compliance exclusively for new drug marketing approval applications, whereas many institutions primarily conduct research under the Clinical Research Act that falls outside this mandate. We included these institutions in our analysis to accurately reflect the current status of adoption, as excluding them would overlook the reality that a significant segment of academia operates outside the regulatory scope.

Regarding the respondents who cited outsourcing, it is important to distinguish this group from institutions that outsource but are considered to have "implemented" CDISC standards. As defined in our survey, "implementation" via outsourcing requires the institution to perform acceptance work using internal CDISC experts. In contrast, we interpret that respondents viewing outsourcing as a reason for nonimplementation may rely entirely on vendors without maintaining internal standards or oversight capabilities. However, as acknowledged in the Limitations section, the lack of explicit definitions in the survey may have led to variations in respondent interpretation regarding this distinction.

XSL•FO
RenderX

Future Policies and Opportunities for Strategic Support

Furthermore, the finding that a significant majority of institutions (66%, 60/91; Table 1) have made "no decision" regarding future CDISC policy suggests a deeper issue than mere resource constraints. Notably, this trend extends even to institutions that have already implemented CDISC standards. Half of these institutions (11/20) are uncertain about, or have decided against, continuing the implementation of CDISC-compliant data in the future, suggesting serious challenges in the sustainability of CDISC operations. This strategic inertia may indicate a systemic barrier, potentially stemming from the lack of regulatory incentives or clear mandates for the application of CDISC standards in clinical research not aimed at marketing approval. We considered that addressing this structural uncertainty is essential to enable institutions to commit to definitive standardization strategies.

While experienced AROs can play a pivotal role in driving adoption, the survey results indicate that 66% (60/91) of institutions specifically expect support from "pharmaceutical companies, CROs, and other AROs," with a primary desire for "materials and information." This highlights that academic institutions often cannot address the implementation gap on their own. Therefore, future strategies should not rely exclusively on peer-to-peer academic support but should also leverage industry resources. Active involvement and support from pharmaceutical companies and CROs were considered essential to provide the resources needed to bridge the gap between supply and demand.

Association Between Staffing Levels and Implementation

The present findings revealed significant variation among institutions in terms of the number of data managers and biostatisticians on staff. However, institutions with more of these specialists tended to be further along in regard to implementing CDISC standards. This result suggests that securing personnel with specialized knowledge is important for the effective implementation of CDISC standards, and as such, data managers and biostatisticians play a central role in the implementation process.

Limitations

A major limitation of this study is that adjustments for institutional resources such as hospital bed count or budget were not performed; these factors may be stronger determinants of CDISC adoption than staffing levels alone. The observed association between dedicated staffing and implementation may, therefore, be a reflection of overall institutional size or resource availability. Furthermore, the primary outcome variable, CDISC implementation status, was based solely on self-reported metrics from respondents and was not verified by external audit or inspection of the actual data standards used. This introduces the potential for response bias, such as the overestimation of institutional compliance. Finally, we acknowledge the nonresponse from specific institutional types; specifically, no responses were received from ministry-affiliated university hospitals. However, as this institutional category comprised only 1.1% (1/91) of the total institutions surveyed, the impact on the overall representativeness of Japanese academic medical centers is likely minimal. Furthermore, this study relies on self-reported data, which may be subject to respondent bias or misunderstanding of technical terms. For instance, a small number of sites reported implementing "ADaM only" without SDTM. Given that ADaM datasets are typically derived from SDTM, this discrepancy suggests a potential lack of accurate understanding of the standards among some respondents. Therefore, the results regarding technical proficiency should be interpreted with caution as they represent the respondents' subjective assessments rather than objectively verified capabilities. Furthermore, the questionnaire option labeled "outsourced, hence no need" was presented without explicit definitions distinguishing between outsourcing as a form of implementation and outsourcing as a reason for nonimplementation. Consequently, respondents may have selected this option based on their own interpretation. This lack of clarity may have led to misclassification, where institutions that had successfully implemented the system via outsourcing (with internal acceptance work) categorized themselves as having "no need."

Recommendations and Future Work

Therefore, developing these specialized human resources is likely essential for promoting their adoption. Expanding training opportunities and improving access to information regarding CDISC standards are key to promoting their wider adoption in Japanese academic medical centers.

Conclusions

The findings of the present study indicate that the implementation of CDISC standards in Japanese academic medical centers remains limited. The primary barrier identified was a lack of human and financial resources. On the other hand, many institutions are interested in implementing CDISC standards and seeking support such as workshops and the provision of materials. To bridge the gap between this high demand and the limited supply, future strategies should involve not only peer-to-peer academic support but also active resource sharing and cooperation from pharmaceutical companies and CROs. Notably, instances were observed where CDISC standards were being used even in clinical research not directly aimed at marketing approval applications, which is interpreted as a preliminary indication of the potential recognition within the research community of the operational efficiencies gained through standardization. Furthermore, the present findings suggest that the number of data managers and biostatisticians on staff is strongly associated with the implementation status of CDISC standards.

Acknowledgments

The authors would like to express their deep gratitude to the personnel of the 84 institutions that responded to the questionnaire, and also to the following individuals for their cooperation in this survey: Dr Hideki Hanaoka, Leader of TG3, National University Hospital Clinical Research Promotion Conference; Ms Mari Tsuchiya of its secretariat; and Ms Yoshiko Ito of the NHO Nagoya Medical Center. The authors used Google Gemini to assist in translating parts of the manuscript from Japanese to English. The authors thank FORTE Science Communications for English language editing.

Funding

This study was conducted as part of the Japan Agency for Medical Research and Development research and development project "Study of CDISC standards implementation in academia" (Principal Investigator: Toshiki Saito, NHO Nagoya Medical Center; Research Period: FY2022–FY2024) and supported by Japan Agency for Medical Research and Development under Grant Number JP22mk0101242 (https://www.amed.go.jp/koubo/11/03/1103C_00016.html). This study aims to comprehensively clarify the current status and challenges of implementing CDISC standards in Japanese academic medical centers.

Data Availability

The datasets generated or analyzed during this study are available from the corresponding author on reasonable request.

Abstract

Background: Software-based and AI-enabled medical devices are increasingly networked and updatable, expanding the attack surface and making cybersecurity governance intersect with quality management and postmarket oversight. Regulated device risk management nevertheless remains primarily oriented toward patient-safety harms under ISO 14971 frameworks, which may not fully capture cybersecurity risks affecting data integrity, system resilience, or service continuity.

Objective: This study aimed to compare how Korea's Ministry of Food and Drug Safety (MFDS), the US Food and Drug Administration (FDA), and the European Union/Medical Device Coordination Group (EU/MDCG) define and operationalize cybersecurity for medical device software across premarket review and postmarket surveillance, and to identify informatics-relevant gaps between safety vigilance and vulnerability-focused cybersecurity practice.

Methods: We conducted a qualitative comparative document analysis of 10 jurisdiction-specific regulatory and guidance documents (MFDS: n=2, FDA: n=4, and EU/MDCG: n=4), supplemented by cross-sectoral instruments and peer-reviewed literature. Using a common analytic framework informed by functional comparative legal analysis, we mapped (1) conceptual scope (definitions and life cycle boundaries), (2) premarket operationalization (required artifacts and evidence such as threat modeling, software bills of materials, and vulnerability management plans), and (3) postmarket operationalization (monitoring, reporting, and update governance).

Results: Of the 10 documents analyzed (MFDS: n=2, FDA: n=4, and EU/MDCG: n=4), all 3 jurisdictions converged on protecting confidentiality, integrity, and availability of data and device functions but embedded these expectations in different regulatory architectures. MFDS emphasized documentation completeness aligned with ISO 14971 risk management; the FDA framed cybersecurity as quality-system and design-control activities spanning the total product life cycle, including statutory requirements for "cyber devices" under Federal Food, Drug, and Cosmetic Act section 524B; and the European Union treated cybersecurity as an extension of safety under the Medical Device Regulation (MDR) and In Vitro Diagnostic Regulation (IVDR), interpreted through MDCG guidance, with additional cross-sector obligations from the Network and Information Security 2 (NIS2) Directive and the General Data Protection Regulation (GDPR). A common limitation was that vigilance pathways were largely triggered by patient-harm thresholds, whereas vulnerabilities and near-miss security events were often managed through parallel information-security processes. Mapping to ISO 13485 Clauses 7.3 and 8 indicated that integration of cybersecurity controls into existing quality management system (QMS) processes is feasible but not consistently mandated.

Conclusions: Across the 3 jurisdictions examined in this study, regulatory approaches to medical device cybersecurity show definitional alignment but operational fragmentation at the interface between patient-safety vigilance and vulnerability-centric cybersecurity practice. Within the limits of this document-based analysis, the findings suggest that integrating cybersecurity as an interoperable process within the QMS—linking vulnerability monitoring, incident response, and software update controls to corrective and preventive action (CAPA) and change control—and expanding postmarket surveillance to incorporate vulnerability and performance signals could support more trustworthy deployment of regulated AI-enabled medical software.

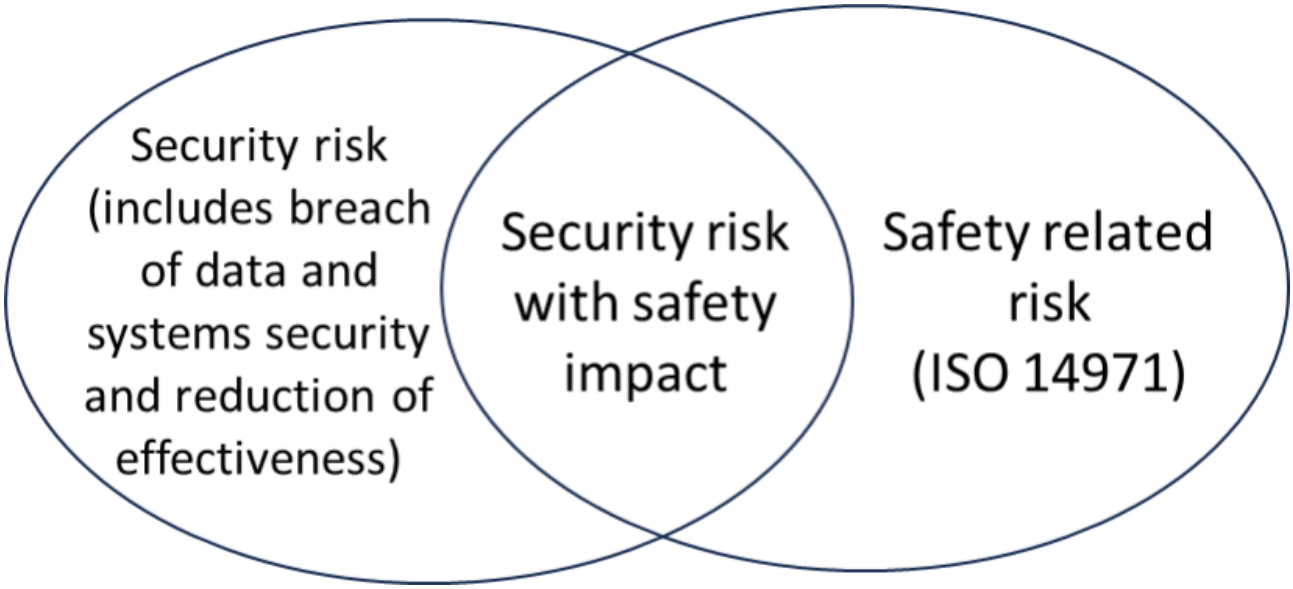
Introduction



Software-based medical devices, including AI-enabled systems, are increasingly deployed as workflow-critical components in clinical environments. As these products become more connected, updateable, and integrated with hospital networks and cloud services, cybersecurity becomes a core determinant of reliability, availability, and clinical trust. This creates a practical need to understand how cybersecurity expectations are translated into evidence requirements, quality processes, and postmarket controls for regulated medical device software (MDSW).

In this paper, we use the term "AI-enabled medical device software" to refer to MDSW that incorporates one or more AI or machine learning components. This includes software as a medical device (SaMD) where the software itself is the regulated product, software in a medical device where AI is embedded in a hardware device, adaptive or continuously learning algorithms, large language and large multimodal models used for medical purposes, and clinical decision-support functions that meet the regulatory definition of a medical device. Where jurisdictional terminology differs (eg, MDSW under the European Union Medical Device Regulation [MDR] and In Vitro Diagnostic Regulation [IVDR]), the corresponding national term is used.

SaMD has advanced rapidly and is increasingly enabling high-performance medical imaging and clinical workflows. Analyses of US and Australian regulatory databases indicate that SaMD is widespread yet not readily distinguishable from other medical-device submissions, partly because regulatory vocabularies and adverse-event codes rely on coarse categories such as "computer software problem" [1,2]. This lack of resolution constrains informatics-enabled safety improvement, including the ability to trace failure modes to software architecture, evaluate downstream effects of cybersecurity weaknesses on clinical performance, and operationalize continuous monitoring approaches that depend on structured, comparable event data.

In parallel, the broader health information technology environment has been repeatedly disrupted by ransomware and data-breach incidents. Thematic analyses of attacks on US hospitals and clinics demonstrate substantial operational and financial impact, even when direct patient harm is difficult to quantify [3,4]. Studies of connected medical devices and hospital networks have documented widespread exposure to known vulnerabilities, highlighting that cyber risk arises not only from individual devices but from their integration into complex sociotechnical systems [5-10] (Figure 1). These realities motivate a comparative examination of how regulators operationalize cybersecurity across premarket review and postmarket surveillance for AI-enabled MDSW.

Figure 1. Conceptual relationship between security risk and safety-related risk in medical devices. This diagram, adapted from Association for the Advancement of Medical Instrumentation TIR57:2016, illustrates that only a subset of cybersecurity risks overlaps with safety-related risks as defined under ISO 14971. While security risks may affect confidentiality, integrity, availability, or system effectiveness, only those that result in patient harm are captured within traditional medical-device safety risk management frameworks.

Regulators and standard-setting bodies have responded by issuing guidance, standards, and frameworks for medical device cybersecurity. These include the National Institute of Standards and Technology (NIST) Cybersecurity Framework 2.0, International Electrotechnical Commission (IEC) 81001-5-1 [11] on health-software safety and security, Association for the Advancement of Medical Instrumentation (AAMI) TIR57 [12] on risk management for security in medical devices, the IEEE/UL standards for connected diabetes devices and clinical internet of things, and IEC 62443 and IEC/TR 60601-4-5 for security in industrial and medical control systems [11-16]. At the same time, cross-sector instruments such as the EU (European Union) Network and Information Security 2 (NIS2) Directive, the AI Act, the Cybersecurity Act, and the General Data Protection Regulation (GDPR) have established horizontal cybersecurity and data-protection requirements for products with digital elements [17-21].

XSL•FO
RenderX

Despite this proliferation of documents, a recent scoping review concluded that current regulations and standards offer only high-level statements on how cybersecurity should be reflected in benefit-risk analysis for medical devices, and rarely provide systematic methods for incorporating cyber risk into regulatory decision-making [22]. Other studies have questioned whether existing technical controls, such as those in ISO/IEC 80001-2-2, are sufficient for contemporary networked medical environments [23-26]. Work on SaMD postmarket surveillance and on clinical monitoring of AI systems likewise points to gaps between regulatory expectations and real-world safety monitoring [27-29].

Korea has recently published dedicated licensing guidelines for large language and multimodal models as medical devices [30-32], whereas equivalent generative AI–specific guidance in the United States and the European Union is still emerging. These contrasting trajectories underscore the need to reconcile traditional, safety-oriented risk management with broader cybersecurity governance for AI-enabled medical devices.

The aim of this study was to compare how 3 major regulatory systems—Korea's Ministry of Food and Drug Safety (MFDS), the US Food and Drug Administration (FDA), and the EU/Medical Device Coordination Group (EU/MDCG)—define and operationalize cybersecurity for MDSW, including AI and generative AI components, across premarket review and postmarket surveillance. Building on this comparison, we sought to (1) characterize structural misalignments between ISO 14971 [33] device risk management and the broader cybersecurity risk space, (2) identify informatics-relevant artifacts (eg, threat modeling, software bills of materials, logging and telemetry, corrective and preventive action [CAPA] linkage, and change control) that can support interoperable life cycle governance, and (3) propose directions for aligning these regimes while preserving their distinct objectives.

Methods

Study Design

We performed a qualitative comparative document analysis to examine how cybersecurity is defined and operationalized for AI-enabled MDSW across Korea, the United States, and the European Union. The unit of analysis was an authoritative regulatory, guidance, or standards document that specifies expectations for cybersecurity-related risk management, evidence generation, and postmarket controls for regulated MDSW. The study design was informed by functional comparative legal research [34], in which legal instruments addressing the same regulatory function across jurisdictions are compared on the basis of the function they perform rather than their formal classification.

All 3 jurisdictions treat medical devices as a regulated industry that requires formal market authorization—premarket approval (PMA), clearance, or licensing—before commercial distribution. Each system pairs primary binding law (Korea: the Medical Device Act, its Enforcement Decree, and Enforcement Rules; United States: the Federal Food, Drug, and Cosmetic Act and FDA implementing regulations; and European Union: the MDR and IVDR) with implementing guidance documents (MFDS guidelines, FDA guidance documents, and MDCG guidance). Although these guidance documents are formally nonbinding in each system, in practice compliance with relevant guidance is required to obtain market authorization; FDA premarket review effectively expects conformity with applicable FDA guidance, MFDS approval review applies the relevant MFDS guidelines, and notified body assessment under MDR/IVDR consults MDCG guidance for interpretive expectations.

This shared regulatory architecture—binding primary law operationalized through compliance-required guidance, applied to the same regulated category of medical devices—provides the basis of functional equivalence on which our cross-jurisdictional comparison rests. The 10 documents in Table 1 were selected because each performs an equivalent regulatory function in its respective jurisdiction, irrespective of its formal classification.

These EU horizontal instruments (NIS2 Directive, AI Act, GDPR, and Cybersecurity Act) were not included in the 10-document core corpus listed in Table 1 but were analyzed as complementary contextual sources to characterize the regulatory environment within which MDR/IVDR Annex I §17.2 operates.

Cross-sectoral instruments (NIST Cybersecurity Framework 2.0, IEC 81001-5-1, AAMI TIR57, ISO 13485 [35], ISO 14971, ISO 27001, ISO 31000, ISO 42001, IEC 62443, and IEC/TR 60601-4-5) and peer-reviewed literature were treated as background and contextual material rather than part of the core corpus, and are cited where relevant in Results and Discussion sections.

United States	Cybersecurity in Medical Devices: Quality System Considerations and Content of Premarket Submissions	FDA[b]	2026
United States	Postmarket Management of Cybersecurity in Medical Devices	FDA	2016
United States	Artificial Intelligence-Enabled Device Software Functions: Lifecycle Management and Marketing Submission Recommendations (draft guidance)	FDA	2025 (draft)
United States	Federal Food, Drug, and Cosmetic Act, Section 524B (“cyber devices” requirements)	US Congress / FDA	2023
European Union	Regulation (EU) 2017/745 on medical devices (MDR[c]), Annex I (general safety and performance requirements)	European Parliament & Council	2017
European Union	Regulation (EU) 2017/746 on in vitro diagnostic medical devices (IVDR[d]), Annex I	European Parliament & Council	2017
European Union	MDCG[e] 2019‐16 Rev.1: Guidance on Cybersecurity for Medical Devices	MDCG	2020
European Union	MDCG 2025‐6: FAQ on the interplay between MDR, IVDR, and the AI Act	MDCG	2025

[a]MFDS: Ministry of Food and Drug Safety.

[b]FDA: US Food and Drug Administration.

[c]MDR: Medical Device Regulation.

[d]IVDR: In Vitro Diagnostic Regulation.

[e]MDCG: Medical Device Coordination Group.

Data Sources and Selection

We assembled a jurisdiction-specific regulatory corpus from publicly available sources, including laws and implementing regulations, regulator-issued guidance, and regulator-endorsed standards frameworks relevant to medical device cybersecurity and software life cycle controls.

To contextualize regulatory expectations, the corpus was supplemented with peer-reviewed literature on (1) SaMD presence, recalls, and software-related adverse events in regulatory databases [1,2,36,37]; (2) vulnerabilities, attacks, and connectivity issues in hospitals and networked medical devices [5-10]; and (3) benefit-risk analysis and postmarket monitoring challenges for software and AI-enabled systems [22,27-29,36].

Inclusion criteria for the core regulatory corpus were as follows: (1) the document was issued by a competent regulatory authority (MFDS, FDA, or EU/MDCG) or was a standards document explicitly referenced by such an authority; (2) the document directly addressed cybersecurity, software life cycle, or AI governance for medical devices; (3) the document was the most recent finalized or draft version available as of March 7, 2026; and (4) an authoritative English version (or, for MFDS documents, the original Korean version with an authorized English translation reference) was publicly accessible. Exclusion criteria were (1) draft documents that had been formally withdrawn or superseded, (2) sector-specific guidance unrelated to MDSW (eg, automotive and energy), and (c) opinion pieces or commentaries without regulatory standing. The 10 documents that constitute the core corpus are listed in Table 1.

XSL•FO
RenderX

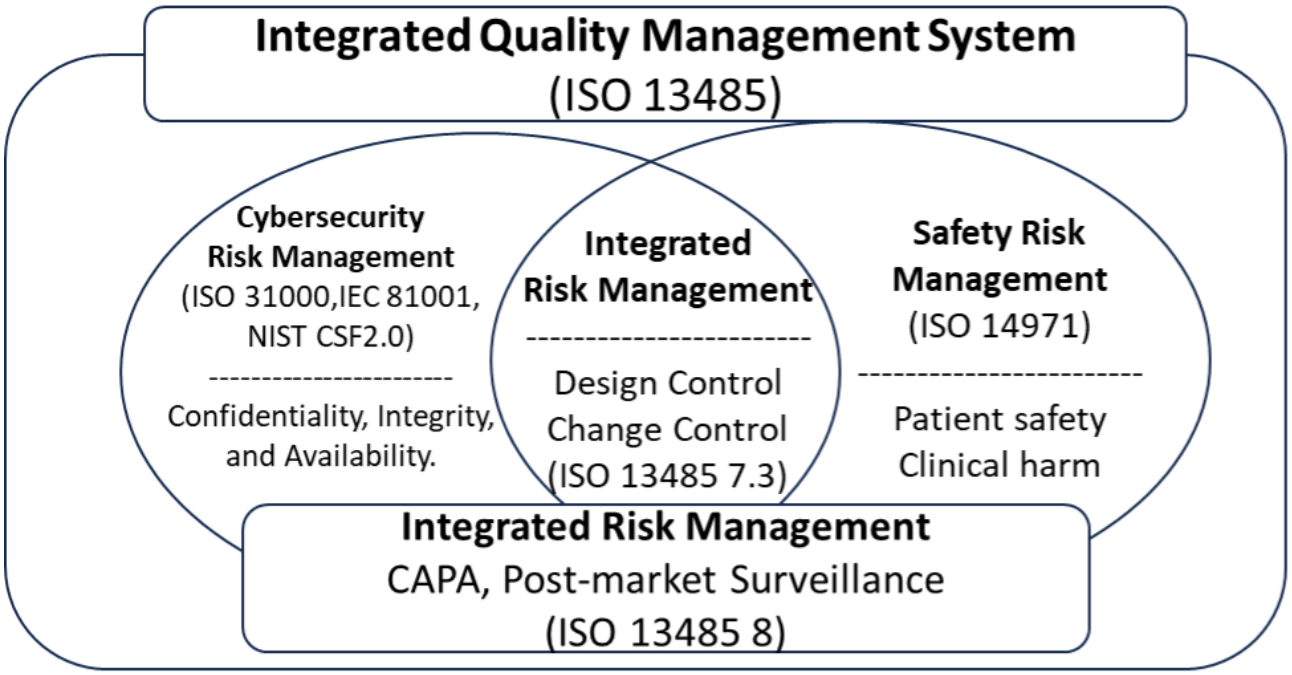
Analytical Approach

To enable cross-jurisdiction comparison, we applied a common analytic framework that mapped document content into three domains: (1) conceptual scope (definitions, protected assets, threat assumptions, and life cycle coverage), (2) premarket operationalization (required artifacts and evidence such as secure design controls, threat modeling, software bills of materials, and vulnerability disclosure and management plans), and (3) postmarket operationalization (monitoring, incident and vulnerability handling, update governance, and mechanisms linking cybersecurity actions to quality management processes such as CAPA and change control). The mapping followed the principles of functional comparative legal analysis; rather than comparing legal terms in isolation, we compared the regulatory functions performed by each instrument across the medical device total product life cycle.

Furthermore, 2 analytic steps supported the synthesis presented in the Discussion section. First, we mapped the cybersecurity-relevant requirements identified in each jurisdiction onto the quality management system (QMS) clauses of ISO 13485:2016, with particular attention to Clause 7.3 (design and development) and Clause 8 (measurement, analysis, and improvement). This mapping is presented in Table 2. Second, we developed a conceptual model (illustrated in Figure 2) that depicts how ISO 14971–aligned safety risk management and ISO 31000-aligned cybersecurity risk management can be maintained as conceptually distinct processes while being operationally integrated within a single QMS.

Together, the predetermined change control plan (PCCP) and the Clause 7.3/Clause 8 axis convert cybersecurity risk management from a 1-time premarket exercise into a sustainable life cycle process that remains coherent across software updates, AI model retraining, and evolving threat landscapes.

Table . Summary mapping of safety and cybersecurity risk management within ISO 13485 (Clauses 7.3 and 8).



ISO 13485 clause	QMS[a] process	Safety risk management (ISO 14971)	Cybersecurity risk management (ISO 31000-aligned)	Integrated QMS interpretation
7.3	Design and development	Identification and control of hazards affecting patient safety and clinical performance throughout design and development.	Identification of cybersecurity threats and vulnerabilities affecting confidentiality, integrity, availability, and system resilience during design.	Distinct safety and cybersecurity risks are addressed in parallel within a unified design-control framework, enabling coordinated risk identification, control, verification, and validation.
8	Measurement, analysis, and improvement	Monitoring of safety performance, adverse events, and residual risks through postmarket surveillance and CAPA[b].	Monitoring of vulnerabilities, security incidents, and performance degradation through continuous surveillance and corrective actions.	Postmarket activities provide a shared governance mechanism for both safety and cybersecurity risks, extending oversight beyond patient harm to system-level and life cycle risks.

[a]QMS: quality management system.

[b]CAPA: corrective and preventive action.

XSL•FO
RenderX

Figure 2. Conceptual model of an integrated quality management system (QMS) for medical devices. This figure illustrates how safety risk management based on ISO 14971 and cybersecurity risk management aligned with ISO 31000-based frameworks can be maintained as conceptually distinct systems while being operationally integrated within a single QMS. Shared QMS processes—such as design control, change management, corrective and preventive action, and postmarket surveillance—provide a unified governance structure across the total product life cycle, enabling consistent oversight of both patient safety and cybersecurity risks.

Researcher Characteristics and Reflexivity

The 2 authors bring complementary backgrounds: SJ (MS, microbiology) works in regulatory and quality consulting for medical technologies and has hands-on experience preparing medical device submissions in Korea, the United States, and the European Union; KS (PhD) is a senior researcher and associate professor in medical informatics, AI in health care. Neither author is employed by, or has consulted for, any of the regulatory agencies whose documents are analyzed. We acknowledge that SJ's submission experience may have introduced a practitioner-oriented framing, while KS's academic perspective emphasized conceptual and informatics-oriented aspects. The 2 authors reviewed each jurisdiction's documents independently using the shared analytic framework and reconciled differences through discussion.

Ethical Considerations

This study analyzed publicly available legal, regulatory, and standards documents and did not involve human participants or identifiable personal data; therefore, institutional ethics approval and informed consent were not required.

Results

Cybersecurity Concepts and Definitions

Across Korea (MFDS), the United States (FDA), and the European Union (EU/MDCG), cybersecurity for AI-enabled MDSW was consistently framed around maintaining the confidentiality, integrity, and availability of information and device functions across the product life cycle (Table 3). However, it was operationalized through different regulatory architectures, which shaped how threat assumptions, required artifacts, and postmarket signals were specified and governed.

XSL•FO
RenderX

Table . Cybersecurity-related terms and definitions in medical device regulations, guidance, and standards (Korea, United States, European Union, and international standards).

Source (issuing authority; jurisdiction)	Definition (quoted or adapted)
Guideline for Cybersecurity in Medical Devices Premarket Submissions (MFDS[a], Republic of Korea)	Security/Cybersecurity—a state in which information and systems are protected from unauthorized activities (eg, access, use, disclosure, interference, modification, or destruction), such that risks to authentication, access control, integrity, confidentiality, data flow, timely response, and availability are maintained at an acceptable level throughout the device life cycle (adapted from IEC[b] TR 60601-4-5:2021).
Cybersecurity in Medical Devices: Quality System Considerations and Content of Premarket Submissions (FDA[c], United States)	Cybersecurity—the process of preventing unauthorized access, modification, misuse, denial of use, or other unauthorized use of information stored in, accessed by, or transferred from a medical device to an external recipient (adapted from IEC 27032:2012).
Postmarket Management of Cybersecurity in Medical Devices (FDA, United States)	Cybersecurity—the ability to protect or defend the use of cyberspace from cyberattacks (adapted from NIST SP 800‐39).
MDCG[d] 2019‐16 Rev.1 (EU/MDCG, European Union)	Cybersecurity (in the EU medical device framework)—the protection of devices and information systems from unauthorized access, use, disclosure, disruption, modification, or destruction, in order to provide confidentiality, integrity, and availability; cybersecurity risks are evaluated as a subset of "risk" under the MDR[e]/IVDR[f], defined as the combination of the probability of occurrence of harm and the severity of that harm. MDCG 2019‐16 Rev.1 explicitly applies this risk concept to security-related risks within the EU regulatory context.
ISO 24971 Annex F (ISO)	Security—a condition resulting from the establishment and maintenance of protective measures that ensure inviolability against hostile acts or influences, whether intentional or unintentional (see IEC Guide 120:2018). In AAMI[g] TIR57:2016 and IEC 80001-1:2010, security is described as an operational state in which information assets are reasonably protected with respect to confidentiality, integrity, and availability.

[a]MFDS: Ministry of Food and Drug Safety.

[b]IEC: International Electrotechnical Commission.

[c]FDA: US Food and Drug Administration.

[d]MDCG: Medical Device Coordination Group

[e]MDR: Medical Device Regulation.

[f]IVDR: In Vitro Diagnostic Regulation.

[g]AAMI: Association for the Advancement of Medical Instrumentation.

In Korea, MFDS's cybersecurity review guidance treats cybersecurity as a life cycle state that protects device information and functions against unauthorized actions, positioning cybersecurity as part of device safety and essential performance and documenting it within technical documentation under an ISO 14971 risk-management approach [38].

In the United States, the FDA final guidance Cybersecurity in Medical Devices: Quality System Considerations and Content of Premarket Submissions (issued February 3, 2026) positions cybersecurity as quality-system and design-control activities spanning the total product life cycle and incorporates recommendations related to Federal Food, Drug, and Cosmetic Act section 524B for "cyber devices" [39]. Postmarket expectations are further articulated in FDA's Postmarket Management of Cybersecurity in Medical Devices (December 2016) and align with NIST terminology that defines cybersecurity as the ability to protect or defend the use of cyberspace from cyberattacks.

In the European Union, MDR/IVDR Annex I embeds cybersecurity-related general safety and performance requirements across both premarket and postmarket phases, and MDCG 2019‐16 Rev.1 provides interpretive guidance for manufacturers on meeting those requirements within an ISO 14971 risk-management lens [40-42].

At the level of binding horizontal legislation, several EU instruments operate in parallel to MDR/IVDR under the New Legislative Framework, as recognized by the Commission's 2022 Blue Guide; to satisfy the cybersecurity-related General Safety and Performance Requirements (GSPRs) of MDR/IVDR, manufacturers therefore also bear compliance responsibilities under the NIS2 Directive (EU) 2022/2555, the AI Act (EU) 2024/1689, the Cybersecurity Act (EU) 2019/881, and the GDPR (EU) 2016/679. MDCG 2025‐6 (issued June 2025 as a finalized FAQ document) interprets the interplay between MDR, IVDR, and the AI Act [43]. Cybersecurity, however, differs from the other essential safety attributes addressed in Annex I in that it cannot be fully internalized within the manufacturer's own design and risk-management process. IEC 80001‐1 frames risk management for IT-networks incorporating medical devices as involving multiple stakeholders—responsible organizations as well as manufacturers—rather than a single party assuming full

XSL•FO
RenderX

responsibility for the network's key properties. European Union Agency for Cybersecurity (ENISA), whose mandate was made permanent by the Cybersecurity Act, issues technical guidance and operates EU cybersecurity certification schemes that manufacturers and notified bodies may invoke as evidence of the "state of the art" required by Annex I §17.2. The security-of-processing obligations of the GDPR apply horizontally to health data handled by AI-enabled devices and conceptually mirror the security-by-design expectation embedded in the GSPR. Accordingly, to achieve full GSPR compliance at the design stage, manufacturers must recognize cybersecurity-specific requirements that fall outside the scope traditionally addressed by ISO 14971-based safety risk management.

Premarket Control of Software and AI-Enabled Devices

Overview

Premarket expectations converged on demonstrable secure development practices, including traceable security requirements, risk assessment, and verification and validation evidence. Jurisdictions differed primarily in how these expectations were presented (documentation checklists vs quality-system controls vs general safety and performance requirements) and in the explicitness of life cycle artifacts such as threat modeling, software bills of materials, coordinated vulnerability disclosure, and update governance.

Across the 3 jurisdictions, premarket pathways for medical devices vary by their regulatory purpose. Approval and clearance pathways—which include 510(k) clearance, De Novo classification, and PMA in the United States; notified-body conformity assessment for higher-risk classes under MDR/IVDR in the European Union [44]; and MFDS licensing review in Korea—involve substantive premarket evaluation of safety and effectiveness, including cybersecurity considerations. Registration or notification pathways—which include Class I exemptions in the United States, self-declaration of conformity for Class I devices in the European Union, and notification for low-risk devices in Korea—serve principally administrative tracking and do not entail equivalent substantive premarket review. Not all medical devices, therefore, undergo third-party conformity assessment or substantive cybersecurity review before market entry. The cybersecurity expectations summarized below apply to those device classes for which the relevant jurisdiction mandates substantive premarket review under the approval or clearance pathway, rather than to devices that are subject only to administrative registration.

MFDS (Korea)

The MFDS premarket cybersecurity requirements are set out in the Guideline for Cybersecurity in Medical Devices Premarket Submissions. The checklist items summarized in Table 4 are largely derived from the International Medical Device Regulators Forum (IMDRF) document Principles and Guidelines for Medical Device Cybersecurity and from the standards IEC 62443-4-2:2019 and IEC TR 60601-4-5:2021. By referencing these documents, the guideline aims to capture the technical characteristics of currently marketed products.

XSL•FO
RenderX

Table . Premarket cybersecurity elements required by MFDS[a], FDA[b], and the European Union.

Competent authority or requirement document	Key elements of cybersecurity	AI or generative AI specific notes
MFDS (Republic of Korea) / Guideline for Cybersecurity in Medical Devices Premarket Submissions (November 2024)	Identification and authentication; usage control; system integrity; data confidentiality; timely event response; resource availability.	Guideline for Generative AI in Medical Devices Premarket Submissions (January 2025). Risk management is applied according to ISO 14971:2019. Examples of AI-specific hazards include: (1) performance hallucination, inconsistency, irrelevancy, lack of uncertainty indicator, limited explainability and interpretability; (2) data quality issues such as incorrect data, mishandling of outliers, incomplete data, subjective data, inconsistent data, domain shift, data drift, and fragmented data; (3) bias, including selection bias, confounding variables, nonnormality, proxy variables, and implicit bias; (4) user-related risks such as overconfidence; (5) adaptive system behavior; and (6) other risks such as lack of operator knowledge.
FDA (United States) / Cybersecurity in Medical Devices: Quality System Considerations and Content of Premarket Submissions (February 3, 2026)	Authentication; (B) authorization; (C) cryptography; (D) code, data, and execution integrity; (E) confidentiality; (F) event detection and logging; (G) resiliency and recovery; (H) firmware and software updates.	Artificial Intelligence-Enabled Device Software Functions: Lifecycle Management and Marketing Submission Recommendations (draft guidance, January 2025). AI components can present cybersecurity risks including data poisoning, model inversion, model stealing, model evasion, data leakage, overfitting, model bias, and performance drift.
European Commission (European Union) / MDCG[c] 2019 - 16 Rev.1, Guidance on Cybersecurity for Medical Devices (December 2019)	IT security: confidentiality of information at rest and in transit; integrity, ensuring information authenticity and accuracy (ie, nonrepudiation); availability of processes, devices, data, and connected systems.	MDCG 2025 - 6 (June 2025). The MDR[d], IVDR[e], and AI Act emphasize the need for robust cybersecurity measures in both the premarket and postmarket stages of high-risk medical device AI (MDAI).

[a]MFDS: Ministry of Food and Drug Safety.

[b]FDA: US Food and Drug Administration.

[c]MDCG: Medical Device Coordination Group.

[d]MDR: Medical Device Regulation.

[e]IVDR: In Vitro Diagnostic Regulation.

In all 3 jurisdictions, premarket cybersecurity evaluation is anchored in ISO 14971–based risk management but implemented through distinct instruments.

The listed items represent the minimum set of cybersecurity requirements that applicants are expected to address in their approval submissions. Where a particular requirement cannot be applied due to the characteristics of the product, the applicant must provide supporting documentation—such as the risk-management file, user manual, or design documentation—justifying the nonapplicability.

For AI-based devices, the guideline introduces the concept of "AI security," described as adding cybersecurity requirements or selecting appropriate requirements from the detailed checklist for additional verification. However, the guideline does not specify AI-specific cybersecurity elements beyond this general instruction. In January 2025, Korea published licensing review guidelines for generative AI–enabled medical devices [31]. For premarket submissions, the guideline instructs sponsors to follow the existing Guideline for Cybersecurity in Medical Devices Premarket Submissions, while also recommending that risk management be tailored to the technologies implemented in the device by explicitly identifying threats unique to generative AI.

ISO 14971–based processes are fundamentally oriented toward patient safety and the clinical performance of medical devices. When risk assessment is conducted solely within that framework, clearly identified cybersecurity threats may be deprioritized if they are not expected to result in patient injury or unacceptable degradation of device performance. As a consequence, AI- and generative AI–specific threats that primarily affect information security or system integrity may be filtered out during premarket evaluation and become visible, if at all, only in the postmarket phase. This limitation reflects that the broader universe of software security and cybersecurity risks extends beyond the risk space formally captured by ISO 14971 [32,45,46].

FDA (United States)

In the premarket context, the FDA expects manufacturers to analyze the configuration and vulnerabilities of medical devices, develop threat models that may affect safety, and verify the effectiveness of corresponding countermeasures. Key cybersecurity activities in this process follow the risk-management approach described in 21 CFR 820.30(g) [47]

XSL•FO
RenderX

on design controls and in the guidance document Cybersecurity in Medical Devices: Quality System Considerations and Content of Premarket Submissions. These expectations are consistent with the IMDRF guidance Principles and Practices for Medical Device Cybersecurity, particularly the recommendations on cybersecurity risk management throughout the device life cycle.

For AI-enabled devices, the FDA guidance further recommends that sponsors develop an explicit threat model as part of the premarket cybersecurity risk-management process. This model should identify AI-specific technical vulnerabilities and associated hazard scenarios, including risks such as data poisoning, model inversion, model stealing, model evasion, data leakage, overfitting, model bias, and performance drift. By structuring these vulnerabilities into a device-specific threat model that is integrated with the quality system, manufacturers can more systematically select security controls, define appropriate test methods, and specify monitoring indicators. When such a device-specific threat model is embedded in the quality system, it operationalizes life cycle cybersecurity risk management and provides a structured basis for postmarket surveillance and for updating controls as new vulnerabilities are identified. Although the FDA's 2025 draft guidance on AI-enabled device software functions provides explicit examples of AI-specific cybersecurity threats, it is at the time of writing a draft document and does not yet carry the binding effect of a final guidance, a point we revisit in the Limitations section.

The EU

Although the EU MDR and IVDR do not contain a dedicated chapter labeled "cybersecurity," cybersecurity requirements can be inferred from the general safety and performance requirements and from related guidance. As discussed above, EU guidance interprets cybersecurity through the ISO 14971 risk-management framework, treating loss of confidentiality, integrity, or availability as a potential source of harm.

Accordingly, the primary objective of premarket cybersecurity evaluation in the EU is to demonstrate that the device can achieve its intended purpose while maintaining an acceptable level of risk to patients and public health. Security-by-design principles and IT security measures required under MDR/IVDR Annex I are therefore expected to be embedded in the manufacturer's ISO 14971–based risk-management process.

MDCG 2019‐16 frames IT security, information security, and operational security as key domains of cybersecurity risk for medical devices. In addition to the IEC 80001 series on networked medical systems, it explicitly refers to the Information Security Management Systems requirements of ISO/IEC 27001 [48] as an Annex III reference standard. MDCG 2025‐6, interpreting the MDR, IVDR, and AI Act, further emphasizes that robust cybersecurity measures are required in both the premarket and postmarket phases of high-risk medical device AI. In our analysis, we treat the NIS2 Directive, the GDPR, and ENISA-issued guidance and threat reports as cross-sectoral instruments that EU manufacturers must reference in order to fulfill the GSPRs of MDR Annex I (notably Sections 17.2 and 17.4 on information security and minimum IT requirements). Specifically, NIS2 obligations apply where a medical device manufacturer or a health care delivery organization meets the criteria of an essential or important entity; GDPR obligations apply whenever personal health data are processed; and ENISA-issued guidance is referenced as nonbinding sectoral interpretation [18,20,21]. A key analytic finding, however, is that although these instruments are referenced in MDCG guidance, they are limited primarily to the broader risk definition (eg, personal data protection, network, and information system resilience) and are not structurally integrated with the cybersecurity definition or operational expectations within the medical device regulatory framework itself. As a consequence, the architectural separation creates a structure in which the requirements of NIS2, GDPR, and ENISA guidance are formally acknowledged but are not readily operationalized within manufacturers' device-centric quality management systems—a structural limitation that we revisit in the Discussion section.

Taken together, these documents suggest that, as in other industries, medical-device manufacturers may adopt ISO/IEC 27001 [48] and ISO/IEC 42001 [49] as harmonized standards by integrating cybersecurity and AI-specific risk management into their QMS. This implies that certain aspects of cybersecurity and AI risk management can appropriately be organized and governed as dedicated (yet QMS-aligned) management systems, rather than being handled only within traditional safety engineering processes.

Postmarket Surveillance and Cyber-Incident Reporting

Postmarket mechanisms showed the clearest signs of fragmentation (Table 5): patient-safety vigilance systems emphasize incidents that result in, or threaten, patient harm, whereas cybersecurity practice often centers on vulnerabilities, exploit intelligence, and near-miss signals that may not immediately manifest as harm. Across jurisdictions, this boundary shaped what was captured, where it was reported, and how quickly mitigation could be coordinated across manufacturers, health care delivery organizations, and national cybersecurity agencies.

XSL•FO
RenderX

Table . Postmarket mechanisms for medical device incident reporting and cybersecurity-related risk collection across MFDS[a], FDA[b], and the European Union.

Regulatory authority	Definition of reportable medical device incidents Cybersecurity incident reporting (mandatory)	Cybersecurity incident reporting
MFDS (Republic of Korea)	Public notice of Serious Adverse Event: (a) causes death or a life-threatening condition, (b) requires hospitalization or prolongation of an existing hospital stay, (c) results in persistent or significant disability or incapacity, and (d) causes a congenital anomaly or birth defect.	Electronic intrusion events: mandatory reporting by manufacturers to MFDS Commissioner, health care service providers, and end users (MFDS Notice No. 2025-30 [50]); voluntary reporting by health care service providers to MFDS Commissioner and manufacturers; technical security activities documentation required
FDA (United States)	Medical Device Reporting (21 CFR Part 803.3(w)): a serious injury is an injury or illness that (1) is life-threatening, (2) results in permanent impairment of a body function or permanent damage to a body structure, or (3) necessitates medical or surgical intervention to preclude permanent impairment of a body function or permanent damage to a body structure. Permanent means irreversible impairment or damage to a body structure or function, excluding trivial impairment or damage.	Voluntary. There is no cybersecurity-specific reporting mandate, and cybersecurity events are captured only through the patient-harm filter of Medical Device Reporting (21 CFR Part 803) and reports of corrections and removals (21 CFR Part 806). Supplementary voluntary or indirect mechanisms include the Recent Medical Device Recalls database and safety alerts, the Voluntary Malfunction Summary Reporting (VMSR) program (final guidance, 2024), Quality Management System Regulation (QMSR) inspections and change-control reviews, and Cybersecurity and Infrastructure Security Agency (CISA) medical device cybersecurity alerts and advisories
European Member States (EU)	Regulation (EU) 2017/745 and Regulation (EU) 2017/746, Article 2: “serious incident” means any incident that directly or indirectly led, might have led, or might lead to (a) the death of a patient, user, or other person; (b) the temporary or permanent serious deterioration of a patient’s, user’s, or other person’s state of health; or (c) a serious public health threat.	Voluntary at the device level. Mandatory cybersecurity-incident reporting exists only at the system or operational level under the NIS2 Directive, not as device-specific vigilance, and device-level cybersecurity is captured only when an event becomes a serious incident under the MDR or IVDR. Supplementary mechanisms include good manufacturing practice change control and notified-body surveillance audits, the manufacturer's postmarket surveillance system (including Article 88 trend reporting), and European Union Agency for Cybersecurity (ENISA) sector-specific threat and incident reports.

[a]MFDS: Ministry of Food and Drug Safety.

[b]FDA: US Food and Drug Administration.

In Korea, the MFDS issued guidance on cybersecurity incident response for digital medical devices in April 2025 (MFDS Notice No. 2025-30) [50], which requires manufacturers to document technical security activities, including file validation, data security, cryptographic key management, security monitoring, and AI-specific security measures, and to prepare a software bill of materials and vulnerability management plan. Under the Digital Medical Products Act Article 13(2), electronic intrusion is broadly defined as any act affecting the safety, efficacy, or performance of digital medical devices through methods such as hacking, computer viruses, logic or mail bombs, denial-of-service attacks, or high-power electromagnetic interference; such events are subject to mandatory reporting to the MFDS Commissioner, health care service providers, and end users. However, the breadth of these obligations is anticipated to create a gap between policy intent and operational implementation in practice. Cybersecurity incidents that do not originate from the medical device itself are subject to separate reporting obligations to the Korea Internet & Security Agency (KISA). Furthermore, the guidance does not articulate an integrated governance mechanism linking these two distinct risk domains, cybersecurity risk management and patient-safety risk management, for postmarket products, a structural gap shared across all 3 jurisdictions examined in this study [50].

In the United States, device-related incidents are reported through the Medical Device Reporting system and corrections-and-removals provisions; data populate databases such as the Manufacturer and User Facility Device Experience database and recall listings. Because there is no cybersecurity-specific reporting mandate, cybersecurity incidents enter these mandatory channels only when they manifest as patient harm; otherwise, they surface through voluntary or indirect routes such as safety communications and recalls coordinated with the Cybersecurity and Infrastructure Security Agency (CISA).. Studies of digital-device product summaries and security features show increasing attention to cybersecurity, but also highlight variability in disclosure practices [36].

In the European Union, serious incidents and field safety corrective actions are reported under the MDR or IVDR,

XSL•FO
RenderX

whereas cybersecurity incidents as such fall outside device vigilance and are addressed at the system level under NIS2, national computer security incident response teams (CSIRTs), and ENISA-led coordination; that is, they are not treated as device-specific cybersecurity reporting.National technical rules, such as Germany's BSI TR-03161 for health care applications, add further layers of requirements [17,51,52]. The GDPR introduces substantial financial penalties for data breaches, indirectly shaping incentives for cybersecurity investment [21].

Across the 3 regions, these arrangements lead to fragmented information flows: device regulators mainly see harm-oriented incident reports, while cybersecurity agencies handle broader vulnerability and breach data. AI-specific clinical monitoring schemes are still in early stages and vary widely between jurisdictions.

Discussion

Principal Results

This comparative document analysis of 10 jurisdiction-specific regulatory and guidance instruments produced 3 main findings. First, the 3 jurisdictions show clear definitional alignment around protecting confidentiality, integrity, and availability of medical device information and functions. Second, despite this conceptual convergence, cybersecurity is operationalized predominantly through ISO 14971–based safety risk management, which prioritizes patient harm and device performance and therefore tends to filter out cyber risks whose primary impact is on data, services, or system-level resilience. Third, postmarket surveillance shows the greatest fragmentation: device vigilance and information-security reporting flow through different institutions, with limited integration of vulnerability and near-miss security signals into device regulators' visibility. Together, these findings indicate that current regimes converge on what cybersecurity is for, but diverge on how cybersecurity is governed and surveilled across the life cycle.

Misalignment Between ISO 14971–Oriented Safety Risk Management and Cybersecurity Risk Management

First, ISO 14971 primarily targets hazards that can be directly linked to patient injury or unacceptable degradation of device performance. As a result, cybersecurity threats that predominantly affect confidentiality, data integrity, or service availability—such as ransomware attacks on Picture Archiving and Communication Systems, exploitation of third-party communication stacks, or large-scale data exfiltration—may not be captured as device hazards unless a clear causal link to clinical harm is established [3-8,10].

On June 27, 2019, the FDA and a manufacturer jointly disclosed wireless radio-frequency communication vulnerabilities affecting the Medtronic MiniMed 508 and Paradigm insulin pumps, issuing an urgent safety notice and recommending replacement of older devices. Although no confirmed adverse patient events had occurred, the vulnerabilities could have enabled unauthorized modification of pump settings or insulin delivery via nearby wireless signals, prompting proactive mitigation [53,54]. Similarly, on October 1, 2019, the FDA announced the URGENT/11 (IPnet) communication-stack vulnerabilities, which affected not only individual medical devices but also hospital networks, creating risks of remote control, denial of service, and unauthorized information disclosure [54]. In both cases, regulatory intervention was triggered by the potential for systemic impact rather than by documented patient harm, underscoring that cybersecurity risks can materially affect clinical safety even before traditional ISO 14971 safety end points are breached.

Beyond these traditional cybersecurity threats, AI-enabled MDSW introduces additional risk vectors including training-data poisoning, model manipulation, adversarial inputs, and prompt-based exploitation, while social engineering remains among the most prevalent threats to medical device security and patient safety.

Second, many cybersecurity obligations relevant to medical devices arise outside the conventional device-regulation domain. Legislative and regulatory instruments, such as the NIS2 Directive, the AI Act, the Cybersecurity Act, the GDPR, and national technical rules, impose requirements on manufacturers, operators, and service providers irrespective of medical-device classification [17-21,52]. These frameworks implement different risk concepts—such as essential-service continuity, data protection, and systemic resilience—and distinct reporting triggers, including "significant incidents" or personal-data breaches, which do not map neatly onto ISO 14971 hazard categories or medical-device vigilance definitions. Consequently, cybersecurity events with substantial operational or societal impact may be managed through parallel information-security channels without being recognized as device-related risks.

Third, AI-enabled and generative AI systems introduce additional forms of risk that further strain existing categories. Threats, such as data poisoning, model inversion, hallucination, bias, and performance drift, can compromise both cybersecurity and clinical performance, yet current guidance often distributes these concerns across safety, performance, and data-protection sections without an integrated view of AI-specific cyber risk or explicit expectations for continuous monitoring [32,37,45]. As software-based medical devices evolve after deployment—shaped by user behavior, organizational policies, configuration changes, and environmental conditions—new vulnerabilities may emerge that are not captured by static performance metrics or adverse-event reports.

Taken together, these factors suggest that monitoring device performance and patient-harm outcomes alone may be insufficient for cybersecurity risk management. Postmarket surveillance may benefit from extending beyond the individual device to encompass the broader technical and organizational environment, including third-party software components, communication interfaces, configuration management, and abnormal data flows. Without such an expanded perspective, detection of emerging risks may be delayed, accountability blurred, and the overall benefit-risk profile of digital medical products—particularly in large-scale, multivendor health care environments—more difficult to assess.

XSL•FO
RenderX

Governance Fragmentation and a Tiered, Mammography Quality Standards Act–Analogous Response

Across the 3 jurisdictions, device regulators, manufacturers, health care delivery organizations (HDOs), and national cybersecurity agencies—KISA, CISA, ENISA, and national CSIRTs—operate within distinct reporting structures: device regulators primarily receive harm-oriented incident reports, whereas cybersecurity agencies handle vulnerability disclosures and breach data that need not satisfy patient-harm thresholds. Within manufacturers, regulatory affairs, quality, product security, and AI engineering teams likewise sit under separate management systems, and within HDOs, information-security operations and clinical risk management rarely share a common escalation pathway. This bifurcation slows correlation between vulnerability disclosures and clinical impact, complicates coordinated mitigation when a single vulnerability affects multiple manufacturers or shared hospital infrastructure, and limits systematic learning from near-miss events that are visible only within the cybersecurity domain. Frameworks such as the NIST Cybersecurity Framework 2.0 articulate multistakeholder risk governance in principle but stop short of specifying the institutional mechanisms by which such coordination occurs in clinical practice. At the policy level, the European Commission's 2025 action plan on the cybersecurity of hospitals and health care providers (COM/2025/10 final) represents one recent attempt to bridge these silos through coordinated information-sharing, incident-response support, and threat-intelligence services for the health care sector [55].

To operationalize this coordination, we propose an interlocking 3-party model that distributes responsibility across the actors already present in the regulatory ecosystem. Manufacturers would extend the PCCP [56] beyond algorithm performance characteristics to incorporate manufacturer-defined threat models, making cybersecurity assumptions and the envelope of acceptable change explicit and auditable. HDOs would route cybersecurity events to the relevant national cybersecurity agency while concurrently flagging—jointly with the manufacturer—any observed conditions that fall outside the manufacturer's PCCP. Within HDOs, this dual reporting is most effectively executed through standing multidisciplinary AI-cybersecurity review committees that combine clinical, biomedical engineering, information security, and quality and risk-management expertise; such committees provide the institutional substrate for triaging cybersecurity events with potential safety implications, deciding whether to escalate, and maintaining auditable links between security advisories and clinical change management. This dual-channel, voluntary reporting closes the gap between patient-safety vigilance and vulnerability-centric surveillance, and provides regulators with structured signals at the intersection of clinical use and cyber exposure.

A useful institutional precedent for this facility-anchored, multidisciplinary review function is the United States Mammography Quality Standards Act (MQSA) of 1992 (Public Law 102 - 539; 21 CFR Part 900) [57]. MQSA itself regulates mammography image quality and does not address AI-enabled medical devices or cybersecurity; the analogy invoked here is institutional rather than substantive. Specifically, §900.3(b)(1) requires accreditation bodies to meet reliability and objectivity criteria when evaluating mammography facilities, demonstrating that an independent, multidisciplinary expert review function can be situated at the facility level and maintained over more than 3 decades through codified accreditation standards. The proposed AI-cybersecurity review committees draw on this model in structural form only—independent, multidisciplinary, and facility-anchored—while their remit (cybersecurity exposure, AI-specific risk such as data poisoning and model drift, and PCCP envelope monitoring) is categorically distinct from mammography image quality. Adopting this architecture would add a coordinating institutional layer between manufacturer postmarket obligations and device-specific vigilance pathways, through which voluntary reports of incidents and PCCP deviations can be triaged by cybersecurity experts working alongside clinical reviewers. Over time, this approach would accumulate a body of real-world response cases that translates principle-level coordination into concrete operational practice, addressing the fragmented oversight identified across Korea, the United States, and the European Union without requiring harmonization of underlying device-regulation frameworks.

Implications for Manufacturers: an Integrated Multistandard QMS

The facility-anchored architecture described above must be matched by a corresponding integration at the manufacturer's management-system level. We propose that ISO 14971–based safety risk management be combined with ISO/IEC 27001 (information security) [48], ISO/IEC 42001 (AI management systems) [49], and ISO 31000 (enterprise risk management for assets, personal data, and service continuity) [58] within a single, harmonized medical device QMS. The feasibility of such multistandard integration is already established in regulatory practice: CEN/TR 17223 clarifies the relationship between EN ISO 13485 and the MDR/IVDR, and IMDRF guidance on risk-management integration provides a structured basis for aligning safety, security, and AI governance under common QMS controls. A cross-sector precedent is offered by the automotive industry, where ISO 9001/IATF 16949 functions as a quality backbone through which ISO/IEC 27001 and ISO/IEC 42001 are operationalized as distinct yet interoperable risk domains, with controls executed via shared QMS mechanisms (design inputs, supplier qualification, configuration and change management, internal audit, CAPA, and management review).

This integration materially broadens the universe of formally managed risk beyond patient harm. Cybersecurity threats that primarily affect confidentiality, data integrity, or service availability—including those framed through information-security or AI-governance lenses such as personal-data exposure, asset compromise, model integrity loss, and disruption of dependent clinical services—are explicitly recognized as managed risks within the QMS, rather than being deferred to parallel information-security processes outside the device file. The manufacturer's risk register therefore captures both ISO 14971-relevant safety hazards and ISO 31000-relevant

XSL•FO
RenderX

operational and informational risks, with bidirectional traceability where a cybersecurity event has potential safety consequences. This dual recognition addresses the structural limitation identified in our analysis, in which clearly characterized cybersecurity threats may be deprioritized when they do not breach traditional patient-harm thresholds.

Operationally, manufacturers can anchor this integrated approach in 2 complementary mechanisms. First, the PCCP—extended, as proposed above, to incorporate manufacturer-defined threat models—serves as the controlled instrument through which cybersecurity assumptions, acceptable change envelopes, and trigger conditions for re-evaluation are pre-specified for both algorithmic and security parameters. Second, the ISO 13485 design and life cycle clauses provide the sustaining backbone: Clause 7.3 (design and development) controls hazard and threat identification, security and AI-governance design inputs, and verification and validation of risk-control measures during development, while Clause 8 (measurement, analysis, and improvement) governs continuing monitoring of vulnerabilities, performance drift, and CAPA-linked improvement during the postmarket phase.

Limitations

This study has several limitations. First, the analysis relies on publicly available regulatory documents and selected academic literature; we did not conduct stakeholder interviews or collect quantitative data on incident frequency or device outcomes. We partially mitigated this by triangulating regulatory documents with peer-reviewed analyses of recalls, vulnerabilities, and postmarket monitoring practices.

Second, the regulatory landscape is evolving rapidly, and several documents in our corpus—particularly the FDA's 2025 draft guidance on AI-enabled device software functions—are likely to be revised or finalized after the analysis cutoff. We anchored inclusion to the most recent version available as of March 2026 and explicitly identified draft versus final status in Tables 1 and 4; findings may need to be revisited as new guidance is issued, especially for generative AI.

Third, much of the analysis relies on guidance documents that are generally nonbinding and reflect interpretive recommendations rather than directly enforceable obligations, with practical influence varying across jurisdictions. We have therefore framed these documents as expected interpretations of binding regulations rather than as enforcement standards in themselves.

Fourth, the functional comparative approach enables cross-jurisdictional comparison on shared regulatory functions but abstracts from the broader legal-cultural context of each instrument; our claims are accordingly confined to convergence and divergence in operational expectations rather than to underlying legal-systemic differences.

Comparison With Prior Work

Our findings align with prior reviews that note limited operational integration of cybersecurity considerations into traditional benefit-risk and vigilance frameworks for medical devices [22,27,29,36].

Recommendations and Future Work

On the basis of this comparative analysis, future research and policy work could usefully address: (1) empirical evaluation of whether integrating cybersecurity controls into ISO 13485-aligned QMS processes improves incident response timeliness, (2) development of shared reporting taxonomies that allow vulnerability and near-miss data to be exchanged between device regulators and national cybersecurity agencies without overburdening manufacturers, (3) jurisdiction-specific operational guidance on AI-cybersecurity threats (data poisoning, prompt injection, model inversion) for high-risk medical device AI, and (4) qualitative studies of how multidisciplinary hospital governance structures handle cybersecurity events with potential clinical impact.

Conclusions

In this comparative document analysis of regulatory and guidance instruments from Korea, the United States, and the European Union, the three jurisdictions shared a common conceptual foundation for medical device cybersecurity centered on protecting confidentiality, integrity, and availability of information and system functions across the product life cycle, but operationalized this foundation through different regulatory architectures. When cybersecurity is implemented primarily through safety-oriented, ISO 14971-based regulatory frameworks, important categories of cybersecurity risk—particularly those affecting service continuity, data protection, and system-level resilience—may remain partially outside the scope of device-centric risk management.

Across the documents analyzed, cybersecurity oversight was distributed across multiple regulatory and institutional domains, including medical device regulation, information security, health information technology governance, and horizontal cybersecurity law. As a result, cybersecurity incidents and vulnerabilities that did not immediately manifest as patient harm tended to be managed through parallel reporting and surveillance mechanisms rather than through medical device vigilance systems. Within the limits of a document-based design, these findings indicate that aligning cybersecurity risk management with QMS processes—while maintaining conceptual distinction from safety risk management—offers a coherent direction for life cycle oversight of AI-enabled MDSW, and warrants empirical evaluation in subsequent studies.

Funding

This work was supported by an internal fund of the Electronics and Telecommunications Research Institute (ETRI) under project 25YR1610 (Next-Generation Mammography: Development of Personalized Precision Breast Cancer Diagnostic Core Technology Utilizing Radiomics, AI, and Targeted Contrast Agents). Although the parent project focuses on AI-based breast cancer diagnostics, that work surfaced cross-cutting questions about the regulatory and cybersecurity governance of AI-enabled medical device software—particularly the interface between safety-oriented device risk management and broader cybersecurity expectations. The present comparative regulatory analysis was conducted to address these cross-cutting questions and to inform downstream regulatory and quality-system planning for AI-enabled medical device software developed within the project. The funder had no role in study design, document selection, analysis, or the decision to submit for publication.

Data Availability

All materials analyzed in this study are publicly available regulatory documents, laws, guidance, and standards, and are listed in the References. No participant-level data were collected, and no new datasets were generated. The structured extraction matrix used during analysis is available from the corresponding author on reasonable request.

Abstract

Background: The increasing reliance on online surveys for collecting patient-reported feedback for health care research has led to growing concerns over fraudulent responses generated by bots. These automated responses threaten data integrity by fabricating survey results, distorting statistical analyses, and potentially misguiding policy decisions. Addressing this issue is critical for maintaining the validity of research findings that inform health care practice and policy.

Objective: This study aimed to develop a robust set of criteria for identifying bot-generated responses in online health care surveys and to examine how these responses impact data quality. We then explored differences in survey results between probable human and suspected bot respondents in a survey assessing patient-reported outcome measures and patient-reported experience measures within a geographic region in Ontario, Canada.

Methods: A survey was conducted from July to October 2023 using Research Electronic Data Capture (REDCap; Vanderbilt University), distributed with a generic link via email, and later shared on social media. The survey collected data on health care use, patient experiences, health outcomes, digital health care engagement, and demographics. A 3-tier classification system was developed to detect bot responses based on predefined "red flags," including duplicate open-ended responses, inconsistent demographic reporting, identical timestamps, and location discrepancies. Quantitative analysis included chi-square tests to assess differences between probable human and suspected bot responses and Spearman correlation tests to examine relationships among health care indicators.

Results:: Analysis included 1154 responses, with 58% (n=668) classified as suspected bot-generated. The most frequent suspected bot-identification criterion was duplicated open-ended responses (293/668, 44%). Chi-square tests revealed statistically significant differences (P<.05) between suspected bots and probable humans across most survey items. Suspected bots demonstrated response patterns concentrated in the middle of Likert scales, whereas probable humans were more likely to select extreme values. Correlation analyses showed that expected relationships between key health indicators (eg, depression symptoms) were present in probable human responses but reversed in suspected bot-generated data, highlighting the potential for compromised validity in unfiltered survey datasets.

Conclusions: The findings underscore the necessity of implementing bot prevention and detection methods in online health care surveys to preserve data integrity. Failure to do so risks distorting research conclusions, particularly in health equity studies where demographic misclassification may bias results. The study highlights effective bot detection strategies, including open-text analysis, timestamp evaluation, and geographic validation, and recommends integrating these techniques into survey design. As bots continue to evolve, ongoing advancements in bot prevention and detection will be crucial to maintaining the reliability of digital health research.

Introduction

Patient-reported outcome measures (PROMs) and patient-reported experience measures (PREMs) are invaluable tools for understanding and improving health care from the patient's perspective. PROMs assess health status, functional abilities, symptoms, and quality of life directly from patients, often through self-reported questionnaires, providing insights into the impact of interventions and overall care quality [1-3]. PREMs, on the other hand, capture patients' perceptions of their health care experience, focusing on whether key processes

XSL•FO
RenderX

occurred and how care was delivered [2]. These measures are essential for implementing person-centered care, as they enable health care providers to align their practices with patient needs and experiences [4]. PROMs and PREMs have also been incorporated into care routines to support quality improvement initiatives [4]. By prioritizing patient-reported data, health care systems can address inequities, promote patient-centered and value-based care, and ensure that care delivery aligns with the priorities and needs of diverse patient populations [4].

A common approach to collecting PROMs and PREMs is through online surveys. Online surveys have become an increasingly prominent tool for research, particularly in social and behavioral health fields, due to their efficiency, cost-effectiveness, and ability to overcome challenges faced by traditional data collection methods such as face-to-face, mail, or telephone surveys [5,6]. These challenges include declining response rates, rising costs, and the need for social distancing during events like the COVID-19 pandemic [5,7-10]. Internet-based platforms such as Qualtrics (Qualtrics International) Inc., SurveyMonkey (Momentive Inc.), and Research Electronic Data Capture (REDCap; Vanderbilt University) have enabled researchers to collect data remotely, making it possible to reach large general populations [5,7,10]. These tools reduce the resources required for data collection, minimize participant burden, and offer greater anonymity, encouraging honest disclosure of personal or sensitive information [7,10]. Additionally, the limited availability of a sampling frame with accurate contact information has necessitated the use of distribution methods involving generic survey links and promotion through online platforms and social media. Unfortunately, recruiting participants through generic links creates susceptibility to data quality issues [11].

While early guidance on online surveys for health research warned of the risk of hoax responses [12], the increasing use of online surveys has been accompanied by a growing concern over fraudulent responses, particularly from bots - applications that automatically complete surveys – producing insincere data and inaccurate results [13]. These bots are capable of mimicking human behavior by selecting multiple-choice answers and generating plausible open-ended responses, making them difficult to detect. Bots can submit hundreds of fabricated responses within hours, potentially overwhelming researchers with invalid data and causing significant financial loss if participant incentives are misallocated [8]. Their presence threatens data quality, which can distort statistical analyses and compromise research findings [10]. Researchers, evaluators, and program analysts also face challenges in identifying fraudulent responses due to the increasing sophistication of bots and the anonymity of online participants [14]. Despite the implementation of data protection mechanisms to prevent bot responses, such as reCAPTCHA (Google LLC), bot programmers easily bypass these safeguards using virtual private networks or servers [7]. As bots become more prevalent and capable, addressing this issue is critical to ensuring data integrity and the validity of research findings that inform policy and practice.

This study adds to this literature by proposing a structured 3-tier classification system that integrates multiple indicators of responses by suspected bots, offering a robust and transparent protocol for identifying suspected bot responses. Additionally, this study goes beyond merely identifying suspected bot-generated responses in online surveys; it systematically examines how suspected bots influence response patterns in a health care experience survey. While existing research has focused on detecting fraudulent responses, fewer studies have examined how suspected bot-generated data may distort patient-reported experience and outcome measures in health care contexts. Our study extends this work by analyzing discrepancies between suspected bot and probable human responses in a survey of PROMs and PREMs. Such differences provide an assessment of potential bias and the relative importance of detection.

Methods

Survey

This study was undertaken within a broader evaluation of Ontario Health Teams (OHT), focusing on patient experiences and outcomes. A patient survey was implemented to support planning and evaluation of integrated care for attributed populations in Ontario, Canada. Consent was obtained from all respondents included in the analysis. The survey was intended for patients from a large OHT, gathering data on PREMs and PROMs. Questions included Likert scale items on health care use, health outcomes, accessing care, having someone to count on, being heard, managing health, safety, care transitions, digital health care use, demographics; as well as an open-text section to provide additional feedback. Six timestamps were programmed throughout the survey at multiple points to track survey progress. Data were collected between July 2023 and October 2023 using REDCap. REDCap is a web-based platform designed for research data capture, widely used in academic and clinical studies. The survey was distributed through the OHT's email lists and social media platforms. Social media distribution occurred primarily through Facebook (Meta), which was the OHT's main platform. Posts containing the survey link and QR code were shared periodically between July and October 2023, and a paid Facebook advertisement was implemented in early October to boost participation. Participants were invited to enter a draw for a $25 CAD (US $18.62) gift card as an incentive. Entry into the draw was voluntary and completed through a separate form linked on the survey's thank-you page, allowing respondents to opt out and ensuring that contact information was stored separately from survey responses. A copy of the survey is provided in Multimedia Appendix 1.

Suspected Bot Identification

Upon reviewing the qualitative responses and timestamp data, the research team identified clear evidence of suspected bot-generated responses in the survey. Many responses were duplicative, contained overly formal or generic language, or were nonsensical. The response patterns, combined with irregular timestamp data, confirmed the presence of suspected bots. As a result, the team developed specific criteria to systematically identify and remove suspected bot-generated responses from the dataset.

XSL•FO
RenderX

Criteria to identify suspected bots were developed using the following themes: generic and duplicative open-ended responses; concerns with location as determined by postal code (including postal codes that were invalid or nonsensical); timing irregularities; identical timestamps to other participants; illogical demographic reporting; and discrepancies in reporting health care use. In addition, a "bot takeover day" (October 10 onward) was included as a criterion, reflecting the sudden influx of suspicious responses observed on or after that date.

To identify bots in the survey data, we developed a 3-tier classification system based on specific "red flags" (concerning or questionable features or responses in the data). This approach builds on prior research that has typically relied on individual indicators or sets of criteria considered in parallel to flag fraudulent responses [5,7-9]. By combining multiple indicators into a structured, tiered framework, our system increases the robustness and transparency of suspected bot identification. Tier 1 criteria identified a respondent as a suspected bot if any single criterion occurred on its own (eg, duplicate open-ended responses that were exact full-text matches, not brief "No"-type replies, invalid postal codes, or identical timestamps). Tier 2 classified a respondent as a suspected bot if 2 or more criteria from its list were observed. For example, one tier 2 criterion included having a valid postal code outside of the region where participants received health care services. This criterion was not sufficient on its own to categorize a respondent as a suspected bot, as some participants may legitimately live elsewhere and receive care in the area where the participants were sampled. However, when combined with other criteria, it strengthened the likelihood of being a suspected bot-generated response. Finally, tier 3 flagged respondents as suspected bots if any tier 3 criterion was combined with at least 2 additional criteria from either tier 2 or tier 3, resulting in a total of 3 or more issues. One Tier 3 indicator reflected a sudden influx of suspicious responses observed on October 10, 2023 ("bot takeover day"). This indicator was not used as a standalone criterion and had minimal influence on classification: more than 99% of suspected bot responses were already identified using Tier 1 and/or Tier 2 criteria alone, with only 3 additional responses flagged through the use of this indicator. Demographic characteristics such as race or ethnicity, gender, and sexual orientation were not used as criteria for suspected bot identification. Demographic variables were analyzed only after classification to describe group-level differences between suspected bots and probable humans.

One criterion for identifying suspected bots was the presence of open-text responses that were deemed to be either (1) generic or informal, or (2) had a similar sentence structure to other responses. To evaluate this more subjective criterion, 2 reviewers (LC and SU) independently coded open-ended responses based on these criteria. Responses were categorized as suspected bots if reviewers agreed they met either criterion. When reviewers disagreed on whether open-ended responses should be classified as generic or informal, a third member of the research team (KM) provided the final determination. Interrater reliability between the 2 independent coders was substantial (Cohen κ=0.63, P<.001).

Although this study applied the identification criteria for a survey implemented on the REDCap platform, the 3-tier system is designed to be adaptable across different survey platforms, including Qualtrics, SurveyMonkey, and other online tools. The criteria used (such as duplicated open-text responses, timestamp irregularities, and geographic inconsistencies) are not platform-specific.

Suspected Bot Response Analysis

To examine differences in survey responses between probable humans and suspected bots, bar charts were created to visually compare response patterns. Chi-square tests were conducted to identify significant differences in the proportions of responses between the 2 groups. For select-all-that-apply items, including "Who did you receive care from?," responses were summarized into a mutually exclusive categorical variable prior to analysis. Respondents selecting more than 1 option were classified as having received care from "multiple providers," while those selecting a single option were classified according to that provider type.

To account for multiple comparisons across survey items, a Bonferroni correction was applied (adjusted α=.05/59=0.00085) to control for Type I error. We quantified the magnitude of group differences by calculating effect sizes for each chi-square test. Cramer V was computed for all categorical comparisons, along with 95% CIs.

Additionally, Spearman correlation tests were conducted to evaluate significant relationships between 2 health indicators, analyzed separately for probable humans and suspected bots, to identify patterns that align with or deviate from expected human perception and behavior. Two sets of correlations were examined: (1) the correlation between "little interest or pleasure in doing things" and "feeling down, depressed, or hopeless," and (2) the correlation between self-rated health and the frequency of interaction with the health system. The first pair represents the 2 core items of the Patient Health Questionnaire–2 (PHQ-2), a validated depression screener in which these items are strongly and positively correlated with one another [15]. The second pair was selected because extensive literature has shown that poorer self-rated health is associated with increased health care use, including higher rates of hospitalization and outpatient visits [16,17]. These 2 pairs, therefore, provide theoretically justified validity checks.

Ethical Considerations

This study received approval from the University of Toronto Research Ethics Board (#38072). All procedures were conducted in accordance with institutional ethical standards and the principles of the Declaration of Helsinki. Participants provided informed consent electronically prior to beginning the survey. The consent form outlined the purpose of the study, the voluntary nature of participation, potential risks and benefits, and data management procedures. Participants were informed that they could decline to answer any question or withdraw at any time prior to survey submission. To protect privacy and confidentiality, survey responses were collected anonymously. Any contact information provided for entry into the incentive draw was submitted through a separate form and stored

XSL•FO
RenderX

separately from survey data. Data were stored on secure, password-protected institutional servers accessible only to authorized members of the research team.

Results

Frequency of Suspected Bot Identification

Table 1 illustrates the final criteria for identifying suspected bots and the frequency with which each criterion was met among respondents ultimately classified as suspected bots or probable humans. While some probable human respondents exhibited isolated red flags, they did not meet the necessary combination of criteria required for suspected bot classification. After removing survey responses where substantive questions were not answered (n=231), 1154 survey respondents remained. Among them, 58% (n=668) were categorized as suspected bots, and 42% (n=486) were categorized as probable humans. Table 1 illustrates the number of respondents who met the eligibility criteria for each identification criterion. Overall, 529 survey respondents met the criteria for Tier 1, 570 respondents met the criteria for Tier 2 (136 of whom did not meet the criteria for Tier 1), and 551 respondents met the criteria for Tier 3 (3 of whom did not meet the criteria for Tier 1 or Tier 2).

XSL•FO
RenderX

Table . Frequency of each suspected bot identification criteria. Percentages within each tier sum to greater than 100% because a single respondent may meet multiple identification criteria.

Criteria	Assessed categories		
	Suspected bot (n)	Probable human (n)	Respondents identified as suspected bots who met criteria, n (%)
Tier 1			
Had an identical open-ended question response identical to at least one other respondent (Duplicate open-ended responses that were exact full-text matches, not brief "No"-type replies)	293	0	(293/668) 44%
Open text is generic, informal, or similar sentencing structure	49	0	(49/668) 7%
Duplicate invalid postal codes that were completed on the same day	189	0	(189/668) 28%
Duplicate out-of-province postal codes (excluding Quebec) that were completed on the same day	152	0	(152/668) 23%
Tier 2			
Identical open-ended question marked as "no" that also fell within the same day and similar time frame	80	0	(80/668) 12%
2 or more survey respondents entered their surveys within 30 seconds of one another (but not identical), and this is the case in 3 or more timestamps	340	2	(340/668) 51%
Had an identical timestamp (identical hours, minutes, and seconds) with at least one other respondent on the following timestamps:			
First timestamp	114	0	(114/668) 17%
Second timestamp	93	0	(93/668) 14%
Third timestamp	75	1	(75/668) 11%
Fourth timestamp	80	0	(80/668) 12%
Fifth timestamp	69	2	(69/668) 10%
Sixth timestamp	75	0	(75/668) 11%
Survey was completed between 1 AM and 5:00 AM Eastern Time (as identified on any of the timestamps)	154	7	(154/668) 23%
Time spent on survey is 3 minutes or less (among respondents who completed the survey)	42	11	(42/668) 6%
Invalid postal code (gibberish or numeric)	189	0	(189/668) 28%
Valid postal code but outside of Ontario	153	0	(153/668) 23%
Valid Ontario postal code but outside of the region of the primary care center in which respondents were recruited	165	5	(165/668) 25%

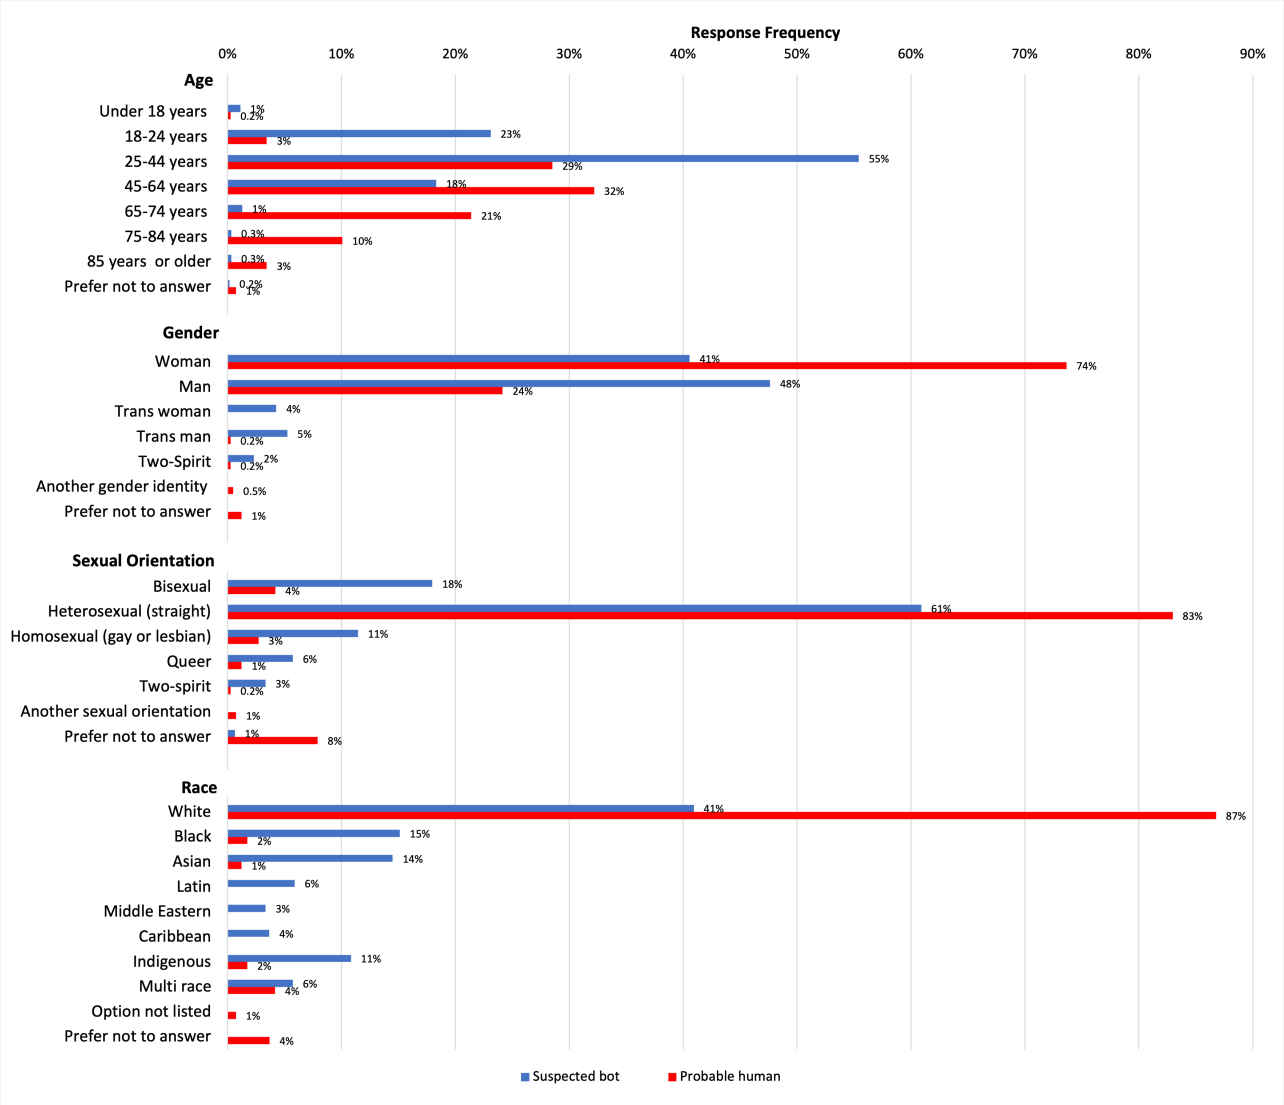
XSL•FO
RenderX

Criteria	Assessed categories		
	Suspected bot (n)	Probable human (n)	Respondents identified as suspected bots who met criteria, n (%)
Discrepancy in reporting ED[a] visits	347	55	(347/668) 52%
Between the ages of <18 - 44 years but reported living in a retirement home or long-term care facility.	123	1	(123/668)18%
Tier 3			
Bot takeover day of October 10 or after	618	94	(618/668) 93%
Postal code from neighboring province	55	3	(55/668) 8%

[a]ED: emergency department.

In tier 1, the most commonly reported “red flag” was having an identical open-ended response to another survey respondent. In tier 2, the most common ’red flag’ was a discrepancy in reporting an emergency department visit, where respondents indicated they had received care from the emergency department in 1 question but later reported that they had not been to the emergency department in the past 12 months. There was also a high frequency of respondents completing their surveys within similar timeframes (completing 3 or more of the same sections within 30 s of another respondent).

Differences in Responses Between Suspected Bots and Probable Humans



Overall, probable humans had a higher average percentage of missingness on all questions (mean 13% [for probable humans vs mean 5% for suspected bots).

Chi-square tests revealed significant differences ($P<.05$) in response distributions between probable humans and suspected bots for 55 out of 59 survey questions. After Bonferroni correction for multiple comparisons (adjusted $\alpha=.00085$), 50 of 59 valid comparisons remained statistically significant (Table S1 in Multimedia Appendix 2). The magnitude of effect sizes ranged from Cramer V=0.01 (“When you left the hospital were you provided with easy to follow instructions on whom to contact if you had a question about your treatment or if your condition became worse?”) to Cramer V=0.72 (“In general, do your health care providers encourage you to bring someone with you to your appointments?”), with a mean Cramer V of 0.31 (Table S1 in Multimedia Appendix 2). Among the 9 survey questions that showed no statistically significant difference between probable humans and suspected bots, most items were binary (yes or no) questions that followed branching logic and were therefore presented only to a subset of respondents. The remaining non-significant items were measured on a 5-point response scale, where probable humans tended to provide slightly less positively skewed responses (for example, being more likely to select experiencing “slight pain or discomfort” rather than “no pain or discomfort”).

In terms of demographics (Figure 1), suspected bots more often reported younger ages (under 18–44 years) and being male, while probable humans more often reported being female. Both groups most frequently identified as heterosexual and White, but suspected bots more often selected minority sexual orientations (eg, bisexual, queer, and two-spirit) and racial or ethnic categories (eg, Black, Asian, Latin, and Indigenous).

XSL•FO
RenderX

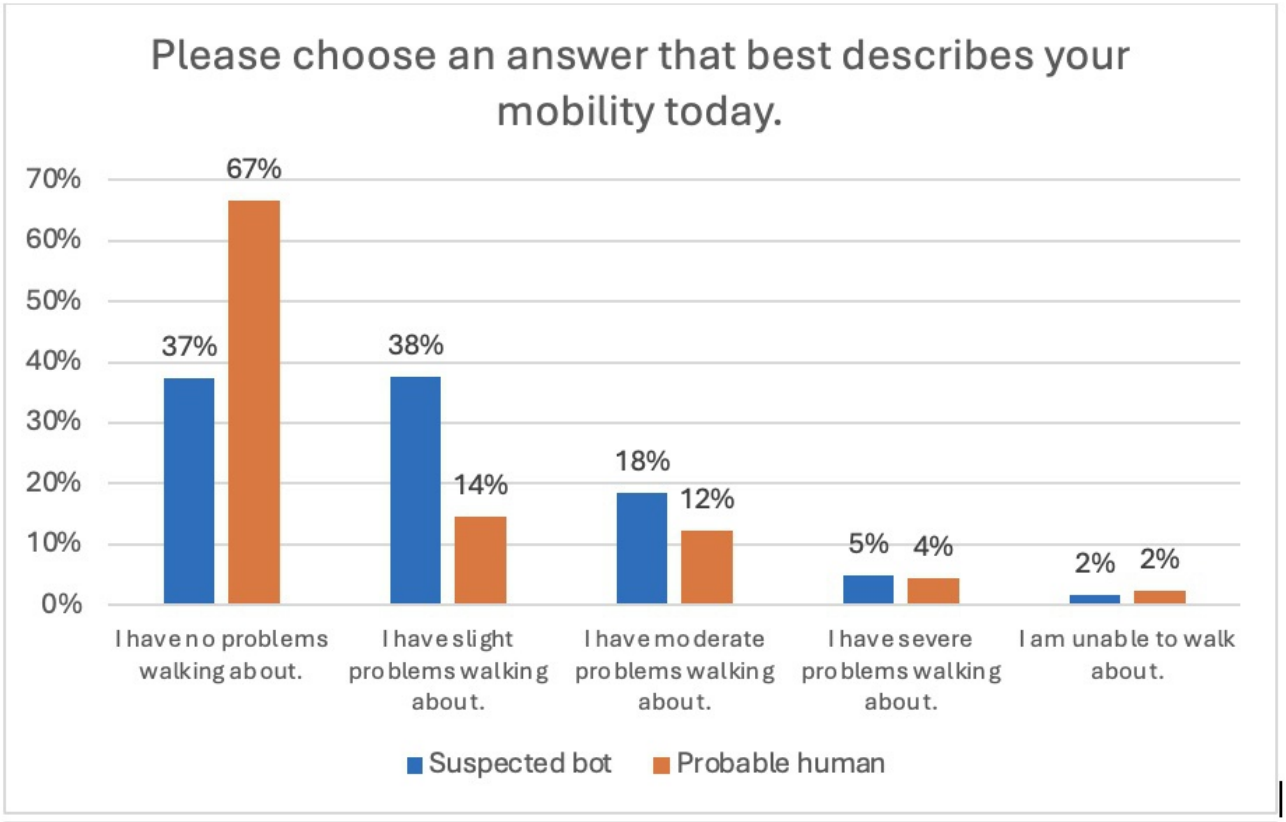


Figure 1. Distribution of demographics for suspected bots versus probable humans.

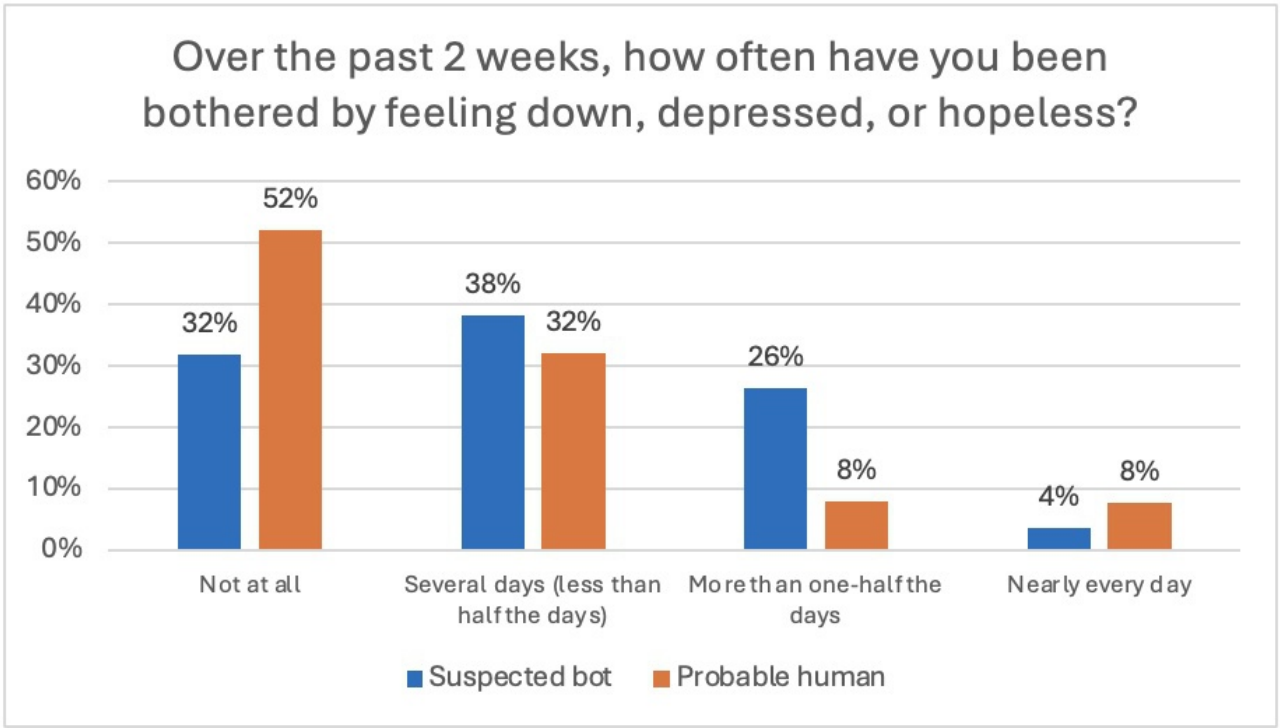
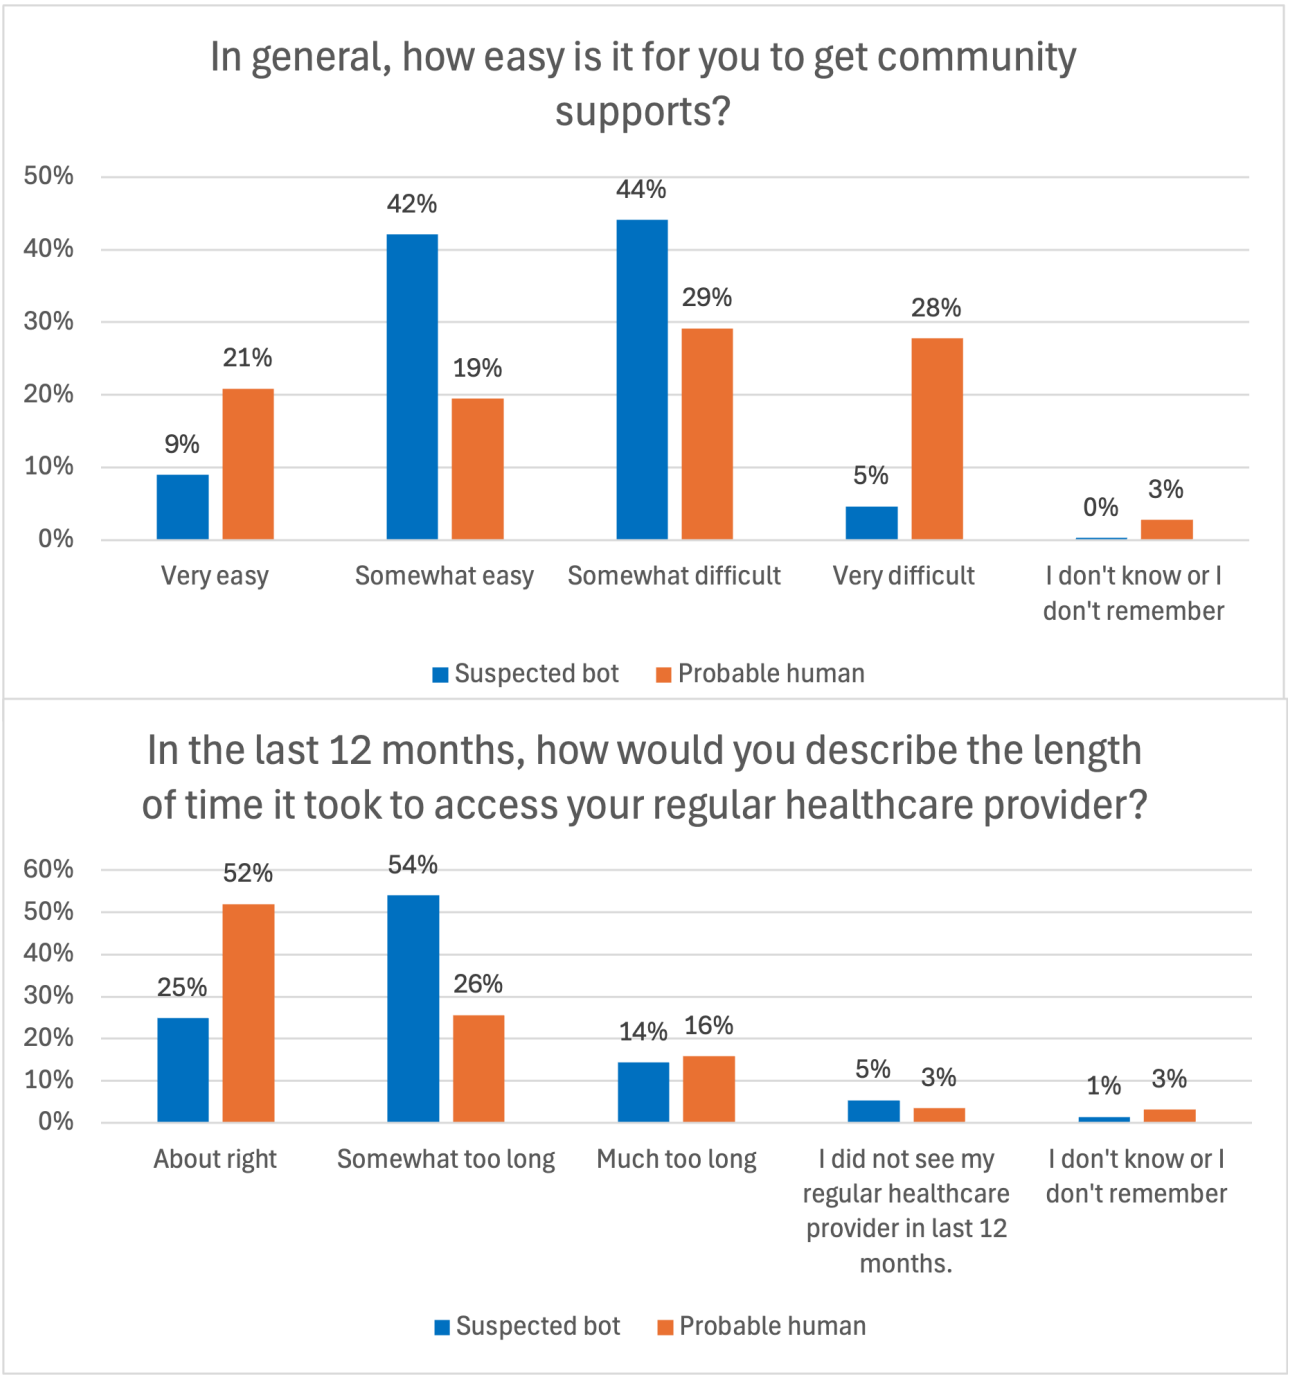


Visualizations (Figures 2 and 3) showed that suspected bots tended to cluster at mid-scale responses, while probable humans more often selected extreme values. For PROMs, probable humans were more likely to report the most favorable outcomes (eg, “no problems walking about”) and the least favorable (eg, “nearly every day” feeling depressed), whereas suspected bots gravitated toward midpoints (eg, “slight problems,” “several days”). Similar patterns appeared in PREMs, where suspected bots more frequently selected “somewhat” responses (eg, “somewhat easy” to access supports, “somewhat too long” to get care), while probable humans showed a greater spread across extremes.

XSL•FO
RenderX

Figure 2. Distribution of probable human and suspected bot responses for patient-reported outcome measures.



The survey also assessed health service use, including emergency department visits, hospitalizations, and specialist care in the past year. Suspected bots more frequently reported using the emergency department and being hospitalized compared to probable humans. When asked yes or no questions about these services (such as whether an emergency department visit could have been managed by a regular provider, whether their provider was informed after hospital discharge, or whether a specialist had relevant medical information), suspected bots were more likely to respond "yes" than probable humans. This was consistent with other patterns, such as reporting "somewhat confident" when asked about managing health post-emergency department visit, while probable humans were more likely to select "very confident" or "not at all confident."

The survey included 1 nominal question, which asked about the main reason participants had not looked at their medical records online (for those who indicated this to be the case). There did not appear to be any trend or pattern for the distribution of

XSL•FO
RenderX

responses. Ironically, a substantially higher percentage of suspected bots (compared to probable humans) indicated that a reason for not having looked at medical records online was not having reliable access to the internet.

Figure 3. Distribution of probable human and suspected bot responses for patient-reported experience measures.

Correlations

Spearman correlations indicated significant correlations between the indicators of having "little interest or pleasure in doing things" and "feeling down, depressed, or hopeless," both of which are indicators of depression. For probable humans, the Spearman correlation was 0.48 (P<.001), indicating a moderate positive correlation between the 2 variables, whereas for suspected bots, the Spearman correlation of −0.33 (P<.001) indicated a moderate negative correlation between the 2 variables.

When analyzing the correlation between self-rated health ("how do you rate your own health?") and frequency of interacting with the health system ("how often do you interact with the health system?"), a Spearman correlation of −0.07 for probable humans indicated a weak negative correlation; however, this was not significant (P=.15). For suspected bots, the Spearman correlation was 0.06, indicating a weak positive correlation; however, this was also not significant (P=.15).

Discussion

Principal Findings

The results of this study demonstrate the imperative need for researchers, evaluators, and program analysts in the health care field to recognize and address the potential threats posed by bots in online survey research. Failure to detect and remove bot-generated responses can lead to compromised data quality and incorrect inferences. Implementing robust data screening strategies is important for reducing fraudulent responses and improving the likelihood that valid data are retained. These responses respect the integrity of genuine participants whose experiences deserve to be accurately reported.

Implications of Including Bot Data in Health Care Surveys

Our findings extend prior work on bot response patterns by demonstrating how these differences manifest in PROMs and PREMs, with implications for health care survey research. Across multiple survey domains—health outcomes, health care access, and experiences—probable humans were more likely than suspected bots to select the most favorable outcomes (or in some cases, the least favorable response options). In contrast, suspected bots exhibited a tendency to select responses clustered around the middle of the scale. As a result, the presence of bot-generated data could dilute the strength of human responses, skewing average scores toward the midpoint and diminishing the ability to detect meaningful trends. This issue extends beyond scaled responses; even in nominal questions, such as the reason for not accessing medical records online, suspected bots disproportionately selected specific response options, such as lacking reliable internet access. This discrepancy suggests that bot-generated data may introduce artificial patterns in categorical variables, leading to inaccurate estimates of barriers to health care access and potentially misinforming policy decisions. This distortion may undermine construct validity, as the data fail to capture real-world experiences. Additionally, probable humans demonstrated a higher level of missingness compared to suspected bots. This likely reflects natural variation in survey completion behavior (such as skipped or unanswered questions). In contrast, the lower level of missingness among suspected bots may indicate automated completion rather than a marker of higher data quality. This difference underscores the importance of evaluating missing data patterns alongside other indicators when assessing data integrity.

Beyond response patterns, the inclusion of bot-generated data introduces a significant risk of bias, particularly in research focusing on health equity. The demographics of suspected bot responses differed notably from those of probable human participants. These patterns may reflect random bot response patterns inflating less common categories; however, this pattern may be partially driven by the ordering of the race or ethnicity response options. In the survey, several minority categories appear in the middle of the list, whereas “White” appears at the bottom. Given the tendency of suspected bots to select middle-of-the-scale responses, the positioning of race or ethnicity response options likely contributed to the higher selection of minority categories among bots. We also acknowledge the possibility that some marginalized respondents were misclassified as suspected bots. This discrepancy poses a major threat to the validity of studies that examine health care use and outcomes among specific demographic subgroups. In equity-focused research, where accurate representation of marginalized populations is crucial, failing to filter out bots could lead to misleading conclusions and inappropriate policy recommendations.

The impact of suspected bot interference is further underscored when examining the relationship between key indicators of depression. Among probable human respondents, the correlation between “having little interest or pleasure in doing things” and “feeling down, depressed, or hopeless” aligned with established patterns in the literature, reflecting a logical association between these 2 related constructs. However, among suspected bot-generated responses, this relationship was unexpectedly reversed, indicating a negative correlation that does not align with theoretical expectations. Notably, a moderate negative correlation suggests a systematic response pattern (such as contradictory response selection) rather than a pattern consistent with genuine symptom co-occurrence. This inconsistency suggests that suspected bot responses do not accurately reflect underlying psychological constructs, reinforcing the need to identify and eliminate suspected bots from survey research. The inconsistency also provides face validity to our bot-detection algorithm.

Bot Detection Strategies

Several methods to identify suspected bots that were used in this study align with those used in similar research. These include: analyzing open-ended responses for nonsensical, duplicative, or inconsistent data [5,8,10,18]; tracking survey completion times [5,7,8,13,19,20]; flagging surveys that were completed at unusual times of the day [8]; and identifying suspicious patterns related to zip codes and geographic location [20]. We applied all applicable bot detection strategies for which we had data available. There are additional bot detection techniques that were not used in this study but have been used in prior research. These include: checking participants' responses to questions that are asked in 2 ways [8,14,19], (such as “how old are you?” and “what y were you born?”); using IP addresses to check for responses that were completed in the same household or very close to one another in relation to the time the survey was submitted [5,14]; and examining email addresses for suspicious wording or similar content [8,20]. Another strategy involves external validation of participant information, such as verifying names, addresses, phone numbers, and birth dates to ensure responses are unique and legitimate [21]. Investigators can also cross-reference participants’ details using publicly available databases, social media, or professional networking sites to further confirm authenticity, although ethical considerations must be weighed when implementing such approaches [21]. While these strategies may help reduce fraudulent responses, they can also create additional burdens and reduce anonymity for legitimate participants.

Among the bot detection strategies used in this study, some were particularly effective in identifying suspected bot-generated responses. Notably, open-ended responses provided valuable

XSL•FO
RenderX

insight, as suspected bot-generated answers often contained repetitive, illogical, or off-topic content across multiple responses. Unusual quantitative responses alone can be difficult to interpret, as they might seem plausible despite being artificially generated. However, open-ended responses can provide valuable context that may help in assessing the authenticity of data. Unlike structured response options, which bots can randomly or systematically select, qualitative responses require coherence and reasoning, making them a powerful tool for distinguishing between genuine participants and automated responses. That said, recent advances in generative artificial intelligence mean that open-text answers are becoming increasingly sophisticated and may no longer be a fully reliable safeguard against fraud [22]. Geographic inconsistencies, such as invalid or duplicate postal codes, or locations outside the intended survey region, were also strong indicators of suspected bot activity, although individual respondents may misreport to preserve anonymity. Additionally, anomalies in time-related metrics, including extremely short survey completion times, completion at unusual hours, or multiple surveys submitted at identical timestamps, further helped differentiate suspected bots from probable human respondents. Based on these findings, we recommend collecting postal or ZIP codes and incorporating multiple timestamps within surveys to enhance suspected bot detection. While no single strategy is universally effective across all surveys, we recommend using a combination of detection methods tailored to the specific survey and target population.

While several strategies are outlined to detect bots, it is also important to prevent bots from entering surveys in the first place. Tools such as Completely Automated Public Turing test to tell Computers and Humans Apart (CAPTCHA) have been developed to offer an additional level of security against bot infiltration [23]. However, research has shown that these tools can be bypassed, as bots are increasingly programmed to recognize and circumvent such challenges [7,20,24]. Similarly, honeypot questions (hidden prompts designed to engage only automated respondents) have also proven ineffective, as more sophisticated bots can now avoid these traps [8,20]. Indeed, researchers who have used this method have reported that bots did not provide responses to these questions [8]. Given the growing complexity of automated survey fraud, it is essential for technology companies to continue developing advanced bot detection solutions. Survey platforms such as REDCap and Qualtrics should integrate these technologies to automate bot prevention, reducing the burden on researchers and ensuring more consistent data quality measures.

Recommendations

It is recommended that bot detection strategies be implemented at multiple stages in the research process. This includes prior to data collection (eg, using targeted recruitment with specific distribution lists), during data collection (eg, monitoring data daily to identify potential fraud), and following data collection (eg, implementing a systemic check of potential fraud) [18]. Finally, increasing awareness among researchers about the impact of bots in survey research is crucial. We recommend that training in bot prevention and detection be incorporated into research methods and survey design coursework to equip researchers with the necessary skills to safeguard data integrity. There will continue to be a value and need to reach out with surveys to broad groups of public and enabling survey research in this context will continue to be important.

As internet-based research (and survey research in particular) continues to expand, there is a growing opportunity for researchers across disciplines to contribute to the development of comprehensive bot detection methodologies. Moving forward, greater efforts should be directed toward developing universal technologies and initiatives for bot detection. Standardized approaches that can be seamlessly integrated across different research platforms will help safeguard the validity of online data collection and ensure that digital survey research remains a trusted tool for generating meaningful insights.

Limitations

While this study offers valuable insights, several limitations must be acknowledged. Since bot detection methods were applied to a single case study, their effectiveness has yet to be evaluated across different datasets, which may limit generalizability. Additionally, the data were collected within one region of Ontario, and the characteristics of the probable human responses, and their differences from suspected bot responses, may not be representative of broader populations. As response patterns may vary across settings, researchers working in other regions or with different populations should assess whether similar differences between suspected bot and probable human data are observed. However, the bot identification framework is adaptable, as criteria, such as postal or ZIP code validation, open-text analysis, and completion times can be tailored to reflect local contexts. Differences observed between probable human and suspected bot responses may also partially reflect differences between recruitment channels, such as respondents reached through email lists versus social media postings. Survey respondents recruited via open online platforms may differ systematically in demographics or response behaviors, independent of bot activity. Although some degree of misclassification is therefore possible, our detection framework was deliberately conservative and assumed responses were human unless sufficient evidence across multiple indicators suggested otherwise. Despite using various suspected bot detection strategies, there is also potential for undetected sophisticated bots, which could still impact the dataset's validity. Furthermore, the study was conducted at a specific point in time, and as automated response technologies evolve, the effectiveness of these detection methods may diminish. The study relied on assumed response patterns to identify suspected bots, but without absolute verification, such as IP tracking or manual validation, there remains some uncertainty in classification. Finally, while we observed that suspected bot responses reversed an expected positive correlation between depression-related items, this pattern was not incorporated into our 3-tier classification framework. Such a pattern would align conceptually with a Tier 3 criterion, as it represents a complex and context-dependent anomaly that would require corroboration from additional indicators to support classification. Future research should examine whether anomalies in response patterns, in addition to structural indicators, can serve as reliable markers of fraudulent responses.

XSL•FO
RenderX

Conclusions

This study provides criteria for identifying bots in online surveys. In comparing survey results from the suspected bots and probable humans, identified by the developed criteria, we found important differences in response patterns that would jeopardize data validity if bots were not correctly identified. By incorporating robust data validation protocols early in the research process, researchers can minimize bias and prevent the inclusion of inauthentic data, strengthening the reliability of findings. This study should be interpreted as a cautionary case rather than a prescriptive template. Without verified contact lists or other forms of participant validation, open online surveys will remain vulnerable to contamination despite the use of screening methods.

Acknowledgments

Artificial intelligence tools were used to assist with technical tasks such as formatting tables and supporting code refinement during data analysis. All analytic decisions, code implementation, result verification, and manuscript content were developed and reviewed by the authors.

Funding

This research was supported by a grant from the Ontario Ministry of Health to the Health System Performance Network (#694). The funders had no role in data analysis, decision to publish, or preparation of the report.

Data Availability

The datasets that were created and analyzed during this study are not publicly available, as public data sharing was not included in the original research ethics approval and participant consent form. Deidentified data may be made available for research purposes upon reasonable request to the corresponding author, subject to institutional approvals and data-sharing agreements, and provided that participant confidentiality can be maintained.

Authors' Contributions

EH and KM contributed to the conceptualization and methodology of the study, curated the data, and developed and implemented the coding criteria to identify suspected bots (with oversight from WW). EH completed the analysis and drafted the manuscript. KM and WW provided critical revision and editing of the manuscript.

Abstract

Background: Existing work to understand adults' health care experiences has focused on the analysis of patient feedback provided as written responses to after-visit surveys or social media discourse. Often, such written feedback has been studied using natural language processing techniques, such as topic detection and sentiment analysis, to provide coarse-grained insights. Storytelling is a powerful form of communication and may provide insights into factors contributing to gaps in health care outcomes and avenues for improvement. In addition, studying health care experiences using natural language processing techniques has been limited to patients. The experiences of stakeholders, such as caregivers and health care providers, remain underexplored.

Objective: We extract fine-grained insights from health care experiences through narratives collected from patients, caregivers, and health care providers using large language models (LLMs). Topic detection, together with hierarchical summarization of long-form stories from individuals, offers fine-grained insights. Furthermore, the study demonstrates that generated summaries can be evaluated using the LLM-as-a-judge framework and validates the outcomes through comparisons with 2 domain experts.

Methods: Fifty automatically transcribed stories of African American experiences were used to identify topics in their experiences using the latent Dirichlet allocation (LDA) technique. Stories about a given topic were summarized using an open-source LLM-based hierarchical summarization approach. Topic summaries were generated by summarizing across story summaries for each story that addressed a given topic. The generated topic summaries were rated for fabrication, accuracy, comprehensiveness, and usefulness by the GPT-4 model; its reliability was validated against the original story summaries by 2 domain experts.

Results: Whisper-based automatic transcription of audio narrations achieved a Levenshtein score of 6%. Twenty-six topics were identified using LDA and labeled using the LLM in the 50 African American stories. The GPT-4 ratings suggest that topic summaries were free from fabrication, highly accurate, comprehensive, and useful. The reliability of GPT ratings compared to expert assessments showed moderate-to-high agreement (Bennett *S*-score of 0.65 or higher). Our approach identified African American experience-relevant topics, such as health behaviors, interactions with medical team members, caregiving, and symptom management, among others. Such insights could help researchers learn from unstructured datasets in an efficient manner—leveraging the communicative power of storytelling.

Conclusions: The use of LDA and LLMs to identify and summarize the experiences of African American individuals suggests a variety of possible avenues for health research and possible clinical improvements to support patients and caregivers, thereby improving health outcomes.

Introduction

Motivation

Storytelling is a narrative style that captures information beyond objective facts by catering to the beliefs and emotions of both the narrator and the audience. Sharing lived experiences with others through stories can overcome the limitations caused by extreme objectivity in alternatives such as didactic communication [1,2]. Storytelling can successfully share health knowledge [1-4], potentially providing insight into how illness shapes people's lives, promoting behavior change, and suggesting avenues for improving health care [5-11]. Such stories—sharing the topics deemed most important by the storyteller—can suggest innovative avenues for interventions to improve the health care ecosystem. Hence, there is a need for the health informatics community to investigate narratives of health care experiences.

Despite the efficacy of narratives in health care, their usage poses certain challenges. Information stored as oral recordings is less accessible and searchable than structured data. Furthermore, moving from a single anecdote to the derivation of common themes can be expensive and time-consuming. The use of natural language processing (NLP) techniques may help to overcome these challenges. Prior studies have examined structured feedback from patients [12], free-text feedback from social media [13], and electronic health records [14] to identify themes or topics using NLP techniques. Often, topic detection has been paired with sentiment analysis to infer an individual's sentiments toward the topic. Such solutions offer automated approaches for understanding limitations in health care environments, the efficacy of treatment approaches, and overall experiences in patient care to provide tailored solutions [12]. However, existing literature has largely focused on structured, written-language data, with relatively limited exploration of unstructured sources such as spoken-dialogue narratives.

Spoken-dialogue narratives present a unique set of challenges; they are syntactically and semantically different from written language [15], are often lengthy, and tend to cover multiple topics within a single dialogue. Under such conditions, topic-specific sentiment analysis becomes challenging due to the lack of defined topic boundaries in the data. Summarization approaches address this limitation and are also more informative, as they provide fine-grained analysis compared to single sentiment labels derived from conventional sentiment analysis. The recent rapid expansion in applications of LLMs has demonstrated that they excel at summarizing documents across domains (including health care [16]) and have shown their efficacy in understanding spoken language [17]. Thus, they offer an effective solution for summarizing spoken dialogue. Despite their ability to process complex patterns, LLMs are constrained by their input context length. For example, the popular open-source LLM, Llama 3.2, has an input context length of 128K tokens. However, topics tend to cover multiple stories whose lengths often exceed the fixed context length of LLMs. In addition, long-form inputs (commonly encountered in spoken-dialogue narrations) pose a challenge, as they run the risk of forgetting intermediate portions of the document [18]. On the other hand, classical methods are not susceptible to such limitations, especially during inference. In this work, we evaluate the capabilities of LLMs in long-form dialogue understanding by leveraging the advantages of classical methods in topic detection to build a topic-aware summarization model for understanding spoken-dialogue narratives about health care experiences.

In this work, spoken narratives of experiences (referred to as "stories") from the African American population are analyzed to identify underlying topics and summarize issues raised about the storytellers' lived health care experiences. The stories are a subset of those stored in the MyPaTH Story Booth archive (termed Story Booth). We focus on stories by African American storytellers because, compared to White individuals in the United States, African Americans experience worse health outcomes and are less likely to receive health care services [19-26], despite numerous efforts to close such gaps [26-28]. Additionally, storytelling may be a particularly appealing avenue for understanding African Americans' health experiences since the community has a strong oral tradition [4,9,10] and may also foster trust-building [24].

We focus on using NLP techniques on stories of health care experiences to identify possible factors contributing to gaps in health care delivery systems, as well as potential avenues for intervention. Storytellers include patients, caregivers, and health care professionals. Our solution offers insights through fine-grained summaries per topic, compared to existing works that are limited to coarse sentiment outcomes. Topic detection was performed over transcriptions of the long-form spoken-dialogue dataset using latent Dirichlet analysis. The detected topics were augmented with topic labels for clinical interpretability using LLMs. Furthermore, we introduce topic-aware summarization, a hierarchical approach to generate topic summaries through summaries of individual stories by topic (termed topic story summary), extracting the nature of the health care experience by each topic from stories, as depicted in the topic story summaries, using LLM-based summarization.

Background

Attempts to develop automated solutions for topic detection and sentiment analysis often involve manual annotations. One such approach [29] found appointment access and wait times, empathy, explanation, friendliness, practice environment, and overall experiences as frequent topics in patient feedback. Similarly, another study [14] analyzed electronic health records to identify goals of care in patient care. Topic detection was used to identify suicide profiles from 300,000 decedents [30]. Researchers found that suicide profiles broadly covered 5 classes: mental health and substance problems, mental health problems, crisis, alcohol-related, and intimate partner problems, physical health problems, and polysubstance problems. Furthermore, they found demographic shifts in the suicide profiles with time showing an evolving landscape of health care needs. A recent review [12] of NLP techniques to understand patient-experience feedback compared literature in terms of machine learning techniques (supervised vs unsupervised) and data collection approaches (social media vs structured surveys). Among supervised approaches, the Naïve Bayes classifier was

XSL•FO
RenderX

the best performing, while the unsupervised latent Dirichlet allocation (LDA) model was the popular alternative for topic detection. In addition to sentiment detection from human-annotated labels of patient comments, affordable annotation approaches were recently explored [31]. Using LLMs for annotating patient comments revealed that despite their ability to detect in zero-shot and few-shot settings, LLMs underperformed compared to human annotators.

A recent survey [32] confirmed that most existing literature on understanding patient experience is limited to topic detection and sentiment analysis of written feedback. The ease of data collection through the structured written language has led to its popularity in understanding health care experience feedback. Despite its advantages, the use of narrative-based approaches has been limited [32-34]. One study examined supervised models for topic detection in patient-doctor conversations [35]. The researchers used turn-level manual annotations as a gold-standard reference. They varied the input context length for the supervised models and found that topic detection improves with an increase in input context length. Summaries of spoken-dialogue medical conversations between patients and doctors were studied [36] for commercial applications such as note-taking. This line of work, which focuses on summarizing patient-doctor conversations, has been gaining attention in NLP and informatics communities [36,37]. We build upon this work by shifting the focus to the health care experiences of adults, shared through storytelling. Our narratives are focused on the quality of clinical interactions, their outcomes, and the broader impact on the day-to-day lives of patients, providers, and caregivers to identify potential causes and areas of health care disparity.

Our work leverages fine-grained details in participants' conversational style data about their health care experiences. We believe that such details offer a nuanced understanding of problems in the health care experiences of marginalized communities. This is achieved by using a topic-aware hierarchical summarization approach to health care feedback. In the following sections, we describe the dataset, techniques for topic detection, and hierarchical summarization, and present the findings about health care experiences from the generated summaries.

Methods

Dataset

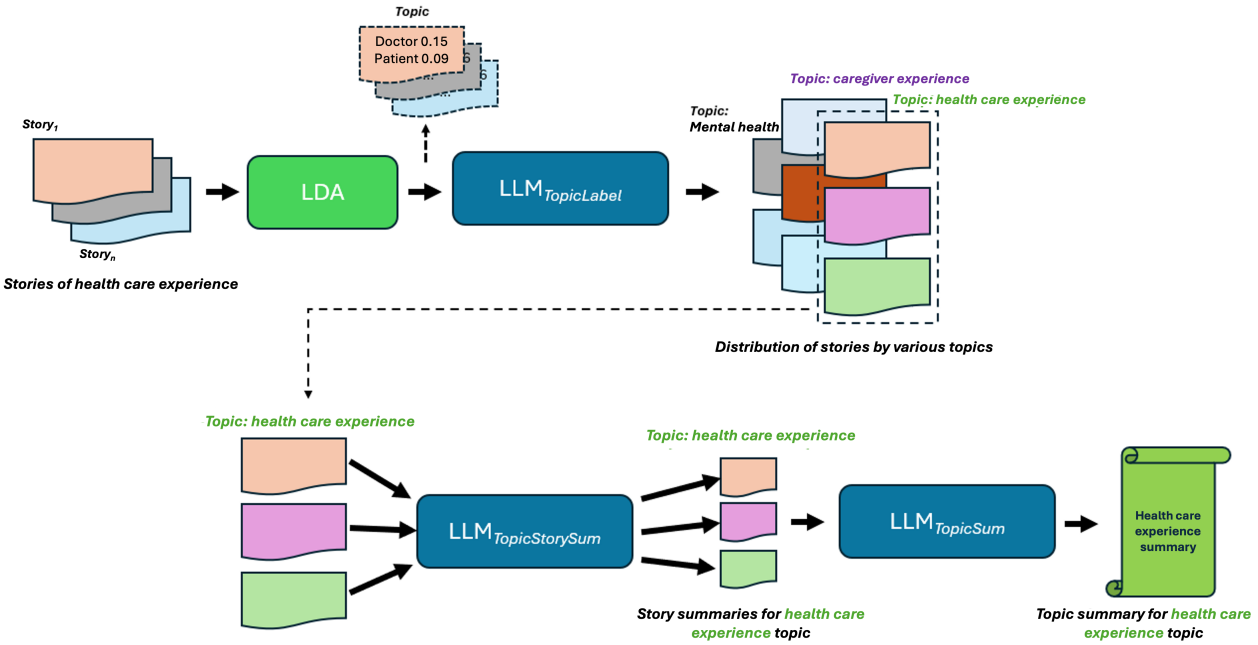
The MyPaTH Story Booth [38] archive is a collection of individual experiences, told from the perspective of a patient, caregiver, or health care provider. Developed as community engagement infrastructure for the PaTH Clinical Research Network, the archive includes over 1500 stories related to experiences with illness, efforts to maintain health, and interactions with health care systems [39]. Story recordings were conducted in-person or by telephone. Participants can opt to share an unstructured story or to answer prompts selected from a preapproved list. They are asked to limit their stories to 20 minutes in length or less. Funding for the MyPaTH Story Booth project was awarded in 2015, and recruitment began in March 2016. Between March 24, 2016, and August 8, 2024, 1266 stories were collected by the University of Pittsburgh Story Booth team; 167 stories were provided by African American participants (n=167, 13.2%). As of February 6, 2026, 1537 stories had been recorded in the archive.

The dataset used in this work is limited to 1120 stories—the full set collected by the University of Pittsburgh staff and fully processed at the outset of this study. From this set, 50 stories from African American participants were randomly selected for summarization and analysis. OpenAI's Whisper model [40] was used for diarization (speaker detection and transcription) of the audio recordings. Due to the limited involvement of the interviewers, we focused only on the participants' statements. We validated the Whisper transcriptions against manual transcriptions from the 50 validation stories to observe 35,030 out of 565,372 character-level changes (insertions, deletions, or substitutions), that is, a Levenshtein distance [41] of 6%. Manual inspection found that the diarization quality was satisfactory and that differences in labeling conventions between manual and automatic Whisper approaches were the major source of diarization errors.

Ethical Considerations

The University of Pittsburgh's Human Research Protection Office reviewed this study (protocols STUDY19020307 and STUDY20110315) and approved it, with a determination of no greater than minimal risk.

Stories in the database are collected with informed consent and recorded as audio files. For privacy, storytellers are instructed to avoid naming people or places. Recorded stories are reviewed, and specific identifiers (eg, names and places) are redacted, but it is possible that voices could be recognized. Narratives are included on the public Story Booth website only with the storytellers' permission. When stories are elicited to learn about the perspectives of a specific population, storytellers are compensated at the rate of US $100 per story. Compensation policies have evolved over time, and earlier stories were collected without compensation.



Analysis

Overview

The method for topic-aware summarization of long-form health care experiences combined classical methods of topic detection with recent advances in LLMs through a multistep process. First, topic detection was performed using the LDA approach [42]. The identified topics were then labeled for interpretability using LLMs, and topic story summaries were generated. Finally, topic labels and story-topic distributions from the LDA were leveraged for topic-aware summarization using a hierarchical summarization approach powered by LLMs. Individual steps are further described in the *Topic Detection and Labeling* and *Hierarchical Summarization* sections. Figure 1 shows various components of the proposed approach.

XSL•FO
RenderX

Figure 1. Various steps in the proposed approach for a topic-aware large language model (LLM) for long-form spoken-dialogue summarization. LDA: latent Dirichlet allocation.

Topic Detection and Labeling

To understand recurring topics from health care experience stories, it was necessary to identify the topics across stories. Topic modeling approaches such as LDA are often the go-to solutions for such problems and are widely used in studying health care experiences, as discussed in the related work. LDA is a probabilistic topic modeling method that captures the likelihood of topics across documents (here, stories) and simultaneously the distribution of words in each topic. LDA was used to detect topics across all 1120 stories from the dataset. The topic detection model was tuned by varying the number of topics between 50 and 1000 in steps of 50. The optimal number of topics was identified using a perplexity criterion on our validation set.

The word distributions in each topic offered a naive understanding of topics. They presented the likelihood of words in each topic but were often hard to interpret. They might also contain contradictory, ambiguous, or unrelated words under the same topic. This issue was more prevalent in the dataset, considering that the participant perspectives included patients, caregivers, and health care professionals, each offering a variety of perspectives, which made understanding the conversational themes more challenging. To overcome this limitation in interpretation, word clouds of topics were labeled using a pretrained Llama-3.1 model [43]. The Llama is an open-source LLM with competitive performance against closed-source alternatives such as GPT-4 [44] and GPT-3.5 Turbo [45]. For all LLM experiments, the 70B parameter model was used due to its long context length of 128K tokens. The inference time was optimized using the *llama.cpp* [46] framework with 4-bit quantization and GPT-Generated Unified Format encoding.

Given the challenging nature of the task, labels for each topic were derived within the context of each story. The LLM input consisted of a story and the word list from the topic-word distribution (Multimedia Appendix 1). The words were ranked in the order of their likelihood in the topic as determined by the LDA. Topic labels derived in the context of a story tend to overfit to a specific story. Moreover, across multiple stories, the topic label was found to be paraphrases of one another. To establish the consistency of topic labels across all relevant stories, the most frequent label of the topic across all stories was chosen as the final topic label.

Hierarchical Summarization

Figure 2 presents a step-by-step overview of the approach. The LDA-identified topics were leveraged to summarize the stories from the validation set. To overcome the input context length limitations, a hierarchical summarization approach was used. The hierarchical summarization approach involved 2 steps. In the first step, topic summarization for each story was performed (Multimedia Appendix 1). This greatly consolidated the input and overcame the limitation of input context length for long-form summarization with LLMs. Following this, individual topic story summaries were further summarized to generate a holistic summary of all the stories under the topic (Multimedia Appendix 1). The hierarchical summarization also offered interpretability through tracing elements of the holistic summary.

Algorithm 1 Topic-aware hierarchical summarization using Large-Language Model

Require: Dataset $D = \{s_1, s_2, ..., s_n\}$ of n stories. D_{valid} is the validation set.
Require: $LLM_{TopicLabel}, LLM_{TopicStorySum}, LLM_{TopicSum}$ be the LLM configured for topic labeling, summarizing a story given topic, and summarizing a topic given one or more story summaries respectively.
Ensure:
$TopicStory, WordTopic \leftarrow LDA(D)$ ▷ train LDA for likelihood for topic-story and word-topic distributions
$TopicStory_{valid}, WordTopic_{valid} \leftarrow LDA(D_{valid})$ ▷ predict likelihood for topic-story and word-topic distributions on D_{valid}
Let $Topics_{valid}$ be the set of topics where $TopicStory_{valid} <= TopicProbThresh$ ▷ TopicProbThresh = 0.05
for topic t in $Topics_{valid}$ **do**
  $TopicLabels \leftarrow list()$ ▷ label for topic t inferred from each story s
  for story s in D_{valid} **do**
    $TopicLabels \leftarrow LLM_{TopicLabel}(storys, WordTopic_{w,t})$
  end for
  $TopicLabel_t \leftarrow mode(TopicLabels)$ ▷ most common label across stories is used as the final topic label
  for story s in D_{valid} **do**
    $TopicStorySum_{t,s} \leftarrow LLM_{TopicStorySumm}(s, TopicLabel_t)$
  end for
  $TopicSum_t \leftarrow LLM_{TopicSum}(TopicStorySum_{t,.}, TopicLabel_t)$
end for
return $TopicSum$

Evaluation

A strong evaluation of generative models was critical to understanding their limitations. Conventional evaluation metrics, such as ROUGE (Recall-Oriented Understudy for Gisting Evaluation) [47], only account for co-occurrence similarity between generated and reference text. Hence, in the context of LLMs, these similarity-based metrics make little sense. LLM-generated content is also prone to a distinct set of challenges, such as hallucinations and inadvertent safety limitations, which are not studied using such conventional metrics. To account for these shortcomings, we used the multidimensional evaluation framework developed with a focus on the quality of information, understanding and reasoning, expression style and persona, safety and harm, and trust and confidence principles, referred to as QUEST [48], to evaluate the generated summaries. The evaluation dimensions for this summarization task include comprehensiveness, fabrication, accuracy, and usefulness.

Human evaluation was often expensive and time-consuming, so the LLM's ability to generate topic summaries was assessed using the LLM-as-a-judge approach. To eliminate self-enhancement bias in LLMs, GPT-4 Turbo was used as the judge. GPT-4 was found to correlate well with human raters and was less susceptible to position bias [49]. Individual topic summaries, together with the respective topic story summaries, were used as input to rate the 4 QUEST dimensions on a 5-point Likert scale (see Table S1 in Multimedia Appendix 2 for the definition of our Likert scale). The reliability of the GPT responses was quantified against 2 domain experts as human raters. Raters were assigned 4 topics (chronic pain management, medical treatment, caregiving experience, and health concerns) to rate the QUEST dimensions on the same Likert scale as the GPT model. Discrepancies in Likert values between the 2 human raters were discussed and adjudicated by those raters to provide a final rating, which was compared to the GPT responses. The Bennett *S*-score [50] was used with quadratic weighting to calculate agreement between the raters and the GPT responses.

Results

Topic Detection and Labeling

The LDA model yielded 150 topics on the training set. For the validation set, we inferred document-level topic distributions and applied a threshold on topic probabilities to identify highly relevant topics for each story and to avoid spurious assignments. For stories where the topic probability did not exceed the threshold, the most likely topic was assigned. This approach allowed us to minimize the adverse downstream effects in the hierarchical summarization pipeline due to incoherent topic assignment. Using this approach, 40 topics were identified in the validation set.

Topic labels for the LDA topics were necessary for the topic-aware summarization approach. Such labels also improved topic interpretability for domain experts. As mentioned in the *Methods* section, the topic labeling approach using LLM resulted in 26 topic labels across all the stories (see Table 1 for topic labels, where the numbers in parentheses indicate the number of stories that address each topic), while the remaining 14 topics were omitted due to the inherent difficulty in labeling topics based on the distribution of words and redundancy among the labels. These topic labels were then used in the summarization step.

Hierarchical Summarization

The topic labels, together with the corresponding stories, were used to generate topic summaries through the intermediate topic story summaries. The results of hierarchical summarization for 2 sample topics are provided in Table 2 (see Table S1 in Multimedia Appendix 3 for summaries from corresponding topics). We found that the summaries for each topic were comprehensive, coherent, and aligned with the topic label derived based on the LDA topic-word distribution.

XSL•FO
RenderX

Table . Sample summaries for 2 different topics from our hierarchical summarization approach.

Topic label	Topic summary
Chronic pain management	Participants dealing with chronic pain management reported various challenges and experiences. Many struggled with inadequate pain management, including ineffective treatments, lack of effective pain medication, and hesitation from health care providers to treat their pain. Some participants felt that their pain was not taken seriously, leading to frustration and increased severity. Others found alternative methods, such as cannabidiol oil, yoga, and herbs, to be helpful in managing their pain. A few participants benefited from working with supportive doctors, pain clinics, and transportation programs that helped them access necessary care. Despite these efforts, many participants continued to experience chronic pain, numbness, and debilitating symptoms, affecting their daily lives and relationships.
Caregiver experience	Caregivers face numerous challenges, including lack of support, financial struggles, and emotional toll. Many participants expressed the importance of compassion, patience, and affection when caring for loved ones, particularly those with dementia or Alzheimer disease. Some participants had to navigate complex health care systems, advocate for their loved ones' needs, and deal with the emotional impact of caregiving. Others appreciated the support of family members, health care providers, and online support groups. Several participants highlighted the need for respite care, financial assistance, and guidance for caregivers. Some also emphasized the importance of acknowledging stress and seeking help. Additionally, participants noted that health care providers should advise patients on healthy living and provide resources for caregivers. Overall, caregiving experiences varied, but many participants shared the common theme of needing more support and resources to effectively care for their loved ones.

Evaluation

We evaluated the generated summaries alongside topic story summaries to perform a human evaluation. Table 3 presents the interrater and GPT-rater agreements derived from our evaluation approach. A moderate-to-high agreement was noticed between the GPT responses and the raters. The level of agreement was particularly strong for the fabrication and comprehensiveness of the generated summaries. This suggested that the GPT evaluation of generated summaries overlapped with human raters and could be used reliably to evaluate the topic-aware hierarchical summarization model. GPT responses for all topics included in the validation set are provided in Table S2 in Multimedia Appendix 2. The accuracy of the generated summaries was consistently good for most topics, except for *diagnosis*, where the generated summary likely changed the interpretation of the topic because of one substantive point within it. The usefulness of the summaries was found to be mostly high, indicating that the approach was promising to use in place of manually identifying themes in the story and summarizing them, as defined by our Likert scale for evaluation. Although these findings were based on 4 topics, together they covered up to 30 stories from the validation set of 50 stories across the 4 QUEST dimensions, thus allowing for diversity both in terms of stories and assessment criteria.

Table . Bennett *S*-score agreement between raters and GPT averaged over 4 topics after adjudication[a].

QUEST[b] dimension	*S*-score (R1, R2)	*S*-score (GPT, R1)	*S*-score (GPT, R2)	$\sum_i$S-score (GPT, R_i)/2
Fabrication	0.94	0.94	1.00	0.97
Accuracy	0.81	0.62	0.69	0.65
Comprehensiveness	0.94	0.94	0.87	0.91
Usefulness	1.00	0.75	0.75	0.75

[a]The score ranges from −1 to 1, where −1, 0, and 1 indicate perfect disagreement, chance-level agreement, and perfect agreement, respectively. *S*-score (A, B) denotes the agreement between raters A and B.

[b]QUEST: quality of information, understanding and reasoning, expression style and persona, safety and harm, and trust and confidence.

In addition to the ratings from experts, their free-form comments suggested that our transcription and summarization processes were error-prone. Errors, such as incorrect dosage units when referring to medication intake ("I take *30 kilos* of medication a day. I used to take *50 kilos* a day"), were due to difficulties and challenges in our Whisper-based transcription approach where "30 pills" was incorrectly transcribed as "30 kilos." Lexical inconsistencies when referring to a single story ("*Many* participants expressed the importance of compassion, patience…" was actually expressed by only 1 person), deviations from the topic of interest, and a lack of cohesion in topic with fewer stories can also be observed.

Discussion

Principal Contributions and Findings

We introduce a computational method using automated transcription, topic modeling, and summarization to extract insights from narratives of health care experiences. It was found that automated approaches provide quality transcriptions when validated against manual transcriptions, and topic modeling identified 26 topics. Some common topics from our dataset include health care experiences, healthy eating, caregiving, doctor-patient relationships, symptom management, cancer treatment, and chronic pain management. Through our summarization approach, we expand the scope of understanding health care experiences beyond the conventional coarse sentiment analysis [12,13,32] to offer details related to clinical interactions, treatment efficacy, and their outcomes from individual narratives. Generated summaries, when assessed using the LLM-as-a-judge framework, were found to be free from fabrication, highly accurate, comprehensive, and useful. LLM assessments of generated summaries concur with expert findings. Our hierarchical summarization approach is particularly useful for extracting such insights from large narrative datasets. The summaries for all 26 topics identified from the narratives can be found in Table S2 in Multimedia Appendix 4.

Topic Detection and Labeling

An important component of our proposed approach is topic modeling using LDA. Among the 150 topics identified in the training set, 40 were present in the validation set. This difference in topic coverage between the training and validation sets could be due to 2 factors. First, the validation set constitutes only about 5% of the training set. Thus, several topics that were observed in the training set may not be sufficiently captured in the validation set. Alternatively, our topic probability threshold prioritized topic relevance over coverage to limit any adverse effect on the downstream hierarchical summarization due to incoherent topic assignments. Interestingly, only 26 out of 40 topics can be labeled for topic names using the LLM. This difficulty in topic labeling was also observed during the early attempts to manually assign topic labels using the topic distribution of words by domain experts. This suggests that both humans and LLMs find it challenging to attribute an interpretable topic label from the high-dimensional representation of topics and words. Despite the modest number of topics, redundancy among the topics is noticeable. Topics such as *health care experience and health care system*, *caregiving experience and caregiving*, *and doctor-patient relationship and doctor experience* are closely related. The authors would like to highlight that such redundancy in topics is an expected outcome of LDA and the choice of hyperparameters; addressing it remains an active area of research in NLP [51]. In addition, this redundancy hinders interpretability for domain experts in designing interventions. We believe ontology-based approaches, such as the graph-sparse LDA [52] or semantic LDA [53], could be explored. Such approaches leverage the structure of the vocabulary to enforce sparsity or capture semantic meaning, which limits such redundancy and improves interpretability. While LDA is a popular choice for topic modeling, it assumes a Dirichlet distribution of topics in a document. Alternatives, such as probabilistic latent semantic indexing [54], may result in different topics. The authors would also like to highlight that, in addition to probabilistic generative approaches, such as LDA and probabilistic latent semantic indexing, the NLP community has also begun exploring LLMs for topic modeling [55,56].

Hierarchical Summarization and Evaluation

The summarization step leverages the superior summarization capabilities of LLMs to offer additional insights into the narratives. The hierarchical summarization overcomes the challenge of the limited input context of LLMs by generating individual topic story summaries, followed by topic summaries for corresponding stories. The evaluation framework addresses the limitations of conventional metrics for summarization, such as ROUGE, by using a multidimensional approach derived from the QUEST framework. It was found that GPT-4 Turbo evaluations concur with human evaluations, and the summaries provided by our approach are comprehensive, accurate, free of fabrication, and useful.

Human evaluation is often expensive and time-consuming. Here, we found that LLMs can help to summarize story contents, identifying several relevant insights and key topics in an efficient and timely manner. However, tradeoffs are involved, such as considerable topic redundancy and uncertainty regarding accuracy in summary details. Maintaining a human element in the evaluation process can help to identify and address such concerns.

Limitations and Future Work

This work also has some limitations. The automatic transcription was evaluated against only a small set of human transcriptions. Findings suggest that minor but critical errors in transcription, such as misinterpreting units of medication (*kilos* for *pills*), propagate to the final summary. Early manual intervention to correct transcription errors, including those due to differences in speaker accents, linguistics, and environmental variables, through a larger dataset remains a future endeavor. Such manual intervention could prevent error propagation to later stages of the pipeline. Recent work [55,56] studied the efficacy of LLMs and prompting techniques on topic modeling, finding that LLMs can identify topics and offer explainability. We believe that this direction may help address the topic redundancy and lack of explainability limitations of conventional topic models such as LDA. The hierarchical summarization uses a 70B parameter Llama LLM due to its demonstrated task generalization performance (eg, 82% in reading comprehension, 93% in math reasoning, and 85% in common sense understanding) and emergent capabilities [57]. However, the rapidly evolving LLM landscape warrants a comparison between alternative choices, such as Qwen [58] and DeepSeek [59], to help identify the optimal model for summarization. The GPT-based approach for summarization evaluation was limited to comparing topic summaries with individual story-topic summaries rather than comparing the topic summaries against the original transcripts. This assumes that the generated story-topic summaries are sufficiently comprehensive, accurate, and free from any fabrication. Future work shall incorporate the human evaluation

XSL•FO
RenderX

of generated topic summaries through comparison with the original stories from each topic to better assess summary accuracy. The quantitative measures of agreement in human evaluation should be interpreted while keeping the limited focus on 4 topics in perspective. The small dataset (50 stories) limits the topic detection and summarization outcomes. However, it reflects a design choice put in place to enable a future analysis directly comparing LLM and traditional qualitative evaluations. Future work shall consider larger datasets collected from different geographical locations and health care infrastructures for a better understanding of experiences. Large-scale datasets could offer greater insights into the health care experience through improved topic coverage and diversity. It is also possible that summarizing larger datasets may lead to an increase in the risk of hallucinations and reduced factuality due to the lack of access to a comprehensive ontology that spans across the health care ecosystem. Evaluating such large-scale systems requires rater agreements to be studied on a large number and variety of topics. However, when selecting topics, care should be taken to avoid the risk of rater fatigue, as a given summary may require assessing tens or hundreds of its constituent stories. Pipeline-based approaches, such as our topic detection followed by hierarchical summarization, are brittle due to error propagation between successive steps (as observed with the transcription error). End-to-end approaches overcome this limitation; we believe that exploring end-to-end approaches by integrating topic modeling together with summarization is another exciting direction for future research.

Conclusions

This work contributes to the health care informatics domain using NLP techniques (topic detection and hierarchical summarization) to offer an understanding of narratives of health care experiences beyond the conventional sentiment analysis approach, which is popular in existing literature on health care experiences. We leverage both traditional and modern NLP techniques, such as LDA and LLMs, to achieve this goal. Using widely accepted quantitative metrics for reliability, it was demonstrated that crucial steps in the proposed approach (such as transcription of audio recordings of the narratives and evaluation of summaries) can be performed with sufficient reliability using recent advances in speech processing and LLMs. We believe that this provides an opportunity to attract interest from the community and accelerate research using narratives to improve health care experiences and health equity through computational methods.

Acknowledgments

No generative artificial intelligence tools were used in the preparation of the manuscript.

Funding

This work is a part of the Story Booth project coordinated by the University of Pittsburgh, and partially funded through Patient-Centered Outcomes Research Institute awards (RI-PITT-01-PS8 and RI-PITT-01-PS1) and National Institutes of Health awards (UL1TR001857, U24TR004111, R01LM014306, and R01LM014588). The views presented in this paper are solely the responsibility of the authors and do not necessarily represent the views of the National Institutes of Health and Patient-Centered Outcomes Research Institute, its Board of Governors, or Methodology Committee.

Abstract

Background: As health care delivery shifts toward value-based care, proactive strategies to close preventive care gaps are essential. However, patient engagement remains suboptimal due to logistical, behavioral, and socioeconomic barriers. Traditional outreach methods, such as phone calls, emails, and postal mail, have long been used, but emerging digital approaches, such as chatbot-based messaging, offer potential advantages in scalability and personalization. Their comparative effectiveness, however, remains underexplored.

Objective: This study aimed to evaluate the effectiveness of chatbot outreach compared with traditional communication methods (phone, email, mail, and multichannel) in promoting compliance with preventive screenings and wellness visits defined by the Healthcare Effectiveness Data and Information Set and the Centers for Medicare & Medicaid Services guidelines.

Methods: This retrospective study evaluated patient outreach campaigns conducted from 2021 to 2023 across an integrated health system in New York. The final analytic sample included 50,145 care gaps from 41,959 eligible participants, predominantly female (29,989/50,145, 60%), White (31,857/50,145, 64%), with mean age ranging from 49.36 to 72.81 years over the study period. All participants were residents of New York state, and 81% (40,553/50,145) maintained an active relationship with a primary care provider during the participation year. Outreach modalities included automated chatbot SMS text messages, nonautomated phone calls, and organization-led email or mail campaigns. Participant data were enriched with social vulnerability scores to account for community-level disadvantages. Exposure was defined as the outreach method (chatbot, phone, email, mail, or multichannel), with assignment based on engagement history and operational protocols. The primary outcome was care-gap closure or compliance with identified measure gaps annually. Logistic regression and chi-square analyses examined associations between outreach method, patient demographics, primary care physician relationship, social vulnerability index (SVI), and compliance.

Results: Phone outreach consistently achieved higher compliance than chatbot or multichannel outreach across most groups and years. Chatbot messages outperformed phone calls only in diabetes care in 2023 (odds ratio [OR] 1.81, 95% CI 1.48-2.21; $P<.001$). Primary care physician continuity remained a strong predictor of gap closure, especially in primary care (ORs ranged 1.36-2.61; $P<.001$). Higher SVI quartiles were associated with lower compliance in blood pressure, cancer care, and diabetes care groups; however, primary care outcomes showed higher odds of compliance in the third quartile of SVI, contradicting the typical linear-deprivation narrative. Women, Hispanic or Latino individuals, and Asian patients demonstrated higher odds of compliance in some groups and years.

Conclusions: Outreach modality is an important, modifiable factor in preventive care adherence. While phone-based outreach remains the most effective overall approach, chatbot-based strategies may have targeted applications in digitally engaged

XSL•FO
RenderX

populations such as the diabetic group. Segmented, equity-informed outreach strategies that integrate technology, patient preferences, and primary care continuity are essential to achieving high-impact, scalable outcomes in value-based care settings.

KEYWORDS

chatbot outreach; digital health; health communications; health equity, preventive care gaps; value-based care

Introduction

Background and Rationale

The development of health care delivery in the United States over the past decade has increasingly centered on value-based care (VBC), which emphasizes quality, outcomes, and cost-effectiveness over service volume. Promoted by the Centers for Medicare & Medicaid Services (CMS), the value-based preventive care concept represents a focused application of the VBC framework that prioritizes proactive prevention and early disease detection, aligning financial incentives with population health goals [1,2]. This approach is particularly relevant for managing chronic diseases and addressing preventive care needs in large, diverse patient populations [3].

Despite widespread consensus on the benefits of preventive services such as annual wellness visits, cancer screenings (CXs), diabetes care (DB), and blood pressure (BP) monitoring, patient adherence remains suboptimal [4-6]. Barriers to engagement include socioeconomic challenges, low health literacy, lack of awareness, and fragmented communication between care providers [7,8]. Health systems have historically used outreach methods such as telephone calls, emails, and postal mail to notify and engage patients with gaps in preventive care. However, these approaches can be resource-intensive and vary in their reach and effectiveness, particularly among hard-to-engage populations [9].

Emerging digital outreach tools, including automated chatbots and SMS text messaging, may offer a promising alternative for improving engagement at scale. These technologies can support bidirectional communication, personalize patient interactions, and reduce administrative burdens [10]. Several public health campaigns, particularly during the COVID-19 pandemic, have demonstrated the feasibility of chatbot-based outreach in promoting vaccine uptake and disseminating timely health information. However, the use of these tools for broader preventive care engagement, particularly in chronic disease management and CX, remains underexplored [11].

Based on a previous systematic review conducted on this topic by Chacko et al [11], the current state indicates a limited body of evidence on chatbot outreach beyond immunization programs, highlighting a need for further research into their effectiveness, cost-efficiency, and equity impact. Studies reporting on outreach mechanisms for preventive care have varied in their implementation approaches and study methodologies. Therefore, drawing a generalizable conclusion is not possible. It is uncertain if benefits of chatbot outreach apply uniformly across various demographic and clinical groups. Moreover, the integration of these tools into large health systems workflows may present unique challenges that remain underexplored in the literature [11].

Objectives

To address these gaps, this study aims to evaluate the impact of emerging technology, such as chatbot-based outreach, on preventive screening uptake compared to conventional methods, such as outreach via phone calls and email communications. The authors posited that the use of chatbots in preventive care will significantly increase the uptake of screening for annual wellness visits, hypertension, diabetes, and CXs compared to traditional methods of communication. Conducted at a large integrated delivery network in New York, the study focused on patients identified as having care gaps using the Healthcare Effectiveness Data and Information Set (HEDIS) and CMS preventive screening criteria. This study builds upon recent findings that suggest automated outreach tools may offer scalable and equitable solutions for preventive health engagement [11]. By evaluating their effectiveness across multiple screening domains, which included CXs, DB, and hypertension screening, along with primary care (PC) measures such as annual wellness visits, the study contributes to the growing body of evidence informing digital outreach strategies in VBC-aligned care delivery. Findings from this evaluation may help guide future investments in digital health infrastructure and support the implementation of targeted, technology-enabled outreach programs.

Methods

Study Design

This study retrospectively evaluated data collected from VBC outreach activities conducted over a 3-year period, from 2021 to 2023. Members identified by their insurance carrier as having care gaps, attributed to the health system, were targeted for outreach. Outreach was conducted using phone calls, web-based chatbots, email messages, mailed letters, and sometimes a combination of these methods. The strategy for outreach method allocation was dependent on operational capacity and technology adoption. During year 1 (2021), due to reduced operational capacity following the 2020 pandemic year, new technology was piloted to aid in outreach. The subsequent years' attribution strategy was adjusted to maintain a balance between outreach methods with increased volume of gaps, capacity in the workforce, and efficiencies found in technology adoption. Multichannel outreach involves the sequential use of 2 or more methods within the same measurement year when initial outreach attempts fail to result in engagement. Due to the inability to attribute the outcome to any single method alone, outreach using multiple methods was grouped into 1 category. Outreach method assignments followed operational protocols

XSL•FO
RenderX

and capacities that varied each year, rather than being randomized. Therefore, this study is exploratory in nature, focused on understanding trends that may drive empirical decisions about the modality of outreach in the future.

Data Sources

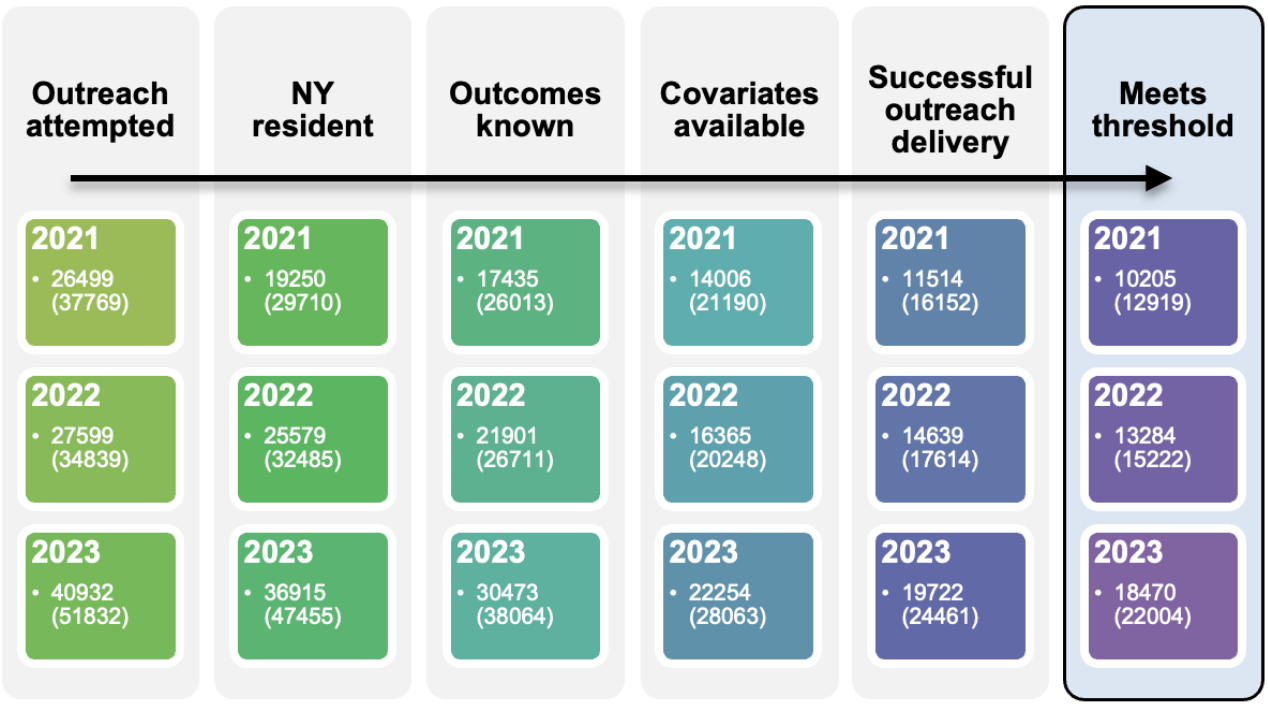
Participant demographic information was collected from the health system's electronic medical record (EMR). Outreach process measures and final compliance data were collected 3 months post each study year from the respective operational teams performing outreach. These data included an indicator for participant relationship with primary care provider (PCP) within the health system and the total number of care gaps for the given year per participant. Deidentification was completed before the data were shared with researchers. The social vulnerability index (SVI) was acquired from the 2022 dataset compiled by the Centers for Disease Control and Prevention [12]. The census tract level SVI was mapped to participant zip code with the aid of cross-mapping from the Department of Housing and Urban Development, accessed in June 2024 [13].

Inclusion Criteria

Participant eligibility for the identified gap measures was a primary inclusion criterion. Clinical criteria for eligibility are industry-defined guidelines (electronic Clinical Quality Measures), maintained by CMS [14], or HEDIS specifications provided by the National Committee for Quality Assurance [15], with changes published each year publicly. These define the required age ranges, diagnosis inclusion, and completion intervals for preventive services such as wellness visits, CX, BP, and DB. The other important criterion determining inclusion in the final analysis was having at least one outreach attempt using a phone, chatbot, email, or letter during the measurement year. As the study focused on understanding the efficiency of outreach methods, the population that received no outreach was outside the scope of this study.

Exclusion Criteria

Preventive measure groups and individual measures with an insufficient sample size (n<10) were excluded due to the need for valid statistical and comparative testing. Records with unknown outcomes (ie, unverified or missing documentation of care gap closure) or missing demographic variables (age, gender, race, ethnicity, and address [needed for SVI grouping]) were excluded. For example, if there was no known address for the patient documented, it would not be possible to map an SVI and include the participant in the stratified analysis, and therefore, such participants' data were removed from all study datasets before any analysis was conducted. Process measures such as documented patient engagement steps (eg, message opened or call answered) were collected and used to define successful outreach delivery. Unsuccessful outreach deliveries (eg, in case of erroneous contact information) were excluded.



The dataset remained representative of the population served by the health system and met eligibility criteria for each measure throughout this process. Four measure groups remained eligible for analysis after the applied exclusions: PC, BP, CX, and DB. Multimedia Appendix 1 provides the distribution of participants and measure gaps within each group.

Data Management

Deidentified data were aggregated at the patient-gap-year granularity using Microsoft Power BI [16]. Individual preventive measures were grouped into care domains (eg, PC, CX, etc) based on clinical relevance and alignment with HEDIS and CMS quality measurement categories. The grouping was determined by the study team using established measure definitions to facilitate domain-level comparisons. The case of multiple SVIs mapped to a single participant due to geographic overlap in the data was resolved by assigning the SVI from the most populous county to the participant, which is a common approach in health care research. Figure 1 shows the flow of participants and gaps volume through the applied exclusions.

XSL•FO
RenderX

Figure 1. Participant and measure gap flow diagram for each year in the study, listing participant volume first and gaps (n) in parentheses. NY: New York.

Study Variables

The primary independent variable, also referred to as the outreach method or intervention, was coded as 1 of the 4 single-channel methods (phone, chatbot, email, and mail) or multichannel to indicate any combination of these methods. Multichannel methods were grouped because the sample sizes in individual groups did not meet the statistical validity requirements for comparison.

The primary outcome or dependent variable evaluated was the completion of or compliance with the identified measure, measured 3 months following each study year (eg, March 2022 for the study year of 2021). It was documented separately for each year of the study, 3 months post end of year, and represented as a binary variable, indicated by 1 for "yes" and 0 for "no." The primary outcome was collected as part of the operational process of verifying completion of or compliance with the measure gap within the reporting period. This may include a verification by patient report, EMR validation, or a confirmation by payor data sharing. The authors collected this information retrospectively from data reported to governing agencies for each year.

Demographic data, including age, gender, race, ethnicity, and the SVI, were used to study covariates that could potentially impact the outcomes of outreach. Additionally, covariates included the presence of an active relationship with a PCP (defined as having a designated PCP of record within the health system and at least 1 documented encounter with that provider or associated practice within the preceding 18 months) and the burden of unmet care (defined as the total count of gaps for each participant per year).

Among the continuous variables, age was capped at 89 years to prevent reidentification. The count of gaps variable was used to assess potential imbalances in record weighting within the grouped measure files, as the datasets were analyzed at a gap level (n=1 gap per participant) rather than at a participant level. Tables S1-S4 in Multimedia Appendix 2 demonstrate the range and mean of the count of gaps per year for each measure group.

Categorical variables included demographic factors, gender, race group, ethnicity, socioeconomic factors, SVI, and active PCP relationship. Gender was coded into male/female as collected in the EMR. Race was grouped into White, Black or African American, Asian, and other. The other race group included Pacific Islander, Alaskan, and Native Americans, as well as patient self-reported "other" race identity. Ethnicity was only collected as a bivariate containing options for Hispanic and Latino or not Hispanic or Latino. Each participant was assigned an SVI quartile (1-4), where quartile 1 was the group with the least social vulnerability, and quartile 4 was the group with the most social vulnerability.

Statistical Analysis

All statistical analyses were conducted using IBM SPSS Statistics for Windows (version 29.0) [17]. The dataset was divided into measure-group files for each year. Analysis was performed for each measure group, with BP as an exception because it contained only 1 measure. Textbox 1 provides a list of subgroups (measures) within each measure group that were included in the final analysis. Descriptive statistics and contingency tables verified adequate cell counts (n≥10) for bivariate analyses per measure group, and any variables not meeting the threshold were excluded from final analysis for the respective measure group [18,19]. Notably, SVI quartile 2 often did not meet the valid n threshold, as was the case when the outreach method was email only. These were excluded from statistical analysis. This conservative approach ensured the robustness of the reported associations while maintaining data

XSL•FO
RenderX

integrity across all measure groups. Effect sizes are reported as odds ratios (ORs) with 95% CI and *P* values. Categorical variables were converted into dummy variables using reference coding (eg, phone outreach, male, White, non-Hispanic/Latino, SVI quartile 1, and no active PCP as baseline categories) before logistic regression analysis.

Textbox 1. Measure groups and subgroups 2021-2023.

Primary care

- Annual wellness visit
- Pediatric well-care visit

Blood pressure (single measure only)

Cancer screening

- Breast cancer screening
- Cervical cancer screening
- Colorectal cancer screening

Diabetes care

- Hemoglobin A1c control <8.0% in diabetes
- Hemoglobin A1c poor control >9.0% in diabetes
- Hemoglobin A1c testing in diabetes
- Nephropathy assessment
- Retinal eye examination
- Kidney health evaluation for participants with diabetes

Collinearity was assessed between included variables, which led to the exclusion of the insurance group from the final analysis due to its high correlation with age in this dataset. Chi-square tests identified preliminary predictors among the categorical variables, after which a 2-step backward stepwise logistic regression was performed. Step 1 entered all demographic variables and PCP relationship. Step 2 introduced outreach modality to quantify its independent association with the final compliance outcome, that is, gap closure after controlling significant covariates in the previous step. A chi-square test was also conducted between the PCP relationship variable and outreach methods to examine any existing associations before both were included in the regression model. Statistical significance was set at α=.05.

Ethical Considerations

The Northwell Institutional Review Board reviewed this study protocol and approved it on August 15, 2024 (HSRD24-0151), with a waiver of consent requirements in accordance with research involving deidentified secondary data. No patient contact or intervention occurred as part of the study, and all data were fully anonymized prior to analysis. To minimize analytic bias, eligibility and exclusion criteria were applied consistently using standardized definitions from HEDIS and CMS electronic Clinical Quality Measures.

Results

Participant Characteristics and Descriptive Statistics

After applying exclusions, the analytic dataset contained 12,919, 15,222, and 22,004 care gaps for 2021, 2022, and 2023, respectively, bringing the overall volume of gaps to 50,145. Gap volumes increased by approximately 18% (15,222/12,919) in 2022 and 45% (22,004/15,222) in 2023, with PC accounting for 47% (23,481/50,145) of gaps, CX 31% (15,335/50,145), BP 12% (5891/50,145), and DB 11% (5438/50,145). A total of 81% (40,553/50,145) of gaps came from participants who had an active relationship with the PCP during the participating year. Women predominated in all groups except diabetes in 2021-2022, and the cancer cohort showed an expected skew due to female-targeted measures. Among the 50,145 gaps, participants mostly belonged to the White racial group at 64% (31,857), followed by other 18% (8812), Black at 12% (6230), Asian at 6% (3246), and Hispanic/Latino at 16% (8199). The mean age for the PC group declined from 72.8 (SD 11.6) years in 2021 to 60.2 (SD 27.1) years and 49.4 (SD 30.5) years in 2022 and 2023, respectively, resulting from the gradual inclusion of the pediatric subgroup. All other measure groups had a mean age range from 56.4 to 66.3 years. The average gaps per participant were below 2 for all measures except DB, which had 2.9 gaps per participant in 2021, 2 in 2022, and 2.2 in 2023. See Multimedia Appendix 2 (Tables S1-S4) for detailed distribution for all 3 years.

Outreach included phone, chat, email, and multichannel approaches. Email was only valid for PC in 2021 and DB in 2023. Multichannel cohort met criteria in PC and CX across all years and DB and BP in 2023. Outreach shifted from phone-dominated in 2021 to greater chatbot and multichannel use by 2023. Multimedia Appendix 2 displays this trend with detailed values for each group.

XSL•FO
RenderX

Compliance Trends and Bivariate Associations

Multimedia Appendix 3 indicates the compliance rate for all 3 years across the measure groups. All measure groups indicate the highest compliance rate in 2021 and a subsequent decrease in 2022. While other measure groups have increased compliance in 2023, possibly indicating a postpandemic stabilization, compliance in the BP group continues to decrease this year. This decrease, however, is relative, as BP continues to be the group with the highest compliance rate each year (1042/1486, 70% to 1440/2550, 56%), while CX is the group with the lowest compliance rate (1698/4264, 40% to 1600/7656, 21%).

Across all measure groups, the outreach method showed a significant association with compliance. The PC group demonstrated the strongest relationship in 2021 with a large effect size (χ^2_3=1767.8; *P*<.001; V=0.57). Though this association persisted for all 3 years, its magnitude decreased, showing a moderate effect size in 2022 (χ^2_2 =220.3; *P*<.001; V=0.16) and 2023 (χ^2_2=409.5; *P*<.001; V=0.21). A significant but weak association was observed for the DB group in 2021 (χ^2_1=10.1; *P*=.001; ϕ=0.08) and a moderate effect size emerged in 2023 (χ^2_3=41.3; *P*<.001; V=0.14). The CX group showed a significant association in 2022 (χ^2_2=14.1; *P*<.001; V=0.10) and 2023 (χ^2_2=70.2; *P*<.001; V=0.10), though effect sizes remained weak throughout. BP had significant but weak associations between intervention and outcome for all 3 years. All significant chi-square test results are listed in Table 1, along with the analytic sample size. A complete report on all variables is available in Multimedia Appendix 4.

[a]PCP: primary care provider.

[b]SVI: social vulnerability index.

The PCP relationship was significantly associated with preventive care gap closure across several measure groups. In the PC group, a moderate association was observed in 2021 (χ^2_1=270.8; *P*<.001; ϕ=0.22), with significance maintained through 2023 (*P*<.001; ϕ=0.17). In the BP group, associations were significant in 2021 (χ^2_1=6.8; *P*=.009; ϕ=0.07) and stronger in 2022 (χ^2_1=135.7; *P*<.001; ϕ=0.27) but not sustained in 2023. The DB group followed a similar pattern, showing small but significant associations in 2021 (χ^2_1=29.9; *P*<.001; ϕ=0.13) and 2022 (χ^2_1=7.2; *P*=.007; ϕ=0.07), which was not sustained in 2023. The CX group showed inconsistent results, with weak associations in 2021 (χ^2_1=8.2; *P*=.004; ϕ=0.03) and 2023 (χ^2_1=4.4; *P*=.04; ϕ=0.02).

The association between SVI and compliance showed dynamic patterns across years. SVI demonstrated a consistent association with compliance in the BP group for all 3 years, peaking in 2022 with the strongest effect size (χ^2_3=21.7; *P*<.001; V=0.11). In contrast, the CX group (χ^2_2=17.0; *P*<.001; V=0.05) and the DB group (χ^2_2=18.6; *P*<.001; V=0.09) showed this association in 2023 only, both with small effect sizes. The same association weakened over time in the PC group, with significant, weak associations observed in 2021 (χ^2_2=25.2; *P*<.001; V=0.07) and 2022 (χ^2_2=10.4; *P*=.006; V=0.04), and no significant association detected in 2023.

Race was significantly associated with compliance in the PC group across all years, but effect sizes were negligible (Cramer V ranged from 0.04 to 0.08). A similar near-zero association was observed for the CX group (V=0.004) in 2022 only. Ethnicity demonstrated small but consistent associations with PC compliance in 2022 (χ^2_1=41.4; *P*<.001; ϕ=0.07) and 2023 (χ^2_1=46.8; *P*<.001; ϕ=0.07). In the CX group, ethnicity was associated in 2022 (χ^2_1=15.4; *P*<.001; ϕ=0.07) with a small effect, and in 2023 with a weaker effect (χ^2_1=6.1; *P*=.01; ϕ=0.03). No significant associations with race or ethnicity were observed in the DB or BP groups.

A significant but small and diminishing association between gender and compliance was noted in the PC group across all 3 years, with effect sizes ranging from 0.02 to 0.04. For the BP and DB groups in 2022 only, gender was significantly associated with compliance with weak effect sizes. Gender associations in the CX group are not reported because most measures in this group specifically targeted women.

Regression Analysis of Compliance Predictors

After adjusting for other significant predictors, the outreach method remained significantly associated with compliance. Compared with phone call outreach, chatbot outreach consistently reduced the odds of gap closure across PC, BP, and CX measures, with a 30%-65% decrease in likelihood, as shown in Figures 2-4. An exception was observed in the DB group in 2023, where chatbot outreach outperformed phone calls (OR 1.81, 95% CI 1.48-2.21; *P*<.001). Multichannel campaigns were generally less effective than phone calls and chatbot outreach, except in the CX group in 2021, where multichannel outreach increased the odds of gap closure compared with phone calls (OR 2.12, 95% CI 1.01-4.44; *P*=.047). This was likely a reflection of the relatively smaller sample size that year, whereas subsequent years had greater representation of multichannel outreach, yielding narrower CIs.

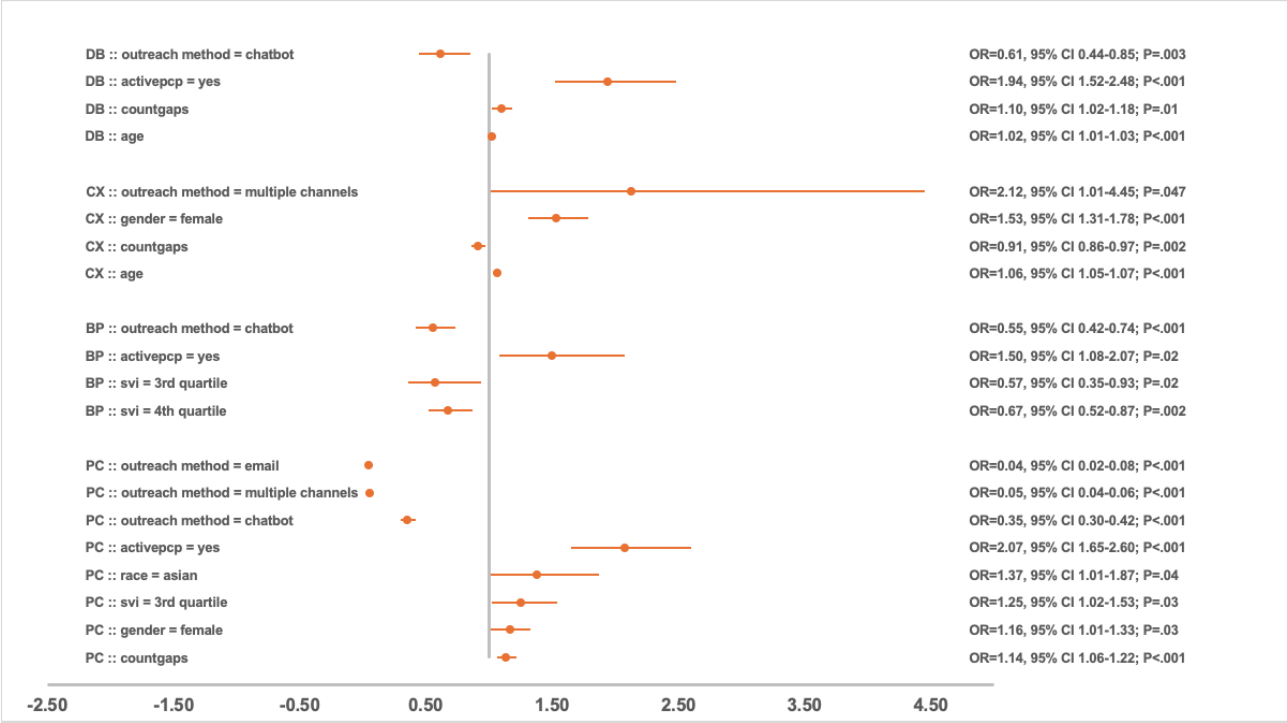
Figure 2. Odds ratio and 95% CI by significant predictors and measure group in 2021. BP: blood pressure; CX: cancer screening; DB: diabetes care; OR: odds ratio; PC: primary care; PCP: primary care provider; SVI: social vulnerability index.



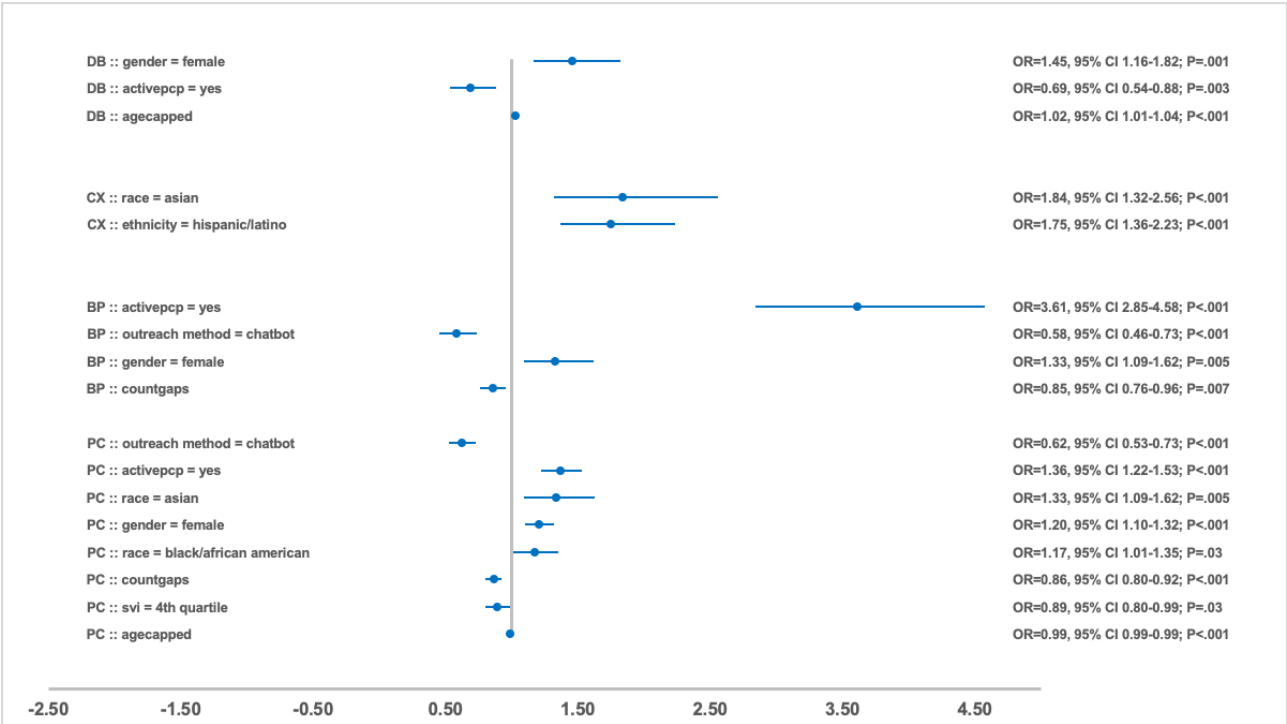


Figure 3. Odds ratio and 95% CI by significant predictors and measure group in 2022. BP: blood pressure; CX: cancer screening; DB: diabetes care; OR: odds ratio; PC: primary care; PCP: primary care provider; SVI: social vulnerability index.

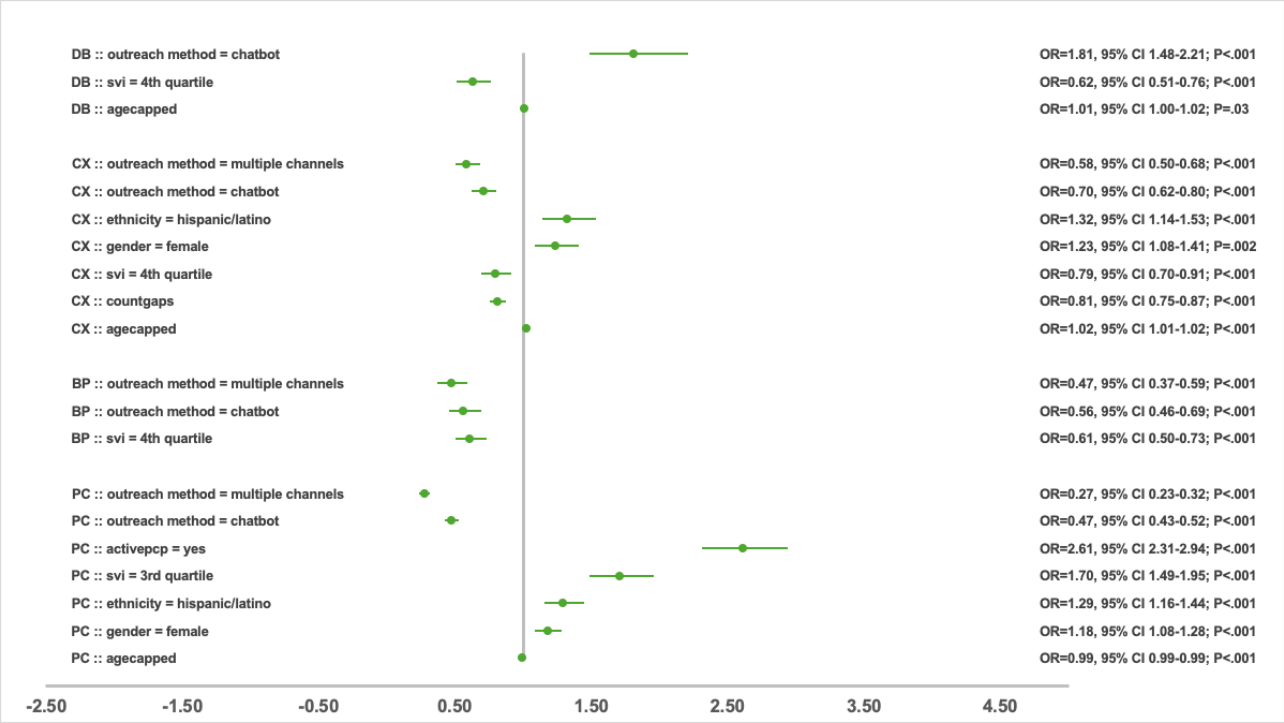
Taking account of other covariates, having a PCP relationship was the strongest predictor (P<.001) for care gaps compliance in the PC measure group, with ORs 2.07 (95% CI 1.65-2.60), 1.36 (95% CI 1.22-1.53), and 2.61 (95% CI 2.31-2.94) for 2021, 2022, and 2023 respectively. BP and DB had similarly significant associations in 2021 (BP: OR 1.50, 95% CI 1.08-2.07; P=.02; DB: OR 1.94, 95% CI 1.52-2.48; P<.001) and 2022 (BP: OR 3.61, 95% CI 2.85-4.58; P<.001; DB: OR 0.69, 95% CI 0.54-0.88; P=.003), but this association was not sustained in 2023. The final model for the CX group did not surface the PCP relationship as a predictor.

The SVI quartile demonstrated a complex relationship with compliance in the PC group. Participants in the third quartile were more likely to close gaps in 2021 (OR 1.25, 95% CI 1.02-1.53; P=.03) and 2023 (OR 1.70, 95% CI 1.49-1.95; P<.001) compared with the less vulnerable first quartile. In

XSL•FO
RenderX



contrast, in 2022, participants in the fourth quartile were less likely to close gaps (OR 0.89, 95% CI 0.80-0.99; *P*=.03) relative to the first quartile group. For the BP group, lower odds of gap closure were observed among the third quartile (OR 0.57, 95% CI 0.35-0.93; *P*=.02) and fourth quartile (OR 0.67, 95% CI 0.52-0.87; *P*=.002) in 2021, as well as the fourth quartile in 2023 (OR 0.61, 95% CI 0.50-0.73; *P*<.001). Similar patterns were noted for the CX and DB groups in 2023, where participants in the fourth quartile had reduced odds of closing gaps (CX: OR 0.79, 95% CI 0.70-0.91; *P*<.001; DB: OR 0.62, 95% CI 0.51-0.76; *P*<.001).

Women in the PC group had higher odds of compliance than men across all years, with ORs of 1.16 (95% CI 1.01-1.33; *P*=.03) in 2021, 1.20 (95% CI 1.10-1.32; *P*<.001) in 2022, and 1.18 (95% CI 1.08-1.28; *P*<.001) in 2023. Higher odds of gap closure for women were also observed in 2022 for the BP group (OR 1.33, 95% CI 1.09-1.62; *P*=.005) and DB group (OR 1.45, 95% CI 1.16-1.82; *P*=.001).

Asians were more likely to close gaps in PC group during 2021 (OR 1.37, 95% CI 1.01-1.87; *P*=.04) and 2022 (OR 1.33, 95% CI 1.09-1.62; *P*=.005) compared with White participants. They also showed higher odds of compliance in the CX group in 2022 (OR 1.84, 95% CI 1.32-2.56; *P*<.001). Race and ethnicity were not retained in the final model for BP and DB across all 3 years. However, ethnicity had a positive influence compliance in the CX group in 2022 (OR 1.75, 95% CI 1.36-2.23; *P*<.001) and 2023 (OR 1.32, 95% CI 1.14-1.53; *P*<.001), as well as in the PC group in 2023 (OR 1.29, 95% CI 1.16-1.44; *P*<.001).

Increasing age (capped at 89 years) showed a small, diminishing association with compliance. In the DB group, each additional year of age was associated with 1%-2% higher likelihood of gap closure, while in the CX group, the increased likelihood was 6% in 2021 and 2% in 2023. In contrast, in the PC group, older age was associated with a 1% lower likelihood of closing gaps in 2022 and 2023. Age was not a significant predictor in the final BP models across all 3 years. All percentage values for likelihood are reported based on the OR values in Figures 2-4.

Figure 4. Odds ratio and 95% CI by significant predictors and measure group in 2023. BP: blood pressure; CX: cancer screening; DB: diabetes care; OR: odds ratio; PC: primary care; PCP: primary care provider; SVI: social vulnerability index.

An increase in the number of gaps was associated with a higher likelihood of gap closure in the DB group only in 2021 (OR 1.10, 95% CI 1.02-1.18; *P*=.01), with no significant effects observed in later years. Unlike the DB group, BP and CX groups showed an inverse relationship, where each additional gap decreased the likelihood of compliance (BP 2022: OR 0.85, 95% CI 0.76-0.96; *P*=.007; CX 2021: OR 0.91, 95% CI 0.86-0.97; *P*=.002; CX 2023: OR 0.81, 95% CI 0.75-0.87; *P*<.001). The PC group demonstrated inconsistency, with more gaps increasing the odds of compliance in 2021 (OR 1.14, 95% CI 1.06-1.22; *P*<.001) but decreasing them in 2022 (OR 0.86, 95% CI 0.80-0.92; *P*<.001). ORs, 95% CIs, and *P* values for all variables with significant association in the final regression models are presented in Figures 2-4 across the 3 years. Each point in these figures represents the OR for the listed cohort and variable group on the left, and the line through the point represents the CI. The actual numbers for OR, CI, and *P* value are listed on the right side. Reference values for each category include male, White, non-Hispanic/Latino, SVI first quartile, no active PCP, and phone outreach. Any subgroups excluded due to low volume (<10) for the year are not included in the regression analysis.

Model discrimination, as assessed by the area under the receiver operating characteristic curve (AUC), was highest for the PC measure group in 2021 (AUC=0.82), indicating good

XSL•FO
RenderX

discriminatory ability. Other measure groups demonstrated modest discrimination, with AUCs ranging from 0.59 to 0.68 across years. In 2021, the model also achieved the highest classification accuracy for the PC group (78.6%), while the classification accuracy for other groups varied, ranging from 70.6% (BP) to 63.5% (CX) and 67% (DB).

Across all models, chi-square statistics were significant (P<.001), suggesting that the models were statistically associated with the outcomes. Nagelkerke R^2 values, reflecting the proportion of variance explained, were highest in 2021 for the PC group (R^2=0.41) and lower for other models, ranging from 0.02 to 0.13. Calibration, as assessed by the Hosmer-Lemeshow goodness-of-fit test, showed acceptable fit for some models (eg, CX in 2022 and 2023: P=.85 and P=.98; DB in 2022 and 2023: P=.34), but poorer fit in others (eg, PC in 2023: P<.001), indicating room for improvement in predicted versus observed outcomes alignment. Complete model diagnostics are provided in Table 2.

Table 2. Final regression model metrics for each measure group, 2021-2023.

Year and measure group	Chi-square (*df*)	*P* value	Nagelkerke R^2	*P* value (Hosmer–Lemeshow)	Overall classification accuracy, %	AUC[a]
2021

Discussion

Key Findings

Outreach modality remains the key modifiable lever for influencing preventive care gap closure strategies. However, its impact is declining in the PC group across the 3 years, is marginal in the BP and CX group, and needs continued studies in the DB group to establish a trend and sustained evidence of association. In VBC, where outreach for gaps in care is conducted at scale, even smaller effect sizes are worth noting, as they highlight the need for ongoing research to further understand nuances between measure groups and outreach technology preferences for optimizing operational efficiencies.

Among the outreach methods, phone calls demonstrated a stronger positive impact on outcomes compared to chatbots. This may be attributed to the chatbot's deterministic, rule-based design, which lacks the interactivity and adaptability of more advanced artificial intelligence (AI)–powered conversational agents. These results are also in agreement with the recent findings from McDowell et al [20], who presented health communication preferences from their study to show that while the majority of participants preferred SMS text messaging communication in interactions with family and friends, their preference in communicating with health care providers was primarily by use of the phone call. Even though the chatbot design for this study was a web-based chat conversation, it was initiated through an SMS text message seeking consent for further communication. As noted by Fanaroff [21], SMS text messaging–based communication, though universally accessible, may face barriers in health communications due to privacy laws such as the HIPAA (Health Insurance Portability and Accountability Act)–related security constraints imposed during implementation, which can create barriers like requiring multiple clicks to get to the core of the message. This can erode patient trust in digital health technologies, especially as incidences of

XSL•FO
RenderX

SMS text message phishing attacks have increased in the last 5 years [22]. The 2023 diabetes group exception may point to a self-management culture within DB, suggesting potential for enhanced impact through digital engagement. It certainly points to a need for segmentation by measure groups when designing outreach strategies, as well as a need for further exploration of the underlying factors driving these emerging behavioral patterns.

Sustained PCP relationships more than doubled the odds of closing gaps in PC, reinforcing the understanding that it facilitates preventive measures and use in agreement with previous findings [23]. However, the effect reversed for diabetes in 2022, suggesting disease-specific pathways (eg, endocrinology follow-up may supplant the PCP role for glycemic monitoring). The lack of association between PCP relationships and BP, DB, and CX in the 2023 regression models suggests that outreach strategies should be customized by measure and specifically address the distinct impact of PCP relationships within each measure group.

Socioeconomic vulnerability appears to be an emerging barrier. The strengthening association and effect size for this covariate in the BP group over time suggest that an equity-focused resource allocation for hypertension is warranted. The association that emerged in the CX and DB groups in 2023 cannot be ignored. These results are consistent with evidence that shows neighborhood-level disadvantage suppresses screening adherence, with Montgomery et al [24] presenting one recent example of such evidence in a cancer cohort. However, the differential effect between third and fourth quartile participants in the PC group contradicts the usual linear-deprivation narrative. This highlights the need to study community-level resilience factors and changing attitudes toward PC since the 2020 pandemic.

Other demographic predictors had a relatively smaller impact. Race and ethnicity became significant variables for PC and CX outcomes in 2022 and 2023 with small effect sizes. Specifically, the positive direction of the OR for minority groups like Asians and Hispanics is surprising and suggests the need for further targeted research into culture-based practices that promote positive outcomes, so outreach strategies can be culturally tailored for better effectiveness. Gender effects in the PC group are consistently small but show higher odds of compliance among women, agreeing with prior findings [11]. In contrast, gender effects in the BP and DB groups are inconsistent across the 3 years, while interpretation within the CX group is limited due to 2 of its 3 measures being restricted to female participants.

The overall compliance rate difference between the various measure groups does indicate some weight for the burden of completion. For example, the BP measure can be completed with a single PCP visit during the year, whereas CX measures require multiple engagements with health care, which may include imaging appointments or laboratory work in addition to follow-up visits. Complex measures should be complemented with additional support or touchpoints for optimal outreach strategies.

Limitations

This study has several limitations that should be considered when interpreting the findings. First, although the analysis draws from a large sample of individuals with preventive care gaps, the retrospective observational design limits the explanatory power of the findings. Additionally, the outreach method distribution was not uniform across measure groups; for instance, email-only and multichannel outreach cohorts did not consistently meet inclusion thresholds, restricting comparative analyses within certain subgroups. Because outreach assignments followed operational workflows rather than randomization, some selection bias may exist. Exclusions for incomplete or low-volume subgroups were applied to ensure valid statistical testing and consistent data quality. While these steps may modestly limit generalizability, the retained sample remained representative of the health system's attributed population, supporting the internal validity of findings. Generalizability is therefore most applicable to similar real-world VBC settings.

An additional limitation of this study was the presence of unmeasured variables that may account for differences in the efficiency of outreach methods. Factors such as participants' language preference, digital literacy, barriers to completion, comorbidities, and other psychosocial or contextual influences were not consistently captured across all outreach methods, likely contributing to the limited variance explained by several models. Although classification accuracy was acceptable in some cases (eg, 78.6% for PC in 2021), lower performance metrics, including the area under the receiver operating characteristic curve (eg, 0.59 for CX in 2022), indicate potential model under specification. Future research should incorporate more granular clinical, behavioral, and sociodemographic variables to enhance understanding and optimization of outreach effectiveness.

Recommendations for Practice

Even though this is not a randomized trial, the findings from this study apply to a large representative population, therefore several practical recommendations can be made to enhance the design and implementation of outreach strategies for value-based cohorts. Phone calls consistently outperformed chatbots and multichannel campaigns in driving preventive care gap closure across most measure groups and years. Health systems should continue to prioritize phone-based outreach, particularly for high-impact measure groups such as PC, while evaluating digital methods as supplementary rather than primary channels until they are more effective or better personalized. The study highlights meaningful variations in outreach effectiveness by measure group and socioeconomic status. To maximize effectiveness, outreach strategies should be customized according to the specific clinical area and complexity of the care gap, such as differentiating approaches for PC, chronic disease management, and more complex screening measures. For example, the stronger performance of chatbot outreach in the DB group in 2023 suggests that measure-specific digital readiness may guide outreach channel selection.

We also recommend enhancing chatbots for better engagement. Chatbots are an emerging technology that offers better

XSL•FO
RenderX

scalability than phone calls. The rule-based design of the chatbot used in this study likely limited its effectiveness. Transitioning to more advanced, AI-powered conversational agents that support interactive dialogue and user personalization could improve patient engagement and outcomes [25].

Socioeconomic vulnerability was a significant and increasing barrier to care gap closure, particularly in the BP group. Health systems should adopt equity-focused outreach strategies that prioritize high-SVI communities for additional support, such as community health worker involvement or tailored messaging. This is especially important in measure groups with heavier burdens of completion, like CX or chronic disease monitoring.

The relatively low explanatory power of the models underscores the need to expand the range of included variables. Incorporating clinical data (eg, comorbidities and medication adherence), behavioral factors (eg, health beliefs and prior screening history), and social determinants of health (eg, transportation access and housing stability) could significantly enhance the precision of predictive models used to guide outreach prioritization.

Conclusion

In conclusion, this study found that there is variability in the effectiveness of chatbots in outperforming traditional outreach methods for preventive screenings. The findings confirm that outreach modality continues to be a key, modifiable factor in closing preventive care gaps, with phone-based outreach consistently outperforming chatbots and multichannel strategies across most measure groups. However, the effectiveness of each outreach method varied notably by clinical context and patient subgroup, highlighting the need for a segmented outreach design that accounts for differences in patient preferences, health conditions, and burden of gap completion. The limited effectiveness of deterministic, rule-based chatbots points to the potential value of transitioning to more adaptive, AI-enabled engagement tools, particularly those capable of personalized communication and responsiveness to digital literacy. Socioeconomic vulnerability remained a key barrier, with differing trends between the third and fourth SVI quartiles indicating that vulnerability is not a linear predictor of behavior. Incorporating structured data on preferences, barriers, and comorbidities will improve model accuracy. Future research using prospective, randomized designs should further evaluate outreach modality, language, and communication preferences to guide inclusive, high-impact preventive care.

Acknowledgments

The authors would like to recognize the contributions of Mathew Sabu for data cleaning, deidentification, and analysis support during the early stages of this study.

The authors would also like to acknowledge the use of artificial intelligence tools, such as the built-in Microsoft text editor and Grammarly, to refine and clarify text that was primarily written by humans in the preparation of this manuscript.

Funding

This study did not receive external funding. The analysis was conducted as part of an operational quality improvement initiative at Northwell Health and as a component of the author’s doctoral dissertation at Rutgers University, with academic oversight provided by faculty advisors.

Data Availability

The datasets analyzed in this study were derived from health system operational data and accessed under applicable data use agreements that restrict public dissemination, even in deidentified form. Due to such contractual, ethical, and governance constraints, the data are not publicly available. Access may be considered upon reasonable request to the corresponding author and is subject to approval by the data-owning institution and execution of an appropriate data use agreement.

Authors' Contributions

JC led the conceptualization and project administration of the study and was responsible for data curation, formal analysis, visualization, and writing of the original draft. Conceptualization and methodology were jointly contributed by JC, YJ, KS, KM, DK, MD, and LC. Investigation and interpretation of findings were conducted by JC, YJ, KS, and LC. Data curation and resources were supported by KS and DK. Supervision and methodological oversight were provided by YJ, LC, KM, and MD. Writing, review, and editing were performed by all authors. All authors reviewed and approved the final manuscript and agree to be accountable for all aspects of the work in accordance with the International Committee of Medical Journal Editors and CRediT taxonomy guidelines.

Conflicts of Interest

Some authors are employed by Northwell Health, which supported this study as part of internal evaluation and quality improvement activities. Other authors are affiliated with Rutgers University as doctoral student or faculty and contributed to the study

Abstract

Background: As the core documentation of the clinical diagnosis and treatment process, the quality of medical records is directly related to medical safety and efficiency. However, traditional manual quality control (QC) has limitations such as limited coverage, low efficiency, and inconsistent standards, making it difficult to meet the high standards of modern hospitals.

Objective: The purpose of this study was to develop a medical record QC platform based on AI technology and to build a multilevel QC system relying on the platform to comprehensively improve the form and content of electronic medical records (EMRs).

Methods: This study established a QC rule database based on relevant medical record writing standards, combined deep learning and natural language processing technologies to build an AI-driven QC engine, designed a 4-level QC and management process, and implemented the system in a comprehensive tertiary hospital in China.

Results: After applying AI for the first level of QC, the coverage rate of automated initial screening of EMRs reached 100%. On this basis, combined with manual participation in the second to fourth level of QC, a new model of medical record quality management was formed, featuring human-machine collaboration, interaction between QC units and clinical departments, efficient closed-loop operation, and equal emphasis on form and connotation. The completeness, timeliness, consistency, and accuracy of EMRs significantly improved, while various indicators, such as the grade A rate and excellent rate, continued to increase (all P<.001).

Conclusions: This study demonstrated that the implementation of an AI-based 4-level QC management model helped overcome the limitations of traditional manual QC methods to a certain extent, facilitated comprehensive, dynamic, and closed-loop management of EMRs, and effectively improved the overall quality of medical records. This model can provide a reference for other hospitals seeking to reform their QC models.

KEYWORDS

medical record quality; AI; 4-level quality control; full-process quality control; closed-loop management

Introduction

With the continuous advancement of medical informatics, electronic medical records (EMRs) have been widely used in medical institutions. As repositories of medical data such as patient disease information, diagnosis processes, and treatment plans, EMRs are not only the cornerstone of clinical decision support systems and medical insurance payments but also the legal basis for handling medical disputes and a source of information for hospital teaching and scientific research. Improving the quality of EMRs plays a key role in ensuring patient safety, enhancing medical quality, and increasing hospital operational efficiency. In recent years, the National Health Commission of China has successively issued a series of relevant

XSL•FO
RenderX

documents, including *Key Points of Core Systems for Medical Quality and Safety* [1] and *Quality Control Indicators for Medical Record Management* (*2021 Edition*) [2], which put forward requirements for the quality of medical record writing. The *Action Plan for Comprehensive Improvement of Medical Quality* (*2023-2025*) [3] issued in 2023 lists the medical record quality improvement project as a special action, emphasizing the core tasks of improving the connotation quality, integrity, and timeliness of medical records; strengthening coding management and medical record quality training; and standardizing medical record writing. At the same time, it points out the objectives of improving the quality and safety management system and mechanism while enhancing the degree of refinement and scientificity. Therefore, how to take effective quality control (QC) and management measures to further improve the timeliness, completeness, and accuracy of EMRs has become a focus of attention for many hospitals.

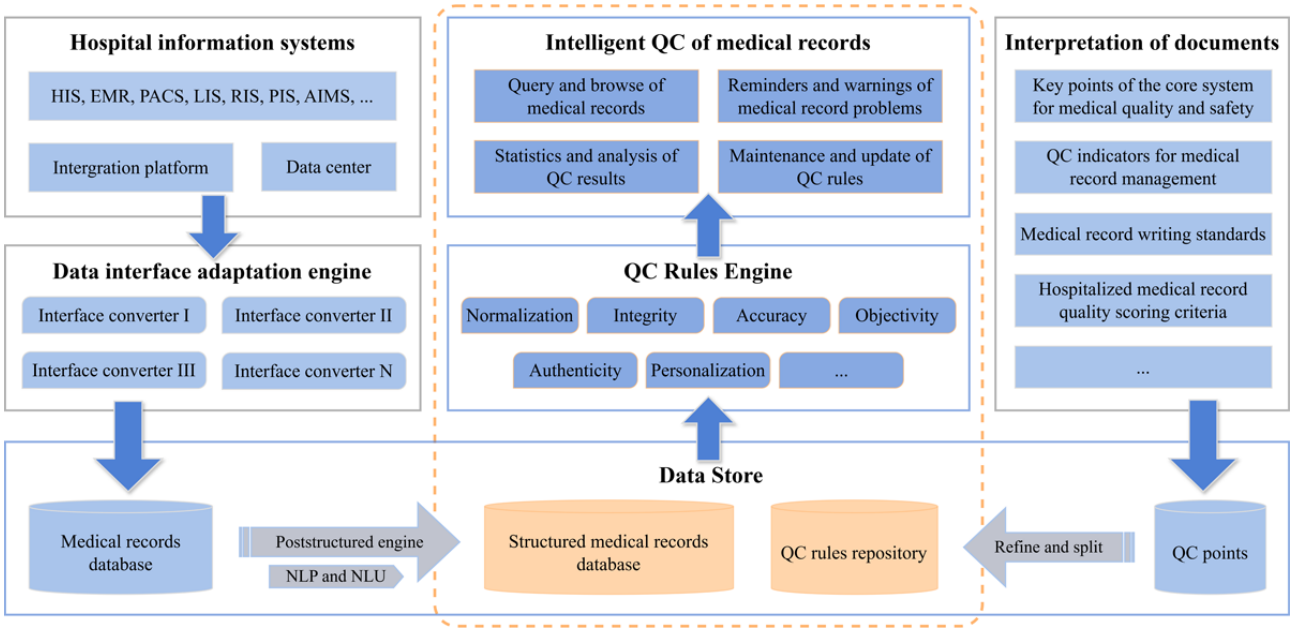
However, the traditional QC of EMRs in China still faces many challenges [4-8]. Multiple platforms, such as the hospital information system (HIS), laboratory information system (LIS), and picture archiving and communication system (PACS), are often independent of each other, and the problem of data islands is serious, which increases the workload of medical record QC. Clinicians' overreliance on the automation advantages of the EMR system often leads to problems such as input errors and repetitive contextual content, and it is difficult to track and solve such medical record quality risks in real time using a QC model that emphasizes terminal review while ignoring the process. The summary of the various QC outcome indicators mainly relies on manual statistics, which has the disadvantages of being slow speed and poor accuracy, so it is impossible to carry out timely, targeted medical record quality improvement according to comprehensive and accurate feedback. In addition, the weak awareness of clinicians' standardized writing of medical records, the lack of professional competence of medical record QC staff, and the lack of a related supervision system are also important factors influencing the effect of QC.

To address the aforementioned issues, some studies have explored the optimization of EMR QC methods. Song et al [9] analyzed the internal quality problems of medical records in their hospital by sampling 10 medical records every month and carried out thinking and explored aspects such as medical record writing training, improvement of archiving processes, and team building. Li [10] adopted the Plan-Do-Check-Act cycle method, which includes making plans, strict implementation, repeated inspections, and scientific treatment, for the management of medical record quality problems to improve the situation of medical record defects. A tertiary hospital in Chongqing summarized and processed various indicators and combined data cleaning, quantitative classification, and natural language processing (NLP) technology to achieve automatic detection of medical record QC indicators [11]. Although these measures improved problems with medical record writing to some extent, there were still limitations, such as insufficient use of AI technology, low participation of relevant personnel, and disconnection between the system and management. Therefore, to further enhance the efficiency of QC, this study built an intelligent QC management platform based on technologies such as NLP and machine learning. Relying on the platform, a 4-level QC system and a closed-loop management model were constructed to overcome the limitations of traditional QC and form an innovative AI-assisted QC (AI-QC) paradigm, thereby achieving continuous and systematic improvement in the quality of medical records.

Methods

Research Setting and Team Composition

This study was conducted at a large, comprehensive, tertiary-level hospital in Zhejiang Province. The project team consisted of 2 working groups. One was a platform construction group composed of platform architects, information technology experts, and data engineers, which was mainly responsible for the development, maintenance, and optimization of the system. The other was a collaborative management group composed of QC experts, medical record managers, clinicians, and medical information coordinators, which was mainly responsible for medical record quality monitoring, result analysis, and cross-departmental liaison.



Design and Build an Intelligent Quality Management System

The platform adopted a 3-layer modular design consisting of a data layer, a processing layer, and an application layer, with 3 engines of automated acquisition, intelligent structuring, and rule-based QC as the core (Figure 1). First, the relevant national and provincial regulations and standards for medical record QC were interpreted, and the key QC points were refined and categorized based on the specific needs of our hospital to establish QC rules. A multilayer validation mechanism was used to ensure the rationality and feasibility of these rules: the collaborative management group conducted multiple rounds of professional reviews to confirm clinical applicability and standardization; the platform construction group performed retrospective testing on historical medical records to verify technical executability and logical accuracy; and pilot operations were carried out in selected departments to evaluate the practical application of the rules, with dynamic adjustments made to the rule points based on feedback from clinicians. As a result, a customizable and optimized QC rule repository was formed, covering dimensions such as timeliness, completeness, consistency, standardization, and objectivity, with each rule assigned a specific deduction score. Second, the medical record database was formed by integrating data from existing hospital systems, such as EMR, HIS, LIS, PACS, and the surgical anesthesia system. Poststructured processing of medical record documents, such as free text, pathology reports, and test results, was performed using NLP techniques such as medical word segmentation, entity recognition, multimodal data alignment, and contextual semantic understanding [12,13]. The entity types and attributes were defined based on international and domestic clinical standard terminology, while cross-modal knowledge extraction and relationship establishment were combined with deep learning methods to form a disease knowledge graph [14,15]. Finally, using the QC rules engine, real-time analysis, comparison, judgment, and feedback for noncompliant or discrepant medical record content were carried out, and a

XSL•FO
RenderX

visualization module for QC results was developed to support auxiliary clinical applications, QC management, and medical research.

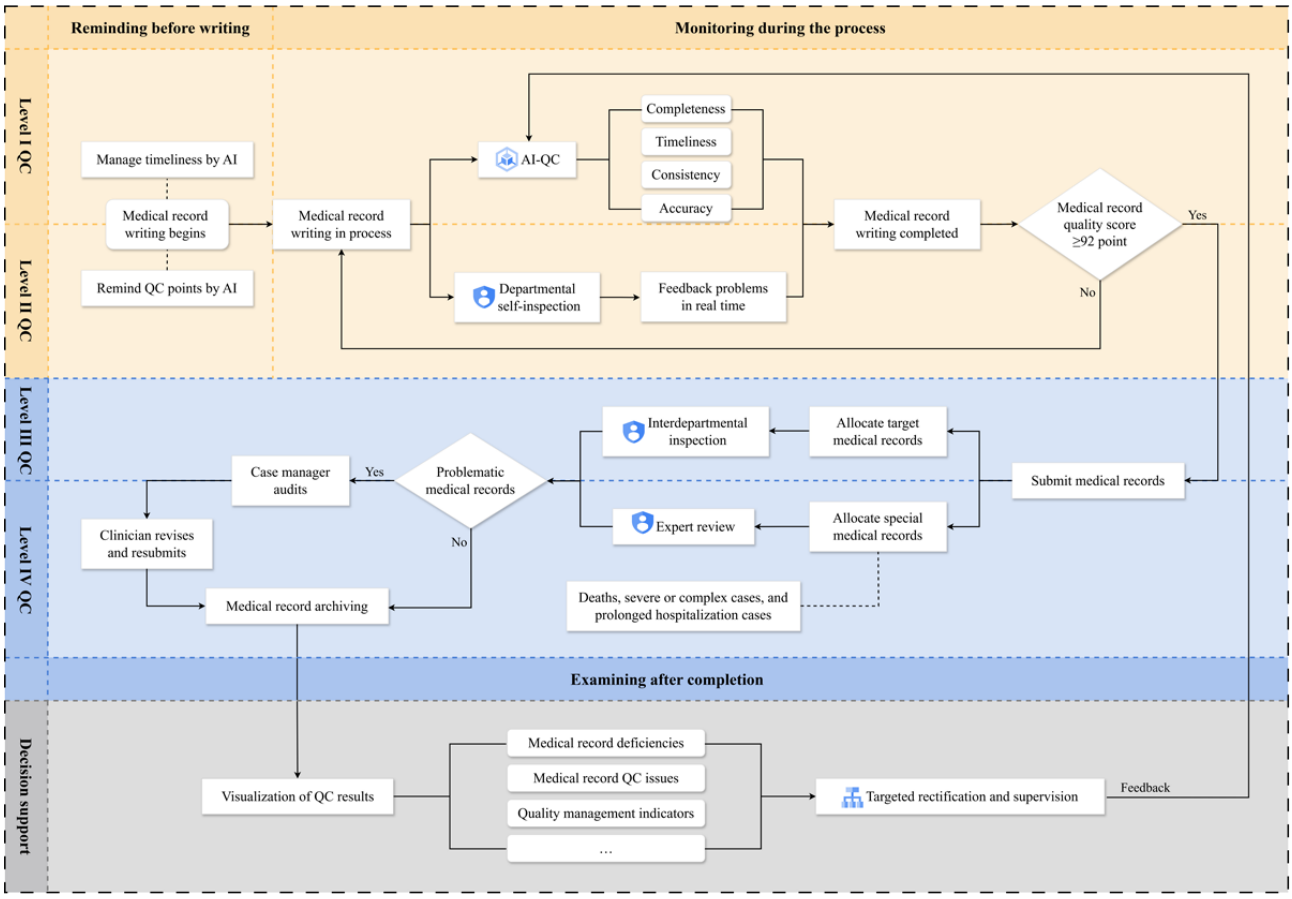
Meanwhile, during the system construction process, we carefully set the minimum score threshold for medical record submission by comprehensively considering national industry norms, policy requirements, and the risk management needs of our hospital. The specific basis is as follows. First, the *Basic Norms for Medical Record Writing* issued by the National Health Commission of China in 2010 require that medical records meet core quality criteria, such as completeness, timeliness, and standardization [16]. On the basis of these guidelines, medical institutions have developed quantitative scoring tables, typically setting 90 points as the passing threshold for grade A medical records, indicating that the records contain no major defects [17,18]. This score has become a widely accepted standard in China. Second, the *Evaluation Standards for Tertiary Hospitals* (*2022 Edition*) explicitly stipulate that medical institutions must undergo regular quality assessments, with the compliance rate for grade A medical records serving as a core evaluation indicator [19]. To actively respond to the national evaluation policy, our hospital needed to set corresponding score requirements for medical record submission. Finally, our hospital's internal data reports over the years indicated that medical records with scores below 90 points were significantly associated with higher coding error rates, insurance claim rejection risks, and medical dispute occurrence rates. To strengthen risk prevention and control, this study raised the medical record submission threshold from 90 points to 92 points to further improve the overall quality of medical record writing. Additionally, it should be noted that current AI technology cannot fully replace human judgment in identifying all potential issues. Therefore, even if a record passes the AI-established threshold of 92 points, it is still possible for it to be ultimately classified as a grade B record following manual review.

Form a Medical Record QC Process



Through the operation of the rule base in the intelligent QC system for medical records, the full-process QC of EMRs was achieved, including reminders before writing, supervision during the process, and review after completion. When clinicians start writing medical records, they are intelligently reminded of the QC rules applicable to the documents being created, and time-sensitive management is implemented for instruments with time-limited requirements. In the process of writing medical records, real-time monitoring of the writing situation is carried out according to the preset QC rules, and early warnings and prompts are provided for the identified problems to achieve continuous supervision, reminders, and feedback to improve the standardization of writing. At the end of writing, a cutoff value of 92 points is used to assess whether the record can be submitted, thus reducing the number of single-item rejected medical records. After the medical records are submitted, based on intelligent QC rules and assisted by manual screening, automatic feedback and manual revision are carried out for problematic medical records to complete the final QC.

Establish a 4-Level QC System and Closed-Loop Management Model

The QC management model was optimized based on the intelligent QC management platform and the full-process QC method of EMRs (Figure 2).

XSL•FO
RenderX

Figure 2. The 4-level quality control (QC) system and management model of AI-driven electronic medical records (EMRs). AI-QC: AI-assisted quality control; level I QC: the first level of quality control; level II QC: the second level of quality control; level III QC: the third level of quality control; level IV QC: the fourth level of quality control.

The first level of QC was AI review, which embedded the rule engine into the physician's medical record writing system and intelligently verified various medical record documents, such as admission records, checkup records, surgical records, and informed consent forms. When missing key fields, conflicting time nodes, and nonstandardized terminology were detected, reminders and warnings were provided through hovering pop-up windows to avoid the generation of grade C medical records. The second level of QC was departmental self-inspection, which relied on the QC management platform to formulate a sampling allocation strategy for medical records in operation and conducted in-depth intradepartmental self-inspection of medical record documents with the medical team leader as the core. After writing problems were identified, the results of the inspection were fed back to the physicians in real time through the platform, and they were encouraged to make timely corrections, thereby effectively reducing the incidence of grade B medical records. The third level of QC was an interdepartmental inspection. Through the QC management platform, a random sampling strategy for discharge medical records was generated based on predefined department matching rules, enabling cross-departmental audits. These matching rules were collaboratively established by medical record QC specialists, medical record management personnel, and clinical department directors (Multimedia Appendix 1). After the results of mutual checking were fed back to the case management team, the case managers carefully reviewed the records and returned the medical records with problems to the clinical team for correction, thereby improving the excellent rate of medical record quality. The fourth level of QC consisted of expert review, and the experts from the medical record management committee carried out spot checks of the discharge medical records of patients who had died, had severe and complex conditions, or were hospitalized for a long time. At this stage, QC mainly focused on the internal quality of EMRs, including the accuracy of diagnosis, comprehensiveness of condition analysis, and rationality of treatment plans, drawing on the rich theoretical knowledge and clinical experience of experts to further strengthen the internal quality of medical records.

At the end of the monthly 4-level QC work, the case manager used the dashboard in the QC management platform to conduct intelligent statistical analyses of the medical record defect details, document quality scores, and other indicators, and visualize them according to different departments, medical groups, and QC nodes. They then took corresponding corrective measures depending on the results of the analysis, including perfecting the QC points, clarifying the reward and punishment mechanism, and updating the relevant assessment system. At the same time, the implementation effects of these management decisions were recorded and analyzed by the system, which guided the focus of QC in the next cycle. Eventually, a closed-loop scientific management model was formed, covering problem monitoring, intelligent analysis, precise intervention, and effect tracking.

XSL•FO
RenderX

Statistical Analyses

In this study, categorical data were expressed as frequencies and percentages. The Cochran-Armitage trend test was used to analyze changes in medical record quality indicators over time. To further evaluate the practical clinical and managerial significance of the improvements, the absolute risk difference and its 95% CI were also calculated, with the 95% CI estimated using the Newcombe method. All analyses were performed using R software (version 4.2.1; R Foundation for Statistical Computing), and a 2-sided test of $P<.05$ was considered statistically significant.

Ethical Considerations

This study was approved by the Ethics Committee of Zhejiang Provincial People's Hospital (QT2025135), which waived the requirement for written informed consent because the procedures were part of routine care and did not involve personal or private information. No financial compensation was provided, as this study did not involve direct participant enrollment.

Results

Since its application, the 4-level QC management model for EMRs based on AI has gradually covered all clinical departments of the hospital. It formulated 285 standardized QC rules and 2393 related QC points, achieving 100% QC coverage of the documents. The 4 major issues of completeness, timeliness, consistency, and accuracy in EMR writing significantly improved after AI-QC (Figure 3). Several indicators also significantly improved. For instance, compared with December 2023, the 2-day archiving rate of discharged patients in December 2024 reached 98.10%, an increase of 2.86% year over year. Meanwhile, the signing rate of informed consent forms rose from 99.55% to 99.75%, and the incidence of unreasonable medical record copying dropped from 3.26% to 0.69%. The quality assessment results of the randomly inspected special medical records showed that, with the passage of time across the 3 stages before, during, and after the application of the 4-level QC system, the rate of grade A (z score=13.64; $P<.001$) and the excellence rate (z score=3.88; $P<.001$) of medical record quality showed an upward trend. The rate of grade B (z score=−13.64; $P<.001$) showed a significant downward trend (Table 1). The effect size analysis (Table 2) indicated that the proportion of grade A increased by 9.34% (95% CI 5.34%-13.28%) in the early stage and further increased by 15.61% (95% CI 12.93%-18.46%) in the later stage, resulting in a cumulative improvement of 24.95% (95% CI 21.92%-28.06%). Correspondingly, the proportion of grade B cumulatively decreased by 24.95% (95% CI −28.06% to −21.92%). The excellent rate improved by 2.40% (95% CI 0.56%-5.40%) in the early stage and continued to rise by 3.96% (95% CI 0.50%-7.45%) in the later stage, achieving a cumulative increase of 6.36% (95% CI 3.13%-9.67%).

[a]ARD: absolute risk difference.

The hospital incorporated training on medical record quality into regular management, including regularly holding specialized training lectures, conducting discussions and learning sessions on medical record quality scoring norms, and organizing medical record knowledge competitions. It also developed the Medical Record Quality and Management Manual and released it on the enterprise WeChat (Tencent Holdings Limited) and the hospital's online platform. In addition, the hospital clearly defined multiple requirements for medical record writing, reward and punishment schemes, and supervision and feedback systems, and improved the corresponding standard documents, such as the Medical Record Quality Management System and the Medical Record Quality Assessment System.

Discussion

The quality of medical records is one of the key indicators for performance assessment of national public hospitals and an important reflection of the medical level and comprehensive strength; ensuring and improving the quality of medical records has always been a core task of hospitals at all levels. To overcome the shortcomings of the previous QC model, we established and implemented a 4-level QC and management system based on AI in a tertiary public hospital in Zhejiang Province.

The results of this study showed that after the implementation of the AI-assisted 4-level QC management model, the completeness, timeliness, consistency, and accuracy of EMR writing were effectively improved, and multiple QC indicators of medical records increased, with the overall quality of medical records steadily improving. The effect size analysis further quantitatively supported the practical value of the model at the clinical and management levels. The rate of grade A medical records cumulatively increased by 24.95%, indicating that the basic quality of medical documents was systematically enhanced, which was directly related to the reduction of medical safety and compliance risks. At the same time, the excellent rate cumulatively increased by 6.36%, indicating that quality improvement surpassed the defect correction stage and was steadily moving toward deeper internal quality and excellence standards. These achievements benefited from the in-depth application of information technology and the collaborative optimization of the management system. First, the intelligent QC platform was able to conduct a census of the entire hospital's operating medical records, with 100% QC coverage of EMRs. The preset QC rules engine in the system provided real-time monitoring, reminders, and feedback for medical record problems. This system extended QC from retrospective to concurrent and prospective stages, improving the previous situation of focusing on the end rather than the process. It comprehensively and efficiently reviewed problems that existed in the entire process of medical records from creation to submission. Examples include first attending physician checkup records that were not completed within 48 hours; missing pathology report results in the course of the records; entering the "left side" in the disease information incorrectly as "right side"; and discharge times on the first page that were inconsistent with those in the discharge record [20]. Second, compared with the single-level model in previous studies, which only combined AI-QC with random checking by case managers, the multilevel QC process we constructed had unique advantages. The millisecond response efficiency and session intervention of the first level of QC not only controlled the quality of medical records from the source but also significantly reduced human resource requirements and improved the efficiency of QC. The second level of QC further identified the rationality of the diagnosis and treatment logic that was difficult for AI to determine through the self-inspection mechanism of the medical team. At the same time, it highlighted the supervisory responsibility of the medical team leader and encouraged physicians within the team to actively participate in medical record management. In the third level of QC, surgeons were more likely to identify logical loopholes in documentation, such as the assessment of surgical indications and prevention of postoperative complications, when checking the medical records of physicians, whereas physicians paid more attention to the rationality of perioperative medication and the continuity of chronic disease management when reviewing surgical records. Such complementary review perspectives resulting from professional differences helped overcome the limitations of self-checking and expanded both the breadth and depth of medical record QC. At the fourth level of QC, the in-depth analysis of special medical records by experts accurately identified detailed and underlying errors, such as insufficient diagnostic basis, missing differential diagnoses, and diagnostic and treatment plans that were not in line with the latest guidelines, thereby promoting further enhancement of the internal quality of EMRs. Finally, under the closed-loop scientific management model, we implemented targeted rectifications for key areas, such as standardizing physicians' medical record writing, building a medical record management team, and improving standardized systems, which complemented the QC process and ultimately contributed to the continuous improvement of quality and the dynamic optimization of management.

XSL•FO
RenderX

We accumulated extensive operational experience in the practical application of the 4-level QC management model and developed corresponding plans for ongoing maintenance and optimization of the system. At present, this project plans to deploy DeepSeek, Qwen (Alibaba Cloud), and other large language models (LLMs) in the intelligent QC management system (Multimedia Appendix 2) to further enhance the system's ability to analyze complex semantics, cross-paragraph logical contradictions, and unstructured information in medical records. At the technical implementation level, the key steps include building a multimodal interface via middleware to enable data integration with the HISs, performing data cleaning on historical medical records and constructing an annotated corpus, fine-tuning the model by incorporating QC rules and clinical requirements, and conducting regular maintenance and optimization through expert feedback and incremental training. In terms of functional advantages, compared with traditional language tools, LLMs can more accurately parse complex medical terms and ambiguous expressions and leverage long-distance context reasoning to discover hidden defects such as disconnection between medical orders and examination results or conflicts in drug interactions, which are difficult to detect [21,22]. Their incremental learning and dynamic fine-tuning mechanisms enable the model to continuously adapt to updated diagnostic and treatment guidelines and clinical needs [23,24]. In recent years, LLMs such as ChatGPT (OpenAI), Qwen, and DeepSeek have demonstrated outstanding performance in disease diagnosis and diagnostic reasoning [25-27], providing valuable theoretical references for our hospital's deployment of LLMs. At the same time, relevant documents issued in China on data security and ethical review provided policy guarantees for the implementation of this plan within the compliance framework [28-30]. We believe that continued optimization of the system performance will provide more efficient and accurate intelligent solutions for the quality management of EMRs in the future and elevate the quality of medical care to a new height.

This study has some limitations. First, as a systematic reform implemented in a real medical setting, this study adopted a single-group pre-post design without a parallel control group. During the study period, in addition to introducing the AI-QC system, the hospital simultaneously implemented multiple synergistic interventions, such as training programs and incentive mechanisms, and formed a corresponding management model. At the same time, confounding factors such as updates to the HIS and improvements in user proficiency may have been present during the observation period. Therefore, this study was unable to distinguish the contribution of the AI-QC system from the effects of concurrent measures and other confounding factors and could not draw conclusions regarding causal effects. Second, although the QC management model implemented at Zhejiang Provincial People's Hospital was effective, the results were limited to a single hospital, and the generalizability of the findings requires further validation. We believe that the concept of a multilevel QC framework and the closed-loop management model presented in this study have strong cross-institutional applicability and can be promoted as a general management framework, while the deployment of the AI platform is highly dependent on a hospital's IT infrastructure. Therefore, in practical implementation, the heterogeneity of different health care settings must be fully considered, with targeted adjustments made accordingly. For primary community hospitals with weak digital infrastructure, the QC system would need to be adjusted toward a lightweight and modular design, support low-cost and cloud-edge collaborative computing, and focus on basic needs such as chronic disease management and public health services. For health care institutions in the early stages of informatization, a phased implementation path should be designed to progressively enhance multisource heterogeneous data integration capabilities and nonstandardized data processing. For tertiary hospitals with mature information systems, emphasis should be placed on deep integration with existing complex hospital systems and the fine-grained configuration of specialized QC rules. In international applications, regionalized configurations must be developed based on differences in medical standards, relevant regulations, and disease profiles. In the future, we need to collaborate with more medical institutions, through multicenter and multilevel verification to further optimize the elasticity and scalability of this model. Finally, with the rapid development of individualized and specialized diagnosis and treatment approaches at the present stage, hospitals' attention to the QC of medical records for specialized diseases has gradually increased [31,32]; however, our QC system is slightly insufficient in this aspect of in-depth vertical development. In the future, under the premise of meeting the application requirements of medical record QC, our study will formulate personalized connotative QC rules based on different disciplines, different diseases, and different diagnosis and treatment methods for individual diseases, further optimize the QC system, and extend the management model toward greater refinement.

In conclusion, this study constructed a new model of closed-loop QC management with AI technology as the foundation and 4 levels of QC as the structure, which facilitated the comprehensive enhancement of the quality of medical records and the continuous improvement of case management, and can provide a reference for other hospitals to promote the reform of the QC system. At the same time, the QC of medical records is a complex and long-term task, and it is still necessary to observe and summarize the shortcomings of the model in practical applications, make timely corrections and improvements, and continuously explore a better QC management solution for EMRs.

Abstract

Background: Call abandonment is a critical barrier to patient access in health care call centers; yet, predictive modeling efforts are limited by strict privacy regulations that restrict the use of personal or behavioral data. Whether abandonment can be accurately predicted using only anonymized operational metrics remains unclear.

Objective: This study evaluated the feasibility, performance, and operational use of machine learning models trained exclusively on nonpersonal, routinely collected call center metrics to predict call abandonment across distinct organizational phases.

Methods: We analyzed 1,037,363 call records from a large academic health care system spanning 4 operational periods marked by workflow changes and skill consolidation. Features included temporal variables, skill identifiers, and rolling operational metrics (in-queue time, occupancy, handle time, after-call work time, and active agents). Random forest and CatBoost models were trained on 3 phases defined as: (T1 [January-April 2023; original workflows], T2 [May-August 2023; post skill consolidation, cross-training, and new workflows], and T3a [September-December 2023; optimized processes]) using 5-fold cross-validation with 3 imbalance-handling strategies (none, class weighting, and synthetic minority oversampling technique). Temporal generalizability was assessed by evaluating all models on all 4 phases, with T3b serving as an unseen holdout set. Performance was evaluated using area under the curve (AUC), precision-recall area under the curve (PR-AUC), Brier score, and calibration error. Shapley additive explanations (SHAP) values quantified feature contributions.

Results: Across all training phases and algorithms, adding operational metrics improved the area under the receiver operating characteristic curve by 0.03-0.13 vs models using only temporal and skill features. The best configuration was a CatBoost model trained on T2 with operational metrics and no imbalance correction (T3b AUC 0.767, PR-AUC 0.068, expected calibration error 0.006, and Brier 0.027). Models trained solely on preintervention data (T1) generalized poorly to postintervention periods when restricted to temporal and skill features (AUC 0.32-0.38) but achieved AUC 0.715 on T3b when operational metrics were included. SHAP analysis consistently identified in-queue time as the dominant predictor, with the number of logged-in agents, hour-of-day, and skill identifiers comprising the remaining top features. Abandonment declined from 8.7% (20,809/238,722) in T1 to 2.8% (8293/300,060) in T3b; model-based analyses of temporal features (day of week and hour of day) showed the highest risk on Mondays and between 11:00 and 16:00. Skill-level analyses showed marked improvement in high-volume imaging teams with high abandonment.

Conclusions: Models trained on nonpersonal operational data predicted call abandonment on the T3b temporal holdout, with real-time queue and staffing metrics providing the dominant signal. These findings support the feasibility of interpretable, operationally grounded abandonment prediction in health care call centers and indicate that models should be retrained after major operational changes.

KEYWORDS

call abandonment; call center; CatBoost; class imbalance; health care call center; machine learning; operational analytics; patient access; random forest; SHAP; temporal validation

Introduction

Call abandonment is when a caller drops the call while waiting to be connected to an agent. In health care call centers, call abandonment represents a critical challenge, directly affecting patient access to care, institutional revenue, and operational efficiency [1]. Health care call centers manage millions of interactions annually, with abandonment rates varying significantly across organizations, often ranging from 5% to over 20% during peak operational hours, translating into substantial revenue loss and diminished patient satisfaction [2,3]. These statistics underscore the necessity for robust strategies to mitigate call abandonment, particularly in environments where timely access to care is paramount.

Efficient call center operations are critical as they serve as the primary communication link between patients and health care providers, ensuring timely medical services and patient satisfaction [4]. Call abandonment, as a key performance metric, directly impacts operational efficiency and institutional financial health [5]. Health care call centers face unique challenges compared to other industries, including higher abandonment rates compared to retail or banking sectors, and delays in response times, leading to patient dissatisfaction, missed appointments, and reduced trust in health care systems [2,3].

Additionally, stringent privacy regulations limit the availability of the granular caller-specific data necessary for individualized predictive modeling [6,7]. Traditional predictive analytics approaches, which rely heavily on detailed personal datasets such as caller demographics and behavioral patterns, present risks to patient confidentiality and compliance with privacy standards such as the Health Insurance Portability and Accountability Act (HIPAA) [6,7]. This complicates efforts to develop effective predictive models.

Previous studies have used machine learning and queueing theory to forecast call volumes and optimize staffing. For instance, Zeltyn and Mandelbaum [1] modeled call center operations using queueing theory, while Jouini et al [8] applied stochastic models to address performance uncertainties. However, these methods often depend on sensitive data, limiting their feasibility in health care. Moreover, few studies have addressed the adaptability of predictive models to organizational transitions or fluctuating operational conditions [9].

This study addresses these gaps by exploring the feasibility of predicting call abandonment using exclusively anonymized operational metrics routinely collected in call centers, such as call date, time, requested skill, and in-queue time. By leveraging these nonpersonal operational data, our approach aims to provide actionable insights to enhance managerial decision-making, optimize resource allocation, and improve patient experiences without compromising privacy standards [1,5,10].

To address these questions, our research evaluated the feasibility of predicting call abandonment within a health care call center environment through 3 experiments, each designed to assess distinct aspects of predictive use and operational applicability. In the first experiment, we evaluated model generalizability across different operational phases. In the second, we assessed model robustness and adaptability to evolving operational conditions. Finally, the third experiment explicitly investigated the operational use of predictive analytics by examining how accurately identifying key drivers of call abandonment could inform targeted interventions at the skill-specific level. Collectively, these analyses leveraged a dataset comprising over a million calls, segmented into distinct time periods representing preintervention, transitional, and stabilized operational phases, to validate the strategic value of predictive models in health care operations management.

Methods

Datasets

The dataset, provided by Emory Healthcare's call center, comprised anonymized, nonpersonal call data spanning January 2023 to May 2024, totaling over 1.2 million records from approximately 734,000 unique callers. Each call record included the contact identifier, date and time, queue duration, skill group (eg, PA Radiology Surgery and PA Imaging Echo Campaign), agent identifier, team identifier, and outcome (abandoned or connected). To comply with HIPAA, caller phone numbers were anonymized and retained only to identify repeat callers within a 24-hour window for accurate abandonment classification.

The call center system does not provide estimated wait time (EWT) announcements to callers; callers hear a standard hold message without any indication of expected wait duration. Therefore, the predictive power of in-queue time reflects system congestion conditions rather than caller-side information about anticipated waits.

The dataset was partitioned into 4 temporal phases representing distinct operational periods: T1 (preintervention: January-April 2023), T2 (transitional: May-August 2023), T3a (early stabilization: September-December 2023), and T3b (fully stabilized: January-May 2024). These phases corresponded to major organizational changes including skill consolidation, cross-training initiatives, and workflow optimization. T3b served as an unbiased holdout set, never used for model training, enabling evaluation of temporal generalizability.

Data Preparation and Feature Engineering

Data cleaning was systematically performed using the R *tidyverse* package [11] to ensure dataset integrity. Records missing essential attributes (queue duration, outcome, or time stamp) were excluded. Call abandonment was defined as a caller-initiated disconnection before agent connection, following

XSL•FO
RenderX

the standard industry definition where any disconnect prior to service constitutes an abandonment. This excludes technical disconnections (system drops logged separately in the automatic call distributor system) and interqueue transfers, which maintain call connections.

To assess label noise robustness, we conducted a false abandonment sensitivity analysis identifying callers who abandoned but successfully reconnected within 1-hour, 4-hour, 12-hour, and 24-hour windows using the anonymized caller identifier (master_contact_id). False abandonments represented only 1.2%-1.7% of abandoned calls across all phases, and all reconnections occurred within the first hour. Excluding these calls changed model area under the receiver operating characteristic curve (ROC-AUC) by only +0.003 (Table S2 and Figure S12 in Multimedia Appendix 1), confirming that the primary results are robust to this label noise.

Skill Canonicalization

To maintain consistency across operational phases, historical skill labels were mapped to the current taxonomy for a defined subset of legacy queues. A total of 12 legacy skills were consolidated into 3 primary skill groups via exact-match recoding: PA Radiology Surgery (encompassing "PA Radiology-Nutrition," "PA Radiology-Cardiology," "PA Radiology-Gen Surgery," and "PA Radiology-Respiratory"), PA Radiology Team Blue Magic (consolidating "PA Radiology-CT Scan," "PA Radiology-Cardiac PET," "PA Radiology-Nuc Med," and "PA Radiology-IR NR"), and PA Radiology Team Rad Achiever (combining "PA Radiology-MRI," "PA Radiology-Ultrasound," "PA Radiology-Gen Diagnostics," and "PA Radiology-Infusion"). This canonicalization ensured feature consistency across all temporal phases for valid model comparison within these 3 groups.

A separate set of legacy scheduling queues, "Imaging-Mammogram Scheduling," "Imaging-CT Scheduling," "Imaging-MRI Scheduling," "PA Interventional Radiology," and "PA Radiology-IR RN," was retained as distinct skill categories and was not folded into the consolidated groups; these queues are not part of the 12-skill consolidation and remain separately labeled throughout the dataset. Their call volumes declined substantially, in several cases to near zero, in T3a and T3b as call routing shifted away from these legacy queues; we address the implications in the Limitations section.

Temporal Feature Encoding

Temporal features were engineered to capture cyclical patterns in call center operations. Hour of day (0-23) and day of week (Monday-Sunday) were encoded using sine and cosine transformations to preserve their cyclical nature, preventing artificial discontinuities at period boundaries. For a cyclical variable x with period p, the transformation is defined as:

This encoding maps temporal features onto unit circles, ensuring that adjacent time points (eg, 11 PM to 12 AM) are represented as proximate in the feature space rather than numerically distant. A binary holiday indicator was derived using the US federal holiday calendar (*timeDate* package).

Rolling Operational Metrics

To capture operational dynamics available at prediction time, we computed rolling metrics over 60-minute trailing windows within each skill, restricted to information knowable at the moment of each call's arrival (time T). A prior call contributes its in-queue time to inqueue_roll_60m only if it had completed waiting (been answered or abandoned) by T; its handle time to aht_roll_60m only if handling had completed by T; and its after-call work time to acw_roll_60m only if wrap-up had completed by T; agents_logged_in counts distinct agents observed answering calls within the window by T, and occupancy_proxy divides completed busy time by that staffed capacity (defined as 0 when no capacity had been observed). The current call is always excluded from its own windows. Calls with no eligible contributors (eg, the first call after a quiet period) receive missing values; these are median-imputed within the modeling pipeline with accompanying missingness-indicator variables, so that data-sparse periods are represented explicitly rather than as typical load.

Model Development

Algorithms and Feature Sets

Two machine learning algorithms were evaluated: random forest [12] with 800 trees and CatBoost [13] (gradient boosting on decision trees). Each algorithm was trained using 2 feature configurations: BASE (skill group, temporal features with cyclic encoding, holiday indicator) and WITH_AGENTS (BASE features plus rolling operational metrics).

Imbalance Handling Strategies

Three approaches to address class imbalance were systematically compared [14,15]: (1) None (baseline), (2) class weighting (inverse frequency weighting: $w_{minority}=n_{total}/(2\times n_{minority})$, $w_{majority}=n_{total}/(2\times n_{majority})$, and (3) synthetic minority oversampling technique (SMOTE) with over_ratio=0.25. Class weighting adjusts the loss function to penalize misclassifications proportionally to class rarity, while SMOTE generates synthetic minority class examples through k-nearest neighbors interpolation (k=5, adaptively adjusted based on minority class size per fold).

Training Protocol

Models were trained independently on each phase (T1, T2, and T3a) using 5-fold stratified cross-validation (CV) with the outcome (abandon: yes/no) as the stratification variable. We implemented preprocessing pipelines, using the *recipes* R package, that included factor encoding, imputation (median for numeric and mode for categorical), and SMOTE augmentation where applicable. SMOTE augmentation was strictly isolated to training data within each CV fold. Training data was extracted via juice (recipe_prep), which returns the augmented training set including synthetic samples. Validation and test data were processed via bake(recipe_prep, new_data), which applies only deterministic transformations (encoding, imputation) and never generates synthetic observations. No synthetic samples contaminated validation folds or the T3b holdout set. All models

XSL•FO
RenderX

within each algorithm-feature-variant configuration used consistent hyperparameters to isolate the effects of training phase, feature selection, and imbalance handling. To verify that performance differences reflected algorithmic architecture rather than default parameter suitability, we subsequently performed systematic hyperparameter optimization using nested 3-fold CV within each training phase. For random forest, we searched over mtry (2-8) and min_n (5, 10, 20, 50); for CatBoost, we searched over depth (4, 6, 8, 10) and learning_rate (0.01, 0.05, 0.10). Tuned models were evaluated on the T3b holdout set (Figures S13a-S13c and Table S3 in Multimedia Appendix 1).

Each combination of 3 training phases, 2 algorithms, 2 feature sets, and 3 imbalance-handling methods yielded 36 trained models, with full refit on entire phase data post CV for subsequent temporal validation.

Baseline Models

To quantify the marginal use of ensemble methods, we implemented 4 baseline models evaluated on the same T3b holdout set: (1) logistic regression with L2 regularization using the same with_agents feature set; (2) an Erlang-A queuing model (M/M/s+M) parameterized using phase-specific arrival rates, service rates, and exponentially modeled caller patience estimated by maximum likelihood under right-censoring; (3) a temporal heuristic predicting abandonment probability from day-of-week and hour-of-day historical rates alone; and (4) a prevalence-only baseline predicting the marginal abandonment rate for all calls.

Temporal Validation Strategy

Following established practices for time series evaluation [16,17], each trained model was tested on all 4 temporal phases (T1, T2, T3a, and T3b) to assess generalizability and temporal stability. This design does not strictly preserve temporal ordering, because some models were evaluated on data from earlier phases than the period used for training; these results were used descriptively to compare performance across operational regimes. To mimic a prospective deployment scenario, we treated the final phase (T3b) as a future holdout set and emphasized model performance on this period.

The preprocessing pipeline (feature encoding, imputation, and skill mapping) from training was applied to each test set without refitting, maintaining realistic prediction conditions. This yielded 144 model-test combinations (36 trained models × 4 test phases), enabling comprehensive assessment of (1) within-phase performance (model trained and tested on same phase), (2) forward generalization (model tested on later phases), and (3) cross-phase robustness (model tested across disparate operational contexts).

Blocked Temporal Cross-Validation

To assess sensitivity to temporal autocorrelation, we implemented expanding-window blocked temporal CV alongside standard 5-fold CV. Each training phase (~4 months) was split into monthly blocks, and we used an expanding-window protocol: train on month 1, test on month 2; train on months 1-2, test on month 3; train on months 1-2-3, test on month 4. This protocol respects the temporal ordering of observations and reduces potential leakage from short-term operational patterns.

Performance Metrics

Model discrimination was evaluated using the ROC-AUC with DeLong 95% CIs and precision-recall area under the curve (PR-AUC) with bootstrap CIs (500 resamples). Calibration quality was assessed via Brier score (mean squared error between predicted probabilities and binary outcomes), and expected calibration error (ECE) computed across 10 probability bins as the weighted average of absolute differences between bin accuracy and mean confidence.

For clinical interpretability, models were also evaluated at specific operating thresholds using sensitivity (recall), specificity, and F_1-score (harmonic mean of precision and recall). These metrics provided complementary perspectives on model performance relevant to different stakeholder priorities. Overall classification accuracy was not used as a performance metric due to the severe class imbalance (2.8% abandonment prevalence in the holdout set). A naive classifier predicting all calls as nonabandoned would achieve 97.2% accuracy, making this metric uninformative for evaluating model discrimination.

Threshold Optimization and Cost-Benefit Analysis

Optimal decision thresholds were identified through multiple criteria: (1) F_1-score maximization, (2) Youden index (sensitivity + specificity – 1), and (3) cost minimization. A simple cost model assigned a unit cost to false positives (FPs; unnecessary intervention) and a 5-fold cost to false negatives (FNs; missed abandonments). An extended time-varying cost model incorporated differential costs for peak hours (9:00-17:00: FP cost=1.5; FN cost=6.0) vs off-peak hours (FP cost=0.7; FN cost=4.0), reflecting varying operational constraints and patient impact across the day.

For each model-test combination, thresholds were swept from 0.01 to 0.99 in 0.02 increments, computing performance metrics at each point. Bootstrap CIs (50 resamples) quantified threshold stability for groups exceeding 5000 calls. Expected cost reduction and intervention volume were estimated for each policy to inform operational planning. To assess sensitivity to cost assumptions, we conducted a cost ratio sweep varying the FN:FP ratio from 1:1 to 30:1, examining how the optimal decision threshold and operating characteristics change under different assumptions about the relative cost of missed abandonments vs unnecessary interventions (Figure S8 in Multimedia Appendix 1).

Model Interpretability

Shapley additive explanations (SHAP) [18,19] values were computed to quantify feature contributions to predictions, providing model-agnostic interpretability. For each trained model, SHAP values were calculated on a stratified sample of 10,000 calls per test phase using 25 Monte Carlo simulations. Feature importance was aggregated as the mean absolute SHAP value across observations, and directional effects were visualized through SHAP dependence plots. This analysis identified which operational factors (eg, in-queue time, hour of day, and specific skills) most strongly influenced abandonment predictions and

XSL•FO
RenderX

whether their effects remained consistent across temporal phases.

Statistical Analysis

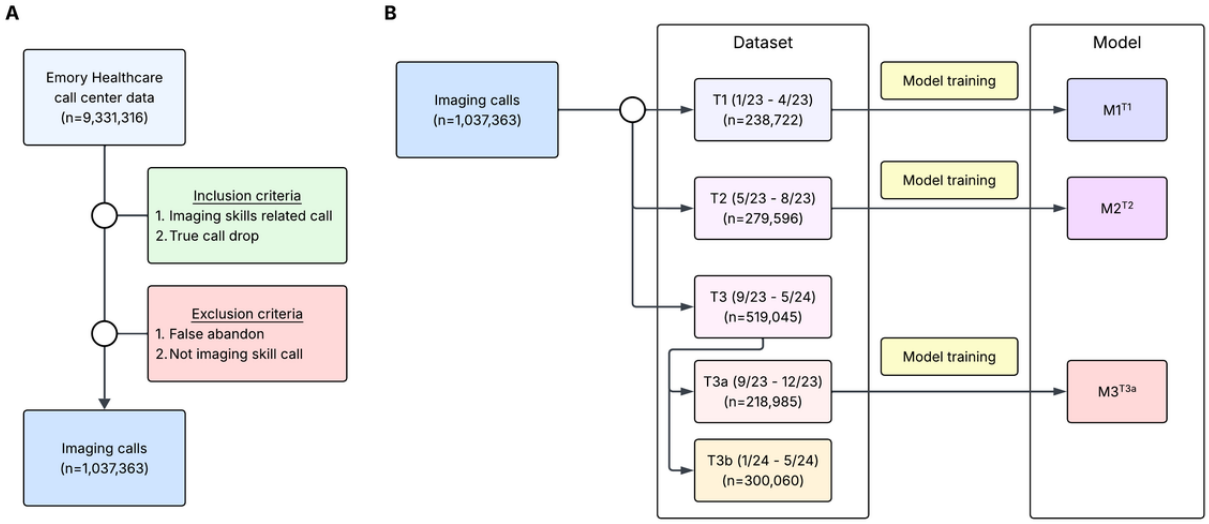
Point-biserial correlation assessed the association between queue duration (continuous) and abandonment (binary), both globally and within each phase, quantifying the strength of this established relationship and detecting temporal variations. Chi-square tests identified significant differences in abandonment rates across categorical predictors (skill group, hour, and month), highlighting operational vulnerabilities through comparison of observed vs expected frequencies.

General linear models examined call volume patterns while controlling for skill, hour, and month, testing for interaction effects and identifying peak demand periods requiring targeted resource allocation. Model comparison used comprehensive ranking across ROC-AUC, PR-AUC, Brier score, and ECE, with primary evaluation on the T3b holdout set. All analyses were conducted using R software (version 4.3.1; R Foundation for Statistical Computing) with packages including *tidyverse* [11], *ranger* (random forest implementation) [20], *catboost* (gradient boosting) [13], recipes/workflows (preprocessing and modeling framework), *fastshap* (SHAP computation) [19], *pROC* (receiver operating characteristic analysis) [21], and *PRROC* (precision-recall curves).

Ethical Considerations

This study did not require institutional review board (IRB) review or approval. In accordance with Emory University's documented institutional determination process (Emory IRB memorandum of July 11, 2019, "Documentation for projects that do not require IRB review"), the project was evaluated using the Emory IRB Non-Human Subjects Research Determination electronic form (completed July 14, 2026), with the recorded determination that the project is not research with human participants, nor a clinical investigation, as defined under the US Department of Health and Human Services regulations at 45 CFR 46.102(e) [22], because the analysis uses exclusively deidentified operational call center data (call time stamps, queue metrics, staffing levels, and call disposition). The completed determination form is retained as institutional documentation and is available on request.

Informed consent was not applicable, as no human participants were involved and only retrospective operational records were analyzed. The dataset contains no patient names, medical record numbers, phone numbers, or other personally identifiable information; caller identifiers (master_contact_id) are system-generated hashes that cannot be linked back to individuals. No participants were enrolled or compensated. No images in the manuscript or supplementary materials contain identifiable individuals.



Results

Dataset Characteristics and Operational Context

The final analytic dataset included 1,037,363 call records spanning January 2023 to May 2024, corresponding to 4 operational phases: T1, T2, T3a, and T3b (Figures 1 and 2; Figure S1 in Multimedia Appendix 1). Abandonment rates declined from 8.7% (20,809/238,722) in T1 to 2.8% (8293/300,060) in T3b (Table 1). Mean in-queue time decreased from 279 seconds in T1 to approximately 50 seconds in T3a and T3b, and median queue times decreased from 21-25 seconds to 2 seconds. Staffing levels during business hours ranged from 14-17 active agents, and mean occupancy under the corrected (knowability-gated) definition ranged between 31% (SD 14.1%) and 42% (SD 22.5%; Table 1). A sensitivity analysis confirmed that false abandonments (callers who abandoned but reconnected within 24 hours) represented only 1.2%-1.7% of abandoned calls and had negligible impact on model performance (ROC-AUC delta: +0.003; Figure S12 in Multimedia Appendix 1).

Figure 1. CONSORT (Consolidated Standards of Reporting Trials) chart and study design. (A) The CONSORT flowchart illustrating data flow from the initial dataset through inclusion and exclusion criteria to final analysis set. The initial Emory Healthcare Call Center dataset (n=9,331,316 calls) was filtered using inclusion criteria (imaging skills-related calls and true call drops) and exclusion criteria (false abandons and nonimaging skill calls), resulting in the final imaging calls dataset (n=1,037,363). (B) The study design showing dataset partitioning and model training structure. The imaging calls were divided into 4 temporal phases: T1 (preintervention: January-April 2023, n=238,722), T2 (transitional: May-August 2023, n=279,596), T3 (September 2023-May 2024, n=519,045), subdivided into T3a (early stabilization: September-December 2023, n=218,985) and T3b (holdout validation: January-May 2024, n=300,060). Three models were trained: M1 (superscript T1) on the T1 dataset, M2 (superscript T2) on the T2 dataset, and M3 (superscript T3a) on the T3a dataset, with T3b reserved as an independent holdout set for temporal validation.

Figure 2. Study design and analytical framework overview of study design, temporal phases, and analytical approach for call abandonment prediction. (A) Temporal study phases with call volumes across 4 operational periods (T1: preintervention, T2: transitional, T3a: early stabilization, T3b: holdout validation). (B) The analytical workflow from data processing through model development, temporal validation, and interpretability analysis. (C) Comparison of feature sets, contrasting base features (temporal patterns and skill assignments) with operational features (including agent metrics, queue times, and occupancy rates). The dataset comprised 1,037,363 call records spanning 17 months across organizational transitions involving skill consolidation, cross-training, and workflow optimization. ACW: after-call work; AHT: average handle time; CV: cross-validation.

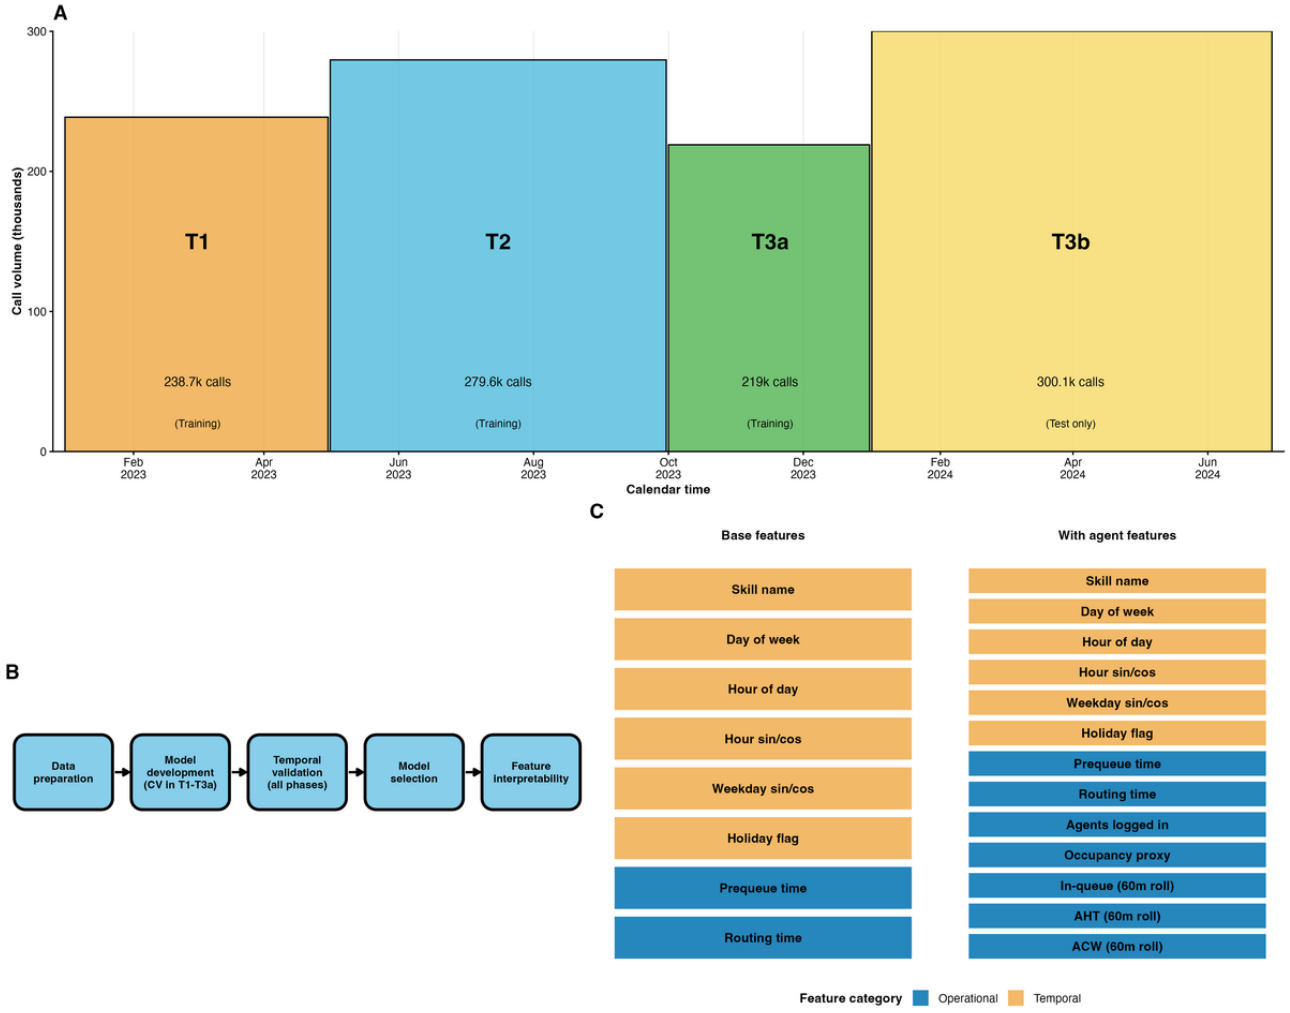

Table 1. Operational characteristics by phase: summary of operational metrics across 4 temporal phases (T1: preintervention, T2: transitional, T3a: early stabilization, and T3b: holdout validation). Metrics include total calls, abandoned calls, abandonment rate, mean and median in-queue time, average handle time (AHT), after-call work (ACW) time, mean agents logged in, and occupancy proxy. The table demonstrates substantial improvement in abandonment rates from 8.7% in T1 to 2.8% in T3b, accompanied by reductions in queue times while maintaining stable staffing levels.

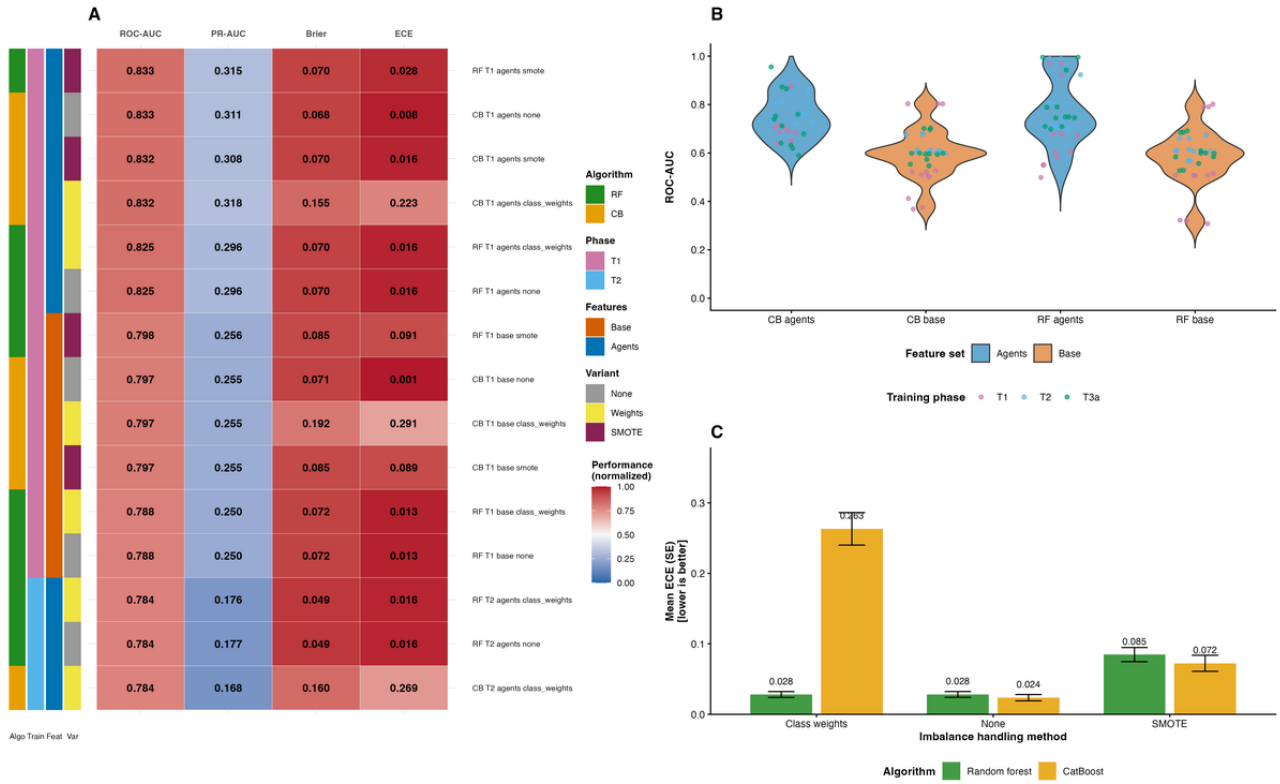

Phase	Total calls	Abandoned calls, n (%)	In-queue time (seconds), mean (SD)	In-queue time (seconds), median (IQR)	AHT 60 m rolling (seconds), mean (SD)	ACW 60 m rolling (seconds), mean (SD)	Agents logged in, mean (SD)	Occupancy (%), mean (SD)
T1	238,722	20,809 (8.7)	279.5 (553.8)	21.0 (2.0-306.0)	233.1 (72.4)	73.3 (52.5)	13.6 (5.9)	31.4 (14.1)
T2	279,596	15,122 (5.4)	132.5 (298.0)	25.0 (2.0-149.0)	240.3 (61.4)	74.8 (60.4)	15.0 (8.1)	41.9 (22.5)
T3a	218,985	5725 (2.6)	49.4 (106.1)	2.0 (2.0-56.0)	252.4 (57.3)	74.5 (54.4)	17.1 (8.0)	34.6 (11.9)
T3b	300,060	8293 (2.8)	53.4 (114.0)	2.0 (2.0-61.0)	251.4 (57.9)	78.1 (57.2)	16.3 (7.9)	35.7 (12.6)

Model Development and Cross-Validation Performance

Cross-validation results varied by training phase and feature configuration (Figure 3A; Table 2). Across all phases and algorithms, incorporating operational features (in-queue time, handle time, after-call work time, occupancy, active agent count) improved cross-validated ROC-AUC by 0.03-0.13 compared with BASE models using only skill and temporal features (smallest for T1-trained CatBoost and largest for T2-trained models); on the T3b holdout the corresponding gains were 0.11-0.34 (Table S7 in Multimedia Appendix 1).

Figure 3. Model performance comparison across configurations: systematic comparison of model performance across algorithms, training phases, feature sets, and imbalance handling strategies. (A) A heatmap of 5-fold cross-validation performance (area under the receiver operating characteristic curve [ROC-AUC], precision-recall area under the curve [PR-AUC], Brier score, and expected calibration error [ECE]) for the top 15 of 36 model configurations ranked by cross-validated ROC-AUC, with row annotations for algorithm, training phase, feature set, and imbalance variant. (B) Violin plots of ROC-AUC across all 144 model-test-phase combinations, grouped by algorithm and feature set and colored by training phase, demonstrating the consistent improvement from operational (with_agents) features. (C) Mean ECE (SE) by imbalance handling method and algorithm, showing that models without imbalance correction achieve the best calibration and that class weighting severely degrades CatBoost calibration (mean ECE 0.263, SD 0.113) while leaving random forest (RF) calibration essentially unchanged (mean ECE 0.028, SD 0.020). Lower ECE values indicate better-calibrated probability estimates. SMOTE: synthetic minority oversampling technique.

Table 2. Model performance leaderboard (top 10 models on T3b holdout): ranking of top 10 model configurations by performance on the T3b holdout set. Columns include rank, training phase, algorithm, feature set, imbalance handling method, area under the curve (AUC), precision-recall AUC (PR-AUC), Brier score, and expected calibration error (ECE). The leaderboard reveals that models trained on postintervention data (T2 and T3a) with operational metrics and no imbalance correction achieved the strongest prospective performance, with the top-ranked model (CatBoost trained on T2) achieving an AUC of 0.767 and an ECE of 0.006. Aggregate algorithm-level performance is summarized in Table S10 in Multimedia Appendix 1, and the complete 36-model leaderboard is provided in Table S11 in Multimedia Appendix 1.

Rank	Training phase	Algorithm	Feature set	Variant	CV[a] AUC (95% CI)	CV PR-AUC	CV ECE	T3b AUC (95% CI)	T3b PR-AUC	T3b ECE	T3b Brier

Baseline Comparison

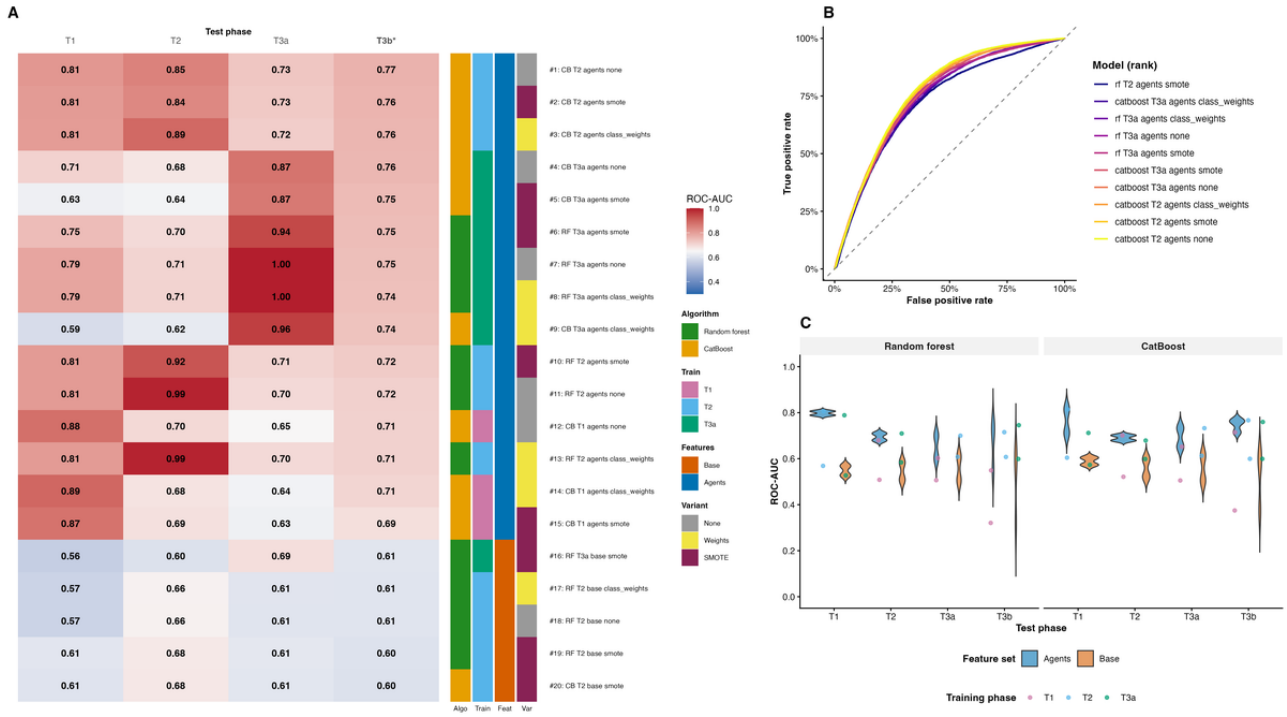
Baseline comparisons demonstrated substantial machine learning uplift on the T3b holdout. Logistic regression achieved an ROC-AUC of 0.736, confirming that operational features carry a strong linear signal. However, CatBoost achieved an absolute improvement of 0.031 ROC-AUC (3.1 percentage points; 4.2% relative improvement) over logistic regression (0.767 vs 0.736), with gains concentrated in the high-risk tail of the distribution. The Erlang-A queuing model (ROC-AUC=0.561) and temporal heuristic (ROC-AUC=0.562) performed only marginally above random, demonstrating that classical queuing theory and simple time-of-day patterns alone are insufficient for call-level abandonment prediction. The temporal heuristic's near-random performance demonstrates that day-of-week and hour-of-day patterns alone, while useful for aggregate staffing, cannot predict individual call outcomes (Figure S9 and Table S5 in Multimedia Appendix 1).

Models trained on T1 achieved CV area under the curve (AUC) of approximately 0.83, while those trained on T2 and T3a achieved AUC values of 0.748-0.784. CatBoost models demonstrated marginally better calibration than random forest, though both showed similar feature importance rankings (Figure S5 in Multimedia Appendix 1).

Imbalance-handling strategies showed distinct calibration patterns. Models trained without imbalance correction achieved the lowest ECE (mean ECE ≤0.04 across configurations), whereas class-weighted CatBoost models showed markedly degraded calibration (mean ECE 0.13-0.35; class weighting left random forest calibration essentially unchanged) and SMOTE variants showed intermediate calibration (mean ECE 0.01-0.15; Figure 3C; Table S9 in Multimedia Appendix 1). The minority class remained substantial across phases (>5700 abandoned calls per phase). Point-biserial correlations between in-queue time and abandonment ranged from r=0.18-0.31.

XSL•FO
RenderX

Temporal Validation and Generalizability



Models trained on postintervention data (T2 or T3a) demonstrated the strongest forward generalization, with AUC values of 0.72-0.77 on the T3b holdout set; unweighted and SMOTE variants maintained ECE ≤0.04, while class-weighted variants showed degraded calibration (Figure 4; Table 2). The highest-performing configuration was CatBoost trained on T2 with operational metrics and no imbalance correction (AUC 0.77; ECE 0.006).

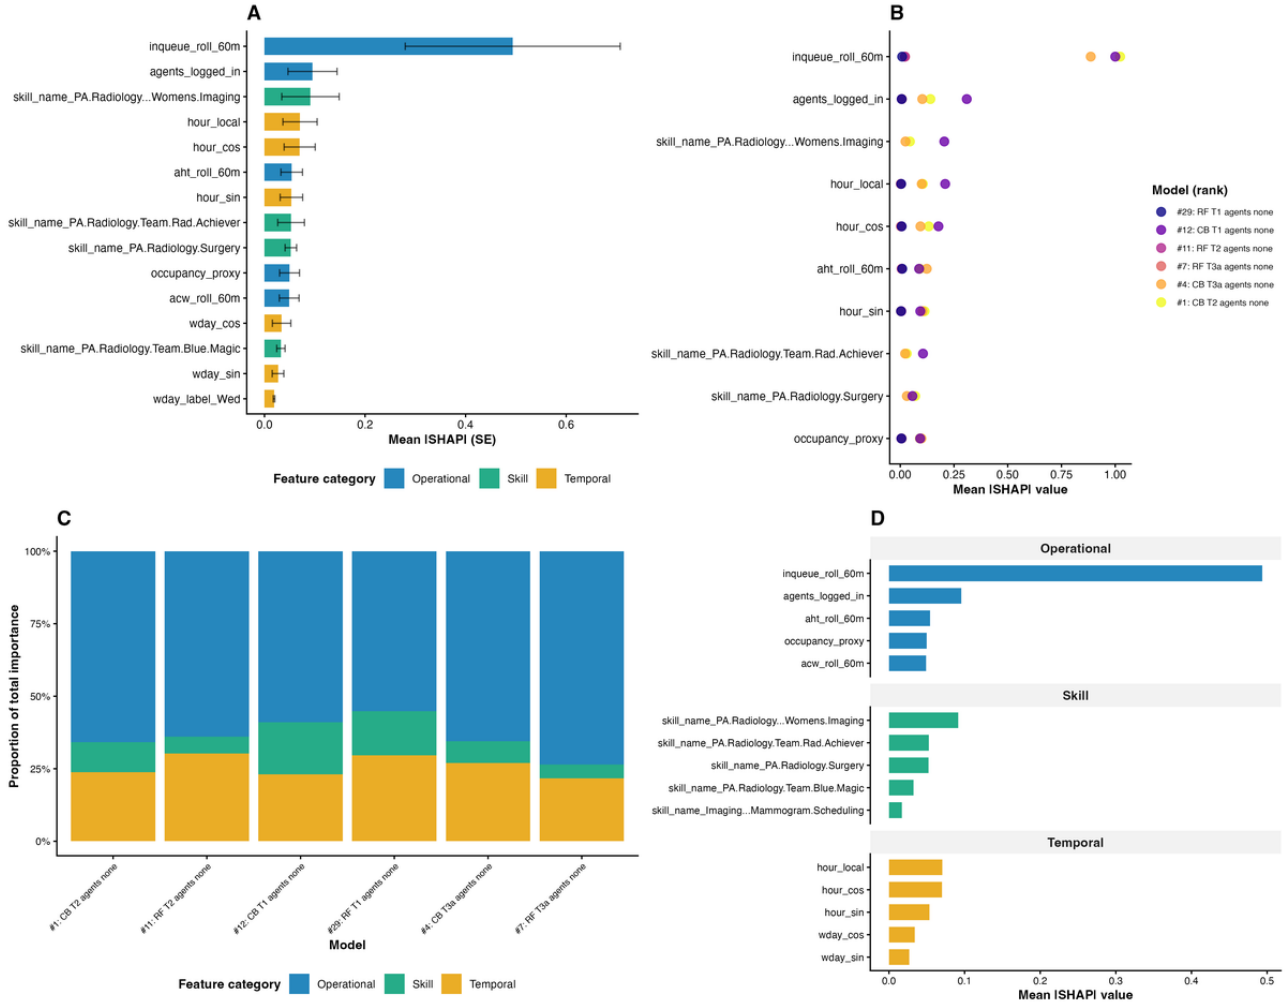
Models trained on T1 with BASE features showed poor forward generalization on T3b (AUC 0.32-0.38) despite high within-phase in-sample performance (Table S8 in Multimedia Appendix 1). This pattern is consistent with concept drift: the decline in abandonment rate from T1 to T3b, driven by skill consolidation and staffing adjustments, fundamentally altered the relationships between predictive features and outcomes. Adding operational metrics improved T1-trained models to AUC 0.715 (CatBoost) and 0.549 (random forest) on T3b, still well below their T2-trained counterparts, and with greater variability across the 4 test phases (SD 0.099 for CatBoost T1/with_agents vs 0.051 for the corresponding T2-trained model; Table S8 in Multimedia Appendix 1).

Across all temporal test sets (T1, T2, T3a, and T3b), T2-trained CatBoost models with operational features (unweighted and SMOTE variants) achieved AUC values of 0.73-0.85 and maintained consistent calibration (Figure S2 in Multimedia Appendix 1). Top-performing models achieved PR-AUC values of 0.068-0.071 on T3b, representing 2.47-2.58× lift over the T3b prevalence baseline of 0.0276 (Table S6 in Multimedia Appendix 1).

In contrast, Erlang-A (PR-AUC=0.031; 1.1× lift) and temporal heuristic (0.034; 1.2× lift) baselines achieved minimal discrimination above chance. The model's value lies in ranking calls by risk to enable targeted interventions rather than requiring high absolute precision at any single threshold (Figure S4 in Multimedia Appendix 1).

Figure 4. Temporal validation and generalizability: comprehensive temporal validation showing model performance across time periods and operational regimes. (A) A heatmap of the top 20 models evaluated across 4 temporal test phases (T1, T2, T3a, and T3b), with area under the curve (AUC) values shown for each model-phase combination. Diagonal (within-phase) cells display within-phase in-sample AUC, as in Table S8 in Multimedia Appendix 1, not the 5-fold cross-validation AUC reported in Table 2; the 2 metrics differ by construction. Models are ordered by T3b holdout performance and include both with_agents and base-feature variants to allow visual comparison of the contribution of operational features; the 3 base-feature configurations appearing at the bottom of the ranking (rows 18-20) achieve substantially lower discrimination across all test phases. Color intensity indicates discrimination quality, revealing that models trained on recent data (T2 and T3a) maintain consistent performance across phases, while models trained on preintervention data (T1) show marked degradation on postintervention test sets. (B) Receiver operating characteristic curves for the top 5 performing models on the T3b holdout set, with AUC values ranging from 0.752 to 0.767. (C) compares temporal stability across model characteristics, showing mean AUC and SD across test phases stratified by training phase, feature set, and algorithm. ROC-AUC: area under the receiver operating characteristic curve; SMOTE: synthetic minority oversampling technique.

Model Interpretability and Feature Importance



SHAP analysis identified in-queue time as the dominant predictor, with a mean absolute SHAP value of 0.494 compared with 0.096 for the second-ranked feature (number of agents logged in; Figure 5; Table 3). Agent staffing, skill identifiers, and hour-of-day features occupied the next ranks, with the remaining rolling operational metrics (average handle time, occupancy rate, and after-call work time) closely behind; in-queue time's dominance was consistent across training phases and algorithms (Figure S5 in Multimedia Appendix 1). The missingness-indicator variables introduced by the corrected feature specification carried negligible importance (mean |SHAP|

XSL•FO
RenderX

≤0.004), confirming that predictive signal does not derive from missingness patterns.

Temporal features (hour and day encoded via sine/cosine) showed lower SHAP magnitudes than in-queue time and agent staffing in all configurations, and skill identifiers appeared inconsistently and with lower importance (Figure 5; Figure S5 in Multimedia Appendix 1). Per-observation SHAP waterfall analysis illustrates feature directionality for representative T3b calls scored by the CatBoost T3a/with_agents configuration (Figure S10 in Multimedia Appendix 1). For a high-risk call (P[abandon]=0.727; actual: abandoned), the dominant drivers were routing to the specialized PA Interventional Radiology queue (SHAP=+1.3), a late-evening arrival (hour 23, SHAP=+0.8), zero observed occupancy (occupancy_proxy=0, SHAP=+0.7), and no agents observed answering within the prior hour (agents_logged_in=0, SHAP=+0.3). A borderline answered call (P[abandon]=0.010) showed offsetting contributions, with elevated recent queue time increasing risk (inqueue_roll_60m=50.5 seconds, SHAP=+0.6) offset by an off-peak arrival hour (SHAP=–0.3) and adequate staffing (agents_logged_in=13, SHAP=-0.2). Conversely, a low-risk call (P[abandon] <.001; actual: answered) was driven by short recent queue time (inqueue_roll_60m=2.4 seconds, SHAP=–1.4), zero after-call work in the window (SHAP=–0.7), and low occupancy (SHAP=–0.6). These examples confirm that the model's decision logic aligns with operational intuition.

Figure 5. Shapley additive explanations (SHAP) feature importance for top-performing models: SHAP-based interpretability analysis across the 6 primary configurations (random forest and CatBoost trained on T1, T2, and T3a with operational features, no imbalance correction), the same set summarized in Table 3. (A) Ranking of the top 15 features by mean absolute SHAP value, revealing in-queue time as the dominant predictor (mean |SHAP| 0.494, SD 0.524, approximately 5 times the second-ranked feature, the number of agents logged in), followed by skill identifiers, hour-of-day encodings, and the remaining rolling operational metrics. (B) Comparison of feature importance across the 6 models individually, demonstrating that in-queue time's dominance is consistent across training phases and algorithms. (C) Breaks down of each model's total attributed importance by feature category (operational metrics, temporal patterns, skill identifiers): operational features account for approximately 64% (range 55%-74%) of total importance on average. (D) Ranking of the leading features within each category, showing that in-queue time and agent staffing lead the operational category by a wide margin.

XSL•FO
RenderX

Table 3. Feature importance rankings (mean absolute Shapley additive explanations [SHAP] values): top 15 features ranked by mean absolute SHAP value across top-performing models. Columns include rank, feature name, feature category (operational, temporal, or skill), mean |SHAP| value, SD, and coefficient of variation (CV). In-queue time dominates as the most important predictor (mean |SHAP| 0.494, SD 0.524), followed by the number of agents logged in, skill identifiers, and hour-of-day features, with the remaining rolling operational metrics closely behind. In-queue time and agent staffing—both operational metrics—occupy the top 2 ranks, underscoring the primacy of queue-state information for abandonment prediction.

Hyperparameter Tuning Impact

Hyperparameter tuning yielded marginal changes relative to default configurations for with_agents models (–0.008 to +0.015 ROC-AUC; maximum gain: CatBoost T3a/with_agents, 0.760 to 0.774), with 1 larger decline for a base configuration already performing below chance (CatBoost T1/base, –0.059). CatBoost selected depth=8 (matching the default) for the 3 base configurations but depth=10 for all 3 with_agents configurations. The performance advantage of CatBoost over random forest persisted after tuning (0.774 vs 0.754 for best with_agents models), confirming that the difference reflects algorithmic architecture rather than default parameter suitability (Figures S13a-S13c in Multimedia Appendix 1).

Robustness Checks

Blocked temporal CV consistently produced lower performance estimates (mean delta: –0.079 ROC-AUC) than standard 5-fold CV, confirming some temporal autocorrelation within phases. Model ranking was preserved—CatBoost with agent features remained the top performer under both schemes—although with_agents configurations trained on the shorter posttransition phases scored 0.656-0.663 under blocked CV, indicating that standard CV materially overstates within-phase performance for these models. Our primary evaluation on the T3b holdout set, which inherently respects temporal ordering, provides the definitive performance assessment (Figure S11 and Table S4 in Multimedia Appendix 1).

Cost sensitivity analysis showed that at conventional false-negative to false-positive cost ratios (up to 11:1) the cost-minimizing policy was to flag no calls, because the model's precision at practical operating points (approximately 5%-8%) does not offset the cost of FPs; flagging became cost-effective only at ratios of 12:1 and above (eg, a threshold of 0.08 achieving 22.1% sensitivity at 12:1, rising to 72.9% at 30:1). Cost-based deployment of this model is therefore appropriate only where a missed abandonment is weighted at least an order of magnitude more heavily than an unnecessary intervention (Figure S8 in Multimedia Appendix 1).

Operational Patterns and Statistical Analysis

Skill-level analyses showed substantial variation across phases. The highest-volume skill (PA Radiology-Womens Imaging) accounted for 366,542 calls (35% of volume) and exhibited an abandonment decline from 13.9% in T1 to 0.5% in T3b (Table 4; Figure S6 in Multimedia Appendix 1). Consolidated high-volume skills showed transient increases during T2 before decreasing in T3b, while lower-volume specialized skills showed higher and more variable abandonment rates (>20% in T1). Across phases, the 3 highest-volume skills accounted for 73%-84% of total call volume.

Temporal patterns were consistent across operational phases (Tables S1a and S1b in Multimedia Appendix 1). Mondays had the highest abandonment rates (5274/48,411, 10.9% in T1, decreasing to 1999/58,049, 3.4% in T3b). Peak abandonment occurred from 11:00-16:00, coinciding with peak call volumes,

XSL•FO
RenderX

while early morning and late afternoon periods showed lower abandonment rates. Operational metrics showed positive correlations with abandonment for in-queue time (r=0.18-0.31) and occupancy (r=0.03-0.07), and small negative correlations for handle time and after-call work time (r=–0.03 to –0.18).

Table 4. Skill-level performance matrix: summary of call volume and abandonment rates for major skills across all 4 operational phases. For each skill, the table shows total calls and abandonment percentage in T1, T2, T3a, and T3b. The matrix reveals heterogeneous adaptation patterns, with the highest-volume skill (PA Radiology-Womens Imaging) showing dramatic improvement from 13.9% abandonment in T1 to 0.5% in T3b, while consolidated skills showed varied trajectories including transient increases during the transitional period.

Skill name	Total	T1 (abandon), n (%)	T2 (abandon), n (%)	T3a (abandon), n (%)	T3b (abandon), n (%)
PA Radiology-Womens Imaging	366,542	90,167 (13.9)	93,066 (5.2)	81,169 (2.6)	102,140 (0.5)
PA Radiology Team Rad Achiever	256,641	48,490 (1.6)	68,081 (6.3)	57,656 (3.3)	82,414 (4.9)
PA Radiology Team Blue Magic	189,344	32,695 (1.6)	50,764 (6.7)	43,206 (2.5)	62,679 (4.3)
PA Radiology Surgery	89,275	14,614 (2.8)	24,988 (1.9)	20,554 (1.1)	29,119 (1.3)
PA Interventional Radiology	53,182	11,819 (2.4)	13,031 (2.1)	11,461 (2.3)	16,871 (3)
Imaging-Mammogram Scheduling	35,166	23,867 (23)	11,297 (6.6)	1 (0)	1 (100)
Imaging-CT Scheduling	12,570	7375 (1.1)	5188 (4)	0 (0)	7 (85.7)

Threshold Optimization

Seven threshold optimization policies were evaluated, each mapping to a specific deployment scenario [16] (Figure S7 in Multimedia Appendix 1). These included F_1-maximizing (balanced precision-recall), Youden J (sensitivity-specificity balance), cost-minimizing under the assumed 5:1 FN:FP ratio, precision-targeted at 95%, recall-targeted at 90%, volume-based (top 10% risk decile), and maximum false positive rate constrained at 5%. The F_1-maximizing threshold was approximately 0.06, identifying about 14% (43,063/300,060) of calls as positive predictions. Youden-index optimization produced a threshold near 0.02. Under the assumed 5:1 false-negative-weighted cost model, cost minimization favored flagging no calls, because the model's precision at this prevalence does not offset false-positive costs at that ratio (Figure S8 in Multimedia Appendix 1).

Target-recall optimization for 90% abandonment sensitivity required a threshold near 0.012, flagging approximately 52% (157,052/300,060) of calls (sensitivity 90.0%, 7463 of 8293 positives correctly identified; specificity 48.8%; precision 0.047). At threshold 0.03, the same model achieves sensitivity of 72.9% (6045/8293 positives) at a lower flagging volume of 32.2% (96,626/300,060), illustrating the recall-volume trade-off inherent to rare-event detection at low prevalence. Operating thresholds also transfer prospectively: under a Youden-index policy, the threshold derived on T3a (0.03) achieves 72.9% sensitivity on T3b vs 82.1% for the T3b-optimal threshold (0.02), and under the 90%-sensitivity-target policy the T3a-derived threshold coincides with the T3b-optimal threshold.

Discussion

Principal Findings

This study set out with a fundamental question: could call abandonment in health care call centers be predicted using machine learning in conjunction with nonpersonal operational data? This question emerged from the pressing need to balance operational efficiency with increasingly stringent patient privacy requirements in health care settings [6,7]. Using an extensive longitudinal dataset spanning 17 months and comprising over 1.2 million calls from Emory Healthcare's call center, we explored the feasibility of abandonment prediction across distinct operational phases marked by significant organizational transitions. By leveraging random forest and CatBoost algorithms combined with interpretable machine learning approaches, we aimed to develop a privacy-compliant framework capable of adapting to evolving call center conditions while maintaining robust predictive power [10].

Our findings demonstrate that call abandonment can be accurately predicted using exclusively nonpersonal operational metrics, with real-time queue dynamics emerging as the most influential determinants. These metrics, particularly in-queue time and agent staffing, consistently carried substantially more predictive signal than temporal patterns or skill assignments. This highlights that abandonment behavior reflects immediate

XSL•FO
RenderX

system conditions rather than fixed characteristics of callers or services. Importantly, models trained on data reflecting the current operational structure retained strong discrimination and calibration, whereas models trained on preintervention data showed substantial degradation when applied prospectively. This reinforces that organizational shifts, such as skill consolidation or workflow restructuring, fundamentally reshape relationships between features and outcomes, and therefore predictive models must be retrained following operational change.

Comparison With Prior Work

These observations align closely with foundational queueing theory, which posits that customer abandonment is driven primarily by perceived waiting burden and system congestion rather than arrival patterns or service categories [1,8]. Our results extend this theory into the health care domain, providing large-scale empirical validation using machine learning rather than stylized analytical models. They also support prior evidence that predictive model performance in health care systems is sensitive to workflow changes and organizational redesign [1,9]. Notably, our work adds nuance to this literature by showing that models trained during transitional periods, typically avoided by practitioners, can generalize effectively, likely because transitional variability exposes algorithms to a wider distribution of operational conditions, consistent with robustness research in uncertain environments [2].

Skill-level analysis revealed that while aggregate abandonment rates improved following consolidation, this improvement was not uniform. High-volume core skills such as “PA Radiology-Womens Imaging” showed substantial reductions in abandonment, while consolidated queues including “PA Radiology Team Rad Achiever” and “Team Blue Magic” experienced transient worsening during the transitional period before partial stabilization in T3b. SHAP analysis corroborates this heterogeneity, with certain specialized skill queues consistently appearing as top abandonment risk drivers. These findings suggest that consolidation strategies may create unintended bottlenecks in specialized service lines, and flexible surge capacity may be needed to accommodate adjustment-related increases.

Operational Implications

A key conceptual contribution of this study is demonstrating that strong predictive performance does not require patient demographics or identifiable behavioral histories. Traditional customer service analytics frequently rely on such data, but these features introduce substantial privacy and compliance barriers in health care contexts [6,7]. By showing that nonpersonal operational data alone is sufficient for robust prediction, we provide health care organizations with a viable and compliant pathway for implementing predictive analytics. The interpretability of the resulting models reinforces their practical use: unlike demographic predictors, operational metrics translate directly into actionable interventions that call center supervisors can modify, such as staffing adjustments, routing logic, or queue management policies. In practice, these capabilities support several deployment modes: real-time staffing alerts triggered when aggregate risk scores exceed queue-level thresholds, dynamic routing of high-risk calls toward less congested skill queues, and proactive callback offers via interactive voice response when predicted abandonment probability exceeds a configurable threshold. At a strategic level, historical patterns of risk by hour, day, and skill queue can inform staffing schedules and capacity planning. Each pathway carries different tolerance for FPs, which the threshold optimization policies described above are designed to accommodate.

The consistency of certain temporal patterns, such as higher abandonment on Mondays and peak loads during late morning and midday, further suggests that health care–seeking behavior follows stable rhythms independent of workflow changes. These patterns align with previous observations in health care operations research [3,5] and offer predictable levers for resource planning. Skill-level variation, however, points to the need for differentiated management strategies. High-volume core skills demonstrated stability and improvement, whereas lower-volume specialized skills showed greater volatility and higher baseline abandonment. This suggests that uniform staffing strategies may be suboptimal, and that flexible or surge capacity may be more effective for specialized services encountering sporadic but impactful variability. Importantly, even in the stabilized holdout environment, where low median queue times and reduced abandonment suggest a well-optimized system, the right-skewed distribution of queue conditions means that abandonment events cluster during peak hours and at the start of the work week, when transient capacity constraints emerge. The model’s practical value in such settings lies not in predicting routine calls, but in detecting these episodic windows of elevated risk through real-time operational signals rather than static temporal heuristics.

Limitations

First, this study used data from a single health care system; although the underlying principles, such as the primacy of queue-based metrics and the need for retraining after workflow changes, are likely generalizable, specific performance metrics may differ in other contexts with distinct operational structures or patient populations [7]. Future multicenter studies would strengthen external validity.

Second, absolute precision remains modest at most operating thresholds, inherent to predicting a rare event at low prevalence. While lift over the prevalence baseline demonstrates meaningful discrimination, deployment must account for FP burden. The model is best suited for risk ranking and aggregate alert systems rather than individual-call binary classification.

Third, the consolidation of skill assignments during the study period introduces some confounding, as performance changes cannot be fully disentangled from structural reorganization. Relatedly, several legacy scheduling queues that were not part of the twelve-skill consolidation, “Imaging-Mammogram Scheduling” (23,867 calls in T1, declining to 1 call in T3a and 1 in T3b), “Imaging-CT Scheduling” (7375 calls in T1, 0 in T3a, and 7 in T3b), and “Imaging-MRI Scheduling” (3718 calls in T1, 0 in T3a, and 4 in T3b), dropped to near-zero call volume in the later phases as operations shifted away from them. This constitutes a form of feature drift: these queues contribute to

XSL•FO
RenderX

model interpretability rankings despite carrying almost no signal in T3a/T3b, and interpretability findings attributable specifically to these queues should be interpreted in light of this volume collapse rather than as evidence of a stable, generalizable relationship.

The study period of 17 months, while spanning significant operational changes, may not encompass longer-term secular trends. Blocked temporal CV confirmed some temporal autocorrelation in within-phase estimates, though model ranking was preserved and the prospective holdout evaluation inherently respects temporal ordering.

Fourth, the absence of EWT announcements in our setting simplifies interpretation of in-queue time as a pure system-state indicator but limits generalizability. In settings where EWT announcements are provided, this information may represent a primary causal mechanism for abandonment and should be included as a feature in future multisite studies.

Fifth, calls are treated as independent observations. While individual callers may contribute multiple calls, the false abandonment analysis revealed that only a small fraction of abandoned calls involved callers who reconnected, suggesting limited within-caller dependence. Future work could explore mixed-effects models or clustered SEs to formally account for caller-level clustering.

Future Directions

Future work should focus on multicenter validation to evaluate generalizability across diverse health care systems with varying operational structures [4]. Prospective real-time deployment studies will be essential to characterize the full intervention loop: prediction generation, operational responses, and impact on abandonment rates [9]. Integrating predictive models with workforce management platforms could enable automated staffing or routing adjustments in response to predicted congestion. Methodological extensions, such as reinforcement learning for optimal intervention policies, causal inference for identifying modifiable drivers, or privacy-preserving modeling architectures, could further strengthen applicability while maintaining compliance. Beyond abandonment prediction, applying similar frameworks to outcomes such as first-call resolution, appointment completion, or patient satisfaction could support a unified predictive ecosystem for health care access optimization.

For production deployment, we recommend (1) quarterly retraining on the most recent operational window to match current conditions, (2) continuous monitoring of calibration metrics on live predictions, (3) an alert trigger when rolling discrimination drops below an acceptable threshold to flag retraining needs, and (4) tracking feature distribution shifts (eg, changes in mean agent availability or queue congestion metrics) as early warning indicators of concept drift before performance degrades [17,23].

Decision-oriented evaluation frameworks, as advocated by Itzhak et al [16] for rare-event prediction under temporal dynamics, highlight the importance of matching evaluation metrics to deployment objectives. Our threshold optimization policies directly instantiate this principle, providing deployment-ready operating points rather than relying solely on aggregate discrimination metrics.

Conclusions

Call abandonment in a health care call center can be predicted from nonpersonal operational data alone, with CatBoost trained on a postintervention phase achieving ROC-AUC 0.767 (95% CI 0.762-0.771) and PR-AUC 0.068 (2.47× lift over the T3b prevalence baseline 0.0276) on a 300,060-call temporal holdout. Real-time queue dynamics, particularly in-queue time and active agent count, provide the dominant predictive signal, and models trained on data reflecting current operational conditions generalize better to subsequent periods than models trained on preintervention data.

Abstract

Background: The growing need for and interest in geomatics in the medical sector, as well as the pandemic crisis, led us to create a France-wide geomatics project aimed at producing several atlases of all-cause mortality at the municipal and submunicipal district levels via uMap France, a free and open-source collaborative map-sharing platform. In 2020, we decided to circumvent the obstacle of accessing detailed COVID-19 data by adopting a mortality-based approach to map the consequences of the crisis.

Objective: The aim of the uMap study was to provide a webmapping platform with original visualization and knowledge as well as decision-making aids that complement existing information and are relevant to public and health care professionals. Our main hypotheses were as follows: (1) The medical sector could develop a private uMap platform dedicated to health; (2) interest in a municipal mortality atlas for France linked to the pandemic crisis will increase, even if it is produced after the pandemic; and (3) sharing the atlases with the uMap community will enhance their appeal and inspire the creation of similar atlases, owing to the new "experimental choropleth layer" recently developed by the uMap team.

Methods: This approach focused on 3 main parts—data management (data collection, cleansing, and scheduling) and geomatic engineering through a 2-step geomatic action plan to create atlases of the first lockdown period in France displayed on the uMap platform. A logarithmically transformed variable allowed us to obtain an immediate statistical signal of excess mortality or submortality via the Traffic-Light Atlas.

Results: The uMap Traffic-Light Atlas display provides instant statistical signals at a glance, owing to the semantic interplay of colors. The atlas's double legends make it easy to compare specific regions (northeast, northwest, southeast, and southwest) with all of France. The atlas revealed excess mortality in 41.7% (14,503/34,833) of the municipalities. Of the municipalities, 35% (12,198/34,833) were in the green class (close to average to 2 times the average), 5% (1724/34,833) were in the orange class (2 - 4 times the average), and 1.7% (581/34,833) were in the red class (4 - 11 times higher than average).

Conclusions: We innovated, enriched, and reinforced the value of uMap for visual rendering by instantiating colored choropleth map atlases and double legends and showed its relevance to the health care sector. We focused on the Traffic-Light Atlas, which is the most relevant aspect because of the instant message it conveys and its interpretability for all audiences. The uMap community can share our all-cause mortality atlases. A second version of the atlas encompassing 4 periods in 2020 and containing a minor error will be updated using either the "experimental choropleth layer" feature recently developed by the uMap team or, if this feature proves insufficient, the geomatic optimization process via the R project.

Introduction

Background

The growing need for and interest in geomatics in the medical sector, particularly in hospitals, have led us to strengthen our interdisciplinary collaborations on joint geomatics research projects over the past 2 decades [1-3] (Multimedia Appendix 1). Geomatics is, in a way, the combination of computer science and geography, providing digital mapping via easy-to-use software through the use of more complex software environments such as geographic information systems (GIS), programming languages, scripting languages, and geoservers to produce online maps [3]. Mapping can be an individual project or a collaborative project, owing to platforms with or without the ability to share cartographic productions. More information is provided in Multimedia Appendix 1 and Multimedia Appendix 2.

The COVID-19 pandemic led us to create an all-cause mortality atlas in France (version 1—the period of the first French lockdown) with maps that can be viewed at a very detailed level for municipalities and submunicipal districts (Marseille, Lyon, and Paris) [1,4-7]. This atlas offers a retrospective view of the period under study during the 2020 crisis. The inability to access data on reported SARS-CoV-2 cases with detailed geographical origins at the municipal level in 2020 for the purpose of mapping coronavirus cases at a fine mesh explains our choice to circumvent this obstacle. We therefore decided to use the (open) database of French mortality data from 2020 provided by the French National Institute of Statistics and Economic Studies (INSEE; Multimedia Appendix 3), which has several advantages: (1) The data are broken down at the municipal level (fine grain); (2) access is open (open data); and (3) we can avoid using young coronavirus databases (at the time of our data collection process) that have significant biases, such as “coding errors for deaths due to coronavirus” [8]. However, our monitoring of the evolution of the COVID-19 pandemic has shown, on the one hand, that epidemiological data on the incidence of coronavirus have become unavailable at the municipal level and the few coronavirus cluster maps available at the municipal level have eventually disappeared from the French media. On the other hand, in our neighboring country, Belgium, the incidence of coronavirus per 100,000 inhabitants was reported at the municipal level [9]. Many French studies and accompanying maps are also based on highly aggregated open coronavirus data [10].

Our monitoring of technologies, IT developments, and data sources led us, at the beginning of our mortality atlas project, to focus on 2 geomatic environments. Here, we present a study of geomatics based on uMap France (OpenStreetMap [OSM] server), a free and open-source software (FOSS) [11]. E-atlases based on a developed environment are now available online [7]. Upon querying the OSM server [12,13], we found no “color-coded thematic maps (also known as choropleth maps) with associated legends” created, shared, or posted online by uMap France community users. Examples of inventory maps and analysis maps (the former allowing users to move, explore, identify, place, locate, intervene, allocate, and manage and the latter allowing users to understand, evaluate, and analyze), as well as 2 other projects—uMap Framacarte (Framasoft server) and the uMap of public service (government server)—are displayed on the new uMap project home page created by Yohan Boniface [14].

The main geomatic methodological approaches for obtaining results were divided into 2 stages: step 1: geomatics without webmapping and step 2: geomatics with webmapping [15]. Our atlas maps (instances) were the main results of our study. Among the 3 e-atlases, each created from a statistical variable, the thematic “Traffic-Light Atlas” created from the “Khi2LnFr” variable displays 1 of 3 colors—red, orange, or green—if the municipality exclusively had an excess mortality statistical signal. For the submortality values, a pale yellow color represented values outside the Traffic-Light semantics. The Traffic-Light Atlas appears even more relevant, as cartographic information is instantly visible and easily interpreted by the human eye. We qualified this Traffic-Light Atlas as the best messenger.

Aims and Objectives

We had 3 main goals for this geomatics project for mortality atlases.

The first was to provide an original and relevant decision-making aid in the “uMap - FOSS online geomatic and mapping platform” [11] (on a French scale), which allowed us to produce and disseminate our mortality atlas for which the statistical and geographical information was processed and analyzed then mapped on a fine territorial grid (municipalities and submunicipal districts). This high level of detail in the processing of information provided new insights compared with studies in which information was aggregated at coarser departmental and regional administrative levels, leading to visualization and interpretation biases (ie, a mesh that is too aggregated can hide or render invisible or imperceptible other information remaining to be discovered) [16]. The departmental level is an administrative division between the municipality and the region. It has an elected council and a prefecture, which stands for the state. A regional level consists of an administrative division, with its own regional government.

The second goal for our version 1 atlas was to process information on mortality in 2020 (compared with 2018 and 2019) based on the period of the first French lockdown.

The third goal was to facilitate the comprehension of thematic information mapped on the scale of France and its overseas departments and regions (DROMs)—administrative divisions in France—for a wide audience of users (the general public, health care professionals, and the uMap community) of our atlases in uMap. To this end, we constructed statistical indicators

XSL•FO
RenderX

of excess mortality, which are displayed when the mouse pointer is hovered over the maps in the atlas. These excess mortality indicators (per 10,000 inhabitants at the municipal level) are also displayed in the map tool tips of the atlas. Users can connect to the uMap environment for each atlas instance associated with a statistical variable in 4 layers to subdivide France into 4 geographical areas: northeast, northwest, southeast, and southwest.

Hypotheses

The first hypothesis was that the evaluation of geomatic environments in the health sector provides new perspectives for medical disciplines in terms of information and communications technology (ICT) knowledge, ICT development, and the use of geomatic tools for the health sector. If this hypothesis is confirmed, this research will create a new knowledge base for developing a local uMap server dedicated to the health sector.

The second hypothesis posited that user interest in a municipal mortality atlas related to the pandemic crisis will increase, even if it is put into production after the pandemic, owing to the general public's interest in examining whether there was excess mortality in their municipality during the crisis (during or outside the lockdown period, versions 1 and 2 of the atlas), made possible by the fine mesh of the atlas maps, the instant visualization of excess mortality by the Traffic-Light Atlas, and the sharing of maps via the uMap France platform and the Grouping of the Institut Catholique de Lille Hospitals (GHICL) website [6,7,17,18]. If this hypothesis is confirmed, the uMap Traffic-Light Atlas will become more appealing due to its semantics (by ending map interpretation errors in excess mortality or submortality).

The third hypothesis posited that uMap is a remarkably interesting alternative to existing geomatics methods and platforms for collaborative online mapping. First, uMap offers attractive features. The most important of these is its minimal programming requirements. Second, the uMap team allows users to request help or new features as needed. Finally, we demonstrated the feasibility of implementing choropleth maps (based on GeoJSON) with associated double legends (based on image format) through this study and by contacting the uMap team. If this hypothesis is confirmed, the uMap team will be able to provide support and new features concerning the facilitation of creating and associating a legend (image file) with a choropleth map (GeoJSON file). In the short to medium term, we hoped that sharing these atlases with the uMap community will enhance their appeal through their visual and semantic quality and inspire the creation of other similar atlases, owing to the newly and recently developed experimental choropleth layer.

After the introduction and background, we describe the methods and processes involved in developing atlas maps for the uMap environment, followed by the results focused on the Traffic-Light Atlas and the ease of use (platform ergonomics) and cartography (information visualization and interpretation) of uMap France. We then present discussions on the geomatic process (uMap software package) and on the advantages and disadvantages in terms of design and use. The article then describes how the evaluation of the uMap environment and related tasks can be assessed in terms of performance, attractiveness, and profitability and what new developments, geomatic instantiations, and other improvements to the environment can be envisaged. We end with our conclusions.

Multimedia Appendix 2 provides further information on the state of the art in geomatics, including a history of digital cartography and an introduction to geomatics in health care.

Methods

Materials

Summary

This section describes the key material, data sources, software, formats, and standards used in this geomatics research project (see Table 1); for more details, see Multimedia Appendix 3, Multimedia Appendix 4, and Multimedia Appendix 5. We combined French open data sources with a hybrid software ecosystem (open source and proprietary) for spatial analysis of mortality data. The technical architecture enabled seamless integration between free software and specialized proprietary solutions, perfecting the mortality and geomatic data-processing pipeline (see Figures 1 and 2).

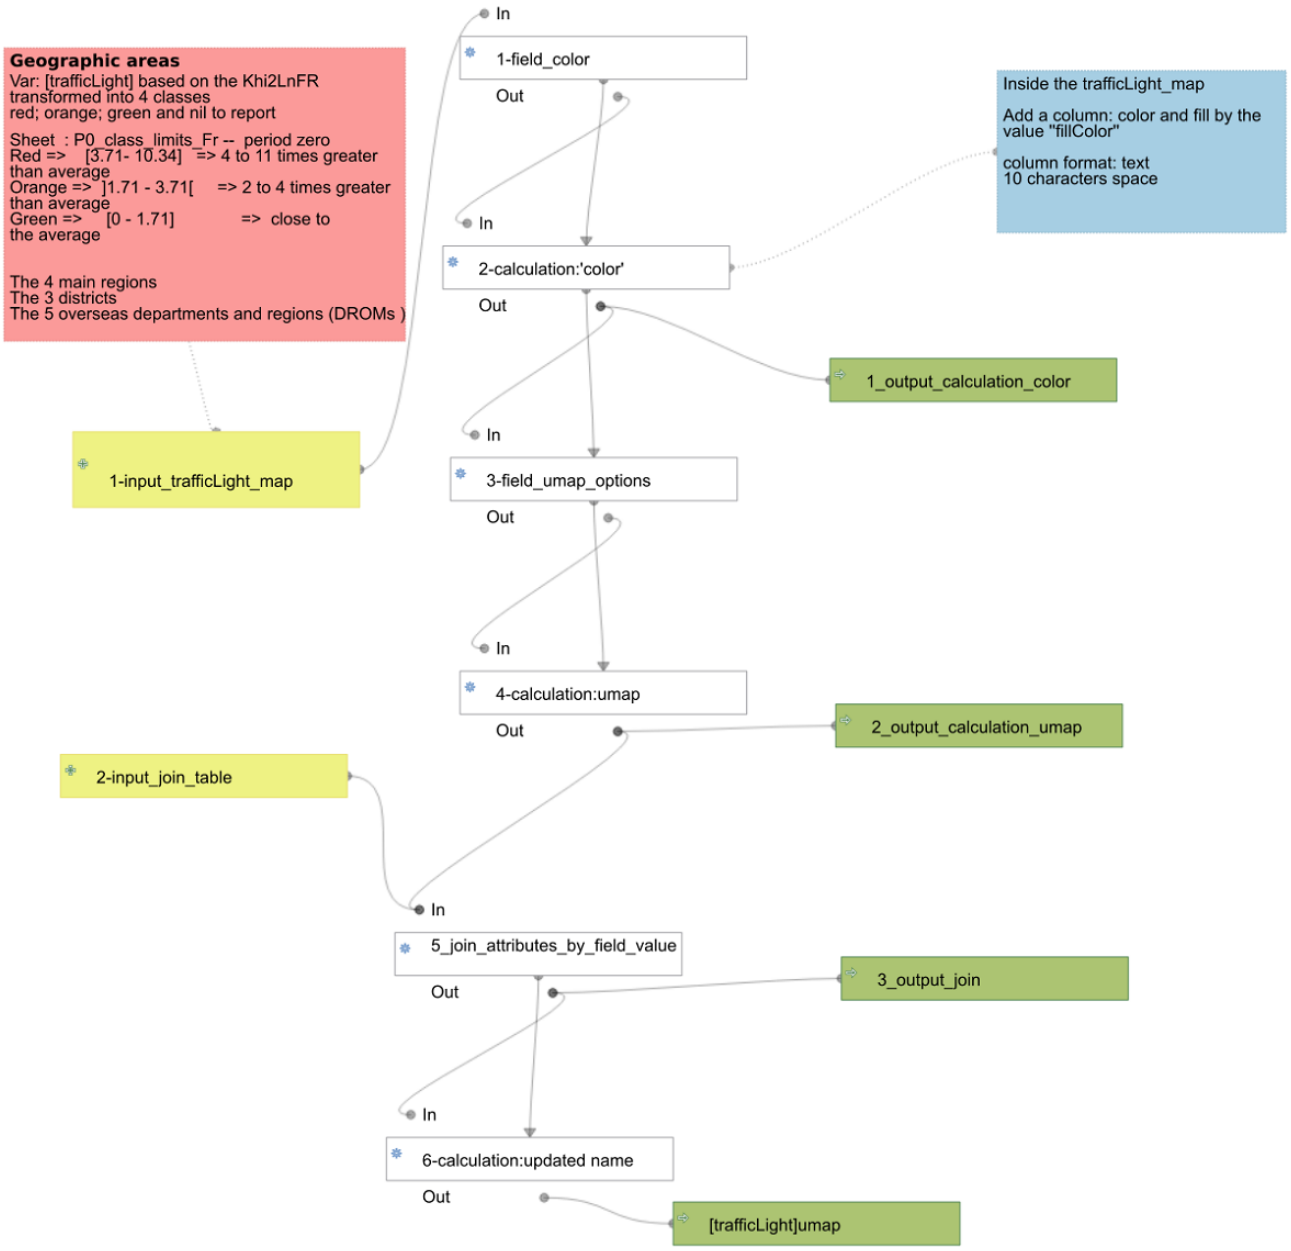
Rationale for Primary Tool Selection

Philcarto is French statistical data cartographic software specifically designed by a geographer. It implements Jenks natural breaks optimization directly on statistical tabular data, applying validated cartographic semiology rules (color palettes, class breaks) and natively producing Keyhole Markup Language (KML)–Direct output for subsequent use in other geomatic environments. Philcarto is the only tool in our workflow that simultaneously performs (1) statistical classification of Khi2LnFr, (2) Traffic-Light color encoding, and (3) KML export in a single, validated operation. It has been used in French academic geomatics workflows for more than 15 years.

QGIS is used exclusively for the spatial engineering step that Philcarto cannot perform: joining the Philcarto-classified KML attribute table to the French National Institute of Geographic and Forest Information (IGN) ADMIN-EXPRESS municipal geometry shapefile and converting the result to GeoJSON via the QGIS Model3 Graphical Modeler for reproducible batch processing.

This sequential, nonredundant use of both tools reflects their respective strengths: Philcarto for expert cartographic classification and QGIS for spatial data engineering and format interoperability. This division of labor is consistent with the multisoftware public health surveillance workflows described in the literature [68].

In addition, we used a number of other tools for specific functions. Google Earth was used to visually verify the data generated by KML-Direct, which was then exported in an indirect KML format (transformed) in the auxiliary optimization step. In Visual Studio (VS) Code, KML-Indirect files were manually inspected and converted to the GeoJSON format using the “View Map GDV 2.4” extension so that they can be read and processed by QGIS, also in the auxiliary optimization step. Mapshaper was used for GeoJSON file size reduction to meet the uMap server upload constraints during the auxiliary optimization step.



R, RMarkdown, and Excel were used for all statistical computations (SMM_10000, DENSI, Khi2LnFr) and to produce the ready-to-use input files for Philcarto. R scripts and RMarkdown programs are available in the public repository. SQLite was used for structured storage and querying of intermediate mortality tables during data preparation. See also Multimedia Appendix 5 and Figures 3-5.

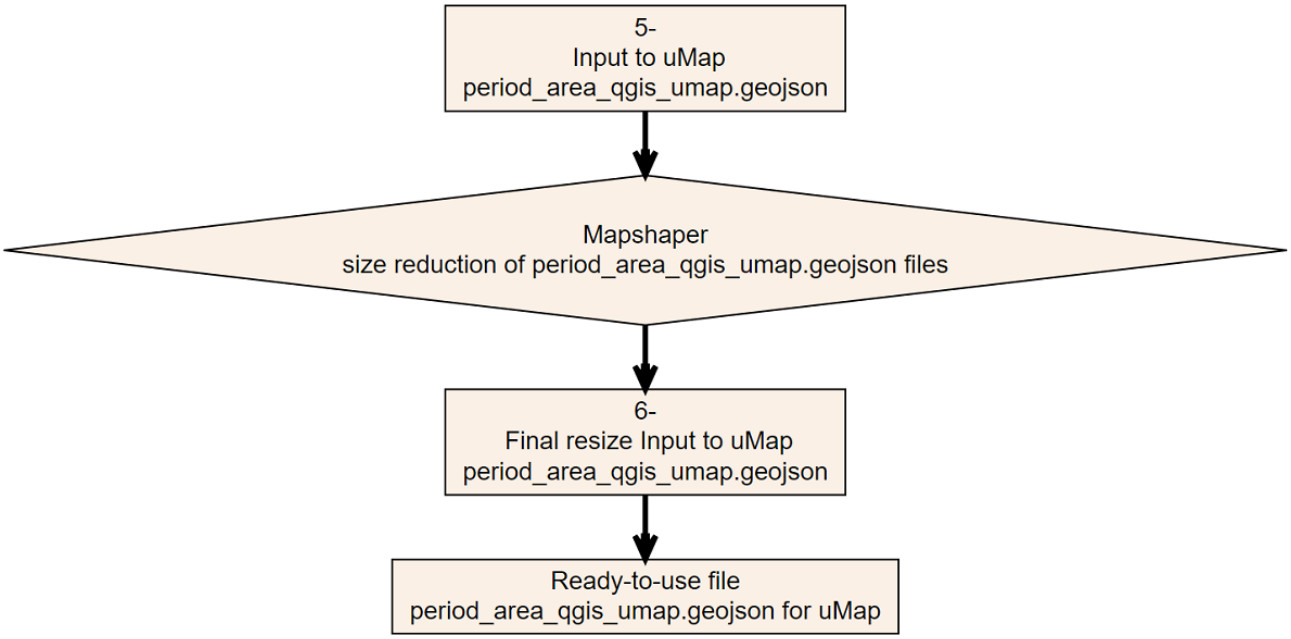
Overview of Methodologies

This methodological approach consisted of 3 main parts: data architecture, step 1: geomatics without webmapping, and step 2: geomatics with webmapping.



The first goal was to present the software architecture, which includes a description of the data processing stages (Figures 1 and 2), including the data transformation diagram (Figure 2B). In this study, data management was an essential process carried out in different software environments involving data collection, cleansing, and ordering processes [71]; specialized concepts; processes such as geomatic data processing pipelines; databases; and the extract, transform, and load (ETL) process. We schematized our methodological approaches to enable better monitoring of data pipelines in step 1: geomatics without webmapping or step 2: geomatics with webmapping.

For step 1: geomatics without webmapping, the data pipeline diagram for transforming KML into a GeoJSON file is shown in Figure 3, and the schematics for processing automation in QGIS are shown in Figures 4 and 5.

For step 2: geomatics with webmapping, the resizing processing schematic in Mapshaper is shown in Figure 6. The double caption processing diagram in the computer-aided design (CAD) software and uMap is shown in Figure 7, and the thumbnail processing diagram in the CAD software is shown in Figure 8. Finally, Figure 9 presents the Photoshop processing automation diagram.

Methodologies

The Software Architecture: Geomatic Action Plan—Essential and Auxiliary Steps

See Figure 1 for the software architecture of the mortality atlas for uMap.

INSEE Death Data Engineering

All the data sources (Table 1) shared a common identifier: the 5-character INSEE municipality code (eg, 2A014). SQL was used to analyze and process the data in SQLite [25]. All the processing is automated except for one process that stays manual. A simplified data transformation diagram is shown in Figure 2.

The CSV data were imported into SQLite and combined to produce an "insee_death" table. An analysis of the fields (variables) indicated that days and months of birth were not systematically filled in. The age of each individual was calculated, except for those for whom the specific day or month of birth was not documented. The data were then aggregated by the INSEE municipal code, after which the following metrics were calculated: average age (excluding date of birth not provided), 2020 mortality, average mortality over the 2 years 2018 and 2019, and difference in mortality. The final stage in the process, as delineated in Figure 2, was the association of the death data with the reference 2017 municipal population. The database thus created, appointed "insee_death_pop," was exported in CSV format. The reference structure of the data corresponding to the mortality variables is shown in Table 2 (see Multimedia Appendix 3 and Multimedia Appendix 4).

Table . Structure of the death database (source: French National Institute of Statistics and Economic Studies [INSEE]).

Variable	Description	Illustrative example
Group 1		
ID_mun	Municipality ID	26362
ID_dep	Departmental ID	26
ID_reg	Regional ID	121
Mun	Municipality name	Valence
Mun_pop_2017	Municipality population number—2017	63,714
Group 2		
Death_2018	Number of deaths in 2018	301
Death_2019	Number of deaths in 2019	295
Avg_death_2018 - 2019	Average number of deaths between 2018 and 2019	298
Death_2020	Number of deaths in 2020	352
Mortality_diff	Difference of deaths between Death_2020 and Avg_death_2018 - 2019	54
Avg_age	Average age at death	79
Group 3		
SMM_10000	Excess mortality or submortality per 10,000 inhabitants	8

INSEE Data Engineering in R and Excel for Philcarto

Several data preprocessing and statistical calculation stages were performed in R, Excel, and Philcarto. In the preprocessing stage (Table 3, line sections [1], [6], [11], [16], and [21]), the output file "insee_death_pop.csv" from Figure 2 needed additional preprocessing stages in R and Excel. These stages primarily entailed the incorporation of statistical variables and the addition and renaming of fields. The enriched death file (Table 3) could then be used in Philcarto and within the processing chain to instantiate atlases in uMap. Compared with the data presented in Table 2, the output file included modified, renamed, created, and reordered variables. The addition of suffixes to variable names enabled direct typing by Philcarto [34,35]. As illustrated in Table 3, the suffix _R_ appointed a report variable, whereas _N_ indicated a nominal variable. After the implementation of the R project program, the resulting XLSX output file had 24 variables.

[31]	ID_region; Khi2LnFr; 10_classes; Class; Traffic-Light;
[36]	Class_1; Excess_mortality_Traffic-Light; Excess_mortality_Traffic-Light_umap;

[a]We wrote the khi-square variables "Khi2 and Khi2LnFr".

[b]Group 1, lines [1] to [21]: 24 variables transformed from R.

[c]_R_: suffix for group 1 variables.

[d]_N_: suffix for group 1 variables.

[e]Group 2, lines a [25] to a [29]: variable numbers 25 to 29 transformed from Excel.

[f]Group 3, lines b [25] to b [29]: variable numbers 25 to 30 transformed for Philcarto.

[g]Group 4, lines [31] to [36]: variable numbers 31 to 38 transformed for the Traffic-Light map, workflows, and tool tips.

In the statistical calculation stage (Table 3, sections a [25] and a [29]), Excel spreadsheets were supplemented with additional statistical variables, namely "raw khi-square" and khi-square with the logarithmic transformation "Khi2LnFr." The methods for calculating these variables are described in the *Computations of the Atlas Variables* section. As outlined in Table 3 (line sections b [25] and b [29]), specific variables may have undergone renaming to align with the Philcarto file header standard. For example, the ratio variable "(Obs - Theo) ^2/Theo_Fr," previously designated "raw khi-square," was then referred to as "DENSI."

At the Traffic-Light classification stage (Table 3, line sections [31] and [36]), a new series of Excel processes was used to classify the values of the variable "Khi2LnFr" to generate the fourth variable of the Traffic-Light Atlas associated with excess mortality in 3 colors and to create subnational maps in Philcarto via the variable "Excess Mortality_Traffic-Light_umap." At this stage, the input file "insee.xlsx" was enriched with information variables such as "Excess Mortality_Traffic-Light_umap," which was directly recognized by the suffix "umap." This variable was used to interactively display the municipal tool tips (on hover) of the uMap atlas instantiations.

At the Philcarto software processing stage (Table 3, line sections [31] and [36]), the following files were presented as inputs to the software: spreadsheet-insee.xlsx (France as a whole; 34,833 municipalities online) and vectorial basemap.shp (georeferenced shapefile for the region or France as a whole) [34,35]. As an output, we obtained a first cartography associated with the 4 atlas variables, designated "SMM_10000," "DENSI," "Khi2LnFr," and "Traffic-Light." The Traffic-Light Atlas variable was named "Excess Mortality_Traffic-Light." The available output formats encompassed Adobe Illustrator (AI), Philcarto macro language (PMC), Enhanced Windows Metafile (EMF), and KML (see Table 1). The KML format was georeferenced with the World Geodetic System (WGS) 1984–EPSG_4326 [53-56,59]. The KML format eased interoperability and started the processing chain in other software environments, with the aim of obtaining a ready-to-use map in GeoJSON format for the "uMapOSM.fr" remote server (Figures 1–3). Choropleth maps, also referred to as color-coded thematic maps, were systematically accompanied by a discretized legend that uses the Jenks method (see the *Jenks Discretization* section) [73,74].

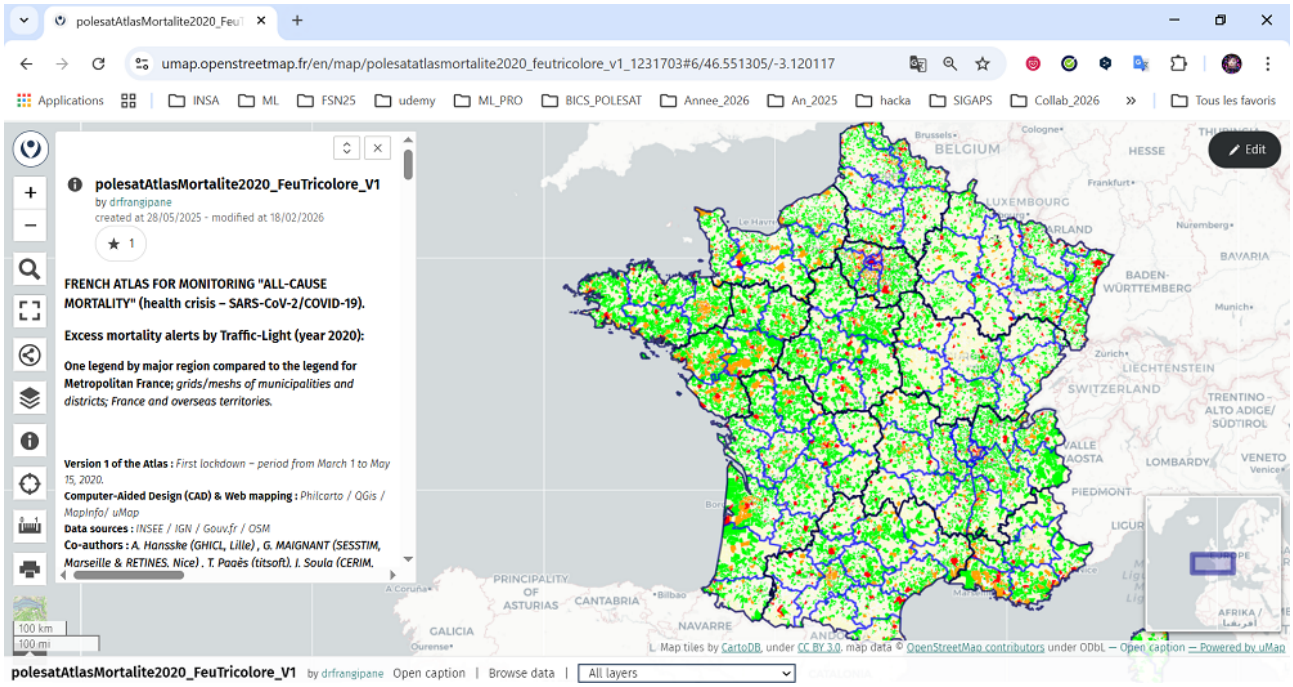
XSL•FO
RenderX

2020 Basemap Data Engineering

Basemaps at the scales of the DROMs; large regions (grouped areas); and submunicipal districts of Lyon, Paris, and Marseille were created via IGN files (Table 1). The georeferencing process was executed in accordance with the WGS84 GPS standard [59], which culminated in the generation of a KML output map for use within CAD software (Table 1; Figures 1-3). The shapefile (SHP) files of France's municipalities were divided into 4 major subnational municipality regions via the Éclats tool [35] due to limitations in vector file size. The basemap was augmented with one or more administrative boundary layers of greater thickness. The quantity of GeoJSON layers given by uMap was related to the number of choropleth maps displayed for each atlas. Finally, the Traffic-Light Atlas had a total of 12 GeoJSON layers, which included 4 large regions, 3 submunicipal districts, and 5 DROMs. For further information on map background engineering, please refer to the authors' previous work [35,75].

Geomatic Data Engineering

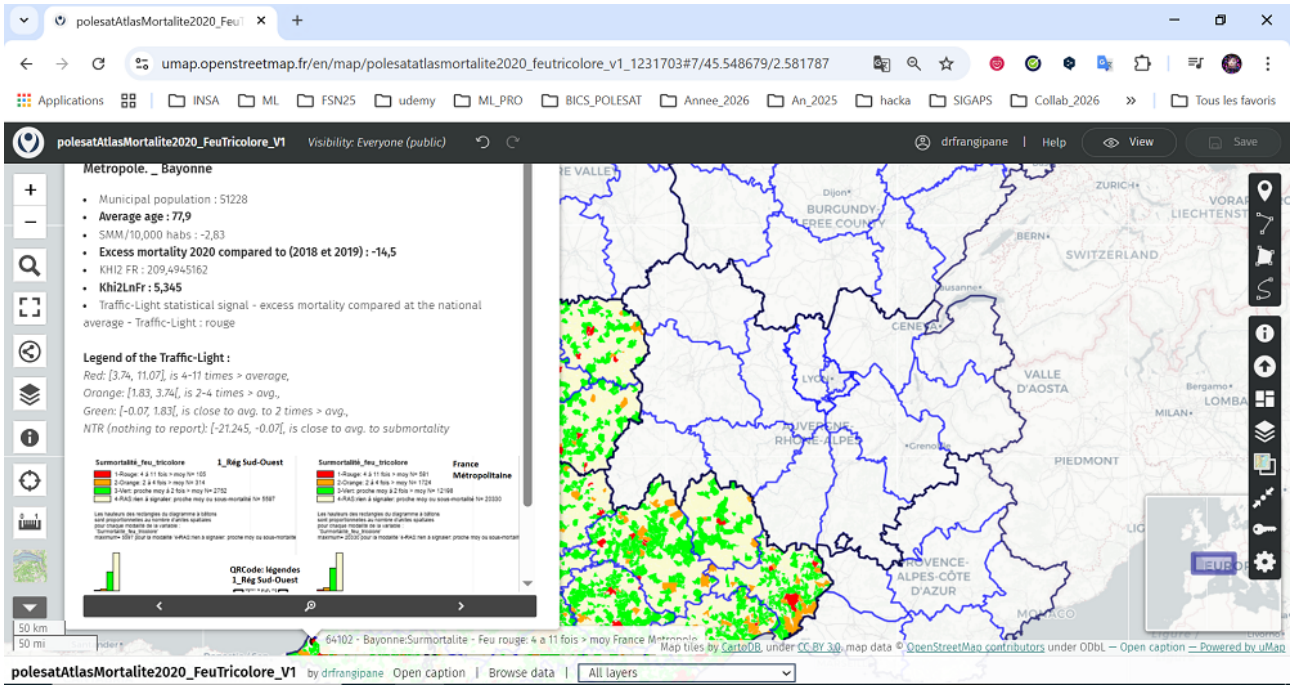
To ensure comprehensibility, geomatic data-processing pipelines and workflows are presented in schematic form.



GeoJSON Creation Stage (Step 1: Geomatics Without Webmapping)

The "direct KML" file produced by Philcarto is an inaugural file subjected to geomatic processing chains (workflow) via a data pipeline (see the *Data Pipelines of the 2-Step Geomatic Action Plan* section). In a multitude of software packages, the execution of transformations on the "direct KML" results in the generation of a final output file in GeoJSON format (Figure 3). The workflow in QGIS was based on 2 input files, "GE_vscode.geojson" and "spreadsheet.csv," and on the workflow model generated via the "modeler designer" tool, which generates files in MODEL3 format. These models ease batch processing. The output files were obtained from QGIS in the form of maps and enriched data in GeoJSON format and were ready for use in uMap (Figures 4 and 5). For example, the Excess Mortality_Traffic-Light_umap variable was automatically transformed to display structured tool tips when the mouse is moved over the Traffic-Light Atlas.

Legends Creation Stage (Step 2: Geomatics With Webmapping)



The GeoJSON map, which was obtained from processing the KML format (step 1: geomatics without webmapping; Figures 3–6), was uploaded as an input file to the French uMap OSM-fr remote server. After its implementation, the GeoJSON map was managed via the uMap "layer window" manager and "dashboard" (Figures 10 and 11). The legend associated with each GeoJSON layer was displayed via the legend creation and formatting data pipeline shown in Figure 7. The workflow for creating caption thumbnails is illustrated in Figure 8, whereas the workflow for formatting captions (automated in Photoshop using "script. ATN") is shown in Figure 9. Legend files in the PNG or JPG format were uploaded to a remote server at the University of Lille, as these formats cannot be hosted on the uMap OSM-fr server, which is reserved exclusively for GeoJSON files [76,77] (Figure 11).

Figure 10. The uMap atlas generated by Traffic-Light, France (see [6]).

Methodologies for Step 1: Geomatics Without Webmapping

Choice of Scales and Meshes

A nationwide French analysis was conducted for the mortality atlases under consideration, including DROMs, within a fine territorial grid of municipalities or submunicipal districts in Lyon, Marseille, and Paris. This approach supplemented existing studies that primarily used information from coarser grids [16].

Computations of the Atlas Variables

Statistical calculations were performed with death data from INSEE to create 4 atlases (see Figures 1 and 2 as well as *The Software Architecture: Geomatic Action Plan—Essential and Auxiliary Steps* section) based on the following 4 variables: (1) "SMM_10000" variable relating to excess mortality and submortality, (2) "DENSI" variable relating to a raw Khi-Square (Raw Khi2), (3) "Khi2LnFr" variable relating to "Khi-Square Ln Fr", and (4) "Traffic-Light" variable.

"SMM_10000" Variable Relating to Excess Mortality and Submortality

The formula used to calculate this variable is as follows:

$$SMM_10000=[Death2020-Death20182019MunicipalPop]*10,000$$

This variable is calculated via municipal death data from all causes from 2018 through 2020. The numerator is the difference between the number of deaths in 2020 and the average number of deaths in 2018 and 2019 divided by the municipal population in 2017. This ratio is then multiplied by 10,000. The resulting variable shows the excess mortality or submortality rate per 10,000 inhabitants.

"DENSI" Variable Relating to a Raw Khi-Square (Raw Khi2)

The formulas used to calculate this variable are as follows:

$$Death2020theoriticalFR=National_Death_Frequency*Municipal_Pop$$

$$National_Death_frequency=\sum Death2020\sum MunicipalPop=151,164639,133=0.0023855$$

$$DENSI=[Obs-Theo2Theo]FR=(Death_2020-Death2020theoricalFR)^2Death2020theoricalFR$$

The density of deaths was calculated as the ratio of the number of national deaths to the total French municipal population (metropolitan or excluding the DROMs [~64 million]). This ratio was then brought down to the municipal population, thereby allowing for comparisons between observed and theoretical deaths. Consequently, we emphasized excess mortality or submortality, which are more relevant and significant in terms of probability than the national average is.

As a sensitivity check, we assumed a Poisson model for municipal deaths with E_i parameter (based on the 2018 - 2019 baseline). Under this assumption, the DENSI corresponded to the classic Pearson khi-square statistic calculated for each municipality based on observed and expected deaths and normalized by the French national reference. DENSI was formally defined as the sum of the squares of the differences between observed and expected deaths for each municipality divided by expected deaths.

"Khi2LnFr" Variable Relating to a "Khi-Square Ln Fr"

The formula used to calculate this variable is as follows:

$$X2=Khi2LnFr=Ln(DENSI)$$

The "DENSI" variable is transformed using a logarithmic scale to show excess mortality or submortality compared with the national average.

For each municipality, the life expectancy at death was calculated based on the 2018 - 2019 average over the same period. The DENSI variable was the standard term for Pearson khi-square, and Khi2LnFr was its log-transformed version used for cartographic discretization. This discretization method compressed extreme values while preserving the order of

XSL•FO
RenderX

municipalities. This transformation facilitated cartographic classification into ordinal classes used for choropleth (Traffic-Light) map representation.

"Traffic-Light" Variable

The excess mortality values of the Khi2LnFr variable were grouped into 3 color classes (green, orange, and red) via the Jenks discretization method in Philcarto. This Traffic-Light–inspired semantic approach provides humans with easily understandable statistical information. Municipalities in the red Traffic-Light class were almost systematically above the upper 95% Poisson bound, whereas pale yellow municipalities fell within or below this bound, supporting the consistency of our classification with a simple count-based model.

Jenks Discretization

The map legend was created via statistical discretization via the Jenks method (the natural threshold method). This method maximizes the variance between classes and minimizes the variation within classes, making each group of geographical units more homogeneous than other methods. Computer calculations can be time-consuming, but the results are optimal. Maps are objective if >5 classes exist. This method is better suited to multimodal variables with a large enough individual to create thresholds. It was developed by GF Jenks, an American cartographer and geographer, in the 1960s [79,80].

10-Class Classification

Overview

The Jenks method was used to create a map of the whole country for each variable, with a legend of 10 classes. The boundary values of the 10 classes were stored in a repository and used to create thematic maps of the same variable on a subnational scale, including 4 geographical areas (northeast, northwest, southeast, and southwest), administrative regions, submunicipal districts, and DROMs.

Example of a 10-Class Frame of Reference

Khi2LnFr and Traffic-Light Variables

Table 4 presents the variables Khi2LnFr and Traffic-Light. The first variable had 10 classes, with the classes corresponding to excess mortality compared with the national average being associated with the 3 colors of the Traffic-Light variable. A change from green to red indicated an increase in excess mortality.

XSL•FO
RenderX

Table . 10-class classification scheme based on Jenks discretization (variable: Khi2LnFr).

Class number	Khi2LnFr interval	Municipalities, n (%)[a]	Class color	Poisson $P<.05$, n (%)[b,c]	Interpretation[d]
Traffic-Light colors					
10	[+3.74 to +11.07]	581 (1.7)	Red[e]	552 (95.01)	High statistical signal
9	[+1.83 to +3.74[	1724 (5)	Orange[f]	642 (37.24)	Moderate statistical signal
8	[+0.75 to +1.83[	4629 (35)[g]	Green[n]	157 (3.39)	Low statistical signal
7	[–0.07 to +0.75[	7569 (35)[g]	Green[i]	0 (0)	Near-average, minimal signal
Outside Traffic-Light colors					
6	[–0.84 to –0.07[	8409 (58.3)[j]	Pale yellow[k]	—[l]	NTR[m]: close to average to submortality
5	[–1.71 to –0.84[	7070 (58.3)[j]	Pale yellow [k]	—	NTR: submortality
4	[–3.06 to –1.71[	3466 (58.3)[j]	Pale yellow[k]	—	NTR: submortality
3	[–5.22 to –3.06[	976 (58.3)[j]	Pale yellow[k]	—	NTR: submortality
2	[–8.78 to –5.22[	340 (58.3)[j]	Pale yellow[k]	—	NTR: submortality
1	[–21.24 to –8.78[	69 (58.3)[j]	Pale yellow[k]	—	NTR: submortality

[a]Municipalities identified in France as a whole: n=34,833 (6 depopulated municipalities with population=0 were excluded from the Poisson calculations).

[b]For each municipality without a filter, a 1-sided exact Poisson test (right-tailed) was computed: $P=P(X\geq O_i|\lambda=E_i)$; Mathematical definition for class k: $\%=100\times|\{i \in class_k: P<.05\}|/N_k$, where N_k=total number of municipalities in class k (denominator=ALL N_k, regardless of E). P=scipy.stats.poisson.sf (O −1, E), strict inequality $P<.05$. $P=P(X\geq O \mid \lambda=E)=1-F(O-1; E)$, where F is the cumulative distribution function (CDF) of Poisson. The value represents the percentage of municipalities within each Traffic-Light class whose observed excess mortality was statistically incompatible with the random Poisson variation around the 2018 - 2019 national baseline at the 5% significance level. For example, 95.01% (552/581) of the red class municipalities individually reached statistical significance at the 5% level, confirming internal coherence of the upper Jenks boundary (Khi2LnFr=+3.74); in other words, a low P value (eg, <.05) suggests significant excess mortality in that municipality (see Multimedia Appendix 13).

[c]No filter on E (E =expected number of deaths).

[d]Probability that the observed excess mortality is incompatible with random Poisson variation around the national baseline (2018 - 2019); gradient from 3.39% (green) to 95.01% (red) confirmed the internal coherence of the Jenks-based Traffic-Light classification.

[e]Highest excess mortality signal (see the *Ordinal Interpretation of the Classification* section).

[f]Moderate excess mortality signal (see the *Ordinal Interpretation of the Classification* section).

[g]Class numbers 7 and 8 were combined for the percentage of municipalities: n=12,198.

[h]Low excess mortality signal (see the *Ordinal Interpretation of the Classification* section).

[i]Near-average to minimal excess mortality signal (see the *Ordinal Interpretation of the Classification* section).

[j]Class numbers 1 through 6 were combined for the percentage of municipalities: n=20,330.

[k]No Traffic-Light response; near-average to submortality (see the *Ordinal Interpretation of the Classification* section).

[l]Not applicable.

[m]NTR: nothing to report.

Internal Coherence of the Classification

The Jenks natural breaks algorithm was applied to the distribution of Khi2LnFr across 34,833 French municipalities, identifying 10 natural classes subsequently merged into 3 Traffic-Light signal bands and 1 “nothing to report (NTR)” category (Table 4). As an internal calibration step of the geomatics pipeline—consistent with the scope of this medical informatics article—a 1-sided exact Poisson test (right-tailed) was computed for each municipality “without a filter” on expected death E_i: $P=P(X\geq O_i|\lambda=E_i)$. The results confirmed a clear, class-dependent gradient of statistical significance: Only 3.39% of green class municipalities reached $P<.05$, compared with 37.24% for orange and 95.01% for red (Table 4). This gradient validated the internal coherence of the classification.

Ordinal Interpretation of the Classification

Excess mortality classes (green, orange, red) were defined by intervals based on Khi2LnFr, so they were ordinal bands derived from the national distribution using the Jenks method, with “interpretations” (Table 4) such as “green class: near-average, minimal signal or low statistical signal,” “orange class: moderate statistical signal,” and “red class: high statistical signal” or by using this second example of “verbal labels” such as “~2–11× above average,” indicating approximate orders of magnitude of the observed/expected (O/E) ratio without exact multiplicative values due to the use of logarithms; the rationale is presented

XSL•FO
RenderX

in Multimedia Appendix 13. Consequently, the primary information conveyed by this second verbal label—"~2 - 11× above average" classification—lies in the relative ranking of units along the excess mortality gradient rather than in the precise numerical value of the O/E ratio. This ordinal approach was intentionally designed to emphasize comparative positioning and spatial contrasts within the national context while limiting overinterpretation of absolute magnitudes that are sensitive to stochastic variability and model assumptions.

Data Pipelines of the 2-Step Geomatic Action Plan

To determine the "environment of the atlas" in uMap, a 2-step geomatic action plan was used. In step 1: geomatics without webmapping, maps were constructed in GeoJSON format outside of uMap (Figures 3-5). In step 2: geomatics with webmapping, legends were created with uMap (Figures 6-9).

Step 1: Geomatics Without Webmapping

Data Pipeline Description

A variety of software and processing methods were used to generate instances of the Traffic-Light Atlas in uMap. To obtain files in KML format and subsequently in GeoJSON format ready for uMap, we processed the information through a software suite producing a data pipeline [32]. The data pipeline was complex. The schematic in Figure 3 shows the tasks organized sequentially in different software programs, with the main packages being CAD, GIS, Globe, source code editors, and spreadsheets (see Table 1).

KML to GeoJSON for the uMap Data Pipeline Diagram

As demonstrated in Figure 3, the maps in the KML file format were transformed to obtain the final GeoJSON format. The KML map, therefore, underwent a series of processes in a pipeline of software environments (Google Earth, VS Code, and QGIS; the GeoJSON file editor) until the final "map.geojson" file was obtained at the conclusion of step 1 (see Figures 1 and 2).

In Figure 3, a distinct shape is shown for each type of information: rectangle: input output result; rhombus or diamond: software processing; and ellipse: QGIS workflow modeler.

The pipeline was sometimes partially automated and sometimes fully automated, as in QGIS workflows (Figures 4 and 5) [32]. The task processing chain was executed within the same software environment. In this particular instance, the "modeler designer" was used [62] to develop a model that automated an entire geomatic processing chain. The model began with an "input" and culminated in the generation of a GeoJSON file (for uMap). Two files were created via the modeler designer (MODEL3) to create a map of France: "file: processing chain" and "file: batch processing" (see Figures 1 and 2).

QGIS Workflow Diagrams

In the QGIS, the workflow was divided into 2 parts, as shown in Figures 4 and 5, allowing processing of the direct KML file to obtain the GeoJSON file for uMap.

Step 2: Geomatics With Webmapping in uMap

After following step 1: geomatics without webmapping, the final "map.geojson" file was ready for use as an "input file" in step 2 [12,13].

The GeoJSON file obtained in step 1 may not be imported in its original state because of size constraints imposed by the OSM server. In this case, we used the Mapshaper tool to reduce the vector shape definition [36,81] and, consequently, the file size.

Reduced GeoJSON Resolution Workflow for uMap Imports

In Figure 6, a distinct shape is associated with each of the 2 types of information: diamond: processing and rectangle: input output result. See Multimedia Appendix 9.

uMap Platform Features

Once the GeoJSON file had been imported into the remote OSM server of uMap, to address the complexity of the processing in step 2, the data pipeline was diagrammed (Figure 7; see Figures 1 and 2 for a reminder).

In the uMap Environment

The uMap dashboard environment is distinguished by a relative paucity of lines of code for control. The map display is configured through the dashboard user interface. Upon initiation of the URL in the browser, uMap continues to load each file about the major regions, submunicipal districts, and DROMs in succession. The final display of the Traffic-Light Atlas can be viewed at the scale of the entire French territory. A map setting template was created using the first dashboard settings for the Traffic-Light Atlas (eg, map display parameters such as titles, fonts, and legends). This template automates the integration and display of atlases and their maps in GeoJSON format in uMap according to a variable, which saves time. The open data layers provide administrative and sanitary boundary lines.

Different Servers for Hosting Maps and Legends

These data were downloaded in GeoJSON format to the remote OSM server of uMap France and managed via the uMap layer manager (see Table 1 and Multimedia Appendix 5). Hosting the legends associated with each GeoJSON map of France's major regions, submunicipal districts, and DROMs required access to a new server because the JPEG and PNG legends cannot be uploaded to the same OSM remote server as the Atlas GeoJSON files. The uMap atlas was secure from creation; it was simply set to secure. Four OSM administrators manage the OSM remote server security, and 3 servers are hosted by OVH Cloud France.

These numbers may have changed since the growth of uMap in 2023 with its new uMap public service platform and government server. The map data in the GeoJSON files are not encrypted on the server. The servers are not compliant with the General Data Protection Regulation (GDPR) [82]. The minor weaknesses of the uMap environment described in the literature [11,83] are not concerns.

XSL•FO
RenderX

Geomatic Data Processing Pipeline Description

To address the complexity of geomatic processing for atlas embellishment in uMap, we schematized the data pipeline to create and associate a double legend for each GeoJSON map.

Double Caption Data Pipeline Diagrams

Figure 7 includes 3 blocks of procedures numbered 1 through 8. We started with a Philcarto file in EMF format. At the end of the chain, a double map legend was shown with a QR code in PNG format. These legends are on a remote server for univ-lille.fr and are associated with each GeoJSON map on uMap OSM-fr.

Thumbnail Workflow Diagrams—Preparation of Legends for Step 2: uMap Geomatics With Webmapping

For more details about the 2 blocks of procedure stages 1-3, see Figure 8.

Workflow Diagram in Photoshop—Double Legends With and Without QR Codes—Step 2: Geomatics With Webmapping

For more details about the Photoshop7 workflow legends with and without QR codes, see Figure 9.

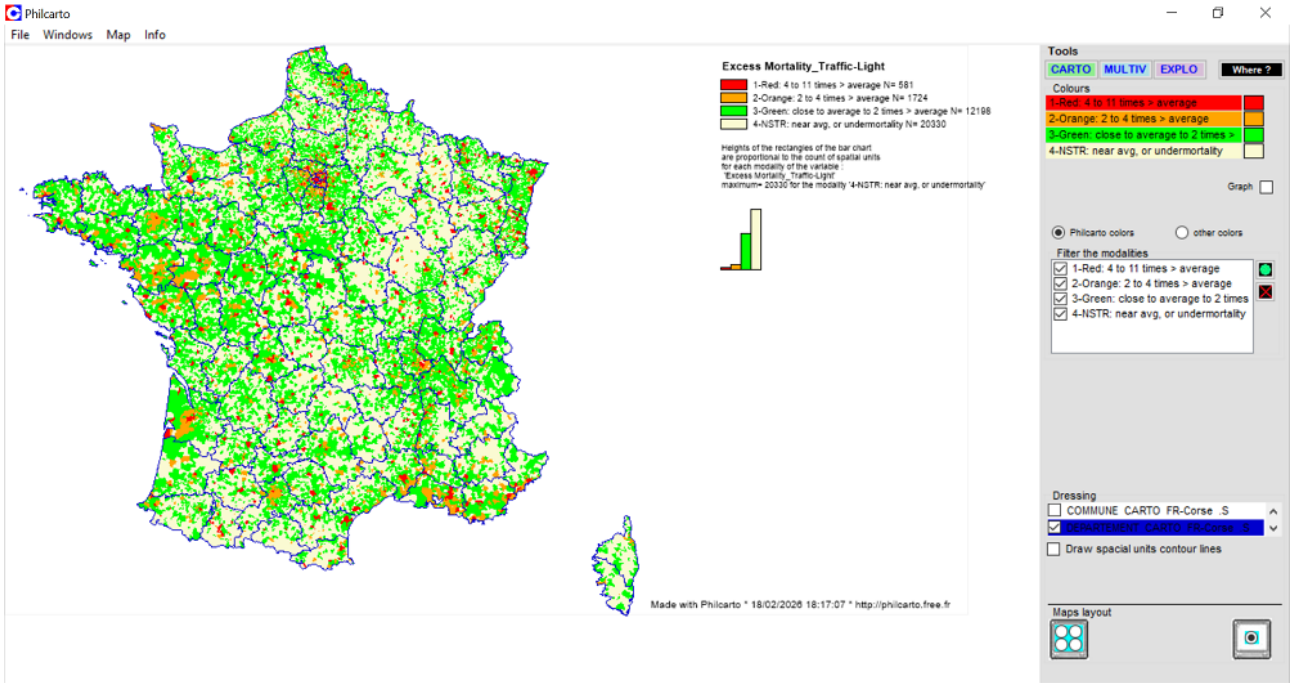
Ethical Considerations

This study did not use any studies with human participants or animals performed by any of the authors. Since the mortality data from the INSEE are public, we were exempt from any request for authorization from an ethics committee. Please refer to the terms of use for INSEE data in [84] and the copyright for INSEE data in [85]. The first part of the copyright notice for the INSEE data says “The publications and data made available on this website are accessible and downloadable free of charge. Unless otherwise specified, they may be reused for commercial purposes, without a license and without the payment of royalties other than those collected by copyright collection and distribution societies governed by Title II of Book III of the Intellectual Property Code. However, reuse is contingent upon maintaining the integrity of the information and data and providing precise citations of sources…” [69].

Results

Overview

This section focuses on the results of the Traffic-Light Atlas. First, we examined the results of the Traffic-Light map in Philcarto during step 1: geomatics without webmapping. We then examined the results of the Traffic-Light Atlas in uMap during step 2: geomatics with webmapping.



In step 1, the initial Philcarto KML map file was processed with VS Code, Google Earth, QGIS, Geojson.io, and Mapshaper, and the spreadsheet data were enriched. In step 2, the atlas was enriched by 2 processing chains prior to obtaining the results of the atlas with its double legends in the uMap environment.

Since the map’s visual aspects remained unchanged throughout step 1, it was unnecessary to display it in intermediate environments until the final GeoJSON file was obtained.

Step 1: Geomatics Without Webmapping—Traffic-Light Choropleth Map Under Philcarto

The cartographic results in the Philcarto environment enabled us to obtain the first exported map in KML format (Figures 1 and 2). This Philcarto environment consisted of a 2-part window: the map result and its single legend on the left and the dashboard for setting map creation on the right (Figure 12).

Figure 12. Map from Philcarto: excess mortality based on the Traffic-Light color system and submortality outside the Traffic-Light system (pale yellow); KML-Direct output format.

XSL•FO
RenderX

Interpreting the Traffic-Light Choropleth Map

Figure 12 shows a choropleth map accompanied by its corresponding single legend for the Traffic-Light variable. The map was augmented with a departmental boundary and presented on a French scale. The first lockdown linked to the COVID-19 crisis (March 1, 2020, through May 15, 2020) was covered.

Based on the Khi2LnFr variable, our statistical indicators were transformed into classes in the legend titled "Excess Mortality Traffic-Light." The variable "Traffic-Light" represented the increasing excess mortality distributed across the 3 color classes. A fourth pale yellow color class was added to denote values that fall outside the Traffic-Light semantic range. The values in question were proximate to the mortality average or less than the average, thus indicating submortality. A total of 34,833 geographical units were incorporated into the map, excluding 6 municipalities whose population was determined to be zero. At the time of the study, the total population of France was 63,639,133. In total, 20,330 municipalities (20,330/34,833, 58.3%) were classified as outside the 3 Traffic-Light colors, and 14,503 municipalities (14,503/34,833, 41.7%) were assigned one of the Traffic-Light colors corresponding to excess mortality.

Details of the Traffic-Light Classification of the 14,503 Municipalities

A total of 12,198 municipalities (12,198/34,833, 35%) belonged to the green class, in the range from "close to the average to 2 times above the average."

A total of 1724 towns (1724/34,833, 5%) belonged to the orange class, in the range "2-4 times above the average."

A total of 581 towns (581/34,833, 1.7%) belonged to the red class, in the range "4–11 times above the average," which represented an extremely significant excess mortality rate.

An assessment based on a simple Poisson model confirmed the consistency of the red class with the expected 95% quantile exceedance, validating the robustness of the classification.

Below the classes in the Excess mortality_Traffic-Light legend in Figure 12 is a bar chart proportional to the number of spatial units (34,833) included in each modality of the variable. From left to right, the heights of the rectangles are 581 (1.7%), 1724 (5%), 12,198 (35%), and 20,330 (58.3%).

The map aims to signal to the observer immediately (visually) and simplify interpretation for the public via familiar semantics.

Step 2: Geomatics With Webmapping—Traffic-Light Atlas Under uMap

The results obtained in step 1 were then used and incorporated into the processing chain in step 2. This section presents the uMap functionalities, the Traffic-Light Atlas results for all of France, and a zoom-in on the southwest region with a tool tip pointing to Bayonne.

Ergonomics and Usability of the uMap

The uMap showcase includes examples of our atlases, which cover all of France and include DROMs. Three URLs provide access to these atlases [6,17,18]. There were as many double legends as there are imported GeoJSON layers. Atlas access and display times were relatively short: Regarding average page load times, the time measured for the first display (including layer toggles) was 1.5 seconds, and the full page load time was 5 seconds. However, loading into uMap was slower because of the display of the complete atlas, which loads GeoJSON layers at the municipality level for the major regions, submunicipal districts, and DROMs, representing 34,833 municipalities. Once the atlas was loaded, the navigation experience in the browser was smooth and without slowdowns. The dashboard allowed one to select and configure the desired display features, including tool tips.

From the uMap user interface, several functions and icons were accessible: zoom in and zoom out; search for place names; take a full-screen view; center the map on a location; measure distances; and select the desired "tile layer" basemap from those provided by the OSM, IGN, or National Aeronautics and Space Administration. The user guides for uMap are available at [6,14,50,82,83,86-88]. Printing atlases requires 2 stages: accessing the data sharing functionality and retrieving exported map data in GPX and KML formats (for printing purposes, see also other GIS or web services such as MyOSMatic [89]). Finally, uMap is an interoperable platform for exporting and printing maps on the basis of the API [11].

Traffic-Light Atlas OSM World Basemap Based

The uMap environment for the uMap atlas generated by Traffic-Light, France (Figure 10) consists of a 3-part window.

The first part combines the visual aspect of the France atlas with several tool buttons on the left of the screen. The main tool button manages and displays layers (GeoJSON maps) and searches for data via the "Browse data" link.

The second part of the screen, on the right, contains the legend tab showing double legends for each layer.

The third part of the user interface displays a banner with the map title, the designer's name, and information about the ownership of the uMap environment [87].

Figure 10 shows the Traffic-Light Atlas from the first French lockdown. It includes departmental and regional outlines, as well as labels for the GeoJSON layers associated with the 4 subnational areas: northeast, northwest, southeast, and southwest. The atlas uses colors on the map to display excess mortality. Double legends allow comparisons between subnational and national distributions. Figure 11 provides additional information about the uMap atlas generated by Traffic-Light, by featuring a tool tip focusing on an enlarged view of the southwestern region of Bayonne town.

Two processing streams were generated for the uMap atlas generated by Traffic-Light, France (Figure 10). The first stream reduced the file size via Mapshaper to import the GeoJSON files to the remote OSM server uMap, whereas the second added a double legend (via a geomatic pipeline) to improve the visualization and statistical interpretation of the atlas.

The following URLs direct the reader to the atlases of the "SMM_10000" variable [17] and the "DENSI" variable [18].

RenderX

Discussion

Principal Findings

In this study, we demonstrated that the uMap webmapping platform can display choropleth maps accompanied by their double legends. Version 1 of the resulting mortality atlases applies to the period of the first lockdown in 2020. Owing to the Traffic-Light variable, we have shown that color semantics applied at the scale of France allow users to assess at a glance where excess mortality is highest in municipalities. This could encourage 2 things among uMap users (professionals and the public), which would therefore confirm our hypotheses. First, they may be motivated to explore our retrospective mortality atlases further to determine whether their municipality experienced excess mortality during the crisis (we present 2 concrete and hypothetical examples illustrating the practical utility of our atlases designed for a regional health agency). Second, our atlases have the potential to motivate uMap users to generate new thematic choropleth atlases in local or remote uMap servers.

In the *Discussion* section, we review the 2-step geomatic action plan, comprising step 1 (without webmapping) and step 2 (with webmapping). Step 1 involved the execution of the data engineering workflow, which encompassed activities such as data collection, cleansing, and planning (or scheduling tasks) related to death data. The subsequent step 2 involved processing chains and optimization for the creation of double legends.

INSEE Death Data Engineering

We made 3 selections from the death datasets of INSEE.

Our first reference was the 2017 census population, which comprises data from aggregate data from 2015 through 2019. The explanation is as follows: Communal censuses are conducted annually on one-fifth of the municipalities with fewer than 10,000 inhabitants and on a yearly basis via a survey of a sample of 8% of the population in municipalities with more than 10,000 inhabitants [90]. The reference population for a given year N includes data from years N–2 to N+2. Finally, the INSEE reports an error margin of less than 0.02% for the survey method.

Second, the municipal population was chosen for the study. The explanation is as follows: There are 2 types of population censuses: (1) “municipal population” and (2) “population counted separately,” including second homes and students [91]. These censuses allowed data from one year to the next to be compared without double counting.

Third, we approximated the average age of death when there were missing values. The explanation is as follows: Some days or months after birth were missing (10,435/1,477,067, 0.7%). This average age could be refined by defining the birth month and day (the 6th month of the year and the 15th day of the month). Our approximation was acceptable for this study given the low percentage of incomplete data.

Database Management Methods in the RStudio Environment

The recent “Cartography” package for R, renamed “mapsf” [73], has great potential because it makes it possible to reproduce step 1 from the input to the output files in GeoJSON format. If the initial step 1 can be replicated exclusively in the RStudio environment, there are many benefits, such as program corrections and one-click process execution. RMarkdown functions as an integrated module in RStudio, enabling users to follow the logic of at least part of the step 1 processing chain. Multimedia Appendix 4 contains a program for obtaining a ready-to-use file for Philcarto. See also Multimedia Appendix 2, Figures 1 and 2, and Table 2.

uMap Webmapping Environment

We chose an open-source software package that is powerful, easy to use, and compatible with other tools because of the interoperability of the software’s input and output file formats. uMap downloads data in UMAP (uMap file format), GeoJSON (OSM proprietary), and KML (Google proprietary, standardized by the Open Geospatial Consortium [OGC] in 2008) formats [11-13,18,54]. It is evident that uMap is an ethical environment because the reuse of GeoJSON data is contingent upon the activation of sharing rights [83]. The uMap application is predicated on the Django framework [14,92].

The uMap application is distinguished by its simplicity and intuitiveness. Our experience has not revealed any significant issues associated with the platform [11]. uMap features a dashboard that facilitates the management and display of available layers and resources, including world map-type maps [82,87,88,93,94]. uMap is equipped with a number of features, including a slideshow [88], an icon for sharing with 8 export options [59,95], and dynamic updating of the GeoJSON file option [96]. Additionally, the uMap package provides a Python and JavaScript-based API [14] that facilitates the local installation of the uMap server, a feature that is particularly advantageous for a local server dedicated exclusively to health care.

The uMap France remote server hosts a global collection of shared maps with a variety of themes and use cases (eg, sports routes, itineraries with hotspot symbolism). A query conducted 4 years ago revealed the absence of shared choropleth maps when both “health” and “mortality” were entered into the uMap France server [97].

A dynamic community of developers and geomatics specialists maintains the software package. Since May 2023, this community has been reinforced by funding from data.gouv.fr [22] for the development of “uMap of public service,” a government platform [12,13,15,46,50,98,99]. Over the past 2 years, uMap has incorporated several new functionalities, including the following: (1) the ability to tag maps for quick retrieval on the server via a tag list, (2) the ability to create choropleth maps with a basic legend, and (3) a collaborative mapping environment.

2-Step Geomatic Action Plan for the uMap Environment

Overview

Maps in the humanities and social sciences are the result of a process that is sometimes complex and involves a considerable amount of software (or system) and file formats with limited automation. This issue was identified in our data processing activities. The time required to generate atlases in uMap is significantly impacted by our complex, noninterconnected, geomatic data-processing pipelines. However, even in the absence of interconnection between systems, software programs themselves generate file formats that enable interoperability when they are transitioning between software environments [99].

Critical Analysis of the 2-Step Geomatic Action Plan: With and Without Webmapping

Despite the problems highlighted, the results obtained through the implementation of the 2-step geomatic action plan demonstrate the efficacy of our approach, which uses licensed open-source software, free software, and licensed open data, as well as environments and functionalities tailored to our needs. These elements have enabled the full automation of certain tasks. The 4 weaknesses of the 2-step geomatic action plan are as follows:

1. Old versions of proprietary software hinder task automation. Our old Adobe Photoshop 7.0 is an example [41].
2. The data pipeline is not automatically interconnected due to a lack of geomatic functionality [99].
3. The dashboard currently lacks the ability to manage and create double legends for the GeoJSON layer: that is, a map devoid of a legend. We have requested this feature from the uMap team [100].
4. A major disadvantage is that many GeoJSON maps must be produced to instantiate the atlases (by variable).

Design of the uMap

Design Benefits

uMap is licensed under a permissive free software license, meaning that it is free of redistribution and modification [48]. We are not responsible for the security of our GeoJSON files on the remote server, which is managed by the OSM. This approach is essential for atlas instantiation. We created the Traffic-Light Atlas, which is considered the best way to signal excess mortality in municipalities and districts, outperforming other atlases such as the “SMM_10000,” “DENSI,” and “Khi2LnFr” variables. The atlas of the SMM_10000 variable functions as an indicator of submortality or excess mortality per 10,000 inhabitants, highlighting disparities in smaller towns that constitute most French territories.

Design Limitations

The geomatic processing chains necessary to obtain ready-to-use GeoJSON layers are cumbersome, complex, and not currently reproducible in a single environment. The main problem is a pipeline system of noninterconnected data, which requires many tools and workflows (only two are fully automated). We call attention to sections of Figures 3 and 4.

At present, there are no new features that facilitate the linking of legend image files to GeoJSON files.

The image format double legends must now be hosted on an additional remote server, as uMap no longer allows them to be uploaded to the OSM remote server.

Uses of the uMap Collaborative Platform

Benefits of Using

uMap, a geomatic environment for collaborative map sharing, has been diverted as a medium for our choropleth maps and double legends representing the mortality atlases [11]. The nationwide Traffic-Light Atlas displayed in uMap has been deemed superior to the regional display (the online second environment [7]), facilitating instant interpretation of excess mortality statistical signals. The use of a municipal grid enhances the appeal of the atlas, allowing users to analyze specific municipalities. Preliminary observations suggest that no technical difficulties have been encountered when displaying the atlases through different web browsers. Building a parameter template via map cloning has been successful.

Main Limitations of Using

It is not possible to group atlases within a single uMap URL. New uMap features and updates since 2023 have caused errors in accessing our atlases. This issue was reported on OSM and GitHub [11-13] and was rapidly resolved.

Step 2: Workflow Optimization for Double Legends

Strengths

We optimized workflows for GeoJSON layer creation in QGIS step 1 and double-legend creation and management in step 2. This section discusses the optimization of the double legends and the limitations encountered.

The Adobe Photoshop actions file format (ATN) script streamlined geomatic processing for double legends in Adobe Photoshop7 through macro recordings. This semiautomated process accelerated captioning and avoided manual errors. Captions were satisfactory, with or without QR codes. Ideally, newer Photoshop versions or nonproprietary free software would be used.

Photoshop Limitations

Batch processing can further optimize ATN scripts but is currently not possible in Photoshop7 because of persistent bugs. Incomplete macro recording with mouse or human-machine interaction limits the use of current ATN files. Editing ATN scripts in XML via JavaScript utilities on a Windows XP virtual machine may resolve this issue [101].

Proliferation of Geomatics Tools, Languages, and Tips

Rapid software evolution in IT and geomatics demands continuous organic (dynamic) monitoring throughout the project [63]. All CAD software used in geomatics, as well as webmapping environments and related platforms, requires substantial investment supported by numerous user guides,

XSL•FO
RenderX

instructional videos [75,102], dedicated geomatics forums, and IT expert exchanges. These systems integrate programming languages such as Python, scripting languages such as Scheme [64], and macro languages such as Visual Basic for Applications and Philcarto. We used basic functions in geomatic environments and specific tools or plugins. QGIS automation used the modeler designer tool and its associated MODEL3 format for workflows.

To optimize repetitive tasks and interconnect systems in a geomatic data processing pipeline [99], geomaticians should continually invest in languages such as Python, Scheme, and JavaScript as well as various tools.

Traffic-Light Atlas

Traffic-Light Atlas Based on Semantic Relevance and Scientific Openness

Maps can be hard to read without knowing the cartographic or graphical semiology background. Our atlas targets a wide audience of users (the public, health care, political decision-makers, and the uMap community) seeking relevant, more comprehensive information that can be communicated to everyone. Intuitive comprehension is paramount for capturing and maintaining users' attention. The Traffic-Light Atlas is particularly clear, offering a comprehensive overview of the current situation for each municipality.

Methods Based on the Statistical Signal Levels of the Traffic-Light Atlas

Although this is not an epidemiological article, this geomatics research project indirectly prompts an examination of the factors contributing to the observed variation in mortality rates across municipalities and districts, with some exhibiting high rates of excess mortality and others demonstrating low rates of submortality (reminder: the excess mortality in 2020 was compared with that in 2018 and 2019). The objective of our research was to provide these atlases at a highly detailed scale, ranging from the municipality to the submunicipal district and encompassing the entirety of France, including the DROMs. This approach enables each inhabitant of a municipality or district to assess its position in relation to its region, department, or national level.

Indirect Epidemiological Approach Based on Municipal Mortality Atlases

Two epidemiological aspects emerged indirectly from our municipal mortality atlases for 2020. The INSEE data used are for municipalities, except Marseille, Lyon, and Paris, which use district data.

The first aspect is that the available and less biased municipal-level statistics on all-cause mortality (see Multimedia Appendix 2 on cartographic information bias) supplement pandemic-era aggregated data studies [16,103-107]. One additional limitation should be highlighted: singular cases of small municipal populations that distort mortality data.

The second aspect is the source of the death data and our approach, which is similar to that of France 3 TV. It consists of a comparative analysis of mortality rates with those of previous years and the municipal grid. According to France 3, "Even if the cause of death is not mentioned in the INSEE data, an excess of mortality, compared with the two previous years, can be an indication of the impact of the coronavirus, whose information has been aggregated at the departmental level. This is how we were able to measure, for example, the impact of the deadly heatwave in France in the summer of 2003" [106].

Utility—Concrete Hypothetical Use Cases

Use Case 1

Use case 1 consists of retrospective audit triggering. A French regional health agency using our atlas would identify municipalities flagged in the orange or red class (Khi2LnFr>1.83; ie, O/E mortality ratio≥2) (see Multimedia Appendix 13). This signal would serve as a first-tier screening criterion to prioritize retrospective audits of death certificates in those municipalities—for example, to assess whether excess deaths reflect underdiagnosis of COVID-19, delayed care for chronic conditions (eg, cardiovascular emergencies), or outbreaks in long-term care facilities. This approach is consistent with published frameworks for excess mortality surveillance at the subnational level [108].

Use Case 2

Use case 2 consists of hospital surge capacity planning and learning. In a postcrisis quality analysis, a hospital network could correlate the geographic distribution of red class municipalities with Poisson $P<.05$ and its 2020 admission data, identifying spatial mismatches between areas of peak excess mortality and available intensive care unit capacity (see Table 4 and Multimedia Appendix 13). This retrospective triangulation could inform prospective surge capacity planning for future health crises.

Limitations—Nonspecificity of the All-Cause Mortality Signal

A fundamental epidemiological limitation of the Traffic-Light Atlas is the nonspecificity of the all-cause mortality signal. Although the use of all-cause mortality data circumvents the well-documented underascertainment issues associated with COVID-19–specific death counts during the early pandemic period, it also means that the excess mortality signal is not attributable solely to direct COVID-19 deaths. During the March 2020–May 2020 lockdown, several concurrent mechanisms may have contributed to or mitigated excess mortality: (1) delayed or foregone care for acute non-COVID-19 conditions (eg, myocardial infarction, stroke), as documented in multiple European studies; (2) reductions in road traffic and occupational accidents; and (3) reduced transmission of seasonal influenza. The Khi2LnFr signal therefore captures the net balance of these competing effects and should be interpreted as "a statistical signal" of municipal-level mortality deviation from the 2018 - 2019 baseline, not as a direct COVID-19 death count. Future work could integrate complementary data sources—notably cause-specific mortality from the French National Institute of Health and Medical Research (Inserm) Center for Epidemiology on Medical Causes of Death (CépiDc) when available at the municipal level, as well as hospital admission data from the "Program for Medicalization of

XSL•FO
RenderX

Information Systems"—to disentangle these contributions and enhance the epidemiological interpretability of the atlas [109].

Perspectives

We must keep in mind that the reproducibility of the research was our guiding principle, which also applied to optimizing, implementing, and developing atlases in uMaps [71,110].

2020 Atlas Project Covering 4 Periods

In addition to the initial version of the Traffic-Light Atlas presented in this study, we produced a second version covering 4 periods in 2020 (website published in November 2024 [7]). Owing to a minor statistical error in version 2 [7], our goal was to revise this version while reducing the software used in the geomatics data processing pipeline. This online version 2 of the atlas links 4 French policy measures to the 4 periods of 2020: from January 1 to February 28 inclusive (excluding the COVID-19 crisis), from March 1 to May 15 inclusive (first lockdown), from May 16 to October 28 inclusive (excluding lockdown), and from October 29 to December 31 inclusive (second French lockdown, less strict). The division into 4 periods facilitated a better analysis of the phenomenon (ie, the Traffic-Light Atlases for each period aligned better or more precisely with the policies implemented during the respective periods).

We began the first statistical exploration of new death data from INSEE on July 23, 2021. We noted that the methods used to collect deaths differed between our current version and the second version, which covered 4 periods. The statistics for version 2 showed that an "excess mortality statistical signal" affected 40% (13,944/34,833) of the municipalities. (Reminder: In version 1, the excess mortality statistical signal concerned 41.7% [14,503/34,833]).

Once the update to version 3 is complete, we will be able to compare the results of the atlases with those of health policies implemented nationwide. This will highlight the impact of effective policies and the more nuanced impact of others. We should cross-reference data on excess mortality or submortality with municipalities' sociodemographic data. Comparing France with a neighboring country such as Belgium might be useful, but there are methodological obstacles to consider. The 4 periods of France and Belgium are out of sync [111], and it is unclear whether 2018 and 2019 are reference years.

Notwithstanding the disparities between Belgium and France regarding the covered time periods, it can be asserted that the methodology used in this study is applicable to any geographical area for which data on mortality (all causes combined) are available.

Geomatic Optimization and Reproducibility Based on the R Project

With and without webmapping, geomatic processing chains, such as the production of GeoJSON layers for the uMap Traffic-Light Atlas with "double legends and tool tips," must be optimized. We also plan to improve how different environments work together. To do this, we could use (1) an ETL pipeline architecture consisting of proprietary software under different types of licenses and (2) a programming language such as Python, where libraries exist for most purposes [99,112]. In the short to medium term, the goal is to revise the atlases. As planned, we may switch to the R project to improve the reproducibility of the "geomatic data processing pipeline in step 1," thereby eliminating the need for Excel, Philcarto, Google Earth, VS Code, and QGIS.

Digital advances and developers' interest in geomatics mean that this challenge can be met by streamlining the geomatic processing chain and developing new mapping packages (in accordance with graphic semiology standards). These developers invite us to use the same software environment and R project to process all the data and generate maps; they encourage us to support reproducible cartography [74,110]. The "Cartography" package, now renamed "mapsf," is more user-friendly, lighter, and more robust [73,74]. Our study's methodological stages (data collection and cleansing-scheduling processes, analysis, and cartographic representation) could soon be followed and conducted in the same software environment to produce atlases, thus avoiding task dispersion and complications. In other words, this approach serves to unify the workflow and map reproducibility process. The R project could be considered an optimal choice for the geomatic data processing pipeline in step 1 without webmapping.

Reproducible cartography poses a challenge with respect to sensitive, regulated, or inaccessible health data. We cannot make health data available for cartographic reproduction, even for a designated health care community. This barrier is even stronger for nonhealth care communities. Nevertheless, new positive perspectives are emerging as "think tanks" made up of health care professionals [113] working to improve the reusability of health care data, particularly hospital data, for public health and epidemiological research.

uMap: Conceptual Evolution and Targeted Geomatic Development

Conceptual Evolution Through Sharing Our Atlas

Since uMap is a collaborative map-sharing platform, we decided to share our atlases and provide additional meaning. Users can now share our atlas URLs, download the source files in various formats (GeoJSON, GPX, KML, and CSV), share all the properties and data, and embed atlases in an iframe (for distribution and personalized comments) [11,88]. This initiative aimed to receive feedback from the uMap community and determine how many people have viewed the atlases. At this juncture, an evaluation has yet to be conducted to ascertain whether the use of our atlases within the uMap environment results in enhanced decision-making by users, whether they be professionals or others. In fact, regarding basic usage analysis, we know that we cannot obtain statistical evaluations from the "uMap OSM France server environment." However, it may be possible to obtain them via the "uMap Framacarte - remote Framasoft server" or "a local uMap server dedicated to health and associated with a Matomo script" [114].

In summary, the use of Traffic-Light semantics should reinforce the appeal of the Traffic-Light Atlas. All-cause mortality atlases at the municipal level, fed by an open INSEE data source, can

XSL•FO
RenderX

be included in this collaborative map-sharing concept without ethical constraints.

uMap France: Evolving and Progressing

We met with the creator of uMap in May 2023 and sent him our preprint article as soon as it was published in the summer of 2024. Moreover, we suggested some improvements to the uMap project's GitHub site and reported an access error to our atlases [12,13,102]. Our geomatic study, the implementation of the atlases in uMap, and discussions with the uMap team ultimately led to a new feature developed by uMap called the "experimental choropleth layer," which partially addresses our need to "create choropleth maps with associated double legends" [115]. It is accessible from the dashboard. We now need to evaluate this feature and provide our beta tester feedback.

In summary, a new "experimental choropleth layer" is available in the uMap dashboard. This requires testing; if it proves effective, this could eliminate the geomatic processing of "steps 1 and 2" considered in the R project. We have partially confirmed hypothesis 3: uMap is growing rapidly, owing to funding from the "uMap of public service" platform, a government server.

Toward a Conceptual Evolution: uMap Platform Dedicated to Health

The open-source nature of uMap allows the development of a dedicated health platform. However, health data are subject to a different regulatory framework than INSEE data. Therefore, it appears probable that a health platform would be reserved, in whole or in part, for private use. The new "uMap of public service" platform is reserved exclusively for civil servants.

In summary, the development of a private "uMap-Health" platform would be legitimate within the restrictive framework for health data. Based on the example of the Pixacare medical photo library, we could explore the development and diversification of the use of the "uMap-Health" platform with a new "collaborative health map library" feature [116].

Conclusions

Value

We have demonstrated the value of the FOSS uMap [11], a collaborative and interoperable mapping platform that is experiencing rapid growth. By instantiating all-cause mortality atlases at the municipal level (covering the first lockdown in France), we demonstrated the potential of uMap by creating a new type of map in uMap: the choropleth map and double legends, which did not exist at the beginning of our atlas project. Among the atlases developed, we presented the main one in this study: the Traffic-Light Atlas. Owing to its strengths in terms of displaying and visualizing results, our France-wide atlas offers enormous potential in terms of attractiveness and usability (ergonomics) and in terms of understanding and semantic interpretation of cartographic and statistical results. This atlas is relevant because the instant message it conveys is easily interpretable by all audiences, particularly for the general public. In this context, existing maps related to COVID-19 have been supplemented by all-cause mortality Traffic-Light Atlas creation. In keeping with the concept of the uMap platform, our mortality atlases have been published within uMap and made available to users for sharing. The databases use open data from INSEE [84] and are based on a license not subject to the GDPR. To achieve the desired results, the uMap platform does not require any additional IT development or management of the remote uMap server (handled by OSM-fr).

Utility for Professionals

This municipality-level interactive uMap atlas is designed to support both operational public health decision-making and retrospective quality analyses (Multimedia Appendix 2 and Multimedia Appendix 13).

First, local public health teams and municipal crisis management units can use the interface for situational awareness by continuously monitoring spatial and temporal variations in mortality across municipalities, identifying emerging mortality hotspots, and promptly targeting public health communications, resource allocation, and preventive interventions (eg, action protocols during heat or pandemic waves and reinforced medical screening during epidemics).

Second, quality assurance, epidemiology, and health information teams can use atlases to plan and prioritize retrospective audits by systematically flagging municipalities, time periods (version 1 or version 2), and excess deaths relative to comparable areas and atypical trends. These signals then guide focused chart reviews, audit investigations of clinical care pathways, assessment of local health system capacity, and verification of data completeness and coding accuracy in mortality reporting systems.

By providing fine-grained, geocoded mortality intelligence at the municipal level—a resolution not systematically available in routine departmental or regional dashboards—this application complements existing surveillance systems rather than replacing them and supports evidence-based public health action at the local level where resource allocation and outbreak response decisions are made (Multimedia Appendix 2).

When available, basic usage analytics characterize how different stakeholder groups engage with the tool uMap atlases in real-world practice.

For future use of uMap, it would first be legitimate, within the restrictive framework of health data, to create a private uMap platform dedicated to health [116]. Second, as part of an epidemiological approach, our mortality atlases are useful in the retrospective context of the pandemic. To improve our understanding of the municipal landscape, following the detection of excess mortality or submortality statistical signals, we could consider combining our results with sociodemographic data from municipalities. Third, a second version of the Traffic-Light Atlas, encompassing 4 periods in 2020, will be updated using either the "experimental choropleth layer" feature recently developed by the uMap team or, if this feature proves insufficient, the geomatic optimization process via the R project. Finally, for real-time crisis management monitoring, the uMap collaborative platform could be relevant because of its new "choropleth layer" feature and its overall active development.

Acknowledgments

This research was supported by the Lille University Hospital (CHU de Lille), the Grouping of the Institut Catholique de Lille Hospitals (GHICL), and the Risques, Epidémiologie, Territoires, Informations, Education et Santé (RETINES) laboratory of Nice. We thank the creators and contributors of uMap, especially Yohan Boniface, as well as the OSGeo and OpenStreetMap communities. We are also grateful to French National Institute of Statistics and Economic Studies' (INSEE's) open data providers and the developers who shared their software freely. To reduce the amount of original text and improve clarity, we created a table with the assistance of Perplexity Pro (web version; Perplexity AI). We used the artificial intelligence (AI) system to create a table from our original "Materials" section. After thorough review and correction of the content, the formatting of the table was finalized. The original text from the "Materials" section is included as an additional file in Multimedia Appendix 5.

Funding

The Grouping of the Institut Catholique de Lille Hospitals (GHICL) funded the translation and publication costs. Lille University Hospital is supporting the research work by AQB.

Data Availability

All the raw data on deaths extracted from the French National Institute of Statistics and Economic Studies (INSEE) on May 22, 2020, in support of the conclusions of our study, are referenced and available in Multimedia Appendix 3.

Abstract

Background: Acquiring medical expertise from the vast body of medical text is a critical component of medical education. However, the majority of medical knowledge resides in unstructured texts. Data heterogeneity across institutions and strict privacy regulations hinder the use of general-purpose analysis tools. This creates a substantial barrier to the efficient acquisition of expertise for learners.

Objective: This study aimed to design, develop, and evaluate MExplore, an interactive visual analytics system to facilitate the acquisition of medical expertise from unstructured clinical texts.

Methods: We propose a localized, cost-effective workflow for the automatic extraction of medical entities. Building on this workflow, MExplore provides a multilevel visual framework featuring coordinated views for progressive, entity-centered exploration. The system was evaluated through case studies conducted with domain experts, a user study, and semistructured interviews.

Results: The evaluation demonstrated that MExplore significantly enhances the medical expertise acquisition process. Our findings confirm that MExplore provides an effective and interactive approach for structuring complex knowledge, facilitating the construction of illness scripts, and strengthening knowledge retention.

Conclusions: MExplore provides an intuitive and powerful approach for acquiring medical expertise. The results suggest that it effectively supports medical learners in conducting in-depth data exploration and developing robust clinical reasoning skills.

medical text; medical expertise; illness script; visualization; visual analytics

Introduction

The rapid expansion of medical education has intensified the demand for efficient expertise acquisition [1,2]. Medical expertise is characterized by a highly organized and differentiated knowledge base, technical skills, and perceptual capabilities acquired through extensive domain-related practice [3]. The acquisition of medical expertise is a complex cognitive process that involves constructing abstract knowledge networks and iteratively refining them into narrative structures known as "illness scripts" [4]—cognitive frameworks that link clinical features to diagnoses and enable clinicians to perform complex reasoning tasks efficiently [5]. Traditional learning relies heavily on textbooks and often overlooks real-world medical documents (MDs) such as electronic medical records. Although these documents provide rich, detailed cases for refining illness scripts, their unstructured nature and volume make it difficult for novices to extract and synthesize information.

While large language models (LLMs) have emerged as tools for information synthesis, their utility is limited by practical barriers, such as privacy regulations and computational costs [6]. Furthermore, their direct application in medical education is fraught with risks. Research indicates that LLMs are prone to "deceptive expertise," generating plausible yet factually incorrect information while failing to recognize their own limitations [7,8]. Overreliance may lead to cognitive offloading, impairing learners' ability to critically evaluate artificial intelligence–generated outputs [9-12]—a particularly concerning issue in medical education, where independent clinical reasoning is essential. Consequently, there is a pressing need for

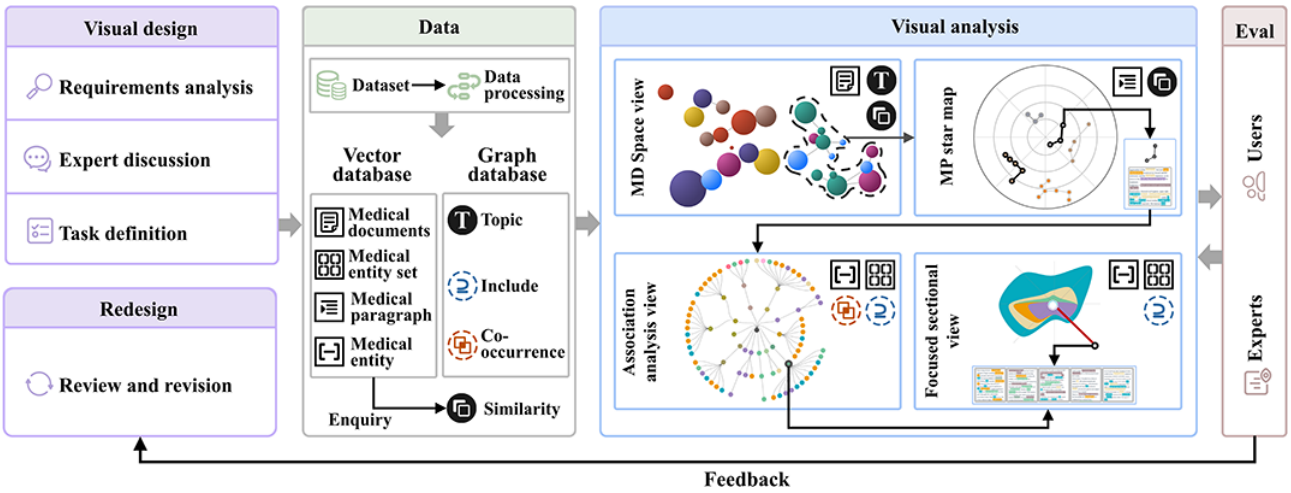
XSL•FO
RenderX

frameworks that support exploratory learning and active engagement with data, rather than systems that encourage the passive acceptance of output [9,13].

Visual analytics, which integrates human expertise with machine intelligence in a "human-in-the-loop" paradigm, offers a viable approach for such exploratory frameworks. By visualizing complex data, these systems can facilitate the construction of mental models. However, the application of visual analytics to medical expertise acquisition remains underdeveloped. Much of the existing work in this domain has focused on analyzing individual patient electronic medical records to support clinical decision-making for specific cases [14,15], which does not facilitate the higher-level organization of generalizable medical knowledge required for education. Other studies have visualized health care data but often neglect the underlying semantics of the content [16,17], limiting the user's ability to understand deep clinical relationships. Therefore, a gap exists for a system that can aggregate unstructured text and present it in a semantically meaningful, multilevel structure suitable for learning.

Named entity recognition (NER) serves as a key technique for transforming unstructured text into structured representations. It involves identifying and classifying domain-specific concepts, such as symptoms, diseases, and treatments, within a text [18,19]. While recent advancements in deep learning and transformer-based architectures such as BERT (Bidirectional Encoder Representations From Transformers) have significantly improved the accuracy of extracting these medical entities (MEs) [20-23], the potential of using extracted entities as "anchors" to construct visual knowledge networks remains largely unexplored. Integrating NER with visual analytics offers a novel pathway to transform raw clinical text into structured learning pathways, thereby accelerating the construction of illness scripts.

We present MExplore, a system that leverages NER to extract MEs from unstructured text and organizes them into a coherent visual structure based on a multilevel metaphor. This design allows learners to explore medical knowledge at varying granularities—including MDs, medical paragraphs (MPs), medical entity sets (MESs), and individual MEs. This approach actively engages users in reasoning, reducing the passive learning common in chat-based interfaces [24,25], and reinforcing the cognitive links necessary for robust illness scripts. We validate the system through a multifaceted evaluation involving domain expert case studies, a controlled user study with medical students, and expert interviews to assess clinical validity and user acceptance [26].



Methods

Study Design

Design Methodology and Workflow

We used a user-centered design process [27], as illustrated in Figure 1. Initially, we collaborated with domain experts to analyze requirements and define specific visual analytics tasks. Guided by these tasks, we established the hierarchy, structural organization, and computational metrics for the textual data. We subsequently designed and developed a multilevel visual analytics framework tailored to these data specifications. Throughout the development lifecycle, we engaged in close collaboration with experts and users, conducting multiple rounds of testing and validation. The feedback and recommendations from these sessions drove iterative redesigns, ensuring continuous system optimization.

Figure 1. The MExplore workflow encompasses visual design, data processing, storage, and query handling, culminating in multilevel visual analysis. The process incorporates iterative redesigns driven by user and expert feedback. MD: medical document; MP: medical paragraph.

Requirements Analysis

Requirement Elicitation

We collaborated closely with 10 domain experts (E1-E10). E1 and E2 are PhD candidates specializing in medical studies, with 4 and 5 years of focused research experience; E3 is a professor at a medical college with 8 years of teaching experience; E4 is a medical researcher with a decade of research expertise; E5 is a dentist with 10 years of professional practice; E6-E8 are experienced physicians with 5 - 10 years of clinical practice; and E9 and E10 are visualization researchers, with 5 - 10 years of experience in visual analytics.

Through iterative discussions, the experts (specifically E3-E8) emphasized that acquiring expertise involves refining knowledge

XSL•FO
RenderX

into "illness scripts" [4]. These scripts enable clinicians to integrate disease-relevant information and enhance both recall and application [28,29]. To support this, we identified 4 key requirements.

R1: Extraction of Core Knowledge Units From Complex Texts

Unstructured medical texts create a high cognitive load for novice learners due to their density and complexity [30]. Novices often face a "reading bottleneck" [31] where resources are consumed by decoding information rather than deep comprehension. Therefore, it is essential to extract core knowledge units and filter out redundant information to mitigate extraneous cognitive load [32,33].

R2: Organization of Text With Varying Knowledge Density to Support Gradual Exploration

Presenting excessive details simultaneously causes cognitive overload [32,34]. Experts suggest that information should be presented at appropriate levels of abstraction [35]. Medical texts must be restructured with varying knowledge densities to support an incremental learning process, moving from high-level overviews to granular details [36].

R3: Revealing the Interconnections Between Knowledge Units

Rote memorization is insufficient for long-term retention [37]. Learners must actively integrate new information with existing schemas [38]. Consequently, there is a need to visually reveal the logical interconnections and inclusion relationships between knowledge units to support structural understanding.

R4: Focused Analysis of the Key Knowledge Units

Effective knowledge acquisition relies on identifying and analyzing key knowledge units that serve as cognitive "anchors" [39,40]. Focused analysis of these units not only deepens understanding but also facilitates the establishment of broader connections within the medical field [40], thereby reinforcing long-term retention.

Visual Analytics Tasks

Based on the requirements (R1-R4), we derived 4 visual analytics tasks (T1-T4) to guide the system implementation.

T1: Extract MEs From Real-World Medical Texts

The system must automatically extract MEs from raw medical texts and categorize them. This transforms unstructured data into discrete, manageable knowledge units (R1), which serve as the foundational elements for visualization.

T2: Support for Cascading Visual Analysis and Exploration of Texts With Varying Knowledge Densities

The system should organize extracted data into a hierarchical structure. It must provide cascading views that allow users to transition seamlessly from a high-level thematic overview to coarse-grained paragraph relations, and finally to fine-grained entity details. This capability facilitates incremental exploration and understanding of complex medical knowledge (R2).

T3: Establishing a Clear Structure for Association Analysis

The system needs to construct and visualize a clear mapping of relationships, specifically the inclusion of MEs within paragraphs and the co-occurrence of elements. This visualization should clarify how knowledge units are structurally connected (R3).

T4: Support for Entity-Centric Pattern Analysis

The system must provide interaction mechanisms to select a specific ME or MES as a focal point. Upon selection, the visualization should be dynamically reconfigured to display the distribution, composition, and associated context centered around the target knowledge unit (R4).

Dataset Construction

Data Source

In this paper, we analyze and process 2 realistic datasets. The first dataset is the Chinese Biomedical Language Understanding Evaluation (CBLUE) provided by the Key Laboratory of Computational Linguistics (Peking University, China) [41]. CBLUE is a comprehensive benchmark compiled from authoritative medical textbooks and clinical practice records. The dataset contains approximately 96,000 MDs, covering a wide range of more than 500 common diseases. To ensure high quality, the MEs within the dataset were meticulously annotated by medical experts. These MEs are categorized into 9 classes on the basis of Chinese ME annotation standards [41]: disease (dis), clinical symptoms (sym), drugs (dru), medical equipment (equ), medical procedures (pro), body (bod), medical examination items (ite), microorganisms (mic), and department (dep).

The second dataset, the Medical Text of West China School (Hospital) of Stomatology (MWCSS), was collected between 2023 and 2025 and provided by the West China School (Hospital) of Stomatology (Sichuan University, China). This dataset contains a large volume of unstructured text data from clinical practice. It includes approximately 100,000 MDs, covering various facets of medical processes, such as clinical diagnoses, treatment processes, specialist examinations, auxiliary examinations, treatment plans, interventions, and drug instructions.

ME Extraction Comparative Analysis

The accuracy of ME extraction is critical to the effectiveness of data processing and visual analytics. Therefore, we systematically assessed the performance and computational resource demands of several models for ME extraction.

Due to strict data confidentiality protocols, which preclude the transmission of data to external servers, models must be deployable locally. In light of the practical limitations of resource-constrained environments, and based on the latest benchmark list from FlagEval [42], we selected high-performing, open-source LLMs for evaluation: DeepSeek-70B and Qwen-32B. Additionally, we included MacBERT, an enhanced BERT model with a novel masked language modeling correction pretraining task [43], which has been identified as the

XSL•FO
RenderX

top-performing BERT-based model according to the CBLUE benchmark, for comparison.

Fine-tuning and inference were performed via two NVIDIA A10 GPUs or a single NVIDIA RTX 4060 Ti GPU for MacBERT. The fine-tuning parameters were as follows: learning rate of 3e-5, 2 epochs, batch size of 16, and warm-up ratio of 0.1. For DeepSeek-70B and Qwen-32B, both models required two A10 GPUs and were instruction-tuned via 4-bit quantized models with QLoRA (Quantized Low-Rank Adaptation) [44] (LoRA [Low-Rank Adaptation] settings: r=16, α=64, dropout=0.05). All the fine-tuning parameters and LLM prompt words were selected based on benchmark tests [41] and relevant comparative experiments [45] and have been validated. The computational resource consumption for each model is summarized in Table 1.

Table . Computational resource consumption comparison.

Model	GPU configuration (NVIDIA)	Fine-tuning time (hours)	Inference time (hours)
DeepSeek-70B	2 A10	167.23	134.27
Qwen-32B	2 A10	101.46	83.58
MacBERT	2 A10	0.77	0.18
MacBERT	1 RTX 4060 Ti	5.16	0.35

The results highlight a significant disparity in resource demand. While LLMs (DeepSeek-70B and Qwen-32B) require substantial fine-tuning and inference time on dual A10 GPUs, MacBERT demonstrates remarkable efficiency, completing the same tasks in a fraction of the time. Notably, MacBERT's inference speed on consumer-grade hardware (a single RTX 4060 Ti) suggests that it is highly suitable for local deployment in practical medical environments where high-end computational clusters may not be available.

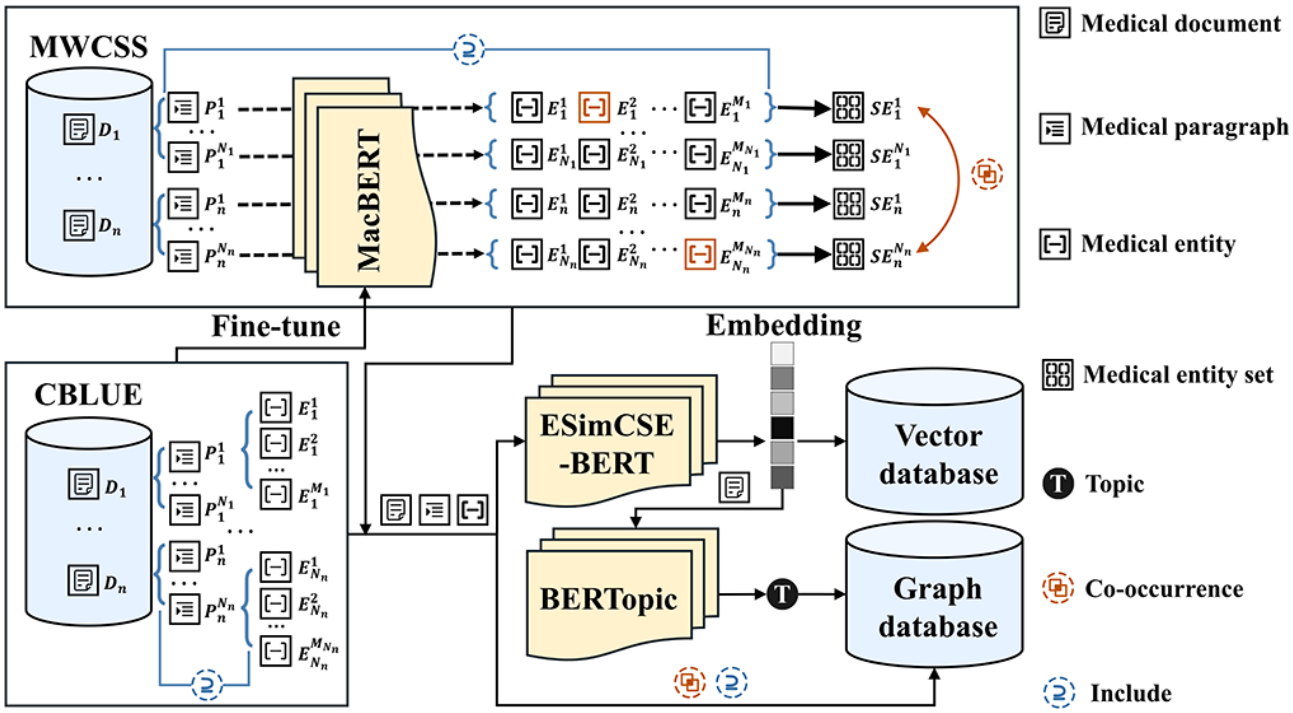
Table 2 summarizes the performance metrics for each model. Fine-tuning consistently improved performance across all the models. Notably, the fine-tuned MacBERT model achieves the highest F_1-score (0.605), surpassing both LLMs, and its precision approaches human annotation levels [41].

Table . Performance comparison of models for medical entity extraction.

Model	Type	Precision	Recall	F_1-score
DeepSeek-70B	Base	0.548	0.487	0.516
DeepSeek-70B	Fine-tuned	0.593	0.521	0.535
Qwen-32B	Base	0.554	0.491	0.525
Qwen-32B	Fine-tuned	0.608	0.542	0.561
MacBERT	Base	0.595	0.549	0.571
MacBERT	Fine-tuned	0.636	0.579	0.605

This analysis demonstrates that MacBERT not only delivers the best performance after fine-tuning but also requires significantly fewer computational resources than the LLMs. MacBERT, therefore, emerges as the optimal choice for ME extraction tasks. This conclusion aligns with the literature [46], which emphasizes that while LLMs excel in generative tasks, BERT-based models retain distinct advantages in NER and other specialized domains [47] and sentiment analysis [48].

Beyond common medical conditions, the system's robustness concerning rare diseases and less common terminology warrants further discussion. Although our evaluation used a dataset of common diseases—where MacBERT demonstrated strong performance—recent research [49] suggests that the performance landscape may shift when encountering "long-tail" medical data. Specifically, while fine-tuned BERT-based models generally maintain overall superiority, LLMs can exhibit superior capabilities in identifying rare disease entities in few-shot settings. Therefore, for specialized tasks focusing on rare diseases where relevant samples and sufficient computational resources are available, LLMs may be used to achieve higher precision. Nevertheless, within our current visual analytics framework centered on general-purpose unstructured medical text, MacBERT provides the most reliable performance-to-cost ratio.



For NER requiring deep semantic insight, language-specific pretrained models often outperform general multilingual models [50]. In this study, we use MacBERT—the top-performing model on the CBLUE dataset—to maximize extraction accuracy for Chinese corpora. Notably, the underlying pipeline remains highly adaptable; the base encoder can be seamlessly replaced (eg, substituting BioBERT [51] for MacBERT) to process English or other language datasets.

Data Processing

Figure 2 shows the pipeline of data processing. The process can be described as follows.

XSL•FO
RenderX

Figure 2. Pipeline of data processing. First, MacBERT was fine-tuned using labeled data from CBLUE. Individual MPs within the MDs are processed via the fine-tuned MacBERT model to extract MEs, which are subsequently organized into MESs. These texts are input into ESimCSE-BERT to generate embeddings, which are then stored in a vector database. The MD embeddings serve as the basis for topic clustering in BERTopic. The resulting topics of MDs, along with all medical texts and their inclusion and co-occurrence relationships, are then structured into a graph and stored in a graph database. CBLUE: Chinese Biomedical Language Understanding Evaluation; *D*: medical document; *E*: medical entity; MD: medical document; ME: medical entity; MES: medical entity set; MP: medical paragraph; MWCSS: Medical Text of West China School (Hospital) of Stomatology; *P*: medical paragraph; *SE*: medical entity set.

Step 1: ME Extraction and Structuring

According to the results of the ME Extraction comparative analysis, we used the MacBERT model fine-tuned with the CBLUE dataset to extract MEs from MWCSS, using MP of MD D_i as the extraction unit, thereby constructing MESs.

Step 2: Vectorization

All the text from CBLUE and MWCSS, including MDs, MPs, MESs, and MEs, is processed via ESimCSE-BERT [52]—an efficient and improved unsupervised sentence embedding method that generates high-quality sentence vectors.

Step 3: Topic Clustering

The high-quality MD vectors from step 2 were input into the BERTopic model. By leveraging these superior embeddings, the clustering process produces topic assignments for each MD. The results yielded a topic diversity score [53] of 0.975, indicating a high degree of distinctness among the generated categories. To further validate the clinical utility, a 5-point Likert scale assessment was conducted by medical experts (E3, E4, E6, E7, and E8) to evaluate the effectiveness of the generated topics and keywords (Table 3). Following the evaluation framework proposed in [54], the results suggest that the interpretability, distinctiveness, and relevance of the topic clusters are at a high level. These findings further corroborate the superiority of transformer-based topic models as discussed in [54].

Table . Evaluation of topic clustering (1 - 5 Likert scale).

Evaluation	Explanation	Score, mean (SD)
Interpretability	How easily a human can assign a coherent meaning to the topic.	4.3 (0.57)
Distinctiveness	How well the topic is differentiated from other topics.	4.4 (0.41)
Relevance	How well the topic captures meaningful domain content.	4.6 (0.22)

Step 4: Relationship Mapping and Storage

To support complex analytical queries, we implemented a dual-storage strategy addressing the inherent relational complexity and interconnectedness of medical data.

Semantic Storage in the Vector Database

All textual elements (MDs, MPs, MESs, and MEs) are embedded into high-dimensional vectors and stored in a vector database. This infrastructure leverages various optimization

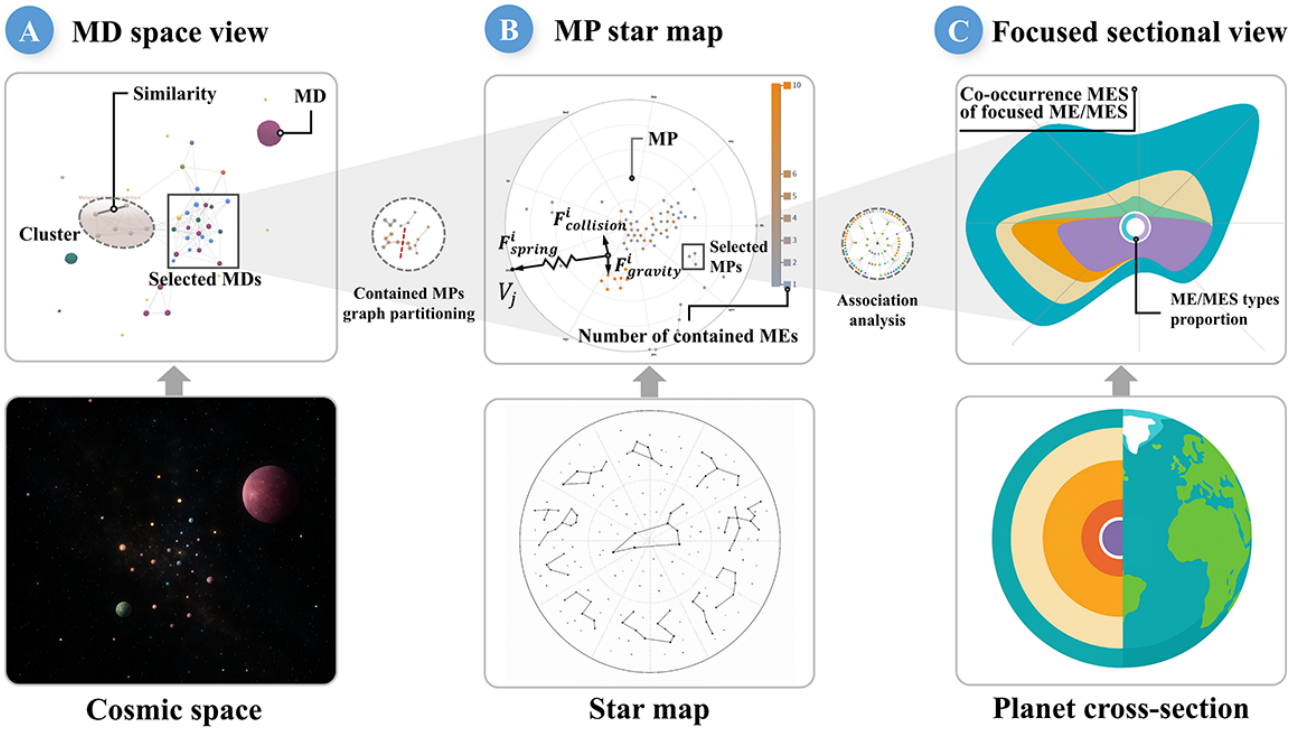
XSL•FO
RenderX

algorithms to enable the efficient execution of similarity-based queries and fast calculations across datasets in the tens of millions [55].

Structural Storage in the Graph Database

Each text unit is modeled as a vertex, with MD vertices carrying the topic attributes derived from clustering. The inclusion relationships between texts and the co-occurrence of MEs within MESs are represented as edges. This graph structure is stored in a graph database to facilitate high-performance queries across complex entity relationships [56]. The scalability and query efficiency of this graph-based approach have become increasingly evident with larger datasets [57].

Visual Analytics Systems Development



System Overview and Workflow

Building upon the constructed dataset, we developed MExplore, a multilevel visual analytics system designed to facilitate progressive exploration and cascading visual analysis (T2). The system adopts a 3-tiered metaphor—cosmic space, star map, and planet cross-section—which inspires the design of the MD space view (Figure 3A), the MP star map (Figure 3B), and the focused sectional view (Figure 3C). We use a hierarchical layout that systematically guides users from macrolevel document retrieval to microlevel detail exploration.

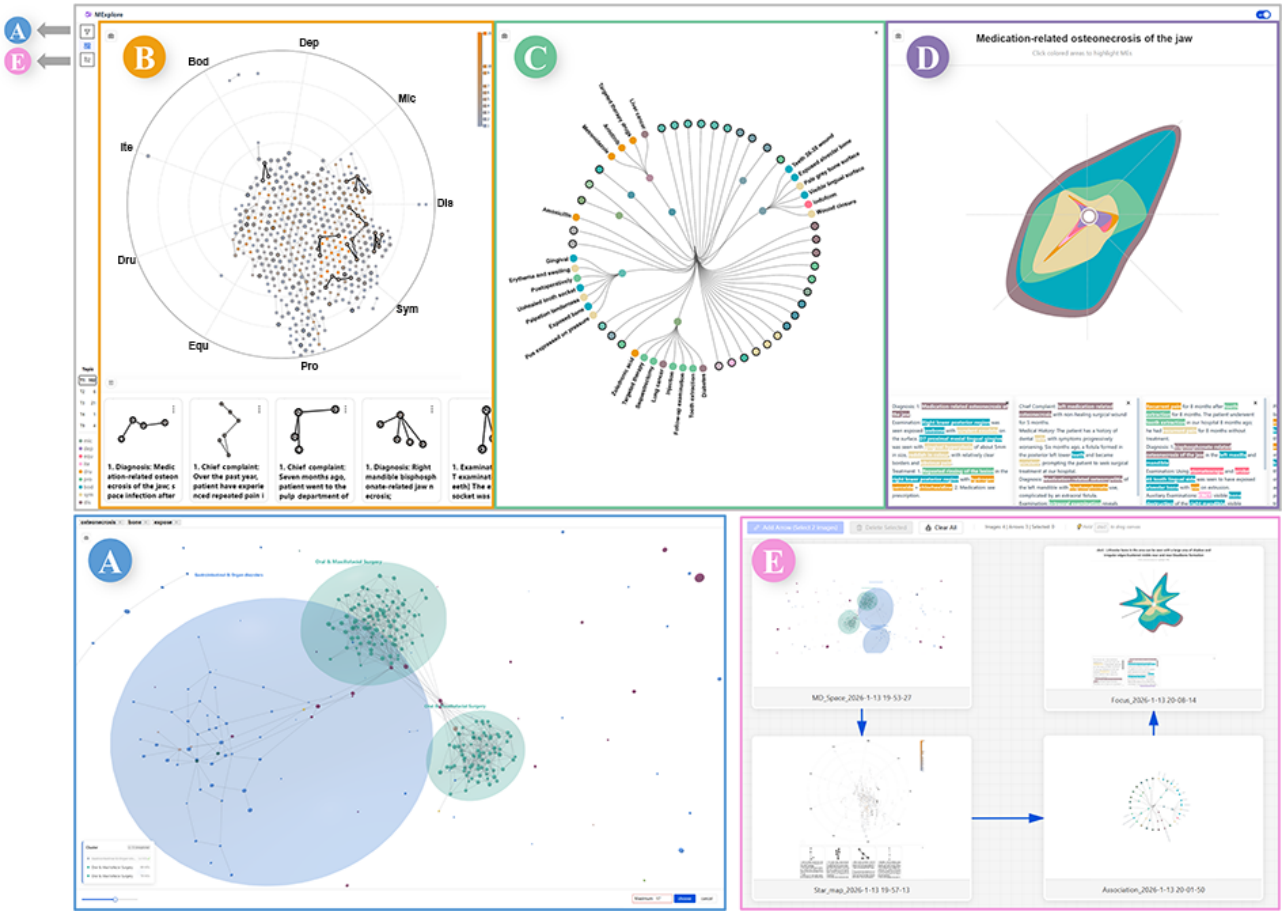
The analytical workflow follows a top-down trajectory (Figure 3), starting from the MD space view, where users filter and define a subset of MDs as the basis for all subsequent analysis based on cluster and spatial distributions. Once the analytical scope is established, the system transitions to the MP star map, enabling users to identify structural patterns and semantic clusters within MP subgraphs. From there, users can incorporate specific subgraphs into the association analysis view to reveal intricate relationships between MESs and MEs. For the most granular inquiry, users can select individual nodes within this view to generate a corresponding focused sectional view, facilitating a deep dive into the target knowledge unit's context.

By structuring the analysis as an interactive, stepwise process, MExplore allows users to progressively increase analytical granularity without losing global contextual coherence [58]. Furthermore, the design leverages grounded metaphors to map complex information onto pre-existing cognitive schemas [59], effectively mitigating the visual complexity encountered by the user and enhancing memory encoding for knowledge retention [60]. Ultimately, this multitiered approach facilitates a continuous analytical loop.

Figure 3. The MExplore framework: (A) the MD space view, inspired by cosmic space, where users select MDs and construct and partition graphs of the contained MPs; (B) the MP Star map, inspired by the star map, where users choose corresponding MP subgraphs and perform relational analysis; (C) the focused sectional view, inspired by the planet cross-section, which enables detailed, focused analysis of the selected data. $F_{collision}$: the collision force; $F_{gravity}$: the gravity force; F_{spring}: the spring force; MD: medical document; ME: medical entity; MES: medical entity set; MP: medical paragraph.

MD Space View

As shown in Figure 4A, upon entering keywords, the system executes a full-text vector search to retrieve relevant MDs. The retrieved MDs are mapped into a 3D force-directed graph where each MD is represented as a planet—its size encodes text length, and its position is determined by semantic similarity. Interdocument links visualize this similarity. Users can adjust a threshold slider to filter connections by similarity, aggregating MDs into topic-based clusters represented as nebulae labeled with topic titles. This layout emphasizes core structural relationships and allows users to follow a progressive approach starting from these nebulae, clicking a specific nebula to enter



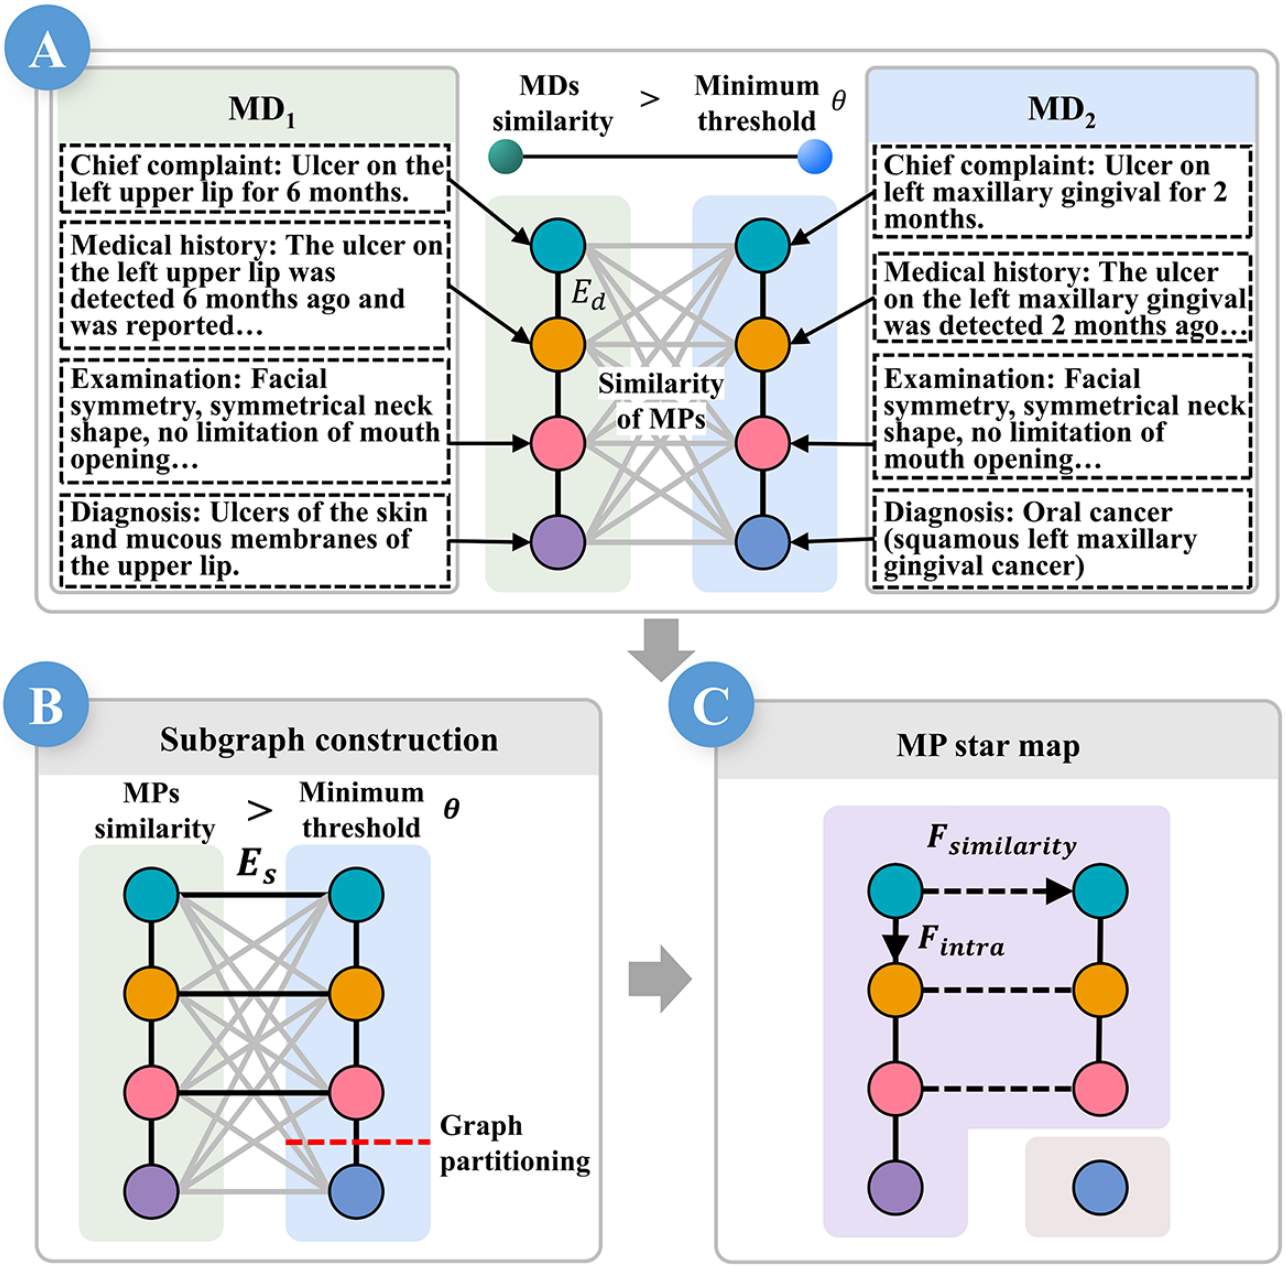
XSL•FO
RenderX

Focus Mode to explore individual MDs in detail. This interaction mechanism leverages spatial proximity to facilitate the efficient identification of areas of interest [61].

The colors of the nebulae and their constituent planets represent their respective topics. This color encoding is discarded upon transitioning to detailed analysis views, preventing semantic interference between the MD topic and ME attributes.

To facilitate comprehensive discovery, a guide for unexplored nebulae is displayed in the lower-left corner, allowing for thorough exploration and rapid focusing by clicking. Simultaneously, the panel below ranks MDs by vector similarity scores to support instant focused viewing and prevent users from overlooking important MDs. Throughout this process, users iteratively select MDs to build an analytical collection, which serves as the foundation for all subsequent analysis views.

Figure 4. The MExplore system: (A) MD space view; (B) MP star map; (C) association analysis view; (D) focused sectional view; (E) provenance view. MD: medical document; MP: medical paragraph.



MP Star Map

Relying solely on full-text embedding similarity can introduce bias, as document representations may disproportionately reflect longer sections while overshadowing concise but critical information. For instance, detailed medical histories in outpatient records can overshadow concise diagnosis sections during similarity computation.

To mitigate this, MDs are decomposed into MPs, each modeled as a graph vertex. Intradocument edges E_d connect the MPs within the same MD. Cross-document MP pairs (Figure 5A) exceeding the similarity threshold set in Figure 4A are linked by similarity edges E_s. The KaFFPa algorithm [62] then partitions the graph, segregating semantically distinct MPs into subgraphs (Figure 5B).

XSL•FO
RenderX

Figure 5. For detailed analysis, MDs are decomposed into MPs. (A) MPs are represented as vertices, with E_d connecting MPs within the same MD, and the similarity of MPs across connected MDs is computed. (B) MPs whose similarity is greater θ than are connected by E_s, and the graph is partitioned by KaFFPa. (C) The partitioned subgraphs are visualized via the constellation metaphor, where E_d are shown as lines and the MPs are shown as stars. Each star is subject to F_{intra} from E_d and $F_{similarity}$ from E_s. MD: medical document; MP: medical paragraph.

Each resulting subgraph is visualized as a constellation in the MP star map (Figure 4B), the MPs are depicted as stars, and E_d is rendered as a constellation line, whereas E_s is omitted to reduce clutter but is retained as latent factors influencing the layout, the similarity-based gravitational force $F_{similarity}$, and the structural gravitational force F_{intra} (Figure 4C). The combined gravitational force of the star i is calculated as follows:

(1)Fgravityi=Fintrai+Fsimilarityi

(2)Fsimilarityi=∑(i,j)similarityij>θ(‖ F ‖ ·similarityij) ·dij^

where F_{intra} is the link force connecting the MPs within the same MD, with a magnitude of unit force ‖ F ‖, θ is the threshold set by the user, and similarityij is the similarity between MP i and MP j. d^ij is the unit vector of the force direction from MP i to MP j.

In addition, each star i is subjected to spring forces Fspringi from 9 ME-type poles uniformly distributed on the circular boundary of the star map:

(3)Fspringi=∑j=19numijnumi· ‖ F ‖ ·d^ij

where numij is the number of MEs of type j in MP i, and num_i is the total number of MEs in MP i. d^ij is the unit vector of the force direction from MP i to V_j.

To prevent occlusion, each star i is subject to the collision force Fcollisioni of stars that may overlap it. The final combined force Fcollisioni is calculated as follows:

XSL•FO
RenderX

(4)Fcombinedi=Fgravityi+Fspringi+Fcollisioni

This multiforce design achieved semantically coherent clustering (F_{spring}), representation of cross-document similarity and structural relationships ($F_{gravity}$), and clear visualization ($F_{collision}$) (Figure 4B). Stars within the same constellation are assigned a uniform color, allowing users to quickly identify them even on a densely populated map. This color is modulated by a sequential luminance gradient [63] to encode the star count: brighter constellations denote a greater number of constituent stars, enabling users to efficiently pinpoint pattern-dense regions. The luminance of star borders encodes the ME count, providing information density cues (T2). To preserve macrocontext awareness during the analysis of MPs and subsequent tasks, a topic navigation list at the bottom of the sidebar (Figure 4) visualizes the topic information of selected MDs. In the MP star map and subsequent views, users can click on MP/MES nodes or document cards to highlight the topic of the corresponding document. This mechanism enables on-demand backtracking, ensuring users remain oriented within the macrolevel topic context. This design facilitates progressive schema construction [33,34] and supports iterative exploratory learning.

Association Analysis View

Leveraging the concepts within MPs to create visual representations of hierarchical structures can significantly increase the efficiency of knowledge navigation [64,65]. Therefore, we extract MEs from each MP (T1), compose the MES, and visualize the resulting data via a radial dendrogram. Compared with alternative text visualization methods, such as word clouds or Sankey diagrams, this approach effectively captures both inclusion and relational connections among elements while accurately displaying hierarchical structures. To further enhance visualization, we propose an algorithm that groups MESs containing shared MEs into the same tree branch, thereby emphasizing co-occurrence relationships between the MESs (T3). The algorithm is outlined in Textbox 1.

Textbox 1. Algorithm for tree construction.

Input:

1. Root node of the tree: rtree
2. Set of nodes to be added: Nadd

Output: Root node of the tree: rtree

1. **for** each node ni in Nadd**do**
2. C=GetMEs(ni)
3. N,Mchecked=TraverseTree(rtree,C)
4. end for
5. Nchildern N∪Mchecked
6. **for** each node ni in N**do**
7. RemoveFromTree(rtree,ni)
8. **end for**
9. **if**LN>1**then**
10. nf CommonFatherNode(rtree,N)
11. **if**nf is not (null or rtree)**then**
12. nf·Children Nchildren
13. **else**
14. rtree·children rtree·Children ∪ Nchildren
15. **end if**
16. **end if**
17. **return**rtree

For each MP, the extracted MEs form an MES, which acts as a node. The newly added node set N_{add}, along with the root node of the tree r_{tree}, is provided as input. For each node n_i in N_{add}, the algorithm retrieves its associated MEs via *GetMEs*(n_i) function. It then traverses the tree through *TraverseTree* to identify the set $M_{checked}$ of co-occurring MEs, along with the node set N containing these MEs. They are all grouped into the set $N_{children}$, which are subsequently added as children to the appropriate parent nodes.

If multiple nodes intersect, their common ancestor is identified by *CommonFatherNode*, and the new nodes are added as children of this ancestor. The nodes are added directly to the root if no common ancestor is found. The process concludes by returning the updated tree structure.

XSL•FO
RenderX

Based on the algorithm described above, the association analysis view is constructed (Figure 4C). To manage the cognitive load and ensure visual consistency, the system uses a synchronized color encoding strategy and a progressive disclosure mechanism. Categorical colors are assigned to ME nodes based on their entity types, while for MES nodes, the color is derived from a weighted mixture of its constituent ME types. To maintain cross-view coherence, this encoding scheme is applied uniformly across both the association analysis and focused sectional views, supported by a persistent legend in the sidebar that ensures color-to-type mappings remain readily accessible throughout the analytical process.

The risk of information overload is further mitigated by initially displaying only the aggregated MES nodes, allowing users to perceive the high-level relational structure without being overwhelmed by individual entities. Users can then interactively expand specific MES nodes to reveal their constituent MEs as independent child nodes. This progressive disclosure strategy enables users to manage information density dynamically according to their analytical needs.

These design choices facilitate the perception of complex hierarchical and relational patterns, thereby supporting schema construction and clinical reasoning by externalizing the learner's cognitive processes [66,67]. Furthermore, the system architecture supports the dynamic addition of new MPs, enabling real-time reconstruction of the association tree. This capability allows seamless integration of new clinical information into the existing cognitive framework of the user, promoting iterative, exploratory learning and long-term memory retrieval [68].

Focused Sectional View

To enable granular analysis of a specific ME or MES, the focused sectional view (Figure 4D) uses a "planetary layer" metaphor to organize complex co-occurrence data. The central ring functions as a donut chart that encodes the proportional distribution of ME classifications. If the analytical focus is a single ME, this layer identifies its specific classification. Surrounding this core, the mantle layer uses a polar-axis-aligned area chart to visualize co-occurring MESs. In this arrangement, each radial axis represents a distinct MES, with the axis height being Nik∗ht, which represents the number of MEs belonging to class k in the ith MES. To emphasize semantic continuity across the dataset, areas representing the same ME classification are connected across adjacent axes. Compared with traditional area or stream charts, this radial layout effectively portrays the compositional richness and semantic associations of the target entity within a compact structural signature.

To bridge the gap between visualization and raw text, the system allows users to click a radial axis to query the underlying database and retrieve the corresponding MD, which is then displayed as a document card in the panel below. This design enables users to revert to the original evidence for detailed, word-by-word analysis. To further prevent highlighting overload in the text view, the system implements a selective filtering strategy. While the card highlights various extracted MEs, users can click specific semantic regions in the polar area chart to isolate and highlight only the ME category of interest. This interaction triggers the document card to automatically scroll to the relevant text segment, enabling an efficient and focused review of the original evidence without cognitive distraction.

The resulting structural signatures illustrate the contextual association patterns unique to each focused ME/MES (T4). Furthermore, the mantle's radial patterns facilitate the interactive comparison of MESs with similar ME configurations. This comparative analysis fosters deeper cognitive engagement and more enduring conceptual impressions, supporting the learner's ability to internalize complex clinical relationships [67].

Provenance View

To facilitate knowledge retention and structure the analytical process, we developed the provenance view (Figure 4E). This view enables users to capture high-fidelity snapshots from any analytical view on demand. These snapshots function as interactive nodes on a scalable, zoomable canvas, allowing users to freely organize layouts and establish logical links between visual findings. By externalizing exploration history into an explicit visual learning path, users can revisit and inspect detailed analytical states at any time, effectively transforming ephemeral interactions into organized knowledge assets.

Evaluation Design

Evaluation Overview

To comprehensively evaluate the usability, effectiveness, and expertise acquisition capabilities of MExplore, we used a mixed methods evaluation strategy comprising three components: (1) case studies with domain experts to assess the practicality, (2) a comparative user study with medical students to quantify learning outcomes, and (3) semistructured interviews with experts to evaluate usability and future potential of the system.

Implementation and Apparatus

As a web-based visual analysis system, MExplore was developed using the d3.js and Django frameworks. A Microsoft Windows platform with a 2.71 GHz Intel Core i5-7300 CPU and 8 GB of memory was used as the front-end page server. The evaluation experiments were performed via a Google Chrome web browser.

Case Study

The case study can demonstrate feasibility and usability in performing real-world tasks [69]. Therefore, we conducted case studies with domain experts (E3 and E5) to evaluate MExplore within authentic analytical scenarios. Through extensive discussion, the experts identified three critical stages of medical expertise acquisition as core tasks: (1) the discovery of areas of interest, (2) the association analysis, and (3) the construction of illness scripts. The session commenced with a 20-minute tutorial on MExplore's features, followed by 1 hour of autonomous exploration focused on the predefined tasks. To capture nuanced qualitative feedback, a think-aloud protocol was used, which encouraged participants to externalize their thought process, ask questions, or provide verbal comments throughout the session.

XSL•FO
RenderX

User Study

Study Overview

The primary objective of the user study was to quantitatively assess the effectiveness of MExplore in facilitating the acquisition of medical expertise. We adopted illness script construction as the evaluative metric to operationalize the measurement of expertise [4]. The experimental design and comparative study protocols were informed by established methodologies in visual analytics and medical education research [15,70-72].

Participants

We recruited 20 second-year undergraduate medical students (10 male and 10 female). None of the participants had systematic prior knowledge of the specific diseases selected for the task, thereby minimizing potential confounding effects from background knowledge.

Tasks and Materials

Three diseases—oral candidiasis (D1), meningitis (D2), and herpes zoster (D3)—were selected from a list of diseases for which illness scripts could be activated [73]. The participants had not studied these diseases systematically beforehand, thereby eliminating the potential confounding effect of prior knowledge. Following prior studies [70], the task began by providing the participants with a brief description of typical cases for each disease, including relevant medical history and examination results, excluding the disease name. Based on this information, participants were asked to identify the disease and complete an illness script template, the information of which was divided into 3 categories: enabling conditions (EC), fault (FT), and consequences (CQ) [28,73].

Experimental Procedure

Participants were randomly assigned to two balanced groups (n=10 each, 5 males and 5 females). The experimental group (MEX) used MExplore to complete the tasks. The control group (OTH) was permitted to use external resources (eg, textbooks, case retrieval systems, and LLMs) but was restricted from using MExplore. Before the main task, the MEX group received a detailed introduction and a 20-minute training session to familiarize themselves with the visual views.

Metrics

Performance was evaluated based on the accuracy and time taken to form illness scripts. Accuracy was scored by comparing responses to a standardized answer key established by the expert panel. Each correct information unit was awarded one point. The total score was normalized to a percentage [74]. Furthermore, to assess the long-term impact of MExplore on expertise retention, a follow-up test was conducted 2 weeks after the initial experiment. The participants were asked to fill out the answer sheets again based solely on recall, without access to the system or external aids [75].

Statistical Analysis

All analyses were conducted via Python (version 3.10). The performance was evaluated via 3 metrics: accuracy, retention accuracy, and completion time. Both accuracy and retention accuracy are expressed as percentages. Independent sample *t* tests were used to compare the mean differences between the MEX and OTH groups. Two-sided $P<.05$ was considered statistically significant.

Expert Interview

We conducted semistructured interviews with domain experts (E1-E10); such qualitative feedback is essential to verify whether users benefit from the system support in their specific domain problems [27]. Each expert subsequently completed a 10-item standardized questionnaire (Table 4) via a 5-point Likert scale to assess their attitudes toward MExplore.

XSL•FO
RenderX

Table . Expert interview questionnaire[a].

Question	Question content
Q1	MExplore is very easy (difficult) to learn.
Q2	MExplore is very easy (difficult) to use.
Q3	The visual design of MExplore is easy (difficult) to understand.
Q4	The visual interactions of MExplore are easy (difficult) to use.
Q5	I am very willing (unwilling) to use MExplore in exploring and acquiring medical expertise.
Q6	Using MExplore, I can (cannot) efficiently identify core knowledge units within complex medical texts. (R1)
Q7	Using MExplore, I can (cannot) explore medical texts in a gradual, structured manner. (R2)
Q8	Using MExplore, I can (cannot) identify and analyze the interconnections between knowledge units. (R3)
Q9	Using MExplore, I can (cannot) focus on and analyze key knowledge units in detail. (R4)
Q10	MExplore can (cannot) help me construct a comprehensive and reliable illness script.

[a]Q1-Q5 focus on assessing the system performance of MExplore, Q6-Q9 evaluate whether the key analysis requirements (R1-R4) are satisfied, and Q10 is the overall objective.

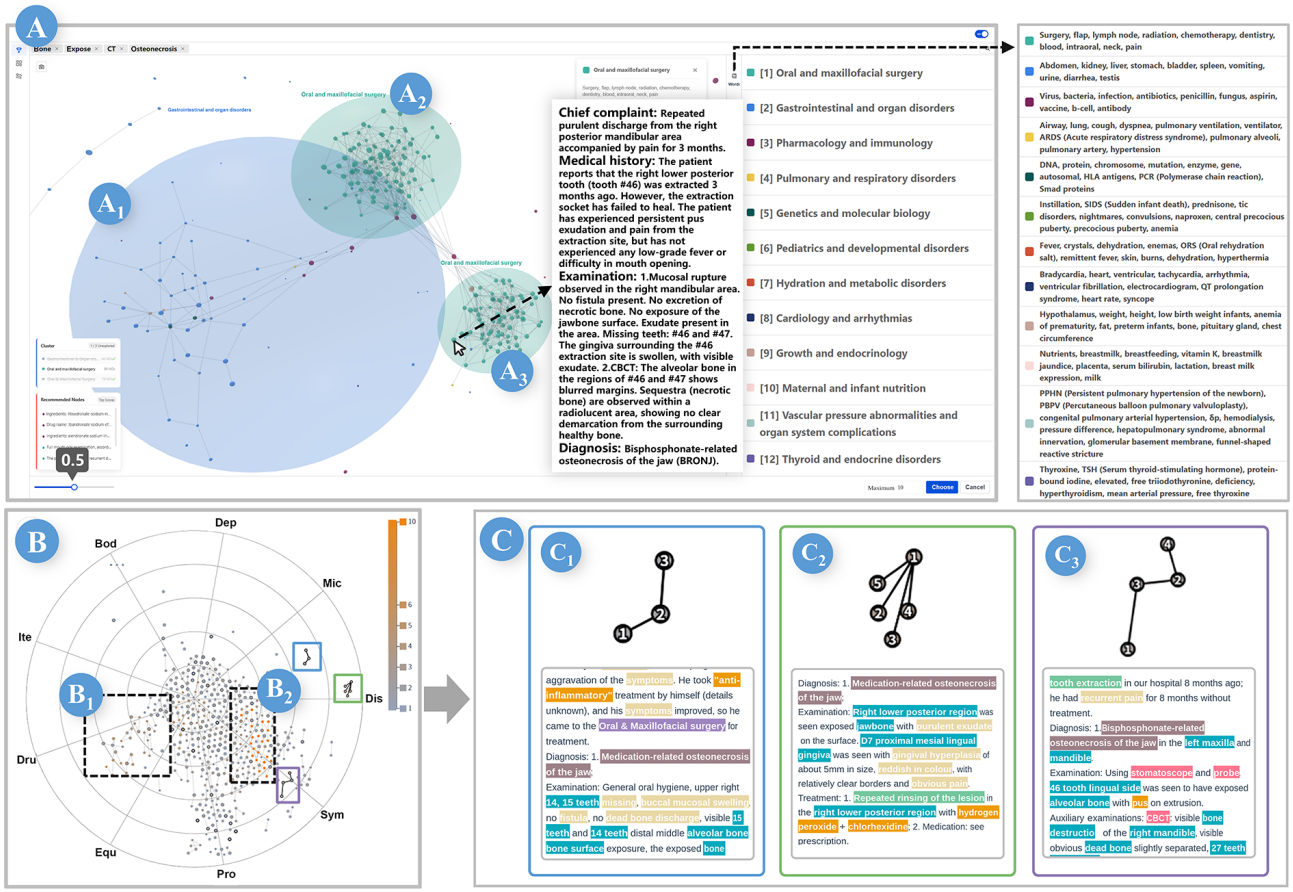
Ethical Considerations

The study received ethics approval from the Institutional Review Board of West China Hospital of Stomatology, Sichuan University (ethical approval number: WCHSIRB-D-2024‐335; approval date: August 9, 2024). Due to its retrospective nature, this study required no informed consent. All collected data were fully anonymized, and no personally identifiable information was included. No financial or material incentives were provided to the participants.

Results

Case Study

Case 1: Identification and Exploration of Areas of Interest



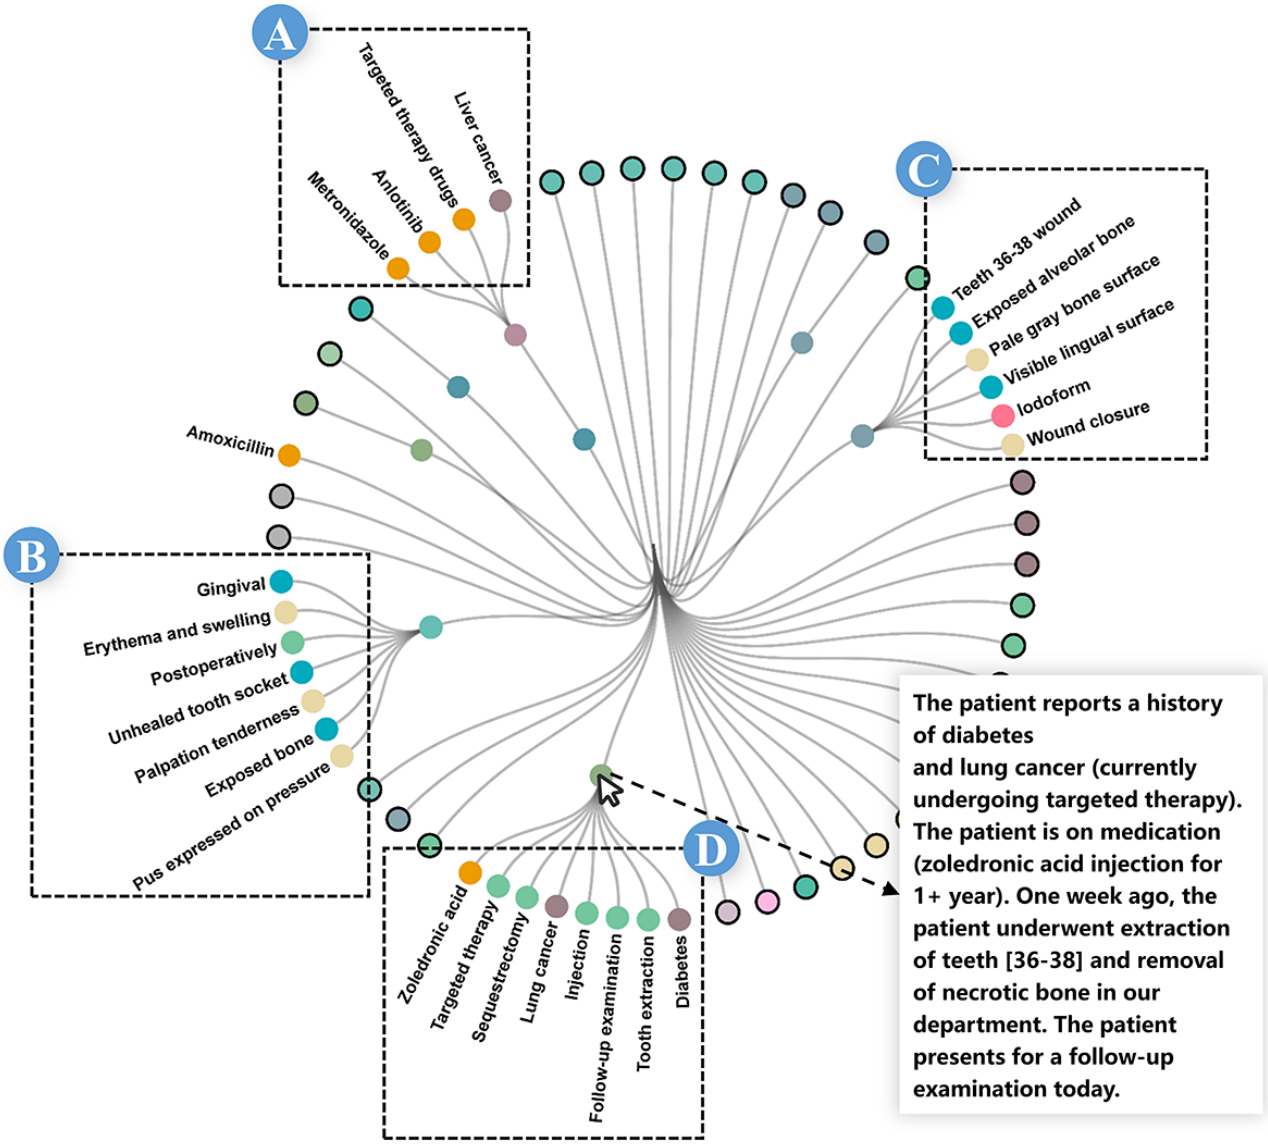
The case study begins with a real scenario with exposed bone in the facial area. A CT scan confirmed the presence of osteonecrosis. The experts entered the keywords *bone*, *expose*, *CT*, and *osteonecrosis* in MExplore. This query generated an MD space where, upon setting the similarity threshold to 0.5, a distinct structure comprising 3 nebulae (A1, A2, and A3) emerged (Figure 6A).

The color of nebula A1 corresponded to topic 2 (*Gastrointestinal and Organ Disorders*), whereas A2 and A3 aligned with topic 1 (*Oral and Maxillofacial Surgery*). Consistent with the patient's clinical presentation in the maxillofacial region, the experts disregarded A1 to concentrate their analysis on A2 and A3. A detailed exploration of A3 revealed that it contained MDs describing symptoms highly congruent with the patient's condition. Notably, these MDs demonstrated strong connectivity to nodes in topic 3 (*Pharmacology and Immunology*), which also appeared in the recommendation list, confirming their high relevance to the search query. Consequently, E3 selected these MDs, along with those in A3, and transitioned them to the MP star map. The maximum size of the subgraph was set to 10, which was determined during the experts' free exploration and proved effective for segmenting common MDs.

In the MP star map (Figure 6B), E5 first examined subgraphs close to *dis* and *sym* to identify the specific conditions. Three subgraphs were selected to review the text. After these MDs were compared with the original MDs (Figure 6C), the experts concluded that the target disease was medication-related osteonecrosis of the jaw (MRONJ). E5 commented, "Compared with standard search engines, MExplore facilitates the discovery of trustworthy MDs. The structured visual representations of knowledge units enable users to identify the target disease through interactive reasoning rather than randomly searching through uncertain sources."

XSL•FO
RenderX

Figure 6. (A) Topics and distribution of keyword-related MDs, with a connection threshold set to 0.5. (B) Distribution of MP subgraphs within the MDs in A2. (C) The original MD texts of the selected MP subgraphs, with border color annotations indicating their corresponding constellation in the star map. MD: medical document; MP: medical paragraph.



Case 2: Association Analysis and Identification of Key Factors

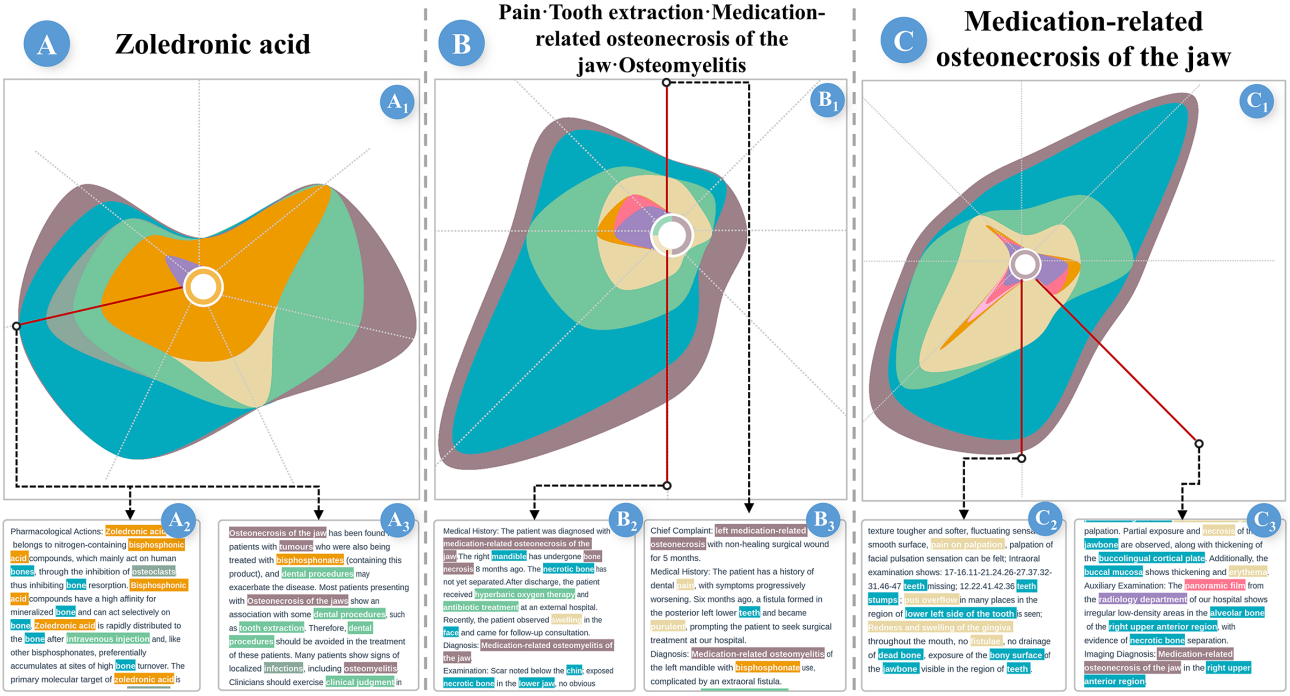
Upon identifying the target disease, the experts conducted an association analysis to determine the key factors related to the illness script. As defined by Feltovich and Barrows [29], illness scripts consist of 3 components: EC, FT, and CQ. In this case, the disease's name suggested a connection to the medication, leading the experts to select subgraphs that distribute bias toward *dru* (Figure 6B1). Additionally, the subgraphs adjacent to the target disease with a high total number of MEs were selected (Figure 6B2).

The selected subgraphs were organized into the association analysis view (Figure 7). The experts first analyzed the MES (Figure 7A), which is distinguished by a high proportion of *dru* MEs based on its color encoding. Upon clicking to expand this MES, it was found to contain the *targeted therapy drugs*, *Anlotinib*, which is closely associated with the *liver cancer* ME, indicating the patient had a history of malignancy and related drug treatment. The text in Figure 7D further corroborated this by containing *lung cancer* and *targeted therapy*, noting specifically that the patient was using *zoledronic acid*. Therefore, E3 concluded that cancer status and related medications were factors associated with EC and FT. Regarding CQ, E3 analyzed the MES characterized by high *bod* and *sym* proportions (Figure 7B and C), identifying bone exposure and exudate as primary CQ factors. E3 concluded, "Performing association analyses on real-case factors can be integrated into clinical reasoning training, enhancing learners' clinical analysis skills."

XSL•FO
RenderX

Figure 7. The association analysis view of the MES and MEs within the selected subgraph facilitates the exploratory analysis of relationships. ME: medical entity; MES: medical entity set.

Case 3: In-Depth Analysis and Construction of Illness Scripts



To construct a comprehensive illness script, the experts began by analyzing the factors presented in case 2. E5 was initially interested in the role of *zoledronic acid* as an EC for the development of MRONJ, so he focused on it and generated a focused sectional view (Figure 8A1). The relevant MES includes a *mic* ME potentially related to the FT. A review of the corresponding MD (Figure 8A2) revealed that this ME pertains to *osteoclasts*, detailing the drug's pharmacological action of inhibiting osteoclast growth, which may impair bone repair. The MD further indicates that when bisphosphonates are used in cancer patients, concurrent dental procedures such as tooth extraction may trigger MRONJ (Figure 8A3).

Subsequently, E3 examined a medical history MES involving *tooth extraction*, such MESs typically feature a relatively high density of *pro* and *dis* MEs (Figure 8B1). By examining the MDs of associated chief complaints and other medical history MESs (Figure 8B2 and B3), multiple co-occurring *pro* MEs were found to mention *osteomyelitis*, which was also referenced in Figure 8A3, suggesting that osteomyelitis may have developed as a CQ of MRONJ, likely secondary to an underlying infection.

To obtain a more definitive CQ, E5 performed a focus analysis of MRONJ (Figure 8C1), reviewing the MDs corresponding to the MESs that have *sym* and *equ* MEs (Figure 8C2 and C3). The analysis revealed that bone exposure and pus discharge were prominent clinical symptoms, whereas necrotic bone and radiolucent areas observed on panoramic radiographs emerged as distinctive imaging features. These findings can be used as reliable criteria for clinical diagnosis.

XSL•FO
RenderX

Figure 8. (A) Focused analysis of zoledronic acid. (B) Focused analysis of the medical history of MES, including tooth extraction. (C) Focused analysis of MRONJ. MES: medical entity set; MRONJ: medication-related osteonecrosis of the jaw.

This analysis enabled the experts to construct a comprehensive illness script for MRONJ as follows:

- **EC:** Received treatment with bisphosphonates or related medications; a history of cancer or related systemic diseases; recent dental procedures.
- **FT:** Medications such as bisphosphonates inhibit osteoclast function, while dental procedures, particularly tooth extractions, can cause trauma, both of which contribute to the onset of MRONJ.
- **CQ:** Exposed bone, pus drainage, and potential for subsequent infections, such as osteomyelitis.

As E3 noted, "MExplore enables learners to construct illness scripts in a short period, facilitating rapid clinical reasoning and enhancing long-term retention of script knowledge."

User Study

Tables 5 and 6 present the mean accuracy and retention scores, whereas Table 7 provides the detailed completion time for each disease across various information classification methods. A more granular comparison of accuracy and retention performance is illustrated in Figure 9.

Table . User study accuracy score results.

	Max score	Accuracy score		
		MEX[a], mean (SD)	OTH[b], mean (SD)	*P* value
Oral candidiasis				
Enabling conditions	7	6.3 (0.48)	5.9 (0.57)	.11
Fault	7	6.1 (0.32)	5.7 (0.48)	.04
Consequences	8	7.3 (0.48)	7 (0.47)	.18
Meningitis				
Enabling conditions	7	6.1 (0.56)	5.8 (0.92)	.39
Fault	10	9.1 (0.32)	8.4 (0.52)	.002
Consequences	10	9.3 (0.67)	8 (0.47)	<.001
Herpes zoster				
Enabling conditions	9	7.9 (0.88)	7.1 (0.57)	.03
Fault	10	8.9 (0.57)	8.2 (0.42)	.006
Consequences	8	7.4 (0.52)	6.9 (0.57)	.05

Table . User study retention accuracy score results.

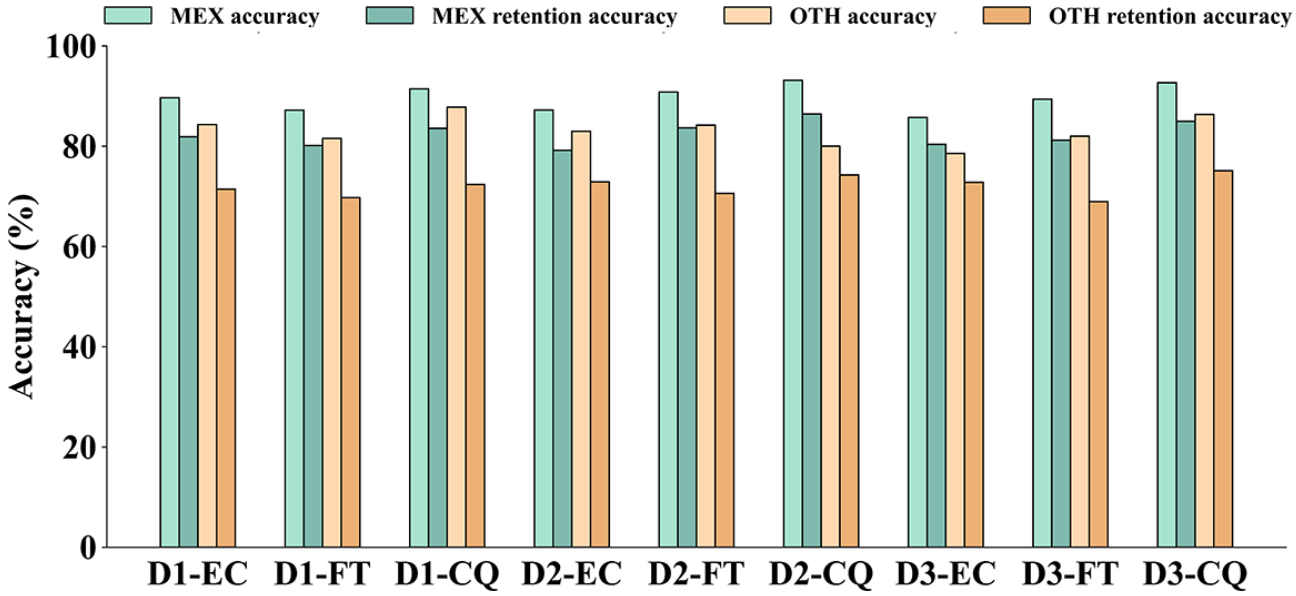
	Max score	Retention accuracy score		
		MEX[a], mean (SD)	OTH[b], mean (SD)	*P* value
Oral candidiasis				
Enabling conditions	7	5.7 (0.67)	5 (1.05)	.09
Fault	7	5.6 (0.70)	4.9 (0.74)	.04
Consequences	8	6.7 (0.67)	5.7 (1.34)	.05
Meningitis				
Enabling conditions	7	5.5 (0.53)	5.1 (0.99)	.28
Fault	10	8.4 (0.70)	7.1 (0.88)	.002
Consequences	10	8.6 (0.84)	7.4 (0.97)	.008
Herpes zoster				
Enabling conditions	9	7.2 (1.03)	6.7 (1.06)	.30
Fault	10	8.1 (0.74)	6.9 (0.99)	.007
Consequences	8	6.8 (1.03)	6 (1.15)	.11

[a]Acquiring expertise via MExplore.

[b]Acquiring expertise without MExplore but using other resources.

Table . User study completion time results.

	Completion time (minutes)		*P* value
	MEX[a], mean (SD)	OTH[b], mean (SD)	
Oral candidiasis	10.45 (1.41)	12.32 (1.88)	.02
Meningitis	13.40 (1.73)	13.85 (2.41)	.64
Herpes zoster	11.82 (1.76)	15.05 (2.54)	.004



[a]Acquiring expertise via MExplore.

[b]Acquiring expertise without MExplore but using other resources.

The results showed that the MEX group demonstrated superior performance. Independent *t* tests confirmed significant improvements in overall mean accuracy (68.3 out of 76 (90%) vs 63.1 out of 76 (83%), *P*<.001). This advantage persisted in long-term retention: the MEX group achieved an overall mean retention accuracy of 62.5 out of 76 (82%), significantly surpassing the 54.7 out of 76 (72%) observed in the OTH group (*P*=.003). These findings suggest that the multilevel metaphors and interactive exploration in MEX may facilitate knowledge consolidation into long-term memory. Regarding efficiency, the MEX group had significantly shorter completion times for D1 (*P*=.02) and D3 (*P*=.004). Beyond speed, the MEX group exhibited consistently lower SDs across all tasks (Table 7), suggesting that the structured exploration path may reduce user disorientation and cognitive load when navigating complex medical knowledge.

Expert Interview

The results of the questionnaire are presented in Figure 10.

Figure 10. Results of the questionnaire. The number at the top represents the number of expert responses. The color of the bar represents the degree of negative (1 and 2), positive (4 and 5), or neutral (3) response.

System Performance

The experts all recommended MExplore for its user-friendly interface and interaction capabilities. The system's hierarchical visualization, organized by data granularity and incremental exploration ability, significantly enhances user understanding and analysis. Although some of the experts (E5-E8) had no prior experience with visual analytics systems, they were able to easily comprehend and effectively use the system after receiving minimal training. E4 concurred that the ME-based exploration

XSL•FO
RenderX

learning process in MExplore allows learners to focus on the core concepts of the target domain while creating an independent exploration path. E2 suggested incorporating features such as exploration playback and snapshot functionality to further increase the system's usability. In summary, the experts highly praised the system's visual design and interaction approach, asserting that it holds significant potential to improve the efficiency of knowledge acquisition for medical professionals.

Analysis Requirements

As shown in Figure 10, the experts believe that most of the key analytical requirements have been well met. E9 noted that the design of the association analysis view and the focused sectional view enabled users to correlate and concentrate their analysis on key knowledge points, thereby identifying relevant and valuable information—an essential aspect of the knowledge acquisition process. E8 noted that compared with search-based learning methods or chatbots, which have become popular in recent years, this approach can exercise the learner's thinking ability and improve knowledge retention and accumulation. E5 further highlighted, "In addition to assisting novices in acquiring expertise, MExplore can also support experts and researchers in disease studies by aiding in research, summarization, and the discovery of new features."

Discussion

Lessons Learned

The key insight from this study is the importance of comprehensibility. Learners must be able to focus on acquiring knowledge throughout the learning process, and the visualizations and interactions should be designed in a way that does not overwhelm or distract users. Through an iterative design process involving both experts and users, we find a clear preference for simple and intuitive visual forms. Based on this feedback, we developed a multilevel metaphor visual analytics framework to reduce cognitive strain and facilitate a shift in paradigm from traditional learning methods to more interactive forms of knowledge acquisition.

Generalizability

Language Adaptability

Although MExplore uses a model pretrained on Chinese corpora, the framework is not strictly bound by linguistic characteristics. Transformer-based architectures have demonstrated robust concept understanding across diverse languages when fine-tuned on domain-specific data [76]. Consequently, the pipeline can support cross-lingual applications by incorporating domain-specific clinical corpora.

User Adaptability

As experts indicated in the Analysis Requirements section, MExplore's extraction and knowledge association capabilities benefit a broad spectrum of users, not limited to novices. It can further assist senior clinicians and researchers in identifying novel disease features and advancing clinical studies.

Data Adaptability

To ensure broad generalizability, our retrieval and filtering mechanisms primarily leverage the semantic embedding similarity of unstructured text. However, we recognize that practical medical education often requires precise constraints. Our framework allows users to incorporate a deterministic metadata filtering layer (eg, filtering by visit date, department, and document type) into the search module tailored to their specific datasets. This enables the framework to meet curriculum-specific requirements and adapt to diverse educational goals beyond unstructured content analysis.

Domain Adaptability

The methodology can be extended beyond medicine to other domains requiring structured knowledge exploration, such as jurisprudence. By fine-tuning predictive models on annotated domain-specific texts, the MExplore framework can be repurposed to visualize entity relationships and facilitate knowledge acquisition in nonclinical fields.

Limitations

A notable limitation is the linguistic specificity of the current dataset. Clinical documents in different languages exhibit unique syntactic complexities and sublanguages. While our pipeline is architecture-agnostic, performance in non-Chinese contexts depends on the availability of high-quality domain-specific corpora. Future iterations could incorporate neural machine translation and annotation projection to automatically generate training resources for low-resource languages, thereby enhancing multilingual applicability. Additionally, we plan to expand the dataset through multi-institutional collaboration to cover a broader range of diseases. While the system currently supports large-scale queries, further optimizations—such as approximate nearest neighbor search and WebGL rendering—will be explored to accommodate expanding data volumes. Lastly, the user study was conducted with a cohort of medical students (n=20). While suitable for testing learnability, this demographic may not reflect expert clinical decision-making. Future work will expand evaluations to practicing clinicians to better validate the system's professional utility and generalizability.

Conclusions

In this paper, we introduced MExplore, a visual analysis tool designed to support medical learners in exploring and acquiring medical knowledge. MExplore extracts MEs from large-scale medical texts and constructs a knowledge structure, offering a multilevel metaphor visual analytics framework. This framework includes 4 coordinated views: the MD space view, the MP star map, the association analysis view, and the focused sectional view. Together, these views enable users to tailor their learning paths, fostering deeper comprehension and improved retention. By facilitating the construction of complex, interconnected schemas typical of medicine, MExplore significantly supports learners in acquiring medical expertise.

We conducted 3 case studies, a user study with real-world datasets, and expert interviews. The results highlight MExplore's effectiveness in facilitating the exploration and analysis of medical texts, significantly enhancing learning efficiency and supporting the acquisition of medical expertise.

Funding

This work was supported in part by the Industry-University-Research Innovation Fund for Chinese Universities (2024XL004), the Sichuan Science and Technology Program (2025ZNSFSC0459), and the Comprehensive Reform Project on Innovation-Oriented Practical Education Empowered by Artificial Intelligence at Sichuan University.

Data Availability

The Chinese Biomedical Language Understanding Evaluation (CBLUE) dataset analyzed in this study is publicly available through the Aliyun platform [77]. The Medical Text of West China School (Hospital) of Stomatology (MWCSS) dataset, which contains sensitive clinical data, is subject to strict confidentiality agreements and institutional privacy policies and is not publicly available. However, deidentified data may be shared by the authors upon reasonable request, subject to institutional approval and a formal data-use agreement. Both the source code and the fine-tuned MacBERT model weights are publicly accessible in our GitHub repository [78].

Authors' Contributions

XP and CL conceptualized the study. JL and YH contributed to data curation. XP, CL, and YH developed and validated the software. XP drafted the original manuscript. JL and ML reviewed and edited the manuscript. All the authors have read and approved the final manuscript. JL and ML contributed equally as the corresponding authors of this manuscript.

Abstract

Background: Emergency physicians face considerable workflow challenges in the emergency department (ED) due to unpredictable work environments, frequent interruptions, and mounting documentation requirements, all of which contribute to substantial computer-based work. Excessive time away from direct patient care is increasingly viewed as detrimental to the quality of care, communication, and patient safety.

Objective: This study aimed to quantify and visualize how emergency physicians allocate their time during ED shifts, particularly the time spent on the computer.

Methods: This cross-sectional observational time-motion study was conducted in a high-volume, urban ED. We used the validated TimeCaT application to continuously track physician activities, including computer use, direct patient care, communication, and all other tasks carried out during the shift. Electronic health record event log data were queried to estimate physicians' computer use after their scheduled shift. The main outcome was the proportion of time spent on each activity. The primary measure was the total minutes of computer use (during and after the shift) per scheduled hour of clinical work. Additionally, we generated data visualizations to illustrate ED workflow-sequencing, task switching, and between-shift variability.

Results: We observed 20 emergency physicians for one 8- to 9-hour clinical shift each, generating over 150.0 hours of real-time observation data quantifying physicians' ED workflow. Physicians spent a median of 34.1% of their shift minutes using the computer (156.5, IQR 145.2-179.3 min) and 26.9% with patients (115.2, IQR 102.0-154.1 min). Other activities included 15.9% for verbal communication with staff (73.3, IQR 45.6-96.4 min), 9.5% phone use (41.4, IQR 33.4-59.2 min), 5.5% miscellaneous tasks (24.2, IQR 18.4-30.1 min), 3.9% personal time (16.8, IQR 9.9-25.4 min), 0.7% electrocardiogram review (3.8, IQR 1.4–5.0 min), and 0.4% other procedures (median 1.7, IQR 0.6-6.4 min). Electronic health record log analysis showed that physicians spent an additional median 1.3 (IQR 0.5 - 2.6) hours using the computer after their scheduled shifts, for a combined 29.8 (IQR 25.6 - 38.5) minutes on the computer per scheduled hour of their ED shift. Workflow visualizations showed frequent alternation among activity categories and noticeable variability in within-shift fragmentation across physicians.

Conclusions: Emergency physicians spent more than one-third of their ED shift working on the computer, which was more time than they spent with patients. They also spent 1 to 2 hours using the computer after their scheduled shift. These findings demonstrate the need for strategies to reduce unnecessary computer use during and after clinical shifts to enhance workflow efficiency and improve patient care.

Introduction

Background

There is rising concern that spending too much time away from the bedside may undermine the quality of medical care by reducing opportunities for direct patient interaction and face-to-face communication among care team members [1-3]. Studies of emergency department (ED) physician workflow in the United States and internationally have reported that frequent interruptions, multitasking, and documentation demands are common in ED care and may contribute to cognitive burden, reduce efficiency, and raise important patient safety concerns [4-6]. The ED setting is among the most cognitively and operationally challenging work environments for physicians due to its high acuity, time pressures, and inherent unpredictability [7]. While prior literature has demonstrated that persistent interruptions and task switching can increase cognitive load and impair clinical efficiency [8-10], these aspects of workflow variability may also serve a functional purpose for timely information transfer and coordination of team-oriented emergency care [11].

In parallel, documentation and information management demands of modern emergency care have increased substantially with the widespread adoption of electronic health records (EHRs) [3,12]. Across various clinical settings, clinicians report spending large portions of their workday interacting with digital systems [12]. EHR work is not always finished within the time frame of a clinical shift, as many clinicians complete documentation and other computer-centered tasks after their scheduled shift, which may further contribute to workload and burnout [13]. Quantifying both on-shift and after-shift EHR work is therefore critical for evaluating EHR use, understanding workflow burden, and informing the design of interventions to improve efficiency and quality while supporting care team coordination.

A foundational step for improving ED work systems is to measure and describe how clinicians allocate time and sequence workflow activities during their clinical shifts. The application of methods from human factors engineering, such as time-motion studies, can help identify targets for workflow improvement and optimize work process design [14-16]. However, because direct observation alone does not account for after-hours work and EHR tracking cannot precisely capture noncomputer activities, an integrated approach that combines structured time-motion observation with EHR use data leverages the strengths of both modalities to more comprehensively characterize ED physician workflow and establish baseline measures for evaluating future workflow interventions.

This study provides a detailed assessment of ED workflow for emergency physicians, focusing on the balance of time spent at the computer versus the patient bedside. Using an integrated measurement approach that combines structured time-motion observation with EHR event log data, this work offers a reproducible mechanism to inform workflow evaluation, EHR design, and interventions aimed at reducing documentation burden while facilitating effective care delivery. Prior ED time-motion research has often concentrated on specific activity subsets or task patterns, such as medication-focused workflows [17]. This investigation, unlike previous ED time-motion studies that quantify only observed on-shift activity, (1) pairs structured time-motion observation with EHR event logs in the same physician cohort to capture both on-shift and after-shift work, (2) uses a validated structured observation tool with a task taxonomy for standardized measurement, and (3) provides workflow visualizations that illustrate how within-shift task switching and workflow heterogeneity occur across physicians.

Objectives

The objective of this descriptive observational time-motion study was to assess and characterize emergency physician workflow by quantifying the time ED physicians allocate to clinical and nonclinical tasks. This was accomplished by (1) measuring the proportion of physicians' time allocated to major on-shift activities using structured time-motion observation and (2) quantifying after-shift work using EHR event logs to track computer-based activity. We created data visualizations of on-shift workflow sequences to illustrate the variability in task density and fragmentation across physicians and their ED shifts in an effort to inform future work system design.

Methods

Study Design and Setting

We conducted a cross-sectional observational time-motion study and reviewed EHR event logs to track emergency physician activities in an urban, high-volume ED that is a comprehensive stroke center, ST-elevation myocardial infarction receiving center, and level-1 trauma center with an annual census of 90,000 ED visits. Daytime shift observations were conducted between May 21, 2019, and November 6, 2019. During the study period, attending emergency physicians supervised or provided care for all patients. Residents from nonemergency medicine specialties (internal medicine, anesthesia, and so on) assisted with care for less than 5% of all visits, and physician assistants were involved in 20%. The number of emergency physicians staffing the ED varied from a minimum of 3 during overnight shifts to a maximum of 6 during peak hours.

Recruitment

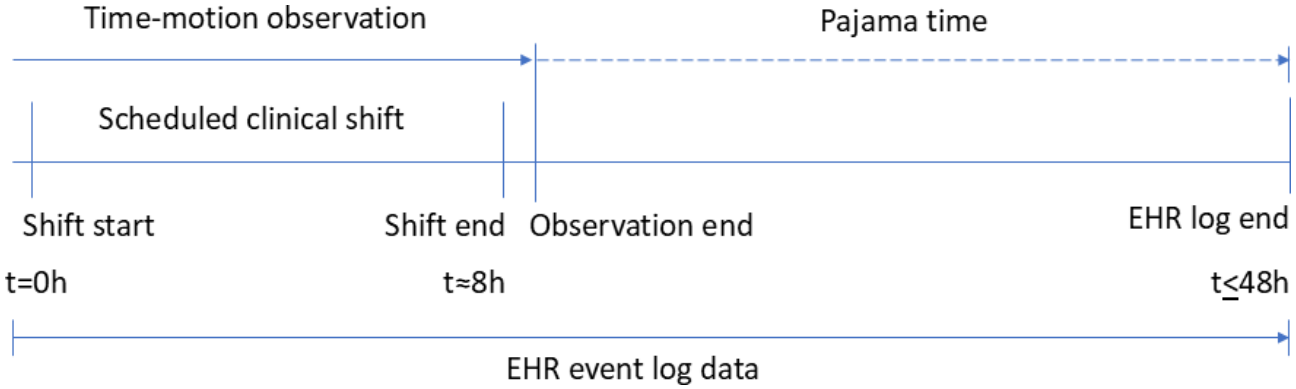
Physicians were recruited through convenience sampling and provided consent to participate in the study in a private setting prior to their observed shift [18]. Participant eligibility criteria included emergency physicians credentialed to practice in the institution's ED. No additional exclusion criteria were applied to this study sample.

Ethical Considerations

This study, involving human participants, was approved by the institutional review board (IRB) of Cedars-Sinai Medical Center (Pro00057066) prior to data collection. The IRB reviewed all recruitment and consent processes prior to recruitment; no concerns were identified beyond standard privacy and confidentiality safeguards. Written informed consent was obtained from each participating physician before their observed shift [18]. The IRB approved a waiver of consent for patients, as the primary focus of the study was to observe physician

XSL•FO
RenderX

activity where direct contact with patients and sensitive information was expected to occur only incidentally. All collected data were stored on secure institutional servers. Participants did not receive compensation for this study.



Measures

The main outcome was the proportion of shift time spent in each activity category. For each observed shift, we calculated the proportion of observed shift time spent in each prespecified activity category recorded in TimeCaT. The primary measure of interest for this investigation was the total minutes of computer time per scheduled hour of the physician's clinical shift. We calculated total computer time per scheduled hour as the sum of (1) directly observed on-shift computer time and (2) after-shift active EHR time from the event logs, divided by scheduled shift hours. The calculation of total computer time included the number of minutes each physician spent on the computer, both during and immediately after their scheduled ED shift. Activity categories included the percentage of time spent on specific shift activities. These categories consisted of computer usage (computer), direct patient interaction (patient), verbal communication with clinical staff (verbal), operating the phone (phone), miscellaneous tasks (miscellaneous), personal tasks (personal), EKG review (EKG), and performing clinical procedures (procedures).

EHR event log data provided detailed time stamps for all user actions carried out within the EHR computer system (eg, "ED Disposition Activity viewed," "User logged in," and "Notes viewed") after each observed shift. EHR use was defined as the number of seconds each physician spent actively using the EHR during their event log timespan, using a 1-minute threshold of inactivity [19]. The physician's EHR use was thus considered inactive if more than 59 seconds elapsed between any 2 successive EHR actions, indicating the physician had left the workstation or diverted their attention to perform other tasks [19,20]. Total active use was determined by calculating the time intervals between access times (access instants) for every active EHR action (ie, the number of seconds between every 2 subsequent logged events).

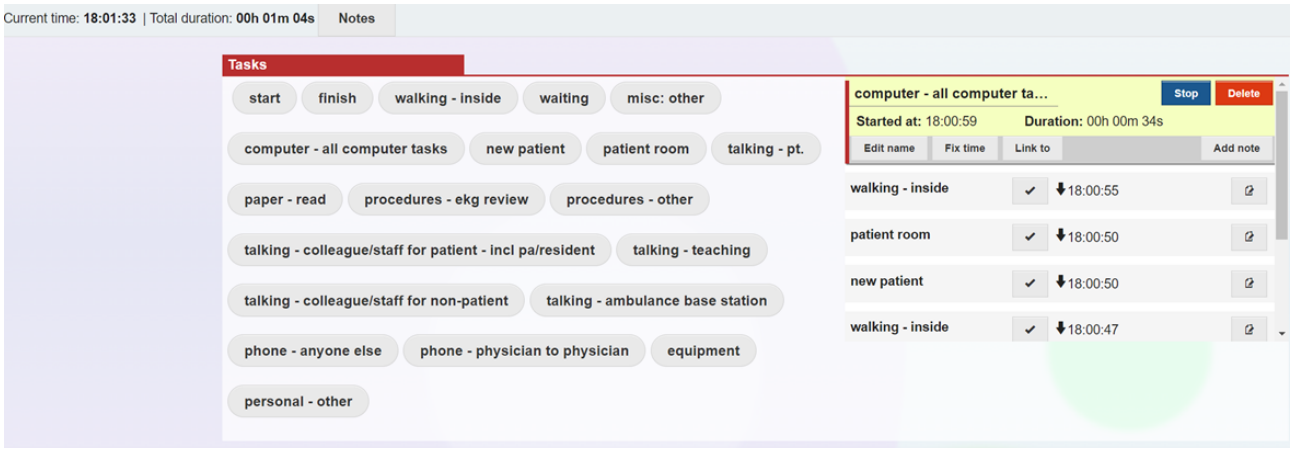
Pajama time is a term attributed in academic literature to characterize physician time spent using the EHR (computer) after the end of their scheduled shift (ie, on administrative actions such as writing clinical notes) [13,21,22]. In this study, we defined pajama time as any active EHR use that occurred after the observed shift concluded, captured up to 48 hours from the end of observation or the physician's next clinical shift [13,21,23]. Pajama time was measured using EHR event logs capturing EHR actions up to 48 hours after the observed shift day (2-d span), which included EHR use occurring either on-site at the medical center or elsewhere (ie, at home). See Figure 1 for a depiction of the combined data collection methods used in this study.

Figure 1. Overview of data collection process. Figure depicts the data collection timeline. In-person time-motion observation began at shift start (t=0) and continued until observation end. After-shift EHR activity ("pajama time") was captured from observation end until up to 48 hours later or the start of the physician's next clinical shift, whichever came first. Pajama time reflects active EHR use after the shift observation period ended, where t represents time markers in the combined data collection period (ranging from 0 h when the observed shift began to 48 h after the observed shift). EHR: electronic health record.

Data Collection

Time-Motion Observation Data

In-person, time-motion observations were conducted to collect workflow data characterizing the time ED physicians spent on prespecified tasks during ED shifts (one observed shift per enrolled physician). A single, trained observer with experience in research and clinical care as an emergency medical technician shadowed enrolled emergency physicians during clinical shifts scheduled to last 8 or 9 hours. Prior to data collection, the observer completed hands-on training to apply the ED task taxonomy and operate the data capture application, including a pilot session to practice real-time shadowing, task classification, and recording task transitions in the ED. Any ambiguities in task categorization and multitasking decision rules were immediately recorded using the application's native time-logged note-taking and annotation features and were discussed with the research team. An observation protocol, operational definitions, and decision rules were established before official data collection and were followed throughout the study to ensure consistent application of standardized task definitions across shifts.



The observer began data collection at the time the shift began and ended only when the physician informed the observer that they were done interacting with patients and planned to either leave the ED or use the computer without further patient interaction. The observer took a 45-minute break from data collection approximately halfway into each shift, and the length

XSL•FO
RenderX

of the shift was adjusted to account for this period prior to analysis.

The trained observer used a digital tablet and a web-based time-motion application (TimeCaT 3.9) to track start and end times (to the nearest second) across a list of prespecified tasks [24]. Time-motion studies are a well-established methodology for workflow research and are considered "gold standard methods" for health care observations [14]. Similarly, the TimeCaT application used for in-person data collection was specifically designed and validated for measuring workflow in health care contexts [24]. See Figure 2 for the graphical user interface used for in-person observation data collection.

Figure 2. TimeCaT data capture interface (Time-motion). The figure presents an example of the TimeCaT 3.9 interface used for in-person observation data collection (time-motion) from the observer's perspective.

Physician workflow (defined as the series of activities carried out by the physician during their shift) [25] was continuously assigned to one dominant task by clicking an activity-specific button in the TimeCaT application. These tasks included computer use, direct patient interaction, variations of phone use, EKG review, other clinical procedures, verbal communication with hospital staff, verbal instruction to staff, reading or writing on paper, waiting for the next task, gathering equipment, walking within the medical center, personal time, and miscellaneous actions. For clarity and comprehension, individual tasks were then combined into the following activity categories: computer use (computer), patient interaction (patient), verbal communication with ED staff (verbal), operating the phone (phone), EKG review (EKG), clinical procedures (procedures), all personal tasks (personal), and any remaining miscellaneous tasks (miscellaneous). See Table 1 for details on how individual tasks were classified into major activities.

Table . Categorization of physician activities (time-motion).

Activity category	Individual task
Computer	Computer—all computer tasks
EKG[a]	Procedures—EKG review
Miscellaneous	Miscellaneous: other
	Paper—read
	Waiting
	Walking—inside
Patient	New patient (unused)
	Patient room
	Talking—patient
Personal	Equipment
	Personal—other
Phone	Phone—physician to physician
	Phone—anyone else
Procedures	Procedures—other (ie, non-EKG)
Verbal	Talking—colleague or staff for patient
	Talking—teaching
	Talking—colleague or staff for nonpatient
	Talking—ambulance base station
Excluded research admin tasks	Start
	Finish

[a]EKG: electrocardiogram.

When the physician entered patient rooms, the observer waited outside the room in the interest of patient privacy, and the time spent inside the patient's room was assumed to be spent on direct patient care. TimeCaT did not include an explicit multitasking measurement in our study's configuration but captured it indirectly as a rapid set of alternations between tasks. When physicians were performing multiple tasks simultaneously (eg, talking on the phone while using the computer), the observer determined which task was the dominant focus of the physician's attention and alternated accordingly. This, in addition to the highly variable nature of ED workflow, resulted in many transitions between tasks during periods of multitasking, which the TimeCaT software was designed to capture [24].

Event Log Data From the EHR

To supplement the time-motion data collected during in-person observations, we also obtained EHR event log data to estimate the amount of time physicians spent on the EHR after the end of each physician's observed shift [12,20,26]. Each event log contained a detailed list of actions performed within the EHR by a particular user over a specified period of time, and each action was accompanied by a time stamp [12,26-29]. We collected the EHR event log data from the time in-person observation ended until up to 48 hours later or the time that the physician's next shift began (whichever was earlier). One physician's EHR event log data was excluded from the "pajama time" analysis because their unique administrative responsibilities suggested that their EHR actions were not directly related to their clinical care.

Analysis

Descriptive analyses were performed using Microsoft Excel and SPSS Statistics (version 24.0; IBM Corp). For each observed shift, we calculated the total time spent in each activity category from TimeCaT's time-stamped task interval data export. Per-shift activity proportions were computed as the time spent in a given category divided by the total observed shift time. We summarized shift-level proportions across physicians using medians and IQRs. For the primary measure of computer use (computer time per scheduled hour), we calculated observed on-shift computer time plus after-shift active EHR time, divided by scheduled shift hours. After-shift active EHR time was computed from audit event logs using a 1-minute inactivity threshold between logged events, as described in the "Measures" section.

Data visualizations were created using Tableau Desktop, Microsoft Office, and Seaborn [30]. The data visualizations were used to illustrate physician workflow allocation by activity type and the sequence of activities over the course of each ED shift.

Results

Overview

Twenty attending emergency physicians were enrolled in the study (5 female and 15 male). The median number of years in practice since residency graduation was 14.5 (IQR 7.5 - 23.0; range 3-44 y), with a residency graduation year range of 1976-2017. We collected a total of 150.0 hours of time-motion

XSL•FO
RenderX

data, with a median observation duration of 7.3 (IQR 7.2 - 8.1) hours per physician. This included a total of fourteen 8-hour shifts and six 9-hour shifts, with a shift start time range of 5 AM to 1 PM.

EHR event log data were obtained for all 20 clinical shifts, starting from the time the shift observation ended and continuing for up to 48 hours or until the beginning of the physician's next clinical shift. Initially, our dataset of EHR event logs included descriptions of physician actions over a total of 200.3 hours including pajama time. After the exclusion of 1 physician with unique administrative responsibilities, EHR event log data used in the reported analysis included a total of 189.1 hours (median 10.1, IQR 8.5 - 10.6 h per physician) across the remaining 19 physicians in the sample.

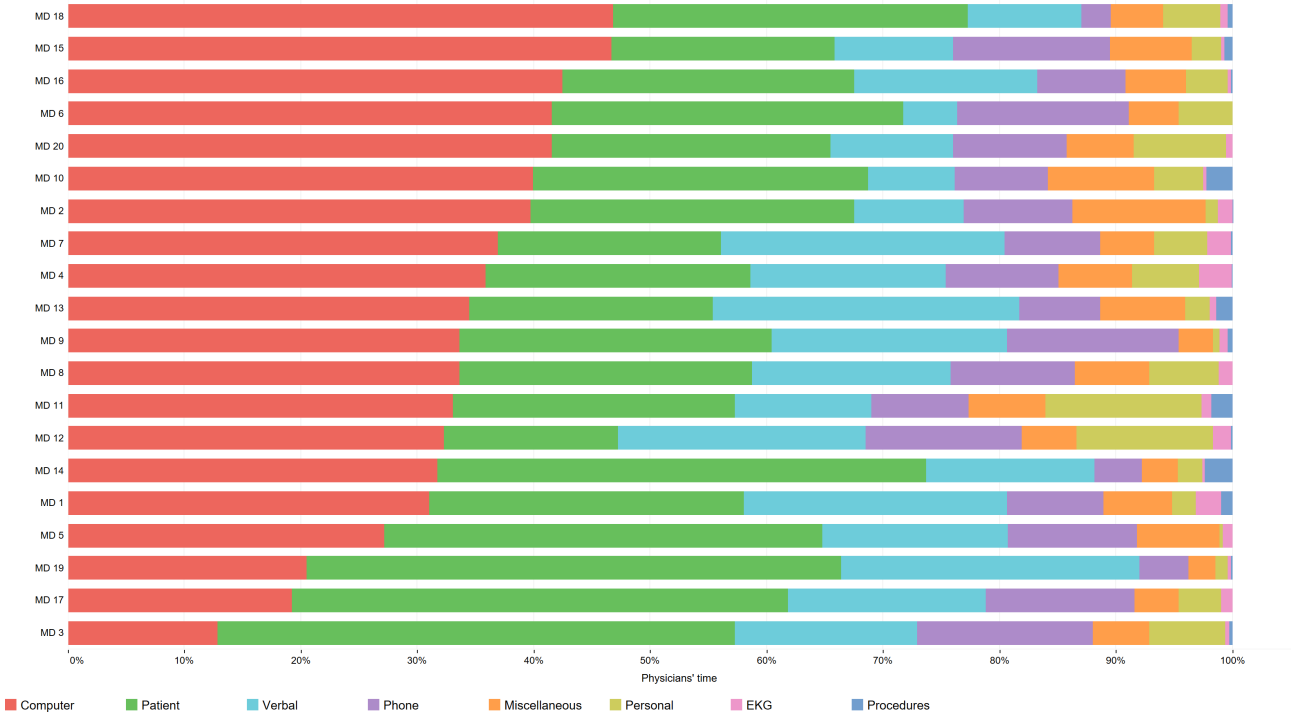
Outcomes

For the primary outcome measure of total computer time per scheduled hour of clinical shift, we found that ED physicians spent a median of 29.8 (IQR 25.6 - 38.5) minutes on the computer per hour of scheduled clinical work. Total minutes spent on the computer included both directly observed computer time during the ED shift and EHR pajama time that occurred after the physician's observed shift.

Direct Observation of On-Shift Activities

Based on real-time observational data across all 20 ED shifts, emergency physicians spent a median of 34.1% of their shift on the computer (156.5, IQR 145.2 - 179.3 min). The longest interval of time away from the computer at any point during a shift was 20.0 minutes (range 8.0-20.0). Secondary to computer use, physicians spent a median of 26.9% of their shift with patients (115.2, IQR 102.0 - 154.1 min). Among all 20 physicians, the longest time continuously spent at a patient's bedside for any physician was 21 minutes 47 seconds (range 7.4-21.8 min).

Additionally, ED physicians spent a median of 15.9% of their shift verbally communicating with staff (73.3, IQR 45.6 - 96.4 min). Physicians spent a median of 9.5% of their total shift using the phone to talk to other health care workers (41.4, IQR 33.4 - 59.2 min), with a median duration of 1.1 minutes per phone task. Miscellaneous clinical tasks constituted a median of 5.5% of their shift (24.2, IQR 18.4 - 30.1 min). Clinical procedures included 0.7% EKG review (3.8, IQR 1.4 - 5.0 min) and 0.4% for other procedures (1.7, IQR 0.6 - 6.4 min). Time spent on EKG review is described in more detail in a related manuscript that focuses on interruptions [31]. Across all physicians, personal time taken while working constituted only 3.9% of their total shift workflow (median 16.8, IQR 9.9 - 25.4 min) and included time spent eating, using the restroom, and personal smartphone use.



Data visualizations of physician workflow illustrate the substantial allocation of time spent on the computer compared to other clinical priorities, as well as variations in workflow between and throughout ED shifts. See Figures-53-5--55-5 for visualizations of physicians' time by activity (Figure 3), by individual shift (Figure 4), and linearly across each shift (Figure 5). The resulting Figure 5 (timelines of physician workflow in the ED) provides a task-level visualization of observed shift activities over time. Each row of the figure represents one observed ED shift, with each diamond indicating a task instance plotted at its measured start time, the color denoting the activity type, and the diamond size reflecting task duration. To improve visual clarity, the least prevalent task categories are depicted in gray (timelines depicting all task instances can be found in Multimedia Appendix 1). This depiction shows frequent alternation among activity categories (task switching) and substantial variability in fragmentation between ED shifts, with some shifts characterized by many high-intensity activity intervals and others containing longer, uninterrupted task periods.

XSL•FO

Figure 5. Timelines of physician workflow in the ED (By physician). The visualization illustrates the timing, sequence, and duration of observed activities during each observed ED shift (N=20). The x-axis shows the time since the shift start (time=0 bottom left) in hours of observed time. Each horizontal row corresponds to one observed physician shift. Shifts are ordered from top to bottom by the total number of recorded tasks (top row=fewest tasks; bottom row=most tasks). Each diamond represents a single observed task; diamonds are plotted at the task start time, color-coded by activity category (legend top right, with the 4 least common categories merged into a single gray color for visual clarity), and scaled in size to represent task duration (larger diamonds=longer tasks). Diamonds are displayed with a slight vertical "jitter" within each row to reduce overlap between closely timed tasks and enhance visual clarity. This visualization is intended to provide a task-level view of workflow fragmentation and task switching over time, and to illustrate variability in workflow sequencing across observed shifts. See Multimedia Appendix 1 for timelines depicting all task category instances. ED: emergency department.

After-Shift Computer Use

Across 19 clinical shifts, we obtained data on 112,396 EHR log events (actions) with a median of 5732 (IQR 5213 - 6519) events per physician and an overallevent rate of 9.9 events per minute. The total EHR log timespan recorded from this data, including active and idle computer use, was approximately 189.1 hours across 19 included physicians. After applying the 1-minute inactivity threshold to calculate total active EHR use after the shift, physicians spent a median of 1.3 (IQR 0.5 - 2.6; range 0.0-5.3) hours on pajama time after the end of their scheduled shift.

Across all logged EHR events, we identified 147 unique EHR actions from the metric names and descriptions present in the audit log, with a median of 57.5 (IQR 50 - 62) unique EHR actions per physician. The most frequently logged EHR actions included: "Report with patient data viewed," "SmartLink used,"

XSL•FO
RenderX

"Visit Navigator template loaded," "Inpatient system list accessed," and "ED Disposition Activity viewed."

Discussion

Principal Results

In this descriptive observational time-motion study of emergency physician workflow in a high-volume, metropolitan, level-1 trauma center, our results reveal that physicians spent more time using computers than engaging in direct patient care—generally spending more than a third of their shift on the computer or approximately half of every scheduled hour when accounting for "pajama time" after their shift. Our results demonstrate that the baseline work system in our ED is complex, involves frequent task switching, and includes substantial time at computer systems. The workflow visualizations presented can be used to support interpretation and guide discussions around ED workflow, including how organizational or health IT changes might influence these patterns. Figure 5 and Multimedia Appendix 1, in particular, provide a task-level depiction of activity sequencing, which can be used as a visual aid to help communicate workflow complexity to clinicians, administrators, and nonclinical stakeholders. These findings add to a growing body of evidence that time spent on direct patient care is limited by competing workflow demands (especially the burden of computer use) associated with ED care delivery [32-36].

These findings identify concrete targets with informatics implications for workflow and EHR improvement in emergency care. The high proportion of computer-based work suggests a need to reduce low-yield documentation and user burden through usability-focused redesign, such as minimizing unnecessary EHR flows for common tasks while preserving team coordination. The task-sequence visualizations also highlight substantial within-shift fragmentation and heterogeneity in task density across shifts, suggesting that interventions should be evaluated not only on total computer time but also on whether they reduce excessive task switching. Finally, because this study integrates structured time-motion observation with EHR event log data in the same cohort, it provides a reproducible measurement approach that can be used to evaluate EHR usability and workflow interventions using consistent, prespecified outcomes.

Direct observation and audit logs have complementary strengths and limitations; combining them provides a more complete characterization of ED workflow than either method alone. Our study combines data from both in-person time-motion observations and EHR event log data to demonstrate that the burden of computer use is not limited to time on-shift but also commonly extends hours beyond the end of clinical shifts [12,13,22]. While EHRs facilitate improved patient care by providing physicians access to patients' prior medical histories and test results, for example, they also complicate the clinical work environment and may lead to unintended consequences such as limiting physician time at patients' bedsides [35,37].

We undertook this study to establish baseline measurements describing the distribution of time spent at the computer and across other activities to prepare for the introduction of policy changes and technologies that could alter workflows. During the study period, our emergency physicians used voice recognition software to assist with producing clinical documentation, including written medical histories, physical examinations, interpretations of diagnostic test results, and medical decision-making notes. While some US documentation requirements have recently been revised to make them less burdensome, emergency physicians are still incentivized to write potentially lengthy medical decision-making notes that fully characterize the complexity of patient encounters so that their institutions can recover the maximum amounts available for the care of each patient [38,39].

Currently available EHR systems were designed to reflect what was previously possible using handwritten notes in paper filing systems, enable the collection of information necessary for billing, and facilitate improved access to essential clinical information. Possibly as a result of this history, persisting user interface and design limitations may place an additional cognitive burden on emergency physicians [40-42]. Usability improvements that are particularly relevant in the ED include reducing clicks and screen changes for common workflows (eg, reviewing results, documenting encounters, and placing orders), facilitating efficient retrieval of time-sensitive data, and minimizing redundant documentation. Streamlining team communication and task coordination within the EHR may also reduce fragmentation without compromising clinical coordination. Overly complicated interfaces and unintuitive action sequences in EHRs may frustrate physicians and increase the risk of medical errors [43-45]. Pragmatic, user-centered design principles should be incorporated as EHR systems are designed and tested, especially for those employed in ED care settings where time-critical actions are commonplace [35].

The development of more user-friendly interfaces that support seamless compliance and mitigate risk could significantly alleviate existing administrative pressures and allow physicians to focus more on patient-centered care [44,46]. Developing these systems requires additional research to understand how clinicians' varied current and future approaches to EHR use may impact the quality of care, for example by assessing whether more "staccato" (frequently interrupted) or, conversely, "legato" (fewer, longer periods of use) interactions are associated with increased efficiency or errors. There is an urgent need for improved EHR design, documentation processes, and other human factors-centered solutions that enhance efficiency and improve quality and safety for patients [35,47,48]. Investing in "elbow-to-elbow" EHR training for emergency physicians may improve understanding of EHR functionalities, thereby enhancing their efficiency and reducing the associated burden for current and future clinicians [49-51].

Emerging technologies designed to decrease documentation burdens have shown early promise, although with some potential downsides. For example, ambient artificial intelligence (AI) scribes use natural language processing to transform real-time audio-recordings of clinical encounters into clinical documentation [52], and this technology is likely to advance rapidly due to advancements in AI capabilities over the last several years [35]. A recent study conducted at sites in 6 different health systems demonstrated an association between

XSL•FO
RenderX

the introduction of ambient AI scribes and a reduction in pajama time [53]. However, careful evaluation of such products must be undertaken to understand the strengths and limitations of the technology and identify unintended consequences for physicians (ie, novel unexpected workflow challenges) as well as patients [54]. Authors of a noteworthy study conducted by Kaiser Permanente reported that early tests of ambient AI scribes were not well-integrated into their EHR at the time of testing, which led to technical difficulties and frustrations due to wasted time [52]. Regardless of specific technological enhancements, proposed workflow solutions should be evaluated against the outcomes used here (on-shift activity distribution, total computer time, and after-shift EHR time) to ensure improvements accurately reflect efficiency rather than redistribution of burden.

Overall, our study underscores the importance of undertaking more rigorous future human factors studies to improve workflow measurement in complex work environments as new technology is introduced, systematically assessing benefits and addressing drawbacks for clinical work. The Cognitive Work Analysis (CWA) framework was recently described as a method to "model and design sustainable sociotechnical ED systems" as new technologies are introduced [55]. Taken together with the Dynamic Sustainability framework [56], administrators and early adopters of technology should anticipate the need to conduct ongoing assessments of how sociotechnical systems are changing so that the needs of clinicians and patients are uncovered and addressed as technologies and tasks evolve over time.

Limitations

Our study has several limitations. First, this was a single-site study, which may limit the generalizability of our results. Additionally, observations were conducted by a single trained observer; however, we used standardized task definitions and a structured, validated observation tool designed to handle task classification discrepancies [24]. Future studies could incorporate multiple observers and formal reliability testing when resources permit. Second, we recruited a convenience sample of attending physicians working day shifts to participate in the study. As such, it is possible that physicians who opted to participate have systematic differences in the way they spend their time compared to those who did not participate, and the findings may not generalize to overnight ED workflow. Physicians in this study varied in years of experience, which may be reflected in their workflow patterns. While our sample was not designed for statistical adjustment, future studies should investigate experience-related differences and night shift variability in workflow. Third, because our observer was instructed not to enter patients' rooms due to privacy concerns, we assumed that time in rooms was entirely spent on direct patient care. Thus, it is possible that we overestimated the amount of direct patient care and underestimated the amount of time spent on other activities such as computer use and phone calls that could have occurred within patient rooms. Fourth, to incorporate EHR event log data into our analyses, we selected inactivity cutoff times based on qualitative comparisons of EHR event log data and in-person observation data that nonetheless may systematically overestimate or underestimate EHR time; however, similar inactivity thresholds have been used for EHR event data in existing literature [19,20]. Lastly, some physicians may have been using pajama time to catch up on documentation from prior shifts, which could have led to overestimation of total computer time. As we could not directly observe physicians after they left the ED, the use of EHR event logs with validated activity thresholds was found to be the most suitable approach for estimating postshift EHR use that would have otherwise gone unmeasured [19,20].

Conclusions

This time-motion study found that emergency physicians allocate more than one-third of their time to computer use during their ED shift. We analyzed EHR event logs to estimate that physicians also spend an additional 1 to 2 hours using the computer after their scheduled shift. In total, emergency physicians spend approximately half of every scheduled shift hour on computer-based work. Future research should investigate strategies to minimize low-yield time at the computer and increase time spent providing direct patient care.

Acknowledgments

No nonhuman assistance was used to conduct this research or create this manuscript.

Funding

This research was supported by internal funding from Cedars-Sinai Medical Center. The funding source did not play any role in the study design, data collection, analysis, interpretation of results, writing, or the decision to submit this paper for publication.

Data Availability

The datasets collected and analyzed in this study are not publicly available to protect participants' privacy, as they include potentially identifiable metadata and are governed by institutional data-sharing policies. Deidentified data are available from the corresponding author upon reasonable request.

Authors' Contributions

CTB conceptualized the study. AJH conducted observations, data collection, and analyses. AJH, CTB, and KLI drafted the manuscript. All authors participated in writing and revision. AJH and CTB accept responsibility for the integrity of the work, maintained full access to the data, and initiated submission for publication.

Abstract

Background: Effective postdischarge management is essential for maintaining disease control and improving long-term outcomes in rheumatoid arthritis (RA). Digital health technologies, particularly intelligent management platforms, provide new opportunities for continuous care and self-management in real-world settings.

Objective: This study aimed to develop a nurse-led artificial intelligence (AI)–assisted interactive management platform for postdischarge RA care and examine its association with patient outcomes in a real-world clinical setting.

Methods: A single-center, multicampus, real-world observational study with a quasi-experimental framework was conducted at Tongji Hospital between November 2024 and October 2025. Participants were allocated to either a platform-based management group (campus 1; n=184) or a comparison group receiving routine postdischarge care (campus 2; n=157). The platform enabled remote monitoring through a smartphone app, which collected information on joint symptoms, fatigue, medication adherence, laboratory results, and emotional status, with data uploaded to a secure cloud server. The AI system analyzed data in real time and alerted health care providers to abnormalities. Nurses and health coaches delivered personalized education and interventions. Primary outcomes were changes in Disease Activity Score in 28 Joints and Health Assessment Questionnaire–II scores at discharge and the 6-month follow-up. Secondary outcomes included medication adherence measured as the proportion of prescribed doses taken and patient satisfaction assessed via a 5-point Likert-scale questionnaire at 6 months.

Results: A total of 341 patients with RA completed the 6-month follow-up. Disease Activity Score in 28 Joints values decreased significantly in the platform-based management group at 6 months (mean 5.04, SD 1.38 at discharge to mean 4.27, SD 1.20 at 6 months; P<.001), showing a greater reduction than in the comparison group (mean 4.86, SD 1.19 at discharge to mean 4.59, SD 1.36 at 6 months; within-group P=.03; between-group P=.02). Health Assessment Questionnaire–II scores improved significantly in the platform-based management group (mean 2.45, SD 0.75 at discharge to mean 1.67, SD 0.56 at 6 months; P<.001), while the comparison group showed no significant change (P=.12; between-group P<.001). Medication adherence was higher in the platform-based group (166/184, 90.2% vs 125/157, 79.6%; χ_1^2=7.6; P=.006). Overall health care satisfaction was also higher in the platform-based group (176/184, 95.7% vs 120/157, 76.4%; χ_1^2=27.8; P<.001), with a greater proportion reporting to be “very satisfied” in this group (150/184, 81.5% vs 59/157, 37.6%).

Conclusions: The intelligent interactive management platform markedly enhanced disease control, functional status, medication adherence, and satisfaction among patients with RA after discharge. This nurse-led, AI-assisted system represents a promising model for improving outpatient RA management.

KEYWORDS

rheumatoid arthritis; intelligent interactive platform; disease activity; medication adherence; patient satisfaction; artificial intelligence; AI

Introduction

Rheumatoid arthritis (RA) is a chronic systemic autoimmune disease with a global prevalence of approximately 1% to 2% [1]. It predominantly affects middle-aged and older adults, with higher prevalence among women aged 40 to 60 years [1,2]. RA is frequently complicated by extra-articular manifestations, including cardiovascular disease, pulmonary dysfunction, neurological involvement, gastrointestinal disturbances, and malnutrition [3]. Although no curative therapy exists, timely and standardized treatment can effectively control disease activity, relieve symptoms, and delay disability [4]. Long-term management commonly involves pharmacological therapy, intra-articular injections, physical rehabilitation, regular follow-up visits, and surgical intervention when indicated [5]. Nevertheless, despite ongoing treatment, many patients experience varying degrees of joint deformity and functional impairment, substantially limiting their daily activities and compromising overall well-being [6].

Given the chronic and progressive nature of RA, effective self-management is essential for maintaining patients' quality of life and delaying disease progression [7]. Conventional nursing models primarily focus on inpatient care, whereas postdischarge management often relies heavily on patient self-management, leading to suboptimal outcomes [8]. Successful RA management requires patients to develop both the confidence and the necessary skills to manage their condition independently [9]. Key components of self-management include self-monitoring of symptoms and disease flares, setting achievable goals, adopting behavioral modifications, adhering to medication, adjusting physical activity levels, and enhancing problem-solving abilities [3]. Robust self-management practices have been shown to improve adherence, reduce disease activity, and slow progression of RA [10,11]. Therefore, innovative and sustainable strategies are needed to enhance postdischarge self-management and continuity of care.

The rapid proliferation of mobile technologies has transformed health service delivery worldwide [12]. As mobile apps become increasingly embedded in routine activities, the delivery of health care through digital platforms has emerged as an inevitable evolution in line with technological advancement [13]. In the context of RA management, mobile health (mHealth) technologies, including smartphones, wearable devices, and disease-specific apps, are playing an increasingly pivotal role [12,14]. These tools enable real-time health data collection, thereby facilitating early detection of disease fluctuations. They empower both patients and health professionals by enhancing disease monitoring, improving medication adherence, and enhancing timely personalized interventions [15]. Such innovations improve the efficiency of disease management by reducing unnecessary hospital visits and optimizing health care resource allocation. Furthermore, instant feedback mechanisms reinforce patients' self-management capabilities and promote active engagement in their own care [16].

Building on our institution's "internet hospital" infrastructure and standardized RA management protocols, we developed an intelligent, nurse-led interactive management platform to support postdischarge care for patients with RA. This study aimed to evaluate the real-world effectiveness of this platform by comparing patients managed through platform-based follow-up to those receiving routine postdischarge care across different hospital campuses under unified clinical standards.

Methods

Study Design and Population

This study used a single-center, multicampus observational design with a quasi-experimental framework conducted at the Department of Rheumatology and Immunology, Tongji Hospital, between November 2024 and October 2025. Tongji Hospital consists of multiple hospital campuses operating under unified clinical guidelines and standardized treatment protocols for RA. An intelligent interactive follow-up platform was first implemented at campus 1 as part of routine postdischarge care, whereas campus 2 had not yet adopted the platform at the time of the study. This natural difference in platform availability allowed for the formation of a platform-based management group (campus 1) and a comparison group receiving usual postdischarge care (campus 2) without individual-level assignment by the research team. Eligible participants were adults (aged ≥18 years) diagnosed with RA according to the 2010 American College of Rheumatology and European Alliance of Associations for Rheumatology classification criteria, receiving standardized RA therapy, and capable of using a smartphone or having a caregiver assist with platform access. Exclusion criteria included inability to comply with follow-up, severe psychiatric or cognitive disorders, visual or hearing impairment precluding platform use, severe systemic comorbidities (eg, advanced cardiac, hepatic, or renal disease), or discontinuation of RA treatment during the follow-up period.

Group Allocation and Blinding

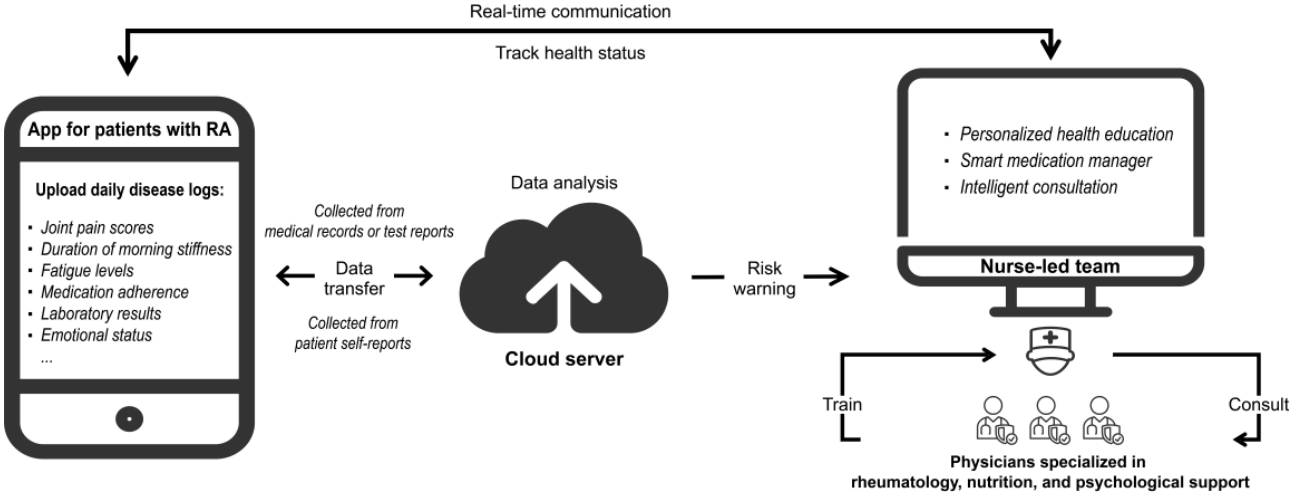
Participants were allocated to study groups based on hospital campus rather than through randomization. Patients discharged from campus 1 were included in the platform-based management group, whereas those discharged from campus 2 constituted the comparison group receiving routine postdischarge care. This campus-based allocation reflected real-world clinical implementation and helped avoid ethical concerns related to unequal access to a newly introduced digital management platform. Given the nature of the platform-based management model, blinding of patients and health care providers was not feasible. However, outcome assessors and data analysts were blinded to group allocation to reduce assessment and analysis bias.

XSL•FO
RenderX

Technical Design and Platform-Based Management Model

Platform Overview

The intelligent interactive platform for RA is a multidisciplinary, nurse-led, and patient-centered digital health management system established within the smart health care ecosystem of Tongji Hospital. Designed to enhance routine outpatient care, the platform incorporates artificial intelligence (AI) and is operated by a specialized team of rheumatology nurses, with additional support from health coaches trained in rheumatology, nutrition, and psychological support.



The primary objective of the platform is to extend continuous care beyond hospital discharge. Timely responses to self-reported symptoms and system-generated alerts support individualized guidance and facilitate timely clinical decision-making during routine follow-up. It also facilitates complication monitoring, self-care education, and psychological support, helping patients manage their condition more effectively during home-based recovery. Integrated communication tools ensure that patients have continuous access to their care team.

Technical Architecture and Core Functions

Overview

The platform was developed collaboratively by the hospital's Information Center and technology partners. Its architecture comprises 3 core components: a patient-facing mobile app, a web-based dashboard for nurses and health coaches, and a cloud-based AI data processing system (Figure 1).

Figure 1. Framework of the intelligent interactive platform for rheumatoid arthritis (RA).

Data Input and Processing

Patients use the mobile app to submit health logs either daily or as needed based on their symptom fluctuations. These logs include joint pain scores measured using a visual analog scale from 1 to 100, duration of morning stiffness, fatigue levels, medication adherence, laboratory results, emotional status, and sleep quality. While the "Smart Medication Manager" provides automated daily notifications for drug intake, other health logs are recorded voluntarily by patients without daily reminders to avoid excessive burden. All data are securely encrypted and transmitted to the cloud server. For image-based data, such as medical records or test reports, a deep learning–based optical character recognition system automatically extracts key information, which is manually verified and structured into the database.

AI-Driven Clinical Decision Support

An embedded AI engine continuously analyzes patient data in real time. Unlike traditional rule-based systems that rely on static, predefined thresholds, our AI engine uses a multilayered approach. A deep learning–based optical character recognition system processes unstructured data from patient-uploaded images (eg, external laboratory reports). In addition, the engine uses longitudinal data processing to monitor trends in disease activity and medication adherence over time. When abnormalities are detected, such as elevated disease activity, decreased medication adherence, or signs of relapse, the system immediately generates alerts for the clinical care team through the dashboard even if individual parameters have not yet exceeded traditional laboratory triggers. Nurses and health coaches can then respond promptly via the app, providing timely follow-up support and facilitating triage for further outpatient or inpatient care if necessary (Multimedia Appendix 1).

Personalized Education and Self-Management Support

Beyond reactive support, the platform provides proactive, personalized health education. On the basis of individual patient assessments and preferences, the care team delivers guidance on diet, exercise, and psychological well-being. This is facilitated by an integrated intelligent education module that pushes customized content to patients (Multimedia Appendix 2). A "Smart Medication Manager" feature allows patients to log their prescribed oral medications and receive automated reminders to enhance adherence (Multimedia Appendix 3). Furthermore, an "Intelligent Consultation" module serves as a knowledge base for frequently asked questions related to RA care, covering topics such as appointments, insurance, follow-ups, and common rheumatological concerns, thereby improving accessibility and potentially reducing unnecessary clinic visits (Multimedia Appendix 4).

XSL•FO
RenderX

Pilot Feasibility Assessment

Prior to the main study, an internal, unpublished pilot test was conducted to evaluate the platform's feasibility and support its user-centered design. The pilot involved 25 patients with RA over a 4-week period. During this phase, the platform demonstrated high levels of engagement. Specifically, the patient self-assessment completion rate rose from 68.0% (17/25) to 88.0% (22/25). To ensure that the intervention was not solely investigator driven, we collected qualitative feedback from participants via telephone interviews and structured satisfaction surveys. Users identified several areas for improvement, such as the need for a more intuitive user interface for joint symptom logging and more flexible medication reminder settings. On the basis of the feedback, the platform underwent iterative refinements, including optimizing user interface responsiveness and streamlining the data entry process before the formal study commenced. While traditional clinical measures such as inflammatory markers and disease activity scores did not show statistically significant changes in the short-term pilot, promising improvements were observed in behavioral outcomes, including follow-up completion rates, platform log-in frequency, and consultation response times, indicating good usability and feasibility for real-world implementation.

Data Collection and Study Procedure

Between November 7, 2024, and April 20, 2025, eligible patients with RA who were clinically stable and scheduled for discharge were consecutively recruited. Baseline data were collected prior to discharge. Participants were allocated to study groups based on hospital campus, reflecting routine clinical implementation of the intelligent interactive platform. All participants were followed up on for 6 months after enrollment, and the final follow-up assessment was completed on October 20, 2025.

During hospitalization, patients in both groups received standardized nursing care and health education in accordance with unified clinical protocols across campuses. This included RA-related disease education, psychological support, medication management, symptom monitoring, rehabilitation guidance, complication prevention, routine follow-up planning, and discharge counseling.

After discharge, patients in the comparison group received routine postdischarge follow-up care, which consisted of periodic assessments of disease status, emotional well-being, medication adherence, and rehabilitation activities. Follow-up was conducted using conventional approaches, including scheduled outpatient visits, telephone consultations, or home visits, during which health care professionals provided individualized guidance and addressed patient concerns as needed.

In addition to routine care, patients in the platform-based management group were supported through the platform. One to 2 days prior to discharge, designated rheumatology nurses introduced the platform to eligible patients using standardized instructions and obtained written informed consent. Nurses then provided individualized, hands-on guidance on platform access, account setup, and creation of a personal health record. Patients were guided through key functional modules to ensure independent use after discharge. For patients without access to a smartphone or those unfamiliar with mobile apps, family members or caregivers were instructed on how to operate the platform on the patient's behalf to support ongoing disease management.

Outcome Measures

Overview

Primary outcomes were disease activity and functional status assessments. Secondary outcomes included medication adherence and health care satisfaction. These outcomes were assessed to examine differences between groups rather than to evaluate causal effects of the platform. Disease activity and functional status were evaluated both at discharge and the 6-month follow-up, whereas secondary outcomes were assessed only at 6 months as many patients were treatment naive at baseline or satisfaction could not be measured until follow-up.

Disease Activity

The Disease Activity Score in 28 Joints (DAS28) was used to assess RA disease activity [17]. It combines a count of 28 swollen and tender joints, a laboratory marker of inflammation (either C-reactive protein or erythrocyte sedimentation rate), and a patient global health assessment. Higher DAS28 scores indicate more severe disease activity.

Functional Status

Functional disability was measured using the Health Assessment Questionnaire–II (HAQ-II) [18]. The HAQ-II is a validated instrument that assesses difficulty in performing activities of daily living across 8 domains (dressing, arising, eating, walking, hygiene, reach, grip, and common activities). It contains 10 items, each scored on a scale from 0 to 3 (0="without difficulty"; 3="unable to do"). The total score is the average of the category scores, with higher scores indicating greater functional impairment. The HAQ-II showed good internal consistency in this study (Cronbach α=0.83), consistent with its original validation (Cronbach α=0.88) [18].

Medication Adherence

Medication adherence was assessed based on participants' self-reported medication intake during the follow-up period. Adherence was operationally defined as the proportion of prescribed doses reportedly taken. Consistent with commonly used adherence definitions in chronic disease management, participants were classified as having good adherence if they reported taking 85% or more of the prescribed medication regimen and poor adherence otherwise [19].

Health Care Satisfaction

Patient satisfaction with care was assessed using a department-developed questionnaire. Responses were recorded on a 5-point Likert scale ("very satisfied," "satisfied," "neutral," "dissatisfied," and "very dissatisfied"). The satisfaction rate was calculated as the percentage of participants reporting being "very satisfied" or "satisfied" among the total respondents. The scale's content validity index was 0.92 as evaluated by a panel of 5 rheumatology experts, and the questionnaire demonstrated good reliability in this study (Cronbach α=0.86).

XSL•FO
RenderX

Data Analysis

Statistical analyses were performed using R (version 4.4.1; R Foundation for Statistical Computing). Continuous variables were described as means and SDs for normally distributed data or medians and IQRs for nonnormally distributed data. Normality was assessed using the Shapiro-Wilk test. Variance homogeneity was evaluated using the Levene test. Between-group comparisons were performed using 2-tailed Student *t* test or Welch *t* test for normally distributed variables and the Mann-Whitney *U* test (Wilcoxon rank-sum test) for nonnormally distributed variables. Categorical variables were compared using the chi-square test or Fisher exact test, as appropriate. All *P* values were 2 sided and are reported as exact values in accordance with JMIR Publications' statistical reporting guidelines.

Ethical Considerations

This study was approved by the Medical Ethics Committee of Tongji Hospital, Tongji Medical College of Huazhong University of Science and Technology (TJ-IRB202411023). The study was conducted in accordance with the Declaration of Helsinki. Participation was voluntary, and written informed consent was obtained from all participants prior to enrollment. Participants retained the right to withdraw from the study at any time without penalty or explanation. All collected data were deidentified and stored securely in compliance with the hospital's scientific research data management standards. Deidentification was performed using a key-encoded system, with reidentification keys securely stored by the study team. No financial incentives were offered to participants. The trial was prospectively registered at the Chinese Clinical Trial Registry (ChiCTR2500115743). This study is reported in accordance with the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guidelines (Checklist 1).

Results

Demographic Characteristics

Between November 7, 2024, and April 20, 2025, a total of 459 patients with RA who met the inclusion criteria were identified at our hospital. Of these 459 patients, 401 (87.4%) consented to participate in the study, including 206 (44.9%) from campus 1 (platform-based management group) and 195 (42.5%) from campus 2 (comparison group). Following baseline assessment, 10.2% (21/206) of the patients from campus 1 and 20.0% (39/195) of the patients from campus 2 were lost to follow-up. The higher retention rate in the platform-based group may reflect the impact of continuous digital engagement. Ultimately, 89.3% (184/206) of the patients from campus 1 and 80.5% (157/195) of the patients from campus 2 completed the 6-month follow-up, resulting in a total of 341 (74.3%) participants included in the final analysis.

The baseline characteristics of the participants are summarized in Table 1. The mean age of the participants was 57.41 (SD 13.45) years in the platform-based management group and 55.47 (SD 13.57) years in the comparison group. Female individuals comprised most of both groups, accounting for 76.1% (140/184) and 78.3% (123/157) in the campus 1 and campus 2 groups, respectively. RA duration was similar between the 2 groups (median 4, IQR 2-12 years vs median 4, IQR 2-10 years). Educational levels, residence, smoking and alcohol consumption, BMI, RA disease duration, comorbidities including hypertension and diabetes, and RA-related complications did not differ significantly between the groups.

[a]Student *t* test. Age: t_{339}=1.321.

[b]Chi-square test.

[c]RA: rheumatoid arthritis.

[d]Mann-Whitney *U* test (Wilcoxon rank-sum test). RA disease duration: *W*=15,003. BMI: *W*=14,695.

[e]Primarily comprising interstitial lung disease, osteoporosis, and femoral head avascular necrosis.

Changes in DAS28 Scores

Changes in disease activity over the 6-month follow-up are shown in Table 2. In the comparison group, the mean DAS28 score decreased from 4.86 (SD 1.19) at discharge to 4.59 (SD 1.36) at 6 months, with a statistically significant within-group change (*P*=.03). In the platform-based management group, the mean DAS28 score decreased from 5.04 (SD 1.38) at discharge to 4.27 (SD 1.20) at 6 months, with a larger within-group change (*P*<.001). Between-group comparison at 6 months indicated a significantly greater reduction in DAS28 scores in the

XSL•FO
RenderX

platform-based management group than in the comparison group (P=.02).

Table . Disease Activity Score in 28 Joints values of the participants. t_{339}=–1.293 and P=.20 at discharge and t_{339}=2.286 and P=.02 at the 6-month follow-up. Disease Activity Score in 28 joints: range 0-9.4; higher scores indicate more activity.

Group	At discharge, mean (SD)	6-month follow-up, mean (SD)	Paired *t* test (*df*)	*P* value
Comparison group	4.86 (1.19)	4.59 (1.36)	2.172 (156)	.03
Platform-based management group	5.04 (1.38)	4.27 (1.20)	7.404 (183)	<.001

Changes in HAQ-II Scores

At discharge, HAQ-II scores were comparable between the comparison group and the platform-based management group (P=.79; Table 3). At the 6-month follow-up, the comparison group showed no significant change from baseline (P=.12), whereas the platform-based management group exhibited a significant reduction (P<.001). Between-group comparison at 6 months indicated a significantly greater improvement in functional status in the platform-based management group than in the comparison group (P<.001).

Table . Health Assessment Questionnaire–II scores of the participants. t_{339}=–1.293 and P=.20 at discharge and t_{339}=2.286 and P=.02 at the 6-month follow-up. Disease Activity Score in 28 joints: range 0-9.4; higher scores indicate more activity.

Group	At discharge, mean (SD)	6-month follow-up, mean (SD)	Paired *t* test (*df*)	*P* value
Comparison group	2.47 (0.60)	2.39 (0.58)	1.565 (156)	.12
Platform-based management group	2.45 (0.75)	1.67 (0.56)	14.529 (183)	<.001

Changes in Medication Adherence

On the basis of the predefined adherence criterion (≥85% of prescribed doses reportedly taken), 90.2% (166/184) of the participants in the platform-based management group exhibited good adherence compared with 79.6% (125/157) in the comparison group (χ_1^2=7.6; P=.006) at the 6-month follow-up.

Changes in Health Care Satisfaction

Table 4 presents the health care satisfaction levels of participants in both groups. The overall satisfaction rates were 76.4% (120/157) in the comparison group and 95.7% (176/184) in the platform-based management group (P<.001). Notably, a greater proportion of participants in the platform-based management group reported being very satisfied compared to the comparison group (150/184, 81.5% vs 59/157, 37.6%, respectively).

Table . Health care satisfaction of the participants.

Group	Very satisfied, n (%)	Satisfied, n (%)	Neutral, n (%)	Dissatisfied, n (%)	Very dissatisfied, n (%)	Satisfaction rate (participants who were very satisfied or satisfied), n (%)[a]
Comparison group (n=157)	59 (37.6)	61 (38.9)	24 (15.3)	13 (8.3)	0 (0.0)	120 (76.4)
Platform-based management group (n=184)	150 (81.5)	26 (14.1)	5 (2.7)	3 (1.6)	0 (0.0)	176 (95.7)

[a]χ_1^2=27.8; P<.001.

Discussion

In this quasi-experimental study conducted in real-world clinical settings, we demonstrated that a nurse-led, AI-assisted intelligent interactive platform significantly improved disease activity, functional status, medication adherence, and satisfaction in patients with RA over a 6-month follow-up period. Specifically, participants in the platform-based management group showed greater reductions in DAS28 scores and more substantial improvements in HAQ-II scores compared with those receiving routine postdischarge care. These findings highlight the potential of digital health interventions to enhance real-world RA management beyond conventional postdischarge care.

Our results align with and expand on evidence from large, multicenter studies showing that digital health apps can contribute to disease control in RA. In a pragmatic randomized clinical trial involving more than 2000 patients with RA, patients using a digital health app to assess patient-reported outcomes had higher rates of achieving a DAS28 based on C-reactive protein score of 3.2 or less at 6 months compared with controls, reflecting improved disease control with digital monitoring and clinician intervention [20]. Additionally, smaller prospective

XSL•FO
RenderX

studies have reported clinically meaningful improvements in disease activity and other patient-reported outcomes following mHealth interventions for patients with inflammatory arthritis, underscoring the potential for mobile platforms to complement standard therapies [21]. There is systematic evidence further suggesting that asynchronous mHealth tools, including smartphone apps, web apps, and SMS text message reminders, are associated with desirable outcomes in RA self-management and health behaviors, although the heterogeneity of existing studies highlights the need for more rigorous designs [22]. Moreover, systematic reviews of digital health interventions for arthritis broadly support the role of these tools in enhancing medication adherence and quality of life, with most randomized controlled trials showing positive contributions of digital health in arthritis populations [23]. Together, these data contextualize our findings and indicate that digital tools, particularly those integrating real-time monitoring and clinician feedback, may improve RA outcomes beyond traditional follow-up models.

The mechanisms underlying observed improvements likely reflect multiple synergistic components of the platform. First, continuous data capture and AI-driven alerts enabled early identification of disease activity fluctuations, facilitating prompt clinical decision-making and adjustment of treatment plans consistent with treat-to-target strategies [24]. Second, personalized patient education modules and self-management support improved disease understanding, reduced anxiety-induced nonadherence, and reinforced positive health behaviors [25,26]. Third, integrated communication tools and nurse-led remote engagement fostered sustained patient-health care team interaction, thereby empowering patients and enhancing self-management [26-28], which are factors strongly associated with improved adherence in chronic disease management models. Collectively, this multimodal approach may underpin the greater improvements in functional status, symptom control, and engagement observed in the platform-based management group.

Importantly, enhanced functional outcomes (as measured using the HAQ-II) in the platform-based management group suggest that early and sustained control of inflammatory activity may translate into preserved musculoskeletal function and reduced disability progression. Remote access to rehabilitation guidance, individualized exercise recommendations, and rehabilitation education likely reduced care barriers for patients with mobility limitations or geographic challenges, expanding continuous care delivery beyond periodic clinic visits [14,25,28]. These effects are consistent with those observed in prior research [13,16] emphasizing the value of remote monitoring and patient engagement in optimizing long-term functional outcomes in chronic musculoskeletal diseases.

The platform significantly improved both medication adherence and patient satisfaction, which is consistent with findings from prior digital health interventions targeting chronic disease management [7,12,28]. Traditional outpatient follow-up is frequently constrained by logistical and geographical barriers, especially in rural or underserved areas, leading to delays in care and reduced compliance [9]. To address these challenges, the platform's integrated "Medication Manager" provided automated medication reminders, individualized dosage guidance, and symptom reporting functions, thereby enabling timely clinical interventions in response to adverse events. Previous studies have provided evidence that such digital tools can decrease medication omissions and enhance treatment persistence in patients with RA and similar chronic conditions [10,23,29]. Moreover, the nurse-led, patient-centered platform empowered patients through shared decision-making, self-monitoring, and goal setting, which contributed to improved self-management. Personalized care plans and ongoing professional support not only reinforced adherence but also enhanced patient and nurse satisfaction with the care process [30,31]. These findings highlight the effectiveness of technology-assisted, nurse-led interventions in promoting satisfaction alongside adherence in remote care [32].

However, several limitations should be acknowledged. The quasi-experimental, campus-based allocation does not fully replicate randomized assignment, although this design reflects real-world implementation and enhances external validity. Participant and provider blinding was not feasible, which might introduce reporting bias; however, outcome assessors and analysts were blinded to mitigate this risk. The high-frequency data collected by the platform, such as daily pain and stiffness scores, were not included in this statistical analysis. Future research should leverage these real-time metrics to better characterize disease trajectories. A notable attrition rate was observed during the 6-month follow-up. Preliminary observations indicated that older patients with limited digital literacy or those with lower treatment compliance were more likely to drop out. These individuals represent a vulnerable population that might benefit the most from digital support but faces significant barriers to technology adoption. The lack of detailed demographics for these participants may limit the generalizability of our results regarding digital health equity. While the 6-month follow-up period was adequate to observe significant clinical improvements, longer follow-up is warranted to evaluate sustained disease control, radiographic progression, long-term disability outcomes, and cost-effectiveness. Future multicenter implementation studies with diverse patient populations, combined with qualitative research to explore user preferences, will be valuable to further validate and optimize digital care strategies for RA.

In conclusion, our study demonstrates that a nurse-led, AI-assisted intelligent interactive platform significantly improved clinical and patient-centered outcomes in postdischarge RA care. By facilitating continuous monitoring, timely clinical action, personalized education, and sustained engagement, this digital intervention offers a scalable model to enhance disease control and patient empowerment in routine rheumatology practice.

Abstract

Background: The expansion of telehealth services, particularly during the COVID-19 pandemic, has transformed health care delivery in the United States. Telehealth promises greater access and resource efficiency by reducing wait times and appointment lengths, especially in specialties like psychiatry, behavioral health, bariatrics, and sleep medicine. However, disparities exist in adoption based on demographics, geography, and socioeconomic status, raising concerns about equitable access and optimal resource use.

Objective: This study aims to evaluate how telehealth impacts health care resource use across 4 specialties by examining 2 key metrics: patient-to-provider ratios and appointment durations. It seeks to understand how factors such as patient demographics, facility characteristics, and social determinants influence telehealth adoption and efficiency using a national dataset spanning from 2018 to 2023.

Methods: We analyzed a deidentified dataset from Epic Cosmos, covering outpatient visits across 48 US states (2018-2023). After data preprocessing and feature engineering, we applied 3 machine learning (ML) models (random forest, extreme gradient boosting, and deep neural networks) to predict resource use. Using the model performing the best, feature importance was assessed using Shapley Additive Explanations values. We then used k-means clustering to group facilities into clusters per specialty. Comparative analyses were conducted to evaluate differences in use among clusters, during and after the pandemic.

Results: Telehealth use peaked in 2020 and has remained above prepandemic levels since then. In 2018-2023, telehealth adoption reached 36.9% (4,543,021/12,311,710) in psychiatry, 23.9% (5,321,099/22,264,013) in behavioral health, 21.2% (924,333/4,360,061) in bariatrics, and 16.8% (851,803/5,070,256) in sleep medicine. Telehealth visits were consistently shorter than office visits (mean reduction 12.24 minutes; SD 3.33 minutes; P=.18), while patient-to-provider ratios varied significantly across specialties. Among ML models, extreme gradient boosting regression achieved the best performance (patient-to-provider ratios: R^2=0.96-0.99; appointment durations: R^2=0.61-0.69). Shapley Additive Explanations analysis identified visit type, telehealth use, facility size, rurality, and Social Vulnerability Index household vulnerability as the strongest predictors. Comparative analyses showed significant differences across clusters (all P<.05).

Conclusions: Telehealth has become a sustainable component of health care, enhancing access and efficiency across both rural and urban areas. However, its impact varies across specialties and regions, highlighting the need for targeted strategies such as staffing support for vulnerable populations, infrastructure investments in rural facilities, and reimbursement models that reflect

telehealth's resource use. This study provides robust evidence from ML and clustering analyses, demonstrating how telehealth shapes resource use and offering actionable insights for equitable and sustainable integration.

(JMIR Med Inform 2026;14:e78030) doi:10.2196/78030

KEYWORDS

telehealth; resource use; machine learning; clustering; COVID-19 pandemic; deep neural networks

Introduction

The health care industry is undergoing a significant transformation due to rapid technological advancements, particularly the rise of telehealth [1]. Telehealth includes a range of remote health care services, bridging gaps between health care demand and supply by providing convenient access to consultations, remote monitoring, and timely interventions [2]. In the United States, telehealth adoption accelerated during the COVID-19 pandemic, highlighting its role in improving access to care [3].

Health care resources include medical personnel, equipment, and facilities required for service delivery [4]. For telehealth, resources also include digital platforms, communication devices, and technical support, while office visits rely on clinical spaces and on-site staff [5]. Resource use measures how efficiently these resources are managed, with studies indicating that telehealth can reduce wait times, increase visit rates, and minimize missed appointments [2,6-10], enhancing care continuity.

Telehealth services were provided by a diverse range of health care facilities. Some adopted telehealth for the first time in response to the pandemic, while others, which already had telehealth services in place, experienced increased demand over the past 4 years. Consequently, facilities had to allocate resources—such as doctors and nurses—across multiple types of visits, including office visits, telehealth appointments, and emergency calls. A study found that larger facilities delivered a higher proportion of their visits through telehealth compared to smaller facilities with fewer doctors and nurses [11]. This suggests that health care facilities vary in their resource use and staffing needs.

Identifying the factors that influence telehealth use and evaluating its impact on health care resources are essential for effective resource planning. Several studies indicate that factors such as technological infrastructure, patient acceptance, and broadband access determine the feasibility and effectiveness of implementing telehealth [12-14]. These studies also highlight variations in adoption across different health care specialties and patient demographics.

One recent study reported that telehealth services improved resource use, as telehealth visits were associated with shorter waiting times and appointment durations compared to office visits in certain specialties. Additionally, both waiting times and appointment durations for telehealth services decreased over the study period [15]. Another study identified disparities in telehealth use, consistent with findings from various data sources and periods [16]. It calls for further research to determine whether differences in telehealth service proportions are linked to hospital or community telehealth capacity and to understand why these service proportions vary across demographic characteristics. These findings highlight the importance of nationwide analyses to assess telehealth use comprehensively.

This study aims to identify factors influencing resource use in health care facilities in the United States and to compare patterns across different settings (telehealth and office visits) and time frames. We focus on 2 metrics, patient-to-provider ratio and appointment duration, as key indicators of how health care resources are allocated and managed. The patient-to-provider ratio reflects the distribution of patient load among providers, serving as an indicator of resource allocation within health care systems. Higher ratios may indicate overburdened providers and diminished quality of care, whereas lower ratios suggest more manageable workloads and potentially improved patient attention. Appointment duration captures how providers allocate time per visit, offering insight into time management and the depth of patient engagement. Together, these metrics provide a comprehensive view of health care resource use in both telehealth and office-based contexts. Using national data from 2018 to 2023, the study seeks to generate new insights into telehealth adoption and resource use, offering a broader perspective than previous research [17-24]. In doing so, it provides evidence to inform health care providers, policymakers, and other stakeholders in planning for sustainable telehealth integration.

Building on these objectives, we focus on 4 specialties, psychiatry, behavioral health, bariatrics, and sleep medicine, due to their relatively higher levels of telehealth use. Specifically, the study examines whether telehealth use and patient- and facility-related factors are associated with variations in patient-to-provider ratios and appointment durations. It also explores whether clusters of health care facilities demonstrate distinct patterns in telehealth adoption, patient-to-provider ratios, and appointment durations over time.

We hypothesize that (1) telehealth visits are associated with lower patient-to-provider ratios and shorter appointment durations than office visits, (2) patient- and facility-related factors significantly impact resource use across care settings, and (3) clusters of health care facilities demonstrate meaningful differences in telehealth adoption and performance metrics (patients per provider and appointment duration) over time.

Methods

Ethical Considerations

Data collection was approved by the institutional review board of the University of Arkansas for Medical Sciences (IRB 276339). It was determined as nonhuman subject research. The

XSL•FO
RenderX

data were deidentified, and there was no interaction with individuals.

Data Collection

Patient data for this study were sourced from Epic Cosmos (hereafter referred to as Cosmos), a robust platform offering a diverse and representative sample of patients across various demographics, including race, sex, age, geographic settings, and insurance types [25]. The dataset spanned patient visits from health care facilities across 48 US states and was fully deidentified to ensure confidentiality. Access to the dataset was facilitated through the Epic Systems Cosmos research platform via a Microsoft SQL Server database.

This study focused on telehealth (audiovisual) and office (face-to-face) visits in the United States between 2018 and 2023, capturing pre-, mid-, and postpandemic periods to evaluate the impact of the COVID-19 pandemic on telehealth adoption and resource use.

Our study used the following data tables from Cosmos:

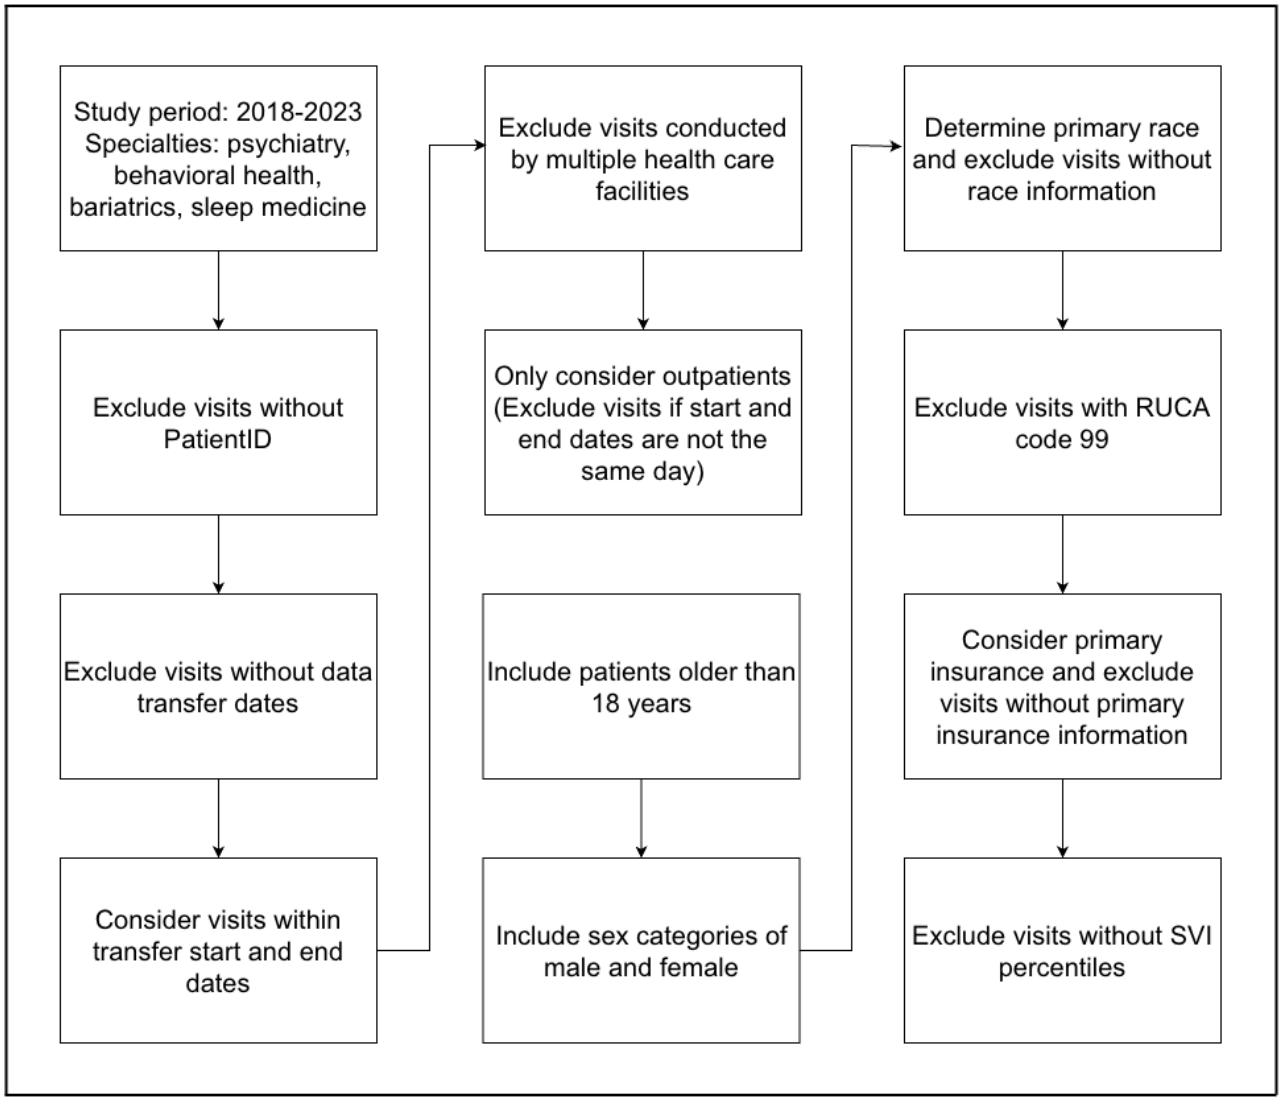
- Encounter table: Details visit-related information, including encounter type (eg, office visits and telehealth), provider details, health care specialties, and appointment times.
- Patient table: Provides patient-related demographics and enables analysis of telehealth access across various populations (eg, older people and rural residents). It also includes the Centers for Disease Control and Prevention or the Agency for Toxic Substances and Disease Registry Social Vulnerability Index (SVI), offering insights into education, financial resources, and transportation needs.
- Insurance table: Contains coverage details for each visit, allowing identification of primary insurance providers.
- Hospital table: Includes data transfer start and end dates for each hospital, aiding in data cleaning processes.

Data Preprocessing

Overview

Data preprocessing, including data cleaning and feature engineering, ensured and improved model performance [26]. This study focused on patient- and facility-related factors and on specialties with the highest rates of telehealth adoption to identify best practices for virtual care.

We processed visit-level data for these specialties using features derived from patient, encounter, insurance, and hospital tables. Recent studies frequently examined demographic factors, including age, sex, race, and rurality [20,27-30]. Age was a key variable, with research comparing use rates across age groups to understand adoption trends. Sex and racial disparities were also explored to identify inequities in telehealth access, while rurality was examined to evaluate telehealth's role in addressing health care gaps in remote areas. Additionally, insurance coverage was a critical determinant, influencing telehealth access through policy and reimbursement mechanisms. These demographic insights informed strategies to enhance equitable access.



We also incorporated the SVI percentiles from the Centers for Disease Control and Prevention to assess the impact of social vulnerability on telehealth use [20,31]. The SVI ranked census tracts based on socioeconomic status, household characteristics, minority and language status, and housing type and transportation. The SVI metric aided in resource allocation for vulnerable populations, enhancing public health preparedness and response efforts [32].

Data Cleaning

The process used to define the subset of visits included in our study is illustrated in Figure 1. We excluded visits without a valid PatientID or transfer date to ensure data completeness. Because facilities periodically transfer electronic health record data, only visits within valid transfer start and end dates were included. We analyzed only same-day outpatient visits and focused on age, race, sex, rurality, insurance, and SVI percentiles. Preprocessing steps for these factors are shown in Figure 1.

XSL•FO
RenderX

Figure 1. Flow diagram for data preprocessing steps. RUCA: rural-urban commuting area; SVI: Social Vulnerability Index.

Data were aggregated at the hospital level by month across 72 periods (2018-2023). Table 1 lists the variables, including temporal features (year, quarter, and month), to capture time trends. For demographics (race, sex, and insurance), we calculated the proportion of telehealth versus office visits; for age, rural-urban commuting area (RUCA), and SVI, we computed median age, average RUCA, and average SVI scores. To evaluate resource use, we calculated the patient-to-provider ratio and appointment duration for telehealth and office visits at each hospital and during each period. Appointment durations shorter than 10 minutes or longer than 100 minutes were excluded to reduce the influence of outliers and potential data entry errors. While such durations may occur in rare cases, they fall outside the typical range for standard provider-patient interactions and could skew the analysis. Finally, we scaled the training data before applying machine learning (ML) models [33].

Model Development

Overview

We conducted a comparative analysis of data from multiple health care facilities (2018-2023) to evaluate the impact of patient characteristics and health care settings on resource use and to identify key drivers. Given the large number of facilities, we used clustering to group similar facilities into meaningful profiles. This approach reduced complexity and highlighted common patterns across facility types, such as those with similar size, service mix, or adoption levels. By comparing these clusters, we provided insights that go beyond individual facilities and offered a clearer understanding of how telehealth influences resource use. In practice, this allowed facilities to benchmark their performance against comparable peers and consider alternative strategies. After clustering, we compared resource use between facility groups during and after the pandemic. Figure 2 illustrates the overall methodology, with details provided in the subsequent section.

XSL•FO
RenderX

Figure 2. Flow diagram of the proposed methodology.

Learning Algorithms

To examine the influence of patient- and facility-related factors on resource use, specifically the patient-to-provider ratio and appointment durations, we used nationwide temporal data and applied ML techniques. Prior work showed that ML improved performance with large health care datasets by uncovering links between demographics, clinical characteristics, and service types [34,35].

We evaluated 3 ML regression models: random forests, extreme gradient boosting (XGBoost), and deep neural networks (DNNs). These models were selected because they are widely used and complementary—random forests provide robustness and interpretability, XGBoost is highly efficient for structured tabular data, and DNNs are well-suited for capturing complex nonlinear relationships in large-scale datasets [36,37]. To optimize performance, we used Optuna, a hyperparameter tuning framework, to efficiently explore the parameter space and identify the best configuration for each specialty [38]. Model performance was assessed using R^2, which measures how well predicted outcomes align with actual values and enables comparison across models and datasets [39]. To determine the relative importance of features on resource use outcomes, we used Shapley Additive Explanations (SHAP), which computes SHAP values to provide interpretable insights into feature contributions [40].

Clustering Model

After evaluating factors influencing resource use, we clustered health care facilities based on shared characteristics so that similar facilities can be analyzed collectively. The model included patient- and facility-related features and resource use metrics. To prepare the data for clustering, we aggregated it at the hospital level using the following methodology:

- Weighted averages: We calculated weighted averages using the number of visits as the weighting factor for the following patient-related factors: age, RUCA code, SVI household, SVI housing, SVI minority, SVI socioeconomic, race, sex, and payment methods (public insurance, private insurance, and self-pay).
- Patient-to-provider ratio: We calculated the weighted average of this ratio with the number of providers as the weighting factor.
- Telehealth use: We summed the total number of telehealth visits and overall visits for each hospital. The proportion of telehealth visits was then determined by dividing the number of telehealth visits by the total number of visits.
- Provider counts: We aggregated the total number of providers offering telehealth and office visits for each hospital.
- Rurality variable: This variable remained unchanged, as it was already defined at the hospital level.

The features initially considered in the clustering model are detailed in Textbox 1. We used *k*-means clustering, a widely used algorithm for partitioning datasets into distinct groups based on feature similarity [41]. First, we evaluated feature correlations and excluded those with a correlation coefficient equal to or higher than 0.70 [42]. Then, we further refined the clustering process by removing outliers using the isolation forest algorithm [43].

XSL•FO
RenderX

Textbox 1. Variables for the clustering model.

Independent variables

- Age
- Rural-urban commuting area code
- Social Vulnerability Index (SVI) household
- SVI housing
- SVI minority
- SVI socioeconomic
- Race
- Sex
- Public insurance
- Private insurance
- Self-pay
- Appointment durations
- Rurality
- Total visits
- Number of telehealth visits
- Number of providers
- Patient-to-provider ratio
- Telehealth use

To determine the optimal number of clusters, we applied the elbow method [44]. The elbow point marked the balance between minimizing inertia and avoiding excessive clustering. Additionally, we considered cluster evaluation metrics, including the Davies-Bouldin Index, where lower values indicate better-defined clusters [45], and the Calinski-Harabasz Index, which favors higher values for compact and well-separated clusters [46]. Once the optimal number of clusters was identified for each specialty, we executed separate clustering models for each specialty. Finally, we assessed feature importance within the clustering model using the variance explanation method [47].

Comparative Analysis

After clustering health care facilities, we analyzed disparities in patient-to-provider ratios and appointment durations. Although we collected data for 3 time periods: pre–COVID-19 (2018-2019), during COVID-19 (2020-2021), and post–COVID-19 (2022-2023), the prepandemic years are excluded due to the limited telehealth adoption.

To investigate whether statistically significant differences exist in appointment durations or patient-to-provider ratios among the clusters of health care facilities, we applied 1-way ANOVA [48]. These analyses are conducted separately by specialty, visit type (telehealth and office visits), and time period (during and postpandemic). The hypotheses are defined as follows:

- H_0: There are no statistically significant differences in patient-to-provider ratios or appointment durations for telehealth or office visits during the pandemic or postpandemic periods among the clusters of health care facilities.
- H_a: There are statistically significant differences in patient-to-provider ratios or appointment durations for telehealth or office visits during the pandemic or postpandemic periods among the clusters of health care facilities.

To further explore temporal differences, we compared patient-to-provider ratios and appointment durations within each cluster between the during pandemic and postpandemic periods using paired 2-tailed *t* tests [49]. These tests were also conducted separately by specialty and visit type. The paired 2-tailed *t* test hypotheses are as follows:

- H_0: There is no statistically significant difference in mean appointment durations or patient-to-provider ratios for telehealth or office visits within each cluster between the during pandemic and postpandemic periods.
- H_a: There is a statistically significant difference in mean appointment durations or patient-to-provider ratios for telehealth or office visits within each cluster between the during pandemic and postpandemic periods.

Before performing these tests, we assessed the assumptions of normality and homogeneity of variance using the Shapiro-Wilk test and the Levene test [50,51]. If these assumptions were violated, alternative nonparametric methods were used: the Kruskal-Wallis test replaced 1-way ANOVA, and the Wilcoxon signed rank test substituted for the paired 2-tailed *t* test. Post-hoc comparisons were conducted using Tukey honestly significant

XSL•FO
RenderX

difference for ANOVA [52] and Dunn test with Bonferroni correction for the Kruskal-Wallis test [53].

Results

Overview

This section presents the results in alignment with Figure 2. We begin with an exploratory data analysis to highlight telehealth trends and resource use patterns. We then present the results of the learning algorithm and identify the factors influencing resource use. Next, we describe the clustering of health care facilities and report the comparative analyses of resource use across these clusters.

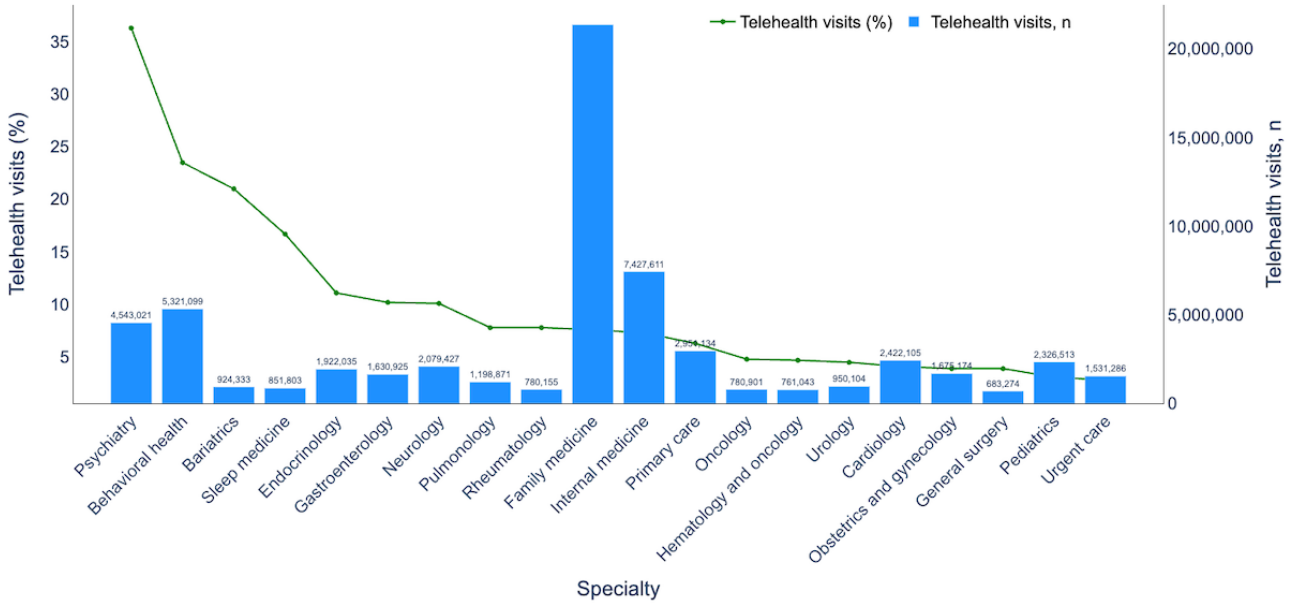
These results directly address the study objectives by examining how telehealth use and patient- and facility-related factors affect patient-to-provider ratios and appointment durations and by exploring how clusters of health care facilities differ in telehealth adoption and performance metrics over time.

Trends in Telehealth and Office Visits

Overview

Table 2 presents the quarterly number of telehealth and office visits from 2018 to 2023. A significant decline in total visits is observed during the early months of the pandemic (Q1 and Q2 2020), accompanied by a sharp increase in telehealth visits, peaking in Q2 2020. Following this surge, telehealth use gradually declined but remained consistently used, underscoring its sustained role in health care delivery through the end of 2023.

Table 2. Number of telehealth and office visits (2018-2023).



Quarter, year	Telehealth visits, n	Office visits, n
Q1, 2018	31,650	38,361,217
Q2, 2018	34,208	39,240,189
Q3, 2018	38,992	38,748,133

Q4, 2022	4,123,914	57,645,034
Q1, 2023	4,318,727	61,454,472
Q2, 2023	3,909,782	62,379,729
Q3, 2023	3,814,827	61,818,757
Q4, 2023	4,207,164	64,956,975

Evaluating Telehealth Use Across Health Care Specialties

We analyzed health care specialties with the highest telehealth adoption to identify best practices for virtual care (Figure 3). Significant variations were observed, with psychiatry leading telehealth visits at 36.9% (4,543,021/12,311,710), followed by behavioral health (5,321,099/22,264,013, 23.9%), bariatrics (924,333/4,360,061, 21.2%), and sleep medicine (851,803/5,070,256, 16.8%). These adoption rates highlight strong telehealth integration within these specialties, offering valuable insights into factors driving adoption and associated outcomes. Visit trends for these specialties can be seen in Multimedia Appendix 1.

XSL•FO
RenderX

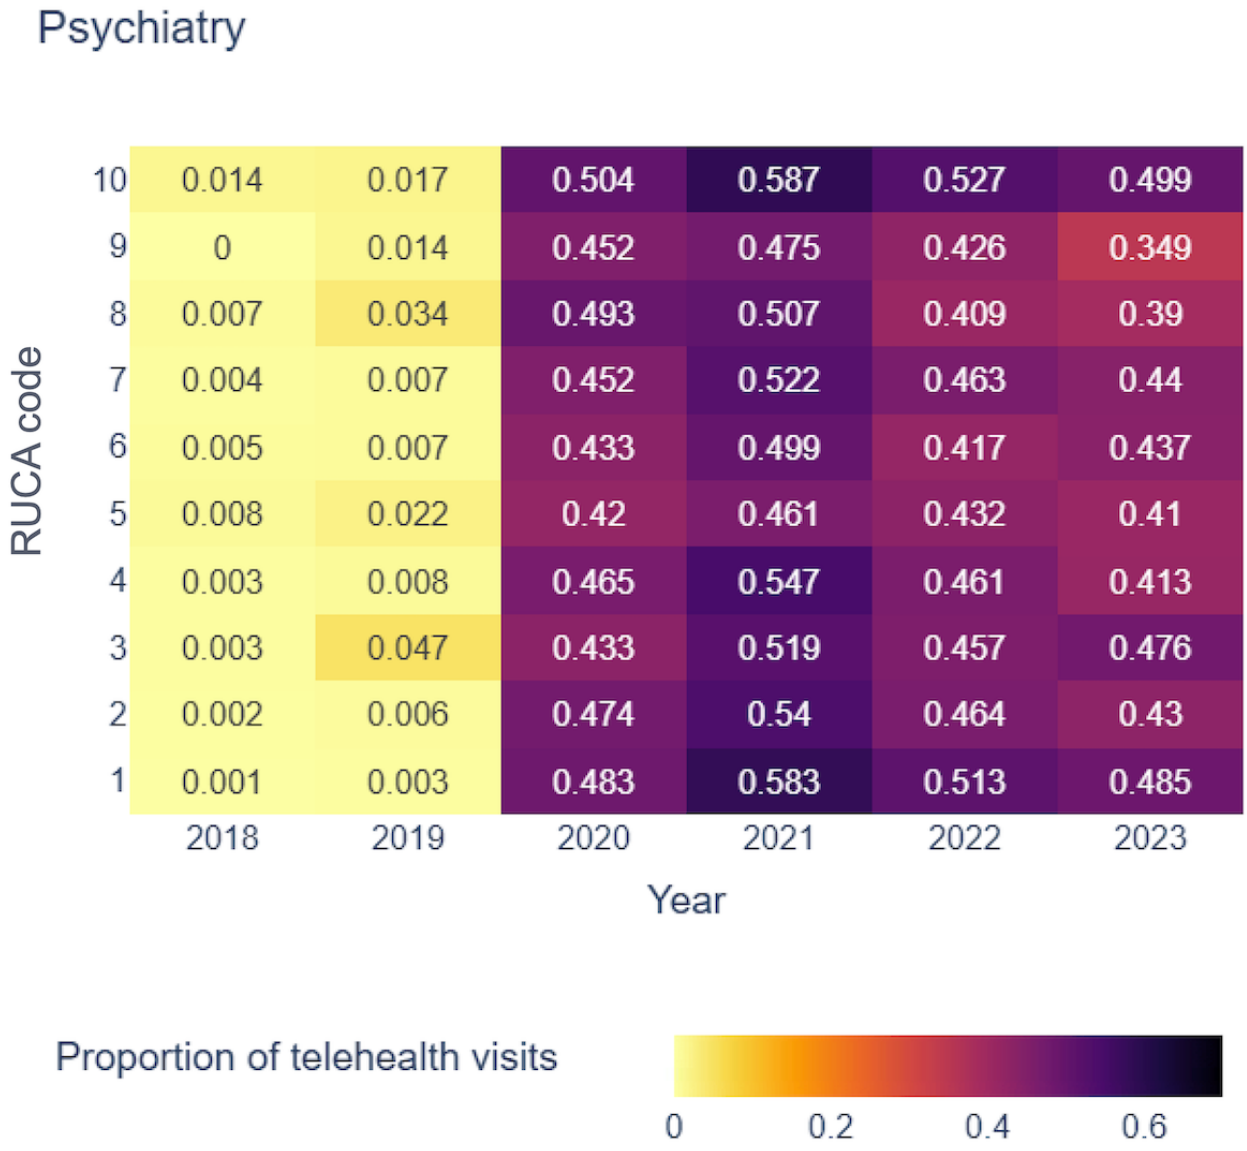
Figure 3. Percentage and number of telehealth visits (2018-2023).

Data Preprocessing

Overview

Table 3 shows the number of visits before and after data preprocessing and outlier removal, broken down by specialty as well as telehealth and office visits. The counts and percentages of visits excluded at each step are provided in Tables S1 and S2 in Multimedia Appendix 2.

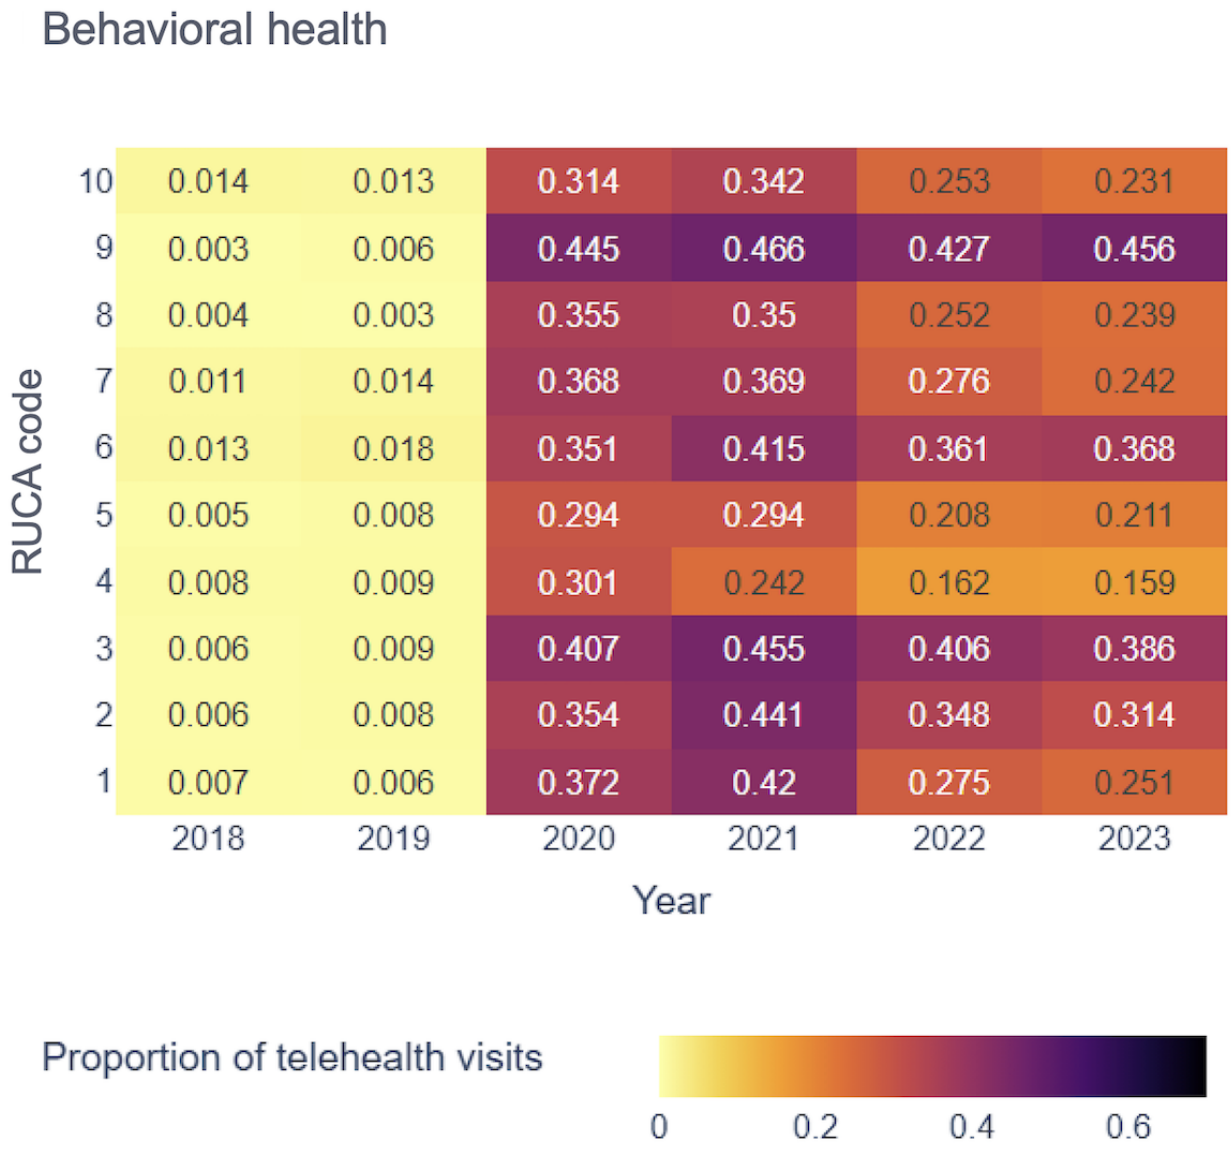
Table 3. Number of visits before and after data preprocessing and excluding outliers.



Specialty	Telehealth			Office		
	Before data preprocessing, n	After data preprocessing, n	After excluding outliers, n	Before data preprocessing, n	After data preprocessing, n	After excluding outliers, n
Psychiatry	4,264,891	2,928,491	2,405,428	7,331,621	4,922,991	4,053,490
Behavioral health	5,241,929	3,977,131	3,361,661	16,527,421	11,699,435	9,589,019
Bariatrics	897,721	664,836	497,262	3,372,671	2,650,826	2,234,762
Sleep medicine	839,368	588,947	405,204	4,168,268	3,152,911	2,737,440

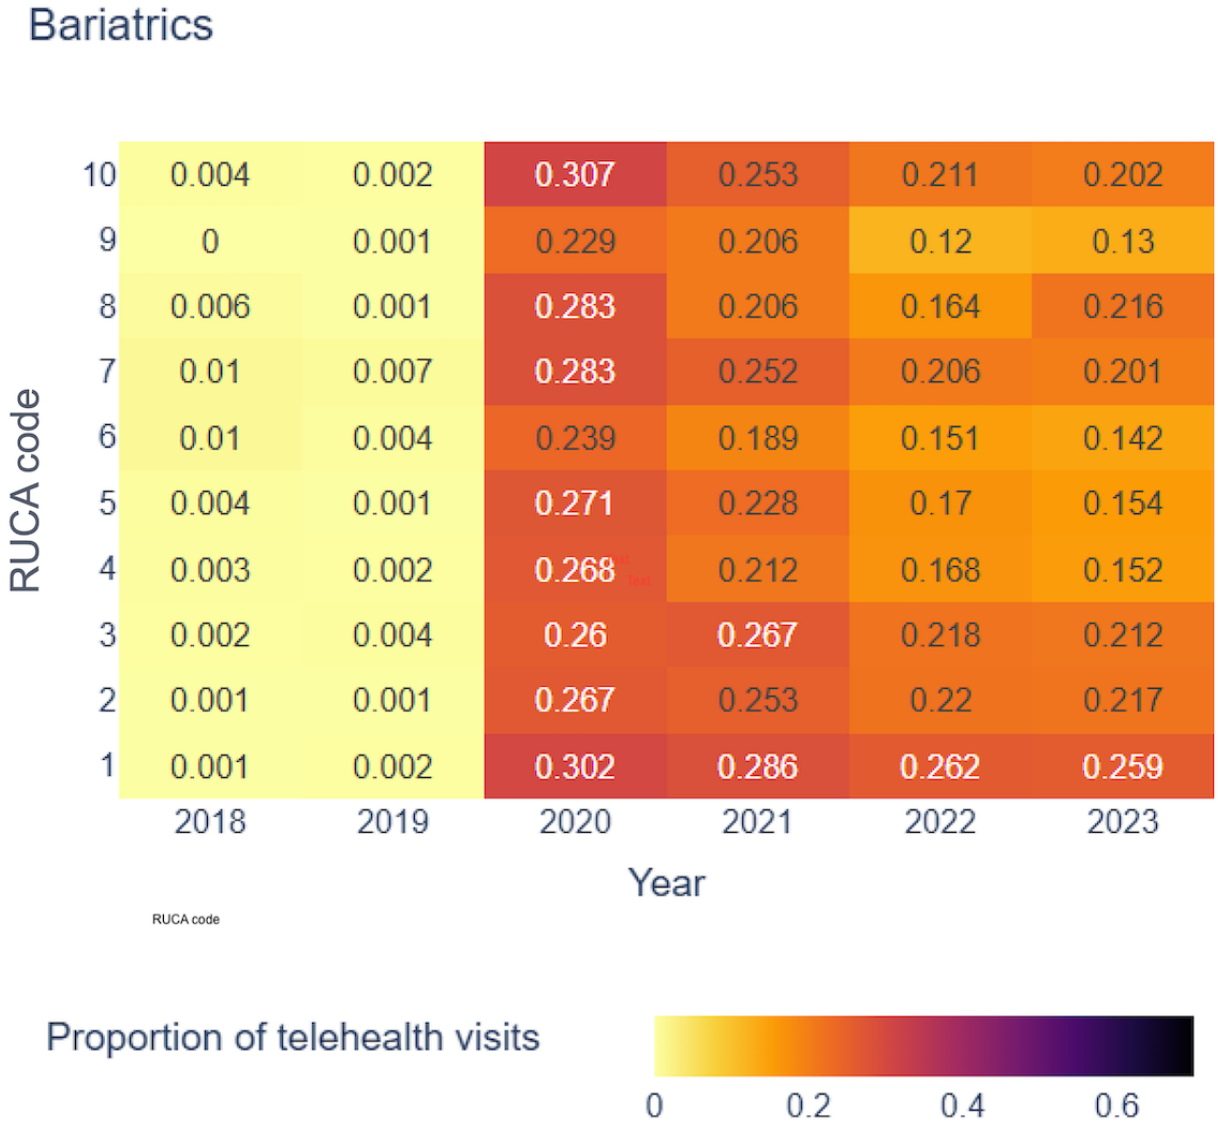
Proportion of Telehealth Visits Over Time Across Rural and Urban Areas

Figures 4-7 display the proportion of telehealth visits across RUCA codes from 2018 to 2023 for the selected 4 specialties.



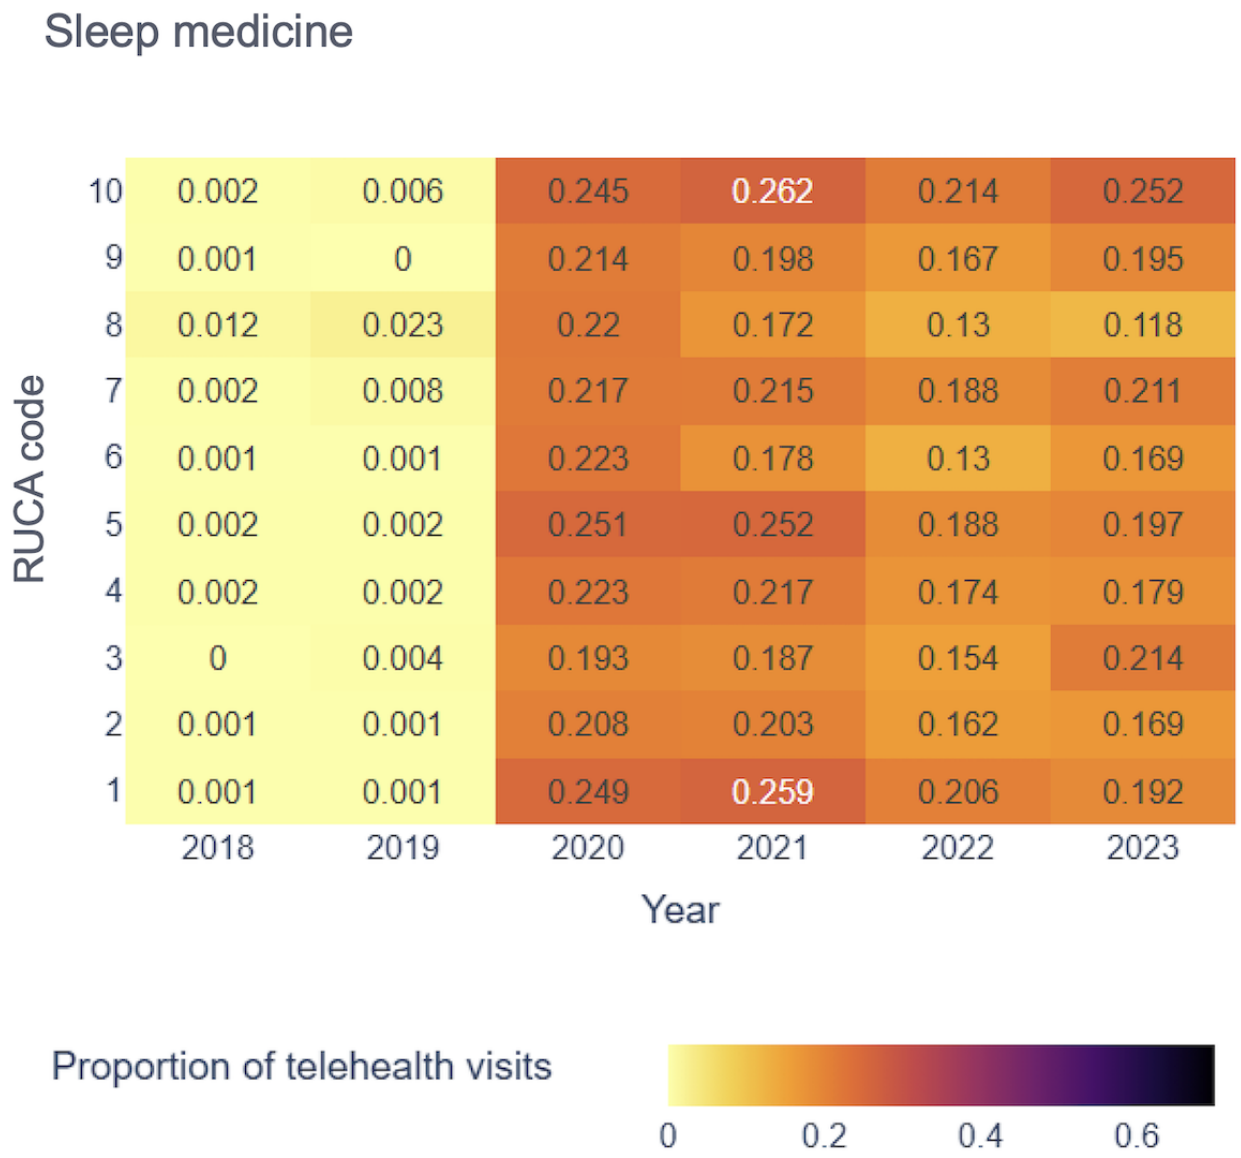
XSL•FO
RenderX

Figure 4. Proportion of telehealth visits over time in psychiatry. RUCA: rural-urban commuting area.



XSL•FO
RenderX

Figure 5. Proportion of telehealth visits over time in behavioral health. RUCA: rural-urban commuting area.



XSL•FO
RenderX

Figure 6. Proportion of telehealth visits over time in bariatrics. RUCA: rural-urban commuting area.

XSL•FO
RenderX

Figure 7. Proportion of telehealth visits over time in sleep medicine. RUCA: rural-urban commuting area.

In psychiatry, telehealth use was minimal before 2020 but increased sharply, particularly in rural areas (RUCA codes 8 and 10). The highest use occurred in 2021, with RUCA code 10 reaching 0.587 and RUCA code 1 at 0.583. RUCA code 10 maintained the highest telehealth use from 2021 to 2023, with RUCA code 1 consistently following. This trend highlights substantial telehealth adoption in psychiatry across both highly rural and urban areas. Behavioral health exhibited a similar trajectory, with negligible telehealth use before 2020. RUCA code 9 peaked at 0.466 in 2021, underscoring telehealth's significance in areas with low commuting rates [54].

In bariatrics, telehealth adoption began in 2020, with RUCA code 10 showing the highest rate (0.307). From 2021 to 2023, RUCA code 1 led telehealth use, reflecting its essential role in both urban and rural settings for bariatric services. Sleep medicine experienced gradual growth in telehealth adoption, with RUCA code 10 reaching its highest rate (0.262) in 2021. By 2023, telehealth use in rural areas remained high.

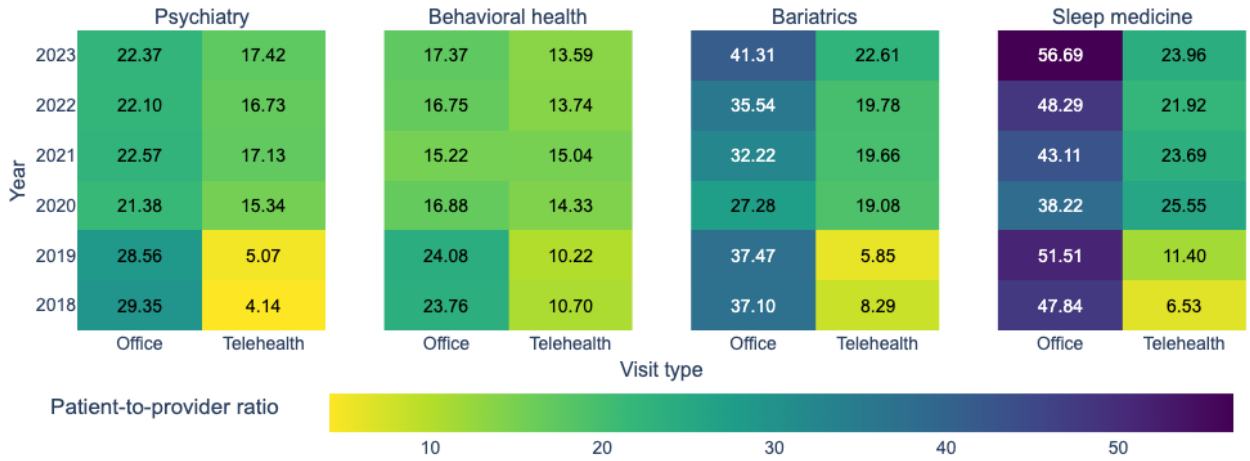
Our analysis revealed a consistent upward trend in telehealth visits across all 4 specialties from 2018 to 2023, particularly pronounced in specific RUCA codes. This underscored the growing acceptance and importance of telehealth services in both the most urban and rural areas. Although telehealth use peaked during the pandemic, it remained widely adopted across regions. However, the absence of uniform patterns across all RUCA codes for every specialty highlighted the unique telehealth use trends within each specialty, emphasizing the need for tailored analyses.

Resource Use Over Time

Figure 8 illustrates the trends in patient-to-provider ratios for telehealth and office visits across specialties from 2018 to 2023. The COVID-19 pandemic in 2020 caused a marked increase in telehealth ratios, as the health care system adapted to unprecedented challenges. In the postpandemic period, these ratios either stabilized or continued to grow, reflecting sustained telehealth adoption and ongoing adjustments in provider practices.

XSL•FO
RenderX

Figure 8. Patient-to-provider ratio over time.



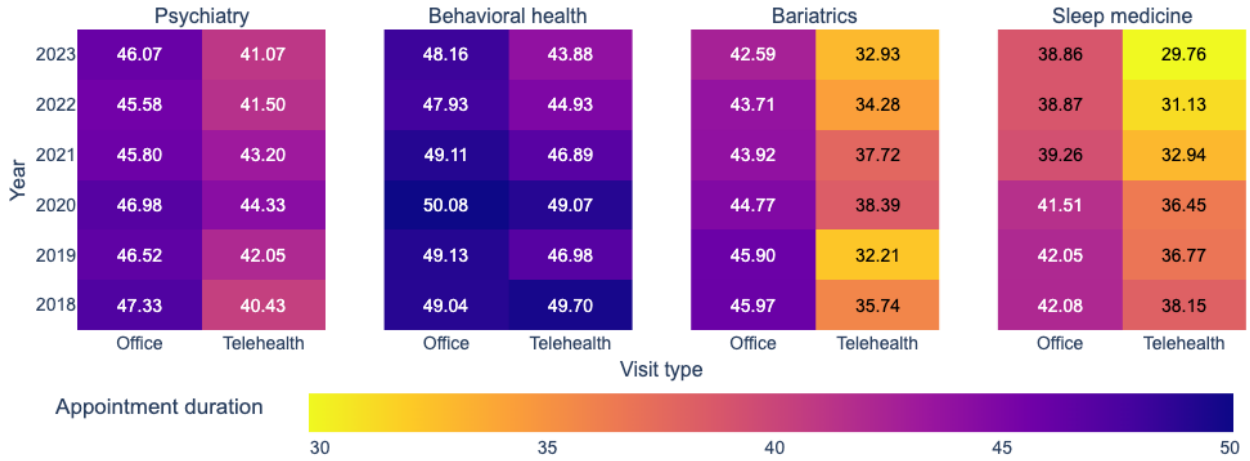


Figure 9 highlights appointment duration trends over the same period. During the pandemic, telehealth appointments were generally longer but eventually stabilized or decreased in the postpandemic period. Telehealth appointments were consistently shorter than office visits, with the exception of behavioral health in 2018.

Figure 9. Appointment durations over time.

Distinct trends across specialties underscore the necessity of analyzing factors influencing patient-to-provider ratios and appointment durations. The substantial variations during and after the pandemic also call for a detailed comparison of these periods.

Given the large number of health care facilities in this study, we applied a clustering approach to group facilities with similar characteristics, allowing more comprehensive comparisons and clearer interpretation of patterns. Building on this, we developed models to examine resource use, its influencing factors, followed by a comparative analysis.

Learning Algorithms

To analyze the impact of patient- and facility-related factors on resource use, we evaluated 3 ML regression models, including random forest, XGBoost, and DNN models (see Tables S1-S3 in Multimedia Appendix 3 for model performances and hyperparameters). Ultimately, XGBoost was chosen due to its superior predictive performance.

XGBoost Regression Model

Separate models were developed for each specialty, with hyperparameters optimized using Optuna. Typically, data were divided into an 80% training and 20% testing split to balance learning and evaluation [55]. However, to improve model performance, we adjusted the splits to 90%-10% split based on R^2 results. Table 4 shows the number of training and testing rows per specialty.

XSL•FO
RenderX

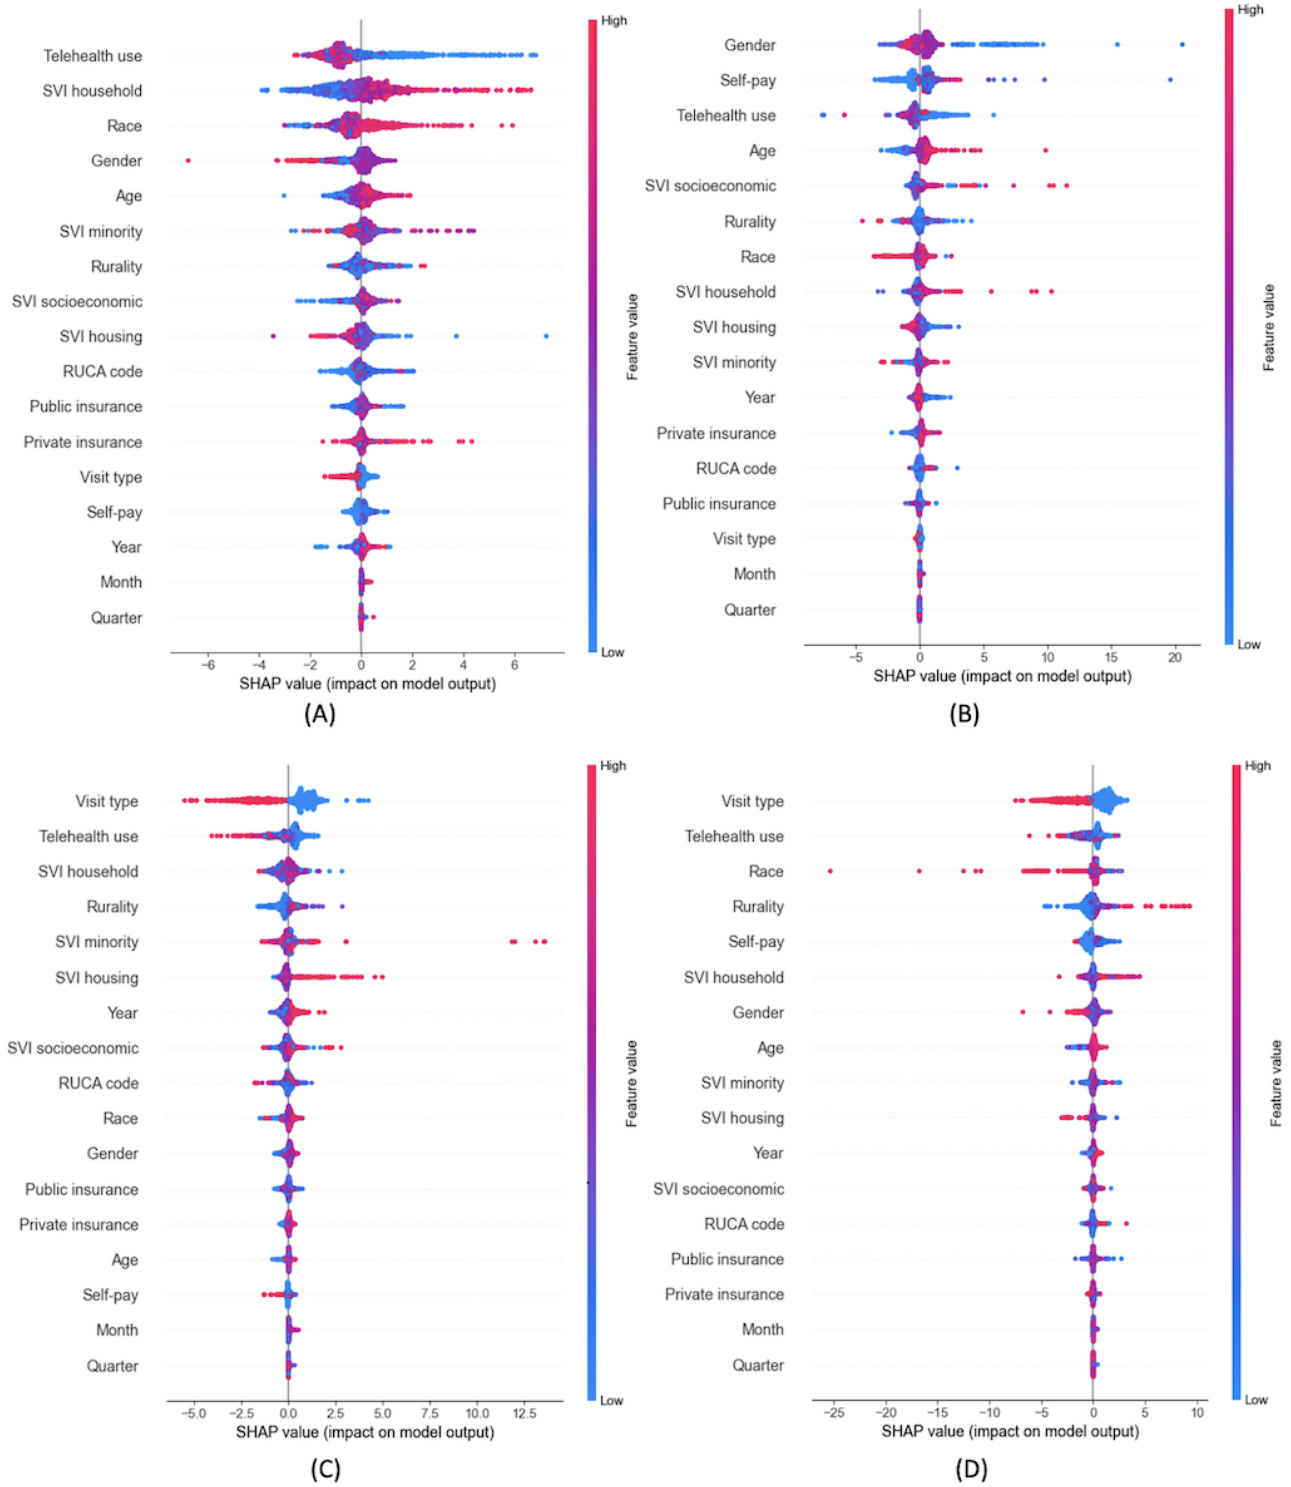
Table 4. Training and testing splits for the models.

Specialty	Training	Testing
Psychiatry	9335	1038
Behavioral health	8464	941
Bariatrics	8892	989
Sleep medicine	9427	1049

R^2 values were calculated to evaluate model performance, showing strong predictive power for patient-to-provider ratios and moderate power for appointment durations (Table 5). All results were obtained within 4 seconds.

Table 5. R2 values for extreme gradient boosting regression models.

Specialty	Patient-to-provider ratio, R^2	Appointment duration, R^2
Psychiatry	0.9935	0.6923
Behavioral health	0.9689	0.6673
Bariatrics	0.9948	0.6519
Sleep medicine	0.9934	0.6101



Feature Importance

In SHAP summary plots, red points indicate higher feature values and blue points indicate lower values; their position on the x-axis shows whether they increase (right) or decrease (left) the prediction.

Figures 10A-10D displays SHAP summary plots for output 1 (patient-to-provider ratio) across the selected specialties. Across all specialties, telehealth use emerges as an important factor, with higher telehealth use generally resulting in fewer patients per provider.

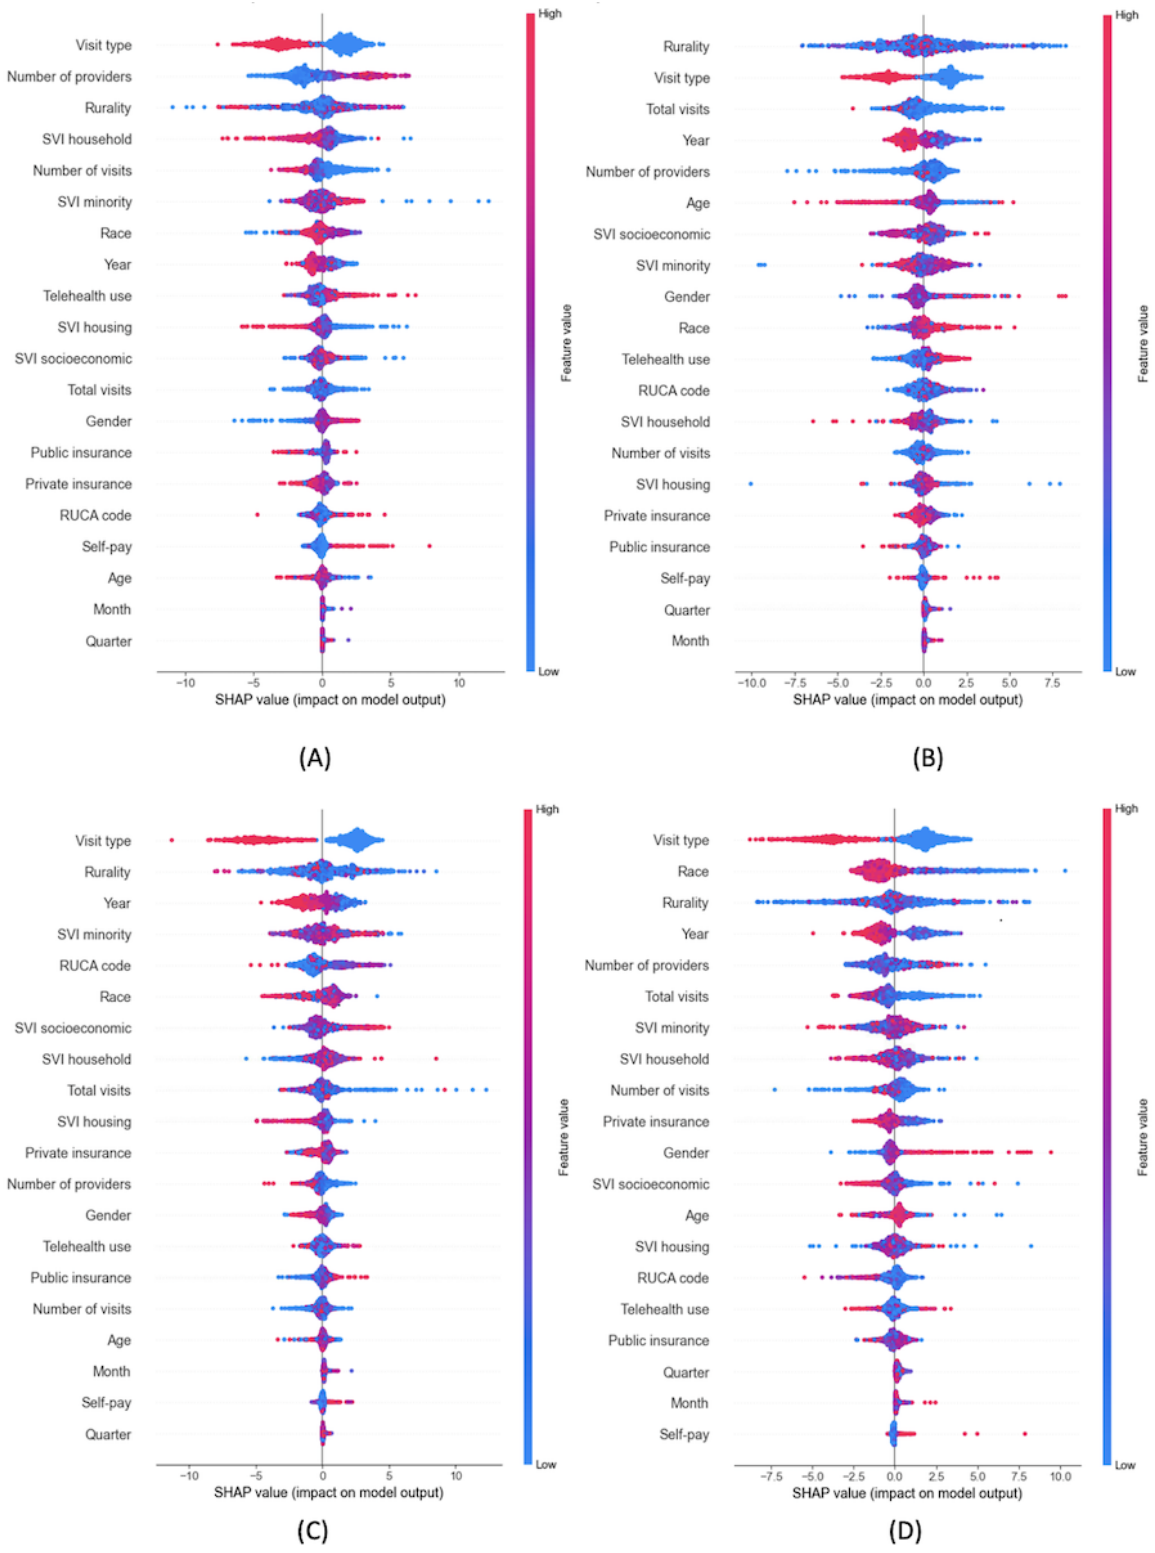
XSL•FO
RenderX

Figure 10. SHAP summary plots—patient-to-provider ratio. (A) Psychiatry, (B) behavioral health, (C) bariatrics, and (D) sleep medicine. RUCA: rural-urban commuting area; SHAP: Shapley Additive Explanations; SVI: Social Vulnerability Index.

In psychiatry, SVI household and race significantly influence patient loads, reflecting socioeconomic and demographic factors. Higher SVI household values correspond to increased patient loads in psychiatry, behavioral health, and sleep medicine, while in bariatrics, no consistent trend is observed. Similarly, race shows mixed effects: health care facilities with a higher proportion of visits by White patients (red points) are linked to more patients per provider in psychiatry, but with fewer patients per provider in behavioral health and sleep medicine.

In behavioral health, sex is a significant factor, with facilities having a lower proportion of visits by female patients (blue points) associated with higher patient loads. Self-pay is also significant; however, it shows mixed effects. In bariatrics, visit type emerges as the most critical feature, with telehealth visits (red points) generally associated with fewer patients per provider compared to office visits (blue points), similar to sleep medicine. Telehealth use is the second most influential factor, where higher

XSL•FO
RenderX



telehealth adoption correlates with decreased patient loads, again consistent with findings in sleep medicine.

In summary, while features such as telehealth use, visit type, SVI household, and race are universally important, the varying influence of demographic and socioeconomic factors underscores the diverse drivers of patient distribution across specialties.

Figure 11A-11D displays SHAP summary plots for output 2 (appointment durations). Across specialties, visit type is an important factor: telehealth visits typically result in shorter durations, while office visits are associated with longer durations. Rurality also emerges as a significant factor but exhibits mixed effects across the 4 specialties. Year is another influential variable, with higher values (2021-2023) linked to shorter appointment durations, and lower values (2018-2020) linked to longer durations.

XSL•FO
RenderX

Figure 11. SHAP summary plots—appointment duration. (A) Psychiatry, (B) behavioral health, (C) bariatrics, and (D) sleep medicine. RUCA: rural-urban commuting area; SHAP: Shapley Additive Explanations; SVI: Social Vulnerability Index.

In psychiatry, facilities with more providers (larger health care facilities) tended to have longer appointment durations, whereas the opposite pattern was observed in bariatrics, and no clear trend was evident in behavioral health or sleep medicine. Race is particularly important in sleep medicine, where facilities with a higher proportion of visits by White patients (red points) are associated with shorter durations.

Overall, visit type, rurality, and year consistently emerge as the most influential factors for appointment durations. Telehealth visits generally lead to shorter appointments, more recent years are associated with reduced durations, and rurality shows mixed effects across specialties.

Clustering Model

Overview

Our clustering model selected key features using SHAP analysis across all 4 health care specialties. To ensure diversity, we included 1 feature from each major category: 1 SVI metric, 1 demographic variable, 1 representing facility size, and 1 related to insurance. The final set of features consisted of number of providers, telehealth use, RUCA code, SVI socioeconomic, and public insurance. We applied the isolation forest algorithm with a contamination rate of 0.15 (excluding 15% of data points as anomalies). Table 6 summarizes the number of health care facilities in each specialty before and after data cleaning.

Table 6. Number of health care facilities within the clustering model.

Specialty	Before cleaning, n (%)	After cleaning, n (%)	Clusters created
Psychiatry	134 (24.9)	114 (24.9)	6
Behavioral health	143 (26.5)	121 (26.5)	6
Bariatrics	117 (21.7)	99 (21.7)	6
Sleep medicine	145 (26.9)	123 (26.9)	6

After evaluating clustering metrics, we selected 6 clusters for each specialty. Please see Figure S1A-S1D and Table S1 in Multimedia Appendix 4 and Multimedia Appendix 5 for details on the evaluation of clustering metrics and the importance of factors in the clustering model. Each cluster represents a distinct group of health care facilities. Figure S1A-S1D in Multimedia Appendix 6 displays the average telehealth use, rurality, SVI socioeconomic, SVI minority, and number of providers across clusters for each specialty. Figure S2A-S2D in Multimedia Appendix 6 illustrates the average patient-to-provider ratio, appointment durations, and facility counts per cluster. Additional feature averages for each cluster are detailed in Tables S1-S4 in Multimedia Appendix 6.

Clusters of Health Care Facilities

Each specialty's clusters display unique resource use and patient care characteristics, emphasizing the diverse nature of health care delivery. This analysis highlights opportunities for optimizing health care services for various patient populations and settings.

In Textbox 2, we summarize the clustering results across specialties, focusing on average feature values, resource use, and variations observed during and after the pandemic.

XSL•FO
RenderX

Textbox 2. Highlights by specialty and clusters.

Psychiatry

Telehealth appointments were shorter than office visits, with cluster 6 having the highest telehealth use.

- Cluster 1: Younger patients (average age 40.68 years).
- Cluster 2: Few providers, 27.0% (5647/20,915) telehealth use, high rurality, and low telehealth patient-to-provider ratio during the pandemic, which increased after the pandemic with short telehealth appointments.
- Cluster 3: High public insurance coverage due to older patients (average age 49.8 years).
- Cluster 4: Many providers, 40.0% (48,585/121,463) telehealth use, low rurality, long appointments, and low patient-to-provider ratio.
- Cluster 5: High patient-to-provider ratio, 25.0% (7691/30,764) telehealth use, and vulnerable population based on the following factors: SVI household, housing, minority, and socioeconomic.
- Cluster 6: Few providers, 88.0% (10,607/12,053) telehealth use, low rurality, high self-paid visits, short appointments, and the lowest patient-to-provider ratio.

Behavioral health

After the pandemic, office visits saw higher patient-to-provider ratios and shorter durations, while telehealth ratios were lower.

- Cluster 1: High public insurance coverage.
- Cluster 2: Lowest telehealth use, 9.0% (1813/20,144), low telehealth, and high office patient-to-provider ratios.
- Cluster 3: Few providers, 83.0% (12,870/15,506) telehealth use, long appointments, and the highest patient-to-provider ratio.
- Cluster 4: Most providers and visits, low telehealth patient-to-provider ratio, and moderate telehealth use, 23.0% (39,890/173,435).
- Cluster 5: Moderate providers, 20.0% (18,533/92,665) telehealth use, high rurality, the highest office patient-to-provider ratio, and short telehealth appointments.
- Cluster 6: Few providers, 55.0% (3544/6444) telehealth use, and high self-paid visits.

Bariatrics

Telehealth appointments were shorter than office visits, with 80.0% (119,241/149,051) of visits from female patients.

- Cluster 1: Few providers, 7.0% (2047/29,243) telehealth use, and high rurality.
- Cluster 2: Moderate providers, 42.0% (9888/23,543) telehealth use, and the highest postpandemic telehealth patient-to-provider ratio.
- Cluster 3: Older patients (average age 50.91 years), least vulnerable, 15.0% (3895/25,967) telehealth use, and short appointments.
- Cluster 4: Few providers, 13.0% (1057/8131) telehealth use, the youngest patients, and high public insurance coverage.
- Cluster 5: Most providers, stable telehealth ratios, and increased office patient-to-provider ratio after the pandemic.
- Cluster 6: Few providers, 5.0% (793/15,860) telehealth use, lowest telehealth, and highest office patient-to-provider ratio.

Sleep medicine

After the pandemic, office visits had higher patient-to-provider ratios, telehealth ratios were lower, and sleep medicine had an older patient population with 50.0% (98,312/196,624) female patients.

- Cluster 1: Younger, vulnerable patients, low public insurance, 19.0% (2024/10,651), low telehealth use, 5.0% (1482/29,640), and long appointments.
- Cluster 2: Vulnerable patients and low telehealth use, 7.0% (1747/24,957).
- Cluster 3: High public insurance coverage.
- Cluster 4: Moderate providers, 15.0% (3737/24,913) telehealth use, high rurality, short appointments, and high patient-to-provider ratio.
- Cluster 5: Most providers and visits, low telehealth 9.0% (9171/101,900), and a high female patient proportion.
- Cluster 6: Moderate providers, 47.0% (13,282/28,260) telehealth use, short appointments, high telehealth, and low office patient-to-provider ratios.

Comparative Analysis

Overview

This section examines differences in patient-to-provider ratios and appointment durations between telehealth and office visits during and after the pandemic across specialty-specific clusters. Tables S1 and S1 in Multimedia Appendix 7 provide detailed data on these metrics, with Figures S1A-S1D and S2A-S2D in Multimedia Appendix 7 visualizing these comparisons. A significance threshold of α=.05 was used to assess differences in resource use over time.

XSL•FO
RenderX

Differences Between Clusters

All *P* values obtained are less than .05, indicating that the observed differences in patient-to-provider ratios (or appointment durations) are statistically significant. In addition, we present Dunn test results with corresponding *P* values in Tables S1-S8 in Multimedia Appendix 8. For instance, Table S1 in Multimedia Appendix 8 shows significant differences in telehealth patient-to-provider ratios during the pandemic between cluster 6 and clusters 1-5. After the pandemic, additional differences emerged, such as between cluster 1 and clusters 2 and 3, indicating varying resource allocation and patient needs.

Resource Use During and After the Pandemic

Table 7 summarizes these results. In psychiatry, telehealth appointment durations significantly changed (*P*=.03), while other metrics remained stable. Behavioral health showed significant differences in office visit metrics (*P*=.01) and appointment durations for both telehealth (*P*=.02) and office visits (*P*=.03). Bariatrics exhibited significant changes in telehealth visit patient-to-provider ratios (*P*<.001), and office appointment durations (*P*=.02). Sleep medicine showed marginal significance in telehealth patient-to-provider ratios (*P*=.08) and significant changes in office visit patient-to-provider ratios (*P*<.001). These results underscore the pandemic's varied impact on resource use across specialties and visit types, particularly in behavioral health.

Table 7. Hypothesis testing results for patient-to-provider ratios and appointment durations during and after the pandemic for telehealth and office visit[a].

Specialty	During vs post			
	Patient-to-provider ratio		Appointment durations	
	H_a: $\mu^{d,t,ptp} \neq \mu^{p,t,ptp}$, *P* value	H_a: $\mu^{d,o,ptp} \neq \mu^{p,o,ptp}$, *P* value	H_a: $\mu^{d,t,app} \neq \mu^{p,t,app}$, *P* value	H_a: $\mu^{d,o,app} \neq \mu^{p,o,app}$, *P* value
Psychiatry	.96	.57	.03	.91
Behavioral health	.25	.01	.02	.03
Bariatrics	.92	<.001	.02	.86
Sleep medicine	.08	<.001	.10	.95

[a]$\mu^{d,t,ptp}$, $\mu^{p,t,ptp}$: mean patient-to-provider ratio for telehealth visits during the pandemic and after the pandemic; $\mu^{d,o,ptp}$, $\mu^{p,o,ptp}$ mean patient-to-provider ratio for office visits during the pandemic and after the pandemic; $\mu^{d,t,app}$, $\mu^{p,t,app}$: mean appointment duration for telehealth visits during the pandemic and after the pandemic; and $\mu^{d,o,app}$, $\mu^{p,o,app}$: mean appointment duration for office visits during the pandemic and after the pandemic.

Discussion

Principal Findings

This study analyzed telehealth adoption using a nationwide dataset, focusing on psychiatry, behavioral health, bariatrics, and sleep medicine—specialties with high telehealth use. Our analysis shows that telehealth use peaked in 2020 with the COVID-19 pandemic and, while it has declined since, it remains above prepandemic levels. Telehealth adoption was especially high in both the most urban and most rural areas, underscoring telehealth's role in addressing both access and convenience. Importantly, telehealth continues to be in use, highlighting its lasting role in health care delivery.

In terms of resource use, telehealth visits were typically associated with shorter appointment durations, while patient-to-provider ratios varied across specialties and over time. These findings support our first hypothesis and highlight telehealth's role in improving time efficiency, though its effects on patient load vary across specialties. By combining descriptive, predictive, and clustering analyses, our study offers an integrated understanding of how facility characteristics, patient demographics and socioeconomic factors, and telehealth adoption jointly shape resource use patterns.

Identifying drivers of resource is essential for informing policy and management decisions aimed at optimizing resources, staffing, reimbursement, and equitable access to care. To examine variation in resource use among health care facilities, we clustered similar health care facilities and then compared these clusters. This approach allowed us to generate insights at the group level rather than for individual facilities, where substantial variability might otherwise obscure broader patterns.

Our XGBoost regression model provided a robust analytical framework for examining resource use, capturing both facility- and patient-level factors as well as specialty-specific dynamics. Consistent with our second hypothesis, the model results demonstrate that both patient and facility characteristics significantly impact how health care resources are distributed and used.

Socioeconomic and demographic characteristics distinctly influenced resource use, pointing to the need for tailored strategies across facilities, supporting our second hypothesis. For example, higher SVI household values were associated with increased patient loads in psychiatry, behavioral health, and sleep medicine, while no consistent trend was observed in bariatrics. This suggests that facilities serving populations with greater household vulnerability, such as those with higher proportions of older adults, children, single-parent households, or persons with disabilities, may face greater demand pressures. To respond effectively, such facilities could consider targeted staffing adjustments, optimized resource allocation strategies, and supportive services to reduce provider strain and maintain equitable access to care. Additional steps could include improving coordination among providers, expanding telehealth

XSL•FO
RenderX

to reduce in-person delays, training providers to better serve vulnerable populations, and advocating for policies or reimbursement models that reflect the higher resource needs of these facilities.

Race played a complex role in resource use, with effects varying across specialties. Facilities serving a higher proportion of White patients experienced heavier patient loads in psychiatry but lighter loads in behavioral health and sleep medicine. These contrasting patterns may reflect differences in access, care-seeking behaviors, or service delivery models across patient populations. Recognizing these disparities is important for designing culturally responsive interventions, expanding outreach in underserved groups, and ensuring that telehealth integration supports equitable care delivery.

Beyond sociodemographic influences, the level of telehealth adoption was itself an important determinant of resource use. Facilities with higher telehealth use generally had fewer patients per provider. This finding further supports our first hypothesis and suggests that telehealth can reduce patient load, helping health care facilities manage workloads more effectively and achieve a more balanced distribution of care. To capitalize on this potential, facilities could expand telehealth offerings to mitigate provider restrictions during peak demand and implement scheduling systems that direct appropriate cases to telehealth. In addition, investing in provider training and digital infrastructure can ensure that reduced patient loads translate into improved care quality rather than inefficiencies. Policy support for telehealth reimbursement can further encourage its integration into routine practice.

Telehealth visits were typically shorter in duration than office visits, largely due to the minimization of administrative tasks and the absence of physical examinations. Shorter appointments do not necessarily indicate lower quality of care and should not be viewed as a trigger for additional follow-ups. In fact, a study by Epic Research found that follow-up visits were less common after telehealth visits than after office visits across specialties such as psychiatry, behavioral health, bariatrics, and sleep medicine, suggesting that telehealth can be effective even with shorter durations [56]. Moreover, telehealth visits are often billed at lower levels of service than office visits within the same specialty, reflecting the simpler nature of these visits [57].

The number of providers in a facility also influenced appointment durations, but the effects differed by specialty. In psychiatry, larger facilities with more providers were linked to longer appointments, possibly due to the added complexity of coordinating care or the flexibility to spend more time with each patient. In contrast, bariatric facilities with more providers tended to have shorter appointments, which may result from greater specialization or streamlined workflows. These patterns show that facility size and staffing models affect how care is delivered and how time is allocated, shaping the role telehealth can play across different specialties. These results support our second hypothesis, indicating that organizational capacity and structure play an important role in resource use.

Additionally, supporting our third hypothesis, our clustering and comparative analyses showed clear differences among health care facilities in terms of patient demographics, resources, and telehealth adoption. These patterns highlight that health care delivery varies widely depending on facility characteristics and patient populations, meaning a single strategy will not work for all facilities. Therefore, policies should be tailored to the specific needs of different types of facilities. Facilities serving vulnerable populations may require additional funding, staffing, and stronger reimbursement policies to avoid overloading providers and to ensure fair access to care. Small facilities with few providers but high telehealth use would benefit from investments in digital infrastructure and training. Larger facilities with more providers but longer appointment times (such as in psychiatry) may need stronger care coordination systems and efficiency measures to ensure that time is used effectively. Rural facilities, where shorter appointments may reflect efficiency pressures, could benefit from standardized protocols and resource-sharing networks to balance time with quality. Specialties with low telehealth adoption, such as some bariatrics and sleep medicine clusters, should receive targeted support to address barriers like broadband access, patient acceptance, or reimbursement issues.

Sharing best practices from clusters with high telehealth adoption can guide regions with lower adoption, ensuring equitable access and improved service quality. Our findings emphasize the need for specialty-specific telehealth integration, supportive reimbursement models, and user-friendly platforms. Investing in telehealth literacy, infrastructure, and tailored policies will optimize resource use and enhance patient outcomes across diverse settings.

Limitations

A key limitation of this study is the inability to directly analyze broadband access, a well-established determinant of telehealth use [13], because the Cosmos dataset does not keep track of broadband availability. However, prior research indicates that SVI themes are strongly associated with broadband access and adoption [58]. As such, while we cannot analyze broadband directly, the use of SVI themes provides a meaningful proxy for understanding disparities in telehealth access. Figure S1 in Multimedia Appendix 9 [59] provides an overview of county-level RUCA codes, and Figure S2 in Multimedia Appendix 9 shows declining broadband subscription rates with increasing RUCA codes, further supporting the relevance of our rurality and vulnerability measures in capturing connectivity-related barriers.

Another limitation relates to the potential selection bias stemming from the use of Epic's Cosmos dataset. Although Epic is used by a diverse range of health care organizations, it tends to be more commonly adopted by larger health systems. This could limit the generalizability of our findings to smaller or independent providers. We believe that clustering health care facilities based on multiple factors—including the number of providers—helped mitigate this issue by grouping facilities with similar characteristics, thereby enabling more balanced comparisons.

Additionally, the randomized date shifting in the Cosmos dataset for confidentiality, with patient visit dates adjusted by 0 to 30 days, may affect temporal precision. However, the small shift does not significantly impact the overall findings. Additionally, the absence of zip code information for health care facilities

XSL•FO
RenderX

limits certain geographic analyses. Using a smaller subset of facilities could address this but would reduce population coverage. Nonetheless, Cosmos mitigates the complexity of diverse electronic health record systems by using a standardized system, ensuring consistent data processing across facilities.

Conclusions

This study presents a comprehensive analysis of telehealth adoption and resource use across psychiatry, behavioral health, bariatrics, and sleep medicine using a nationwide dataset. Our findings highlight significant shifts in telehealth and office visits during and after the COVID-19 pandemic, with notable regional and specialty-specific variations. By examining the impact of telehealth use, patient- and facility-level factors on resource use, and identifying facility clusters, this study provides a multifaceted understanding of telehealth's role in shaping health care delivery. Consistent with our first hypothesis, telehealth visits were associated with shorter appointment durations. However, patient-to-provider ratios varied across visit types, reflecting the diverse ways telehealth influences resource use.

The second and third hypotheses were also supported. Patient- and facility-level factors significantly impacted resource use, while clustering revealed distinct groups of health care facilities with varying levels of telehealth adoption and resource use. These findings underscore that resource use is shaped not only by technology adoption but also by demographic, socioeconomic, and organizational factors. For example, sociodemographic characteristics, such as household vulnerability and race, impacted patient loads and appointment durations, suggesting the need for equity-focused policies. Facility size also played a role, indicating that organizational capacity must be considered when planning telehealth integration. Clustering further revealed distinct facility profiles, showing that telehealth strategies must be tailored to local contexts rather than relying on universal approaches.

Telehealth not only enhances health care efficiency but also offers opportunities to reshape care models and policies. For example, maintaining high telehealth capacity in psychiatry and behavioral health could help address workforce shortages, while in bariatrics, virtual follow-ups can support long-term weight management. In sleep medicine, telehealth can be used for screening and treatment monitoring, complemented by office visits for diagnostic testing. Integrating telehealth into primary and specialty care workflows can expand access, especially for underserved populations, while necessitating policy updates to support equitable infrastructure investments and tailored reimbursement models.

As a valuable tool for improving accessibility and efficiency, telehealth enables health care systems to balance quality, cost, and access. Overall, these findings confirm that telehealth can improve efficiency when guided by specialty-specific strategies. Implementing customized strategies, such as targeted training for providers in specialties with lower telehealth readiness, region-specific infrastructure support, and specialty-appropriate virtual care protocols, can better align telehealth services with patient and provider needs. Addressing specialty- and region-specific needs can optimize telehealth services, improve patient outcomes, and ensure sustainable growth. The use of a nationwide dataset strengthens these findings and provides a solid foundation for future research. Future studies should explore the evolving dynamics of telehealth use and evaluate the effectiveness of these targeted interventions, translating insights into actionable strategies for policymakers, providers, and health care administrators.

Acknowledgments

BE was affiliated with the University of Arkansas at the time the work was done and is currently affiliated with Texas Tech University.

The authors wish to acknowledge the late Dr. Hari Eswaran for his valuable contributions to this work. Dr. Eswaran was involved in the early stages of the study, including study design and initial development of the manuscript. He passed away in May 2025 prior to the submission of this article, and for this reason is not included in the final authorship list. The authors are grateful for his contributions and honor his memory.

Data Availability

All data generated during this study are included in this published paper and its supplementary information files. However, the data used in the analysis came from Epic Cosmos and are not available for public use. Access to the Epic Cosmos dataset requires affiliation with a participating health organization, as it is a restricted Health Insurance Portability and Accountability Act (HIPAA)–defined limited dataset.

Funding

The study was supported by the US Health Resources and Services Administration (award U3GRH40001).

Authors' Contributions

ABC, BE, and SDE conceptualized the study and determined the methodology. ABC and CH acquired the datasets. ABC curated and processed the data and conducted the formal analysis. ABC also wrote the original draft of the manuscript. All authors reviewed and edited the final manuscript. BE and SDE provided supervision. BE, SDE, and CH were involved in funding acquisition.

Abstract

Background: Telemedicine may improve access to specialized care, but its use for supervision during critical anesthesia situations remains underexplored. A standardized tele-supervision (TSV) solution for operating rooms (ORs) is lacking.

Objective: This study aimed to evaluate a novel telemedical supervision system for critical anesthetic scenarios in a simulated OR environment and compare it to traditional on-site supervision. Specifically, adherence to standard operating procedures (SOPs), the number and modality of senior physician contacts, workload, and user perceptions were assessed.

Methods: In this randomized controlled simulation study, 16 anesthesiology residents in their first 2 years of training at the Uniklinik Rheinisch-Westfälische Technische Hochschule (RWTH) Aachen (Germany) were randomized using block randomization into 2 groups. The intervention group received remote support exclusively via a TSV system, while the control group used a conventional phone with on-site support. The telemedical system comprised an anesthesia workstation that integrated data from the patient monitor, anesthesia device, and syringe pumps using the Institute of Electrical and Electronics Engineers (IEEE) 11073 Service-Oriented Device Connectivity (SDC) standard and a mobile supervision workstation that enabled the senior physician to monitor multiple ORs and communicate via text, audio, and video. The simulated scenario involved a male patient aged 51 years undergoing an appendectomy who developed an anaphylactic reaction 3 minutes after receiving cefuroxime. Primary outcomes focused on the completion rate of necessary SOP measures. Secondary outcomes included workload, measured using the NASA Task Load Index (NASA-TLX), and participants' postscenario questionnaire responses. Statistical comparisons were performed using a Welch *t* test.

Results: All participants in both groups contacted the senior physician at least once. The control group had a mean of 6.44 (SD 4.80) SOP measures supported by the senior physician, whereas the intervention group had a mean of 5.00 (SD 3.06). The mean SOP completion rate was 92.5% (SD 0.04%) in the control group and 91.6% (SD 0.05%) in the intervention group, with no significant difference ($t_{11.94}$=0.439; *P*=.67). NASA-TLX scores revealed that compared to the control group, there was lower mental demand in the TSV group but higher temporal demand. Subjective evaluations indicated mixed preferences regarding on-site support; however, most participants acknowledged the TSV system as a viable alternative when on-site support was not feasible.

Conclusions: This study demonstrated no statistically significant differences between the groups, indicating similar performance with high adherence to SOPs and comparable clinical decision-making in a simulated high-stakes environment. Despite increased temporal workload, user feedback was positive, underscoring the system's potential to address staffing shortages and resource limitations. Further research in real clinical settings is needed to optimize usability and validate these findings.

KEYWORDS

telemedicine; telesupervision; interoperability; service-oriented device connectivity; SDC; anesthesia

Introduction

The rapid evolution of telemedicine has transformed health care delivery by improving access to specialized care, reducing costs, and enabling timely interventions in diverse clinical settings. Numerous systematic reviews and meta-analyses have demonstrated that telemedicine is effective in critical care, emergency medical services, and chronic disease management, where remote monitoring and consultation have enhanced patient outcomes or have been shown to be noninferior to conventional solutions [1-3]. In anesthesiology, telemedicine has been successfully applied to preoperative evaluations, intraoperative monitoring, and postoperative follow-up, thereby improving workflow efficiency and patient safety [4-8]. For example, tele-preoperative assessments have been associated with high patient satisfaction and comparable surgical outcomes compared to traditional in-person evaluations [9-11].

Despite these promising advances, a universal telemedicine solution tailored specifically to the complex environment of the operating room (OR) has yet to be established. In the OR, where rapid and precise decision-making is crucial, the integration of real-time data from multiple medical devices with effective remote supervision remains a significant challenge. Existing systems are often limited by technological readiness, inconsistent user training, and variability in clinical scenarios, highlighting the need for a standardized, robust telesupervision (TSV) platform for anesthesia care [12].

Because of these limitations, the development and adoption of an interoperable approach could offer a widespread and sustainable solution for TSV in the OR. The prototype used in this study leverages the Institute of Electrical and Electronics Engineers (IEEE) 11073 Service-Oriented Device Connectivity (SDC) interoperability standard [13,14], which enables seamless integration of critical patient and device data. Although this prototype was previously evaluated for general usability and user feedback in less critical scenarios, its performance in managing potentially life-threatening events within the OR has not been assessed. This study, therefore, aims to build upon prior work by evaluating the system's effectiveness in a high-fidelity, simulation-based environment under conditions that mirror real clinical challenges. By comparing its performance to that of traditional on-site supervision in a potentially life-threatening scenario, we aim to demonstrate that remote support can maintain adherence to standard operating procedures (SOPs) without compromising clinical decision-making or increasing workload. The ultimate goal is to bridge the gap between the demonstrated strengths of telemedicine in other fields and the specific demands of anesthesia supervision in the OR.

Methods

Telemedical Supervision System

The telemedical supervision system used in this study was developed under the PriMed—Process Optimization Through Integrated Medical Devices in the Operating Room and Clinic research project, funded by the German State of North-Rhine Westphalia and the European Commission—European Regional Development Fund (Europäischer Fonds für regionale Entwicklung [EFRE]; grant EFRE-0801359) [15]. This system comprises 2 primary components: the anesthesia workstation located within the OR and a mobile supervision workstation for the senior physician.

The anesthesia workstation integrates data from the patient monitor, anesthesia machine, and syringe pumps within the OR using the IEEE 11073 SDC interoperability standard [13,14]. This integration facilitates the reception and display of data on the anesthesia workstation. Additionally, the anesthesia workstation provides communication options, allowing the anesthetist to connect with the senior physician via text chat or audio or video call.

On the senior physician's side, the supervision workstation mirrors the data collected from the medical devices in the OR and offers the capability to switch between multiple ORs. It enables the supervisor to contact anesthetists in each OR using a telemedical module ("TeleDoc"; Docs in Clouds TeleCare GmbH). Once an audio or video connection is established, the supervisor can choose to view the anesthetist through the OR's webcam or use a ceiling-mounted pan-tilt-zoom (PTZ) camera. This PTZ camera allows remote observation within the OR, enabling inspection of specific points of interest related either to the patient or to the overall scenario.

The supervision workstation has 3 key features.

The first feature is data integration and access. All critical patient and device data available on the anesthesia workstation through the SDC protocol are transmitted to the supervision workstation, enabling senior physicians to monitor multiple ORs from a single device. However, for this study, a proprietary protocol was used to transfer the data to the senior physician because of the lack of SDC capabilities of the devices used.

The second feature is communication capability. The telemedical module supports real-time text, audio, and video communication between the supervision workstation and each OR workstation, providing senior physicians with a reliable communication channel.

The third feature is mobile and lightweight design. The supervision workstation was designed as a fast, lightweight web application optimized for low-end mobile devices, such as tablets. Built with JavaScript and *React.js*, it is accessible through standard web browsers, ensuring portability and ease of use on various devices.

XSL•FO
RenderX

The integration of these workstations and the addition of the telemedical module created a functional, flexible system that enables senior anesthetists to support their colleagues remotely while maintaining critical access to real-time patient and device data.

Study Design

Previous discussions about the system used and an evaluation of its acceptance by users highlighted its potential [15]. The goal was not to replace on-site senior physicians but instead to offer aid for hospitals and scenarios where currently no senior physician is present because of cost or staffing constraints. However, previous studies were limited to simple simulation scenarios that were rather uncritical for the resident anesthetist. This study focused on potentially life-threatening scenarios.

This randomized controlled evaluation study was designed to involve anesthesiology resident physicians from the Uniklinik Rheinisch-Westfälische Technische Hochschule (RWTH) Aachen (Germany) in their first 2 years of training. Due to shortages during the COVID-19 pandemic, the original goal of recruiting 20 participants was not reached; ultimately, 16 participants were recruited and randomly assigned to 2 groups using block randomization with 2 blocks of 10 participants each.

Given the early development stage of the supervision system, its evaluation was conducted using a human patient simulator (HPS; Elevate Healthcare) in a simulated OR. Anesthetists were confronted with a realistic anesthesiology scenario to assess the system's effectiveness through a comparative approach.

In the defined scenario, for dealing with a critical event, the first group (intervention group) could receive support only via TSV, without being able to call the senior physician by phone and ask them to come to the OR. The second (control) group had access to a conventional phone for calling assistance and could ask the physician to be present in the OR.

To ensure a meaningful evaluation of the telemedical system's capabilities, we deliberately chose not to allow the intervention group to summon the senior physician for in-person support. Although including this option might have further reinforced the comparability of outcomes—particularly if participants chose not to use it—we recognized a significant risk: participants might default to using the TSV system merely as a digital phone to request the supervisor's physical presence. This concern was based on the participants' habitual use of phone-based communication in clinical practice and their lack of prior exposure to TSV tools. By removing the fallback to in-person support, we sought to isolate and rigorously evaluate the functionality and effectiveness of remote supervision alone. This edge-case design enabled us to test whether performance under telemedical guidance, without any possibility of on-site intervention, could still match that under conventional supervision in a high-stakes clinical scenario.

To test the efficacy of the TSV system under this constrained setup, the following high-fidelity scenario was developed to simulate a critical medical emergency. The patient—a male aged 51 years weighing 85 kg and measuring 183 cm, with no known allergies—underwent an appendectomy. The surgeon requested the administration of cefuroxime as an antibiotic, to which the patient exhibited an anaphylactic reaction. Participants were required to react appropriately according to the SOPs of the Uniklinik RWTH Aachen, based on the "Guideline for Acute Therapy and Management of Anaphylaxis" [16]. This SOP was divided into basic measures applicable immediately after diagnosing a potential anaphylactic reaction and further measures necessary for different stages and severity levels of anaphylaxis (Multimedia Appendix 1).

The primary outcome measure was the proportion of correctly executed necessary SOP measures, calculated as the number of correctly performed measures divided by the total number of measures deemed necessary for each case. On the basis of the simulation model, early proactive reactions could prevent a more severe anaphylactic reaction, rendering certain measures unnecessary, while delayed or inadequate responses could lead to more severe reactions requiring additional interventions.

Observations also recorded whether these measures were executed at the participant's own discretion or were instructed by the senior physician. Three minutes after the administration of cefuroxime, the HPS operator triggered the first stage of the anaphylactic reaction.

Secondary outcomes included workload, measured using the NASA Task Load Index (NASA-TLX) [17], and participants' postscenario questionnaire responses, with different questions for the 2 groups. Although the intervention group was interviewed about its feedback and impression of the TSV system, the control group was asked whether it could imagine solving the situation with telemedical support and whether the presence of the senior physician was important to its members.

The NASA-TLX is a widely used tool to assess perceived workload, weighted from 0 to 100, across 6 dimensions: mental demand (the degree of cognitive effort required for the task), physical demand (the level of physical activity involved), temporal demand (the pressure related to time constraints), performance (self-assessed success in task execution), effort (the total mental and physical effort exerted), and frustration (the extent of stress, irritation, or satisfaction experienced during the task).

Video recordings from 3 cameras and screen recordings of the patient monitor were used for postscenario evaluations. Participants practiced the "thinking-aloud protocol" prior to the scenario, encouraging them to verbalize their actions and thoughts, thereby allowing precise monitoring of behavior and actions. The completion of corresponding SOP measures was logged, and each contact with the senior physician was noted, including the situation, reason, and time stamp.

Each simulation cycle involved an anesthesia nurse familiar with the simulation environment to support the anesthetist in the OR, a simulation technician from Aachener Interdisziplinäres Trainingszentrum für medizinische Ausbildung (AIXTRA), a technical manager to control the HPS and scenario settings, and a senior physician to address any questions from the participant.

Ethical Considerations

All participants provided written informed consent before participating in the study. Participants were pseudonymized,

XSL•FO
RenderX

and data protection and confidentiality were maintained in accordance with institutional protocols. Video recordings used to verify participants' actions, measures, and behavior were deleted after data acquisition. Participants did not receive any compensation for their participation. The study was approved by the Ethics Committee of the Uniklinik RWTH Aachen (EK 314-21). The participants were all medical residents who participated in a simulated scenario, so there were no direct health-related outcomes, and thus the study was not preregistered.

Statistical Methods

For the comparison of the performances of the 2 groups, an independent 2-sample *t* test (Welch *t* test) was used. To check its applicability, a Shapiro-Wilk test was performed to test for normal distribution, and the Levene test was performed to assess the homogeneity of variances.

Results

Observation of Performance and Use

A total of 16 resident anesthetists from the Uniklinik RWTH Aachen, all in their first 2 years of postgraduate specialty training, were recruited and included in the study. Of these, 9 (56%) were female and 7 (43.8%) were male, with ages ranging from 25 to 35 years. Their clinical experience as anesthetists varied from 2 to 25 months. Participants were randomly assigned to either the control group (n=9, 56.2%) or the intervention group (n=7, 43.8%) using block randomization with a block size of 10 to ensure balanced group distribution.

During the simulated anesthesia scenario, in which a patient was at risk of developing anaphylactic shock, all resident anesthetists contacted the senior physician and requested support at least once.

The amount of assistance requested, defined as the number of SOP measures for anaphylactic shock in which the senior physician was involved, varied among participants. The proportion of supported SOP measures ranged from 0% to 79% in the control group, with a median of 39%. In the intervention group, this proportion ranged from 0% to 64%, with a median of 43%. Within the control group, the mean number of supported SOP measures was 6.44 (SD 4.80), whereas the intervention group had a mean of 5 (SD 3.06) supported measures.

According to the study setup, different communication methods were used in the 2 groups when senior assistance was required. In the intervention group, communication was exclusively remote via the tele supervision workstation. In contrast, participants in the control group primarily used the phone to request in-person support from the senior physician. In the control group, 79% (46/58) of the SOP measures assisted by the senior physician were carried out in person, while 12 (21%) were supported via phone communication.

The diagnosis of anaphylaxis was made independently by 4 (44%) of the 9 resident anesthetists in the control group and 4 (57%) of the 7 resident anesthetists in the intervention group.

Furthermore, the completion rate of necessary SOP measures was examined. The percentage of required measures performed varied depending on how early anaphylaxis was detected and treated, as some SOP steps for severe anaphylactic shock remained unnecessary when early interventions were successful. The mean completion rate was 92.5% (SD 0.04%; median 93.8%) in the control group and 91.6% (SD 0.05%; median 92.3%) in the intervention group. The IQR was 88.9% to 94.7% for the control group and 87.5% to 93.5% for the intervention group.

To test for a normal distribution, the Shapiro-Wilk test was performed, resulting in a *P* value of .27 for the control group and a *P* value of .33 for the intervention group. As both *P* values were >.05, we do not reject the null hypothesis that the data are normally distributed. To test for equality of variances, the Levene test was used and yielded *P*=.81. This high *P* value suggests that we do not reject the null hypothesis that the variances of the 2 groups are equal.

Thus, we were able to use the independent 2-sample *t* test (Welch *t* test), with $t_{11.94}$=0.439, which showed no significant difference (*P*=.67) between the 2 groups.

Evaluation of the System and Workload by Participants

After the simulation, participants completed the NASA-TLX questionnaire to assess workload (Figure 1). Mean scores and SDs for both groups are shown in Table 1.

XSL•FO
RenderX

Figure 1. Assessment of perceived workload for both groups (white: control group; gray: intervention group) using the NASA Task Load Index (NASA-TLX), evaluating the demands across the 6 dimensions on a scale of 0 to 100.

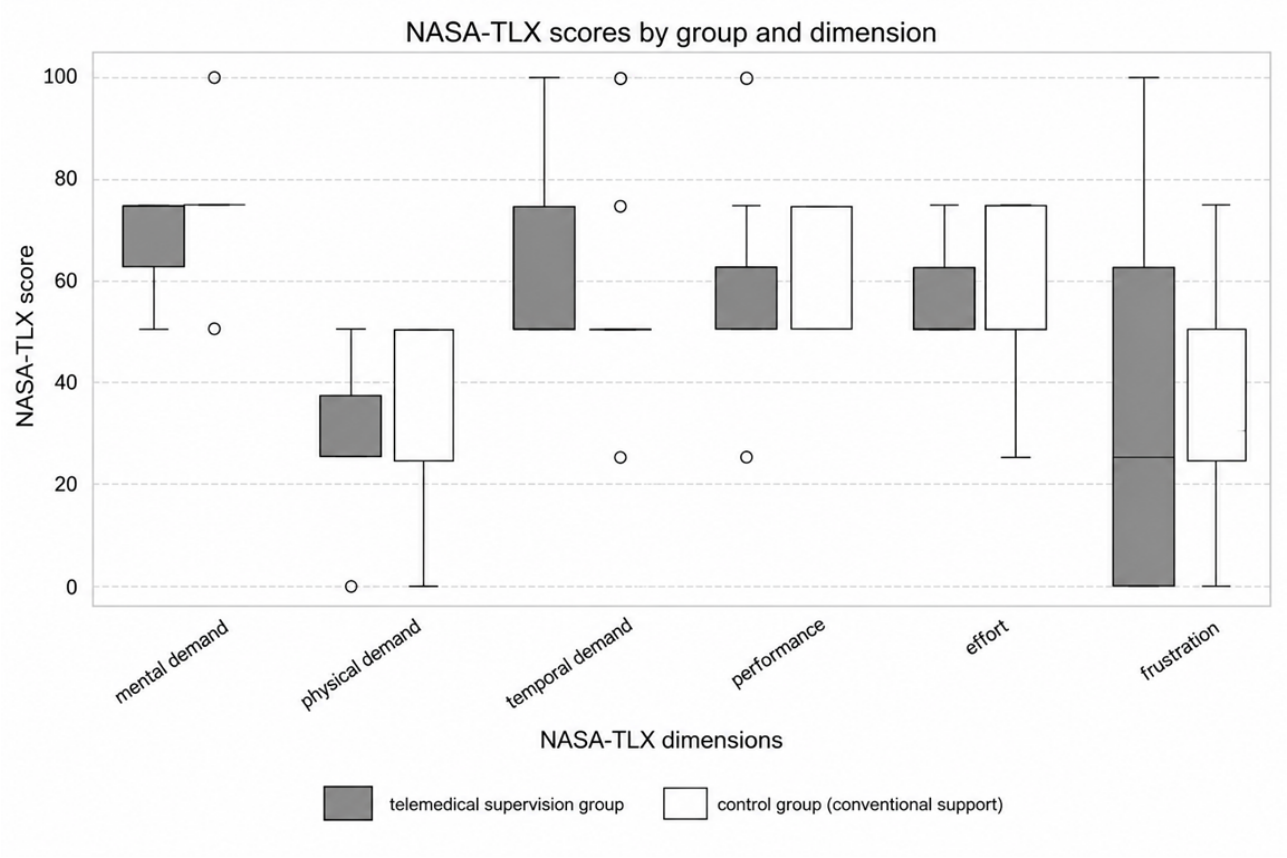

Table 1. Mean scores for the 6 NASA Task Load Index (NASA-TLX) categories in the 2 groups.

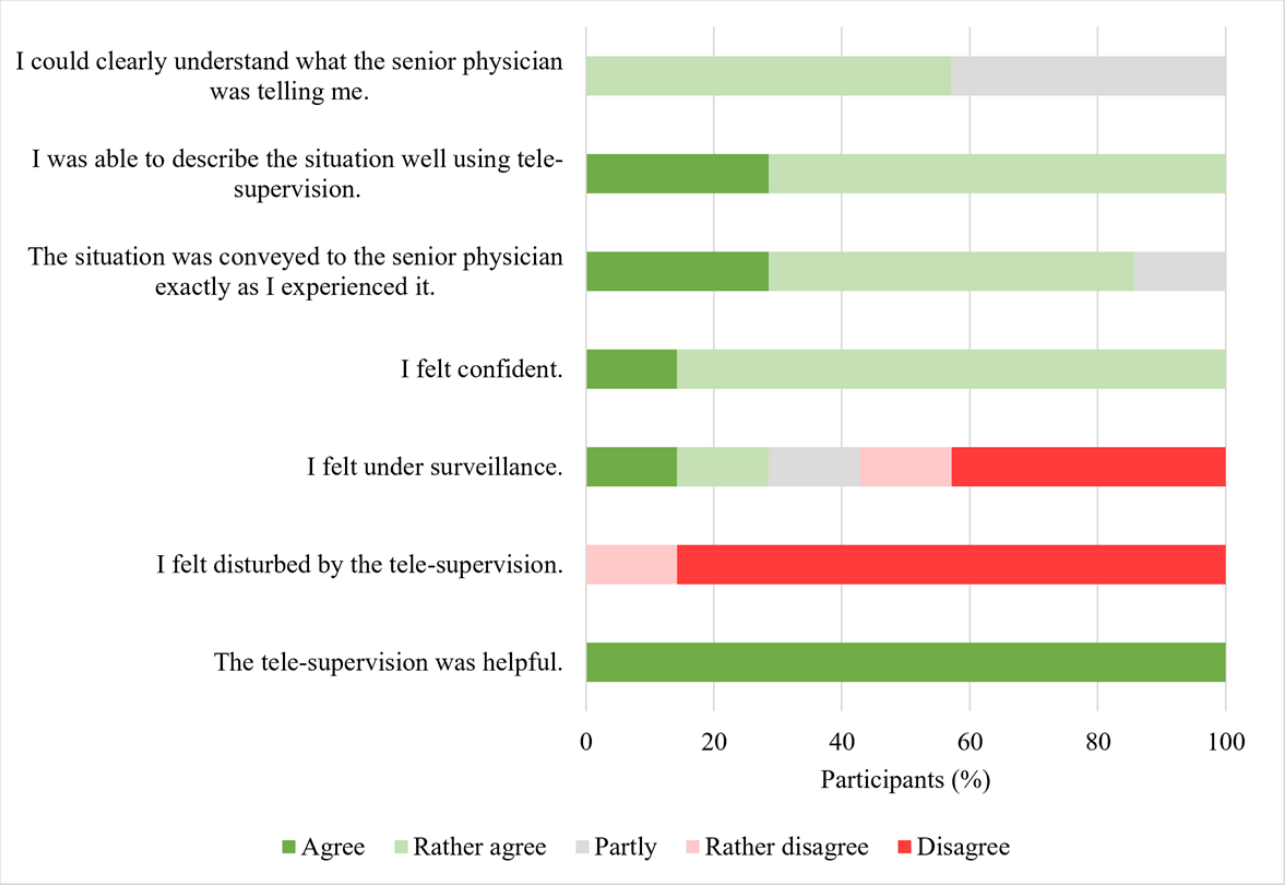
NASA-TLX dimension	Intervention group, mean (SD)	Control group, mean (SD)
Mental demand	67.9 (12.2)	77.8 (15)
Physical demand	28.6 (17.3)	30.6 (16.7)
Temporal demand	64.3 (19.7)	55.6 (20.8)
Performance	57.1 (23.8)	58.3 (12.5)
Effort	57.1 (12.2)	55.6 (16.7)
Frustration	35.7 (40.5)	30.6 (24.3)

The TSV setup was rated as mentally and physically less demanding. However, temporal demand was rated differently, with the TSV setup being rated as more demanding. In all other workload categories, the perceived demand was very similar.

Participants in the intervention group were asked whether they would have preferred the option to call the senior physician on-site. Overall, 2 (28.6%) participants rather agreed, 3 (42.9%) were neutral, and 2 (28.6%) rather disagreed.



Participants in the control group were asked whether they believed they could have managed the scenario using the telemedical system and whether the presence of the senior physician was important to them. Of the 9 participants in the control group, 5 (55.6%) agreed or rather agreed that they could have handled the situation with the telemedical system, while the remaining 4 (44.4%) participants were neutral. Of the 9 participants in the control group, 7 (77.8%) considered the senior physician's physical presence important, while 2 (22.2%) rather disagreed.

Feedback on the TSV System

Participants who used the TSV system provided feedback on 7 predefined statements (Figure 2). None of the participants reported difficulties in understanding the senior physician or describing the situation effectively using the system. All participants perceived that the senior physician was able to assess the situation appropriately using the system. Additionally, all participants reported feeling confident during the scenario.

XSL•FO
RenderX

Figure 2. Feedback on the use of the telesupervision system by the intervention group, assessed through a questionnaire.

Responses regarding whether the system created a sense of being under surveillance were mixed. No participants reported feeling disturbed by the system, and all participants agreed that the system was helpful.

Discussion

Principal Findings

This randomized controlled simulation study investigated the effectiveness of a telemedical supervision system for anesthesiology residents managing a life-threatening intraoperative emergency. Participants were assigned to either a TSV group, supported remotely via a dedicated remote senior physician, or a control group with the conventional setup, in which a senior physician could be consulted by phone or requested for on-site support. The primary outcome was the completion rate of necessary SOP measures during an anaphylactic reaction triggered in a simulated patient. Both groups achieved similarly high SOP adherence, with no statistically significant difference between them, suggesting that remote supervision using the telemedical system did not compromise clinical performance in this high-fidelity simulation. These findings align with evidence from intensive care settings, where remote monitoring has maintained care quality and improved workflow efficiency [18]. Secondary findings revealed that although participants under TSV reported slightly lower mental demand, they experienced higher temporal demand. However, subjective evaluations highlighted general acceptance of the system, although some participants still preferred the physical presence of supervisors.

Observation of Performance and Use

One of the key findings of this study is that both groups frequently sought assistance from senior physicians, with all participants reaching out at least once during the simulated anaphylaxis scenario. Given that all participating residents had less than 2 years of anesthesiology experience, this result emphasizes the critical importance of having a senior physician readily available for consultation in complex or deteriorating situations—both to ensure patient safety and to support clinical decision-making.

From a legal and organizational perspective, this is particularly relevant in Germany, where current regulations stipulate that a fully qualified anesthesiologist (“*Facharzt*”) must be immediately available when procedures are carried out by a resident. Traditionally, this has meant one-to-one supervision with physical presence or rapid on-site availability. From a legal and organizational perspective, these findings suggest that telemedical supervision may have the potential to contribute to fulfilling the requirement for immediate senior physician availability. However, this simulation study does not constitute legal validation, and whether TSV satisfies applicable regulatory requirements must ultimately be evaluated in real clinical practice and interpreted within the relevant legal framework. Compared to other previously proposed or used systems for telemedical support in anesthesia [6-8], the use of the IEEE 11073 SDC interoperability standard allows the full integration of secure data from connected medical devices. To date, telemedical solutions have either provided only a video signal or included selected parameters that were received proprietarily.

XSL•FO
RenderX

Building upon a standardized interoperable protocol would enable widely applicable solutions, providing access to any captured or measured data points in a manufacturer-independent way and providing a foundation for more advanced analytical tools or decision support systems.

The study also observed that, in both groups, more than one-third of the executed SOP measures were completed with support from the senior physician. This further highlights the importance of expert supervision during the early training stages. Notably, in the control group, 79% (46/58) of all SOP measures assisted by the senior physician were carried out in person rather than via phone. This finding suggests that most critical assistance in conventional workflows still depends on physical presence. However, the comparable performance of the TSV group implies that the novel system could substitute many of these in-person support functions in this simulated scenario, providing remote clinical guidance without reducing SOP adherence.

In approximately half of all cases, the diagnosis of anaphylaxis was not made independently by the resident but required senior physician input, suggesting that, without guidance, outcomes could have been critical for the simulated patient.

Although the study focused on the German legal framework, it is important to note that in many other countries, particularly in resource-limited or rural settings, it is common for1 senior physician to supervise multiple ORs simultaneously—or even for nonphysician anesthesia providers to operate under remote supervision. In these settings, as seen in prior studies on tele-anesthesia and surgical tele-support [19], remote solutions have been key to enabling equitable care delivery. The demonstrated ability of TSV to maintain protocol adherence and decision-making quality could be particularly impactful. This approach may help standardize the quality of care across facilities and bridge geographic disparities in specialist availability.

Additionally, although this study exclusively assessed resident-initiated contact, it is conceivable that future implementations could include proactive monitoring by supervisors. A system like the one tested here would enable a senior physician to observe multiple ORs simultaneously and intervene early when needed, thereby providing a scalable and legally compliant alternative to conventional on-site oversight.

Finally, the completion rate of necessary SOP measures, which served as the primary objective parameter to monitor performance in this study, was nearly identical between the 2 groups. The control group achieved a mean SOP completion rate of 92.5%, while the intervention group achieved a mean rate of 91.6%.

These findings indicate that the TSV system did not compromise residents' adherence to protocol during a critical incident.

An interesting observation was that 79% (46/58) of all senior physician–assisted SOP measures in the control group were ultimately supported in person rather than via telephone alone. This likely reflects a limitation of conventional phone-based communication, which provides only verbal information and often requires the supervisor to enter the OR to obtain a complete understanding of the situation. In contrast, the TSV system provided simultaneous access to patient data, medical device information, and audiovisual communication, potentially replacing many situations in which physical presence would otherwise have been necessary. Therefore, the observed preference for in-person support in the control group should not be interpreted as evidence that physical presence is inherently superior but rather as evidence that conventional telephone communication alone may be insufficient for many complex intraoperative situations.

Evaluation of the System and Workload by Participants

However, the participants' subjective experiences, as captured by the NASA-TLX, revealed some distinctions. Although the intervention group reported less mental demand when using the novel system, they perceived greater temporal demand. This finding is interesting, as it highlights the potential cognitive challenges associated with managing remote support provided through a technological solution during a high-stress situation. Being supervised remotely can heighten the feeling of being observed and evaluated without the personal rapport of in-person supervision, possibly making participants feel pressured to perform quickly. Conventional in-person supervision may represent a more familiar interaction, at least until such systems become more widely used and integrated into education and training.

When asked about their preferences, 2 (28.6%) of the 7 participants in the intervention group expressed a desire for on-site senior physician support, with 2 (28.6%) participants leaning toward agreement. In contrast, more than half of the control group indicated that they believed they could have managed the situation using the TSV system. Still, most valued the physical presence of the senior physician, with 7 (77.8%) of the 9 participants finding it important. Although this study focused on the experiences of the resident physicians, it must be noted that TSV may pose additional challenges for the supervising senior physician as well. Managing critical events remotely, without being physically present, can be disorienting, cognitively demanding, and may introduce a perceived or real sense of medicolegal risk. This study used only 1 experienced senior physician for all simulations, which limited the scope for evaluating this aspect. Future research should explore how TSV is perceived and handled by multiple supervising physicians across various levels of experience, to better understand its implications on both sides of the interaction.

Although some participants expressed a preference for the senior physician's physical presence, this should not be generalized as a universal requirement. The need for on-site support may vary considerably depending on the nature of the problem being addressed. Organizational or procedural questions might be efficiently handled via phone, while more complex clinical issues may benefit from TSV, particularly when shared visual access to monitors and vital signs is crucial. Some scenarios, such as those requiring manual intervention, may truly demand physical presence in the OR. The size of this subset remains an open question. Future studies should aim to categorize the types of supervisory needs and identify their optimal support

XSL•FO
RenderX

modalities. Additionally, the level of experience of the resident anesthetist plays a critical role. Although this study focused on early-stage residents with less than 2 years of experience, it is plausible that after approximately 12 months of practice, many clinical situations could be managed safely and effectively under remote supervision. Investigating the threshold of clinical experience required for safe and efficient TSV could inform staffing models that allow 1 senior physician to supervise multiple ORs without compromising patient safety. In addition, increasing staffing shortages and constrained resources in rural areas might be important limiting factors [20,21], for which TSV could provide a solution.

Feedback on the TSV System

Regarding the user experience of this first demonstrator, participants using the system generally provided positive feedback regarding its functionality. They reported no issues in communicating with the senior physician and felt confident throughout the scenario. However, a notable proportion of participants expressed mixed feelings regarding the sensation of being under surveillance, even though none felt disturbed by the system. Indicators on the system interface or an indicator light on the webcam could potentially mitigate concerns about being observed without notice; however, this possibility was not further investigated in this study. Despite this, all participants agreed that the system was helpful during the scenario.

Limitations

The study was conducted in a patient simulator environment, which, although highly controlled, might not fully replicate the complexities of real-world clinical situations. This could affect the generalizability of the findings. A similar demonstrator with a higher technology readiness level should be further evaluated in a real clinical environment with a safe fallback option.

Another key limitation is the small sample size and the exclusive focus on a single type of critical incident (anaphylaxis). The relatively small sample size limits the ability to detect small differences between groups. Although no statistically significant differences were observed for the primary end point, the study should be regarded as exploratory and was not powered to establish equivalence or noninferiority. Larger studies will be required to confirm these findings and to evaluate secondary outcomes with greater statistical precision. Broader scenarios involving various intraoperative emergencies, as well as a more diverse participant pool, will be necessary to generalize the results across different clinical contexts. The selection of a single anaphylaxis scenario was intended to provide a standardized and reproducible evaluation of the TSV system. Future studies should investigate additional intraoperative emergencies, such as major hemorrhage, difficult airway situations, or cardiac arrest, to assess the generalizability of the findings across a broader spectrum of clinical challenges. Moreover, the current evaluation focused solely on resident physicians with <2 years of clinical experience, without stratifying results based on experience level. Resident experience ranged from 2 to 25 months and was not used as a stratification variable during randomization. Although all participants were within the first 2 years of anesthesiology training, differences in experience may have influenced diagnostic accuracy, help-seeking behavior, and workload perception. Future studies with larger cohorts should stratify participants by training level or include experience as a covariate in the statistical analysis.

Although the completion rate of SOP measures was used as the primary outcome, the timing of individual actions was not systematically analyzed. In acute anesthetic emergencies, time to diagnosis and time to treatment may be clinically just as important as the eventual completion of SOP measures. TSV has the theoretical advantage of enabling immediate expert involvement without the delay associated with physically traveling to the OR. However, because both groups in this simulation received immediate access to senior physician support once contact was initiated, the present study was not designed to evaluate potential time-related benefits. Future studies should include time-to-event metrics, such as time to diagnosis, time to first epinephrine administration, or time to completion of critical interventions, to better assess potential efficiency gains associated with TSV.

A further limitation concerns the 1-sided perspective of the feedback: this study collected only residents' impressions. Feedback from senior physicians, who supervised all simulations remotely, would provide valuable insight into usability, cognitive workload, clinical safety, situational awareness, and potential medicolegal concerns from the supervisor's perspective. However, only 1 senior physician participated in this study, precluding such analysis. Including multiple senior physicians in future research will be essential to assess interindividual variation, supervisor acceptance, and broader applicability.

Another design constraint was that the TSV group was not permitted to use a phone or request the supervisor's physical presence. Although this design enabled a clearer evaluation of the stand-alone telemedical system, it does not reflect the real-world flexibility of hybrid models (eg, initial tele-consultation followed by physical support if needed). Future studies could allow participants to freely choose between telemedical support, phone calls, and summoning the supervisor on-site. However, this would require significantly larger sample sizes and more complex study protocols to account for the resulting variability. At the same time, other potential benefits of widespread implementation of this novel telemedical supervision system were not directly evaluated either. The system used in this study would allow the supervisor to seamlessly switch between different ORs and potentially even between different clinics. This could offer a huge potential for process optimization and more efficient use of personnel resources.

Finally, the TSV system evaluated in this study was still in the prototype stage. The user interface (UI) was in the early stages of development, and full integration of device data and clinical information had not yet been achieved. Future iterations could benefit from enhanced UI design, more intuitive interaction mechanisms, and real-time integration of patient data streams, which may further increase effectiveness, usability, and user acceptance.

Conclusions and Outlook

In this randomized controlled study, we evaluated a telemedical supervision system for anesthesia residents managing critical scenarios. The study demonstrated performance similar to traditional on-site supervision, with similar completion rates of necessary SOP measures. Despite increased temporal demands reported by participants, the system was well received overall, highlighting its potential to address staffing shortages and resource limitations.

These findings carry important implications for the future of telemedicine in anesthesiology and beyond. First, the comparable adherence to SOPs in a high-stakes scenario suggests that TSV could be a viable option in situations where on-site senior staff is unavailable. This may be particularly relevant for rural hospitals, understaffed departments, or nighttime operations, where immediate in-person support may not always be feasible.

Second, the ability of the telemedical system to integrate real-time device and patient data using the IEEE 11073 SDC interoperability standard lays the groundwork for scalable, interoperable, and future-ready supervision models. As digital infrastructure in hospitals continues to evolve, systems like this could be enhanced with decision support tools, AI-based alerts, or predictive analytics to further assist both supervisors and residents.

Third, the study highlights the need for careful integration of new technology into clinical workflows. The increased temporal workload and the mixed feelings regarding remote observation underline the importance of proper training, user adaptation, and human-centered design. Future implementations should include training sessions as part of clinical education, possibly even integrating telemedical scenarios into simulation-based curricula.

Moving forward, real-world evaluations are essential to validate these findings in clinical practice. Pilot deployments in hospitals, supported by fallback mechanisms and mixed-modality supervision models, could test how the system performs under actual operating conditions. Additionally, future studies could expand the scope to include different critical events, surgical disciplines, or varying levels of clinician experience. Longitudinal research could also examine how repeated exposure and increasing familiarity affect both performance and user perceptions over time.

Finally, beyond anesthesiology, the architecture of such an interoperable telemedical system could be adapted for or combined with existing proprietary solutions for use in other high-acuity areas such as emergency departments, intensive care units, or interhospital consultations. With the global trend toward digital transformation in health care, establishing robust, interoperable TSV systems has the potential to reshape clinical collaboration and training, ultimately improving patient care and operational efficiency.

Funding

The study, as a part of the research project PriMed—Process Optimization Through Integrated Medical Devices in the Operating Room and Clinic, was funded by the German State of North-Rhine Westphalia and the European Commission—European Regional Development Fund (Europäischer Fonds für regionale Entwicklung; grant EFRE-0801359).

Abstract

Background: Population aging and geographic health disparities challenge health care delivery in rural settings worldwide. Point-of-care ultrasound (PoCUS) combined with teleconsultation may enhance home-based medical care by extending specialist expertise to underserved communities, yet evidence from real-world implementation in Asian settings remains scarce. Taiwan, with its high digital literacy and universal National Health Insurance (NHI) system, provides a unique context for evaluating integrated PoCUS-teleconsultation service delivery.

Objective: This study aimed to describe the implementation, clinical applications, and financial sustainability of an integrated PoCUS-teleconsultation service within a dedicated home-based medical care practice in rural eastern Taiwan.

Methods: We conducted a retrospective analysis of prospectively recorded routine care data at D Clinic, Taitung County, from April 2020 to May 2022. PoCUS examinations conducted in the clinic, during home visits, and through mobile outreach were recorded. A business-to-business-to-consumer (B2B2C) teleconsultation model linking on-site physicians with remote specialists via real-time ultrasound streaming was implemented from March 2021. Seven-year net present value (NPV) analyses evaluated financial viability across 24 equipment reimbursement scenarios.

Results: Among the 26 patients who received teleconsultation, the mean age was 79.4 (SD 9.2) years, 15 (58%) were male, and 20 (77%) were in the intensive home health care tier. A total of 676 PoCUS examinations (defined as single-region imaging studies) were performed by 3 trained physicians in the following settings: 375 (55.5%) in the clinic, 174 (25.7%) during home visits, and 127 (18.8%) as mobile outreach. Twenty-six teleconsultation sessions were conducted (n=15, 58% during home visits; n=7, 27% during mobile outreach; and n=4, 15% in the clinic), with 13 (50%) involving multitarget scanning (cardiac, pulmonary, and abdominal). Of the 26 sessions, 24 (92%) were completed without technical interruption, while 2 (8%) experienced transient 4G buffering but were completed. Monthly PoCUS volume reached a sustained plateau of ≥28 examinations from month 17 of implementation. Four clinical service domains were identified: hospital-at-home acute management, home-based hospice multiorgan support, green channel surgical referral, and chronic disease serial monitoring. NPV analysis demonstrated that wireless PoCUS equipment with the proposed, but not yet implemented, dual-specialist teleconsultation reimbursement achieved the most favorable projected return (NT $882,000; NT $1=US $0.036 in 2021 on average), requiring only 2.72 monthly cases to break even under the modeled assumptions.

Conclusions: Integrating PoCUS with teleconsultation is operationally feasible in rural home-based care when wireless equipment is adopted. Financial scenario modeling suggests favorable projected returns under proposed reimbursement structures, although these remain contingent on NHI policy adoption. These findings are hypothesis generating and require validation through multisite studies with patient-level outcome measurement before informing national reimbursement policy.

Introduction

The global demographic transition toward aging populations presents unprecedented challenges for health care systems, particularly in countries experiencing rapidly declining fertility rates and growing populations of older adults [1]. Taiwan exemplifies this demographic urgency: the National Development Council projected that by 2025, 1 in 5 citizens would be aged ≥65 years, classifying Taiwan as a "superaged" society—the fastest demographic transition among high-income nations [2]. In rural and mountainous regions such as Taitung County in eastern Taiwan, these challenges are compounded by physician shortages, limited specialist access, and transportation barriers that disproportionately affect homebound older adult populations.

The hospital-at-home (HaH) model has emerged as a promising strategy to address these disparities by delivering acute and chronic care services in patients' residences [3,4]. Meta-analyses have demonstrated that HaH programs reduce mortality, readmission rates, and health care costs while improving patient and caregiver satisfaction [3]. Recent evidence from Israel's largest health maintenance organization demonstrated that integrating telemedicine into HaH services enhanced clinical decision-making and reduced unnecessary emergency department use [5]. However, the diagnostic capabilities of HaH programs remain limited by the absence of bedside imaging—a gap that point-of-care ultrasound (PoCUS) is uniquely positioned to fill.

PoCUS has evolved from a hospital-centric diagnostic modality to a portable, clinician-performed bedside tool with broad applications across emergency, critical care, and primary care settings [6-8]. Position statements from the Society of Hospital Medicine and the Society of General Internal Medicine now endorse PoCUS as a core competency for hospitalists, encompassing cardiac, pulmonary, abdominal, vascular, and musculoskeletal domains [9-11]. The indication, acquisition, interpretation, and medical decision-making (I-AIM) framework provides a structured approach to PoCUS documentation and quality assurance [12,13].

Tele-ultrasound—the remote guidance and interpretation of ultrasound examinations—has shown promise in extending specialist expertise to underserved settings. A systematic review by Kariman et al [14] of 31 studies in pregnancy care found fetal tele-ultrasound services (11 studies) to be feasible and particularly valuable in rural areas and in settings where specialist care is centralized, although study quality was generally low to fair and the evidence was confined to obstetric applications. A comparable synthesis of home-based, multiorgan tele-ultrasound in adults is lacking. Kirkpatrick et al [15] demonstrated that novice operators performing PoCUS in home environments during the COVID-19 pandemic could achieve diagnostic-quality images with remote expert guidance, suggesting that tele-mentored PoCUS is feasible even with limited prior training.

Taiwan's telemedicine regulatory framework has evolved substantially since its initial legislation in 1986, with landmark amendments in 2018 permitting teleconsultation for patients in remote areas, long-term care facilities, and emergency situations, and further expansion in 2024 removing geographic restrictions entirely [16,17]. The COVID-19 pandemic catalyzed a 72-fold surge in National Health Insurance (NHI) teleconsultation claims, from 2330 cases in 2019 to approximately 169,044 in 2022 [18,19]. However, the existing NHI reimbursement structure lacks dedicated codes for multitarget bedside ultrasound in home settings and does not recognize business-to-business (B2B) specialist teleconsultation fees—creating a policy gap that threatens the financial sustainability of integrated PoCUS-teleconsultation services.

Notably, South Korea provides a regional precedent: following the introduction of dedicated PoCUS reimbursement codes (single-target ultrasound [STU] and multitarget ultrasound [MTU]) in July 2019, Kang et al [20] documented a 4-fold increase in emergency department PoCUS use, demonstrating that reimbursement policy directly drives adoption [21].

Taiwan's high smartphone penetration rate (exceeding 85% among adults) and widespread 4G or 5G network coverage, including in rural eastern regions, provide a favorable digital infrastructure foundation for teleconsultation implementation. The business-to-business-to-consumer (B2B2C) model extends conventional physician-to-physician teleconsultation by adding a direct patient-facing service delivery component, operationally distinguishing it from standard telemedicine by embedding the remote consultation within a structured home visit workflow rather than replacing the in-person encounter.

Despite growing interest in both PoCUS and telemedicine, to our knowledge, no published study has systematically examined the integration of PoCUS with specialist teleconsultation within a dedicated home-based medical care practice, nor has any study provided financial modeling to assess the sustainability of such integration under different reimbursement scenarios. This study aimed to fill these gaps by reporting the implementation experience, clinical applications, learning curve dynamics, and economic analysis of a PoCUS-teleconsultation service at D Clinic, a dedicated home-based medical care practice in Taitung County, eastern Taiwan.

Methods

Study Design and Setting

We conducted a retrospective analysis of prospectively recorded routine care data at D Clinic, the first dedicated home-based medical care clinic in Taitung County, eastern Taiwan,

XSL•FO
RenderX

established in December 2017. The study period for PoCUS use spanned April 2020 to May 2022, with teleconsultation services initiated in March 2021 during the Delta and Omicron waves of the COVID-19 pandemic. The clinic serves approximately 90 home health care patients and manages 120 long-term care disability assessment cases across Dulan, Xingchang, and Longchang villages and is staffed by 3 physicians (2 in family medicine and 1 in neurology) and 1 nursing case manager.

Patient Population and Care Tiers

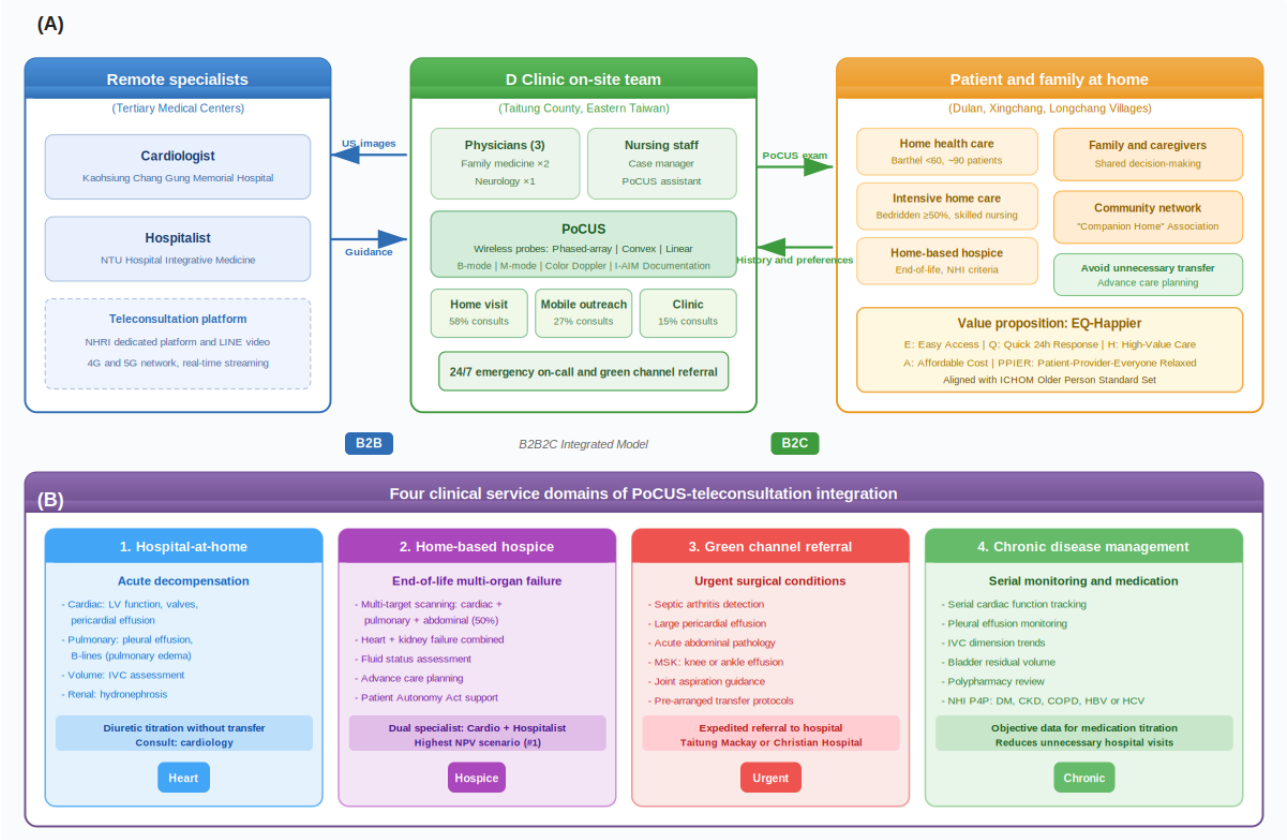
Patients were enrolled in 3 NHI-defined care tiers: (1) home health care (Barthel Index <60), (2) intensive home health care (bedridden for ≥50% of waking hours and requiring skilled nursing), and (3) home-based hospice (terminal conditions meeting NHI criteria). Clinical indications for PoCUS-teleconsultation included acute decompensation of chronic conditions, suspected surgical emergencies, end-of-life symptom management requiring multiorgan assessment, and chronic disease monitoring requiring specialist input for medication adjustment.

PoCUS Equipment and Teleconsultation Platform

Both wired and wireless ultrasound systems were evaluated during the study period (Table 1). Equipment selection criteria included portability (<400 g for wireless devices), battery life, ease of disinfection, imaging modes (B-mode, M-mode, and color Doppler), and connectivity for real-time image streaming. Teleconsultation was conducted using a hybrid platform combining LINE (LY Corp) video calling and the National Health Research Institutes dedicated teleconsultation platform via 4G cellular networks. Remote specialists included a cardiologist (at Kaohsiung Chang Gung Memorial Hospital) and a hospitalist (in integrative medicine at National Taiwan University Hospital). The I-AIM framework was adopted for standardized PoCUS documentation and quality assurance [12,13].

Table 1. Point-of-care ultrasound equipment specifications and cost comparison.

Parameters	Option A: wired phased-array+linear	Option B: wired convex+linear	Option C: wireless phased-array+linear	Option D: wireless convex+linear
Representative device	BENQ T3300	BENQ T3300	Philips Lumify or GE Vscan air	Philips Lumify or GE Vscan air
Weight	2.7 kg (system)	2.7 kg (system)	<400 g (probe only)	<400 g (probe only)
Probe types	Phased-array+linear	Convex+linear	Phased-array+linear	Convex+linear
Imaging modes	B-mode, M-mode, and color Doppler	B-mode, M-mode, and color Doppler	B-mode, M-mode, and color Doppler	B-mode, M-mode, and color Doppler
Cost (NTD)[a]	1 million	1 million	550,000	500,000
Probe depreciation (years)	7	7	7	7
Portability rating	Moderate	Moderate	Excellent	Excellent
Disinfection ease	Moderate	Moderate	High	High



[a]NT $1=US $0.036 in 2021 on average. Costs reflect 2021 procurement prices. Depreciation follows the standard National Health Insurance medical equipment schedule.

B2B2C Teleconsultation Model

The teleconsultation workflow followed a B2B2C model (Figure 1A): the on-site D Clinic physician performed PoCUS examinations at the patient's home, streamed real-time ultrasound images and clinical findings to remote specialists (B2B component), who provided diagnostic interpretation and therapeutic recommendations that were communicated back to the patient and family (business-to-consumer [B2C] component). Sessions were categorized by consultation type: image interpretation with medication adjustment and image interpretation only. Dual-specialist consultations (cardiologist and hospitalist) were arranged for complex end-of-life cases involving multiorgan failure.

Figure 1. Business-to-business-to-consumer (B2B2C)–integrated point-of-care ultrasound (PoCUS)–teleconsultation model for home-based medical care. (A) Three-tier model showing remote specialists (business-to-business [B2B]), the D clinic on-site team (hub), and patients and families at home (business-to-consumer [B2C]). (B) Four clinical service domains identified through case-review analysis. I-AIM: indication, acquisition, interpretation, and medical decision-making; ICHOM: International Consortium for Health Outcomes Measurement; NHI: National Health Insurance.

Data Collection and Outcomes

Data were recorded routinely during clinical care and retrospectively compiled for this analysis; they included (1) monthly PoCUS examination counts by clinical setting (clinic, home visit, and mobile outreach) and examination type (abdominal, bladder, cardiac, musculoskeletal, thyroid, and extremity); (2) teleconsultation session characteristics, including specialist type, consultation duration, multitarget scanning status, and clinical indication; (3) qualitative learning curve indicators, including temporal trends in monthly volume, scope expansion, and communication competency milestones; and (4) clinical service domain categorization based on case-review analysis. Each PoCUS examination was defined as a single imaging study targeting 1 anatomical region (eg, cardiac, pulmonary, abdominal, or vascular). A single patient encounter could generate multiple examinations if multiple regions were scanned; the 676 examinations therefore represent imaging studies, not unique patient encounters. Billing classification followed NHI reimbursement rules: examinations qualifying under existing NHI ultrasound codes—abdominal ultrasound (19001C, 882 points), follow-up ultrasound (19009C, 643 points), and head-and-neck ultrasound for thyroid studies (19012C, 610 points)—were classified as billed, whereas point-of-care examinations reported under the generic “other ultrasound” code (19005C, 600 points) and abdominal screening performed without a specific coded indication were classified as unbilled. The clinic did not bill echocardiography (18005C). Clinical service domains were identified through retrospective case-review analysis conducted independently by both authors using a consensus-based approach. Teleconsultation sessions were initiated at the discretion of the on-site physician when clinical findings exceeded the scope of independent management or when multiorgan assessment required specialist input; no prespecified severity threshold was applied. All 26 sessions during the study period are reported; no eligible cases were excluded. The teleconsultation trigger rate was defined as the proportion of PoCUS examinations that prompted a real-time remote specialist consultation.

Financial Analysis

A 7-year net present value (NPV) analysis was performed to evaluate financial viability across 24 scenarios combining 4 equipment options (Table 1) with 6 consultation reimbursement structures, using the cost and volume parameters of the source financial model developed for this service [22]. Equipment costs (NT $1=US $0.036 in 2021 on average) ranged from NT $500,000 (wireless convex and linear) to NT $1 million (wired phased-array and linear or wired convex and linear), with the ultrasound probe depreciated over 7 years and ancillary electronic equipment over 3 years (Table S5 in Multimedia Appendix 1). All 24 scenarios, together with the record of their verification against that model, are provided in Multimedia Appendix 2. Proposed reimbursement rates included NT $3000 per remote specialist session (image interpretation and medication adjustment) or NT $2000 (image interpretation only), plus NT $1200 for an on-site multitarget PoCUS examination. Case volume projections followed: year 1, 26

XSL•FO
RenderX

cases; year 2, 57; year 3, 80; and steady-state (years 4-7), 100 cases annually. A 6% discount rate was applied. Break-even analysis identified the minimum monthly case volume required for each scenario. Under the current NHI framework, no dedicated B2B teleconsultation fee exists; the proposed reimbursement rates used in modeling reflect advocacy proposals. Remote specialists participated through professional collegial arrangements during the study period without direct NHI reimbursement. Sensitivity analyses varying the discount rate (3%-9%), steady-state annual case volume (50-125), and remote specialist fee are reported in Multimedia Appendix 1. Equipment was depreciated on a mixed schedule following the source model: the ultrasound probe and teleconsultation cart over 7 years and all ancillary electronic equipment over 3 years, with corporate income tax (17%) applied to positive pretax profit from the third year onward. A complete depreciation schedule and a year-by-year cash-flow reconciliation for the top-ranked scenario are provided in Tables S5 and S6 of Multimedia Appendix 1. The financial model and the clinical case study data reported here derive from an executive master of business administration (MBA) thesis by HBT [22], a retrospective business-model case study of D Clinic. Reused elements comprise the equipment cost structure, the reimbursement assumptions, and the 24 modeled scenarios (appendix 1 in HBT's thesis [22]); the examination and teleconsultation counts in Tables 2 and 3 (the table labeled 4-4 in HBT's thesis [22]); the 4 service domains; and the learning curve observations. This report also adds an independently reproducible year-by-year NPV recomputation with sensitivity analysis and a structured clinical-implementation presentation following the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) reporting guideline.

PoCUS Training and Quality Assurance

All 3 clinic physicians (2 in family medicine and 1 in neurology) completed a 40-hour PoCUS training program accredited by the Taiwan Society of Ultrasound in Medicine, consisting of 16 hours of didactic instruction covering cardiac, pulmonary, abdominal, and vascular applications, and 24 hours of supervised hands-on scanning. An additional 8-hour musculoskeletal PoCUS workshop in October 2021, led by a board-certified rehabilitation medicine specialist, expanded the examination repertoire. All 3 physicians performed PoCUS examinations during the study period in approximately equal proportions when on duty. The reported use patterns therefore reflect a multiprovider implementation metric rather than an individual practitioner trajectory. Ongoing quality assurance was maintained through the I-AIM framework, with teleconsultation images reviewed by the remote specialist in real time. No formal competency assessment tool (eg, Objective Structured Assessment of Ultrasound Skills) was applied; image archiving was limited to representative still images shared via the teleconsultation platform.

Ethical Considerations

This study was conducted in accordance with the Declaration of Helsinki. The PoCUS-teleconsultation service was established in April 2020 as a clinical quality improvement initiative within the home-based medical care program at D Clinic. Throughout the service period (April 2020 to May 2022), examination, teleconsultation, and cost data were recorded as part of routine service documentation and internal quality monitoring rather than under a research protocol. After the service period had ended, the investigators judged that the accumulated implementation experience and financial data had value beyond internal quality improvement, and the activity was accordingly converted into a formal research study. Ethics approval was therefore sought and obtained after data collection had been completed. The study protocol (version 2, July 31, 2023) was reviewed and approved by the National Taiwan University Hospital Research Ethics Committee C through expedited review (202112086RINC) on August 21, 2023, approximately 15 months after the end of the study period. The approval covers the retrospective analysis and publication of the deidentified clinical, operational, and cost data collected between April 2020 and May 2022. Written informed consent for teleconsultation was obtained from all patients or their legal representatives prior to each session, covering both the clinical procedure and the use of anonymized data for quality improvement reporting. Because the service was later converted into a formal research study, the subsequent research ethics committee approval (202112086RINC) specifically covers the retrospective use of these deidentified data for research and publication, extending the original quality improvement consent to the research use reported here. Separate informed consent forms were approved for community and remote medical care, expert consultation meetings, and patient and family participation in teaching recordings. All real-time ultrasound streaming was conducted via encrypted video calls within a password-protected clinical network.

Results

PoCUS Use Patterns

The 26 patients enrolled in the PoCUS-teleconsultation service had a mean age of 79.4 (SD 9.2) years; 15 (58%) were male. A total of 20 (77%) were in the intensive home health care tier (Barthel Index <35), 4 (15%) were in standard home health care (Barthel Index <60), and 2 (8%) were in palliative home care. The most common primary diagnoses were cerebrovascular disease (n=8, 31%), heart failure (n=6, 23%), and chronic kidney disease (n=4, 15%). During the 26-month study period (April 2020 to May 2022), a total of 676 PoCUS examinations were performed across 3 clinical settings: 375 (55.5%) in clinic, 174 (25.7%) during home visits, and 127 (18.8%) during mobile outreach (Figure 2A). Abdominal examinations constituted the largest category, with 210 (31.1%) unbilled PoCUS screening examinations and 167 (24.7%) billable abdominal ultrasounds (Figure 2B). Bladder ultrasound (n=102, 15.1%), musculoskeletal PoCUS (n=76, 11.2%), thyroid ultrasound (n=35, 5.2%), and cardiac PoCUS (n=29, 4.3% screening and n=36, 5.3% focused, for a total of n=65, 9.6%) accounted for most of the remainder, with follow-up abdominal ultrasound (n=15, 2.2%) and extremity PoCUS (n=6, 0.9%) making up the smallest categories (Table 2). Examinations were logged at the encounter level in the clinic's routine service record, which did not link individual examinations to patient identifiers; the number of distinct patients contributing to the 676 examinations

XSL•FO
RenderX

therefore cannot be established retrospectively. Patient-level characteristics are consequently reported only for the 26 patients who received teleconsultation, for whom individual case records were maintained.

Figure 2. Distribution of point-of-care ultrasound (PoCUS) examinations by clinical setting and examination type (N=676). (A) Donut chart showing distribution across 3 clinical settings; (B) horizontal bar chart of examination types, sorted by frequency; and (C) teleconsultation trigger rate by clinical setting. US: ultrasound.

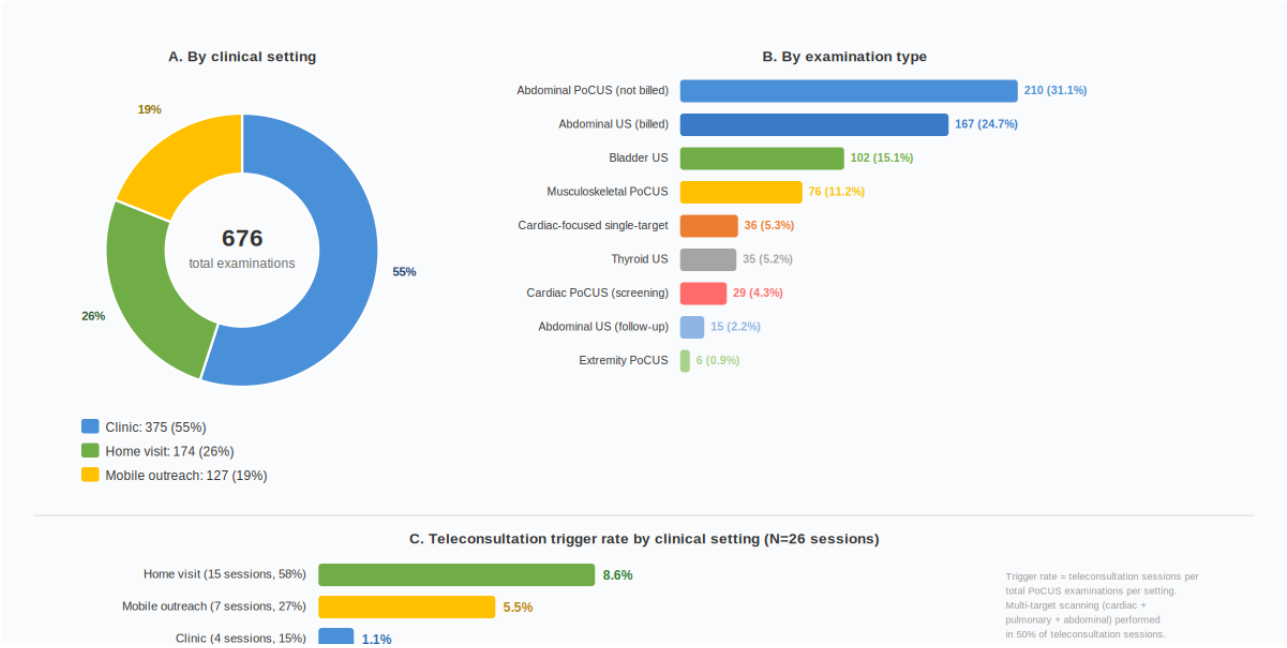

Table 2. Point-of-care ultrasound (PoCUS) examinations by clinical setting and examination type (N=676).

Examination type	Clinic (n=375), n (%)	Home visit (n=174), n (%)	Mobile outreach (n=127), n (%)
Abdominal PoCUS (not billed)	101 (26.9)	73 (42)	36 (28.3)
Abdominal ultrasound (billed, 19001C)	100 (26.7)	29 (16.7)	38 (29.9)
Bladder ultrasound	50 (13.3)	42 (24.1)	10 (7.9)
Musculoskeletal PoCUS	54 (14.4)	4 (2.3)	18 (14.2)
Thyroid ultrasound	34 (9.1)	0 (0)	1 (0.8)
Cardiac-focused single-target PoCUS	10 (2.7)	17 (9.8)	9 (7.1)
Cardiac PoCUS (screening)	8 (2.1)	6 (3.4)	15 (11.8)
Abdominal ultrasound (follow-up, 19009C)	12 (3.2)	3 (1.7)	0 (0)
Extremity PoCUS	6 (1.6)	0 (0)	0 (0)

Teleconsultation Characteristics

Twenty-six teleconsultation sessions were conducted from March 2021 to May 2022: 15 (57.7%) during home visits, 7 (26.9%) during mobile outreach, and 4 (15.4%) in clinic (Table 3). The teleconsultation trigger rate—defined as the proportion of PoCUS examinations prompting specialist consultation—was highest during home visits (15/174, 8.6%), followed by mobile outreach (7/127, 5.5%) and in-clinic examinations (4/375, 1.1%; Figure 2C). Multitarget scanning involving cardiac, pulmonary, and abdominal assessment was performed in 50% (13/26) of teleconsultation sessions. Session duration was typically 30 minutes, with complex dual-specialist consultations extending to 50 minutes. Of the 26 sessions, 24 (92%) were completed without technical interruption. Only 2 (8%) sessions experienced transient 4G connectivity degradation, resulting in temporary image buffering lasting 30 to 90 seconds, but both were completed after signal recovery. No sessions were aborted due to technical failure.

XSL•FO
RenderX

Table 3. Teleconsultation session characteristics (N=26).

Characteristics	Sessions, n (%)
Setting	
Home visit	15 (57.7)
Mobile outreach	7 (26.9)
Clinic	4 (15.4)
Specialist type	
Cardiologist only	12 (46.2)
Hospitalist only	6 (23.1)
Dual specialist (cardiologist+hospitalist)	8 (30.8)
Multitarget scanning (cardiac+pulmonary+abdominal)	13 (50)
Session duration (minutes)	
≤30	18 (69.2)
31-50	8 (30.8)
Consultation type	
Image interpretation+medication adjustment	18 (69.2)
Image interpretation only	8 (30.8)
Teleconsultation trigger rate[a]	
Home visit (n=174)	15 (8.6)
Mobile outreach (n=127)	7 (5.5)
Clinic (n=375)	4 (1.1)

[a]For the teleconsultation trigger rate rows, percentages are calculated using the total number of point-of-care ultrasound (PoCUS) examinations performed in the respective clinical setting as the denominator because the trigger rate represents the proportion of PoCUS examinations that prompted a teleconsultation.

Learning Curve Dynamics

Monthly PoCUS volume demonstrated a progressive growth pattern, reaching a sustained plateau of ≥28 examinations per month from August 2021 onward. Three distinct learning phases were observed: (1) an initiation phase (April 2020 to July 2020) characterized by low monthly volume, primarily limited to abdominal and bladder applications; (2) an expansion phase (August 2020 to July 2021) with progressive incorporation of cardiac and thyroid examinations and increasing home-visit use; and (3) a maturation phase (August 2021 to May 2022) marked by sustained high-volume practice, rapid musculoskeletal PoCUS growth following an October 2021 training workshop, and qualitative improvements in diagnostic communication, ultrasound terminology, and the use of proactive provisional diagnoses by on-site physicians during teleconsultation [22].

Clinical Service Domains

Case-review analysis identified 4 distinct clinical service domains of PoCUS-teleconsultation integration (Figure 1B).

Domain 1: HaH Acute Management

PoCUS-guided fluid assessment (cardiac function, pleural effusion, and inferior vena cava dimensions) with remote cardiologist input enabled diuretic titration for acutely decompensated heart failure without hospital transfer. Real-time ultrasound streaming allowed the remote specialist to guide probe positioning and confirm findings before recommending medication adjustments.

Domain 2: Home-Based Hospice Multiorgan Support

End-of-life patients with concurrent cardiac and renal failure required dual-specialist teleconsultation (cardiologist and hospitalist). Multitarget PoCUS scanning enabled comprehensive organ assessment to support advance care planning discussions under Taiwan's Patient Right to Autonomy Act [23]. This domain corresponded to the highest-NPV financial scenario.

Domain 3: Green Channel Surgical Referral

PoCUS findings indicating potential surgical emergencies—including septic arthritis with joint effusion, large pericardial effusion, and acute abdominal pathology—triggered expedited "green channel" transfer to Taitung Mackay Memorial Hospital. PoCUS-documented findings accompanying the referral facilitated prearrival surgical planning and reduced emergency department triage time.

Domain 4: Chronic Disease Serial Monitoring

Serial PoCUS examinations (cardiac function, pleural effusion, inferior vena cava dimensions, and bladder residual volume) provided objective longitudinal data for chronic disease medication titration, complementing the NHI

XSL•FO
RenderX

pay-for-performance programs for diabetes, chronic kidney disease, chronic obstructive pulmonary disease, and hepatitis B or C.

Financial Analysis

No adverse events attributable to the PoCUS-teleconsultation workflow were identified during the study period. No cases of delayed diagnosis, missed surgical emergency, or medication error resulting from teleconsultation-guided adjustment were documented. However, formal adverse event tracking was not implemented as a structured protocol.

NPV analysis across 24 scenarios revealed a clear bifurcation between wireless and wired equipment viability (Figure 3). The top 5 positive-NPV scenarios all involved wireless PoCUS equipment (Table 4); the complete set of 24 scenarios is reported in Multimedia Appendix 2. The highest-NPV scenario—dual-specialist teleconsultation with medication adjustment using wireless convex and linear probes (option D)—yielded an NT $882,000 NPV over 7 years with a break-even threshold of only 2.72 monthly cases, a volume consistent with the observed teleconsultation pattern. Single-specialist cardiology teleconsultation with medication adjustment using wireless phased-array and linear probes (option C) achieved a positive NPV with a break-even threshold of 6.65 monthly cases—achievable with moderate use growth. In contrast, every wired equipment scenario (options A and B) returned a negative NPV, with break-even thresholds ranging from 4.09 to 20.38 monthly cases, rendering them financially unfavorable under the modeled assumptions at current or projected use levels.

Figure 3. Seven-year net present value (NPV) analysis of point-of-care ultrasound (PoCUS)–teleconsultation scenarios. (A) Top 5 scenarios with positive NPV, ranked as reported in Table 4, with corresponding clinical applications. (B) NPV comparison across 4 equipment options under the optimal dual-specialist and medication adjustment (Rx) scenario. The discount rate was 6%. Green bars indicate positive NPV, and red bars indicate negative NPV. BE: break-even; CL: convex+linear; HF: heart failure; PL: phased-array+linear.

XSL•FO
RenderX

Table 4. Top 5 positive net present value (NPV) scenarios for point-of-care ultrasound—teleconsultation integration[a].

Rank	Consultation type	Equipment	NPV (NT $[b])	Break-even volume (cases/month)	Primary clinical application
1	Dual specialist+Rx[c]	Option D: wireless CL[d]	882,000	2.72	Hospice: cardiac and renal failure and medication adjustment
2	Dual specialist+Rx	Option C: wireless PL[e]	822,000	2.86	Hospice: detailed cardiac assessment and medication adjustment
3	Dual-specialist image	Option D: wireless CL	137,000	5.04	Hospice: transfer decision or advance care planning
4	Cardiology+Rx	Option C: wireless PL	115,000	6.65	Intensive home care: heart failure medication titration
5	Dual-specialist image	Option C: wireless PL	92,000	5.29	Hospice: cardiac and renal evaluation for transfer decisions

[a]Discount rate was 6%. Depreciation followed a mixed schedule, with the probe and cart depreciated over 7 years and ancillary equipment over 3 years (Table S5 in Multimedia Appendix 1). All NPVs and break-even figures were independently recomputed from the source cost structure and reproduced the source model, except for the rank 4 break-even value (6.65 monthly cases), which was taken directly from the source text and was not independently recomputed because the underlying variable-cost rows were incompletely legible in the source document.

[b]NT $1=US $0.036 in 2021 on average.

[c]Rx: medication adjustment.

[d]CL: convex+linear.

[e]PL: phased-array+linear.

Under the existing NHI reimbursement structure—in which multitarget bedside examinations fall only under a generic "other ultrasound" code (19005C, 600 NHI points), with no dedicated multitarget or B2B specialist fees—equipment cost recovery would require approximately 14.6 years, exceeding the equipment depreciation horizon and underscoring the urgent need for reimbursement reform.

Discussion

Principal Findings

This study represents, to our knowledge, the first report of integrated PoCUS-teleconsultation implementation within a dedicated home-based medical care practice in an Asian setting and the first to provide financial modeling for such integration under different reimbursement scenarios. Our findings extend the existing evidence base in several important dimensions.

Comparison With Existing Evidence

Our 676-examination dataset represents the largest reported PoCUS use series in an Asian home-based care context. The observed teleconsultation trigger rate of 8.6% during home visits aligns with the concept of PoCUS as a diagnostic triage tool—identifying cases requiring specialist input while enabling most examinations to inform on-site clinical decisions independently. This pattern is consistent with findings by Kirkpatrick et al [15] that novice operators can achieve diagnostic-quality PoCUS images in home settings with remote guidance and supports the broader tele-ultrasound evidence synthesized by Recker et al [24].

The progressive learning curve that reached a sustained plateau of 28 or more monthly examinations by month 17 of implementation is notable. Although formal competency frameworks, such as I-AIM, define individual skill acquisition milestones [12,13], our data suggest that practice-level adoption follows a distinct trajectory characterized by volume growth, scope expansion (particularly musculoskeletal applications postworkshop training), and qualitative communication maturation during teleconsultation encounters.

International comparison supports the relevance of these findings. A Spanish HaH PoCUS study [25] reported 85 ultrasounds among 72 patients, with hospital displacement avoided in 73% of cases, and the Canadian ACCUMEN-POCUS (Aiding Chronic Obstructive Pulmonary Disease and Congestive Heart Failure Ultrasound-Guided Management Through Enhanced Point-of-Care Ultrasound) trial [26] represents the first randomized controlled trial protocol evaluating remotely interpreted PoCUS in HaH settings. A 2024 scoping review of tele-ultrasound [27] identified connectivity, training, and regulatory frameworks as key enablers, consistent with the barriers observed in our implementation.

The B2B2C Model: Policy Implications

Our B2B2C teleconsultation model addresses a structural gap in existing telemedicine frameworks, which predominantly assume a direct physician-to-patient (B2C) or physician-to-physician referral (B2B) paradigm. The integrated model—where an on-site generalist performs PoCUS, streams findings to a remote specialist who provides diagnostic and therapeutic guidance that is communicated back to the patient—creates value at multiple levels consistent with the Porter high-value health care framework [28]. For patients, the model avoids the physical, emotional, and financial burden of hospital transfer; for the health care system, it may reduce emergency department use and inpatient admissions; and for clinicians, it enables knowledge transfer and progressive skill development.

South Korea's experience with dedicated PoCUS reimbursement codes provides evidence supporting the role of reimbursement

XSL•FO
RenderX

policy in driving use [20,21]. Kang et al [20] demonstrated a 4-fold increase in emergency department PoCUS use following the introduction of STU and MTU codes in July 2019. Taiwan's NHI system should consider adopting analogous codes to incentivize PoCUS integration in home-based care settings.

The 2024 amendments removing geographic restrictions on telemedicine were enacted after the study period (2020 to 2022). Our operational data were generated under the pre-2024 regulatory framework, which restricted teleconsultation to patients in designated remote areas, long-term care facilities, or emergencies. The financial model applicability may differ under the expanded 2024 framework, where eligibility is broader, but reimbursement structures may also evolve.

Challenges and Barriers

Several challenges were identified during implementation. First, the absence of dedicated NHI reimbursement for multitarget bedside ultrasound and B2B specialist teleconsultation represents the primary barrier to financial sustainability. The current generic code (19005C, 600 points) grossly undervalues the clinical and time investment required for comprehensive cardiac, pulmonary, and abdominal PoCUS assessment with real-time specialist guidance. Second, 4G network latency in mountainous Taitung terrain occasionally compromised real-time image streaming quality; Taiwan's 5G infrastructure expansion pilot in Taitung offers a potential solution [29]. Third, the limited pool of specialists willing to participate in B2B teleconsultation—particularly during nonbusiness hours—constrains service scalability. Finally, I-AIM documentation requirements add approximately 5 to 10 minutes per examination, which may limit adoption in time-pressured home-visit contexts.

The study period (April 2020 to May 2022) overlapped substantially with the COVID-19 pandemic, which may have influenced findings in several ways. Temporary NHI regulatory relaxations expanded telemedicine eligibility, potentially increasing clinician willingness to adopt teleconsultation. Infection control concerns may have increased preference for remote specialist input over in-person referrals. Conversely, pandemic-related travel restrictions reduced mobile outreach capacity during local outbreak periods. The extent to which the normalization of postpandemic regulations will affect teleconsultation demand remains uncertain.

Strengths and Limitations

This study has several strengths: real-world implementation in a resource-constrained rural setting, a substantial PoCUS use dataset (676 examinations over 26 months), and an integrated financial analysis framework. However, several limitations should be noted. First, the single-site design with 3 operators limits external validity, although the multiprovider implementation strengthens the generalizability of the learning curve observations compared with those of a single-operator study. Second, the small teleconsultation sample (n=26, 3.8% of total examinations) constrains conclusions about teleconsultation scalability and effectiveness. Third, D Clinic is a dedicated home-based medical care practice; traditional rural clinics would face substantially different operational barriers to implementing this model. Fourth, examinations were recorded at the encounter level without linkage to patient identifiers, so the number of unique patients underlying the 676 examinations could not be determined; use is therefore expressed as examinations rather than as examinations per patient, and the extent of repeat scanning in individual patients is unknown. Fifth, the financial analysis relies on proposed reimbursement rates not yet adopted by NHI, making the projections hypothetical. Sixth, adverse event tracking was observational rather than protocol-driven. Seventh, confirmatory diagnosis rates for PoCUS-triggered surgical referrals were not tracked. Eighth, the study period overlapped with the COVID-19 pandemic, which may have influenced teleconsultation adoption. Finally, patient-reported outcome measures (PROMs) and patient-reported experience measures (PREMs) were not collected.

Future Directions

Although these findings suggest potential policy directions, including dedicated NHI reimbursement codes for multitarget bedside ultrasound and B2B teleconsultation fees, the absence of controlled clinical outcome data means that these recommendations should be considered preliminary. Rigorous multisite studies with patient-level outcome measurement, formal cost-effectiveness analysis, and comparison with standard care pathways are needed before advocating for national reimbursement policy changes. Future work should also evaluate the model across diverse rural settings with varying digital infrastructure, physician density, and patient demographics.

Conclusions

This pilot study demonstrates the feasibility of integrating PoCUS into rural home-based medical care, with 676 examinations across 3 clinical settings over 26 months. The teleconsultation component, while limited to 26 sessions (3.8% of total examinations), illustrated the operational workflow and potential clinical utility of the B2B2C model. Financial scenario modeling suggests favorable projected returns for wireless equipment configurations under proposed but not yet implemented reimbursement structures. These findings should be interpreted as hypothesis generating and as a basis for future multisite studies with patient-level outcome measurement rather than as definitive evidence of clinical effectiveness or financial viability.

Acknowledgments

The authors thank the physicians, nurses, and staff of D Clinic for their dedication to delivering home-based care. The authors acknowledge the remote specialists for their participation in the teleconsultation service. The authors also thank the patients and families who consented to participate in teleconsultation sessions. Generative AI (Claude Opus 4.8; Anthropic PBC) was used

All authors approved the final version of the manuscript.

Conflicts of Interest

SJY is the founder and medical director of D Clinic, which creates a potential for reporting bias. To mitigate this, all financial assumptions were benchmarked against published National Health Insurance (NHI) reimbursement rates and standard equipment procurement costs rather than clinic-specific negotiated prices. Volume projections were subjected to sensitivity analysis. The first author (HBT) independently verified all data tabulations and financial calculations. None of the authors have financial relationships with ultrasound equipment manufacturers, and no other authors declare any conflicts of interest.

Abstract

Background: Timely access to stroke care is critical for patient prognosis. Despite the growing use of digital health strategies in stroke management, evidence supporting seamless and timely care coordination from the emergency medical services (EMS) to the emergency department (ED) remains limited. *Brain Saver*, a newly developed mobile app, addresses this gap by facilitating real-time data sharing between EMS personnel and ED clinicians during stroke transport.

Objective: This study aimed to examine the potential of the Brain Saver protocol to improve existing EMS-ED workflows in emergency stroke transport by describing its functional components, implementing a pilot intervention in a real-world setting, and exploring its preliminary impact on treatment timeliness.

Methods: Data were collected in Pohang, South Korea, from December 2023 to April 2024 through collaboration with 2 fire stations, eight 119 EMS and safety centers, 3 hospitals, and SEERS Technology. Preintervention training and postintervention surveys were conducted among EMS personnel (n=80) and clinicians (n=24). In this pilot, patients with stroke (*ICD-10* [*International Classification of Diseases, Tenth Revision*] codes I60-I63) in the intervention group (n=34) were transported using ambulances equipped with the Brain Saver mobile app, while the comparison group (n=129) was transported by standard ambulances to the same hospitals during the study period. With “needle” defined as any parenteral treatment, onset-to-door time

XSL•FO
RenderX

and door-to-needle time were compared by group. After exact matching on age, baseline stroke severity, stroke type, and destination hospital, intervention effects were estimated using generalized estimating equations.

Results: Participants (N=163) had a mean age of 69.4 (SD 15.2) years, 50.3% (82/163) were male, and 65.6% (107/163) had ischemic stroke. No significant baseline differences, including stroke severity, were observed between groups. The median onset-to-needle time was shorter in the intervention group than in the comparison group (114 vs 204 minutes; *P*=.03). In the matched analytic sample (n=91), the intervention group showed significant reductions in onset-to-needle time (Exp(β)=0.49; *P*=.009) and door-to-needle time (Exp(β)=0.67; *P*=.04) compared with the comparison group.

Conclusions: Integrating digital health into emergency stroke transport may improve care timeliness by supporting real-time prehospital notification and facilitating prompt in-hospital responses. The Brain Saver mobile app shows potential use for reducing onset-to-treatment time. Further larger-scale studies are needed to evaluate implementation fidelity and scalability.

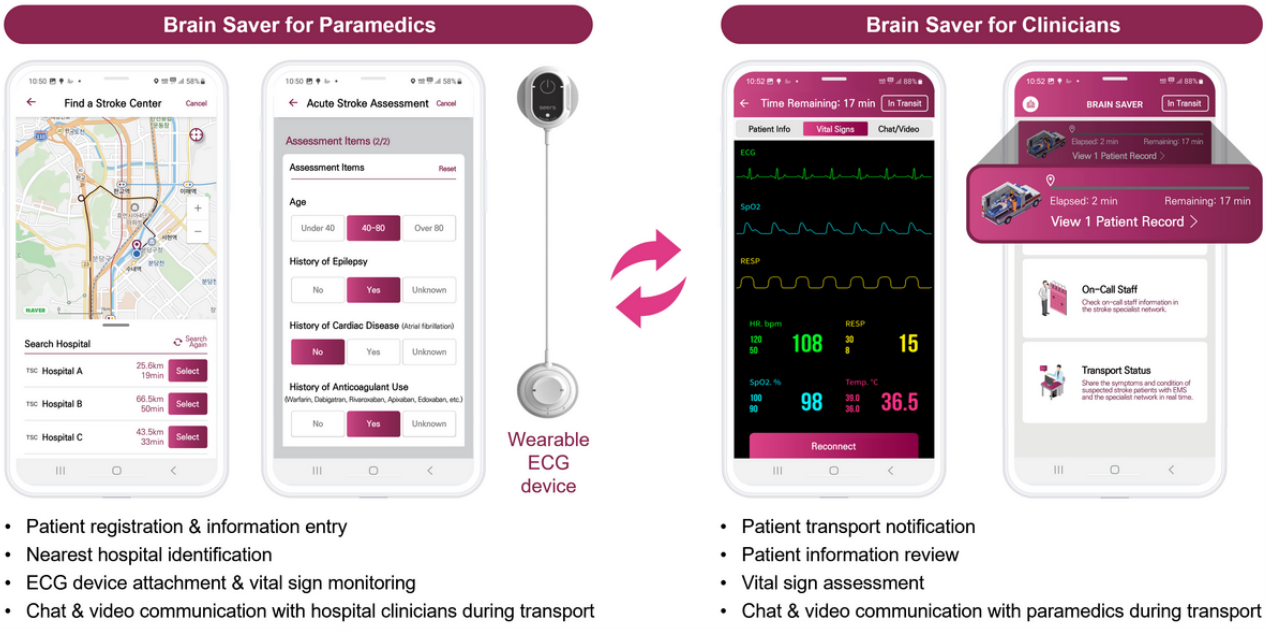
KEYWORDS

digital health; emergency medical services; mobile apps; stroke; time-to-treatment; transportation of patients

Introduction

Rapid response at stroke onset is critical in minimizing stroke-related brain damage, reflecting the principle that “time is brain” [1]. Early transport and treatment after stroke symptom onset are associated with better outcomes, including lower in-hospital mortality [2,3] and improved functional recovery [4,5]. Accordingly, clinical guidelines for acute ischemic stroke emphasize timely care by minimizing prehospital delays and achieving treatment within 3-4.5 hours of symptom onset [6-8].



To improve access to stroke care and management, a range of digital health approaches have been developed [9]. In particular, mobile apps have demonstrated potential in reducing delays in stroke detection and clinical evaluation. For example, wearable devices paired with mobile apps can capture vital signs and detect abnormal pulse patterns, prompting timely medical attention [10]. Other applications use smartphone-based image or sensor data to identify stroke-related symptoms and activate emergency responses [11,12]. To optimize in-hospital stroke workflows, applications enabling real-time sharing of patient information among on-call stroke team members have been shown to improve interdepartmental team coordination and reduce door-to-needle time [13]. Similarly, a real-time feedback platform for paramedics and the stroke team generates automated time stamps across the stroke care continuum upon app activation, enabling more efficient monitoring of treatment timelines [14].

However, digital health strategies that explicitly integrate emergency medical services (EMS) and emergency department (ED) processes for stroke care remain limited. Although EMS-based hospital admission and direct access to specialized stroke care are key determinants of early presentation [15,16], timely transport of patients with acute stroke to appropriate facilities continues to pose a major challenge, particularly in medically underserved areas [17,18]. Notably, few studies have empirically evaluated such integrated digital interventions within real-world EMS transport settings. Therefore, further empirical evidence is needed to assess the added value of digital health technologies in improving stroke transport efficiency and rapid ED response.

To address this gap, this study implemented an intervention program using a newly developed mobile app, Brain Saver, together with a wearable electrocardiogram device (Figure 1). This app was designed with separate interfaces for paramedics and clinicians to support emergency stroke transport across EMS and ED workflows. When EMS personnel (paramedics) identify a patient with suspected stroke at the scene, they activate the app, enter patient information using 10 assessment items to generate stroke diagnostic scores, and attach a wearable electrocardiogram device. The paramedic interface provides GPS-based hospital recommendations and displays nearby hospitals with maps. After hospital selection, transport-start alerts are automatically sent to the clinician interface. During transport, clinicians can monitor patients’ symptoms, diagnostic scores, electrocardiogram data, and transport status in real time, while paramedics and clinicians communicate through messaging or video calls when needed. Detailed interfaces and functions are provided in Multimedia Appendix 1.

Figure 1. Primary functions of the Brain Saver app. When paramedics activate the app and select the nearest hospital, clinicians receive transport-start alerts and patient information through the app. ECG: electrocardiogram.

This study aimed to examine the potential of the Brain Saver protocol to improve existing EMS-ED workflows. The specific objectives were to (1) describe the development and functional components of the Brain Saver mobile app, (2) document its real-world implementation in emergency stroke transport, and (3) explore its preliminary impact on transport and treatment timeliness.

Methods

Digital Health Intervention: Brain Saver Protocol

This study was conducted in Pohang-si, Gyeongsangbuk-do, South Korea, through a regional Memorandum of Understanding involving Pohang Nambu and Pohang Bukbu fire stations with 2 rescue and EMS centers and six 119 safety centers under their jurisdiction, 3 hospitals, and SEERS Technology. The study comprised (1) preimplementation training, (2) a pilot phase, and (3) a postimplementation survey of app users. To ensure rigorous digital health implementation, the Guidelines and Checklist for the Reporting on Digital Health Implementations (iCHECK-DH) was applied (Multimedia Appendix 2).

Training for EMS Personnel and Clinicians

Before the pilot demonstration, preimplementation training was provided to EMS personnel and clinicians on the use of Brain Saver to clarify roles, standardize handoffs, and reduce field-level confusion. For EMS personnel, training was delivered to 80 staff from 2 fire stations through 6 on-site sessions held from November 13-15, 2023. The curriculum covered when to initiate Brain Saver, how to register patients and enter standardized patient symptoms, how to use distance-based hospital selection, and how to attach the wearable electrocardiogram device for real-time sharing of vital signs with clinicians. For clinicians, training was provided to 24 clinicians on November 22 and 28, 2023, through 3 hospital-specific briefing sessions. Training positioned Brain Saver as a prearrival preparation support tool and focused on standardizing notification handling, patient verification, and readiness procedures. Clinicians were instructed in on-call registration and alert receipt, as well as how to review the app interface.

Pilot Program Process

The pilot intervention program of Brain Saver–based transports was conducted from December 11, 2023, to April 5, 2024, following a standardized end-to-end process that connected EMS-side actions with clinician-side preparation (Table 1).

XSL•FO
RenderX

Table 1. Ten-step Brain Saver process and comparison with the conventional emergency medical services (EMS)-emergency department (ED) workflow.

Step	Activity	Responsible agent	Brain Saver workflow	Conventional EMS-ED workflow
1	Patient occurrence and EMS dispatch	Paramedics	Dispatch EMS after emergency call receipt	Dispatch EMS after emergency call receipt
2	Patient registration	Paramedics	Activate the app interface and enter on-site patient assessment information	Document on-site patient assessment records on paper-based forms
3	Hospital selection and transport	Paramedics	Select the nearest hospital based on app recommendations using GPS	Confirm hospital availability through repeated telephone-based calls until acceptance
4	Transport notification	Clinicians	Receive transport-start and 5-minute-before-arrival alerts	N/A[a]
5	Vital sign recording	Paramedics	Attach a wearable ECG[b] device that transmits vital signs to the app in real time	Perform conventional 12-lead ECG recording and review printed ECG data
6	Prearrival information review	Clinicians	Review app-based diagnostics (Step 2) and vital signs (Step 5) before arrival	N/A
7[c]	Prearrival communication	Paramedics and clinicians	Communicate via messaging or video calls when needed	Communicate via telephone when needed
8	Preparation for patient management	Clinicians	Prepare for in-hospital management before arrival using alerts and patient information	N/A
9	Hospital arrival and handover	Paramedics	Arrive at the hospital and hand over the patient	Arrive at the hospital and hand over the patient with printed ECG data
10	Patient management	Clinicians	Initiate treatment through a preprepared in-hospital workflow	Review the printed ECG data, determine clinical care, and initiate treatment

[a]N/A: not available.

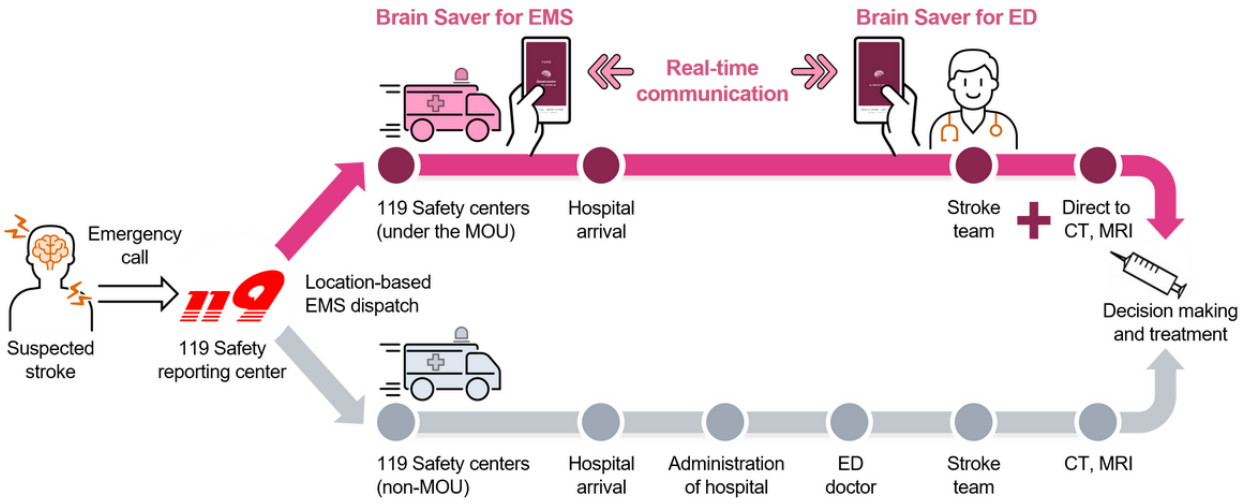
[b]ECG: electrocardiogram.

[c]Step 7 is optional and performed only when prehospital communication and treatment are needed.

For EMS personnel, the pilot workflow began at the scene when a patient was judged to be a suspected stroke case. They launched the app and recorded standardized patient information, then selected a destination hospital using distance-based recommendations, which automatically issued a transport-start alert and provided patient information to on-call clinicians. During transport, EMS personnel attached the wearable electrocardiogram device and shared vital signs through the app, and after arrival, handed over the patient to the stroke team in the ED.

For clinicians, on-call staff were provided with a dedicated Brain Saver smartphone during on-call handover. They received app-based notifications at transport initiation and again 5 minutes before arrival. Clinicians monitored incoming patients' stroke symptoms, diagnostic scores, vital signs, and transport status in real time. When needed, they communicated with EMS personnel via messaging or video calls.

Compared with conventional EMS-ED workflows, Brain Saver provides clinicians with real-time transport notifications (Step 4) and prearrival patient information review (Step 6). These functions facilitate prearrival preparation in the ED (Step 8), whereas conventional workflows allow patient assessment only after hospital arrival without prearrival alerts. For EMS personnel, Brain Saver supports hospital selection (Step 3) and digitizes several previously paper-based or manual processes (Steps 2, 3, and 5).



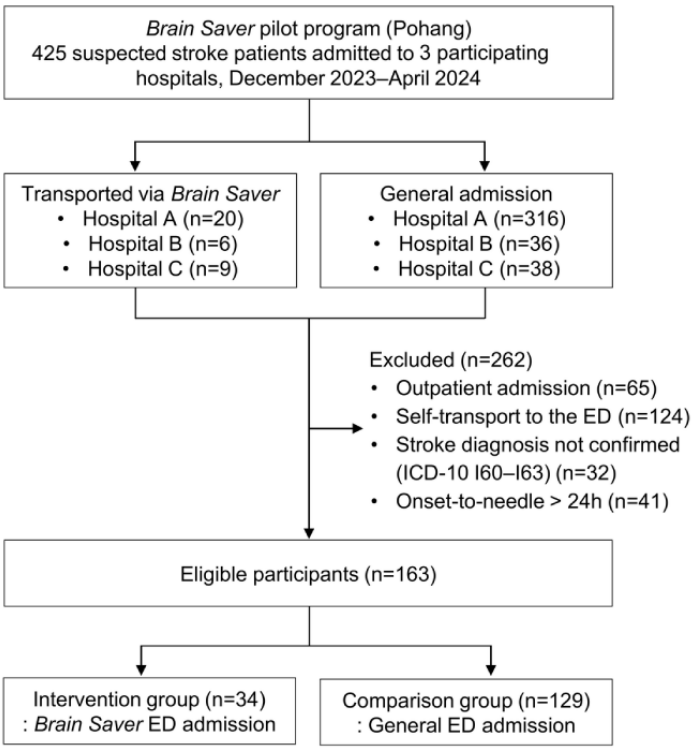
A postimplementation survey of app users was conducted from April 3 to 19, 2024, to assess Brain Saver usability and to identify user needs encountered during real-world operation. The survey was distributed to all individuals who had completed the pretraining, yielding response rates of 52.5% (42/80) for EMS personnel and 54.2% (13/24) for clinicians.

Study Design

To assess the effect of the pilot intervention program, we defined an intervention group and a comparison group based on the intervention allocation process (Figure 2). When patients with suspected stroke contacted the 119 safety reporting center, the nearest 119 safety center was dispatched according to the patient's location, as each center operates within an assigned jurisdiction. Detailed geographic information on the study regions is provided in sections A and B in Multimedia Appendix 3.

XSL•FO
RenderX

Figure 2. Emergency stroke transport scenarios for comparison and intervention groups. Depending on the emergency medical services (EMS) dispatch site, patients transported by Brain Saver–equipped ambulances were assigned to the intervention group, whereas those transported by conventional ambulances were assigned to the comparison group. CT: computed tomography; ED: emergency department; MOU: Memorandum of Understanding; MRI: magnetic resonance imaging.



The intervention group comprised patients with stroke transported by Brain Saver–equipped ambulances from 8 participating 119 safety centers (2 rescue and EMS and 6 safety centers) to the EDs of 3 hospitals. The comparison group consisted of patients with stroke transported to the same EDs by conventional ambulances from the remaining eight 119 safety centers or by private ambulances during the study period in Pohang-si, Korea. This group served as a nonequivalent control group without random assignment, consistent with a quasi-experimental study design.

Study Population

We initially defined the target population as all patients with suspected stroke transported by ambulance, whereas the study population was restricted to patients with confirmed ischemic or hemorrhagic stroke (*ICD-10* codes I60-I63). A total of 425 patients with suspected stroke admitted to the 3 hospitals during the study period were identified. Patients without confirmed stroke diagnoses were present only in the comparison group (n=32) and were excluded to improve comparability between groups. Eligibility was restricted to patients transported to the ED by ambulance, excluding those admitted via outpatient clinics (n=65) or self-transport (n=124). Nonacute cases with symptom onset-to-needle times exceeding 24 hours were also excluded (n=41), consistent with the study focus on acute stroke transport. Ultimately, 163 consecutive patients comprised the analytic population (34 in the intervention and 129 in the comparison group; Figure 3).

XSL•FO
RenderX

Figure 3. Flowchart of study population selection. Three participating hospitals in Pohang-si, South Korea, identified 425 suspected stroke admissions between December 2023 and April 2024. After exclusions, 163 ambulance-transported patients with confirmed stroke were included. ED: emergency department; ICD-10: International Classification of Diseases, Tenth Revision.

Data Collection

The analytic dataset linked hospital electronic medical records and Brain Saver app logs. Hospital records provided sex, age, *ICD-10* diagnosis codes, National Institutes of Health Stroke Scale (NIHSS) and modified Rankin Scale (mRS) scores, treatment modalities (eg, intravenous thrombolysis—tissue plasminogen activator [tPA] and endovascular thrombectomy [EVT]), discharge outcomes, and in-hospital time stamps. App logs provided granular prehospital time intervals for the intervention group, including symptom onset, dispatch, and clinician handover times, whereas symptom onset time for the comparison group was obtained from hospital records. Despite missing data during on-site data entry into the app and during the linkage of app logs with hospital records, all available observations were retained for each analysis.

Time Interval Measures

Time-related outcome variables were defined across two phases: (1) onset-to-door (OTD) time, defined as the interval from initial stroke symptom onset to ED arrival; and (2) door-to-needle (DTN) time, defined as the interval from ED arrival to initiation of parenteral treatment by clinicians. “Needle” in this study refers to the initiation of any parenteral treatment, including intravenous thrombolysis (eg, tPA) and other injectable treatments (eg, osmotic agents or diuretics), as the study included both patients with ischemic stroke and patients with hemorrhagic stroke. Onset-to-needle (OTN) time, encompassing both phases, represented the total time from symptom onset to treatment initiation. Length of hospital stay (LOS) was also evaluated as a measure of care quality and operational efficiency in early stroke management [19].

During data cleaning, logically implausible values (eg, 0 minutes for OTD time) and extreme outliers identified using the 3×IQR rule after log transformation of time variables were treated as missing values, as detailed in section C in Multimedia Appendix 3.

Statistical Analyses

To evaluate the effect of the pilot intervention program, characteristics between the intervention and comparison groups were compared using Fisher exact test or Pearson chi-square test for categorical variables, Welch *t* test for mean differences, and the Wilcoxon rank-sum test for median differences. To compare the cumulative incidence of discharge between groups over time, adjusted Fine-Gray competing risks regression analyses were performed to estimate subdistribution hazard ratios (SHRs). In-hospital death was treated as a competing event and transfer to tertiary hospitals as a censoring event. Sex, age, NIHSS score at admission, stroke type, and destination hospital were included as covariates.

To enhance comparability between groups given the limited sample size, we used an exact matching approach on key covariates. Matching strata were defined by age (<65 and ≥65 years), baseline NIHSS category at admission (0, 1-4, 5-15, and 16-42), stroke subtype (ischemic and hemorrhagic), and destination hospital (A, B, or C). All eligible comparison patients within each stratum were retained, yielding a many-to-many matched design. Due to missing baseline NIHSS data and unmatched strata, the analytic sample was restricted to 91 patients (19 intervention and 72 comparison). With individuals contributing repeatedly within strata, the analysis included 271-309 paired observations across models. To account for within-stratum correlation induced by this repeated

XSL•FO
RenderX

contribution, we fitted generalized estimating equations (GEE) with a robust variance estimator, modeling log-transformed outcomes with a Gaussian distribution and an identity link. All analyses were performed using SAS (version 9.4; SAS Institute Inc) and R software (version 4.4.2; R Foundation for Statistical Computing).

Ethical Considerations

The research protocol was approved by the institutional review boards of the 3 hospitals that participated in the pilot program: Pohang Stroke and Spine Hospital (IRB number PSSH0475-202405-HR-009-01); Pohang St Mary's Hospital (IRB number 0749-240603-HR-075-01); and Pohang Semyeong Christianity Hospital (IRB number PSMCHIRB-2024-25). Because patient data were collected and analyzed in an anonymized form, the requirement for informed consent was waived.

Regarding patient information security, the Brain Saver app was designed to protect patient privacy throughout data collection, storage, and transmission processes. All collected data were deidentified before storage and transmission to minimize the risk of patient identification. Transmitted data were protected using encrypted communication protocols (eg, Transport Layer Security), reducing the risk of external interception or unauthorized access. The system complied with the Personal Information Protection Act and the Medical Service Act of South Korea.

Results

The geographic and temporal distribution of intervention cases during the pilot program are presented in sections A and B in Multimedia Appendix 3. The postimplementation survey of app users indicated that EMS personnel and clinicians valued key operational functions of Brain Saver, particularly access to patient assessment results, distance-based hospital recommendations, and transport status tracking (Table 2). In contrast, 36% (15/42) of EMS personnel reported difficulty entering information into the app and suggested additional functions for electrocardiogram storage and clinician confirmation of transport alerts. Clinicians suggested enhancing the basic patient information displayed in the app and reducing frequent alerts.

Table 2. Findings from the Brain Saver user experience survey among emergency medical services (EMS) personnel and clinicians[a].

Survey item	Key findings
EMS personnel (n=42)	
Most satisfying functions (top 3)[b]	• Diagnostic result display (30%) • Distance-based hospital recommendation (18%) • Automatic current-location entry (17%)
User experience with app functions	• Chat and video: 7 (17%) respondents used the messaging function during transport to share biological information other than ECGc data, provide estimated arrival times, and confirm EDd availability. • Posttransport feedback: 35 (83%) respondents reported positive perceptions of the final diagnosis confirmation function after transport
Difficulties in data input	• 15 (36%) respondents reported difficulty entering the patient information
Additional improvement requests	• A function for storing ECG data in the app • A feedback mechanism indicating whether clinicians have checked transport-related information • Integration with existing fire-service systems to reduce duplicated work
Clinicians (n=13)	
Most satisfying functions (top 3)[b]	• Transport status tracking via the status bar (40%) • Viewing the patient diagnostic score (31%) • Viewing the on-call clinician list within the same hospital (10%)
User experience with app functions	• Real-time ECG sharing: 11 (85%) received notifications; 10 reported it supported clinical decision-making • Arrhythmia alarm: 5 (38%) received alerts; 4 reported it supported clinical decision-making
Additional improvement requests	• Improving basic patient information • Addressing workflow burden caused by frequent arrhythmia alerts • Clarifying legal issues related to patient privacy and medical liability

[a]The survey was distributed to all personnel who completed the pretraining; response rates were 52.5% (42/80) for EMS personnel and 54.2% (13/24) for clinicians.

[b]Percentages are each feature's share of the total weighted score, with first, second, and third place weighted 100, 70, and 30, respectively. See Multimedia Appendix 4 for details.

[c]ECG: electrocardiogram.

[d]ED: emergency department.

Table 3 presents the descriptive characteristics of the intervention (n=34) and comparison (n=129) groups. No statistically significant differences were observed in overall characteristics between the 2 groups. All participants (N=163) were 50.3% (n=82) men and had a mean age of 69.4 (SD 15.2) years; 65.6% (n=107) were diagnosed with ischemic stroke and 34.4% (n=56) with hemorrhagic stroke; 17% (16/94) of patients with ischemic stroke received intravenous tPA, and 28.9% (26/90) underwent EVT. At admission, NIHSS-based stroke severity did not differ significantly between groups (median 9, IQR 5-12 vs median 6, IQR 2-12; *P*=.12). Discharge NIHSS scores and mRS (a measure of functional outcome) also showed no significant differences. Regarding the discharge destination, 27.3% (6/22) of patients in the intervention group were discharged directly to home, compared with 45% (58/129) in the comparison group (*P*=.12).

XSL•FO

Tertiary hospital	14 (9.3)	4 (18.2)	10 (7.8)	
In-hospital death	11 (7.3)	3 (13.6)	8 (6.2)	

[a]Categorical variables were compared using the Fisher exact test or Pearson chi-square test, depending on sample size. Median differences were compared using the Wilcoxon rank-sum test, and mean differences using the Welch *t* test.

[b]Percentages for tissue plasminogen activator and endovascular thrombectomy were calculated only among patients with ischemic stroke and available treatment data, after excluding cases with missing treatment data.

[c]tPA: tissue plasminogen activator.

[d]EVT: endovascular thrombectomy.

[e]NIHSS: National Institutes of Health Stroke Scale.

[f]NIHSS scores at hospital admission and discharge were presented only for patients who survived, ensuring that the same study population was compared at both time points.

[g]mRS: modified Rankin Scale.

Table 4 summarizes the timeline from symptom onset to discharge. Overall, the median OTD, DTN, and OTN times were 88 (IQR 48-273), 58 (IQR 39-98), and 177 (IQR 100-426) minutes, respectively, and the median LOS was 19 (IQR 10-29) days. The intervention group had a significantly shorter median OTN time than the comparison group (114, IQR 82-258 minutes vs 204, IQR 105-460 minutes; *P*=.03).

XSL•FO
RenderX

Table 4. Timeline from symptom onset to hospital discharge among patients with stroke in intervention and comparison groups.

	Total (N=163)	Intervention (n=34)	Comparison (n=129)	*P* value[a]
Onset-to-door time (A), n	155	29	126	
Minutes, mean (SD)	230.9 (300.8)	253.6 (350.2)	225.6 (289.6)	.69
Minutes, median (minimum-maximum)	88 (19-1438)	58 (19-1102)	105 (20-1438)	.18
Door-to-needle time (B)[b], n	153	28	125	
Minutes, mean (SD)	125.7 (220.1)	74.7 (57.0)	137.1 (240.7)	.01
Minutes, median (minimum-maximum)	58 (3-1248)	52 (8-234)	59 (3-1248)	.74
Onset-to-needle time (A+B)[b], n	152	26	126	
Minutes, mean (SD)	331.1 (340.6)	254.3 (306.0)	347.0 (346.3)	.18
Minutes, median (minimum-maximum)	177 (25-1390)	114 (26-999)	204 (25-1390)	.03
Length of stay among patients discharged alive[c], n	131	18	113	
Day, mean (SD)	23.0 (16.9)	19.9 (15.4)	23.5 (17.2)	.38
Day, median (minimum-maximum)	19 (1-89)	16 (1-58)	20 (2-89)	.39

[a]Median differences were compared using the Wilcoxon rank-sum test, and mean differences using the Welch *t* test.

[b]"Needle" refers to overall injectable treatment provision across both stroke subtypes.

[c]Length of stay was estimated among patients discharged alive after excluding 11 in-hospital deaths, 14 transfers to tertiary hospitals, and cases with missing data.

More detailed time-interval data were available only for the intervention group (section D in Multimedia Appendix 3), with median times of 7 (IQR 4-9) minutes from dispatch to hospital arrival and 6 (IQR 4-8) minutes from arrival to clinician handover. By stroke subtype (section E in Multimedia Appendix 3), patients with ischemic stroke had a median OTN time of 223 (IQR 118-460) minutes, and 59.6% (59/99) achieved an OTN time within the clinically relevant 4.5-hour treatment window.

Table 5 presents the cumulative incidence of discharge over time by group, accounting for competing risks and censoring. A higher NIHSS score at admission was associated with delayed discharge (SHR=0.94 per 1-point increase; *P*<.001), whereas the intervention was not significantly associated with the timing of discharge (SHR=0.78; *P*=.37).

Table 5. Fine-Gray competing risks regression of discharge cumulative incidence[a].

	β	Exp(β), SHR[b] (95% CI)	SE	Z value	*P* value
Intervention (reference: comparison)	–.25	0.78 (0.46-1.34)	0.28	–0.89	.37
Age	–.00	1.00 (0.99-1.01)	0.01	–0.47	.64
Female (reference: male)	–.09	0.91 (0.62-1.35)	0.20	–0.47	.64
NIHSS[c] score at admission	–.06	0.94 (0.92-0.97)	0.01	–4.60	<.001
Ischemic stroke (reference: hemorrhagic stroke)	.28	1.33 (0.91-1.95)	0.19	1.47	.14
Hospital B (reference: Hospital A)	–.79	0.45 (0.12-1.74)	0.69	–1.16	.25
Hospital C (reference: Hospital A)	–.32	0.72 (0.33-1.57)	0.40	–0.82	.41

[a]In-hospital death was treated as a competing event and transfer to tertiary hospitals as a censoring event.

[b]SHR: subdistribution hazard ratio.

[c]NIHSS: National Institutes of Health Stroke Scale.

Table 6 presents the intervention effects on transport time and length of stay in a sample matched on age, baseline NIHSS score category, stroke type, and destination hospital. The intervention group showed a statistically significant 33% reduction in DTN time (Exp(β)=0.67; *P*=.04) and a 51% reduction in OTN time (Exp(β)=0.49; *P*=.009). The intervention group also showed a 22% reduction in LOS compared with the comparison group (Exp(β)=0.78; *P*=.007) in this matched sample, which adjusted for potential confounders.

XSL•FO
RenderX

Table 6. Effects of Brain Saver intervention on transport time and length of stay: generalized estimating equation models (GEE) analyses using a many-to-many matched sample.a

GEE with a normal distribution and identity link	Intervention vs comparison (reference)			
	Estimate, β	Exp(β)[b]	Z value	*P* value
Model 1: Y=ln(Onset-to-door time)	–0.62	0.54	–1.88	.06
Model 2: Y=ln(Door-to-needle time)	–0.40	0.67	–2.02	.04
Model 3: Y=ln(Onset-to-needle time)	–0.72	0.49	–2.61	.009
Model 4: Y=ln(Length of stay among patients discharged alive)	–0.25	0.78	–2.72	.007

[a]Each GEE model accounted for matching strata defined by age category, National Institutes of Health Stroke Scale (NIHSS) category at admission, stroke subtype, and destination hospital. Due to missing baseline NIHSS data and unmatched strata, the analytic sample was restricted to 91 patients (19 intervention and 72 comparison). Through many-to-many matching across 10 matching strata, these 91 patients contributed 293 (model 1), 309 (model 2), 290 (model 3), and 271 (model 4) observations to the GEE analyses, respectively.

[b]Exponentiated estimates are reported for log-transformed continuous outcomes.

Discussion

Principal Findings

The Brain Saver mobile app was integrated into standard EMS and ED workflows and streamlined operational processes, with generally positive user feedback. Through real-time collaboration between paramedics and clinicians, the app supports nearest-hospital navigation and emergency alert activation, enabling rapid in-hospital response upon patient arrival based on app-entered data. This prehospital intervention facilitates timely access to stroke care, potentially reducing OTN time.

EMS personnel and clinicians identified the app-based prenotification process as the most useful component for situational awareness and decision-support. Given that documentation burden in clinical settings can hinder the development of shared situational awareness [20], the app-based intuitive presentation and transfer of information may support clear and concise communication, thereby enhancing continuity of care. Moreover, prior evidence indicates that cognitive aids, such as checklists and decision-support tools, can reduce missed care and improve accuracy, particularly in clinical emergencies [21]. In this context, Brain Saver functions, such as tracking transport status and summarizing stroke assessment scores, may serve as meaningful clinical decision-support tools. In addition, digitalized recording of electrocardiogram data and patient information through the app may improve EMS-ED workflow efficiency by replacing paper-based and manual processes.

The principal finding of this pilot study was that the intervention group experienced shorter OTN times in both unadjusted median comparisons and matched-sample analyses. This improvement may be driven more by reduced DTN time than by OTD time, because DTN time showed significant GEE-estimated reductions, whereas OTD time did not differ significantly in any analysis. The core function of Brain Saver, which provides prenotification and patient information during transport, may facilitate hospital preparedness before patient arrival. Previous studies have similarly shown that, among the various advantages of EMS transport, prenotification systems in particular facilitate more rapid in-hospital evaluation by reducing door-to-imaging time, which in turn leads to shorter DTN and OTN times [22-26].

No significant difference in OTD time was observed between groups. A previous study using a real-time feedback mobile app for stroke emergency management similarly reported no significant effect on OTD time following the intervention [27]. One plausible explanation relates to the study design, in which both groups consisted of patients transported by EMS, which itself is a strong predictor of early hospital arrival [15,28]. Moreover, the findings of this study suggest that OTD time may have been largely determined by symptom onset-to-dispatch time, given that dispatch-to-hospital arrival times in the intervention group were relatively short, ranging from only 3-18 minutes (section D in Multimedia Appendix 3).

Regarding LOS, the findings warrant cautious interpretation. Although mean and median LOS and cumulative discharge patterns did not differ significantly between groups, GEE analyses in the matched sample estimated a shorter overall LOS in the intervention group. This discrepancy may reflect differences in discharge timing distributions and baseline stroke severity between groups. The comparison group included relatively more patients with mild stroke and showed faster early discharge but more extreme LOS values, whereas the intervention group showed generally slower discharge with fewer extreme values (section F in Multimedia Appendix 3). Previous studies have suggested that shorter LOS may reflect higher quality of care during the early phase of stroke management [19], while the association between stroke severity and LOS may be nonlinear or bidirectional depending on severity level [29]. Definitive conclusions cannot be drawn from this small sample, and larger studies are needed to improve generalizability.

Study Strengths

Drawing on real-world deployment, this study provides empirical evidence supporting the expanding role of digital health in seamless care transitions for stroke transport. We adopted a quasi-experimental study design and incorporated a structured familiarization phase to support adherence to standardized end-to-end protocols. This approach enhances data reliability and partially strengthens causal inference compared with previous cross-sectional [12] or retrospective observational

XSL•FO
RenderX

studies [27,30] that addressed similar research objectives. In addition, we captured the complete care timeline from symptom onset to hospital discharge, extending beyond prior studies focused primarily on postadmission phases [13,14,30].

Notably, the Brain Saver intervention also has important practical implications. This pilot program aligns with best-practice strategies for stroke quality improvement, including "EMS prenotification, rapid triage and stroke team notification protocols, single-call activation, and a team-based approach" [25,31,32], and extends their implementation through digital integration. Our findings suggest the added value of strengthening continuity across the EMS-ED interface, beyond established benefits of mobile and wearable technologies in stroke care [33,34]. Such coordinated processes may support shared decision-making and facilitate timely stroke care.

Limitations

There are several limitations. First, the definitions of the study population and time-to-needle variables should be interpreted with caution. We included both patients with ischemic stroke and patients with hemorrhagic stroke and defined "needle" time as the initiation of any parenteral treatment, whereas most previous studies have focused exclusively on patients with ischemic stroke receiving tPA-specific therapy. Second, several primary variables had substantial missing data. Some symptom-onset data were missing in the intervention group during on-site data entry into the app. Missing in-hospital treatment data were likely due to the fragmented data-linkage process between app logs and hospital records. In addition, logical errors in the OTD time (eg, 0 minutes) were identified in the comparison group, whose data were derived from hospital records. These data quality issues emerged during the 4-month real-world pilot implementation involving multiple agencies and hospitals. Third, detailed prehospital time intervals were available only for the intervention group, limiting comparability between groups. Fourth, the absence of nonconfirmed stroke cases in the intervention group may reflect a field-level selection mechanism, whereby the app was initiated preferentially for clinically apparent stroke presentations. Fifth, given the quasi-experimental study design with a newly adopted device, the Hawthorne effect—heightened performance under observation—cannot be entirely excluded and may have contributed to the shorter treatment times observed in the intervention group. Finally, the matched analytic sample was limited (n=91 in the GEE model, and fewer in the LOS analysis), constraining statistical power and the generalizability of the results.

Future Work

This pilot study provides preliminary evidence on the feasibility of applying a newly developed digital health intervention in real-world EMS-ED workflows. Given the small sample, larger studies are needed to improve comparability and generalizability of the findings. Future studies could investigate broader populations and more detailed prehospital time intervals, including patients with suspected stroke or those with OTN times exceeding 24 hours, which were beyond the scope of this study.

Regarding app functionality, app users in this pilot study suggested improvements to the alert system, particularly reducing alert frequency for clinicians and providing EMS personnel with feedback on whether clinicians had acknowledged the alerts. In addition, the criteria for app activation (ie, those determining inclusion in the intervention group) warrant further refinement to cover less typical or ambiguous stroke presentations.

To optimize EMS-ED workflows, interoperability challenges within existing EMS systems remain an important concern [35]. As our approach relies on an app-based digital system, transitioning ambulance documentation from paper to digital systems will be crucial. The app could initially serve as a complement to existing workflows and, through stepwise implementation, eventually function as a complete substitute for paper-based workflows. Reflecting the app-user survey, efforts to minimize duplicated documentation tasks during this transition will be important.

Conclusions

This formative, quasi-experimental pilot study suggests that Brain Saver can be integrated into routine EMS and ED workflows for stroke transport. By facilitating real-time prenotification and prearrival preparation, Brain Saver was associated with shorter OTN time. App-user feedback further supported the feasibility of the intervention among EMS personnel and clinicians, emphasizing the value of rapid triage and shared situational awareness. Taken together, these findings highlight the potential of digital health interventions to enhance coordinated EMS-ED workflows and improve timely stroke treatment across the care continuum.

Acknowledgments

This study reports findings from the Digital Healthcare-Based Comprehensive Stroke Patient Management intervention conducted in the Gyeongsangbuk-do region, South Korea. The project was initiated under a multi-institutional Memorandum of Understanding signed in November 2023 among the Korean Telemedicine Society, Seoul National University Community Health Innovation Center, Korean Stroke Society, Gyeongsangbuk-do Fire Headquarters, Pohang City, Pohang Stroke and Spine Hospital, Pohang St Mary's Hospital, Pohang Semyeong Christianity Hospital, and SEERS Technology Co, Ltd. This field demonstration formed part of the study entitled "Research service for establishing a digital health care–based comprehensive management system for patients with stroke in Gyeongbuk," supported by the Korea National Institute of Health. The generative AI tool ChatGPT (version 5.2) was used exclusively for language editing and did not contribute to the generation of text, figures, or other scientific content of this manuscript.

Abstract

Background: Shared decision-making (SDM) is critical for managing clinically ambiguous conditions such as benign breast disease (BBD), requiring reliable health information. In China, WeChat public accounts (WPAs) run by hospitals serve as a major health information channel, yet their quality remains unevaluated.

Objective: This study aimed to evaluate the quality of BBD-related articles on hospital WPAs in China.

Methods: Using a multistage stratified random sampling approach, we conducted a nationwide survey examining the quality of articles published from January 2020 to November 2024. The articles were evaluated for accessibility (readability, image quality, and user-friendliness) and SDM readiness (credibility, balance, and decision relevance) using validated instruments and content analysis.

Results: Among 276,617 articles from 158 sampled hospitals, 464 were related to BBD. Accessibility was generally good: 72.4% (336/464) were written at a junior high school reading level. Visual presentation was acceptable, although only 10.2% (42/410) had complete image labeling. The Patient Education Materials Assessment Tool for Printable Materials (PEMAT-P) scores showed moderate understandability (mean 73.6%, SD 17.3%) but limited actionability (mean 50%, SD 23.2%). For SDM readiness, the mean Quality Evaluation Scoring Tool (QUEST) score was 14.9 (SD 4.7) out of 28, with treatment-related articles scoring lower than prevention-related articles (P<.001). In the balance evaluation, using Brief DISCERN, 84.3% (182/216) of articles were below the high-quality threshold, often lacking information on treatment risks and quality-of-life impacts. Decision relevance revealed variability in surgical recommendations, especially regarding excision criteria and pregnancy-related guidance.

Conclusions: WPA articles on BBD showed good accessibility but substantial gaps in SDM support, particularly in information balance and decision relevance. Standardized guidelines and quality improvements are needed to enhance patient-centered online health services.

Introduction

Benign breast disease (BBD) poses a major clinical challenge, accounting for 55% to 90% of all breast lesions [1-3]. The risk of subsequent breast cancer varies considerably, depending on the degree of epithelial proliferation and atypia [4-6]. Unlike malignancy, BBD lacks evidence-based management protocols and often requires individualized strategies such as surveillance, biopsy, surgery, or follow-up [7,8]. This clinical uncertainty necessitates preference-sensitive care, where comparable treatment options require decisions tailored to patient-specific risks and informed preferences [9-11]. Shared decision-making (SDM), recommended by the American Society of Breast Surgeons and European guidelines [7,12], is particularly relevant for younger female patients, who constitute most BBD cases [13-15]. Evidence shows that SDM in surgical care reduces decisional conflict, anxiety, and unnecessary procedures while improving the overall quality of care and reducing costs [16-19]. Despite these well-documented benefits, the routine adoption of SDM in clinical practice remains suboptimal [20]. A critical barrier worldwide is the difficulty of integrating patient decision aids into clinical workflows, particularly in resource-constrained settings [21,22].

Telemedicine plays a supportive and interactive role in facilitating decision-making [23]. In China, the national "Internet + Health Care" initiative has rapidly expanded the model of internet hospitals, with 3340 internet hospitals nationwide as of September 2024 [24]. WeChat public accounts (WPAs), China's dominant social media platform with 1.385 billion active users, have been adopted by most tertiary hospitals to integrate professional expertise with broad digital reach [25,26]. Notably, more than 60% of Chinese health consumers prefer WeChat as their primary source of medical information, highlighting the potential of WPAs as tools for patient education and decision support [27-29]. Among the vast and varied health information available online, hospital-operated WPAs carry unique weight as official institutional voices and tend to be regarded by patients as more credible channels for medical guidance. As time-constrained clinical consultations increasingly drive patients to seek health information online, the BBD-related content patients encounter on WPAs before visits may shape the knowledge, expectations, and preferences they bring into clinical encounters, with potential implications for the starting point and quality of SDM [30,31].

Despite this promise, concerns persist regarding the quality and relevance of WPA content for decision-making [25,32]. Although prior research has evaluated breast cancer information on public platforms such as Twitter and YouTube, a systematic assessment of BBD-related content on hospital-based social media is lacking [33,34]. To address this gap, our nationwide study evaluates whether hospital-based WPAs provide accessible, decision-supportive content that enables informed patient participation in SDM, offering novel insights into digital health communication within China's emerging internet hospital ecosystem.

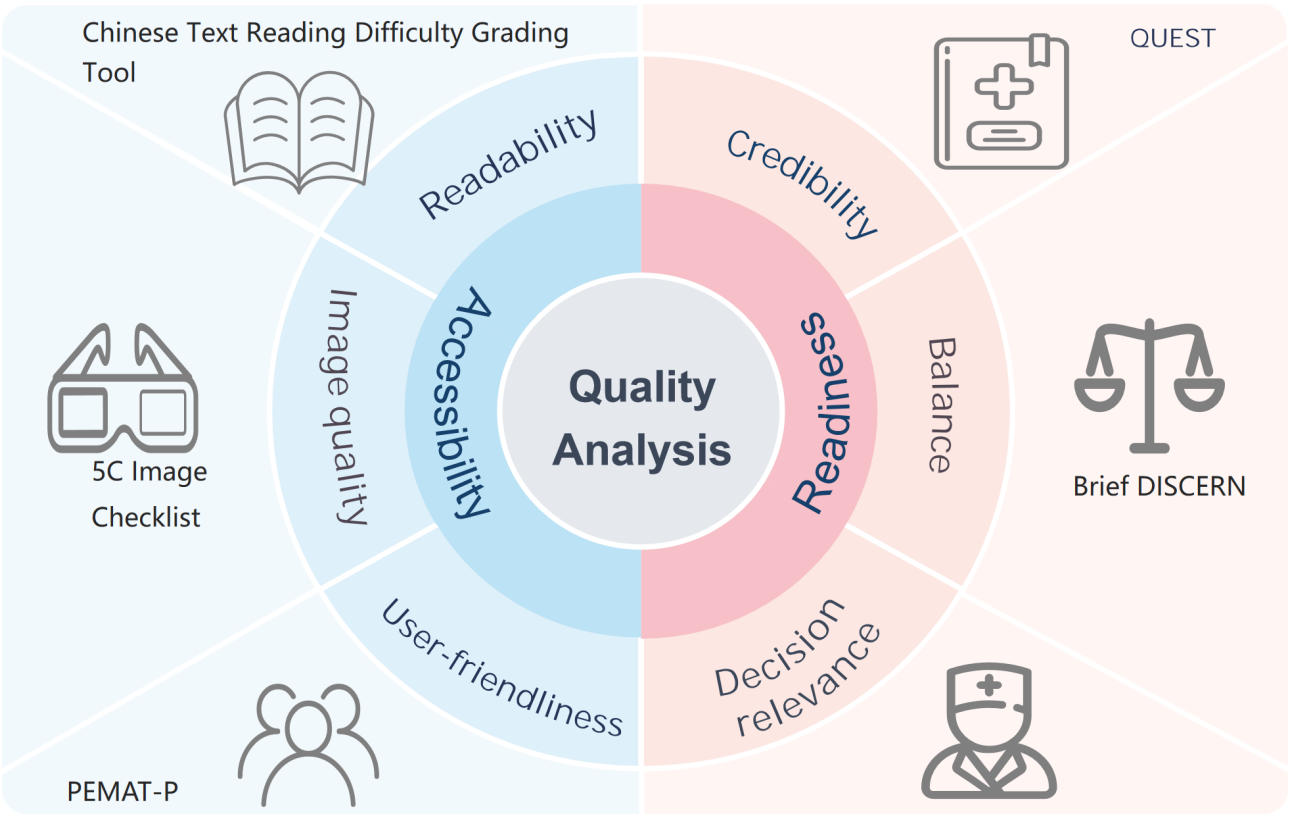
Methods

Study Design and Sampling

A nationwide, multistage random sampling approach was used across 7 geographic regions in China. In each region, 3 provinces were randomly selected, and 2 municipal-level cities were randomly chosen per province (Table S1 in Multimedia Appendix 1). Following the Hospital Classification Management Measures [35], 4 hospitals were sampled per city: 1 maternal and child health (MCH) hospital, 1 traditional Chinese medicine (TCM) hospital, and 2 general hospitals (including 1 tertiary and 1 secondary).

Articles published between January 1, 2020, and November 30, 2024, were collected via automated web scraping with manual verification. Chinese keyword searches identified BBD-related content (Table S2 in Multimedia Appendix 1). Articles explicitly addressing BBD were included, while those addressing malignancy only, administrative or promotional content, or unrelated topics were excluded (Table S3 in Multimedia Appendix 1).

Data Extraction and Screening



Data were extracted at both institutional and article levels. Briefly, institutional data—including hospital characteristics, geographic location, bed capacity, and digital engagement—were sourced from official websites and the National Health Commission database. Article-level data—including publication date, view count, and article content—were obtained directly from the sampled WeChat (Tencent Holdings) public accounts. All article view counts were captured on March 16, 2025; views per day were calculated as cumulative views divided by the number of calendar days since publication.

Evaluation Framework and Assessment Tools

Following established criteria for evaluating online health information [36] and the International Patient Decision Aid Standards (IPDAS) [37], we developed a structured framework encompassing 2 major domains: accessibility and readiness (Figure 1).

XSL•FO
RenderX

Figure 1. Conceptual framework for evaluating benign breast disease articles on Chinese hospital WeChat public accounts (2020 - 2024). PEMAT-P: Patient Education Materials Assessment Tool for Printable Materials; QUEST: Quality Evaluation Scoring Tool.

Accessibility

Accessibility assessed how clearly and effectively health information was delivered and the extent to which the materials supported patient engagement. It comprised 3 dimensions: readability, image quality, and user-friendliness.

First, readability was assessed using the Chinese Text Reading Difficulty Grading Tool, which applies natural language processing techniques to estimate text difficulty based on linguistic features from the Chinese textbook corpus [38,39]. Readability scores were automatically computed for each article without requiring human raters.

Second, image quality was assessed using the 5C Image Checklist, adapted from the Centers for Disease Control and Prevention's (CDC) Simply Put guide [40,41]. The checklist evaluates 5 domains: clarity, contribution, contradiction, caption, and cultural appropriateness. Each article was independently rated by 2 trained reviewers (SW and CH), with discrepancies resolved through discussion.

Finally, user-friendliness was evaluated with the Chinese version of the Patient Education Materials Assessment Tool for Printable Materials (PEMAT-P), including understandability and actionability, with scores reported as continuous percentages (higher values indicate better quality) [42]. To incorporate patient-centered perspectives, 20% (43/216) of treatment-related articles were randomly selected and independently evaluated by a panel of 14 adult patients using the PEMAT-P tool. Evaluators were recruited by convenience sampling from hospitals and had no prior experience in evaluating patient education materials. Their ages ranged from 23 to 42 years; all held bachelor's or master's degrees, and 6 had a personal history of benign breast nodules. Each article was assessed by 2 independent evaluators, with each evaluator reviewing approximately 6 articles.

Readiness

Readiness reflected the extent to which article content could support patients' participation in SDM. It was assessed across 3 dimensions: credibility, balance, and decision relevance.

First, credibility was measured using the Quality Evaluation Scoring Tool (QUEST) [43], covering 6 domains (authorship, attribution, conflict of interest, currency, complementarity, and tone; score range 0-28). Assessments were performed by 2 doctoral students in biomedical engineering with clinical training (JL and WZ).

Second, balance was evaluated using the Brief DISCERN, a validated short version of the DISCERN tool designed for treatment information [44,45]. Six items were assessed: information source, information currency, treatment mechanism, treatment benefits, treatment risks, and impact on quality of life. A score of ≥16 indicated high quality [45]. Two surgeons (LK and ZZ) independently assessed all treatment-related articles.

Finally, decision relevance was examined through directed content analysis of (1) clinical contexts for which treatment was advised and (2) treatment modalities suggested [46]. A coding guide was iteratively developed from 10% (22/216) of treatment-related articles and refined through consensus discussion between 2 reviewers (JL and XW). The final coding guide is presented in Table S4 in Multimedia Appendix 1. All

XSL•FO
RenderX

216 treatment-related articles were then independently double-coded, and discrepancies were resolved through discussion.

Statistical Analysis

Descriptive statistics summarized article and hospital characteristics. Categorical variables were presented as frequencies and percentages. Continuous variables were reported as means (SDs) for normally distributed data or medians (IQR) for skewed data. Chi-square tests were used for categorical variables. Skewed continuous variables were compared using the Kruskal-Wallis test and Bonferroni-corrected Dunn post hoc tests. Interrater reliability for all continuous quality scores (QUEST, Brief DISCERN, and PEMAT-P) was assessed using 2-way random-effects intraclass correlation coefficients for single-rating, absolute agreement ($ICC_{2,1}$). For the categorical variables (5C Image Checklist), Cohen kappa was calculated for each domain. For decision relevance content analysis, percentage agreement was used (with an ≥85% threshold).

Linear regression was used to assess temporal trends in publication volume, with year as the independent variable. Given the nested structure of the data (articles clustered within hospitals), linear mixed-effects models with hospital as a random intercept were fitted using the *lme4* package in R (version 4.5.0; R Foundation for Statistical Computing). *P* values were obtained by likelihood ratio tests. A 2-sided *P* value <.05 was considered statistically significant. NVivo (version 20; QSR International) was used for qualitative data analysis. Datawrapper (Datawrapper GmbH) was used to visualize geographic distribution. Origin 2025 (OriginLab) was used for data visualization.

Ethical Considerations

This study was approved by the ethics committee of Chongqing University Three Gorges Hospital (KLS2025122). As all WPA articles assessed were publicly available and contained no identifying information, the ethics committee granted a waiver of informed consent. Adult patients participated in article evaluation with oral consent. All data were anonymized, and no compensation was provided.

Results

Study Sample and Article Selection

Multistage random sampling yielded 40 city-level units after excluding 2 units: Turpan (Xinjiang) had no independent TCM hospital, and Haibei Prefecture (Qinghai) had no tertiary general hospital at the time of sampling. Of the 160 hospitals expected under the sampling protocol, 158 were included (Figure 2). From these hospitals, 265 WPAs were identified (Figure 2), from which 276,617 articles published between January 2020 and November 2024 were retrieved. After keyword screening, 5526 potentially relevant articles were identified, and 464 BBD-related articles met the inclusion criteria.

Hospital Characteristics and Digital Engagement

The sample comprised 39 tertiary general hospitals, 40 secondary general hospitals, 39 TCM hospitals, and 40 MCH hospitals (Table 1). Overall, 94 (59.5%) hospitals were tertiary-level, and 64 (40.5%) were secondary-level.

In terms of digital engagement, 155 (98.1%) hospitals operated WPAs, achieving full coverage among tertiary general and TCM hospitals. In contrast, only 65.2% (103/158) maintained official websites, ranging from 89.7% (35/39) of tertiary hospitals to 27.5% (11/40) of secondary general hospitals. Certification for internet hospitals was limited (40/158, 25.3%), with the highest proportion among tertiary general hospitals (22/39, 56.4%).

Over the past 5 years, publication volumes on WPAs showed no significant regional differences across China (P>.05; Figure S1 in Multimedia Appendix 1). By hospital type, the median 5-year publication volume ranged from 271 (IQR 83-759) in secondary general hospitals to 743 (IQR 188-1250) in MCH hospitals; secondary general hospitals had significantly lower publication volumes than the other 3 hospital types (Table 1).

Table . Baseline characteristics of Chinese public hospitals sampled across 7 geographic regions (N=158).

Characteristics	Total hospitals	Tertiary general hospitals (n=39)	Secondary general hospitals (n=40)	Traditional Chinese medicine hospitals (n=39)	Maternal and child health hospitals (n=40)
Hospital profile					
Tertiary hospital, n (%)	94 (59.5)	39 (100)	0 (0)	30 (76.9)	25 (62.5)
Beds available, mean (SD)	1058 (980)	2132 (1015)	388 (214)[a]	1046 (751)	589 (563)[b]
Digital engagement, n (%)					
Internet hospital	40 (25.3)	22 (56.4)	2 (5)	10 (25.6)	6 (15)
Hospitals with official websites	103 (65.2)	35 (89.7)	11 (27.5)	31 (79.5)	27 (67.5)
Hospitals with WeChat accounts	155 (98.1)	39 (100)	38 (95)	39 (100)	39 (97.5)
Annual publication volume per hospital, median (IQR)[c]	562 (156-1213)	724 (95-1345)	271 (83-759)	680 (300-1586)	743 (188-1250)

[a]Beds available in secondary general hospitals were significantly lower than those in both tertiary general hospitals and traditional Chinese medicine hospitals (Kruskal-Wallis test followed by Dunn post hoc tests with Bonferroni corrections; P<.05).

[b]Beds available in maternal and child health hospitals were significantly lower than those in both tertiary general hospitals and traditional Chinese medicine hospitals (Kruskal-Wallis test followed by Dunn post hoc tests with Bonferroni corrections; P<.05).

[c]Publication volumes differed significantly among hospital categories (Kruskal-Wallis H=15.520; P=.001). Of the 6 pairwise Dunn post hoc comparisons with Bonferroni correction, 3 remained statistically significant: secondary general hospitals had significantly lower publication volumes than tertiary general hospitals (adjusted P=.01), traditional Chinese medicine hospitals (adjusted P<.001), and maternal and child health hospitals (adjusted P=.03).

Quality Assessment of BBD-Related Articles

Overview

Of the 158 hospitals in the overall sample, 103 contributed at least 1 eligible BBD-related article, yielding 464 articles for analysis. Among these, 248 (53.4%) focused on prevention and 216 (46.6%) on treatment. Linear regression confirmed a significant upward trend in annual publication volume over the 5-year study period (β=15.7 articles per year, 95% CI 6.0-25.4; P=.01; Figure S2 in Multimedia Appendix 1).

Readability

The mean reading grade level was 12.9 (SD 1.7, range 6-20) years. Among these materials, 15.7% (73/464) were written at a primary school level, the majority (336/464, 72.4%) at a junior high school level, and 11.9% (55/464) at a senior high school level, indicating that the overall text complexity was generally acceptable and appropriate for the literacy level of the general population (Table 2).

XSL•FO
RenderX

Table . Multidimensional quality assessment of benign breast disease articles on Chinese hospital WeChat public accounts.[a]

Dimensions and attributes	Articles
Readability (n=464)	
Reading grade level (years), mean (SD; range)	12.9 (1.7; 6-20)
Reading grade level, n (%)	
Primary school level (age group: 6-11 years)	73 (15.7)
Junior high school level (age group: 12-14 years)	336 (72.4)
Senior high school level (age group: 15-18 years)	55 (11.9)
Image quality (n=410), n (%)	
Images clearly recognizable	399 (97.3)
Image reinforcing the text	348 (84.9)
Image consistent with the text	408 (99.5)
Images with captions	42 (10.2)
Image culturally appropriate	408 (99.5)
User-friendliness (%; Patient Education Materials Assessment Tool for Printable Materials; n=43), mean (SD)	
Understandability	73.6 (17.3)
Actionability	50.0 (23.2)
Credibility (n=464)	
QUEST[b] score, mean (SD)	14.9 (4.7)
QUEST score groups, n (%)	
≤7	34 (7.3)
8-14	133 (28.7)
15-21	277 (59.7)
22-28	20 (4.3)
Balance (n=216)	
Brief DISCERN score, median (IQR)	12.5 (10.5-14.5)
Brief DISCERN score groups, n (%)	
6-10	53 (24.5)
11-15	129 (59.7)
16-20	34 (15.7)
21-30	0 (0)

[a]Readability and Quality Evaluation Scoring Tool (QUEST) scores were calculated based on all included articles (n=464); image quality assessment was based on articles containing images (n=410); Brief DISCERN scores were based on treatment-related articles (n=216); and Patient Education Materials Assessment Tool for Printable Materials (PEMAT-P) scores were based on a randomly selected subsample of 43 treatment-related articles.

[b]QUEST: Quality Evaluation Scoring Tool.

Image Quality

Of 410 articles containing images, most visuals were clear (n=399, 97.3%) and consistent with the text (n=408, 99.5%), and 84.9% (n=348) reinforced the content. However, image labeling was inadequate: only 10.2% (n=42) included fully labeled captions, 23.7% (n=97) included partially labeled captions, and 66.1% (n=271) had no labels. Nearly all images (n=408, 99.5%) were culturally appropriate. Cohen κ for the 5C Image Checklist ranged from 0.847 to 1.000 across the 5 domains.

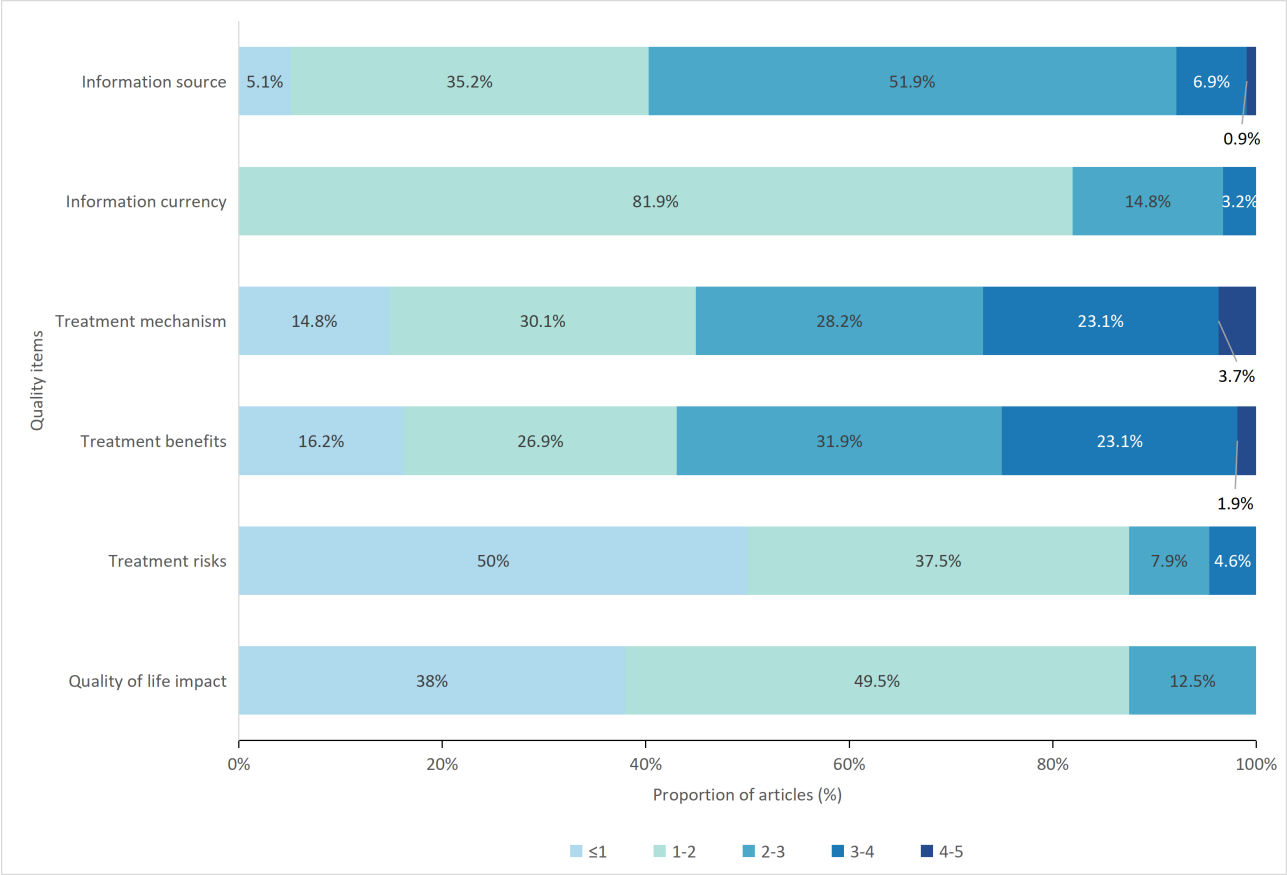
User-Friendliness

Forty-three articles, randomly sampled from 216 (20%) treatment-related articles, were included. The interrater intraclass correlation coefficient ($ICC_{2,1}$) was 0.51. Mean understandability was 73.6% (SD 17.3%), and mean actionability was 50% (SD 23.2%).

Credibility

The mean QUEST score was 14.9 (SD 4.7). Only 4.3% (20/464) of articles scored >21, while 36% (167/464) of articles scored ≤14 (Table 2). Interrater agreement for the QUEST total score was 0.79 ($ICC_{2,1}$). Prevention-related articles scored higher than

XSL•FO
RenderX



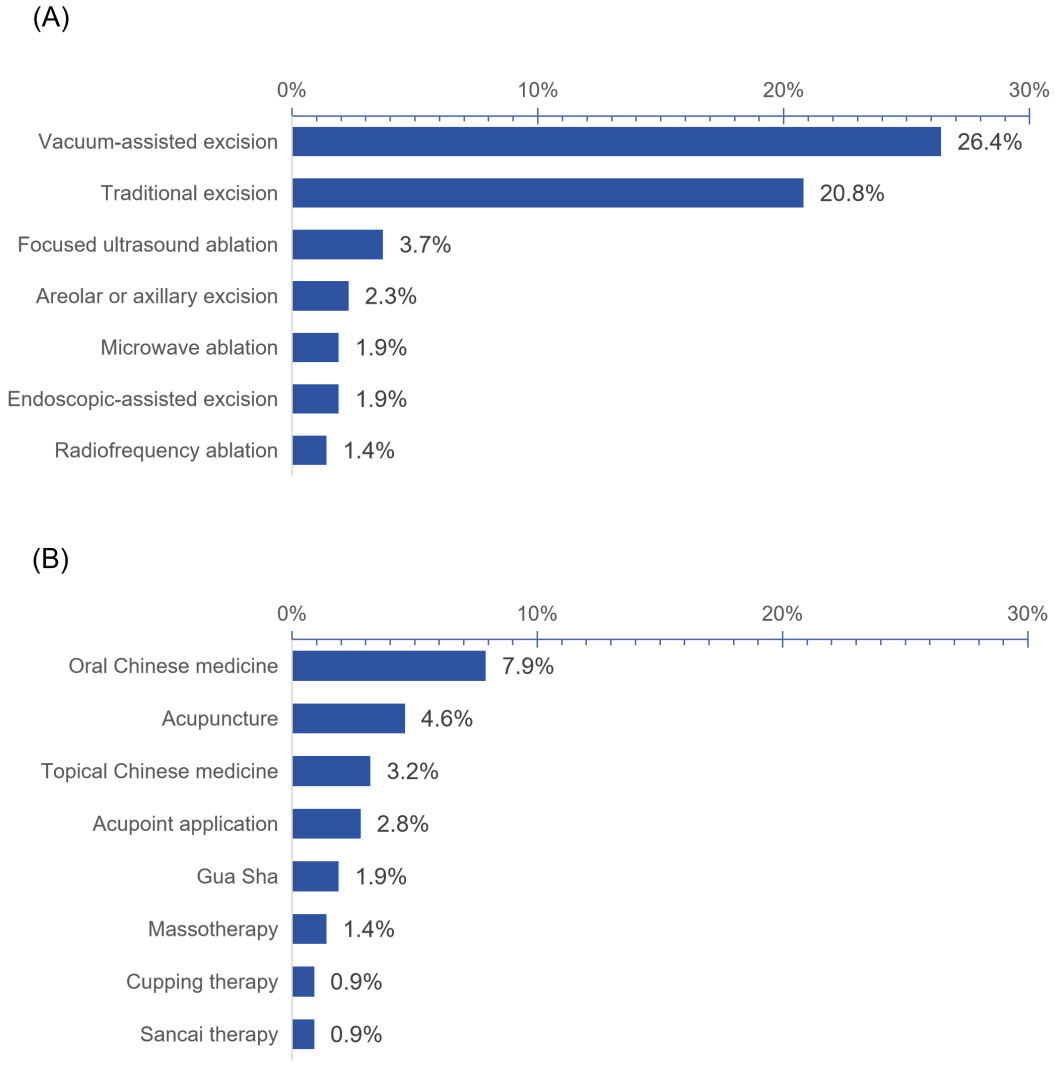
treatment-related articles (mean 15.8, SD 3.8 vs mean 13.8, SD 5.3; *P*<.001; Table S5 in Multimedia Appendix 1).

In multivariable analysis, article content was the only factor independently associated with credibility (β=−2.16; *P*<.001). Neither hospital level nor service mode showed a significant independent association with QUEST scores. For article dissemination, all 3 factors were independently associated with views per day: tertiary hospitals (β=0.38; *P*=.02), internet hospitals (β=0.35; *P*=.008), and treatment-related articles (β=0.20; *P*=.006) each showed higher readership (Table S5 in Multimedia Appendix 1).

Balance

The median Brief DISCERN score for treatment-related articles (n=216) was 12.5 (IQR 10.5-14.5), with 84.3% (182/216) falling below the high-quality threshold of 16 (Table 2). Interrater reliability for the total Brief DISCERN score was 0.57 ($ICC_{2,1}$). Source information was rarely adequate (17/216, 7.8% scoring ≥3), and only 3.2% (7/216) of articles achieved scores ≥3 for currency. Mechanisms and benefits were addressed in more than 50% of articles (scoring ≥2), whereas risks and quality-of-life impacts were addressed in only 12.5% (27/216, scoring ≥2; Figure 3).

Figure 3. Distribution of Brief DISCERN scores across 6 items among 216 treatment-related benign breast disease articles on Chinese hospital WeChat public accounts.



Decision Relevance

Treatment-related articles (n=216) most often described surgery, particularly vacuum-assisted excision (VAE; 57/216, 26.4%) and open surgical excision (OSE; n=45, 20.8%; Figure 4A). Minimally invasive or ablative techniques (eg, focused ultrasound, microwave, and radiofrequency) were rarely mentioned. TCM therapies appeared in 17.6% (38/216) of articles, most often oral medications (n=17, 7.9%) and acupuncture (n=10, 4.6%; Figure 4B). Strengths were consistently emphasized for VAE, while limitations were noted mainly for OSE and seldom for VAE or focused ultrasound (Figure S3 in Multimedia Appendix 1). The coding reproducibility between the 2 independent reviewers across the entire dataset was 90%.

XSL•FO
RenderX

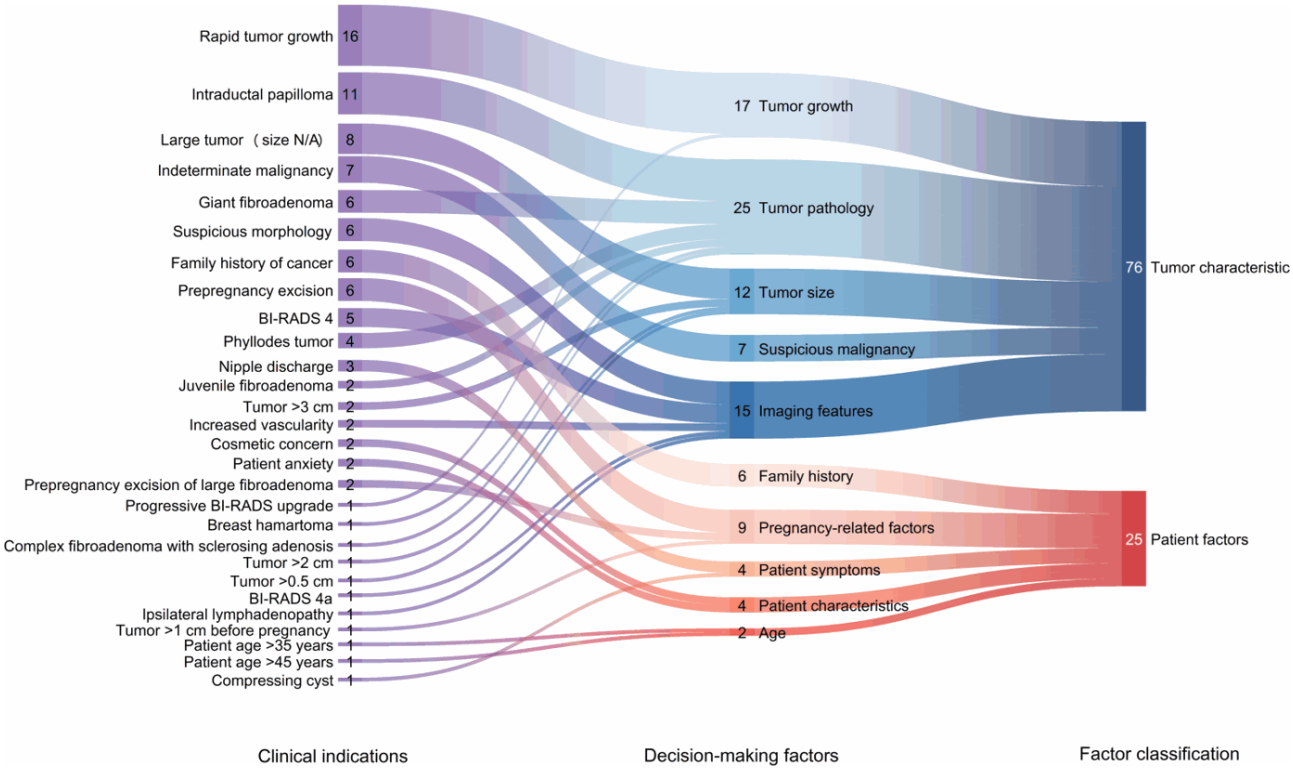


Figure 4. Distribution of treatment approaches for benign breast diseases in 216 treatment-related WeChat articles from Chinese public hospitals. (A) Frequency of surgical treatment approaches and (B) frequency of traditional Chinese medicine–based treatment approaches. Percentages indicate the proportion of articles that mentioned each treatment method.

Clinical indications for surgery were inconsistently reported. Tumor-related factors were most frequently mentioned (n=76, 35.2%), including growth, pathology, size, suspicion of malignancy, and imaging features. Patient-related factors were noted in 25 (11.6%) articles, including pregnancy planning, family history, and age, as well as concerns such as anxiety or cosmetic issues. Detailed distributions are shown in Figure 5.

Discussion

Principal Findings

Using a nationwide random sampling approach, we evaluated the accessibility and SDM readiness of hospital WPAs in the context of BBD. This study, the first to explore this issue in China, revealed that WPA articles were generally accessible and had the potential to extend SDM beyond clinical encounters. However, the risk-benefit balance was often insufficient, and decision relevance was limited.

Availability for Health Information Dissemination

SDM in China is still in its early stage, and successful implementation requires culturally appropriate pathways that are customized to fit the local clinical and resource context [47]. Telemedicine can facilitate SDM, and the rapid development of internet hospitals in China provides a new avenue by allowing patients to access information before consultations [48]. In our study, nearly all sampled hospitals operated WPAs, and approximately one-fourth were certified for internet health care, highlighting their commitment to digital service delivery. As part of the expanding digital health ecosystem, public hospitals are increasingly using online platforms such as WPAs to disseminate medical information and engage with patients [49].

Although decision aids are implemented across diverse areas of health care, multiple studies have consistently highlighted significant barriers to their routine use in clinical practice, including time burden and lack of incentives [50]. Effective decision support should convey the right information to the right person in the right format through the right channel and at the appropriate point in the workflow [51]. Incorporating the patient portal into SDM delivery is a promising strategy, as it does not rely on clinicians' initiation [52-54]. This asynchronous SDM also extends decision-making through written or pictorial exchanges across space and time [55,56]. Developing WeChat-based integration tools could therefore represent a pragmatic strategy for embedding SDM into clinical practice.

Accessibility for Patient Engagement

Despite digital health care platforms providing significant opportunities for SDM, information accessibility remains a critical factor in their effective use. Overall, WPA articles demonstrated acceptable accessibility. Most materials were written at a junior high school level, which was appropriate for the general population, although patients with low health literacy may still face challenges [57]. Visual aids contribute to enhancing patients' comprehension of health information [58-60]. In our study, visual aids were generally suitable, and optimizing captions and explanatory labels would further strengthen their educational value. From a user-friendliness perspective, materials were generally understandable, but actionability was limited. Although patients could follow the presented information, there was little explicit guidance on what steps to take or how to engage in the decision-making process [40].

These findings align with evidence that hospital WPAs function as hybrid platforms integrating health service delivery with health information dissemination; however, their role has yet to fully extend from providing information to actively supporting patient decision-making [61]. In addition, incorporating multimedia formats—such as images, videos, and interactive tools—can improve accessibility, clarify patient preferences, and foster more effective participation in decision-making [62-64]. Emerging digital technologies, including AI-enabled

XSL•FO
RenderX

recommendation systems, may further support personalized decision-making and adherence [65,66].

Readiness for SDM

Effective SDM requires not only the availability of health information but also high-quality and SDM-supportive content [67]. In surgical decision-making for benign tumors, it is crucial for physicians and patients to engage in SDM, with patients receiving balanced information to help them make fully informed choices regarding treatment options [13].

However, balance in treatment-related articles on BBD emerged as a major concern, with only 15.7% (34/216) of articles meeting the criteria for high-quality content. Most articles lacked balanced discussions of potential risks or quality-of-life impacts, both of which are essential for informed decision-making [34]. This aligns with findings from US hospital websites, showing that such imbalanced information could mislead patients and undermine the SDM process [68]. Ensuring that the content patients encounter before consultations is balanced and decision-relevant could make WPAs a practical vehicle for embedding SDM into routine telemedicine.

Patients often rely on clinicians for information, yet inconsistencies arising from institutional practices or individual physician experience may lead to patient confusion [13,69]. Our content analysis revealed wide variation in treatment recommendations, which was primarily reflected in 2 aspects: treatment approaches and surgical decision-making. Most articles presented surgical indications as a combination of tumor characteristics (size and growth rate) and patient-specific factors (symptoms, age, family history, and anxiety), generally supported by literature [4,70-72]. However, the specific thresholds for tumor size that necessitate surgical excision and the definition of “rapidly growing” varied considerably. For instance, the recommended size threshold for fibroadenoma ranged from 2 cm to 3 cm across different regional and international guidelines [70,73,74], resulting in inconsistent information in the WPA articles.

Considerations related to pregnancy were also presented inconsistently. Due to the visible changes in the mammary glands in response to hormonal stimuli, breast masses detected during pregnancy require timely evaluation and individualized management [75,76]. Some of the included WPA articles suggested that surgical management of BBD in the context of pregnancy tends to be proactive in China, which may be partly related to the accessibility of specialized medical services and the anxiety of these patients [77-79]. Women with breast issues often fear the possibility of breast cancer, resulting in unnecessary treatments, patient anxiety, and expenditures [3,80].

Treatment approaches discussed in WeChat articles exhibit a hybrid model that integrates Western medicine and TCM in China [81]. Although VAE remains the dominant surgical approach, emerging treatments such as focused ultrasound also show promising potential [82]. Although TCM has demonstrated benefits in symptom relief and postoperative recovery, its clinical efficacy in treating BBD requires further validation through high-quality studies [83,84]. In the context of BBD, where management options range from observation to intervention, it is important for patients to receive balanced information regarding the risks and benefits of these approaches. Delivering patient-centered care can enhance patient satisfaction and adherence and reduce overtreatment and its adverse impact on quality of life [64,85,86].

Strengths and Limitations

Strengths

This study has several strengths. First, it adopted a nationwide sample covering diverse hospital types and levels of public hospitals across China. Second, it is the first systematic evaluation of the quality and SDM-supportive potential of BBD-related health education articles on hospital WPAs. Finally, a comprehensive assessment framework combining validated tools was applied, incorporating both clinician and patient perspectives to strengthen the reliability of the findings.

Limitations

First, the analysis was restricted to publicly available WPA articles and official institutional data, which may not fully reflect clinical communication and may contain reporting delays. Clinician and patient perspectives could complement these findings in future work. Second, retrospective web scraping may have missed deleted articles, although survivorship bias is likely limited given the large sample and the rarity of content removal by hospital WPAs. Third, the study assessed information quality rather than clinical accuracy. BBD management recommendations vary across guidelines, and future accuracy audits may be informative where consensus exists. Finally, interrater reliability for PEMAT-P was moderate, attributable to the diverse backgrounds of the 14 patient evaluators and the inherent subjectivity of judging understandability, which varies with individual health literacy and experience. The user-friendliness estimates thus warrant cautious interpretation, and more robust assessment tools and approaches are needed to complement the current evaluation.

Conclusions

Hospital WPAs have the potential to support SDM for BBD, owing to the availability and accessibility of medical information. However, their current SDM readiness is limited, underscoring the need for standardization and quality improvement initiatives to optimize patient-centered decision-making.

Abstract

Background: Real-time prediction of sepsis is a critical yet highly challenging task. Existing studies face 2 major limitations. First, they often rely on laboratory test results that are not readily available in real time, making timely diagnosis difficult. Second, the patient's condition evolves as a typical time series, but current methods often adopt coarse modeling strategies, with model architectures that are inefficient to train and deploy effectively.

Objective: This study aimed to develop a prediction model for online sepsis detection using only easily obtainable vital signs, such as heart rate and temperature, with variable-length input sequences while maintaining high predictive performance through the multiscale temporal representation learning.

Methods: We propose a deep learning model, Multi-Scale Temporal-aware Contrastive Learning (MSTCL), for efficient sepsis prediction based on the intensive care unit data derived from publicly available databases. We propose a multiscale temporal model to capture both short- and long-term dependencies in variable-length physiological time series. To enhance the robustness of our model, we used contrastive learning techniques that differentiate between positive and negative sepsis progression trajectories. Input features were limited to 6 vital signs, without reliance on laboratory tests or clinical notes.

Results: The model was evaluated on more than 400 patients with and without sepsis. It achieved an area under the receiver operating characteristic curve of 88.34%, a sensitivity of 89.29%, and a specificity of 73% for predicting sepsis onset based on variable-length vital-sign histories. The normalized mean absolute error for the predicted sepsis onset was 0.11%.

Conclusions: Our proposed model's low complexity and rapid inference make it suitable for deployment in real-time monitoring systems and low-resource environments. The ability to learn from variable-length historical data enhances the clinical applicability of our model. Furthermore, the methodology of temporal-aware contrastive learning offers a robust and efficient solution for online sepsis detection in diverse clinical settings.

sepsis prediction; deep learning; vital signs monitoring; temporal modeling; contrastive learning

Introduction

Sepsis is a life-threatening clinical syndrome caused by a dysregulated host response to infection, leading to acute organ dysfunction [1]. It is a major global health concern, accounting for an estimated 270,000 deaths annually, nearly 30% of all hospital deaths [2,3]. Timely identification and early intervention are critical for improving patient outcomes, as delays in treatment significantly increase mortality and morbidity [4,5]. Accordingly, the development of accurate and timely predictive models for sepsis onset remains a high-priority task in clinical informatics, with the potential to substantially reduce adverse

XSL•FO
RenderX

outcomes through early clinical alerts and proactive management.

Traditional approaches to sepsis prediction, such as the Sequential Organ Failure Assessment and quick Sequential Organ Failure Assessment scores [6], are widely used in clinical practice. These scoring systems rely on predefined thresholds and combinations of physiological and laboratory measurements to assess patient risk. However, their performance is limited by relatively low sensitivity, especially in the early stages of sepsis [7]. Moreover, their reliance on laboratory-based values restricts their applicability in settings where such information is delayed or unavailable [8]. As a result, there has been growing interest in leveraging machine learning and, more recently, deep learning approaches to improve predictive performance in sepsis detection.

Deep learning methods have shown promising results in sepsis prediction tasks [5,9], particularly models based on recurrent neural networks (eg, long short-term memory [LSTM] networks) and convolutional neural networks (CNNs). These models can capture temporal patterns and nonlinear dependencies in high-dimensional physiological data. For example, the Smart Sepsis Predictor [10], using an LSTM-CNN-fully connected architecture trained on intensive care unit (ICU) data, achieved an area under the receiver operating characteristic curve (AUROC) of up to 0.89 using only demographic and vital sign features, and up to 0.92 when laboratory data were included. Another large-scale study [11] used only 5 vital signs and patient age to predict sepsis mortality within 6 to 48 hours, reporting areas under the curve (AUCs) of 0.84 for CNN and 0.761 for LSTM for a 6-hour lead time. Though promising, many of these approaches suffer from practical limitations: they often require a large number of input features, including laboratory results, demographics, and textual data, which limits their deployment in real-time or low-resource settings. Additionally, many models assume fixed-length input sequences, which is incongruent with the inherently irregular and variable-length nature of clinical time-series data. These constraints hinder the usability and generalizability of existing methods across diverse clinical environments.

Recently, transformer-based models [12] have emerged as powerful alternatives for sequence modeling tasks. Originally designed for natural language processing, transformers excel in capturing temporal dependencies through self-attention mechanisms, without relying on recurrent structures. The ability to model sequential data makes transformers particularly well-suited to clinical applications, where patient data may evolve at varying rhythms and durations. For instance, Tang et al [13] proposed CNN-transformer and LSTM-transformer hybrid models for early sepsis prediction, demonstrating nearly 20% improvement over baseline recurrent neural network models for 4- to 12-hour preonset windows. Another recent study by Chang et al [14] designed a transformer-based diffusion probabilistic model to forecast vital signs (heart rate, systolic blood pressure, and diastolic blood pressure) in ICU patients, achieving substantial gains in inference speed over baselines using MIMIC-III data [15]. However, existing transformer-based approaches often still rely on relatively rich sets of inputs—including laboratory measurements and demographic features—or presume that sufficient historical data are available.

In this work, we harnessed the strengths of the transformer architecture to build a lightweight, flexible, and high-performing model for real-time sepsis prediction. Specifically, we proposed Multi-Scale Temporal-aware Contrastive Learning (MSTCL), which models the temporal dependencies in routinely monitored vital signs. Unlike conventional approaches that require a fixed window of input data, our model supports variable-length sequences and enables efficient online inference through an autoregressive encoder-decoder design. This allows real-time prediction of sepsis onset using only a short and dynamically updating history of patient monitoring data, making it suitable for real-time warning systems in intensive care and emergency settings.

To further enhance the model's robustness and applicability in diverse clinical conditions, we intentionally restricted the input features to 6 easily obtainable and commonly monitored vital signs: oxygen saturation, heart rate, body temperature, systolic blood pressure, diastolic blood pressure, and respiratory rate. While this focus on noninvasive data distinguishes our work from methods relying on exhaustive laboratory results, it introduces a significant technical challenge: the reduction in input features may limit the model's ability to capture the subtle, high-dimensional physiological precursors of sepsis. To bridge this information gap and ensure high predictive performance despite the simplified inputs, we proposed the MSTCL framework.

Specifically, in this study, we proposed a hybrid contrastive learning objective that distinguishes patient vital sign sequences from 3 perspectives: positive segments, negative segments, and full sequences, with the last serving as transitional intermediaries. By enforcing distinct distances among the representations of these 3 types of sequences, the model achieves more stable perception of complex dependencies within patient data streams.

In summary, the proposed framework enables multiscale temporal modeling and contrastive representation learning in a lightweight, autoregressive architecture, consuming only 6 vital signs as input. This enables real-time, variable-length sepsis prediction across diverse clinical environments. Our approach demonstrates that accurate online prediction of sepsis is feasible using easily obtainable physiological data while maintaining robust generalization and operational efficiency.

Methods

Dataset

The training and testing data used in this study were sampled from the publicly available PhysioNet Computing in Cardiology 2019 Challenge dataset [16]. This dataset includes ICU records from patients in 3 different hospitals, of which data from 2 hospitals are openly accessible. These 2 sources provide a total of 40,336 patient records, each containing hourly time-stamped information on demographics, vital signs, and laboratory values, which is referred to in this paper as the "original dataset." However, most of these records are temporally sparse. In many

XSL•FO
RenderX

cases, even over dozens of recorded hours, most laboratory values and some vital signs had only a few valid entries. This sparsity highlights the difficulty of obtaining real-time laboratory values in most clinical settings, which in turn motivates our study: to enable real-time sepsis prediction using only easily monitored and frequently available vital signs. To achieve this, we applied the following data filtering procedure. First, we separated the original dataset into records of patients with sepsis (with confirmed sepsis onset) and patients without sepsis (entirely negative throughout the ICU stay). For nonseptic records, we randomly sampled sequences in which the missing rate of vital signs was no more than 50%. For septic records, we first identified the sepsis onset point and then examined a 16-hour window surrounding it. If the missing rate of the 6 selected vital signs within that window was less than 50%, the record was retained in our dataset. This selection was based on the assumption that, to train a real-time predictive model—especially when using a limited number of input variables—the training data must exhibit reasonably high temporal quality. Only with sufficient continuity and density in the input signals can the model effectively learn and capture the underlying temporal dependencies necessary for accurate sepsis onset prediction. Table 1 summarizes the overall demographics of the data sampled from the source dataset for training and testing in this study. The number of qualified vital sign sequences from positive and negative patients was 1093 and 2673, respectively, totaling 3766 sequences—less than one-tenth of the original dataset size of 40,336. The sex ratio and age distribution of the sampled dataset were generally consistent with those of the original dataset. For both positive and negative patients, the number of samples increased progressively with age. The age distribution of positive patients exhibited a more pronounced long-tail pattern compared with that of negative patients. Due to the temporal sparsity of the original PhysioNet Challenge data, we trained and evaluated the proposed MSTCL framework based on these processed samples, which were split into training and test sets using a 4:1 ratio.

Table . Demographic characteristics of patients with sepsis and patients without sepsis.

Demographic variables	Septic (n=1093), n (%)	Nonseptic (n=2673), n (%)	Overall (n=3766), n (%)	Original data (n=40,336) [16], n (%)
Male	656 (60)	1823 (68.2)	2478 (65.8)	22,568 (56)
Age group (years)

Model Architecture

Figure 1 presents an overview of our proposed MSTCL model. We focus on real-time sepsis prediction using only 6 easily obtainable vital signs: oxygen saturation, heart rate, body temperature, systolic blood pressure, diastolic blood pressure, and respiratory rate. As illustrated in Figure 1A, we collected high-quality, continuous sequences from the original dataset to construct our training and testing datasets. The goal of this study was to design a neural network model capable of predicting the current likelihood of sepsis onset in real time, based on variable-length sequences of these vital signs. To effectively model the relationship between this limited set of vital signs and sepsis onset, we proposed a multiscale temporal dependency modeling architecture, MSTCL (TMS), as presented in Figure 1C, which is equipped with the contrastive learning based on the vital sign sequence representations shown in Figure 1B.

Specifically, during training, a given vital sign sequence $S \in R^{t\times 6}$ is first embedded into $X \in R^{t\times d}$ via a linear layer, $X=fh(S)$, where t is the temporal length of the 6D vital signs and *d* is the hidden dimension of the model. Then, the projections for query, key, and value are computed to obtain Q, K, $V \in R^{t\times d}$, respectively. The attention map $MA \in R^{t\times t}$ is computed as the matrix product between Q and K.

To simulate sepsis prediction based solely on the historical vital signs during test time, a causal mask $MC \in R^{t\times t}$ is applied during training. This is achieved via a Hadamard product between MA and MC, ensuring that the attention mechanism is restricted to time steps prior to the current one (ranging from 1 to *t*), resulting in a lower-triangular matrix as illustrated in Figure 1C. The global autoencoded representation of the input sequence is then obtained by the following methodology with residual connections and activation functions omitted for clarity:

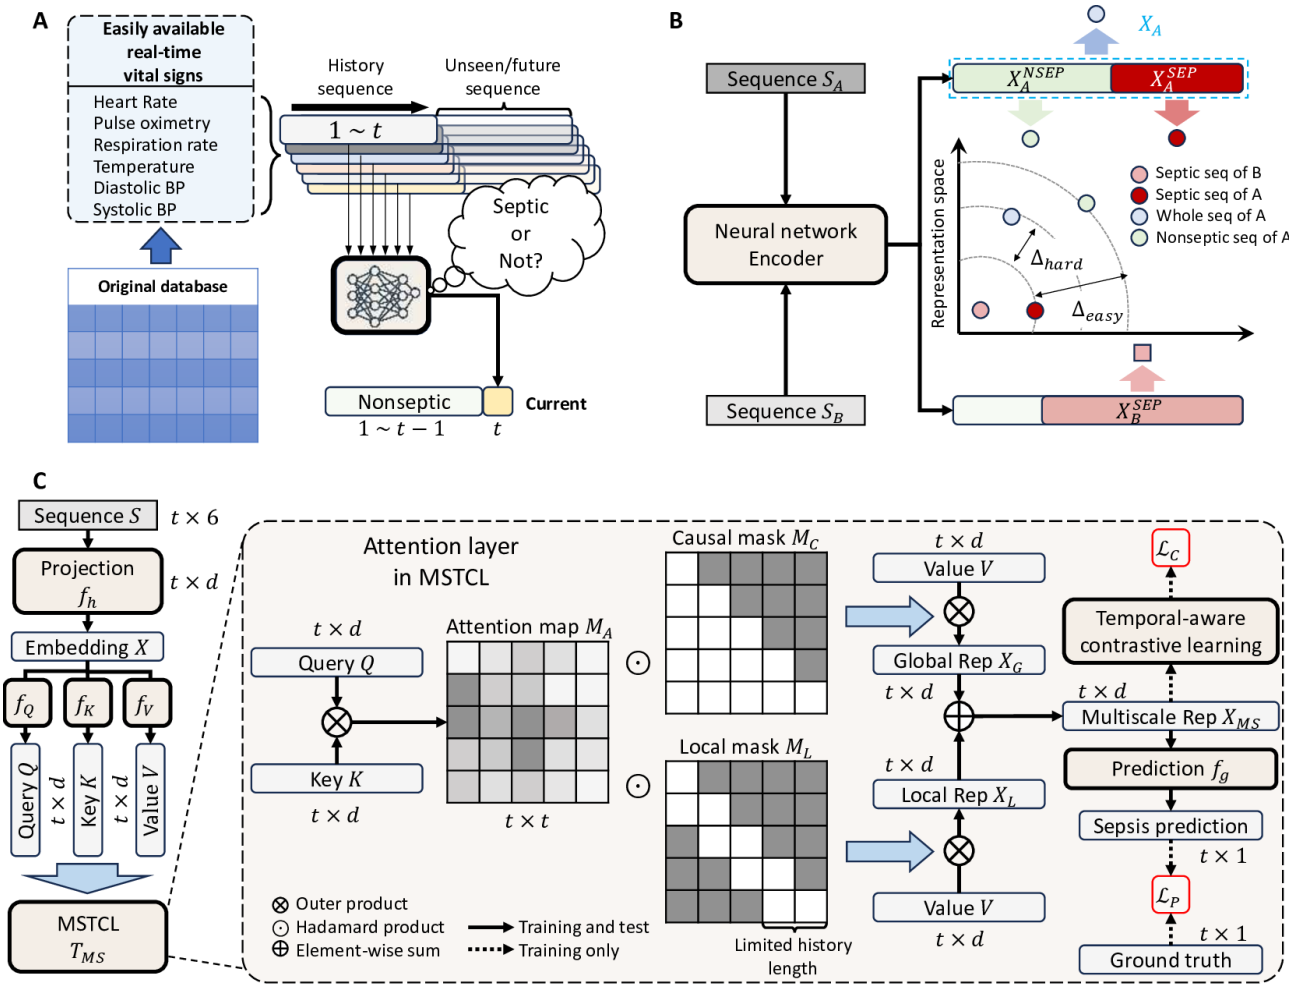
$$\textbf{(1)} XG=QT\otimes K\odot MC\otimes V, XG\in R^{t\times d}$$

While the transformer was originally proposed to model global dependencies in sequence data, sepsis onset is often correlated with local temporal patterns. Therefore, we introduce a local self-attention branch equipped with a local mask $ML \in R^{t\times t}$ to capture short-term dependencies. To implement this, earlier history beyond a predefined window is masked, such that each time step can only attend to a limited portion of the past, enabling localized temporal modeling. The local representation is obtained in a similar manner described in equation 1 as $XL \in R^{t\times d}$. Finally, the multiscale representation of the vital sign sequence is computed as element-wise addition:

$$\textbf{(2)} XMS=TMS(S)=XG\oplus XL$$

Based on this multiscale representation, we proposed a contrastive learning framework to help the model discriminate

XSL•FO
RenderX



between septic and nonseptic sequences. Specifically, as shown in Figure 1B, for any 2 given septic sequences SA and SB, we extract the septic and nonseptic subsequence representations XASEP and XANSEP from SA, along with its full-sequence representation XA, and the septic subsequence representationXBSEP from SB. These representations are obtained by performing average pooling on the feature sequences encoded by the proposed MSTCL model (equation 2). For clarity, we omit the subscript MS on these representations.

Intuitively, the distance between XBSEP and XASEP should be smaller than that between XBSEP and XANSEP, while the distance between XBSEP and XA should lie in between. This assumption is visualized in the schematic of the representation space in Figure 1B. We formalize this assumption as a temporal-aware contrastive learning objective and incorporate it into the training process.

Finally, the sepsis prediction is performed using a linear layer fg followed by a sigmoid activation function to produce the probability of sepsis onset at each time step.

(3)y^=fg(XMS),y^∈ Rt×1

(C) The autoregressive Multi-Scale Temporal-aware Contrastive Learning (MSTCL) architecture using multiscale causal masks, where darker colors represent lower values.

Model Training and Test

The training objective of our model consists of 2 main components: a classification loss between the step-by-step sepsis onset predictions (positive or negative) and ground truth labels y∈ Rt×1, simulated using a causal mask

(4) Lp=−1t∑i=1t(yilog (y^i)+(1−yi)log (1−y^i)),

and a contrastive learning loss based on multiscale representations of the vital sign sequences

[illegible]

where △easy=0.25,△hard=0.2 are set in this study by evaluating three configurations (0.2/0.15, 0.25/0.2, and 0.3/0.25), among which the setting of 0.25/0.2 yields the lowest mean absolute error (MAE) value of 0.113; d(·,·) denotes a distance measure, which is Euclidean distance based on L2-normalized features in this study. Our proposed MSTCL model optimized a combined loss that integrates both objectives.

(6)L=LP+LC

The model was implemented using Python (Python Software Foundation) and PyTorch (version 2.1; PyTorch Foundation) and was trained with the Adam optimizer [17] with an initial

XSL•FO
RenderX

learning rate of 1×10^{-4} for 100 epochs. The proposed MSTCL model contains approximately 0.6 million parameters. Compared with several existing deep learning–based methods, such as temporal convolutional networks [18] (approximately 0.4 million) and the method described by Li et al [19] (approximately 0.45 million), our approach achieved superior performance, even in an online prediction setting, while maintaining a comparable model size. During inference, as illustrated in Figure 1C, neither of the 2 training losses was required. The model is capable of predicting the likelihood of sepsis onset in real-time, based solely on the newly incoming vital sign values at each time step. The inference latency of our MSTCL was 19 milliseconds with 20 MB VRAM on NVIDIA GTX 1650 Ti (4 GB).

Evaluation Metric

In the testing phase, the model encoded the incoming vital signs sequence and performed step-by-step online prediction of y^. When the model predicted a positive case of sepsis, the current sequence is marked as septic, and the difference between the predicted onset and the ground truth is measured using MAE normalized by the input sequence length. If the model does not predict any positive outcome throughout the entire test sequence, the sequence is classified as nonseptic. Accordingly, in addition to MAE, we also used AUROC, area under the precision-recall curve (AUPRC), sensitivity, and specificity to evaluate the model's ability to distinguish between septic and nonseptic sequences. AUROC measures the trade-off between true positive and false positive rates across thresholds. AUPRC focuses on performance under class imbalance by evaluating precision and recall. Sensitivity (true positive rate) assesses the proportion of actual septic cases correctly identified, while specificity (true negative rate) reflects how well the model excludes nonseptic cases.

Ethical Considerations

The publicly available, fully anonymized PhysioNet Computing in Cardiology 2019 Challenge dataset was used in this study. Our study protocol was approved by the Ethics Committee of Tianjin First Central Hospital, which waived ethical review and informed consent, and all experimental practices conformed to institutional and national human research ethics criteria and the World Medical Association Declaration of Helsinki.

Results

Table 2 presents the performance of the proposed method in predicting sepsis onset, measured by AUROC, AUPRC, MAE, sensitivity, and specificity. The reported MAE values are normalized by the input sequence length.

Specifically, 2 types of temporal modeling strategies were considered: local and global, corresponding to "Loc" and "Glb" in the table. For negative sampling in contrastive learning, we compared 2 types: vital sign segments from only negative patients (NegSeq in Table 2), and full-length vital sign sequences (WholeSeq in Table 2). These served as "easy" and "hard" negatives, respectively, relative to the positive sequences derived from patients with sepsis. By performing ablations on these 4 components (eg, Loc, Glb, NegSeq, and WholeSeq), we assessed the individual contributions of each design choice. From the first and second rows of Table 2, we observed that even when negative sampling was optimized for contrastive learning, the absence of either local or global temporal modeling substantially degraded performance (eg, AUROC decreased by 22.9 and 20.9 points, respectively, relative to the best-performing configuration). This finding highlights the foundational role of capturing multiscale temporal dependencies in patient vital signs for effective sepsis prediction. Rows 3, 4, and 5 further examine the impact of introducing full-length sequences as harder, transitional negatives. These helped the model learn more discriminative representations by pushing it to distinguish subtle differences in complex temporal patterns. This effect is further demonstrated through visualization analysis.

We applied the t-distributed stochastic neighbor embedding method to visualize the latent representations of patients' temporal vital sign data before and after training. As shown in Figure 2, compared with the pretraining state (Figure 2A), the full-length vital sign sequences, which include both positive and negative segments, became more distinguishable from purely negative sequences after training (Figure 2B). This aligns with the natural assumption that full sequences are more similar to positive sequences than to negative sequences. Overall, the combination of multiscale temporal modeling and hierarchical contrastive learning yielded the best predictive performance across all metrics.

Figure 2. t-distributed stochastic neighbor embedding (t-SNE) visualization of vital sign representations before and after training. (A) Sequence representation before training and (B) sequence representation after training.

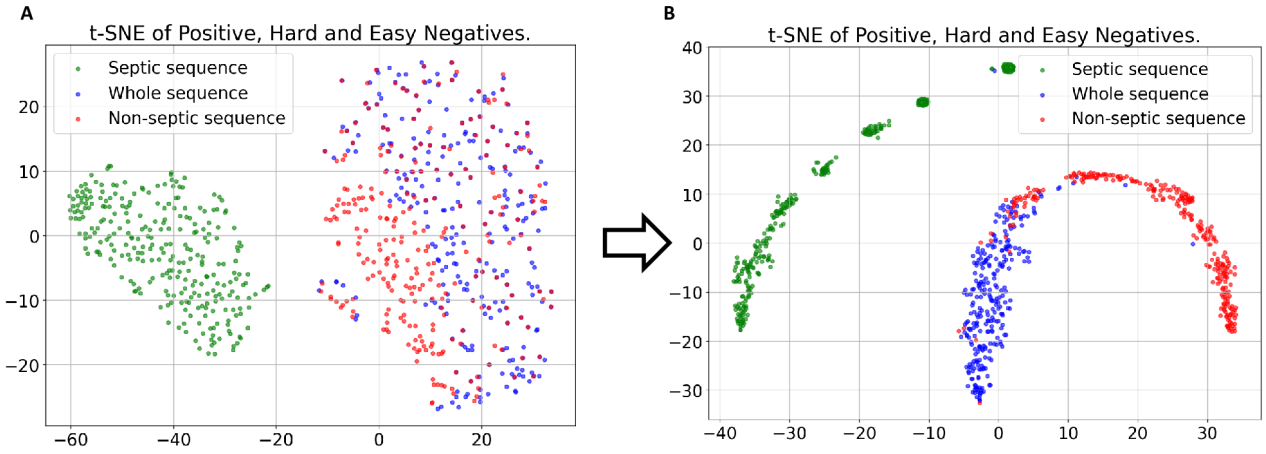

Figure 3 illustrates the stabilization of AUROC, AUPRC, and MAE on the test dataset as the number of training epochs increased. The results cover the first 100 training epochs. All 3 metrics exhibited some fluctuation during the initial 10 epochs. After the 10th epoch, AUROC and AUPRC steadily improved, reaching their peak values, which were 88.3 and 86.7, respectively, around epoch 60, after which they plateaued. Meanwhile, the normalized MAE showed a gradual decline following the 10th epoch, with slightly more fluctuation than AUROC and AUPRC, indicating progressively more accurate predictions of sepsis onset timing. MAE also reached its lowest point around epoch 60, with greater stability in the later training stages compared with earlier ones. One possible reason for the relative instability of MAE is that it is a discrete metric, reflecting the difference between the predicted transition-to-positive point within the model's output sequence and the actual onset time of sepsis.

Figure 3. Visualization of model performance metrics across the training process. AUPRC: area under the precision-recall curve; AUROC: area under the receiver operating characteristic curve; MAE: mean absolute error.

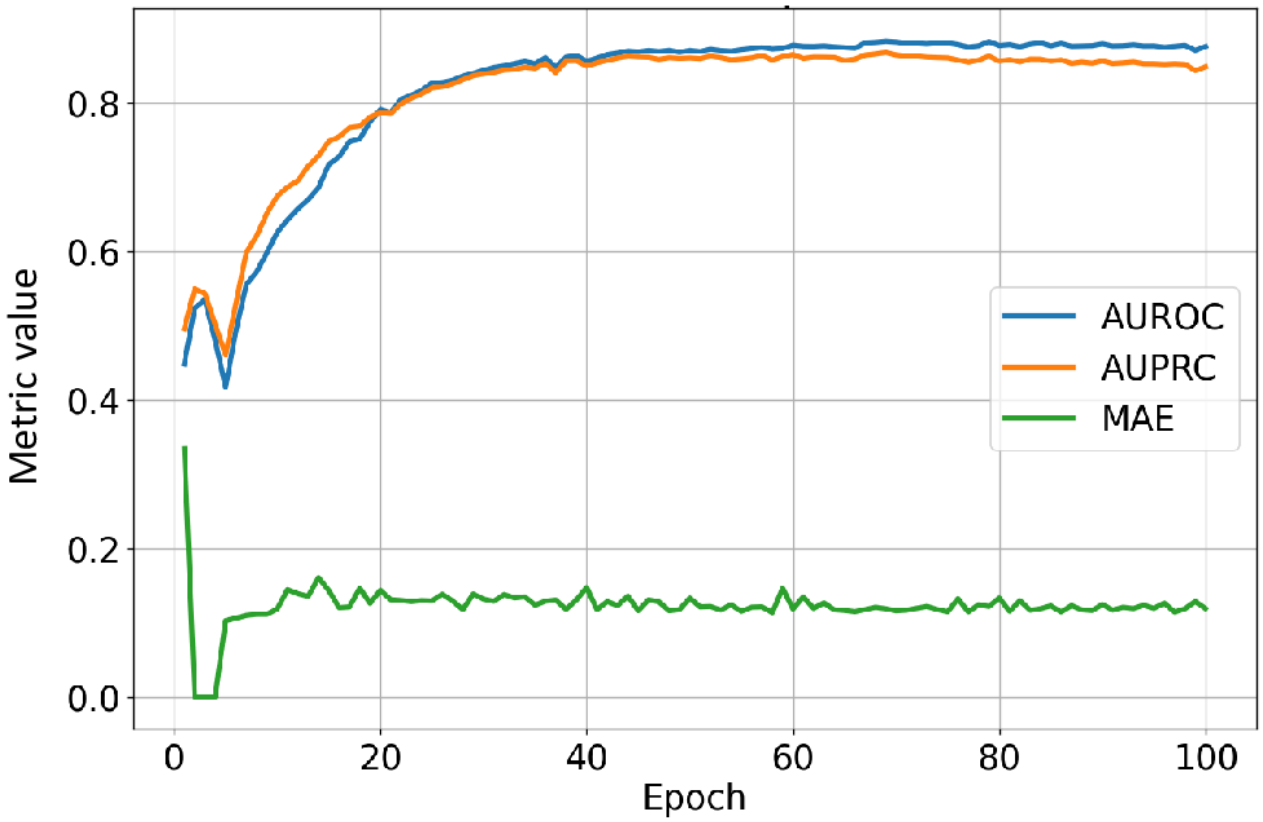

Figure 4 shows the probability distribution of the normalized prediction error, including the probabilities of correct, early, and delayed predictions among all detected sepsis sample sequences. It can be observed that the most frequent errors occur at a lead of 0.11 and a lag of 0.11, accounting for approximately 16% and 21%, respectively. Predictions that are approximately correct (±0.05) each account for about 8%, indicating that more than 64% of predictions fall within a ±0.11 error margin.

Table 3 compares the proposed method with existing related works across several key dimensions, including temporal modeling approach (temporal model), task type (manner), the number of training and testing samples used (samples), the number of input vital signs (input), required historical sequence length (history length), and performance metrics such as AUC and MAE. Regarding the evaluation metrics, we introduced MAE specifically to quantify the model's ability to precisely locate the sepsis transition point in a continuous time series. While traditional metrics like AUC evaluate classification accuracy, MAE provides insight into the 'early warning' lead time, which is a unique focus of our MSTCL framework compared with existing single-point prediction methods. Among all methods listed, aside from our proposed approach, the kinematics approach with neural networks for early detection of sepsis (KANNEDS) [20] uses the fewest types of input signals. It is based on an LSTM architecture designed for sepsis identification but lacks the capability for real-time onset prediction and requires fixed-length historical sequences. The temporal convolutional network [18], on the other hand, supports variable-length input sequences for identifying patients with sepsis but relies on as many as 40 types of input signals and uses the entire original dataset. Zhao et al [21] proposed a model based on light gradient boosting machine, achieving the highest AUC among identification tasks, but it still requires fixed-length historical sequences as input. Li et al [19] introduced a powerful LSTM+CNN-based model capable of predicting sepsis onset, reaching an AUC of 0.96; however, it requires a large amount of training data to achieve such performance. In contrast, our proposed MSTCL achieves efficient and lightweight online sepsis prediction using only a small set of vital signs and approximately one-tenth of the data required by other methods. This demonstrates the model's strong performance and generalizability even under limited data conditions.

To further investigate the importance of the selected 6 vital signs, we evaluated the model's sensitivity by systematically masking each input signal (setting its value to zero) during the inference phase and observing the degradation in predictive performance compared with the full-feature model (ALL).

As verified by the MAE metrics obtained via leave-one-feature-out ablation over 6 vital sign inputs, excluding body temperature yielded the highest MAE (0.18) and triggered the most substantial performance decline, highlighting its critical role in identifying the systemic inflammatory response in sepsis. Removing oxygen saturation, heart rate, and systolic blood pressure separately led to moderate MAE increments of 0.14, 0.15, and 0.13, respectively, while eliminating either diastolic blood pressure or respiratory rate only caused a slight MAE elevation to 0.12; by contrast, incorporating all 6 vital signs achieved the most minimal MAE (0.11). Collectively, these results empirically support the clinical relevance of our 6-feature configuration, which strikes an effective balance between model complexity and predictive power.

XSL•FO
RenderX

The choice of margins △easy and △hard is crucial for hierarchical feature learning. The configuration of (0.25, 0.2) achieved the best prediction performance. However, the performance did not vary significantly with the changes in this parameter. Consequently, when applying the proposed MSTCL framework to other datasets, the setting of this parameter is unlikely to become a performance bottleneck.

Discussion

In this study, we developed a lightweight yet effective framework for real-time sepsis prediction using only 6 commonly available vital signs. Our approach integrates a multiscale transformer-based temporal modeling architecture with a novel temporal-aware contrastive learning strategy, enabling accurate online prediction of sepsis with few input features and significantly fewer samples than most prior studies. This design is motivated by the practical challenge that high-frequency laboratory data and rich clinical notes are often unavailable in many health care settings—particularly in low-resource environments, emergency departments, and wearable-device applications. Our findings demonstrate that sepsis prediction does not necessarily require complex or high-dimensional inputs, as long as the temporal structure of vital sign data is adequately leveraged.

The results from our experiments show that both global and local temporal dependencies play crucial roles in modeling the progression toward sepsis onset. Ablation studies indicate that removing either the global or local attention mechanism substantially degrades predictive performance, underscoring the importance of modeling multiscale dynamics in patient vital signs. This is consistent with prior findings that temporal context and resolution are key factors in accurate time-series modeling for health care applications [22,23]. By combining the 2 scales through residual connections, our model captures both longer-term physiological trends and short-term fluctuations, which are often indicators of clinical deterioration.

Another significant contribution of this work is the introduction of a temporal-aware contrastive learning objective tailored for sepsis trajectory modeling. Unlike standard contrastive learning formulations, which generally rely on static sample augmentations, our framework exploits the natural progression of vital sign sequences by constructing positive, negative, and full-length sequence representations. This hybrid triplet-like structure helps the model better distinguish between subtle temporal variations, especially when labeled data are limited. Similar supervised contrastive approaches have shown promise in related health care domains, such as mortality prediction [24,25] and patient state representation [26,27], and our work further demonstrates their applicability in the context of real-time warning tasks.

Compared with prior studies, our approach requires far fewer training samples. For example, Li et al [19] developed a hybrid CNN-LSTM model that achieved a high AUC (up to 0.96) for sepsis onset prediction but required the full MIMIC dataset and numerous laboratory-based inputs. Other models, such as KANNEDS [20] or light gradient boosting machine–based architectures [21], either relied on fixed-length input windows or used up to 40 types of features, limiting their generalizability and real-time applicability. In contrast, our method achieves comparable performance while being trained on fewer than 10%

XSL•FO
RenderX

of the original dataset and using only 6 vital signs, significantly expanding its deployment potential.

A key clinical advantage of our approach is the reliance on only 6 noninvasive vital signs, a strategy aligned with several established models [28,29]. However, we emphasize that the primary innovation of this study is the MSTCL framework itself rather than the specific feature subset. By enforcing contrastive constraints across multiple temporal scales, the framework captures the fine-grained physiological shifts preceding sepsis onset more effectively. This allows our model to bridge the performance gap between limited input and comprehensive input systems, providing a robust tool for high-precision, real-time clinical monitoring.

Our contrastive visualization results further support the model's ability to learn meaningful representations. As shown in Figure 2, the latent space representations after training display clearer separability between septic and nonseptic patterns, with full-length sequences positioned between the positive and negative extremes. This aligns with clinical intuition and confirms that our contrastive learning framework facilitates more discriminative embedding learning, especially in scenarios with reduced feature sets.

Despite these promising results, there are limitations to our study. First, while the model supports variable-length sequences, extremely short sequences (eg, <4 hours) may not provide enough temporal context for reliable prediction. Although our model is designed to be robust to input length, future work could explore adaptive mechanisms that adjust attention scope based on data sparsity. Second, our evaluation focuses on binary classification of sepsis onset. Extending the framework to estimate time-to-onset as a survival analysis task or to model continuous deterioration risk could offer additional clinical value.

Moreover, our current contrastive design relies on predefined segmentations of sequences into septic and nonseptic windows. While effective, this assumes a clear ground truth onset time in the training phase, which in practice can be noisy or inconsistently recorded across institutions. Future iterations could incorporate soft labels or probabilistic sequence labeling to handle uncertainty in sepsis onset annotations.

From a clinical deployment perspective, the simplicity and efficiency of our model offer distinct advantages. The low computational cost of inference and reliance on readily available vital signs make it suitable for edge deployment on patient monitors or wearable devices. This aligns with broader efforts in ubiquitous health monitoring and early warning systems, where predictive models must operate under resource and latency constraints [30]. The interpretability of the model, particularly via attention visualization or representation clustering, is also a promising direction for integration into clinician-facing decision support tools.

In conclusion, this study presents a novel and efficient framework for online sepsis prediction using only fundamental physiological real-time signals. Through multiscale temporal modeling and contrastive learning, we demonstrate that even with limited data, accurate and timely sepsis detection is achievable. These findings underscore the potential for deploying intelligent monitoring solutions across a wide range of clinical and nonclinical settings, ultimately contributing to better patient outcomes and more efficient resource allocation in critical care.

Abstract

Background: Depression affects over 40% of middle-aged and older Chinese adults living with both hypertension and diabetes, amplifying cardiovascular risk, functional decline, and mortality. Existing screening instruments—such as the 10-item Center for Epidemiologic Studies Depression Scale—focus narrowly on mood symptoms and are rarely feasible in busy primary care consultations. They also omit routine functional, cognitive, and social data that may jointly drive depressive states in cardiometabolic populations.

Objective: This study aimed to develop and validate a concise, clinically actionable nomogram that quantifies individual depression risk using readily available information in Chinese adults aged ≥45 years who have diagnosed hypertension and type 2 diabetes.

Methods: We analyzed anonymized wave 5 China Health and Retirement Longitudinal Study data collected between July 2020 and August 2020. Of 1504 eligible participants, 635 (42.2%) met the Center for Epidemiologic Studies Depression Scale cutoff score of >10 for probable depression. A total of 42 candidate predictors spanning demographics, laboratory values, comorbidities, functional status, and socioenvironmental factors were screened. Least absolute shrinkage and selection operator regression with 10-fold cross-validation identified the most parsimonious set. A multivariable logistic model was built on a 70% training set (n=1052) and evaluated on a 30% testing set (n=452). Performance was assessed using the area under the receiver operating characteristic curve (AUC), calibration plots, decision curve analysis, and Shapley additive explanations for interpretability. Multiple imputation was used to handle <20% missingness.

Results: Nine nonredundant predictors entered the final nomogram: activity of daily living score, memory impairment, number of pain sites, sleep duration, life satisfaction score, self-rated health score, social activity engagement score, retirement status, and memory test score. The model achieved excellent discrimination (training AUC=0.819; testing AUC=0.825) and calibration (mean absolute error ≤0.018). Decision curves demonstrated positive net clinical benefit across clinically relevant threshold probabilities. Shapley additive explanations analysis revealed a 3-fold increase in depression odds per 1-point increase in activity of daily living score, whereas retirement conferred substantial protection (prevalence of depression: 103/635, 16.2% in the retired group vs 269/869, 31.0% in the nonretired group; *P*<.001), mediated by greater social participation.

Conclusions: The 9-item nomogram enables <3-minute depression risk stratification in resource-limited primary care settings for adults with hypertension and diabetes. Functional decline, affective-cognitive burden, and socioeconomic disengagement constitute the dominant causal pathway. Prospective trials should examine whether interventions targeting postretirement social engagement and functional rehabilitation can reduce incident depression in this high-risk population.

Introduction

Depression imposes an additional burden on people living with chronic conditions, especially among middle-aged and older adults who are trying to manage both high blood pressure and diabetes [1]. These physical illnesses often appear together with depressive symptoms, making treatment harder and speeding up the loss of daily function [2]. Studies have shown that, in this group, the rate of depression can reach more than 40% in some samples, and it is linked to poorer treatment adherence, higher heart-related risks, and greater chances of early death [3,4]. Even though depression is clearly important, it is still missed in many primary care visits [5]. The screening tools we have are reliable on paper, but they are hard to fit into busy clinics because of limited time and other practical barriers. The 10-item version of the Center for Epidemiologic Studies Depression Scale (CESD-10), widely used in Chinese-speaking populations, is a good example: when used alone, it cannot draw on the wider set of clinical, behavioral, and social clues that would help physicians spot depression earlier [6,7].

Most earlier models for predicting depression were built for people receiving psychiatric care or used general risk factors, so they do not work well for people who also have long-term illnesses [8,9]. A key weakness is that these models rarely include measures of daily function, such as the ability to bathe, dress, cook, and handle money, together with behavioral and social factors [10]. This omission matters because poor physical function can be both an early sign of depression and a result of uncontrolled blood pressure or blood sugar, making it hard to know which came first [11]. For these reasons, we set out to create a simple, practical tool to estimate depression risk in middle-aged and older adults with hypertension and diabetes. Using data from the China Health and Retirement Longitudinal Study (CHARLS), we examined 42 possible predictors covering medical, psychological, and social areas. Using a logistic regression model improved through machine learning and checked through several validation steps, we carried out 3 tasks: choosing the smallest set of predictors that still separates high-risk from low-risk individuals; turning these predictors into a clear, easy-to-use score that can be applied in busy, low-resource clinics; and showing, with numbers, how much heart- and metabolism-related functional problems act as a link between illness and depression. Rather than focusing only on symptoms, our approach places depression risk within the patient's overall health picture. The resulting model can guide clinicians and also point to potentially modifiable risk factors.

Methods

Ethical Considerations

This study used anonymized data from the fifth wave of the CHARLS. The project was approved by the Peking University Biomedical Ethics Committee in June 2008 (approval IRB00001052–11015). All personal identifiers were removed before our analysis. Patients and the public were not involved in the design, conduct, reporting, or dissemination of this research. All participants provided written informed consent, and the study followed the ethical principles set out in the Declaration of Helsinki. No financial or material compensation was offered to study participants.

Study Population

We carried out a retrospective study using data from the fifth wave of the CHARLS collected between July 2020 and August 2020. Participants had to be aged at least 45 years and have both hypertension and diabetes. We excluded anyone who was missing key details such as CESD-10 score, diagnosis of hypertension or diabetes, or age. After these exclusions, 1504 people were left for the analysis. Depression status was based on the CESD-10, a brief questionnaire that mixes positively and negatively worded statements. Each item is scored from 0 to 3, yielding total scores from 0 to 30; higher scores mean more severe depressive symptoms [12,13]. In Chinese older adults, a score above 10 is generally taken to indicate possible depression, and this cutoff has been shown to work well in previous studies and in latent profile analyses [13,14]. Using this cutoff, of the 1504 participants, we labeled 635 (42.2%) as the depression group and 869 (57.8%) as the nondepression group.

Candidate Predictor Variables

Guided by earlier studies and clinical practice, we chose 42 factors that might relate to depression risk [15-17]. These factors cover basic personal details, overall health, daily habits, blood test results, and how well people manage daily tasks. The full list is as follows: sex, age, marital status, smoking status, drinking status, cancer, lung disease, heart disease, stroke, mental illness, arthritis, high blood fat, liver disease, kidney disease, stomach disease, asthma, memory problems, hip fracture, number of painful body sites, exercise level, sleep hours, social activity engagement, whether the patient was retired, medical insurance, pension insurance, years of schooling, household size, number of living children, household income, recent physician visits, memory test score, activity of daily living (ADL) score, instrumental ADL (IADL) score, self-rated health, and satisfaction with life. Regarding "social activity engagement," it was categorized into the following eight types: (1) interacted with friends (visiting friends or socializing with friends); (2) played mahjong, played chess, played cards, or went to community clubs; (3) provided help to family members, friends, or neighbors who do not live with the participant and who did not pay them for the help; (4) went to a sports, social, or other type of club; (5) took part in community-related organization activities; (6) did voluntary or charity work; (7) attended an educational or training course; and (8) other.

Participants completed the questionnaire based on their actual situation: participation in 1 type of the above activities was recorded as "1," participation in 2 types was recorded as "2," and a higher count indicated a higher level of social activity engagement of the participant. For "life satisfaction," the CHARLS survey asked respondents about their overall satisfaction with their lives, with 5 response options: "extremely satisfied," "very satisfied," "relatively satisfied," "not very satisfied," and "not satisfied at all." For the convenience of statistical analysis, we assigned numerical values to these levels: "1" represented "not satisfied at all," "5" represented "extremely

XSL•FO
RenderX

satisfied," and so on, with each level corresponding to a specific number.

Model Construction Methods

We used least absolute shrinkage and selection operator (LASSO) regression to pick out the most useful risk factors while keeping the list short. Ten-fold cross-validation helped us find the best penalty value (λ). We then split the data into a training set (1052 people) and a testing set (452 people) in a 7:3 ratio. The training set was used to find the key factors linked to depression. These factors were entered into a standard logistic regression, and we drew a simple chart (nomogram) to show how each one affected the risk of depression. To keep the model easy to use, we removed predictors with little impact, reran the logistic regression with the remaining ones, and built the final nomogram.

Model Evaluation Methods

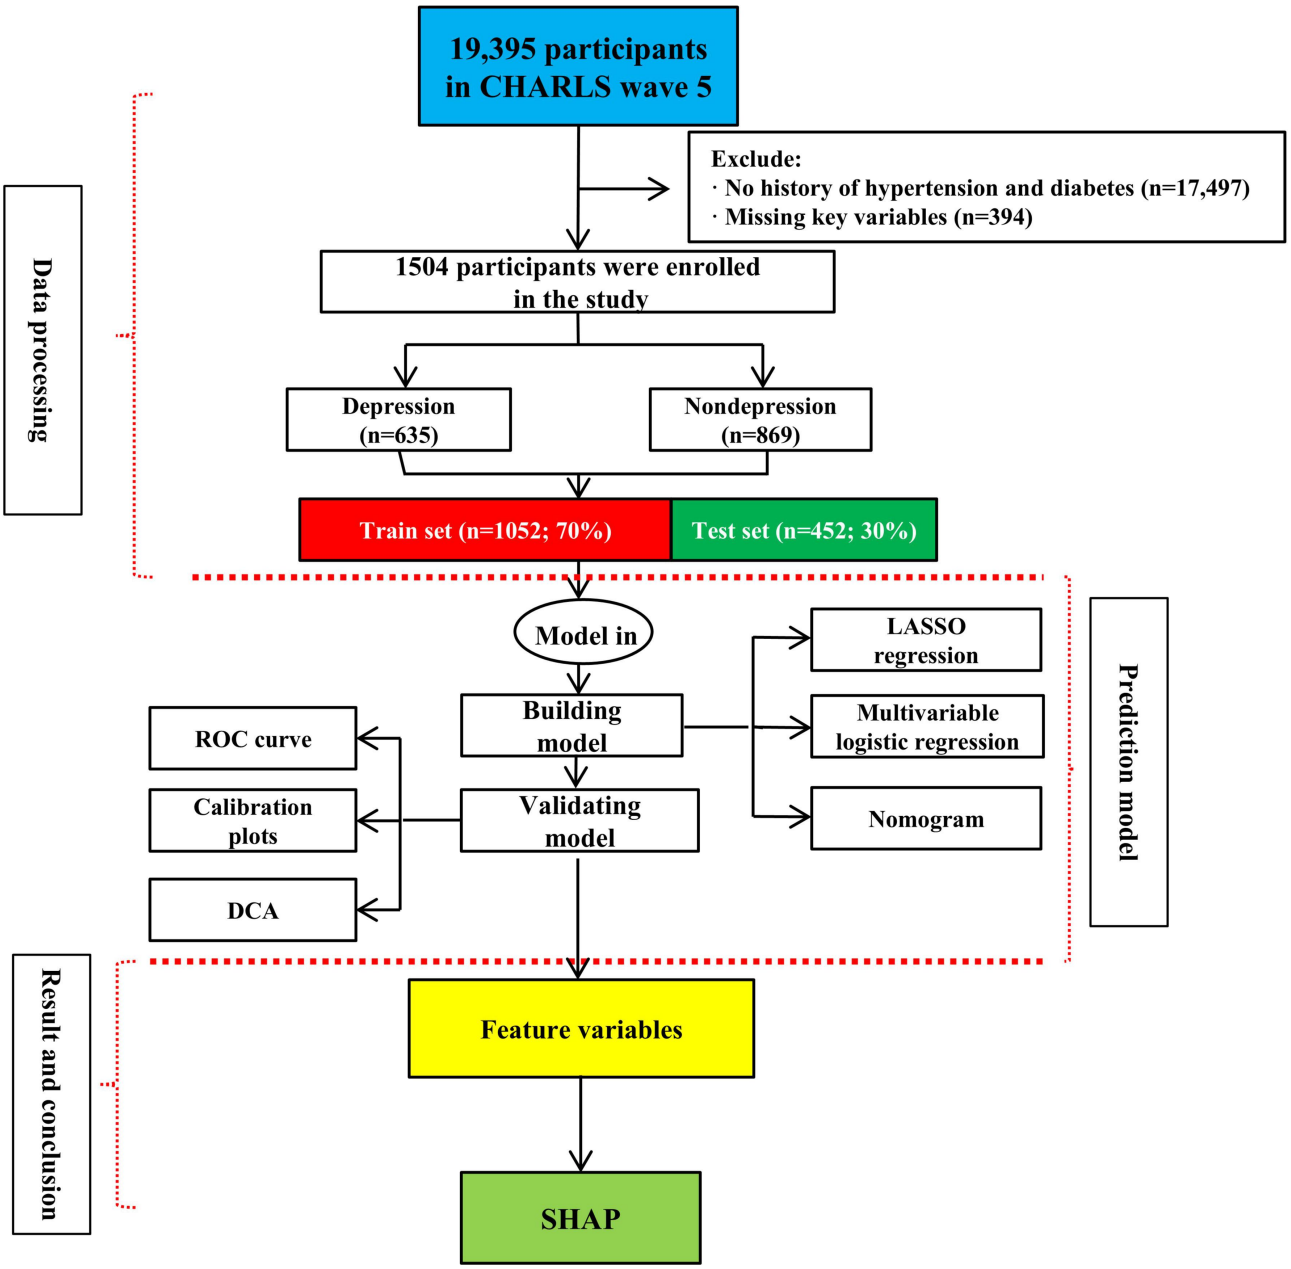
To check how well the model performed, we used receiver operating characteristic curves and the area under these curves (AUC) to measure overall ability to separate people with and without depression, calibration plots to check whether the predicted chances matched what really happened, and decision curve analysis to weigh the benefits of true positive predictions against the harms of false ones, giving a clear picture of both accuracy and clinical value.

Model Interpretation Methods

To make the model easier to understand, we used Shapley additive explanations (SHAP) values to show how much each factor mattered. We drew 4 simple charts (an overall importance plot, a swarm plot, a waterfall plot, and a force plot) that displayed how every factor pushed the risk of depression up or down. These pictures help readers see which factors carry the most weight and how they work together in the model.

Data Processing Methods

All statistical analyses and figure generation were performed using R (R Foundation for Statistical Computing). When less than 20% of the data were missing, we used the *mice* package to run 5 rounds of imputation and kept the set that best matched the overall pattern. We report counts and percentages for categorical variables and means with SDs for continuous variables. We compared groups using 2-tailed *t* tests, chi-square tests, or nonparametric tests as needed; the latter were chosen when the data did not follow the rules for parametric tests. A *P* value <.05 was considered statistically significant.



Results

Flowchart

The study flowchart is presented in Figure 1.

XSL•FO
RenderX

Figure 1. Study flowchart. Analysis of China Health and Retirement Longitudinal Study (CHARLS) wave 5 participants with hypertension and diabetes comorbidity (aged ≥45 years). DCA: decision curve analysis; LASSO: least absolute shrinkage and selection operator; ROC: receiver operating characteristic; SHAP: Shapley additive explanations.

Baseline Characteristics

We included 1504 adults with an average age of 65.99 (SD 8.28) years and 64.93 (SD 8.72) years for those with and without depression, respectively; 678 (45.1%) were men, and 826 (54.9%) were women. Of these 1504 participants, 635 (42.2%) were classed as having possible depression, and 869 (57.8%) were classed as nondepressed. Table 1 shows that the 2 groups differed on many key points. Those with possible depression were more often women, widowed or separated, and less active and reported more illnesses, such as lung disease, heart disease, stroke, arthritis, mental illness, liver disease, kidney disease, stomach disease, asthma, hip fracture, and memory problems. They also had more pain sites; poorer sleep; lower income; fewer years of schooling; smaller households; more physician visits; fewer social activities; and lower scores on memory, daily activities, self-rated health, and life satisfaction (P<.05 in all cases).

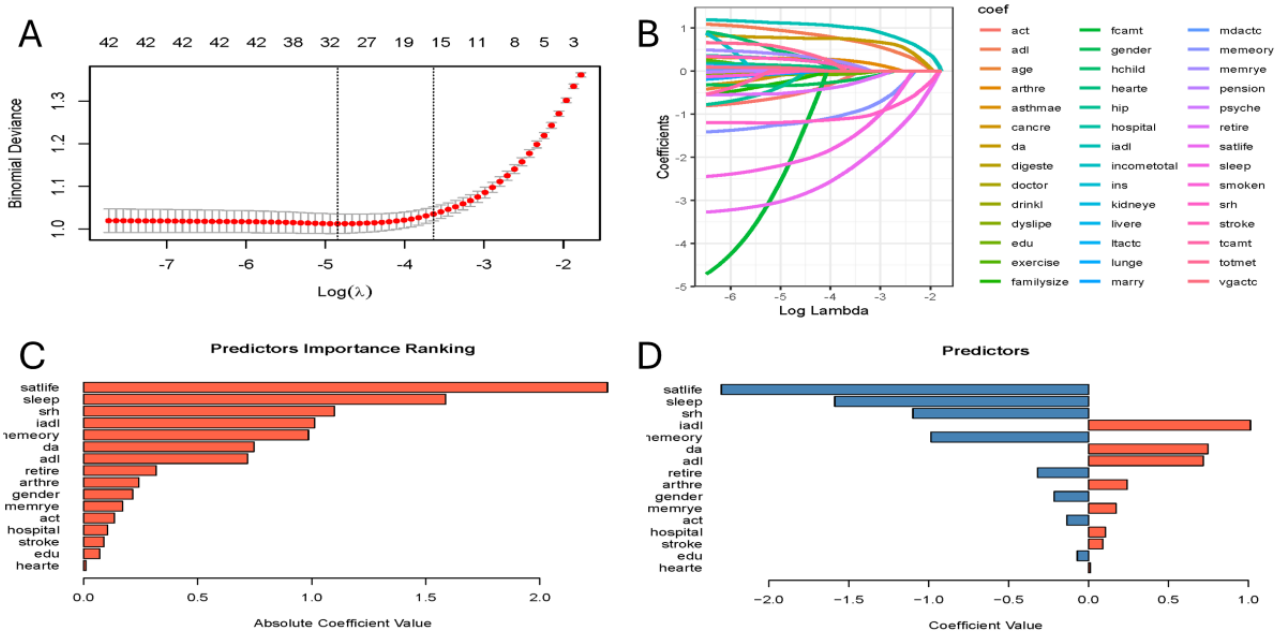
[a]Educational level was scored as follows: 1=illiterate; 2=below junior high school; 3=junior high school and above, below university; 4=university and above.

[b]MET: metabolic equivalent of task.



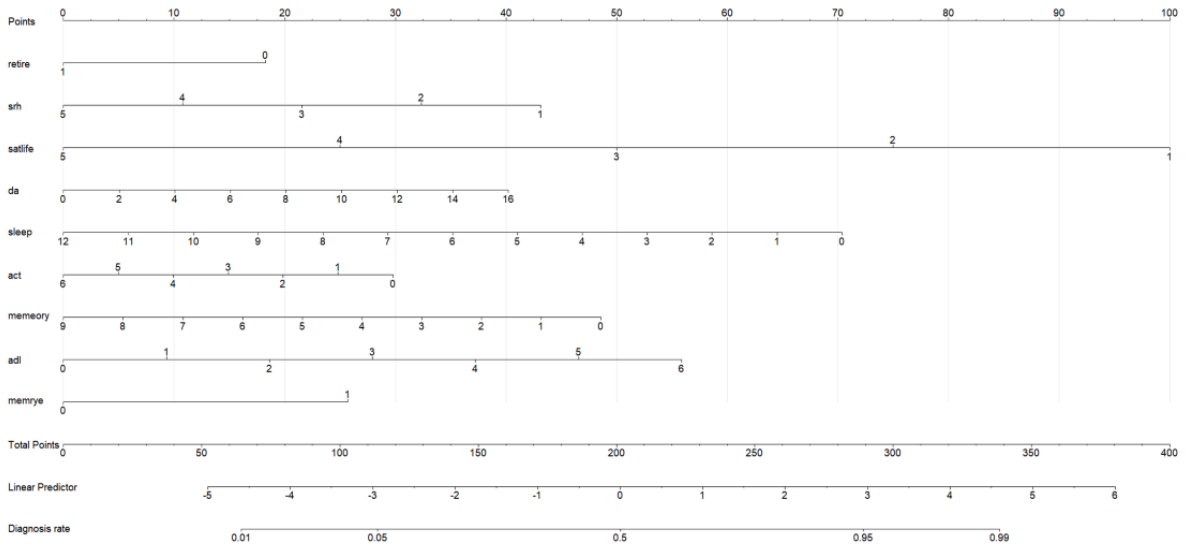
[c]ADL: activity of daily living.

[d]IADL: instrumental ADL.

Results of Model Construction

As the regularization strength (λ) increases, the model error initially decreases and then increases. We chose the simplest model within 1 SE of the minimum error. This left 16 variables whose coefficients stayed above 0 (Figure 2A). Each line in the plot shows one variable's coefficient; as λ grows (moving right), many lines drop to 0 and are removed. In the end, 16 factors remained: life satisfaction score, sleep hours, self-rated health score, IADL score, memory score, pain sites, ADL score, retirement status, arthritis, sex, memory problems, social activity engagement type, recent physician visits, stroke, years of schooling, and heart disease, listed from most to least important (Figure 2C). Figure 2D shows the direction of each factor: red bars mean higher risk, and blue bars mean lower risk.

Figure 2. Predictor selection using least absolute shrinkage and selection operator (LASSO) regression. (A) Cross-validation plot showing the relationship between the regularization parameter (λ) and model deviance. The vertical dashed line indicates the optimal λ value (minimum λ+1 SE). (B) LASSO coefficient path plot showing how variable coefficients shrink toward 0 as λ increases. (C) Ranking of the 16 selected predictors based on their standardized regression coefficients. (D) Coefficient direction plot indicating risk (red=positive coefficient) and protective (blue=negative coefficient) factors for depression. Act: social activity engagement; ADL: activity of daily living; DA: number of pain sites; IADL: instrumental ADL; memrye: memory problems; satlife: life satisfaction score; SRH: self-rated health score.



We took the 16 variables and ran them together in a new regression model and then drew a simple point chart (nomogram). The chart showed which factors mattered the most so that we could drop the weaker ones. After this step, 9 factors remained: retirement status, self-rated health score, life satisfaction score, number of pain sites, sleep hours, social activity engagement type, memory score, ADL score, and memory-related disease. We put these 9 factors into a final regression and built the last nomogram (Figure 3). On the chart, each line shows how many points a person obtains for that

XSL•FO
RenderX

factor; the bottom scale turns the total points into the chance of depression. Higher total points mean higher risk.

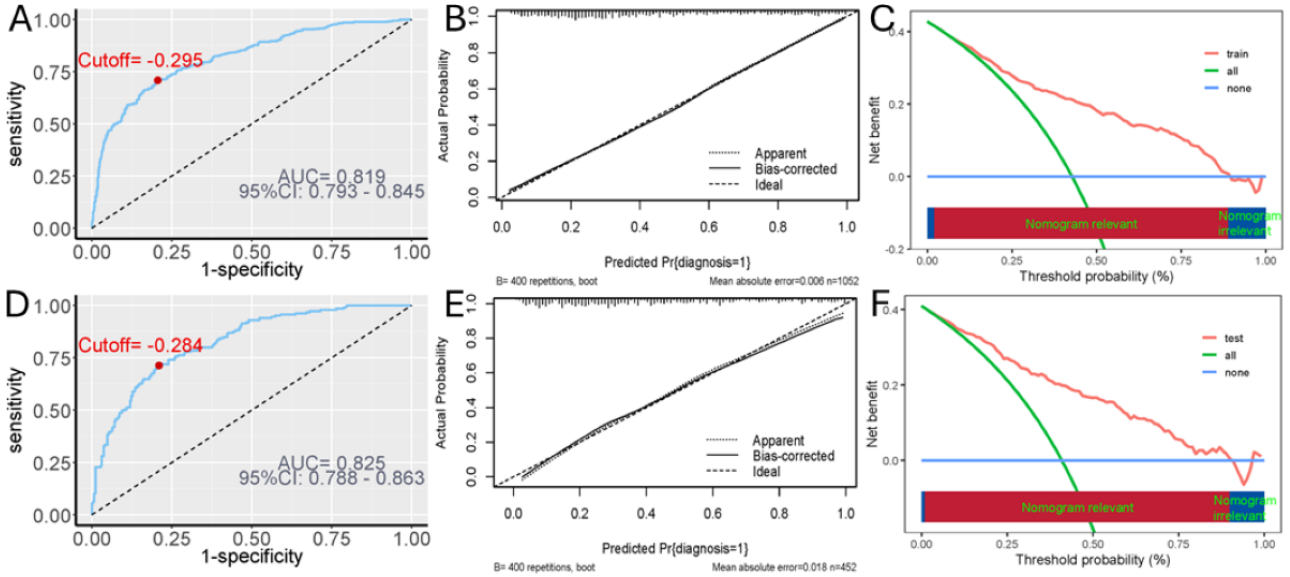


Figure 3. Nomogram for predicting depression risk. The nomogram was constructed using 9 predictors selected from multivariate logistic regression. Each predictor is assigned a point value based on its regression coefficient. The total score corresponds to the predicted probability of depression in the bottom scale. Higher total scores indicate a higher risk of depression. Act: social activity engagement; ADL: activity of daily living; DA: number of pain sites; memrye: memory problems; satlife: life satisfaction score; SRH: self-rated health score.

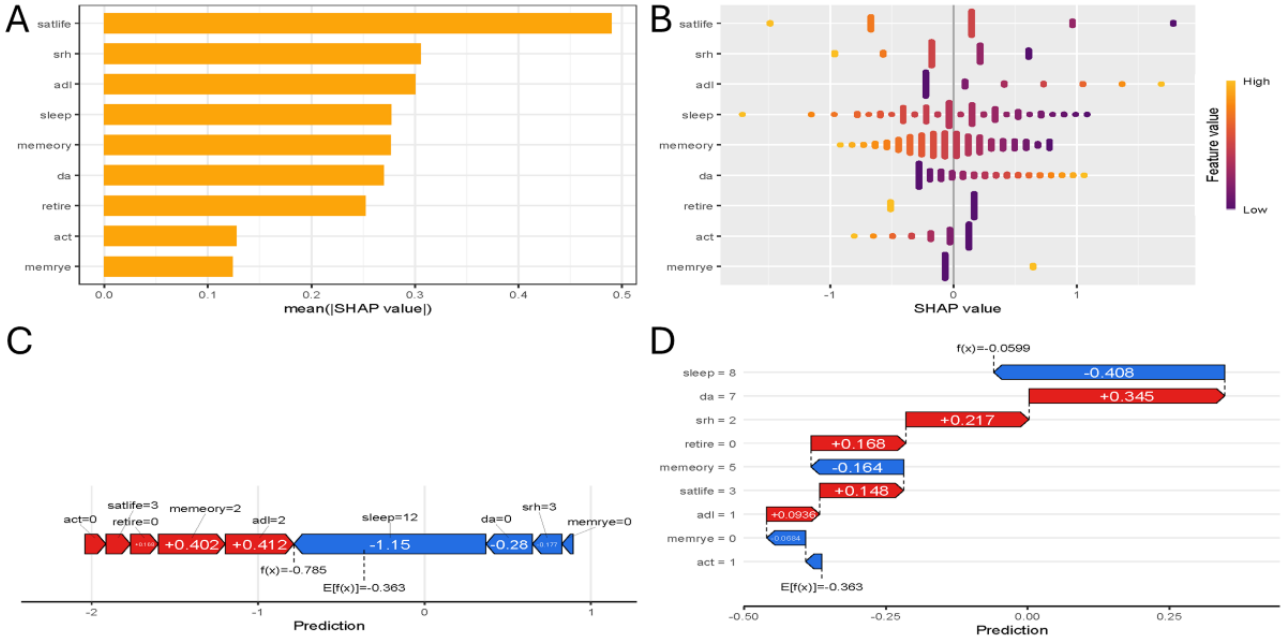
Results of Model Evaluation

We tested how well the model separated people with and without depression using the AUC. In the training data (Figure 4A), the AUC was 0.819, and in the testing data (Figure 4D), it was 0.825, showing good discrimination. The predicted probabilities matched the real outcomes closely in both sets; the average error was only 0.006 in training (Figure 4B) and 0.018 in testing (Figure 4E). Decision curve analysis (Figures 4C and 4F) also showed clear clinical benefit: the model yielded much larger net benefits than the "treat all" or "treat none" approaches. Overall, the nomogram was accurate and clinically useful.

Figure 4. Evaluation of the predictive model. (A) Receiver operating characteristic (ROC) curve and area under the curve (AUC) value in the training set (AUC=0.819). (B) Calibration plot in the training set (mean absolute error=0.006). (C) Decision curve analysis (DCA) in the training set. (D) ROC curve and AUC value in the testing set (AUC=0.825). (E) Calibration plot in the testing set (mean absolute error=0.018). (F) DCA in the testing set. The model demonstrates strong discriminative ability, good calibration, and high clinical utility in both datasets.



Results of Model Interpretation

We used SHAP values to look at the 9 main variables. Global and swarm plots (Figure 5A-B) show how each variable affects the entire sample. ADL score, memory problems, and number of pain sites pushed the risk upward, whereas retirement status, social activity engagement type, sleep hours, life satisfaction score, self-rated health score, and memory score pushed it

XSL•FO
RenderX

downward. To see how these factors worked for individual people, we picked 2 participants at random and used waterfall and force plots (Figure 5C-D) to show each factor's exact contribution.

Figure 5. Shapley additive explanations (SHAP) analysis of the final model. (A) Global SHAP importance plot showing the average impact of each feature on model predictions. (B) SHAP swarm plot illustrating the distribution of SHAP values for each feature across all participants (red=increased risk; blue=decreased risk). (C) Waterfall plot for a randomly selected individual showing the contribution of each feature to the final prediction. (D) Force plot for another individual, highlighting the cumulative effect of features on the predicted probability of depression. Positive SHAP values (red) increase the risk of depression, whereas negative values (blue) decrease it. Act: social activity engagement; ADL: activity of daily living; DA: number of pain sites; memrye: memory problems; satlife: life satisfaction score; SRH: self-rated health score.

Discussion

Principal Findings

This study establishes a clinically operable prediction model for depression risk among middle-aged and older patients with hypertension and diabetes, leveraging multidimensional predictors to achieve robust discrimination (AUC=0.819 - 0.825) and calibration (mean absolute error≤0.018). Nine core variables emerged as significant predictors in the final nomogram: ADL score, memory disorders, number of pain sites, sleep duration, life satisfaction score, self-rated health score, social activity engagement, retirement status, and memory score. The centrality of functional impairment as a mechanistic pathway is underscored by the ADL score's dominant predictive role [18,19], where individuals with depression exhibited markedly elevated scores (mean 1.20, SD 1.60 vs mean 0.34, SD 0.85; *P*<.001). Each unit increase in ADL score corresponded to a 3-fold increase in depression risk, particularly at critical thresholds beyond ADL score ≥2. Retirement status provided substantial protection against depression [19,20], with prevalence rates nearly halved among retirees (103/635, 16.2%) compared to nonretirees (269/869, 31.0%; *P*<.001) mediated by significantly greater social participation (mean activity score 0.94, SD 1.14 vs mean 0.65, SD 0.90; *P*<.001). SHAP value distributions (Figure 5A-B) corroborated a triadic pathogenesis framework. First, functional autonomy erosion (ADL and IADL decline interacting with multisite pain) imposes physical constraints that amplify helplessness [21,22]. Second, affective-cognitive burden manifests through memory disorders (there were memory disorders in 97/635, 15.3% vs 47/869, 5.4% of participants with and without depression, respectively; *P*<.001), and reduced life satisfaction (mean score 2.87, SD 0.87 vs mean score 3.41, SD 0.66 among participants with and without depression; *P*<.001) depletes emotional reserves [23]. Third, socioeconomic disengagement was evidenced by significantly lower household incomes among participants with depression (mean ¥32,470.65 [US $4720.71], SD ¥88,119.77 [US $12,811.20] vs mean ¥54,055.20 [US $7858.73], SD ¥79,512.32 [US $10,687.50], respectively; *P*<.001), constraining access to health-promoting resources [24,25]. The nonlinear inflection point observed in the ADL-depression relationship indicates that moderate functional decline triggers disproportionately severe psychological sequelae, offering an identifiable intercept for targeted interventions [26].

These findings advance beyond prior depression prediction paradigms in several critical dimensions. Traditional screening instruments reliant on mood-based symptomatology such as the Patient Health Questionnaire series demonstrate limited applicability in cardiometabolic populations due to diagnostic circularity: they cannot resolve whether fatigue or anhedonia stems from depression vs underlying chronic disease pathology [27,28]. Our model effectively dissociates these confounds by operationalizing ADLs as an independent construct validated through SHAP's feature dissociation capability. For instance, while arthritis prevalence was markedly higher among participants with depression (389/635, 61.3% vs 324/869, 37.3%; *P*<.001), LASSO selected number of pain sites rather than arthritis diagnosis as the principal pain predictor due to its ability to quantify functional impact severity [29]. When

XSL•FO
RenderX

benchmarked against models with similar AUC values to those of the model evaluated in this study, such as the depressive symptom predictor by Zheng et al [30,31], our algorithm demonstrates superior translational efficiency by using information already captured in routine chronic disease management ADL documentation during nursing assessments, medication review for memory issues, and social history documenting retirement status. This obviates the need for additional screening instruments, reducing assessment time to under 3 minutes. Moreover, we identify novel modifiable pathways absent in prior frameworks. The protective effect of retirement when linked to sustained social activity engagement reveals life transitions as windows for resilience-building interventions [32]. Enhancing life satisfaction emerged as another actionable leverage point given its strong negative association with depression (β=−0.63 via LASSO), suggesting that psychosocial enrichment may disrupt pathogenic cascades more effectively than purely biomedical approaches [33].

Methodologically, the integration of LASSO regression with SHAP value interpretation constitutes a primary strength. LASSO refined the predictor pool from 42 candidates to 9 nonredundant variables, efficiently eliminating noncontributory markers such as cancer or lung disease. SHAP analysis then transformed statistical coefficients—for example, the negative β value for retirement (−0.89)—into clinically interpretable narratives. At an individual level (Figure 5D), retirees maintaining active social roles exhibited an 18-fold depression risk reduction compared to their socially isolated counterparts. The CHARLS cohort's population representativeness further enhances generalizability to China's aging cardiometabolic patient demographic. Four principal limitations warrant acknowledgment. Due to the cross-sectional nature of wave 5 CHARLS data, causal precedence between functional decline and depression could not be definitively established. However, the biological gradient observed in ADL risk proportionality (higher scores predicting depression probability stepwise) lends credibility to functional deterioration as a driver rather than a secondary consequence [34,35]. Second, depression ascertainment using a CESD-10 score >10 may overlook subsyndromal presentations, potentially underestimating risk in highly functional individuals [36]. Third, unmeasured variables influencing both pathways, particularly medication adherence patterns or pharmacodynamic interactions between psychotropics and antihypertensives, were unaccounted for. Finally, sociocultural proxies unique to Chinese aging populations' children's financial support demonstrating borderline significance (*P*=.02-.03) were excluded from the final model despite their potential clinical relevance [37]. Future iterations should address this through culturally adapted predictor sets.

This study was conducted based on statistical data from the CHARLS database. Therefore, the results of this study have limitations in terms of applicability to young and middle-aged populations, as well as populations from different regions and ethnic groups. In future research, we may consider combining data from public databases in the Americas, Europe, and other regions to conduct joint modeling, thereby improving the generalization performance of the model. These findings suggest priority areas for future research and clinical application. Longitudinal analyses using multiwave CHARLS data should test the proposed retirement–social engagement–protection pathway, examining whether weekly social activity sustains resilience to depressive symptoms. A 3-tier risk stratification protocol based on nomogram scores may guide care: individuals scoring ≤150 can continue annual screening; those scoring 150 to 250 should receive functional preservation strategies, including task-oriented exercise and cognitive behavioral approaches to improve ADLs, sleep, and social engagement; and those scoring ≥250 would require multidisciplinary management due to high comorbidity. Embedding this algorithm into electronic health records within China's National Essential Public Health Service Package could enable automated alerts when thresholds are met. Pilot programs should focus on communities where the baseline ADL score is ≥1.5; in this study, 51.2% (325/635) of participants with depression were in this category. Randomized trials are needed to evaluate mediator-targeted interventions, including combined ADL and pain management, structured postretirement social role adaptation, and hemoglobin A_{1c}–stratified memory screening in diabetes. Targeting domain-specific vulnerabilities rather than symptoms alone may reduce depression incidence while optimizing primary care resources.

Conclusions

We developed and validated a depression risk model for middle-aged and older adults with hypertension and diabetes. The nomogram, integrating 9 routinely collected predictors, including ADL score, memory impairment, and pain burden, showed strong discrimination and calibration. Depression risk rose 3-fold for each unit increase in ADL score, whereas retirement was protective. Functional impairment, emotional cognitive burden, and socioeconomic disadvantage formed the dominant risk pathway. LASSO-SHAP integration streamlined predictor selection, enabling screening in under 3 minutes. Prospective trials should test interventions targeting postretirement social engagement and functional rehabilitation, alongside implementing a 3-tier risk stratification protocol in primary care. Targeting these domain-specific risks could reduce depression incidence.

Abstract

Background: Advancements in health technology and the adoption of electronic systems in hospital pharmacies have transformed pharmacy practice and service delivery, with patients and health care providers reporting perceived benefits related to patient care and safety. Therefore, it is of paramount importance to seek patients' opinions based on their experiences in receiving outpatient pharmacy services through automated pharmacy systems.

Objective: This study aimed to investigate patients' experiences and explore their satisfaction with outpatient pharmacy services in hospitals using automated pharmacy systems.

Methods: This cross-sectional study used an online questionnaire to assess patients' experiences of outpatient pharmacy services in governmental hospitals in Kuwait where automated pharmacy systems are implemented.

Results: Almost 95% (393/416) of the participants either agreed or strongly agreed that they were totally satisfied with the services delivered through the automated pharmacy systems. Participants reported the perceived benefits of these outpatient pharmacy services, including perceived prevention of medication errors (211/416, 50.7%), time savings (356/416, 85.6%), and easier access to prescription information at any time (249/416, 59.9%).

Conclusions: Patients' experiences with outpatient pharmacy services in automated pharmacy settings were generally positive, reflecting satisfaction with medication collection and service quality.

Introduction

Over the past years, pharmacy practice has undergone significant transformation with the adoption of electronic prescribing (e-prescribing) and electronic dispensing (e-dispensing; hospital information system [HIS]) systems, resulting in numerous advantages within professional practice settings. Notable examples include reductions in medication errors [1-4], time savings [5,6], and increased work efficiency [1,2,6]. However, such systems also present certain challenges. Reported drawbacks include risks to medication safety (eg, unclear or incorrect dosage instructions or strength) [4], technical issues [1,5], and resistance to adoption among staff [1]. Difficult adoption of automated systems has been reported in previous studies and has been attributed to their incapability to execute some functions that were previously completed manually [2,5,6]. The implementation of e-prescribing and/or e-dispensing systems has been extensively examined in the literature, with a focus on evaluating whether their intended purposes have been achieved and whether the anticipated benefits have been realized.

A systematic review of the literature on the barriers and facilitators to implementing an e-prescribing system highlighted the importance of identifying the perceptions of user groups, including pharmacists, managers, and patients [7]. Patients' involvement in the assessment process is essential because the quality of outpatient pharmacy service delivery is ultimately perceived by them; therefore, patient satisfaction can be considered an indicator of success [8,9]. Previous studies have supported the need for future research to evaluate the impact of

integrated e-prescribing and e-dispensing systems [8,10], as the combination of these 2 domains has the potential to improve various aspects of pharmacy schemes and practice [10].

In this study, the term "automated pharmacy" encompasses 2 key domains. The first is the receipt of prescriptions via an e-prescribing system, also referred to as a "pharmacy information system," which is a subset of a much greater HIS. Within such a system, patient data and medication lists are stored electronically. The second component of the "automated pharmacy" concept involves an e-dispensing system, in which electronic cabinets with the drugs on the shelves (most of which are prepackaged) are used to deliver the prescribed medications to the dispensing area. Briefly, the pharmacist receives the prescription from the patient, reviews it to ensure that the medications are accurately prescribed, and uses the e-prescribing system to send the order to the electronic or automated cabinet. The cabinet prepares the medications and delivers them to the pharmacist, who then dispenses them and provides patient counseling.

In Kuwait, there are 6 general governmental hospitals, all of which have transitioned their outpatient pharmacies from manual processes to automated systems. However, the extent of implementation varies across institutions. In some settings, automated dispensing systems are not fully connected to the e-prescribing platform, while in others, the e-prescribing system functions as a stand-alone tool that is not integrated with the HIS or electronic health records.

Following implementation, several challenges arise for staff operating integrated e-prescribing and automated dispensing systems, despite the technological advancements they offer. These challenges include technical difficulties, workflow and organizational issues, and factors related to users' attitudes, adaptation, and readiness to use technology. Such issues can affect the quality of the outpatient pharmacy services delivered to patients, particularly regarding waiting times, the adequacy of medication counseling, availability of medications, and the accuracy of medication dispensing. These challenges highlight the need to explore patients' experiences to understand their perceptions and satisfaction with outpatient pharmacy care in hospitals, which can help identify areas for improving and optimizing service quality.

Within this context, previous studies in Kuwait have examined the perspectives of health care providers regarding the use of HISs in primary care settings [11,12] or secondary care settings [13]. Patients' satisfaction with e-prescribing and electronic health records has also been explored [14,15]. In the existing literature, there is no research in Kuwait that examined patients' satisfaction based on their experiences with integrated automated outpatient pharmacy services. Thus, this study aimed to assess patients' satisfaction with their experiences in receiving outpatient pharmacy services through integrated e-prescribing and e-dispensing systems in the outpatient pharmacies of secondary care governmental hospitals. This enabled the development of recommendations to improve pharmacy practice in Kuwait.

Methods

Study Design, Sample, and Setting

The design of this study was a cross-sectional survey, using a questionnaire developed in Google Forms that was electronically administered to collect data from patients at their convenience between June and July 2024 at the outpatient pharmacies of 4 governmental hospitals in the state of Kuwait. The selected hospitals were Adan, Jahra, Farwaniya, and Jaber Al-Ahmad, which had all adopted and implemented the concept of automated pharmacy, which is using an integrated e-prescribing and e-dispensing system in the outpatient pharmacies.

A Survey Questionnaire

The items of the questionnaire were taken from previous validated studies [16]. Content validity was evaluated by the research team, which included 2 academic staff members from the Pharmacy Practice Department at the College of Pharmacy, Kuwait University, who are experts in their field, and 1 academic staff member from the College of Medicine with expertise in health informatics. This evaluation involved reviewing the questionnaire items to ensure their relevance to the study objectives and their clarity. Several modifications were made to ensure compatibility and appropriateness for the research aim, sample, and setting. The term "medication teaching" was replaced with "medication counseling," as this terminology is commonly used and understood by patients and pharmacy staff in Kuwait. The section "pharmacy place" was removed because it addressed the physical layout of the pharmacy, which was unrelated to the study's aim and objectives. Additionally, 1 item was excluded, which was about "the availability of a private area for counseling," because this service is not consistently provided across outpatient pharmacies in Kuwait and is not applicable to the local setting. A new section was added, which was about "dispensing medications," and was developed from previous studies [17,18] to explore aspects of communication between pharmacists and patients.

Questionnaire Structure

The questionnaire consisted of 40 items and seven sections: (1) time of prescription dispensing (3 items), (2) pharmacist attitudes (5 items), (3) medication supply (5 items), (4) medication counseling (5 items), (5) dispensing medications (5 items), (6) overall impact of automated pharmacy on outpatient pharmacy services (7 items), and (7) sociodemographic characteristics (10 items).

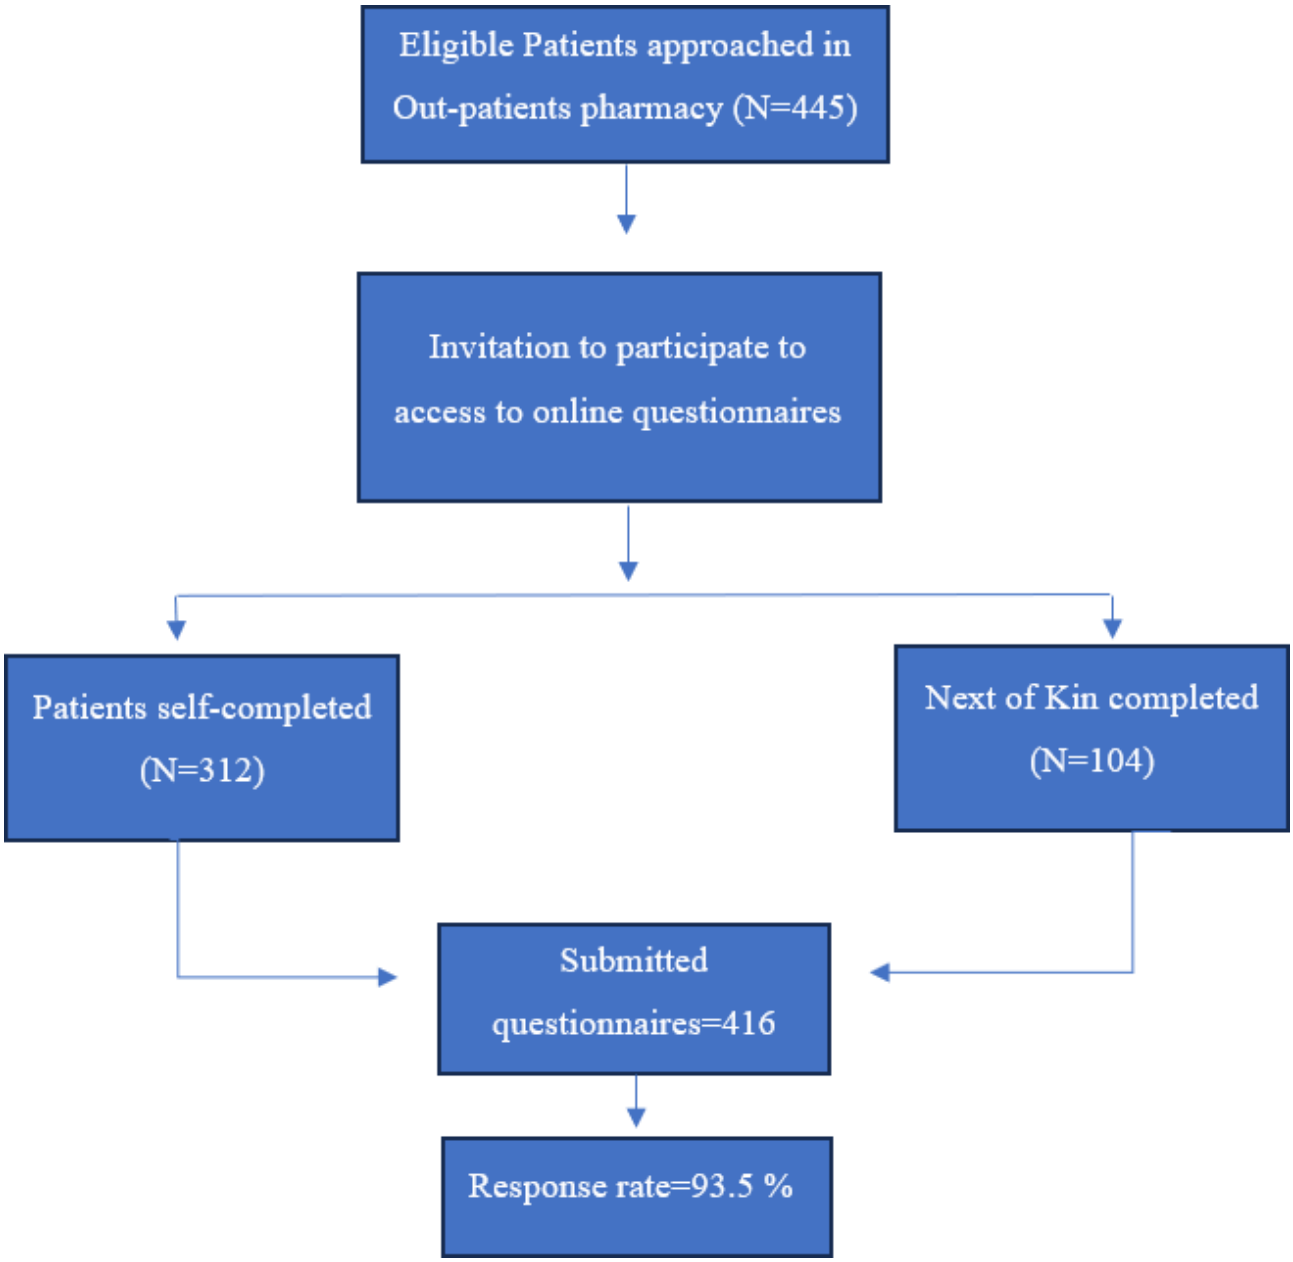
Inclusion and Exclusion Criteria

This study included secondary care hospitals that offer integrated automated outpatient pharmacy services. Patients and/or caregivers who provide close, hands-on care to the patient are familiar with the patient's experiences with outpatient pharmacy services and can offer valuable insights alongside the patients themselves. Eligible participants were those who were able to complete the questionnaire and were therefore invited to take part in the study. Private hospitals and private pharmacies were excluded from this study because they operate under different policies and procedures and do not use integrated e-prescribing

XSL•FO
RenderX

and e-dispensing systems within their outpatient pharmacy services.

Pilot Study



A pilot study was conducted to ensure clarity and readability with 25 patients who were waiting to receive their medications from outpatient pharmacies. The results demonstrated that the questionnaire was easy to understand and well received, confirming its readiness for full-scale distribution.

Recruitment and Data Collection

Patients waiting to receive their medications in the outpatient pharmacy areas were approached and invited to participate voluntarily. The questionnaire was administered to patients using a QR code or via a tablet device, providing direct access to the online questionnaire. No identifying patient information was collected, and responses could not be linked to individual patients. Pharmacy staff were not present while participants completed the survey, which helped maintain anonymity and reduce potential social desirability bias. For patients unable to complete the questionnaire themselves, a next of kin who was familiar with their experience (eg, a spouse, son, or sister) was permitted to respond on their behalf (Figure 1).

The questionnaire was offered in 2 languages, Arabic and English, to accommodate a diverse patient population. The original English version of the questionnaire was translated into Arabic, and the translation was validated using a back-translation method to ensure accuracy and clarity. All patients who met the inclusion criteria were invited to participate. Data collection was undertaken by a group of pharmacy students (n=6) from the College of Pharmacy, Kuwait University. They were available in the waiting areas of the outpatient pharmacies to share the online questionnaire with patients.

Figure 1. The recruitment protocol of the study participants.

RenderX

Construct Validation Using Factor Analysis and Reliability Assessment

The Kaiser-Meyer-Olkin (KMO) test and Bartlett's test of sphericity were used to evaluate sampling adequacy [19]. These tests help determine whether data are suitable for factor analysis. Data factorability was confirmed with a KMO value above 0.50 and a significant Bartlett's test value (P<.05) [19]. Principal component analysis with Promax rotation, an oblique method, was used. Promax was selected because it permits factors to correlate, which aligns with the expected relationships among the constructs [20]. The number of factors was decided based on eigenvalues, scree plots, and explained variance. Exploratory factor analysis was performed with a factor loading cutoff of 0.40 to extract scale dimensions [19,21].

Internal consistency reliability was assessed using Cronbach α coefficient based on a 4-point Likert scale (time of prescription dispensing, pharmacist attitudes, medication supply, medication counseling, and dispensing medications). A Cronbach α value of ≥0.70 was regarded as satisfactory evidence of internal consistency for the new instrument [19,20,22].

Ethical Considerations

Ethical approval for this study was obtained from the The Standing Committee for Coordinating Medical and Health Research prior to data collection (reference number 2352). Participation was voluntary, and informed consent was obtained from all participants before administering the survey. To protect privacy and confidentiality, no personally identifiable information was collected. Surveys were completed anonymously in the outpatient pharmacy waiting area, and participants were informed that they could decline to answer any question or withdraw at any time without any impact on their care or pharmacy services. All collected data were kept confidential, stored securely, and accessible only to the research team. Study findings are reported in aggregate form, ensuring that no individual participant can be identified.

Statistical Data Analysis

Statistical analyses were conducted using IBM SPSS Statistics (version 29; IBM Corp). Descriptive statistics were used to present the data. Categorical variables were presented as frequencies and percentages. To summarize the patients' perspective scores, responses for the questionnaire items were averaged across all items within the category. As an initial exploratory comparison, patient and caregiver perspective scores were compared using the Mann-Whitney U test due to nonnormal score distributions and unequal group sizes.

A normality test for the component scores was undertaken using the Shapiro-Wilk test, which indicated that the data were not normally distributed. Accordingly, results are presented as minimum, maximum, median, and IQR. Nonparametric statistical tests were used to assess associations between component scores and variables of interest, including the Mann-Whitney U test for binary comparisons, the Kruskal-Wallis test for comparisons across multiple groups, Spearman rank correlation for continuous variables, and the chi-square test for trend for ordinal categorical variables.

For analyses based on a priori hypotheses involving comparisons across multiple groups, post hoc pairwise comparisons were conducted following statistically significant Kruskal-Wallis tests, with P values adjusted for multiple comparisons using the Dunn-Bonferroni method. These analyses were planned and considered confirmatory. Effect sizes were reported as rank-biserial correlation coefficients (r_rb) for binary comparisons, epsilon squared (ε^2) for multigroup comparisons, and Spearman correlation coefficient (ρ) for continuous variables.

Multiple linear regression analyses were performed to identify independent factors associated with the overall score across domains of patients' perspectives on automated pharmacy services. Additional association analyses not specified a priori were treated as exploratory and were not adjusted for multiple comparisons; these results are presented for hypothesis generation. Ordinal survey responses were averaged across items within each component to generate composite scores for inferential analyses. Statistical significance was set at P value of <.05.

A sensitivity analysis was conducted to assess the results to potential selection bias arising from voluntary participation and convenience sampling. This analysis examined the possible impact of underrepresentation of less satisfied patients on the study outcomes. Specifically, the patients' perspective score was systematically reduced by 0.3, 0.5, and 1.0 SDs, representing mild, moderate, and severe dissatisfaction scenarios, respectively. These thresholds were selected based on established effect size conventions for continuous outcomes and their application in patient-reported outcome research [23]. For each scenario, the multiple linear regression analyses were repeated using the adjusted outcome variable, while all predictor variables and model specifications remained unchanged.

Results

Sociodemographic Characteristics of the Study Participants

A total of 445 patients were approached, of whom 416 completed the questionnaire, producing a response rate of 93.5%. The sociodemographic characteristics of the study participants are illustrated in Table 1.

XSL•FO
RenderX

Most participants were female (299/416, 71.9%), Kuwaiti nationals (351/416, 84.4%), younger than 29 years (142/416, 34.3%), and married (258/416, 62.0%). Half of the participants (208/416, 50%) held a bachelor's degree. Regarding pharmacy visits, approximately one-third of the participants visited the pharmacy monthly (161/416, 38.7%), while another third reported visiting 3 or 4 times per year (155/416, 37.3%). Most participants were collecting medications for themselves (312/416, 75%) and had between 1 and 5 medications in their prescriptions (331/416, 79.6%). Dispensing waiting times varied, with the majority of participants waiting 6 - 15 minutes (167/416, 40.1%), followed by those waiting less than 5 minutes (136/416, 32.7%), and those waiting more than 15 minutes (80/416, 19.2%).

Based on the exploratory factor analysis results shown in Table 2, each item with a value greater than 0.40 was assigned to an extracted factor. The KMO value of 0.914 indicated that the data were appropriate for factor analysis, and the value of Bartlett's test of sphericity was significant (χ^2_{231}=5140.38; P<.001). The scree plot indicated a 5-component solution, with all items showing acceptable communalities, and eigenvalues greater than 1.0 were extracted, accounting for 67.27% of the total variance. The reliability of the 22-item factored scale was obtained. The overall Cronbach α for the scale showed excellent reliability (α=0.92).

Table . Results of the exploratory factor analysis.

Component	Item	Factor loadings[a]	Eigenvalue	VE[b] (%)	CVE[c] (%)
Time of prescription dispensing			1.79	8.12	8.12
	1.00	0.83

Time of Prescription Dispensing

The results showed that most respondents agreed or strongly agreed that their prescriptions were dispensed within a reasonable time (364/416, 87.5%; Table 3).

XSL•FO
RenderX

Table . Perceptions of e-prescription and automated dispensing systems in outpatient pharmacies at secondary care hospitals (N=416).

Item	Values, n (%)								Range	Overall median score (IQR)[a]
	Strongly agree	Agree	Disagree	Strongly disagree	Never	Rarely	Sometimes	Many times		
Time of prescription dispensing									1.0-4.0	3.0 (0.5)
1. Receive medications within a reasonable time	136 (32.7)	228 (54.8)	38 (9.1)	14 (3.4)	—[b]	—	—	—		
2. Waiting time is acceptable considering the quantity of prescription medication	115 (27.6)	226 (54.3)	63 (15.1)	12 (2.9)	—	—	—	—		
Pharmacist attitude									4.0-1.2	3.4 (1.0)
3. Pharmacist helped me to get the medications	201 (48.3)	201 (48.3)	9 (2.2)	5 (1.2)	—	—	—	—		
4. Pharmacist helped to solve any problem while getting the medication	168 (40.4)	211 (50.7)	33 (7.9)	4 (1.0)						
5. Pharmacist answered my questions	197 (47.4)	200 (48.1)	18 (4.3)	1 (0.2)						
6. Pharmacist understood the medical case	172 (41.3)	222 (53.4)	21 (5.0)	1 (0.2)						
7. Pharmacist treated me with respect	254 (61.1)	153 (36.8)	5 (1.2)	4 (1.0)						
Medication supply									4.0-1.8	3.2 (0.8)
8. Medication quantity was sufficient	178 (42.8)	214 (51.4)	19 (4.6)	5 (1.2)

Item	Values, n (%)								Range	Overall median score (IQR)[a]
	Strongly agree	Agree	Disagree	Strongly disagree	Never	Rarely	Sometimes	Many times		
18. The communication with the pharmacist and/or the doctor was challenging	—	—	—	—	218 (52.4)	111 (26.7)	71 (17.1)	16 (3.8)		
19. The prescription was sent to the wrong pharmacy	—	—	—	—	349 (83.9)	53 (12.7)	12 (2.9)	2 (0.5)		
20. The wrong medication was dispensed to me	—	—	—	—	384 (92.3)	26 (6.3)	4 (1.0)	2 (0.5)		
21. I received wrong instructions regarding the drugs dispensed for me	—	—	—	—	371 (89.2)	31 (7.5)	12 (2.9)	2 (0.5)		
22. My medical prescription or information was not received by the pharmacy	—	—	—	—	294 (70.7)	79 (19.0)	32 (7.7)	11 (2.6)		

[a]For each perspective score, responses for the questionnaire items were averaged across all items within the category.

[b]Not applicable.

Most participants (341/416, 82.0%) also found the waiting time acceptable, considering the number of medications prescribed. A statistically significant association (P=.006; chi-square test) was found between the number of medications prescribed and the reported waiting time (Table 4). Patients prescribed 1 - 5 medications were more likely to experience shorter waiting times: 38.8% (118/304) received their medications within 5 minutes, 41.8% (127/304) waited 6 - 15 minutes, and 19.4% (59/304) waited more than 15 minutes.

Table . Association between the number of medications and the waiting time to receive the medications (P=.006[a]; chi-square for trend).

Number of medications	Waiting time		
	≤5 minutes	6-15 minutes	>15 minutes
1-5 items, n (raw %)	118 (38.8)	127 (41.8)	59 (19.4)
6-10 items, n (raw %)	14 (24)	31 (53)	13 (22)
>10 items, n (raw %)	4 (19)	9 (43)	8 (38)

[a]Chi-square test for trend.

XSL•FO
RenderX

In contrast, patients prescribed 6 - 10 medications experienced longer waiting times. Only 24% (14/58) received their medications within 5 minutes, while 53% (31/58) waited 6 - 15 minutes, and 22% (13/58) waited more than 15 minutes. Among those prescribed more than 10 medications, few (4/21, 19%) received their medications within 5 minutes or less, while many (9/21, 43%) waited 6 - 15 minutes, and a similar proportion (8/21, 38%) waited more than 15 minutes, as shown in Table 4.

Pharmacist Attitudes

As shown in Table 3, the results indicated that most participants had positive perceptions of pharmacist attitudes. The majority agreed or strongly agreed that the pharmacists helped obtain their medications (401/416, 96.5%) and assisted them in resolving issues related to medication access (379/416, 91.1%). In addition, a large proportion reported that the pharmacists answered their questions (397/416, 95.5%) and demonstrated knowledge and understanding toward their medical cases (394/416, 94.7%). Furthermore, most participants shared the perspective that the pharmacists treated them with respect and dignity (407/416, 97.9%).

Medication Supply

Most participants found the quantities of medications dispensed to be sufficient (392/416, 94.2%). Additionally, nearly three-quarters (311/416, 74.8%) reported that all their prescribed medications were available in the pharmacy (Table 3). However, a subset of participants (105/416, 25.2%) encountered instances where 1 or more prescribed medications were unavailable. Medication labels were clear and easy to read for most participants (397/416, 95.5%), and the usage instructions were clear and understandable (394/416, 94.8%). Furthermore, the majority expressed satisfaction with the appearance and quality of the medications provided (406/416, 97.6%).

Medication Counseling

The results revealed that the pharmacists performed well in several key areas of patient counseling (Table 3), which included explaining the purpose of medication use (356/416, 85.6%), providing instructions on correct medication dosage (381/416, 91.6%), and dedicating sufficient time to patients during consultations (317/416, 76.2%). However, notable gaps were identified in some specific aspects of counseling. Only half of the participants reported receiving information about the potential side effects of their medications (211/416, 50.7%). Similarly, counseling on proper medication storage was lacking, with approximately half of the participants not receiving such explanations (206/416, 49.5%).

Dispensing Medications

As shown in Table 3, most participants reported that communication challenges with pharmacists and/or physicians rarely or never occurred (329/416, 79.1%). Similarly, errors in the e-prescribing and e-dispensing process were uncommon. Specifically, the majority of participants agreed that rarely or never were prescriptions sent to the wrong pharmacy (402/416, 96.6%), the wrong medication was dispensed (410/416, 98.6%), incorrect instructions were received regarding the medications dispensed (402/416, 96.7%), or the prescription information was not received by the pharmacy (373/416, 89.7%).

Impact of Automated Pharmacy and Overall Satisfaction With Outpatient Pharmacy Services

The participants identified several perceived benefits of the integrated e-prescribing and e-dispensing systems, reflecting their positive impact on outpatient pharmacy services (Multimedia Appendix 1). These perceived benefits included time savings (356/416, 85.6%), perceived prevention of medication errors (211/416, 50.7%), and convenient access to prescription information at any time (249/416, 59.9%).

Also, the results showed high overall satisfaction with the automated outpatient pharmacy services, as 94.5% (393/416) of participants either agreed or strongly agreed that they were satisfied with the services delivered through the automated systems (Multimedia Appendix 2).

The overall median score for the time of prescription dispensing section was 3.0, while the median score for pharmacist attitudes was 3.4. The median scores for the medication supply, medication counseling, and dispensing medications domains were 3.2, 3.0, and 3.8, respectively (Table 3).

Tables 5 and 6 demonstrate the relationships between sociodemographic characteristics and the overall median scores for each questionnaire component. There were significant differences among hospitals, with small effect sizes for the time of prescription dispensing and the dispensing medications scores (ε^2=0.05 and ε^2=0.02, respectively). The median time of prescription dispensing score for Farwaniya hospital was significantly higher than for Adan hospital (3.2 vs 3.0; adjusted P=.03) and Jaber Al-Ahmad hospital (3.2 vs 3.0; adjusted P<.001). The median dispensing medications score for Jaber Al-Ahmad hospital was significantly higher than for Adan hospital (4.0 vs 3.8; adjusted P=.02) and Jahra hospital (4.0 vs 3.8; adjusted P=.04).

[a]Rank-biserial correlation (r_{rb}) for 2-group comparisons, epsilon squared (ε^2) for multigroup comparisons, and Spearman correlation coefficient for continuous variables. Interpretation thresholds: r_{rb}≈0.10=small, ≈0.30=moderate, and ≥0.50=large; ε^2≈0.01=small, ≈0.06=moderate, and ≥0.14=large; and value of P ranges from −1 to +1, P<.1=small, .1-.3=medium, and >.5=large.

[b]Mann-Whitney *U* tests (2 groups), Kruskal-Wallis tests (≥3 groups), or Spearman rank correlation test (continuous variables).

An indirect correlation coefficient of r=−0.13 was present between age and medication counseling score (P=.007). Likewise, there was an indirect correlation between dispensing medications score and education level (r=−0.11; P=.03). All 4 other domains of the questionnaire had scores that were significantly related to the amount of time it took to receive prescriptions (P<.05), with indirect Spearman rank correlation coefficients ranging from −0.15 to −0.46. Furthermore, a significant indirect correlation coefficient of r=−0.11 was found between number of medications and dispensing medications score (P=.03). For other patient characteristics, no statistically significant differences or associations were observed across any of the 5 perspective domains (all P>.05).

All 5 domains of the questionnaire were significantly related to each other (P≤.001), with Spearman rank correlation coefficients ranging from 0.30 to 0.62 (Table 7). The number of medications a patient was prescribed and the amount of time they waited to obtain those prescriptions had a significant association (P=.006), as seen in Table 4. In other words, the amount of waiting time rises as the number of medications increases (from 1 - 5 items to 6 - 10 items or 10 items or more).

The results showed that there is an inverse relationship between medication dispensing waiting time and patient perceptions of automated outpatient pharmacy services, whereas increased waiting times were associated with less satisfaction of pharmacists' attitudes, medication counseling, and dispensing practices.

Table 8 shows the results of the multiple regression model examining patients' perceptions toward automated outpatient pharmacy services, with total perception scores modeled as a function of sociodemographic and other relevant variables. All variables were entered simultaneously to estimate their independent associations. The model was statistically significant (F_{231}=2.32; *P*=.001) and explained 11% of the variance in patients' perceptions. Compared with patients who waited 5 minutes or less, those who waited 6-15 minutes and more than 15 minutes reported significantly lower perception scores (β=−3.70, 95% CI −5.76 to −1.65, *P*<.001 and β=−6.19, 95% CI −8.82 to −3.56, *P*< .001, respectively).

[a]Results from multivariable linear regression using the total score across all key components of patients' perspectives on automated pharmacy as a continuous outcome variable, along with hospital location, age, nationality, gender, marital status, education, number of pharmacy visits in the last year, dispensed medications, time waited to receive medication, and number of medications in the prescription. The regression coefficients (β) represent the mean difference in the overall patients' perspective score associated with each category increase, holding all other variables constant. The 95% CIs and *P* values are reported.

[b]Not applicable.

The results of the sensitivity analyses are shown in Table 9. Across all simulated dissatisfaction scenarios (−0.3 SD, −0.5 SD, and −1.0 SD), the direction, magnitude, and statistical significance of the regression coefficients remained consistent with those observed in the primary analysis (Table 8). In particular, the association between longer waiting times and lower patient perspective scores persisted across all scenarios, with nearly identical regression coefficients and 95% CIs. As expected, the model intercept decreased progressively with increasing downward shifts, reflecting lower assumed overall patient perspectives under more conservative assumptions. The results showed that there were no remarkable changes in the estimated effects of individual predictors, and no variables changed their significance status across the sensitivity analyses.

Discussion

Principal Findings

Studying patients' opinions and satisfaction provides a clear picture of the perceived impact and success of implementing automated pharmacy systems in the real world. Patient feedback can help determine whether the system meets their needs, improves the quality of outpatient pharmacy services, and achieves its intended goals in practice.

The existing literature has shown numerous advantages of using such technology in pharmacy practice. In this context, this study revealed that patients perceived integrated e-prescribing and e-dispensing systems as beneficial to outpatient pharmacy services and expressed overall satisfaction with their experiences of care, as reported by 95% (393/416) of the participants. Participants cited several key perceived benefits, including time savings, perceived prevention of medication errors, convenient access to prescription information at any time, and effective communication between pharmacists and physicians. These findings are consistent with previous studies, which have similarly reported a perceived reduction in medication errors [1-3], time savings in the prescribing and dispensing process [5,6], and increased work efficiency [1,2,6] following the adoption of automated pharmacy systems.

Influence of Sociodemographic Data on Participant Satisfaction

The findings revealed that the satisfaction levels of the participants varied across several sociodemographic groups. This study found an indirect association between age and medication counseling and between dispensing medications score and educational level. This could be explained by the notion that people with higher education levels could have higher expectations of health care services, which could lead to dissatisfaction when these are unmet [24]. Similar findings were found in a previous study [25], which assessed patient satisfaction toward outpatient pharmacy services among outpatients attending public health clinics in Malaysia. The findings revealed that demographic factors (eg, age, education level, self-perceived health status, and general knowledge of pharmacists) significantly influenced patients' perceptions of health care services. Notably, older age and higher education levels were associated with a lower patient satisfaction mean score [25]. Similarly, a study conducted in Pakistan [26] reported that male patients were significantly more satisfied with community outpatient pharmacy services than females. Younger patients (aged 18 - 27 years) exhibited greater satisfaction than older age groups. Illiterate and less-educated individuals showed greater satisfaction levels, while those with higher education levels were less satisfied, likely due to higher expectations. Marital status and occupation also played a potential role, with married individuals showing greater satisfaction and government employees showing less satisfaction. No significant association was observed among students after statistical adjustment [26].

Patients' Satisfaction With Dispensing Time, Pharmacists' Attitudes, and Medication Supply

Although most patients in this study agreed that their prescriptions were dispensed in a reasonable time, the findings revealed that the patients with more medications experienced longer waiting times, suggesting challenges in processing large or complex orders using the automated pharmacy systems.

These findings aligned with those of a previous study into primary health care settings in Kuwait [27], which found that patients' satisfaction was strongly influenced by the timeliness of prescription fulfillment by physicians. Numerous studies have demonstrated that e-prescription systems reduce dispensing times and improve pharmacy workflow [28]. In this context, a study assessed the impact of e-prescription systems on pharmacy workflow and practice in Finland and found a reduction in both median and average delivery times across various prescription types [29]. In particular, the maximum dispensing time with the adoption of e-prescribing systems was shorter in 2012 (6 minutes and 22 seconds) than the time with the use of non–e-prescribing systems in 2006 (12 minutes and 40 seconds). The study concluded that e-prescribing systems significantly improved the efficiency of prescription processing in Finnish community pharmacies [29]. Additionally, a study conducted in Sweden into the impact of integrated e-prescribing systems on pharmacists' practice found that the pharmacists perceived the system as expediting prescription processing and reducing the risk of medication errors [1]. The results showed a positive

XSL•FO
RenderX

correlation between the perceived usefulness of the electronic system for improving work efficiency and medication safety.

This study revealed that the participants were highly satisfied with the pharmacists' attitudes. Nearly all the participants agreed that the pharmacists helped obtain their medications, effectively resolved issues related to medication access, answered their questions, demonstrated knowledge of their medical conditions, and treated them with dignity and respect. These findings were supported by previous studies showing that e-prescribing systems enhance communication between patients and pharmacists [7], patients and prescribers [5], and pharmacists and other health care providers [30,31]. Similarly, a study conducted in Qatar reported comparable levels of satisfaction among participants regarding pharmacists' empathy and communication skills [16]. Furthermore, effective communication, regardless of whether systems are manual or electronic, has been found to significantly contribute to overall patient satisfaction [7,32].

The findings of this study demonstrated statistically significant differences in patient satisfaction across outpatient pharmacies in the 4 general hospitals, particularly regarding medication dispensing speed and pharmacists' attitudes. These site-level variations may reflect differences in staffing levels, staff competencies, workload, maturity of automation, or local operational workflows. For instance, the higher satisfaction with medication dispensing speed observed at Farwaniya Hospital compared with Adan Hospital may be attributable to shorter waiting times, fewer medications per prescription, or more efficient dispensing practices. While patient satisfaction is an important indicator of service performance, it should be interpreted alongside technical and organizational factors to provide a comprehensive understanding of the effectiveness and efficiency of digital pharmacy systems.

The findings of this study indicated that approximately one-quarter of the surveyed participants experienced medication unavailability. Similar findings have been reported by previous studies [33-36], highlighting the need for improved inventory integration to overcome such issues and enhance patient satisfaction. In this context, a study showed that automated drug-dispensing systems carry advantages over traditional systems in improving inventory control and reducing storage errors, resulting in better patient satisfaction [37,38].

The participants in this study were satisfied with the perceived accuracy of the pharmacy's handling of medical prescription information. In support of the claim that prescription accuracy contributes to patient satisfaction, a systematic review study revealed that the integration of e-prescription and e-dispensing systems significantly reduced pharmacy errors [39]. This indicates that the adoption of automated systems may enhance perceived accuracy and is associated with higher levels of patient satisfaction and perceived safety.

Patients' Satisfaction With Medication Counseling and the Dispensing Process

Despite the growing use of e-prescription and e-dispensing systems, challenges remain in their utilization. The findings of this study indicated that the patients reported high levels of satisfaction with medication counseling overall. Specifically, pharmacists were commended for clearly explaining the purpose of medication use, providing accurate dosage instructions, and allocating sufficient time for patients during consultations. However, approximately half of the participants expressed dissatisfaction with the counseling received regarding potential drug side effects and proper medication storage.

A US study into outpatient use of electronic prescriptions found that the use of an e-prescribing system led to lower rates of adverse drug events among patients, suggesting that appropriate counseling on side effects and storage could further reduce such risks [40]. Therefore, in this study, the lack of counseling regarding the side effects of medications and storage conditions indicates a potential gap in quality of practice. This may pertain to numerous reasons, such as a long queue of patients waiting, leading to time pressures, or pharmacists' limited counseling skills, which would affect the quality of the counseling. This shortcoming may reflect the need for additional pharmacist training to improve their counseling skills and not neglect any important information from patient education. Previous research has shown that training physicians in e-prescribing significantly reduces errors and improves workflow, thus indicating that e-prescription systems alone do not resolve counseling-related challenges unless supplemented by targeted education [41]. Addressing these aspects could significantly enhance both patient satisfaction and medication safety.

In addition, despite the automation of the dispensing process, the findings of this study reported longer waiting times for patients with prescribed multiple medications. This association suggests that prolonged waiting times may negatively influence patients' overall perception of outpatient pharmacy domains, including pharmacists' attitudes, medication counseling, medication supply, and dispensing medications. The literature showed that previous studies are consistent with the findings of this study, indicating that waiting time is a critical determinant of patient satisfaction, irrespective of whether outpatient pharmacy services are delivered through conventional or automated systems [38,42,43]. Therefore, the findings revealed that the success of automated outpatient pharmacy services relies not only on technology use but also on efficient workflow that led to suitable time medication dispensing.

This finding highlights the need for process optimization within pharmacy workflows. As with counseling gaps, delays in dispensing may diminish the perceived benefits of automation. Similar studies conducted in Saudi Arabia [38,44] emphasized the value of integrated pharmacy systems while acknowledging the need for region-specific improvements. These studies support the idea that continuous pharmacist education and the implementation of structured feedback mechanisms are essential for identifying and addressing system inefficiencies. By incorporating such strategies, pharmacies can better meet patient expectations and improve the outpatient pharmacy services.

Impact of E-Prescribing and E-Dispensing Systems on Outpatient Pharmacy Services

This study found that most patients reported a positive impact based on their experiences with the medication dispensing process, with pharmacist communication emerging as a key

XSL•FO
RenderX

contributor to patient satisfaction. These findings are consistent with those of a study in Qatar in 2013, which emphasized the importance of pharmacist-patient communication [16]. While pharmacy staff provide irreplaceable expertise in prescription monitoring and dispensing, the integration of electronic systems may help alleviate workload and reduce cognitive burden. Participants perceived that reducing manual tasks enhanced efficiency and contributed to improved patient safety by minimizing the risk of human error [45]. Pharmacists and pharmacy technicians are susceptible to fatigue, stress, and other human limitations, which may compromise dispensing accuracy. In this context, e-prescription systems serve as a valuable support tool that may help mitigate such risks [18,45]. By providing an additional layer of safety and reliability, these systems can contribute to patients' perceptions of positive outcomes and higher satisfaction levels.

The absence of a comparison group involving nonautomated outpatient pharmacies is considered a key methodological limitation of this study. Consequently, the findings cannot isolate the specific effects of automation from other contextual or organizational factors and should be interpreted as reflecting patient experiences within automated pharmacy settings only, which limits their generalizability to other pharmacy models. Future studies using comparative or quasi-experimental designs are needed to evaluate the incremental impact of automation on patient experience and service performance.

Limitations

This study has several limitations. First, it focused exclusively on patients in Kuwait. While the findings provide valuable insights into local users of outpatient pharmacy services, the generalizability of the results to other populations and health care systems may be limited. In addition, the absence of a comparison group involving nonautomated outpatient pharmacies limits the ability to isolate the specific impact of automation.

Second, patient satisfaction data were self-reported, which may have introduced recall or self-reporting bias and may not accurately reflect the actual quality or safety of outpatient pharmacy services. Third, the presence of pharmacy students in the waiting area may have introduced courtesy or social desirability bias, which may have potentially inflated satisfaction scores (approximately 95% agreement), despite private survey completion. The consistently high levels of agreement observed may therefore partly reflect response tendencies rather than true satisfaction levels. Accordingly, future studies should consider alternative data collection approaches or comparative analyses across sites or time periods to better assess this potential bias. Fourth, despite the sensitivity analyses conducted, voluntary participation and convenience sampling may have introduced selection bias, as patients who were more satisfied or more engaged with automated outpatient pharmacy services may have been more likely to participate. Although the sensitivity analyses suggest that potential underrepresentation of less satisfied patients is unlikely to have materially altered the study conclusions, the findings may not be fully representative of all users of automated outpatient pharmacy systems in Kuwait, particularly individuals who actively avoid or disengage from these systems. Fifth, the study was conducted in 4 governmental hospitals and did not include private hospitals or pharmacies, which may differ in service quality, system implementation, and operational policies. Sixth, the cross-sectional design captured perceptions at a single point in time, limiting the ability to assess changes in patient-reported satisfaction over time.

Finally, although responses were obtained from both patients and caregivers, caregivers represented a smaller proportion of the sample (104/416, 25%). An exploratory comparison using the Mann-Whitney *U* test did not detect statistically significant differences between the 2 groups; therefore, further subgroup analyses were not pursued.

Future Research

Future research should link patient-reported perceptions with objective safety and quality indicators, such as medication dispensing error rates, adverse drug events, dispensing accuracy, workflow measures, and prescription turnaround time, to determine whether perceived benefits correspond to measurable improvements in patient outcomes. Longitudinal and mixed methods designs, including qualitative interviews, may provide deeper insight into how and why perceived benefits evolve over time and whether anticipated benefits are realized in routine practice. Methodologically, probability-based sampling approaches should be considered to improve representativeness and reduce selection bias. In addition, remote or independent survey administration and comparative designs across data collection settings may help assess and minimize social desirability bias. Comparative studies involving governmental and private sector hospitals or pharmacies are also warranted, given potential differences in implementation maturity, staffing, workflows, and service policies. Finally, future studies specifically powered to compare patient and caregiver perspectives, alongside technical and organizational assessments, would provide a more comprehensive evaluation of system effectiveness and help identify actionable improvement strategies.

Conclusions

This study demonstrated that integrated e-prescribing and e-dispensing systems offer clear perceived benefits in outpatient pharmacies within governmental hospitals in Kuwait. This is reflected in the positive experiences reported by patients, reflecting overall perceived satisfaction and perceived service performance within the operating systems.

However, the findings also highlight areas requiring improvement to maximize patients' satisfaction toward pharmacy automation systems. The following clinical implications are made:

1. Workflow design optimization: operational strategies should be implemented to improve pharmacy workflow design within automated pharmacy settings to enhance work efficiency, especially for processing lengthy prescriptions and managing drug inventories to reduce dispensing delays, as well as making sure that a counseling area is available for patient education.

XSL•FO
RenderX

2. E-prescribing system enhancement: counseling prompts should be integrated to ensure that important information is delivered completely and properly to patients.
3. Automated inventory management: enhanced inventory control should be implemented, including proactive stock monitoring to clarify what is available and what is near expiry to improve the supply chain management. This is essential because the results showed that approximately 25% (105/416) of patients reported medication unavailability.
4. Staff training: pharmacy staff should receive comprehensive training on best practices for using integrated e-prescription and e-dispensing systems. This would improve patient counseling, interprofessional communication, patient safety, and overall patient satisfaction.
5. Feedback mechanisms: regular collection of feedback from both patients and pharmacy staff should be instituted to identify and address issues related to waiting times, medication availability, and the quality of counseling services.

By addressing these identified gaps, pharmacists can enhance patient satisfaction and improve the overall performance of outpatient pharmacy services supported by integrated digital systems. Strengthening the digital infrastructure and workflow integration would enable hospitals to optimize outpatient pharmacy services and move toward patient-centered digital pharmacy models that support efficient, reliable, and safe medication services. These findings have relevance beyond the study setting and may inform the development of digital outpatient pharmacy services across hospitals in the Arabian Gulf region.

Acknowledgments

The authors would like to thank the students from the College of Pharmacy at Kuwait University who undertook the data collection: Yousef Bahman, Ritaj Alawadhi, Sadeem Almubarak, Nourah Alshammeri, Zainab Moradi, and Sara Alorf.

Funding

No external financial support or grants were received from any public, commercial, or not-for-profit entities for the research, authorship, or publication of this article.

General Practitioners and Pharmacists' Perspectives on Electronic Prescribing for Multidose Drug Dispensing: Mixed Methods Study

Abstract

Background: Medication safety remains a significant challenge in health care, particularly for patients managing complex treatment regimens. In Norway, the introduction of electronic prescribing (e-prescribing) for multidose drug dispensing (eMDD) aims to improve medication adherence and minimize errors by seamlessly integrating with the national e-prescription infrastructure.

Objective: This study aimed to investigate the challenges faced by general practitioners (GPs) and pharmacists in using eMDD in Norway. Additionally, it sought to gather their recommendations for system improvements to guide future development and nationwide implementation.

Methods: A parallel mixed methods design was used, integrating both quantitative and qualitative data. A structured online survey was distributed to 54 pharmacies and 190 GP surgeries across Norway. The survey included a combination of multiple-choice and open-ended questions. Qualitative responses were analyzed thematically using NVivo, while quantitative data were processed using the built-in analytical tools in Nettskjema.

Results: A total of 70 health care professionals participated in the study, revealing 7 key themes: training, system and technology, communication and interaction, division of responsibilities, medication safety, time and resource use, and implementation challenges. GPs reported inadequate training and an overwhelming volume of communication, while pharmacists identified issues with system integration and unclear role definitions. Both groups emphasized the need for improved system usability, stronger interprofessional collaboration, and a more defined governance structure.

Conclusions: While the eMDD system has the potential to improve medication safety and optimize workflows, its success depends on addressing technical inefficiencies, improving user training, and clarifying role responsibilities. Actively involving end users in system development and policy planning is critical for achieving effective national implementation and ensuring integration with broader eHealth initiatives, such as the Patient's Medication List.

KEYWORDS

electronic prescribing for multidose drug dispensing; eMDD; e-prescribing; e-prescriptions; multidose drug dispensing; medication safety; general practitioner; pharmacist; eHealth; health care communication; system usability; mixed methods

Introduction

Background

Medication safety remains a critical concern in health care, particularly for patients managing complex treatment regimens. In Norway, the multidose drug dispensing (MDD) system was introduced in the early 2000s to reduce manual errors and improve adherence by automating the packaging of medications into labeled sachets. Multidose refers to tablets and capsules for each dosing time that are mechanically packed into patient-specific bags on a continuous roll. Automated preparation, labeling, and pharmacist verification are intended to enhance adherence and minimize errors. The subsequent implementation of electronic prescribing (e-prescribing) for MDD (eMDD) has further improved adherence, increased accuracy in medication administration, and reduced the time burden for health care professionals [1].

Historically, multidose prescriptions were transmitted using paper-based methods, such as fax, PDF attachments, and postal mail. These processes introduced inefficiencies and increased the risk of medication errors due to inconsistent medication lists and delayed updates [1].

XSL•FO
RenderX

To address these challenges, Norway has developed and gradually implemented the eMDD system—as a further development of the multidose service. With eMDD, prescriptions are transmitted electronically through the national e-prescription infrastructure instead of papers or medication cards. This integration enables general practitioners (GPs) to send prescriptions via a centralized prescription intermediary, providing multidose pharmacies with real-time access to updated medication information. The system also supports the use of the Drugs in Use (*LIB: Legemidler i bruk*) message to ensure accurate and timely dispensing [2]. By replacing manual processes, eMDD aims to increase medication safety by ensuring timely medication delivery and supporting efficient workflows across health care services.

All municipalities have implemented electronic prescription systems; however, despite their potential to enhance medication safety and streamline workflows, the adoption of eMDD has been slow. By May 2025, out of 357 municipalities of the country, only 140 had implemented eMDD. Because a single municipality may encompass several general practices and pharmacies, municipal adoption does not fully reflect the system's actual level of use. At the patient level, only about 21% of individuals receiving multidose medications are currently included in the e-prescribing solution, meaning that the remaining 79% still receive multidose rolls produced on the basis of paper-based prescriptions. This situation underscores the importance of establishing reliable and well-functioning electronic solutions now, as the coming years are expected to bring a substantial increase in conversions from paper-based to e-prescribing when the remaining patients transition into the system.

Barriers to adoption include the complexity of transitioning from paper-based systems, insufficient training, and limited interprofessional collaboration. Additionally, discrepancies in medication lists across care settings and unclear role responsibilities among health care providers continue to pose risks to medication safety [3].

The eMDD system is part of a broader national eHealth strategy, which includes initiatives such as e-prescriptions, the Summary Care Record, and the Patient's Medication List. Together, these components aim to establish a unified digital infrastructure to support medication safety and continuity of care. Preliminary studies suggest that eMDD can improve communication, reduce errors, and enhance the quality of care. However, successful implementation requires more than technological readiness; it also demands organizational commitment, comprehensive user training, and well-defined governance structures [1,4]. Despite a systematic search in international databases, we found limited literature addressing eMDD outside Scandinavia. To our knowledge, the existing research is largely confined to Nordic health care systems, suggesting that eMDD may be a regionally specific phenomenon.

This study investigates the current state of eMDD implementation in Norway, identifies key facilitators and barriers, and explores its implications for medication safety and health care efficiency. The findings aim to inform strategies for scaling eMDD nationally and integrating it effectively within the broader eHealth ecosystem.

Objective

The aim of this study is to investigate the challenges associated with the use of eMDD in Norway, as experienced by GPs and pharmacists. As the primary users of the eMDD system, these 2 professional groups offer valuable insights into its practical implementation and operational hurdles. Additionally, the study seeks to gather their recommendations for system improvements, with the ultimate goal of informing future development and facilitating the national scaling of eMDD. The central research question guiding this study is as follows: what are the challenges of using eMDD and how do GPs and pharmacists propose that these challenges be addressed?

Methods

Study Design

In order to answer the research question, we used a parallel mixed methods design, combining quantitative and qualitative data. Mixed methods in a research context consist of different design categories: explanatory, exploratory, parallel, and embedded. We chose the parallel design to gain both measurable results and a deeper understanding of participants' perspectives, feelings, and motivations in addition to quantitative data. Although slightly unconventional, this approach was selected to capture how users experience and interact with eMDD.

In this study, our research group chose to focus exclusively on participants who had already begun using eMDD. This approach was motivated by the need to obtain authentic feedback on challenges and perhaps, most importantly, suggestions for improvement from pharmacists and physicians with practical experiences. Including respondents who had not yet adopted eMDD could have resulted in speculative answers that lacked real insight into the user experience and might have even provided a misleading basis for system enhancements.

To avoid this, we obtained information from all major pharmacy chains and the Norwegian Health Network to identify which pharmacies and medical practices had implemented eMDD. This allowed us to target the survey exclusively to active users of the service.

Regarding the study design, interviews could have provided more in-depth responses. However, given the large pool of potential respondents, this would have been too resource-intensive within the available timeframe. Each pharmacy or medical practice receiving the email could potentially have provided multiple responses, and each municipality includes several such sites. For this reason, we opted for a questionnaire-based approach, which enabled us to reach a broad audience and collect a substantial amount of valuable data. To ensure a practical and efficient approach, we opted for a single, unified questionnaire rather than separate surveys for each professional group. This decision was motivated by the need to reduce complexity and encourage participation, as longer or multiple surveys could have discouraged responses. A shared instrument also provided a stronger basis for comparing similarities and differences between

XSL•FO
RenderX

GPs and pharmacists. Although the survey was anonymous, respondents indicated their professional role, allowing us to differentiate responses during the analysis. Furthermore, using identical questions enabled us to identify challenges and improvement suggestions relevant across systems and professions, while maintaining a comprehensive perspective. For future research—or in a repeated survey after further system development—it could be valuable to explore each professional group in greater depth.

Considering the busy work schedules of both physicians and pharmacists, a survey that could be completed at any time was more practical than arranging joint interview sessions.

Once eMDD is adopted, there is virtually no return to previous practices. We have not encountered any cases of reverting to paper-based systems after transitioning to eMDD, although this observation is anecdotal and not formally documented. For medical practices, the adoption is binary—they either use eMDD or they do not. Pharmacies, however, may receive eMDD prescriptions from 1 medical practice while still handling paper-based multidose prescriptions from another. Consequently, the number of patients converted to eMDD can vary significantly between pharmacies.

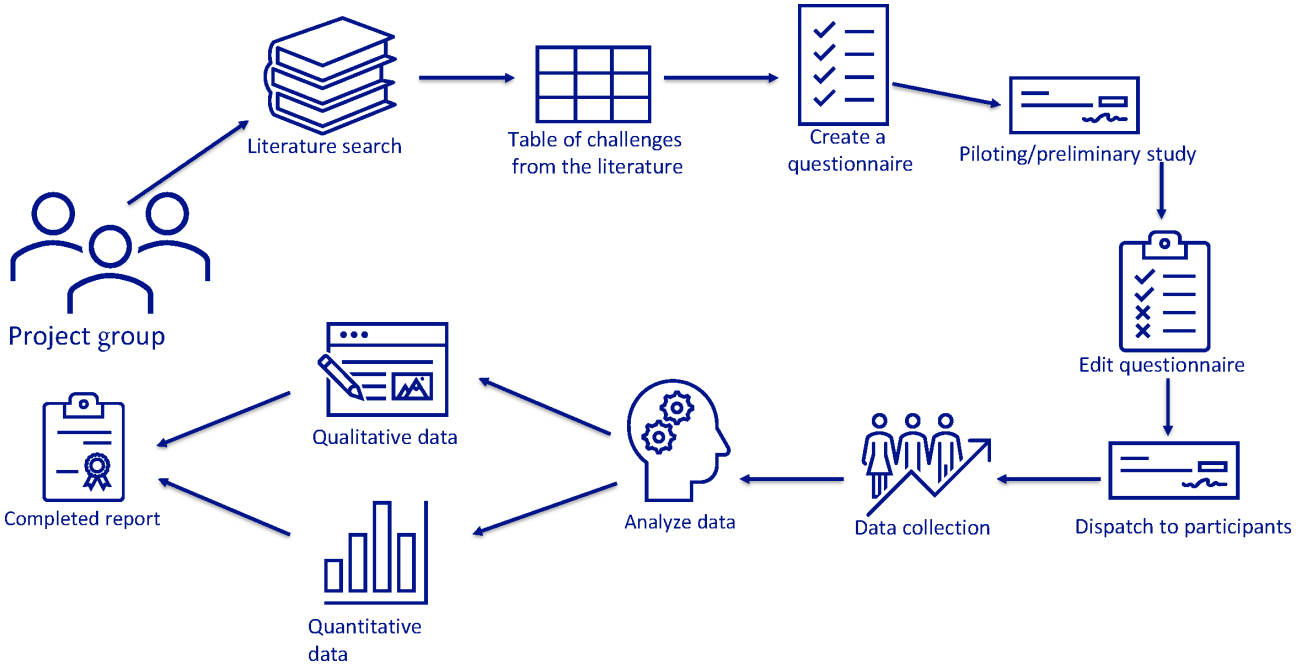
Data Collection

A structured questionnaire was developed and distributed using Nettskjema, a secure and user-friendly online survey platform (Multimedia Appendix 1) [5]. The questionnaire included a combination of single-choice, multiple-choice, matrix, and open-ended questions, with a primary emphasis on qualitative responses to capture user experiences. The survey was designed to be anonymous, concise, and accessible, with an estimated completion time of 10 to 15 minutes.

To ensure clarity and relevance, the questionnaire was piloted with 6 health care professionals experienced in eMDD, including GPs, pharmacists, and a municipal pharmacist. Feedback from the pilot study was used to refine the final version of the questionnaire.

The survey was distributed via email to 54 pharmacies and 190 GP surgeries across Norway. Efforts were made to maximize the number of participants, including follow-up attempts, to address undeliverable emails. The survey remained open for 14 days, with a reminder sent after 8 days.

Ethical Considerations



Ethical approval for the study was obtained from Sikt (ref. no. 887722), the Norwegian Agency for Shared Services in Education and Research [6]. Participation was entirely voluntary and anonymous, with informed consent obtained through the survey introduction. No compensation was provided to participants. All data were handled in accordance with the privacy regulations reviewed by Sikt and securely stored.

Data Analysis

Quantitative data were analyzed using the built-in tools available in Nettskjema. For qualitative data, a thematic analysis was conducted following the 6-step process outlined by Braun and Clarke [7]. The process included (1) familiarization with the data, (2) generating initial codes, (3) developing themes, (4) reviewing themes, (5) defining and naming themes, and (6) reporting the findings.

The analysis was supported by NVivo (Lumivero), a qualitative data analysis software approved for use by the University of Tromsø. NVivo facilitated systematic coding and categorization of responses, enabling meaningful comparisons between the 2 professional groups. Figure 1 provides an overview of the study's methodology, detailing each step from start to finish.

Figure 1. Illustration of the study's methodological process from start to finish.

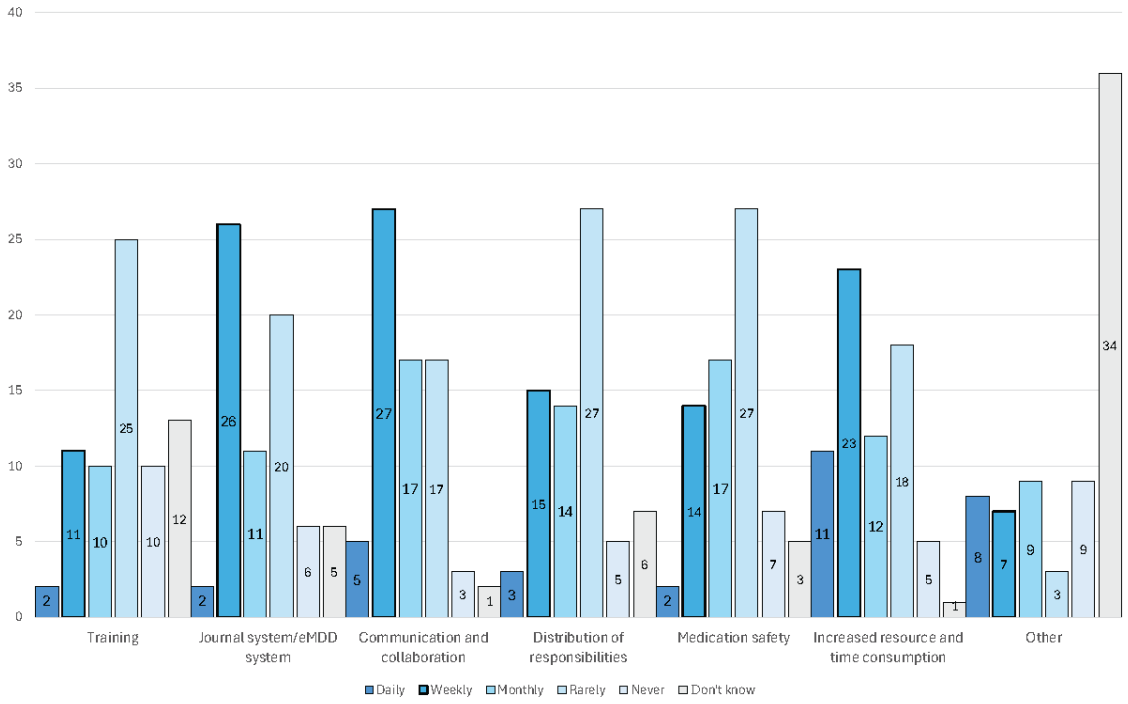
Results

Participant Overview

A total of 70 health care professionals, including GPs (n=55) and pharmacists (n=15) with experience using eMDD, participated in the survey. Thematic analysis of their responses revealed 7 overarching themes: challenges with eMDD, training, system and technology, communication and interaction, division of responsibilities, medication safety, and time and resource use.

The survey's first question used a multiple-choice table to map participants' experiences with challenges and to identify any additional issues. Each main topic was explored through 2 lenses: current challenges and potential improvements. The results are presented by topic and categorized by professional groups (GPs and pharmacists), highlighting key differences in their experiences and perspectives. All participant quotes in this paper were translated from Norwegian into English using Copilot (Microsoft).



Challenges With eMDD

The survey question for eMDD was as follows:

> *How often do you experience challenges around these areas in your work with e-prescribing for multidose drug dispensing?*

Participants reported varying frequencies of challenges in their daily work with eMDD. The most commonly mentioned issues included system-related problems, communication barriers, and time and resource constraints. While some participants indicated that challenges were infrequent, others reported experiencing disruptions on a daily or weekly basis. Figure 2 illustrates these responses.

Figure 2. Participants' responses on how often they experience challenges with electronic prescribing for multidose drug dispensing (eMDD).

Notably, distinct differences emerged between the 2 professional groups:

- Pharmacists more frequently reported issues related to system integration and technical functionality.
- GPs highlighted challenges associated with communication overload, particularly in coordinating with other health care professionals.

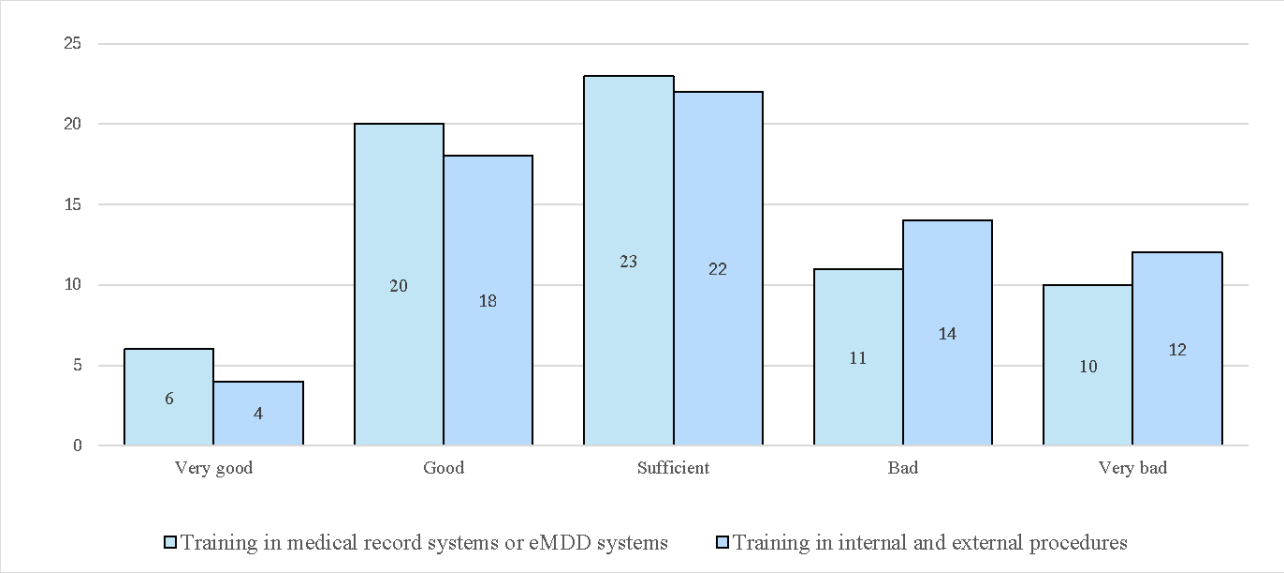
These findings underscore the distinct perspectives of each group, emphasizing the need for tailored solutions to address their specific challenges.

Training

Reported Challenges

The survey question for training was as follows:

> *How has training in the use of e-prescribing for multidose drug dispensing been for you in your workplace?*



Survey responses revealed mixed experiences regarding training in the use of eMDD. While many participants rated their training as "good" or "sufficient," others described it as "poor" or "very poor." There is a notable difference between the 2 professional groups: pharmacists generally rated their training experiences positively, whereas GPs were more likely to rate their training experiences negatively. Figure 3 illustrates these responses.

GPs highlighted the need for improved access to educational resources, such as e-learning modules, instructional videos, websites, or written materials. They also recommended implementing periodic reviews of training after some time using eMDD, as well as mandatory training for all users. Additionally,

XSL•FO
RenderX

GPs called for improved user support and continuous follow-up from the system supplier to address challenges effectively.

Figure 3. Responses from participants about their experiences of training in the use of electronic prescribing for multidose drug dispensing (eMDD).

Quotes From GPs

> *Lack of training is the main problem. If there is a short intro on a website about e-prescribing for MDD, if not—there is a clear need.* [GP]

> *The system freezes, and the feedback has its own tribal language. There are many reports to and from before a multidose is established.* [GP]

Pharmacists suggested clearer training plans and more practical, hands-on training. They also emphasized the importance of collaborative training with GPs to foster better communication and understanding of each other's workflows. This, they suggested, could help reduce waiting times and improve overall efficiency.

Quotes From Pharmacists

> *Took some time in the beginning before the GP cracked the code on how this worked. It is desirable that the GPs also receive training in this, and that this should not be self-taught. They are probably busy enough already without having to learn this themselves.* [Pharmacist]

> *I would like to have a better overview of the system from the GP's side so that we can understand challenges and possibly help solve them.* [Pharmacist]

Participants from both groups identified several areas for improvement in training:

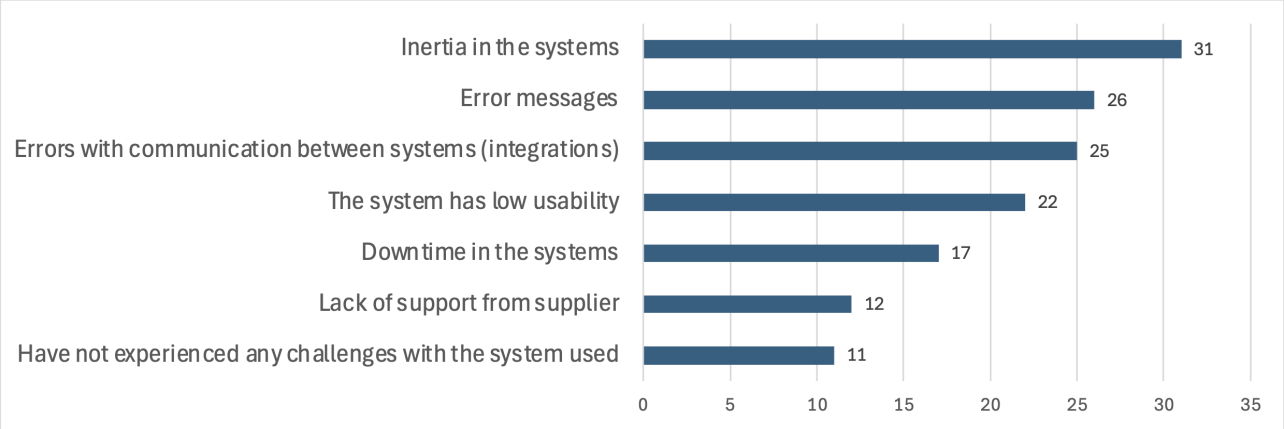
- The need for more training time and ongoing support
- The importance of user-friendly, intuitive systems in reducing the learning curve
- Enhance collaboration between pharmacists and GPs to improve mutual understanding and streamline processes

These findings highlight the importance of tailored, comprehensive training programs that address the challenges faced by each professional group while fostering better interdisciplinary collaboration.

System and Technology

Reported Challenges

The survey question for system and technology was as follows:



> *What challenges have you experienced with the e-prescribing for multidose drug dispensing you use in your workplace?*

The majority of participants reported various challenges with the eMDD system, including sluggish performance, integration errors, frequent error messages, and low usability. Notably, only 11 out of 70 participants indicated that they did not experience any issues. GPs mainly reported concerns related to system slowness, error messages, and poor user-friendliness, whereas pharmacists highlighted issues such as system inertia, downtime, and integration errors. Figure 4 illustrates these responses.

Participants described the eMDD systems as lacking user-friendliness and suggested several improvements, including enhancing usability and simplifying processes, improving functionality to reduce errors and minimize unnecessary tasks, and introducing new features to address recurring challenges. Specific concerns were raised about the duplication of work, particularly when patients are hospitalized or have private multidose arrangements, with hopes that Central Prescribing Module and Patient's Medication List solutions could address these issues. Additionally, technical problems and system slowness were noted as causing time loss and work interruptions. Unnecessary requests and unclear system changes were also identified as key weaknesses that need to be addressed.

XSL•FO
RenderX

Figure 4. Participants' responses to the challenges they experience with systems or the technology used in their work with electronic prescribing for multidose drug dispensing.

Quotes From GPs

Less rigid in terms of generic substitution, dosage form, length of prescriptions and not having to renew prescriptions that are in multidose. [GP]

A lot of notifications, the system sends too many automated messages. I have experienced that they send a message for renewal of prescriptions, even though there is a lot left on the prescription. [GP]

Quotes From Pharmacists

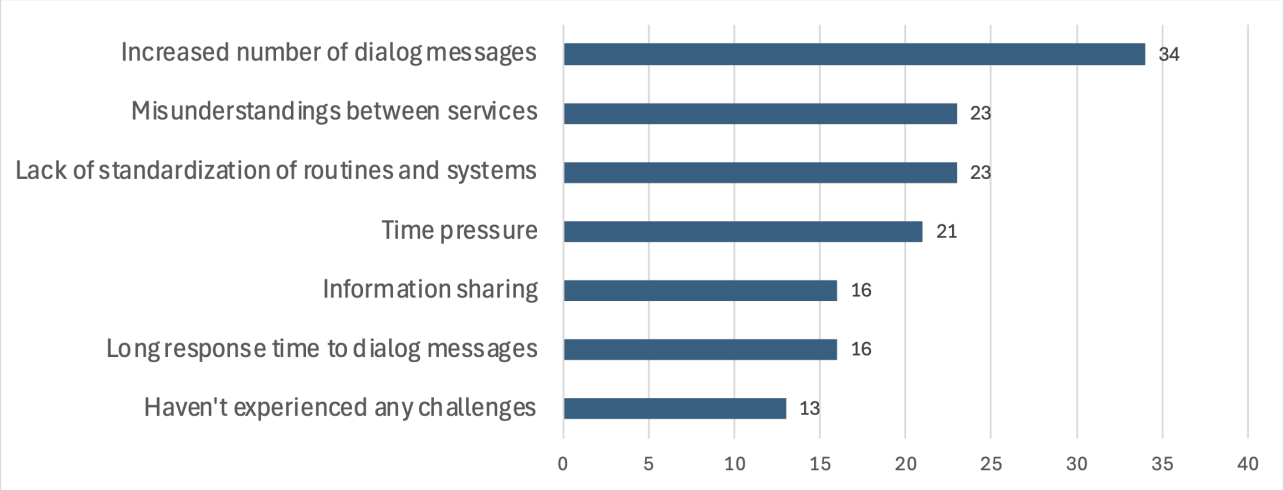
I want a more user-friendly system and a more advanced system that means that the risk of errors is minimal. [Pharmacist]

A dialogue message about missing a prescription should have gone directly to a GP, and it should have been possible to send a dialogue message to the hospital physician regarding prescriptions reimbursed by hospitals. [Pharmacist]

Communication and Interaction

Reported Challenges

The survey question for communication and interaction was as follows:



> *What do you find challenging about communication and interaction between the health services?*

Challenges related to communication and interaction were commonly reported by eMDD users. Key issues included an increased number of dialogue messages, misunderstandings between services, and a lack of standardization in routines and systems. However, 13 out of 70 participants indicated that they did not experience these challenges.

GPs mainly reported an increased number of dialogue messages and misunderstandings between services, whereas pharmacists highlighted long response times and time pressure as significant challenges. Figure 5 illustrates these responses.

GPs recommended a clearer division of responsibilities for medication changes, better documentation in discharge summaries, improved information flow, and fewer but more relevant dialogue messages, as responding to excessive messages was described as time-consuming.

Figure 5. Participants' responses about challenges they face with systems and technology used in electronic prescribing for multidose drug dispensing workflow.

XSL•FO
RenderX

Quotes From GPs

> *Not sending so many messages from the system to the GPs. Enough with one message about one case, not 10 every day!* [GP]
>
> *There should be a common communication platform for pharmacies, GPs and home care services.* [GP]

Pharmacists emphasized the need for clearer prioritization of dialogue messages and prescription requests, as well as faster handling of requests to avoid delays in multidose packaging.

Quotes From Pharmacists

> *The need for renewal of prescriptions should go directly to a GP, so that the pharmacy does not have to ask for every time it is empty.* [Pharmacist]
>
> *We get prescription messages in the system for some e-prescriptions that are not in the prescription intermediary, and the GP is unable to remove or enter new valid prescriptions.* [Pharmacist]

Some participants proposed developing a shared communication platform for pharmacies, GPs, and home care services. Such a platform could streamline communication, reduce misunderstandings, and improve overall efficiency. Additionally, participants noted that technical issues often affect communication between parties, further emphasizing the need for improvements of the system.

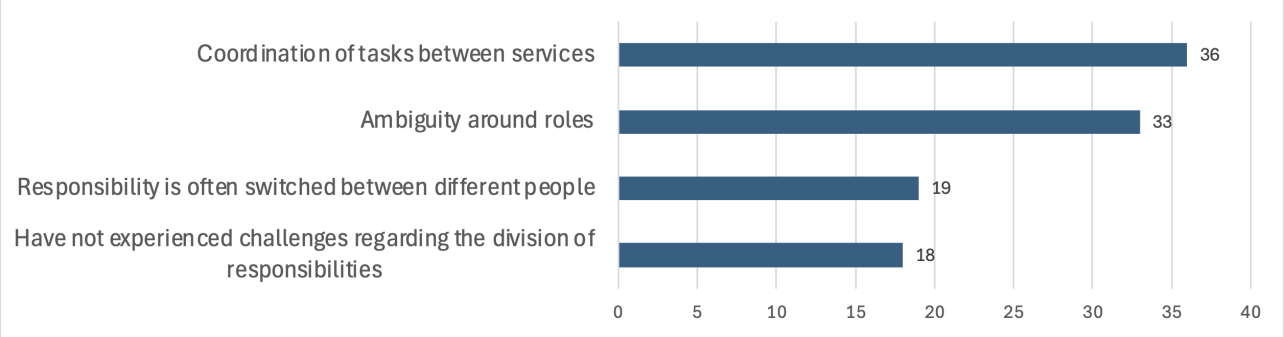
Division of Responsibilities

Reported Challenges

The survey question for division of responsibilities was as follows:

> *What do you think has been challenging about the division of responsibilities related to e-prescribing for multidose drug dispensing?*

The division of responsibilities within the eMDD workflow was identified as a significant challenge, particularly in terms of task coordination and role ambiguity. Moreover, 19 out of 70 participants reported frequent shifts in responsibility between individuals, whereas 18 participants did not experience such challenges. Figure 6 illustrates these responses.



GPs primarily noted issues with task coordination, although some reported no challenges with responsibility division. In contrast, nearly all pharmacists highlighted role ambiguity and frequent shifts in responsibility as key concerns.

Some participants expressed uncertainty about the roles and responsibilities within the eMDD pathway, particularly regarding hospital doctors. They suggested a clearer definition of responsibilities between municipalities and hospitals, as well as improved internal routines to clarify roles.

Participants noted that responsibilities often change hands, leading to forgotten tasks and issues that only the patient's primary GP could address. This problem was particularly evident during holidays or when temporary workers were involved, causing delays in prescription renewals or necessary adjustments.

Challenges with task coordination were especially evident when patients were admitted to hospitals or changed GPs, leading to disruptions in the eMDD workflow and further complicating the process.

Figure 6. Challenges participants have experienced related to the division of responsibilities.

Quotes From GPs

> *Clear internal routines in the different locations. Maybe also useful with some more communication at a higher level [in management].* [GP]
>
> *We have had several different substitute GPs who have to register as a GP in charge of multidose when they are here. High risk of things slipping.* [GP]

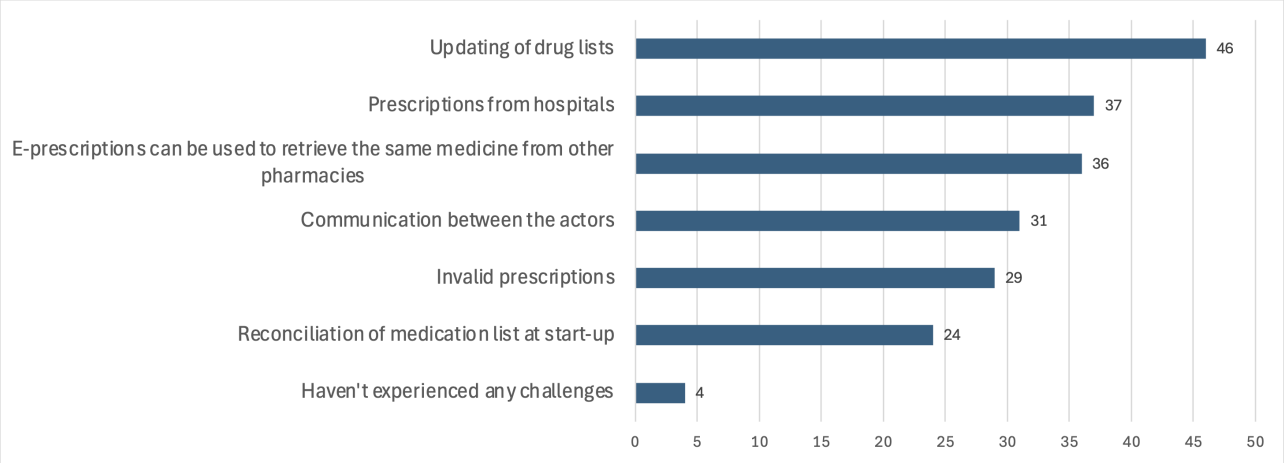
Quotes From Pharmacists

> *All functions should be familiar with their roles and responsibilities, so that the pharmacy does not interfere in prescription orders or dose changes that the pharmacy does not have an overview of, or that the multidose is not stopped because a prescription was not renewed.* [Pharmacist]
>
> *When the patient switches to a GP who is affiliated with e-prescribing for MDD, but the pharmacy has not been notified.* [Pharmacist]

Medication Safety

Reported Challenges

The survey question for medication safety was as follows:



> *What do you think is challenging about medication safety related to e-prescribing for multidose drug dispensing?*

XSL•FO
RenderX

Medication safety was the survey's most frequently discussed theme. Participants identified several key challenges, including updating medication lists, managing hospital prescriptions, and ensuring effective cross-functional communication. Updating medication lists was highlighted by 46 out of 70 participants, mostly GPs. Additionally, 36 participants noted that e-prescriptions used in multidose pharmacies can also be used at other pharmacies, creating risks of duplicate dispensing. This concern was particularly significant for A/B drugs. To address this, participants suggested locking e-prescriptions to the patient's multidose setup and ensuring that other pharmacies are informed about the eMDD enrollment. Pharmacists mainly reported issues with invalid prescriptions and reconciling medication lists for new eMDD. Notably, only 2 GPs and 2 pharmacists reported no challenges with medication safety. Figure 7 illustrates these responses.

GPs and pharmacists suggest establishing clearer *routines* and better interaction when updating medication lists or initiating eMDD. One participant proposed implementing automatic notifications to inform all relevant parties about changes to medication lists.

Figure 7. Challenges participants have experienced related to medication safety.

Quotes From GP

> *Implement better notification systems that automatically notify all actors involved in the event of medication changes.* [GP]

> *It must be possible to lock e-prescribed multidose drugs so that they cannot be duplicated and/or in large quantities by the patient at other pharmacies.* [GP]

Quotes From Pharmacists

> *Reconciliation of medication list for patients at the start of e-prescribing for MDD. I find that many GPs transfer their patients to e-prescribing for MDD in connection with changes, which makes it difficult for the pharmacy to agree or decide whether any medication is missing or discontinued.* [Pharmacist]

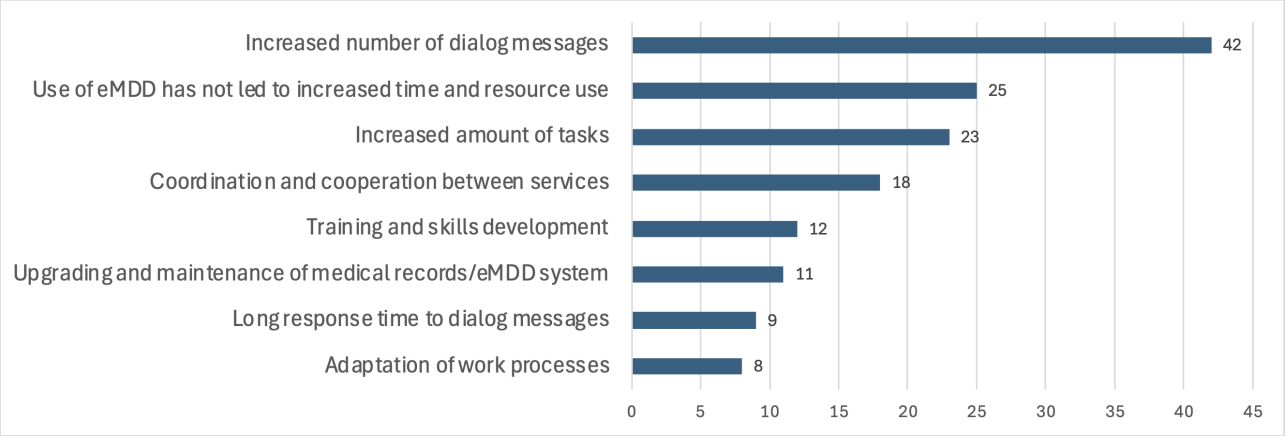
> *Possibility to lock MDD e-prescriptions so that they cannot be collected at other pharmacies by mistake.* [Pharmacist]

Time and Resource Use

Reported Challenges

The survey question for time and resource use was as follows:

> *How has the use of e-prescribing for multidose drug dispensing led to increased time and resource use in your workplace?*



Participants identified increased tasks, dialogue messages, and coordination between services as the main challenges associated with eMDD. Many GPs noted that the rise in dialogue messages has contributed to increased time and resource demands, whereas pharmacists highlighted additional tasks and prolonged response times. However, 25 out of 70 participants, mostly pharmacists, stated that they did not experience increased time or resource use due to eMDD. Figure 8 illustrates these responses.

To address these challenges, participants suggested renewing multiple prescriptions simultaneously to reduce message exchanges. They also proposed enabling pharmacies to send eMDD messages directly to home care services to streamline communication. Additional recommendations included introducing more efficient eMDD features, such as notifications for important changes, the ability to view change reports, and a function to label multiple drugs for control or discontinuation. A better overview of messages was also highlighted as a priority.

Additionally, participants recommended developing a common communication platform for all stakeholders to reduce time and resource use. They also emphasized the importance of training and expressed optimism that the implementation of the Patient's Medication List could help alleviate some of the additional workload.

XSL•FO
RenderX

Figure 8. Reasons for increased time and resource use related to work with electronic prescribing for multidose drug dispensing (eMDD).

Quotes From GPs

It is absolutely necessary to review the regulations. A bit surprising that we get yet another request here when everything that is written has been carefully described before. [GP]

Paying far too little attention to the GPs' busy everyday lives: meaningless messages from pharmacies about one request for renewal per prescription – when the patient has 20 medications, it MUST be possible to renew all of them in one process! [GP]

It is absolutely necessary to review the regulations. A bit surprising that we get yet another request here when everything that is written has been carefully described before. [GP]

Quotes From Pharmacists

We have to approve 'changes' if the GP has only renewed a prescription for on-demand medicine – this is unnecessary and time-consuming. [Pharmacist]

Want an opportunity to see changes that have been perceived by the system, a report or an overview on the change report when approving the prescription card. [Pharmacist]

Discussion

Principal Findings

This study explored the challenges associated with the use of eMDD in Norway, focusing on the perspectives of GPs and pharmacists. The findings reveal that while eMDD systems offer significant advantages over traditional paper-based multidose systems—particularly in terms of medication safety and workflow efficiency—they also introduce new complexities. These challenges include issues related to training, system usability, communication, role clarity, and medication safety (Table 1).

The thematic analysis identified 7 key areas of concern: training, system and technology, communication and interaction, division of responsibilities, medication safety, time and resource use, and broader implementation challenges. These findings are consistent with previous research, which has documented similar issues during the transition from paper-based to electronic systems [8-16].

XSL•FO
RenderX

Table . Summary of findings and improvement proposals.

Theme	Findings	Improvement proposals
Training	Training experiences varied: pharmacists rated it positively, whereas GPs[a] were more critical.	GPs suggested better access to educational resources, mandatory training, follow-up sessions, and improved user support.
System and technology	Participants reported system slowness, integration errors, and poor usability. Only 11 of 70 experienced no issues.	Suggestions included simplifying processes, improving functionality, and reducing duplicated work.
Communication and interaction	Most participants reported issues, such as increased dialogue messages, misunderstandings between services, and lack of standardization. Thirteen out of 70 did not experience these challenges.	GPs called for clearer responsibilities and better discharge documentation, whereas pharmacists emphasized prioritizing and expediting message handling to avoid delays.
Division of responsibilities	Coordination and role ambiguity were major challenges. Nineteen out of 70 participants reported shifting responsibilities, whereas 18 did not experience this.	Participants called for clearer definitions of responsibilities between hospitals and municipalities, noting that shifting responsibility often leads to forgotten tasks and delays—especially during holidays or with temporary staff.
Medication safety	Medication safety was the most reported concern, especially among GPs. Key issues included updating medication lists, hospital prescriptions, and communication. Only 4 participants reported no safety-related issues.	GPs and pharmacists suggested clearer routines and better coordination for updating medication lists or starting eMDD[b], as well as locking e-prescriptions to multidose arrangements to prevent duplicate dispensing.
Time and resource use	Increased tasks, dialogue messages, and coordination demands were key challenges. GPs noted higher time/resource use due to more messages, whereas pharmacists pointed to task load and slow responses.	Participants proposed renewing multiple prescriptions at once, enabling pharmacies to message home care services, and improving eMDD features, such as notifications and change reports. A shared communication platform and better training were also recommended.

[a]GPs: general practitioners.

[b]eMDD: electronic prescribing for multidose drug dispensing.

Comparison With Prior Work

The literature review confirmed that many of the challenges identified in this study are not unique. For instance, studies by Jøsendal and Bergmo [8] and Gullslett and Bergmo [9] highlight common barriers to successful eMDD implementation, including increased workloads, insufficient training, and communication breakdowns. Similarly, technical issues, such as system slowness, error messages, and poor integration with electronic health records, have been widely documented [8,14].

Our findings also align with previous research on the importance of medication reconciliation and the risks associated with inconsistent medication lists [12]. A particularly significant safety concern identified in this study is the ability for patients to collect e-prescribed medications, especially controlled substances from multiple pharmacies. This issue aligns with warnings from the Norwegian Board of Health Supervision and findings from other studies [16].

In a broader international context, Scandinavian countries appear to be at the forefront of integrating eMDD into national e-prescription systems. Norway has implemented a fully digital workflow for eMDD, enabling seamless communication between GPs, pharmacies, and home care services [17]. Finland and Denmark have also integrated eMDD into their e-prescription infrastructures, with Finland legislating its use in 2011 and providing publicly funded access to approximately 95% of eligible patients [17]. Sweden, while having the highest per capita use of automated dose dispensing, has faced challenges related to fragmented prescribing responsibilities and reduced frequency of medication reviews [15].

Outside of Scandinavia, countries such as the Netherlands, Australia, and South Africa have adopted centralized MDD systems, often through hub-and-spoke models [18]. In the Netherlands, Pharmacy Voorzorg serves over 145,000 patients via 540 community pharmacies [18]. South Africa's semiautomated central dispensing unit supports chronic disease management, including HIV care [18]. It is important to distinguish between eMDD and MDD. While MDD refers to a physical dispensing system or automated dispensing device, eMDD denotes a national e-prescribing system. These systems serve distinct functions within the medication management process.

Despite these advancements, evidence on clinical outcomes and cost-effectiveness remains limited, and concerns persist regarding system usability, role clarity, and medication safety—issues that mirror those identified in this study.

Implications for Practice

The results highlight the need for a structured, interdisciplinary approach to training. In the first survey question, we asked respondents which areas they found challenging and how frequently these challenges occurred. Many GPs indicated that

XSL•FO
RenderX

they did not feel fully prepared, often relying on limited documentation or informal, peer-led guidance. To address these gaps, participants recommended implementing modular e-learning programs, video tutorials, and mandatory onboarding sessions for all users. Pharmacists emphasized the value of practical, hands-on training and expressed a strong interest in gaining deeper insights into the GP workflow to enhance collaboration.

System usability remains a major barrier. Participants described the eMDD interface as unintuitive and cumbersome, citing issues such as excessive clicking, unclear feedback, and time-consuming processes. To improve the user experience, they proposed simplifying workflows, improving system responsiveness, and introducing features such as batch prescription renewal and more transparent error messaging.

Communication between health care providers emerged as another critical issue. Although dialogue messages are intended to facilitate coordination, they often lead to information overload for GPs and delays for pharmacists. Participants recommended the development of a unified communication platform that integrates GPs, pharmacists, and home care services, along with the establishment of clearer protocols for handling medication changes during hospital discharges.

Role ambiguity and inconsistent handovers of responsibility, especially during staff absences or transitions, were also highlighted. Participants called for clearer definitions of responsibilities, particularly regarding hospital physicians' roles in updating medication lists. The upcoming national rollout of the Patient's Medication List [19] may help address some of these concerns, but its success will depend on effective implementation and active engagement from all stakeholders.

Limitations

This study has several limitations that should be acknowledged. The sample size (n=70) limits the generalizability of the findings, and the response rate was affected by undelivered emails and potential selection bias. Participants with strong opinions, either positive or negative, about eMDD may have been more likely to respond, potentially skewing the results. Additionally, the survey did not capture the duration of eMDD use, making it difficult to distinguish implementation-related issues from ongoing challenges.

The mixed methods design provided valuable insights, particularly from the qualitative data, which provided a rich exploration of user experiences. However, the limited quantitative data precluded the inferential statistical analysis. Future research with larger, more representative samples and longitudinal designs could provide a more comprehensive understanding of eMDD adoption and its outcomes.

Recommendations for Future Research

Further research should explore the long-term effects of eMDD on clinical workflows, medication safety, and patient outcomes and evaluate the effectiveness of different training models and system design improvements. As the national rollout of the Patient's Medication List advances, studies should assess its integration with eMDD and its impact on interprofessional collaboration and medication reconciliation processes.

Conclusion

This study examined the experiences of Norwegian GPs and pharmacists with the use of eMDD, focusing on key areas such as training, system usability, communication, division of responsibilities, medication safety, and resource use. Using a mixed methods approach that combined a literature review with survey responses from 70 health care professionals, the study identified recurring challenges that hinder the effective implementation and use of eMDD.

The findings indicated that, while eMDD has considerable potential to improve medication safety and streamline workflows, its current effectiveness is limited by gaps in training, technical inefficiencies, fragmented communication, and unclear role definitions. GPs reported insufficient training and support, whereas pharmacists emphasized the need for better coordination and clearer routines. Both groups expressed concerns about system usability, pointing to issues such as slow performance, frequent error messages, and excessive administrative burden.

Communication between health care providers emerged as a critical barrier. Dialogue messages were often perceived as excessive, irrelevant, or delayed, and the absence of a unified communication platform across care levels further complicates coordination, especially during transitions, such as hospital discharges. Similarly, the lack of clarity in the division of responsibilities, particularly regarding medication list updates, contributed to workflow inefficiencies and potential safety risks.

Despite these challenges, the study revealed a strong willingness among health care professionals to improve the system. In contrast to previous research, which has focused primarily on pharmacists, our survey received a notably high number of responses from GPs. Furthermore, participants provided concrete suggestions for improving existing systems, which strengthen the practical relevance of our findings. The proposed solutions included modular e-learning programs, improved system design, clearer communication protocols, and the ability to lock e-prescriptions to prevent duplicate dispensing.

As Norway continues the national rollout of eMDD and prepares for the broader implementation of the Patient's Medication List, these findings underscore the importance of involving end users in system development and policy planning. Addressing the identified challenges through targeted training, technical enhancements, and interprofessional collaboration will be essential to realizing the full potential of eMDD in improving medication safety and health care efficiency.

Abstract

Background: Malnutrition in critically ill patients is associated with increased morbidity and mortality, yet traditional screening tools such as the modified NUTRIC (mNUTRIC) score often rely on subjective assessments or delayed data, limiting their utility for early intervention in the dynamic intensive care unit (ICU) environment. Real-time, data-driven approaches using electronic health records offer a promising solution for automated and objective risk stratification.

Objective: This study aimed to develop and validate a machine learning model, the E-NUTRIC (Ensemble-NUTRIC), for the early prediction of malnutrition risk within the first 24 hours of ICU admission. By integrating multiple algorithms through stacking ensemble learning, we sought to improve predictive performance over traditional scoring systems and individual machine learning models while maintaining clinical interpretability.

Methods: We conducted a retrospective cohort study using data from the Medical Information Mart for Intensive Care (MIMIC-IV, version 3.1). Adult ICU stays exceeding 24 hours were included, and the primary outcome was malnutrition diagnosis. Variables from the first 24 hours (demographics, vitals, and laboratory tests) were extracted and harmonized. Missingness was addressed with k-nearest neighbors imputation, features were standardized, and class imbalance was mitigated via random undersampling. The proposed E-NUTRIC model used a stacking ensemble with 4 base learners—Logistic Regression, Random Forest, Extreme Gradient Boosting (XGBoost), and Light Gradient Boosting Machine—and a logistic metalearner. Performance was assessed on a stratified 80/20 holdout test set using area under the receiver operating characteristic curve (AUROC), area under the precision-recall curve, and calibration curves. The mNUTRIC score served as the clinical benchmark. Model interpretability was derived by applying Shapley Additive Explanations (SHAP) specifically to the highly predictive XGBoost component, while clinical utility was assessed using Platt scaling recalibration.

Results: The final cohort comprised 51,483 patients, of whom 4384 (8.5%) were classified as being at malnutrition risk. The E-NUTRIC model showed superior discrimination with an AUROC of 0.875 (95% CI 0.864 - 0.885), outperforming the mNUTRIC score (AUROC=0.635, P<.001). Relative to individual base learners, E-NUTRIC achieved the best overall performance, exceeding those of the best-performing individual models XGBoost (AUROC=0.871) and Light Gradient Boosting Machine (AUROC=0.866). The area under the precision-recall curve of E-NUTRIC was 0.424, representing approximately a 3.4-fold increase over mNUTRIC (0.126). SHAP analysis highlighted minimum serum albumin, admission weight, early hypokalemia, and specific ICU admission types as key nonlinear predictors of malnutrition risk. Unlike the traditional mNUTRIC score, which compressed predictions into a low-risk tier, the recalibrated E-NUTRIC model effectively spanned the full probability spectrum, thereby isolating high-risk phenotypes.

Conclusions: The E-NUTRIC stacking ensemble provides an interpretable approach for nutritional risk screening in the ICU using routinely available electronic health records data. In this retrospective cohort study, it demonstrated superior discrimination to the mNUTRIC score and offered clinically consistent feature attributions.

Introduction

Malnutrition is a critical prognostic risk factor for patients in the intensive care unit (ICU), significantly influencing clinical outcomes such as length of ICU stay, duration of mechanical ventilation, infection risk, and mortality [1-3]. A meta-analysis of 20 studies reported that the prevalence of malnutrition among ICU patients ranges from 38% to 78%. The physiological stress of critical illness exacerbates this vulnerability, with nutritional risk escalating during prolonged hospitalization [4]. Crucially, research indicates that early prediction and identification of malnourished patients can facilitate timely and appropriate nutritional interventions, thereby mitigating these adverse outcomes. A national cohort study in Switzerland demonstrated that nutritional support significantly reduced patients' all-cause mortality, reduced 30-day rehospitalization rates, and increased the likelihood of discharge to home [5].

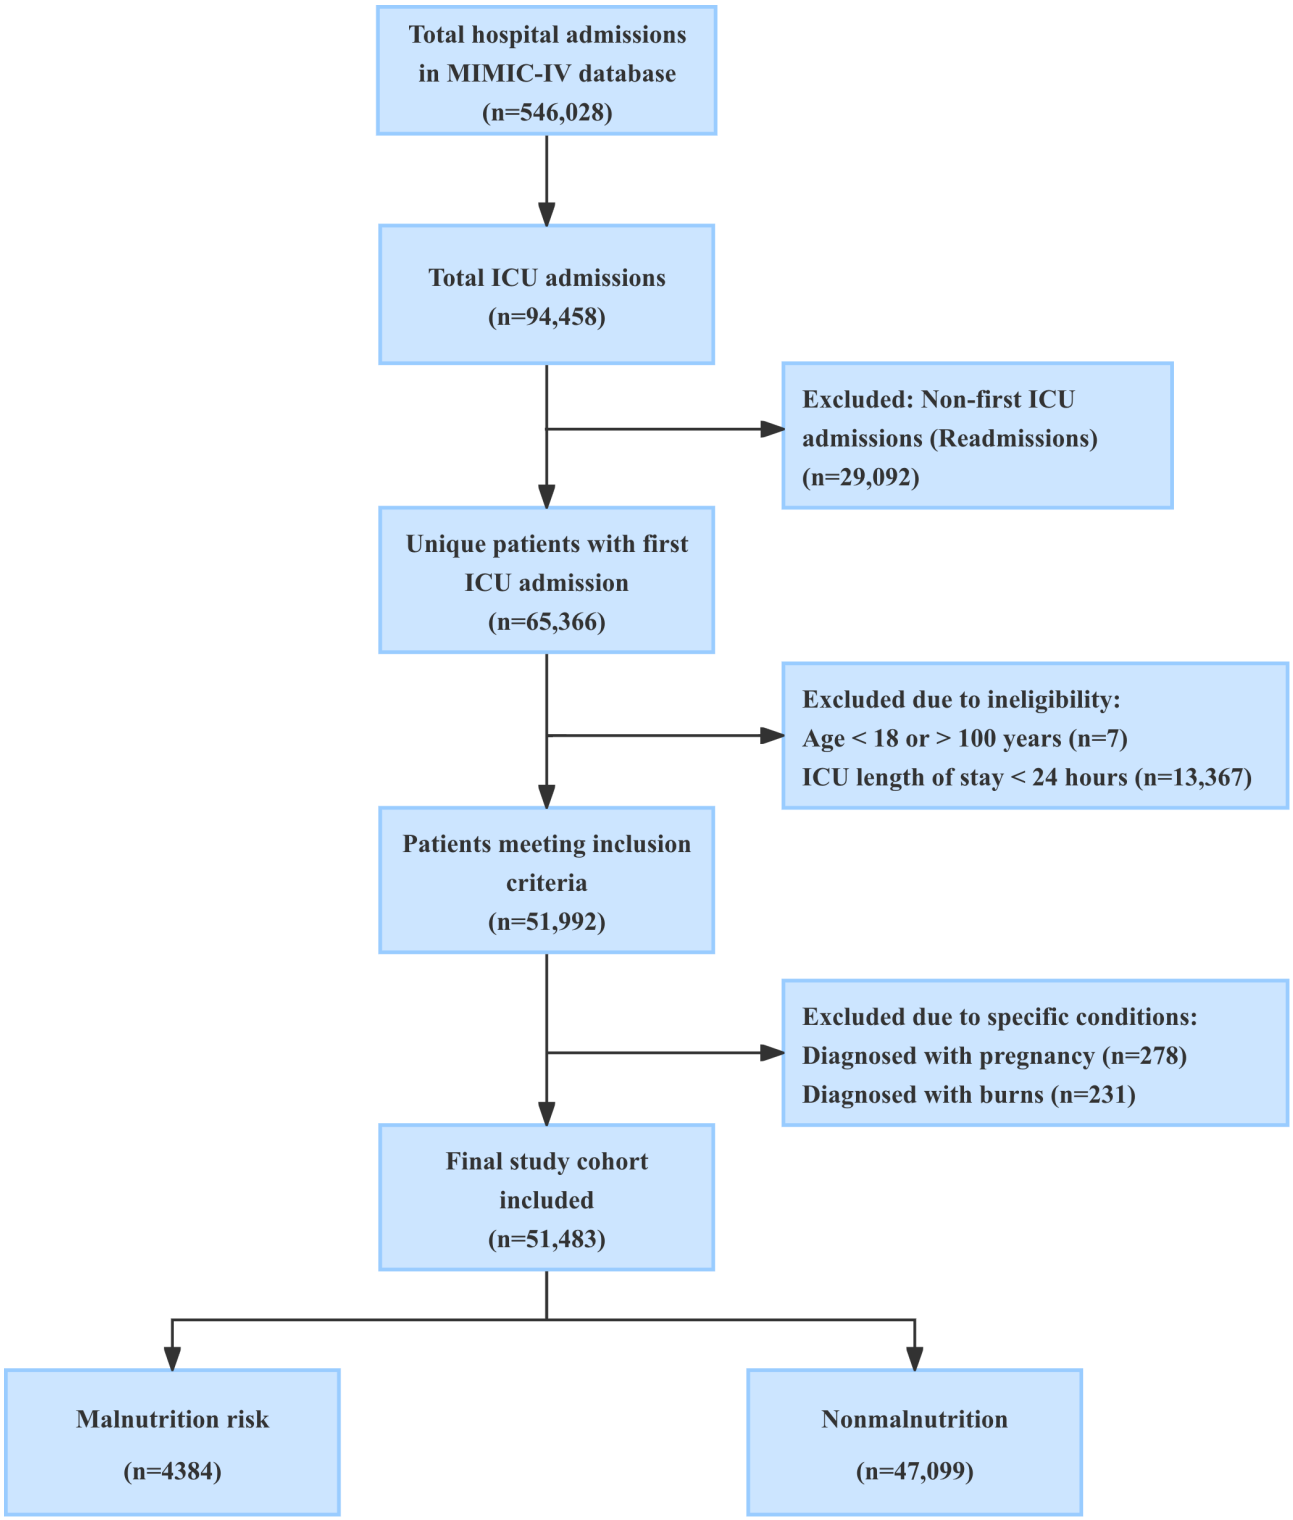
Clinical guidelines recommend that critically ill patients undergo nutritional risk screening within 48 hours of ICU admission to guide therapy [6]. However, the widely used nutritional risk screening tools, such as the Nutritional Risk Screening 2002 [7] and the modified NUTRIC score (mNUTRIC) [8], along with biomarkers such as plasma albumin, have recognized limitations in the ICU setting. These methods can be subjective, require manual data collection which is often delayed, and have demonstrated low recommendation levels for accurately assessing and predicting nutritional status in this dynamic population [9,10]. This highlights a clear need for an objective and early detection method for malnutrition risk in the ICU.

To meet this need, researchers have begun to explore machine learning (ML) algorithms. Early studies often used traditional ML models such as Extreme Gradient Boosting (XGBoost) and Logistic Regression (LR), demonstrating the potential of using electronic health records (EHRs) data to predict malnutrition [11,12]. However, single model approaches often struggle with generalization across diverse patient populations and may suffer from overfitting on imbalanced datasets [13]. Furthermore, previous studies frequently used data from the entire hospitalization period, introducing "look-ahead bias" that limits their utility for early prospective screening [14]. Crucially, complex "black-box" models often lack interpretability, hindering clinical adoption as clinicians require transparent reasoning behind risk predictions to make informed decisions [15]. Few studies have rigorously benchmarked advanced ensemble methods against established clinical scoring systems such as mNUTRIC within a strictly prospective early prediction framework.

This study uses the Medical Information Mart for Intensive Care (MIMIC-IV) database (v3.1) [16], a large, publicly available repository containing comprehensive clinical data. This rich dataset enables the development of robust predictive models based on routinely collected parameters. However, analyzing real-world EHR data presents significant challenges, including high rates of missing data, heterogeneity in variable recording, and pronounced class imbalance, as malnutrition is less common than normal nutritional status [17]. Addressing these challenges through rigorous data preprocessing and advanced modeling strategies is essential for building a reliable clinical decision support tool.

Therefore, the objective of this study is to develop and validate an interpretable stacking ensemble model, named E-NUTRIC (Ensemble-NUTRIC), for the early prediction of malnutrition risk in ICU patients using data exclusively from the first 24 hours of admission. We propose a Stacking Ensemble Learning framework that integrates multiple base learners, including LR, Random Forest (RF), XGBoost, and Light Gradient Boosting Machine (LightGBM), to enhance predictive stability and accuracy compared with individual algorithms. By integrating a well-established ML interpretability framework, Shapley Additive Explanations (SHAP) [18,19], we aim to enhance the transparency and clinical applicability of our model. Ultimately, this work seeks to provide a precise and automated screening tool that outperforms traditional scoring systems, enabling clinicians to intervene earlier and improve patient outcomes.

Methods



Data Source and Study Population

This study was a retrospective cohort analysis using the MIMIC-IV database (version 3.1) [16]. MIMIC-IV is a large, single-center, publicly available relational database containing comprehensive clinical data from patients admitted to the Beth Israel Deaconess Medical Center in Boston, Massachusetts, between 2008 and 2019. The database was approved by the Institutional Review Boards of the Massachusetts Institute of Technology and Beth Israel Deaconess Medical Center. The requirement for individual patient informed consent was waived because all protected health information was deidentified.

We systematically screened all hospital admissions in the MIMIC-IV database to identify eligible patients. To ensure data consistency and minimize bias from repeated measures, we restricted our analysis to the first ICU admission of the first hospitalization for each patient. Patients younger than 18 years or older than 100 years, as well as those with an ICU stay of <24 hours, were excluded from both the positive and negative cohorts. Figure 1 presents the data flow diagram.

XSL•FO
RenderX

Figure 1. Flowchart of patient selection. The diagram illustrates the inclusion and exclusion process applied to the MIMIC-IV database. Starting from total hospital admissions, we sequentially filtered for ICU patients, first admissions, valid age ranges, and sufficient length of stay. Patients with confounding conditions (pregnancy and severe burns) were excluded. The final cohort (n=51,483) was stratified into the malnutrition risk group (defined by *ICD-9* [*International Classification of Diseases, Ninth Revision*] and *ICD-10* [*International Statistical Classification of Diseases, Tenth Revision*] codes) and the nonmalnutrition group for model development. ICU: intensive care unit; MIMIC-IV: Medical Information Mart for Intensive Care.

For the positive cohort (patients with malnutrition), we initially identified 23,099 hospital admissions with a diagnosis of malnutrition. After applying these malnutrition diagnosis criteria and excluding non–first hospitalizations and non–first ICU stays, 5081 patients remained. Further applying the age and ICU stay exclusions yielded a final positive cohort of 4384 patients.

For the negative cohort (patients with no malnutrition), we started with 546,028 total hospital admissions, corresponding to 94,458 ICU admissions. After excluding duplicate ICU admissions, we retained 65,366 first-time ICU patients. Applying the same age and ICU stay exclusions left 51,992 eligible patients. To ensure a clear control group, we further excluded patients diagnosed with conditions that could confound

XSL•FO
RenderX

nutritional status assessment, namely, pregnancy and severe burns. Finally, after removing the 4384 patients already identified in the positive cohort, the final negative cohort comprised 47,099 patients.

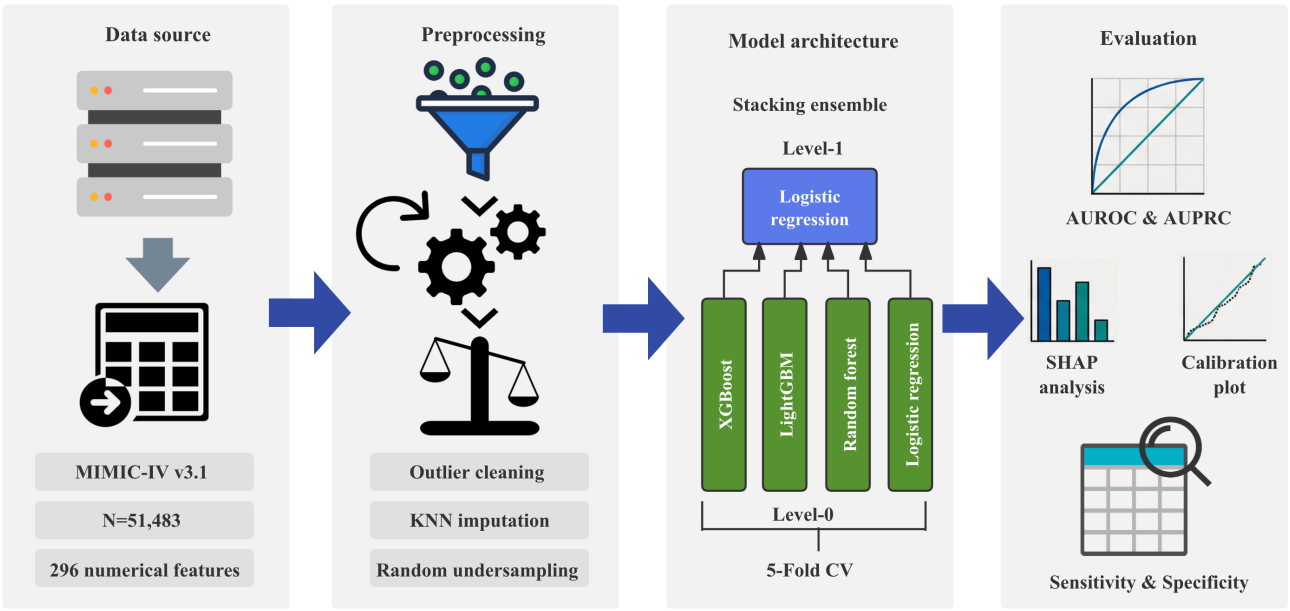
The final study population consisted of 51,483 adult patients, with malnutrition prevalence in 4384 (8.5%) patients. The primary outcome was the diagnosis of malnutrition, defined using *ICD-9* (*International Classification of Diseases, Ninth Revision*) codes 260‐263 and *ICD-10* (*International Statistical Classification of Diseases, Tenth Revision*) codes E40–E46. These codes encompass a spectrum of nutritional deficiencies, including kwashiorkor, nutritional marasmus, and severe to mild protein-calorie malnutrition. All data partitioning into training (80%) and test (20%) sets were performed strictly at the patient level using unique participant identifiers to prevent data leakage.

Feature Extraction and Data Preprocessing

To facilitate early and accurate risk stratification, data extraction was strictly limited to the first 24 hours of ICU admission. This temporal restriction prevents look-ahead bias and ensures that the model relies solely on information available during the early critical phase. We extracted a comprehensive set of clinical variables based on their clinical relevance and data availability in the MIMIC-IV database [16]. These concepts encompassed demographics; vital signs; laboratory tests; therapeutic interventions such as ventilation, dialysis, and vasopressor usage; and clinical severity scores including the Acute Physiology and Chronic Health Evaluation II and the Sequential Organ Failure Assessment (SOFA) scores.

Specific emphasis was placed on laboratory indicators related to nutritional status, inflammation, and metabolic function. The extracted laboratory panel included serum albumin, total cholesterol, lymphocytes, C-reactive protein, erythrocyte sedimentation rate, glucose, lactate, electrolytes, and renal function markers. To capture the dynamic fluctuations inherent in critical illness, we did not rely on single time-point measurements. Instead, for every time-varying vital sign and laboratory parameter, we computed 6 statistical aggregate metrics: mean, SD, minimum, maximum, first value, and last value within the 24-hour window. These statistics, combined with nominal categorical variables, including gender, race, insurance, language, marital status, and ICU unit type, were represented using one-hot encoding with explicit missing-category indicators. After preprocessing and feature expansion, the final model used 296 predictors (see Multimedia Appendix 1 for details).

Before modeling, rigorous data cleaning was performed to address physiological artifacts and measurement errors based on expert consensus [20]. We enforced clinically plausible ranges for key variables; for instance, weight was restricted to 30‐300 kg and BMI to 10‐100 kg/m². Temperature readings required specific handling to harmonize units: values exceeding 50 were interpreted as Fahrenheit and converted to Celsius, after which a valid range of 25 °C to 45 °C was enforced. Values falling outside these predefined thresholds were designated as missing data.



To handle missing data without discarding valuable patient information, we used a k-nearest neighbors (KNN) imputation strategy [21]. This method estimates missing entries by identifying the *k* most similar patients in the feature space, thereby preserving the multivariate correlation structure of the data. We validated this choice through preliminary experiments, where KNN imputation demonstrated superior area under the receiver operating characteristic curve (AUROC) in 5-fold cross-validation compared with simple mean imputation or multivariate imputation by chained equations. Following imputation, all continuous features were standardized using *Z*-score normalization to achieve zero mean and unit variance. This step is critical for algorithms sensitive to feature scaling, such as LR [22], which serves as both a base learner and the metalearner in our ensemble framework.

Given the pronounced class imbalance in our cohort (8.5% malnutrition prevalence), standard training procedures would likely bias the model toward the majority class. To mitigate this, we integrated a random undersampling (RUS) strategy into the training pipeline. Comparative analysis of resampling techniques revealed that RUS yielded a higher area under the precision-recall curve (AUPRC) than Synthetic Minority Over-sampling Technique or class-weighting adjustments. Importantly, this resampling was applied exclusively to the training folds within the cross-validation process, ensuring that the validation and test sets maintained the natural clinical prevalence of malnutrition to provide realistic performance estimates. Preliminary comparisons of imputation methods are detailed in Multimedia Appendix 2.

The final dataset was partitioned into a training set (80%) and an independent test set (20%) using stratified sampling. This approach ensured that the proportion of malnutrition cases remained consistent across splits. No data from the test set were used during the feature engineering, imputation fitting, or model training phases to strictly prevent data leakage. Figure 2 presents the methodological framework of this study.

XSL•FO

Figure 2. Overall experimental workflow and model development pipeline. Clinical data extracted from the MIMIC-IV v3.1 database yielded a final analytic cohort of 51,483 patients. After preprocessing, the final modeling matrix comprised 296 predictors, including one-hot encoded nominal categorical variables. The data preprocessing phase involved outlier cleaning, KNN imputation, and random undersampling to address class imbalance. Subsequently, a 2-level Stacking Ensemble model was constructed under a 5-fold cross-validation framework, using XGBoost, LightGBM, Random Forest, and Logistic Regression (LR) as base learners (level 0) to feed an LR metalearner (level 1). Finally, the predictive performance and clinical interpretability of the model were systematically evaluated using metrics including AUROC, AUPRC, and SHAP analysis and calibration plots. AUPRC: area under the precision-recall curve; AUROC: area under the receiver operating characteristic curve; CV: cross-validation; KNN: k-nearest neighbors; LightGBM: Light Gradient Boosting Machine; MIMIC-IV: Medical Information Mart for Intensive Care; SHAP: Shapley Additive Explanations; XGBoost: Extreme Gradient Boosting.

Model Development

The development of the predictive model was centered on a Stacking Ensemble Learning framework, termed E-NUTRIC, designed to integrate the strengths of diverse ML algorithms for robust risk stratification. This approach was selected to mitigate the limitations of single-model classifiers, which may suffer from overfitting or fail to capture complex nonlinear interactions within high-dimensional clinical data [23,24]. The ensemble architecture consisted of 2 layers: a base layer comprising 4 distinct algorithms and a metalearner layer that synthesized their outputs into a final calibrated probability.

The base layer comprised LR, RF, XGBoost, and LightGBM. LR was chosen as a linear baseline to capture straightforward additive relationships and provide interpretability [25]. RF, a bagging ensemble method, was used for its ability to reduce variance and handle high-dimensional feature spaces effectively [26,27]. XGBoost and LightGBM, both gradient boosting frameworks, were selected for their superior performance on tabular data and their capacity to model complex nonlinear dependencies through iterative error correction [28]. To ensure reproducibility and avoid the potential pitfalls of overfitting during exhaustive hyperparameter searching on a limited dataset, we used a set of fixed, predefined hyperparameters based on established practices for imbalanced clinical datasets rather than performing a grid search. For instance, tree-based models were configured with 500 estimators to ensure sufficient learning capacity, while regularization parameters were set to prevent overfitting. A detailed list of all hyperparameters for each algorithm is provided in Multimedia Appendix 3.

Class imbalance was handled exclusively using foldwise RUS within the training pipeline to prevent information leakage. To avoid mathematically distorting the base learners and causing severe overprediction, no additional algorithm-level class weighting was concurrently applied. Specifically, class weights were explicitly disabled for LR, RF, and the stacking metalearner; scale_pos_weight was dynamically set to 1 for XGBoost; and the is_unbalance flag was disabled for LightGBM.

The stacking process was implemented using a 5-fold cross-validation scheme within the training set. In this procedure, the training data were divided into 5 folds. For each fold, the base models were trained on the remaining 4 folds and then generated predictions for the holdout fold. These out-of-fold predictions from all 4 base learners were then concatenated to construct a new feature matrix, which served as the input for the metalearner. We selected LR as the metalearner to linearly combine the probabilistic outputs of the base models. This choice was motivated by the need for a calibrated and interpretable final score that effectively weighs the confidence of each base classifier. The metalearner was trained on the full set of out-of-fold predictions, enabling it to learn the optimal combination of base model outputs that minimized the overall prediction error.

The final E-NUTRIC model output was a continuous probability score ranging from 0 to 1, representing the risk of malnutrition. To facilitate clinical decision-making, a definitive classification was determined using a probability threshold of 0.5. No early stopping mechanisms were used during training to maintain consistency across all experiments. All modeling was implemented using Python (version 3.10; Python Software

XSL•FO
RenderX

Foundation) with the scikit-learn, xgboost, and lightgbm libraries.

Statistical Analysis and Model Evaluation

Baseline characteristics of the full analytic cohort were rigorously compared between patients with and with no malnutrition risk. Given the inherent long-tail, nonnormal distributions characteristic of large-scale, real-world EHR data, all continuous variables were uniformly summarized as medians with IQRs. Consequently, continuous physiological and laboratory parameters were compared using the nonparametric Mann-Whitney *U* test. Categorical variables—including binary clinical indicators, specific interventions, and one-hot encoded features—were expressed as absolute frequencies and percentages (n, %). Differences in categorical proportions were evaluated using the Pearson Chi-square test when the expected frequency in any cell of a 2×2 contingency table was less than 5. All statistical tests were 2-sided, and a *P* value of <.05 was considered statistically significant.

Model performance was comprehensively evaluated on the held-out test set using a suite of metrics designed for imbalanced classification tasks. The primary evaluation metric was the AUROC, which assesses the model's discriminative ability across all possible thresholds. To rigorously compare the predictive performance of the E-NUTRIC model against the clinical baseline (mNUTRIC score) and individual ML algorithms, we used the DeLong test for correlated receiver operating characteristic curves [29]. In instances where the DeLong test was inconclusive or yielded unstable estimates due to sample size constraints, we used a nonparametric bootstrap method with 1000 resamples to estimate the CIs and statistical significance of the AUROC differences. Additionally, given the low prevalence of malnutrition in our cohort (4384/51,483, 8.5%), we prioritized the AUPRC as a key indicator of model performance, as it is less sensitive to class imbalance than AUROC [13]. We also reported standard classification metrics including Accuracy, Sensitivity, Specificity, and F_1-score based on a probability threshold of 0.5.

To enhance the clinical utility and interpretability of the E-NUTRIC model, we integrated SHAP into our evaluation framework [30]. While stacking ensembles provide superior predictive performance, they lack native transparency because of their complex, heterogeneous architecture. To obtain interpretable and stable local explanations, SHAP analysis was applied specifically to the most predictive component of our ensemble—XGBoost, which was the best-performing individual tree-based base learner. This approach elucidates the critical nonlinear feature interactions driving the risk predictions without compromising computational efficiency. This analysis provided both global feature importance rankings and local explanations for individual patient predictions, offering transparency into the model's decision-making process.

Furthermore, to assess the reliability of the model's risk probabilities, we conducted a comprehensive calibration analysis. For the calibration analysis, mNUTRIC ordinal scores were first converted to predicted probabilities. This was achieved by fitting a univariate LR model on the training set and evaluating its outputs on the held-out test set. For our ML framework, because RUS intrinsically shifts the background prevalence, raw probability outputs from the final Stacking model inherently overestimate risk. Therefore, we performed a post hoc Platt recalibration. The recalibration model was fitted on an independent split within the training dataset and evaluated on the same test set, yielding the Recalibrated E-NUTRIC probabilities. The calibration curve serves as a critical diagnostic for identifying over- or underestimation biases in the predicted risks [31]. All statistical analyses and model development were performed using Python (version 3.10) with the scikit-learn, scipy, shap, and lifelines libraries.

Ethical Considerations

The study was approved by the Institutional Review Board of the Beth Israel Deaconess Medical Center (2001-P-001699/14) and the Massachusetts Institute of Technology (no. 0403000206), and individual consent for this retrospective analysis was waived.

Results

Baseline Characteristics of the Study Population

The final study cohort comprised 51,483 patients, among whom 4384 (8.5%) were identified as being at high risk of malnutrition (Risk Group), while 47,099 (91.5%) were classified as being at no risk of malnutrition (No Risk Group). A summary of key demographic and clinical characteristics is presented in Table 1.

XSL•FO
RenderX

Table . Baseline demographic, anthropometric, clinical, vital sign, and laboratory characteristics of the full analytic cohort stratified by malnutrition risk status. A total of 51,483 patients were enrolled, of whom 47,099 were nonmalnourished and 4384 had malnutrition[a].

Variable	Malnutrition risk group (n=4384)	No risk group (n=47,099)	*P* value
Cholesterol (mg/dL), median (IQR)	117.00 (86.00-152.75)	150.00 (119.00-185.00)	<.001

[a]Continuous variables are expressed as median (IQR) and compared using the Mann-Whitney *U* test. Categorical variables are expressed as counts and percentages, n (%), and compared using the chi-square test. *P* values are 2-tailed, and statistical significance was established at $P<.05$.

[b]ICU: intensive care unit.

[c]CCU: coronary care unit.

[d]CVICU: cardiovascular intensive care unit.

[e]MICU: medical intensive care unit.

[f]SICU: surgical intensive care unit.

[g]ICU type categories in Table 1 were partially aggregated for readability. The SICU category includes MICU/SICU, Neuro SICU, SICU, and TSICU; the Other category includes Neuro Intermediate, Neuro Stepdown, and Other. Detailed ICU subtype distributions are provided in Multimedia Appendix 4.

[h]APACHE II: Acute Physiology and Chronic Health Evaluation II.

[i]SOFA: Sequential Organ Failure Assessment.

[j]BUN: blood urea nitrogen.

The 2 groups were comparable in terms of age and gender distribution. However, significant disparities were observed in anthropometric measurements and clinical severity indices. Patients in the malnutrition risk group had a significantly lower BMI and lower admission weight. Clinical severity was substantially higher in the risk group, as indicated by elevated Acute Physiology and Chronic Health Evaluation II scores, Charlson Comorbidity Index, and SOFA scores. The mNUTRIC score was also significantly higher in the risk group.

Physiological parameters recorded within the first 24 hours further distinguished the 2 groups. The risk group demonstrated signs of hemodynamic instability, characterized by higher heart rates and respiratory rates. Laboratory analyses revealed significant nutritional and inflammatory differences; specifically, minimum serum albumin levels were lower in the risk group. Similarly, total cholesterol levels and lymphocyte counts were significantly reduced in the risk group ($P<.001$), while renal function markers such as blood urea nitrogen were elevated ($P<.001$). These findings indicate that the malnutrition risk group had a higher burden of critical illness and metabolic disturbances upon ICU admission. A comprehensive comparison of all analyzed features is provided in Multimedia Appendix 4.

Predictive Performance Comparison

The proposed E-NUTRIC model demonstrated superior predictive performance compared with both the existing clinical scoring system and the individual ML algorithms. As detailed in Table 2, the E-NUTRIC model achieved the highest discrimination with an AUROC of 0.875 (95% CI 0.864 - 0.885). This represents a substantial and statistically significant improvement over the standard mNUTRIC score, which yielded an AUROC of 0.635 (95% CI 0.617 - 0.652, $P<.001$). The receiver operating characteristic curves presented in Figure 3A illustrate this disparity, showing that the E-NUTRIC model maintains a higher true-positive rate across all decision thresholds compared with the linear clinical baseline.

In the context of the imbalanced dataset, the AUPRC provided a more informative assessment of model utility. The E-NUTRIC model achieved an AUPRC of 0.424, which is more than 3 times that of the mNUTRIC score. Figure 3 highlights this performance gap, showing that the ensemble model maintains precision better as recall increases, whereas the performance of the mNUTRIC score degrades rapidly, approaching the no-skill baseline. Among the individual base learners, XGBoost and LightGBM exhibited strong performance with AUROC of 0.871 and 0.866, respectively.

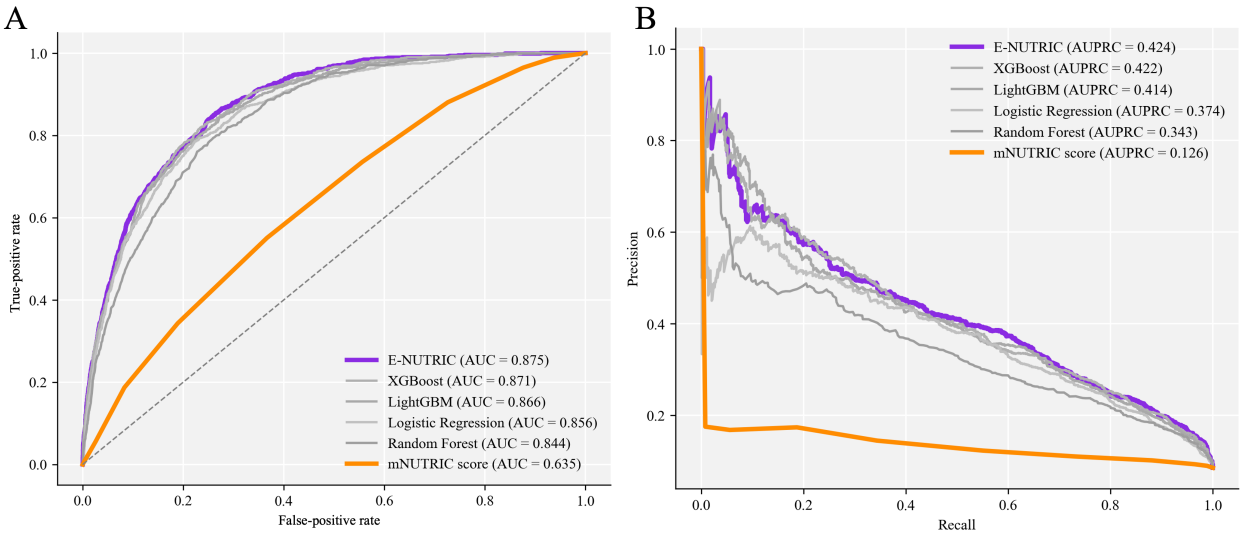
Table . Performance comparison of Ensemble-NUTRIC (E-NUTRIC) with baseline models and clinical scores on the test set.

Model	AUROC[a] (95% CI)	AUPRC[b]	Accuracy	F_1-score	Sensitivity	Specificity
E-NUTRIC	0.875 (0.864-0.885)[c]	0.424	0.785	0.384	0.790	0.784
LightGBM[d]	0.866 (0.854 - 0.877)	0.414	0.770	0.372	0.800	0.767
XGBoost[e]	0.871 (0.860 - 0.882)	0.422	0.774	0.380	0.812	0.770
LR[f]	0.856 (0.844 - 0.869)	0.374	0.783	0.377	0.772	0.784
Random Forest	0.844 (0.831 - 0.855)	0.343	0.723	0.334	0.813	0.715
mNUTRIC[g] Score	0.635 (0.617 - 0.652)	0.126	0.142	0.164	0.989	0.063

[a]AUROC: area under the receiver operating characteristic curve.

[b]AUPRC: area under the precision-recall curve.

[c]The proposed E-NUTRIC model demonstrated statistically significant improvement in AUROC compared with the clinical baseline mNUTRIC score (P<.001) and the best-performing single base learner, XGBoost (P=.018), evaluated via the DeLong test.



[d]LightGBM: Light Gradient Boosting Machine.

[e]XGBoost: Extreme Gradient Boosting.

[f]LR: Logistic Regression.

[g]mNUTRIC: modified NUTRIC.

Figure 3. Discriminative performance of models and score. Receiver operating characteristic curves (A) and precision-recall curves (B). The proposed E-NUTRIC (purple line) significantly outperforms the clinical benchmark mNUTRIC score (orange line). Individual machine learning base learners (XGBoost, LightGBM, Random Forest, and Logistic Regression) are shown in light gray for comparison, demonstrating the superior performance of the ensemble approach. AUC: area under the receiver operating characteristic curve; AUPRC: area under the precision-recall curve; E-NUTRIC: Ensemble-NUTRIC; LightGBM: Light Gradient Boosting Machine; mNUTRIC: modified NUTRIC; XGBoost: Extreme Gradient Boosting.

At the standard probability threshold of 0.5, the E-NUTRIC model demonstrated a balanced classification profile with an accuracy of 0.785, a sensitivity of 0.790, and a specificity of 0.784. In contrast, the mNUTRIC score showed extremely high sensitivity but negligible specificity, indicating a tendency to overpredict risk and generate excessive false positives. The superior F_1-score of the E-NUTRIC model versus mNUTRIC further underscores its robustness in correctly identifying true malnutrition cases while minimizing false positives. Detailed performance curves for all individual base models are provided in Multimedia Appendix 5.

Model Interpretability and Feature Analysis

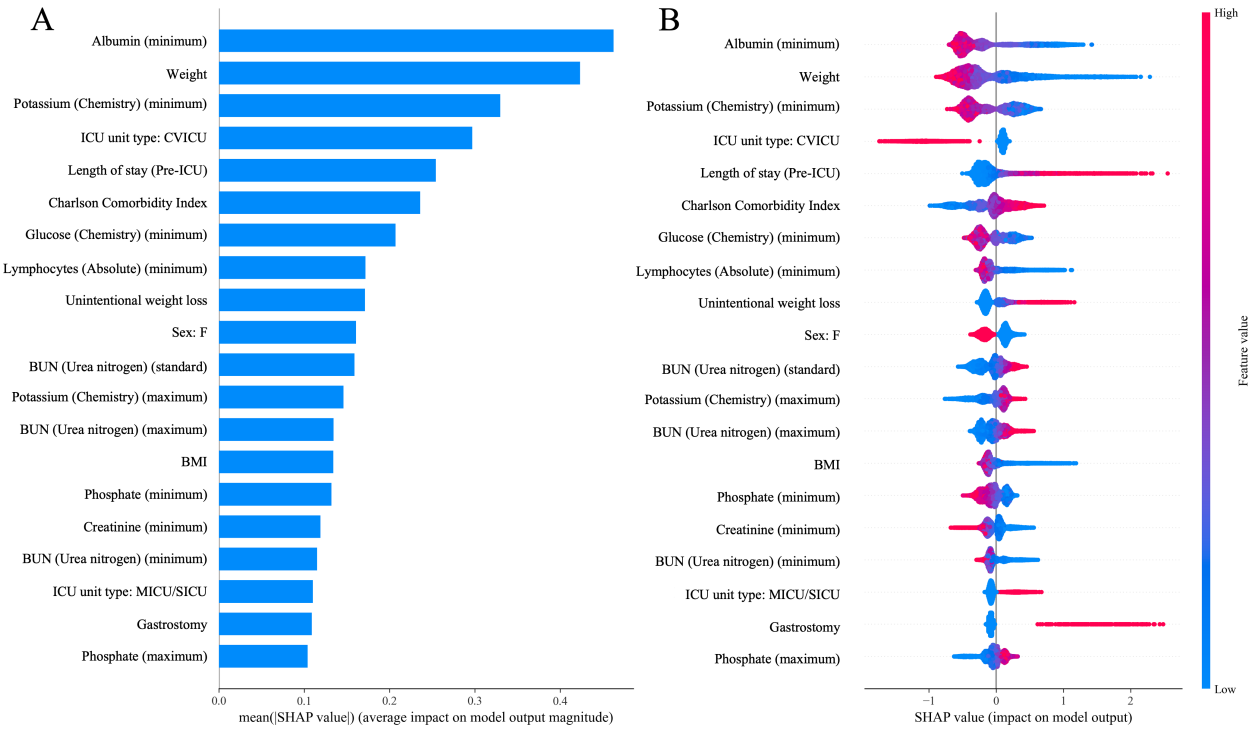
To elucidate the decision-making logic of the predictive framework, we used SHAP values to quantify the contribution of individual features. Given the heterogeneous architecture of the final stacking ensemble, SHAP was applied to its most predictive tree-based component—the XGBoost base learner—to ensure accurate mathematical attribution and computational stability.

Figures 4A and 4B present the global feature importance rankings alongside their directional impacts on the model's

XSL•FO
RenderX

output. Minimum serum albumin emerged as the most dominant predictor, followed strongly by admission weight, minimum potassium levels, and specific ICU admission location. The summary plot delineates distinct clinical phenotypes: lower physiological values (blue dots) of albumin, weight, and blood potassium are aggressively associated with positive SHAP values, increasing the predicted risk of malnutrition. Notably, admission to cardiovascular intensive care unit exerted a distinctly protective effect on the risk score, whereas prolonged pre-ICU length of stay and higher Charlson Comorbidity Index scores were strongly positively correlated with malnutrition risk. This adequately reflects the compounding impact of chronic disease burden and extended hospitalization on nutritional depletion.

Figure 4. SHAP global feature importance and summary analysis derived from the XGBoost component. (A) The bar plot ranks the top 20 features by their mean absolute SHAP value, indicating their overall mathematical contribution to the model's predictions. (B) The summary plot visualizes the distribution of SHAP values across individual patients (represented by dots). Note the color gradient: red indicates a high feature value, and blue indicates a low feature value. A positive SHAP value on the x-axis drives the model toward a higher predicted risk of malnutrition. BUN: blood urea nitrogen; CVICU: cardiovascular intensive care unit; ICU: intensive care unit; MICU: medical intensive care unit; SICU: surgical intensive care unit; SHAP: Shapley Additive Explanations.



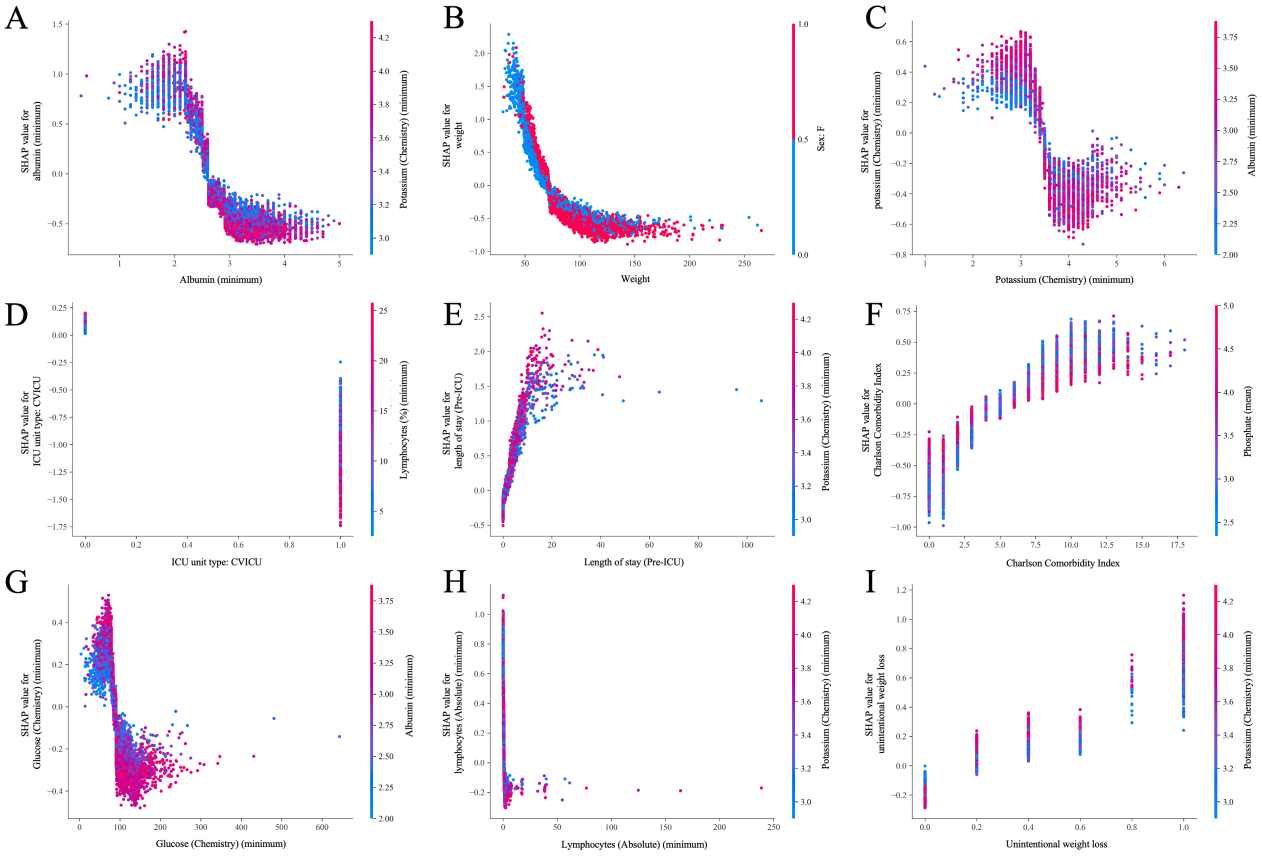


Figure 5A-I further delineate the granular, nonlinear relationships for the top 9 predictive features via SHAP dependence plots. A critical threshold is observed for serum albumin: the risk contribution escalates sharply as levels fall below approximately 2.8 g/dL, corroborating its clinical utility as a potent negative acute-phase reactant. Similarly, the weight dependence plot explicitly demonstrates a steep surge in risk for patients weighing less than 70 kg, which plateaus at higher baseline weights. Electrolyte and metabolic profiles reveal that acute physiological stress—specifically early hypokalemia (<3.5 mEq/L) and hypoglycemia (<100 mg/dL)—disproportionately compounds the predicted risk. Furthermore, severe early lymphopenia (low absolute lymphocytes) and the documented presence of unintentional weight loss exhibited definitive risk spikes. Collectively, these interpretability analyses confirm that the model effectively captured clinically and biologically plausible signals, accurately prioritizing established markers of severe catabolism, structural depletion, and diminished physiological reserve without relying on arbitrary data artifacts. Furthermore, a global SHAP interaction analysis (refer to Multimedia Appendix 6 for details) revealed strong second-order feature dependencies, most notably between absolute admission weight and female gender. This demonstrates the ensemble's capacity to automatically learn sex-specific physiological thresholds for body mass, highlighting a critical advantage of nonlinear ML architectures over traditional additive clinical scores.

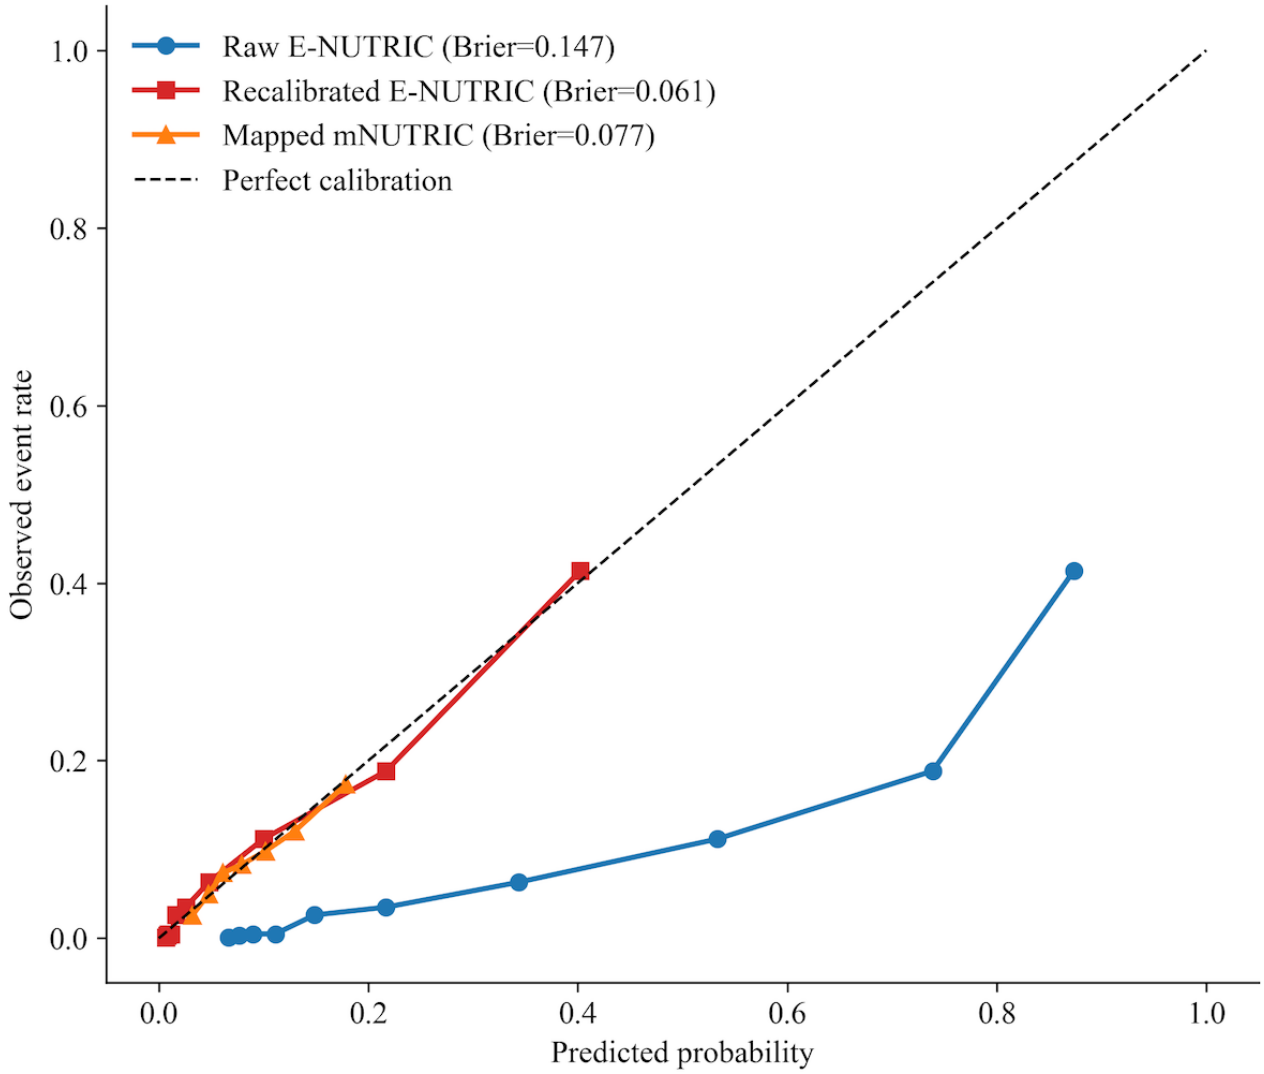
XSL•FO
RenderX

Figure 5. SHAP partial dependence plots showing nonlinear clinical thresholds for the top 9 features: (A) minimum albumin, (B) admission weight, (C) minimum potassium, (D) CVICU admission, (E) pre-ICU length of stay, (F) Charlson Comorbidity Index, (G) minimum glucose, (H) minimum absolute lymphocyte count, and (I) unintentional weight loss. These plots illustrate the marginal effect of each variable on predicted malnutrition risk. The x-axis represents the raw feature value from the electronic health record, and the y-axis represents the corresponding SHAP value. The color bar in each panel indicates the interacting feature value, illustrating multidimensional model behavior. Notable clinically relevant nonlinear thresholds are observed natively in albumin, weight, and absolute lymphocytes. CVICU: cardiovascular intensive care unit; ICU: intensive care unit; SHAP: Shapley Additive Explanations.



Risk Stratification and Calibration Analysis

To evaluate the reliability of the risk predictions across the probability spectrum, a comprehensive calibration analysis was performed on the test set (Figure 6). As expected, the raw E-NUTRIC probabilities—generated directly from the ensemble trained on the RUS balanced dataset—exhibited structural overestimation of absolute risk, deviating systematically below the perfect calibration diagonal (Brier score=0.1471; expected calibration error [ECE]=0.2347). To correct this prevalence-induced probability shift, Platt scaling was applied. The resulting Recalibrated E-NUTRIC model demonstrated excellent alignment with true clinical event rates (Brier score=0.0615; ECE=0.0095), accurately tracking expected outcomes across all risk deciles.

XSL•FO
RenderX

Figure 6. Calibration plots on the test set demonstrating dynamic risk stratification. The diagonal dashed gray line represents perfect calibration, where predicted probabilities perfectly match observed clinical frequencies. The Raw E-NUTRIC probabilities (blue circles) display the expected overestimation inherent to algorithms trained on artificially balanced resampled datasets. Following Platt scaling, the Recalibrated E-NUTRIC (red squares) rigorously corrects this shift, accurately mapping risk across the entire spectrum. The mapped mNUTRIC score (orange triangles)—derived via logistic transformation—is provided for clinical baseline comparison. Notably, while mNUTRIC predictions are severely compressed into the lower probability tier (<0.2), E-NUTRIC effectively spans the full dynamic range to identify critical, high-risk phenotypes. E-NUTRIC: Ensemble-NUTRIC; mNUTRIC: modified NUTRIC.

Following recalibration, we compared the E-NUTRIC ensemble against the baseline mNUTRIC score. To ensure a mathematical equivalent comparison, the ordinal mNUTRIC scores were first mapped to continuous probabilities using a training-set logistic transformation (yielding a Brier score of 0.0765 and an ECE of 0.0045 on the test set). While the mapped mNUTRIC achieved tight calibration metrics, the resulting calibration curve highlights a fundamental limitation of the traditional clinical scoring system: its predicted probabilities are severely compressed, clustering almost entirely below a threshold of 0.20. This indicates that the conventional score lacks the dynamic range necessary to differentiate between moderate-risk and genuinely high-risk patients, effectively categorizing the entire cohort into a low-probability band. In stark contrast, the Recalibrated E-NUTRIC model uses the full probability space. Unlike the mNUTRIC score, which plateaus prematurely, our model effectively isolates a high-risk subgroup of patients at the upper tail of the distribution, providing clinicians with a highly discriminative and granular tool for identifying patients who acutely require intensive nutritional interventions.

Discussion

Principal Findings

In this study, we developed and internally validated the E-NUTRIC model, a stacking ensemble ML framework designed to predict malnutrition risk among critically ill patients using routine EHR data. Our evaluation indicates that the E-NUTRIC ensemble provides superior discriminative capacity compared with the traditional mNUTRIC score, achieving an AUROC of 0.875 compared with 0.635 for the clinical baseline. Notably, in the context of the naturally imbalanced prevalence of ICU malnutrition, the model yielded a substantial, more than 3-fold increase in the AUPRC. This enhancement addresses a recurring limitation in existing additive clinical scoring systems,

XSL•FO
RenderX

which frequently lack the dynamic range necessary to effectively stratify patients at the upper end of the risk spectrum.

While individual tree-based base learners such as XGBoost and LightGBM also exhibited robust performance, the level 1 stacking strategy provided incremental improvement in the stabilization of predictive reliability. This supports the premise that integrating diverse functional algorithms can effectively synthesize complementary clinical signals within complex datasets. Furthermore, to ensure accurate mathematical attribution and avoid the methodological artifacts associated with explaining metalearners, we applied SHAP analysis specifically to the highly predictive XGBoost component. This analytical approach elucidated the nonlinear feature relationships driving the predictions, identifying minimum serum albumin, admission weight, early hypokalemia, and specific ICU unit types as the most influential predictors of malnutrition risk.

Comparison With Prior Work

Previous research in nutritional assessment has predominantly relied on static scoring systems such as the Geriatric Nutrition Risk Index [32], the Controlling Nutrition Status score [33], and the Subjective Global Assessment [9]. While effective in general wards or outpatient oncology settings [34,35], these tools often fail to account for the rapid physiological changes characteristic of the ICU environment. The mNUTRIC score was specifically designed for critically ill patients, yet our findings align with recent studies suggesting its limited discriminatory power without the inclusion of inflammatory markers such as interleukin-6, which are rarely routinely available [36].

In the field of clinical artificial intelligence, recent efforts have applied deep learning and time series analysis to predict patient deterioration [37,38]. However, many of these models prioritize raw predictive accuracy over interpretability and often involve substantial computational demands that limit bedside deployment. Our study differs from such approaches by using a stacking ensemble approach on aggregated clinical features. Unlike single-model approaches or complex deep neural networks, our framework strikes a balance between predictive power and computational efficiency. The superior performance of E-NUTRIC over the mNUTRIC score validates the assertion that nonlinear modeling techniques are necessary to capture the complex interactions between physiological stress, organ failure, and nutritional depletion [39].

Clinical Implications and Biological Plausibility

The interpretability analysis via SHAP values not only confirms the model's reliance on clinically relevant features but also provides biological validation of the algorithm's learning process. Minimum serum albumin emerged as the single most important predictor. Although traditionally viewed as a nutritional marker, hypoalbuminemia in the ICU is a potent indicator of the inflammatory response and capillary leak syndrome, both of which accelerate catabolism and nutritional depletion [40]. The sharp increase in risk when albumin falls below 2.8 g/dL, as observed in our partial dependence plots, aligns with the threshold often cited for severe malnutrition-inflammation complex syndrome.

Similarly, the model identified admission weight and minimum potassium levels as critical features. The nonlinear relationship observed with absolute admission weight—where risk escalates rapidly below 70 kg—was shown in our interaction analysis to be strongly modulated by female gender, dynamically capturing the phenotype of the frail patient with sarcopenia who lacks the metabolic reserve to withstand critical illness [41]. Beyond electrolytes such as potassium—which capture signals related to severe fluid-electrolyte shifts [42]—the model effectively leveraged granular one-hot encoded features, identifying the distinct protective baseline status of cardiovascular intensive care unit admissions and the compounding risk of documented unintentional weight loss and early severe lymphopenia. Unlike the mNUTRIC score, which is heavily weighted by the SOFA score and thus primarily reflects organ failure, E-NUTRIC incorporates these metabolic and anthropometric granularities, offering a more holistic view of the patient's nutritional status.

Furthermore, the calibration analysis revealed a crucial clinical utility finding: the mNUTRIC score effectively "caps" risk prediction at approximately 20%, treating the vast majority of patients as low risk. In stark contrast, following Platt scaling correction for prevalence-induced shifts, the recalibrated E-NUTRIC model accurately spans the full dynamic probability spectrum. This capability allows for the identification of a high-risk cohort that would otherwise be missed by standard screening, enabling clinicians to direct aggressive nutritional interventions—such as early parenteral nutrition or high-protein delivery—to the patients who are most likely to benefit, thereby optimizing resource allocation.

Limitations

Despite these promising results, our study is subject to several limitations. First, the model was developed and validated using the MIMIC-IV database, which represents a single-center cohort at the US tertiary care center. While the sample size is large and diverse, the care protocols and patient demographics may not fully generalize to community hospitals or different health care systems globally. To mitigate this, we used a robust cross-validation scheme and a holdout test set, but external validation on datasets such as the eICU Collaborative Research Database [43] remains a necessary next step to confirm generalizability.

Second, the definition of malnutrition in our study relied on *ICD-10* diagnostic codes. While this is a standard approach in large-scale EHR research, administrative codes typically have high specificity but low sensitivity, potentially leading to an underestimation of malnutrition prevalence. We attempted to address the resulting class imbalance by using RUS and optimizing for AUPRC, yet some in the control group patients may have had undiagnosed malnutrition. Future studies should ideally use prospectively collected data based on the Global Leadership Initiative on Malnutrition criteria to provide a more rigorous ground truth [44].

Third, the retrospective nature of the study necessitates the use of imputation for missing data. Although our preliminary experiments demonstrated that KNN imputation preserved data integrity better than other methods, any imputation introduces a degree of synthetic variability. We mitigated this by selecting

XSL•FO
RenderX

KNN imputation based on preliminary experiments, but the potential for bias cannot be entirely eliminated.

Fourth, while SHAP values provide powerful associations, they do not imply causality. The feature importance rankings indicate which variables drive the prediction, but they do not prove that modifying a feature (eg, correcting hypokalemia) will reduce malnutrition risk. Clinical judgment remains essential in interpreting these outputs [45].

Future Directions

Building on the E-NUTRIC model, future research should focus on prospective validation in a multicenter clinical setting. Integrating this model into an EHR-based clinical decision support system would allow evaluation of its real-world impact on clinical workflow and patient outcomes. Specifically, a randomized controlled trial comparing model-guided nutritional intervention versus standard care would be the gold standard for establishing clinical utility. Additionally, future iterations of the model could incorporate unstructured data, such as nursing notes or dietary intake logs, using natural language processing to further enhance predictive accuracy [46].

Conclusions

This study presents E-NUTRIC, a stacking ensemble ML model designed for the early prediction of malnutrition risk in ICU patients. By integrating robust predictive algorithms with SHAP-based interpretability, E-NUTRIC offers an interpretable approach to risk stratification. Specifically, compared with the mNUTRIC score, the proposed model demonstrates superior discriminative performance and provides a finer-grained probability spectrum, effectively capturing key metabolic, anthropometric, and demographic features associated with malnutrition. Although prospective external validation remains necessary, E-NUTRIC demonstrates substantial potential as a clinical decision support tool to facilitate timely, targeted, and accurate nutritional interventions for critically ill patients at high risk.

Abstract

Background: Cancer risk prediction models are vital for precision prevention, enabling individualized assessment of cancer susceptibility based on genetic, clinical, environmental, and lifestyle factors. However, the practical use of these models is hindered by fragmented resources, heterogeneous reporting, and the absence of transparent, structured systems for systematic discovery and comparison.

Objective: This study aimed to develop a retrieval-augmented, knowledge-guided system that provides accurate recommendations for cancer risk prediction models.

Methods: We developed CanRisk-RAG, a recommendation platform underpinned by a precisely constructed knowledge base comprising more than 800 peer-reviewed cancer risk prediction models spanning diverse cancer types, modeling approaches, and predictive variables. The system integrates (1) large language model (LLM)–based semantic tag extraction, (2) embedding vectorization of structured metadata and abstracts, (3) a multifactor ranking algorithm combining semantic similarity with multiple quality indicators, and (4) LLM-generated literature summarization to support rapid user interpretation. Performance was evaluated across 4 types of representative queries. Eight domain experts independently assessed retrieval quality. CanRisk-RAG was benchmarked against PubMed, ChatGPT-4o, ScholarAI, and Gemini 1.5 Flash.

Results: On the independent validation set, CanRisk-RAG consistently outperformed all 4 baseline applications, achieving the highest overall relevance (8.30 [SD 0.59]) and reliability (7.62 [SD 0.76]) scores on a 10-point scale (P<.05). It also demonstrated high authenticity, data completeness, and consistency. Baseline applications frequently returned incomplete, inconsistent, or fabricated results, especially for complex, multifactorial queries, whereas CanRisk-RAG delivered accurate and structured recommendations grounded in validated evidence.

Conclusions: CanRisk-RAG presents a transparent, domain-specific, and semantically enriched framework for discovering cancer risk prediction models, addressing several limitations of existing keyword-based search tools and general-purpose LLMs. By integrating structured knowledge, multifactor ranking, and LLM-based reasoning, the system aims to improve the precision, reproducibility, and usability of model selection in cancer risk prediction. While our evaluation demonstrates encouraging performance compared with baseline systems, further validation in broader clinical contexts and real-world applications is warranted. The framework's general design may also be adaptable to other clinical model domains, providing a potential foundation for advancing evidence-based model discovery in precision medicine.

Introduction

Cancer risk prediction models are increasingly recognized as essential components of precision medicine, offering clinicians and researchers the ability to estimate an individual's likelihood of developing cancer based on diverse risk factors. These models integrate genetic markers, clinical data, environmental exposures, and lifestyle behaviors, thereby enabling more personalized approaches to prevention and screening [1-4]. These heterogeneous factors are not independent but often interact in complex and nonlinear ways. For example, genetic susceptibility may amplify the carcinogenic effects of smoking or obesity, while lifestyle interventions can partially mitigate inherited risk [5,6]. Understanding and modeling these interdependencies is therefore crucial for accurate cancer risk prediction.

Statistical approaches such as logistic regression, Cox proportional hazards models, and Bayesian networks have traditionally been used to analyze correlations and interactions among these predictors. More recently, advanced machine learning techniques, including random forests, gradient boosting, and deep neural networks, have enabled the modeling of higher-order, nonlinear, and cross-domain relationships between genetic, clinical, and environmental factors [7-10]. These methods can capture subtle patterns that traditional regression frameworks may overlook, thus improving predictive accuracy and interpretability when properly validated.

By identifying individuals at elevated risk, cancer risk prediction models facilitate earlier interventions, targeted monitoring, and ultimately reductions in cancer incidence and mortality [11,12]. Recent advances have demonstrated that combining heterogeneous risk determinants can substantially improve predictive accuracy. For instance, multivariate models that combine germline mutations (eg, BRCA1/2), hormonal and reproductive history, and lifestyle exposures have achieved strong discriminative power in breast cancer risk prediction [13,14], while integrative models linking smoking intensity, air pollution exposure, and genomic markers have improved lung cancer risk stratification [15,16]. Together, these developments highlight both the promise and the complexity of synthesizing genetic, clinical, environmental, and behavioral information into actionable tools for precision prevention.

Despite the promise of cancer risk prediction models, their practical impact is limited by barriers related to accessibility and adoption. A fundamental problem lies in the fragmentation of available models, which vary widely in methodological approach, target population, and predictive variables. Clinicians and researchers often struggle to identify the most appropriate model for a given use case, a challenge compounded by the lack of centralized, structured resources for systematic discovery. General medical retrieval systems are ill-suited to this task, as they are designed primarily to locate literature rather than extract or recommend specialized prediction tools. As a result, existing models are underutilized, research efforts are frequently duplicated, and the translational pathway from model development to clinical implementation remains inefficient. Indeed, it has been observed that most published prediction models are never adopted in clinical practice, highlighting a persistent gap between academic research and implementation [17]. Reviews further emphasize that although many models have been developed, only a small fraction have been successfully translated into clinical or public health practice, largely due to limitations in validation, usability, and acceptability [18,19].

To date, most users seeking cancer risk prediction models have relied on mainstream biomedical databases such as PubMed [20]. While PubMed provides broad access to scientific publications, its keyword-based search mechanisms often generate an overwhelming number of results, many of which are irrelevant for model identification. Moreover, critical details regarding model structure, predictive variables, validation cohorts, or performance metrics are typically buried in unstructured text, making systematic retrieval difficult.

In parallel, institutional platforms have been developed to provide more direct access to specific risk prediction tools. The US National Cancer Institute's Division of Cancer Epidemiology and Genetics offers a set of statistical macros and online calculators covering selected cancer types [21], while the Memorial Sloan Kettering Cancer Center provides nomograms tailored to particular clinical scenarios [22]. Although these resources represent valuable contributions, their scope remains restricted to only several (typically fewer than a dozen) tools, employ relatively narrow modeling methodologies, and lack detailed metadata regarding model characteristics or generalizability.

Large language models (LLMs) have recently been explored as potential solutions to improve medical information access. Their ability to integrate knowledge and process complex clinical text holds significant promise for bridging gaps between scattered information and practical decision-making [23-26]. However, empirical studies highlight critical weaknesses in LLMs, including limited precision, the generation of fabricated or irrelevant outputs, and the opacity of reasoning processes [23,27,28]. Retrieval-augmented generation (RAG) has been proposed as a mechanism to mitigate these shortcomings by grounding model outputs in external knowledge sources [29,30]. Several initiatives illustrate the potential of this approach. RefAI [31], for instance, combines PubMed retrieval with a GPT-4–based summarization system, enabling more effective access to recent biomedical publications. Similarly, WeiseEule [32] integrates keyword-driven retrieval from PubMed with LLM-based responses to improve query precision. However, these systems largely depend on user-defined search terms and ad hoc knowledge construction, leading to inconsistent coverage and limited reproducibility. Moreover, they are not designed to handle structured, model-specific metadata, such as predictive variables, validation cohorts, or performance metrics, that are critical for evidence-based model selection.

To address these challenges, the present study introduces CanRisk-RAG, a knowledge-guided and LLM-enhanced recommendation system designed to systematically retrieve, rank, and summarize cancer risk prediction models. Built on a knowledge base that we systematically constructed to consolidate validated cancer risk prediction models across

XSL•FO
RenderX

multiple cancer types, predictive variables, and methodological frameworks, CanRisk-RAG provides a structured foundation for model discovery and reuse. By combining domain-curated knowledge with LLM-driven semantic reasoning, the system bridges the gap between unstructured user queries and structured model metadata. Furthermore, a multi-factor ranking algorithm integrates semantic similarity with evidence-based indicators, such as publication quality, model performance, and timeliness, ensuring that recommended models are both relevant and scientifically robust. To enhance interpretability and usability, CanRisk-RAG also generates concise LLM-based summaries that highlight key model characteristics.

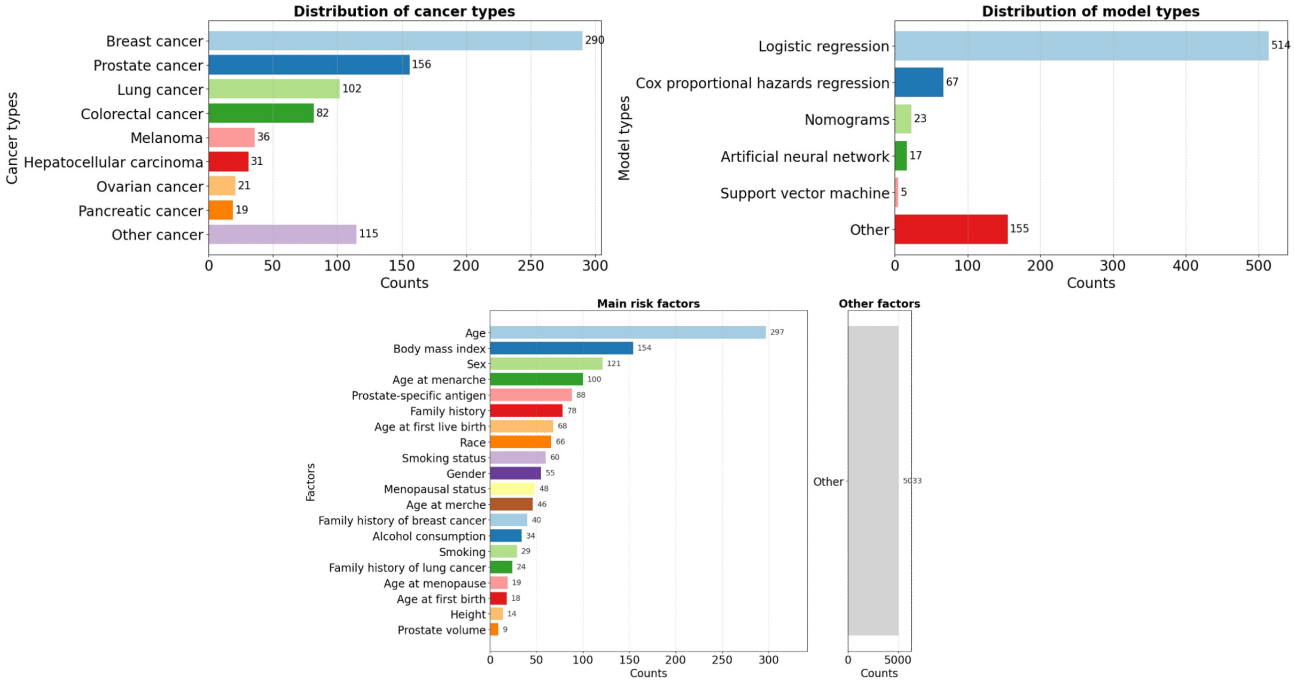
In essence, CanRisk-RAG aims to provide a scalable, transparent, and domain-aware retrieval framework that supports both research and clinical decision-making in cancer risk assessment. By facilitating the efficient reuse of existing models and improving accessibility for diverse user needs, including population-level screening and high-risk cohorts defined by genetic predisposition or family history, it represents a step toward operationalizing precision prevention in oncology.

This paper is organized as follows: We first introduce the data sources and system development workflow. Next, we describe the design of the evaluation tasks and the specific evaluation metrics used. We then present the performance results of CanRisk-RAG in terms of model recommendation and tool usability, along with comparative analyses against four baseline applications. Finally, we discuss the implications of the findings and explore potential directions for extending the system to other cancer research or medical domains.

Methods

Overview

The Methods section outlines the construction of CanRisk-RAG, covering data preparation, semantic vectorization, tag extraction via LLM, hybrid ranking with multiple quality indicators, literature summarization, and comparative evaluation. For more implementation details and technical specifications, please refer to Supplemental Information 1.1 in Multimedia Appendix 1.



Dataset

Data Preparation

We constructed a knowledge base containing peer-reviewed cancer risk prediction models, consolidating clinically developed and validated cancer risk prediction models extracted from PubMed. The detailed search criteria and the inclusion and exclusion standards used for model collection are provided in Supplemental Information 1.2 and 1.3 in Multimedia Appendix 1.

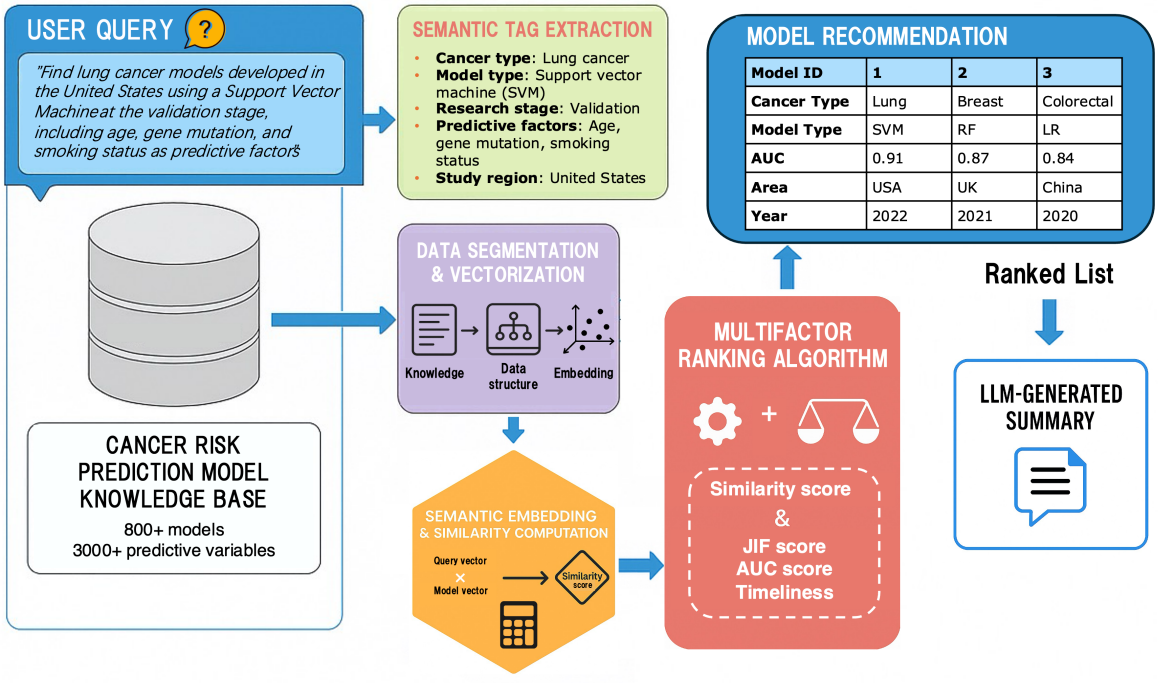
Following this procedure, a total of 808 cancer risk prediction models were included. Each model is uniquely identified by a model ID (MID). Each model was comprehensively described using metadata covering 3 major categories, namely basic information, sample information, and model information, across a total of 36 fields. To facilitate structured storage and interpretation, an Entity–Relationship (ER) diagram was constructed (see Supplemental Information 1.4 in Multimedia Appendix 1). In addition, as illustrated in Figure 1, the knowledge base organizes data across more than 10 cancer types (see Supplemental Information 2.1 in Multimedia Appendix 2 for the full distribution), over 13 methodological frameworks (eg, logistic regression, Cox regression, nomograms), and 3095 predictive factors, including age, body mass index, sex, and family history.

Figure 1. Distribution of cancer types, model types, and predictive factors in the CanRisk-RAG.

XSL•FO
RenderX

Data Segmentation and Vectorization

To enable semantic retrieval, data from the knowledge base were transformed into structured vector representations. Key attributes of each model, including cancer type, methodological approach, research stage, predictive factors, and geographic context were integrated to form composite descriptors that reflect the essential semantic characteristics of the models. These descriptors were then encoded using advanced sentence embedding techniques to generate dense vector representations, ensuring that key semantic meaning was preserved.



In parallel, the textual abstracts of the model research were independently embedded to capture complementary contextual details not fully represented by structured metadata. The combination of structured semantic vectors and unstructured textual embeddings provided a comprehensive representation of each model (see Supplemental Information 1.1 in Multimedia Appendix 1 for details). This dual encoding strategy established the basis for subsequent similarity search and model ranking, allowing the system to align user queries with the most relevant prediction models in a context-aware and interpretable manner.

Workflow of CanRisk-RAG

System Architecture

The overall workflow of CanRisk-RAG comprises a multistage pipeline that transforms unstructured model resources into structured model recommendations (Figure 2). The system integrates several key components: (1) semantic tag extraction, in which user queries are parsed by a LLM into predefined biomedical fields; (2) semantic embedding and vectorization, which encode both structured metadata and unstructured abstracts into dense representations for similarity computation; (3) multifactor ranking, combining semantic similarity with quality indicators such as the journal impact factor (JIF), the area under the curve (AUC), and publication recency to ensure reliable prioritization; and (4) LLM-based summarization, which synthesizes retrieved content into concise and readable outputs. Together, these stages enable CanRisk-RAG to perform context-aware retrieval, interpret complex user intents, and deliver transparent, evidence-based model recommendations supported by structured domain knowledge.

Figure 2. Pipeline of CanRisk-RAG construction. This figure presents the full pipeline of CanRisk-RAG, a retrieval-augmented framework designed to identify and summarize validated cancer risk prediction models from peer-reviewed resources. The workflow proceeds from user query interpretation to model recommendation: (1) users enter a natural language query describing desired model features; (2) a large language model (LLM)–based semantic tag extractor converts the query into structured fields (eg, cancer type, model type, predictive factors, study region); (3) the query is matched against a knowledge base constructed from PubMed containing over 800 cancer risk models and 3000 predictive variables; (4) structured metadata and text are vectorized using optimized sentence embeddings; (5) semantic similarity between query and models is computed; (6) a multifactor ranking algorithm integrates similarity, journal impact factor (JIF), model area under the curve (AUC), and publication recency into a composite score; and (7) top-ranked models are presented with metadata and an LLM-generated summary.

Tag Extraction for Enhanced Semantic Matching

To support efficient retrieval, user queries were first transformed from free text into structured semantic representations. This process was facilitated by a LLM (DeepSeek-V3) [33], chosen for its open-source nature and ability to support scalable deployment. Rather than directly matching raw text against the database, the model extracted predefined semantic fields, including cancer type, model type, research stage, predictive factors, and study region, thereby aligning user intent with structured knowledge (see Supplemental Information 1.5 in Multimedia Appendix 1 for the prompt contents).

XSL•FO
RenderX

An evaluation set of 40 queries (Supplemental Information 1.6 in Multimedia Appendix 1) was constructed to evaluate the tag extraction process. The queries were designed to cover diverse cancer types, model types, predictive factor combinations, geographic contexts, and noisy inputs (eg, typos and incomplete descriptions). Two independent annotators created gold labels following the predefined schema (Cancer_Type, Model_Type, Research_Type, Involved_Factors, Country), and disagreements were adjudicated by a third expert. Precision, recall, and F_1-score were calculated per category and additionally provided uncertainty estimates using Wilson 95% CIs for precision (Supplemental Information 1.7 in Multimedia Appendix 1).

Embedding Model Selection

To prioritize relevant models, CanRisk-RAG employs a ranking strategy primarily driven by semantic similarity. User queries are semantically aligned with database entries through embedding-based similarity, which captures both structured tags and contextual meaning. The similarity score serves as the main determinant, reflecting the degree of correspondence between user intent and model characteristics.

Before performing multifactor ranking, to determine which embedding model achieved the best semantic representation performance, we evaluated four widely used sentence-embedding architectures [34-36], including all-MiniLM-L6-v2, all-MiniLM-L12-v2, all-mpnet-base-v2, and all-distilroberta-v1. Each model's output was assessed by 2 independent evaluators across 12 predefined recommendation queries derived from 4 thematic categories (Textbox 1). For each model, average relevance and reliability scores were calculated. All-distilroberta-v1 achieved the highest overall performance, with statistically significant advantages in both relevance and reliability metrics (see Supplemental Information 2.2 in Multimedia Appendix 2). Therefore, all-distilroberta-v1 was selected as the optimal embedding model for subsequent tool development and deployment.

Textbox 1. Evaluation themes and representative queries used for CanRisk-RAG development.

Model recommendation tasks based on cancer type

- Breast cancer
- Lung cancer
- Prostate cancer

Model recommendation tasks based on model type

- Logistic regression
- Support vector machine
- Neural network

Model recommendation tasks based on predictive factors

- Age, gene mutation, and family history
- PSA level, digital rectal examination, and prior biopsy
- Sex, smoking status, emphysema, and pulmonary nodule

Comprehensive model recommendation tasks

- Gastric cancer; logistic regression; predictive factors: age, family history, and BMI
- Colorectal cancer; Cox proportional hazards regression; predictive factors: prior biopsy, alcohol intake, and height
- Bladder cancer; nomogram models; predictive factors: race, gene mutation, smoking status, and education

Multifactor Ranking Algorithm

To enhance credibility and practical utility, 3 additional factors were integrated into the ranking: the JIF as an indicator of publication quality [31], the AUC as a measure of model performance, and publication recency to emphasize timely contributions. The AUC was treated as a continuous metric using a smoothed compression function, while JIF values were normalized through a log-smoothing transformation to mitigate right-skewed distributions [37]. The publication year was linearly normalized to yield a continuous timeliness score. These components were then combined into a unified weighted scoring function (Equation 1).

(1)Total score=α×similarity score+β×journal impact factor score+γ×AUC score+δ×timeliness score

LLM-Based Literature Summarization

To support user interpretation, CanRisk-RAG incorporates an automated summarization component that synthesizes the content of retrieved studies into concise, coherent overviews. By integrating information across multiple abstracts, the system highlights key findings and methodological features, enabling users to rapidly grasp the essential contributions of relevant models.

XSL•FO

Assessment Experiments

Benchmarking and Evaluation Design

To optimize the performance of CanRisk-RAG, we conducted a comprehensive comparative evaluation using 12 representative queries spanning 4 thematic areas, including cancer types, modeling approaches, predictive factors, and integrated multicomponent queries. Each theme was further divided into subthemes to reflect major research directions in cancer risk prediction [38-47] (see Textbox 1). Eight domain experts, including 3 clinical cancer researchers and 5 biomedical informatics specialists, independently assessed the outputs for all themes, with each query evaluated by 2 experts. In parallel, multiple ablation experiments on the training dataset (Table 1) examining alternative weighting schemes enabled the optimization of the final ranking configuration, ensuring balanced and robust system performance.

Table . Weight configurations for multifactor ranking algorithm used in ablation experiments.

Group	α (Similarity)	β (JIF)[a]	γ (AUC)[b]	δ (Timeliness)
G1 (Proposed)	0.85	0.05	0.05	0.05
G2 (Similarity only)	1	0	0	0
G3 (AUC+)	0.7	0.05	0.2	0.05
G4 (Recency+)	0.7	0.05	0.05	0.2
G5 (JIF+)	0.7	0.2	0.05	0.05
G6 (Similarity + Recency)	0.85	0	0	0.15
G7 (Similarity + AUC)	0.85	0	0.15	0
G8 (Similarity + JIF)	0.85	0.15	0	0
G9 (Similarity + Recency + AUC)	0.8	0	0.1	0.1
G10 (Similarity + Recency + JIF)	0.8	0.1	0	0.1
G11 (Similarity + AUC + JIF)	0.8	0.1	0.1	0

[a]JIF: journal impact factor.

[b]AUC: area under the curve.

At the application level, CanRisk-RAG was benchmarked against PubMed, ChatGPT-4o [48], ScholarAI [49], and Gemini 1.5 Flash [50], each accessed through their respective application programming interfaces under standardized query conditions. Prompts were standardized across systems to maintain fairness in comparison (see Supplemental Information 1.8 in Multimedia Appendix 1).

This stage was evaluated by domain experts. Performance was scored on 5 key dimensions: relevance, reliability, authenticity, data completeness, and consistency (0 - 10 scale). Table 2 summarizes the evaluation types, metrics, and definitions used to assess the 5 applications, including CanRisk-RAG (see Supplemental Information 1.9 in Multimedia Appendix 1 for the scoring criteria of the 5 evaluation metrics).

XSL•FO
RenderX

Table . Evaluation metrics and definitions used for model recommendation and tool usability assessment.

Evaluation metrics type and metric names		Definition
Model recommendation performance evaluation		
	Relevance	The purpose of the relevance assessment is to determine the extent to which the recommended models match the user's specified criteria.
	Reliability	The reliability assessment examines the authority of the sources where the models were published and evaluates the performance of the models themselves.
	Authenticity	Authenticity checks whether the sources of the models are genuine and can be verified in various journal databases.
	Data completeness	Data completeness evaluates the thoroughness of the model information provided by each application, including metadata, cancer type, modeling type, model performance, predictive factors, and more.
	Consistency	Consistency evaluation measures how consistently the model recommendation results align when the same search conditions or prompts are used in 2 separate instances.
Tool usability evaluation		
	User goal achievement	This metric evaluates whether the tool meets users' specific needs and expectations under open-ended, self-defined query scenarios. Participants independently formulated queries based on their own research or clinical information needs. The score reflects the extent to which users were able to successfully locate relevant cancer risk prediction models that satisfied their personalized model recommendation requirements.
	Operative accessibility	Operative accessibility refers to the overall ease of using the tool and encompasses aspects such as deployment complexity, interface design, navigation intuitiveness, and loading speed. A user-friendly tool should minimize operational complexity and cognitive load while offering clearly structured content, intuitive workflows, and comprehensive help pages.

Validation and Usability

To prevent data leakage between hyperparameter tuning and final performance assessment, we strictly separated the datasets used for weight optimization and for comparative evaluation. Weight optimization and ablation analyses were conducted solely on the development dataset, whereas the final benchmarking against baseline applications (PubMed, ChatGPT-4o, ScholarAI, and Gemini 1.5 Flash) was performed on an independent, held-out evaluation set. This evaluation set consisted of 20 carefully designed queries (Supplemental Information 1.10 in Multimedia Appendix 1) covering previously unseen cancer types, modeling approaches, and multifactorial scenarios that jointly specified cancer type, model type, and predictive factors. Recommendation outputs were independently assessed by eight domain experts using the predefined five evaluation dimensions.

In addition, usability was assessed by 10 potential end users, including clinicians and biomedical informatics researchers, based on 2 criteria: goal achievement and operative accessibility (see Supplemental Information 1.11 in Multimedia Appendix 1 for the scoring criteria). Inclusion criteria of potential end users required participants to be able to independently complete retrieval tasks. To mitigate potential conflict-of-interest bias, individuals involved in system development or dataset curation were excluded from usability scoring. None of the evaluators were members of the development team.

This multiperspective evaluation enabled a systematic assessment of CanRisk-RAG's retrieval quality and practical applicability in comparison to existing systems. Table 2 summarizes the evaluation types, metrics, and definitions used for the assessment of CanRisk-RAG.

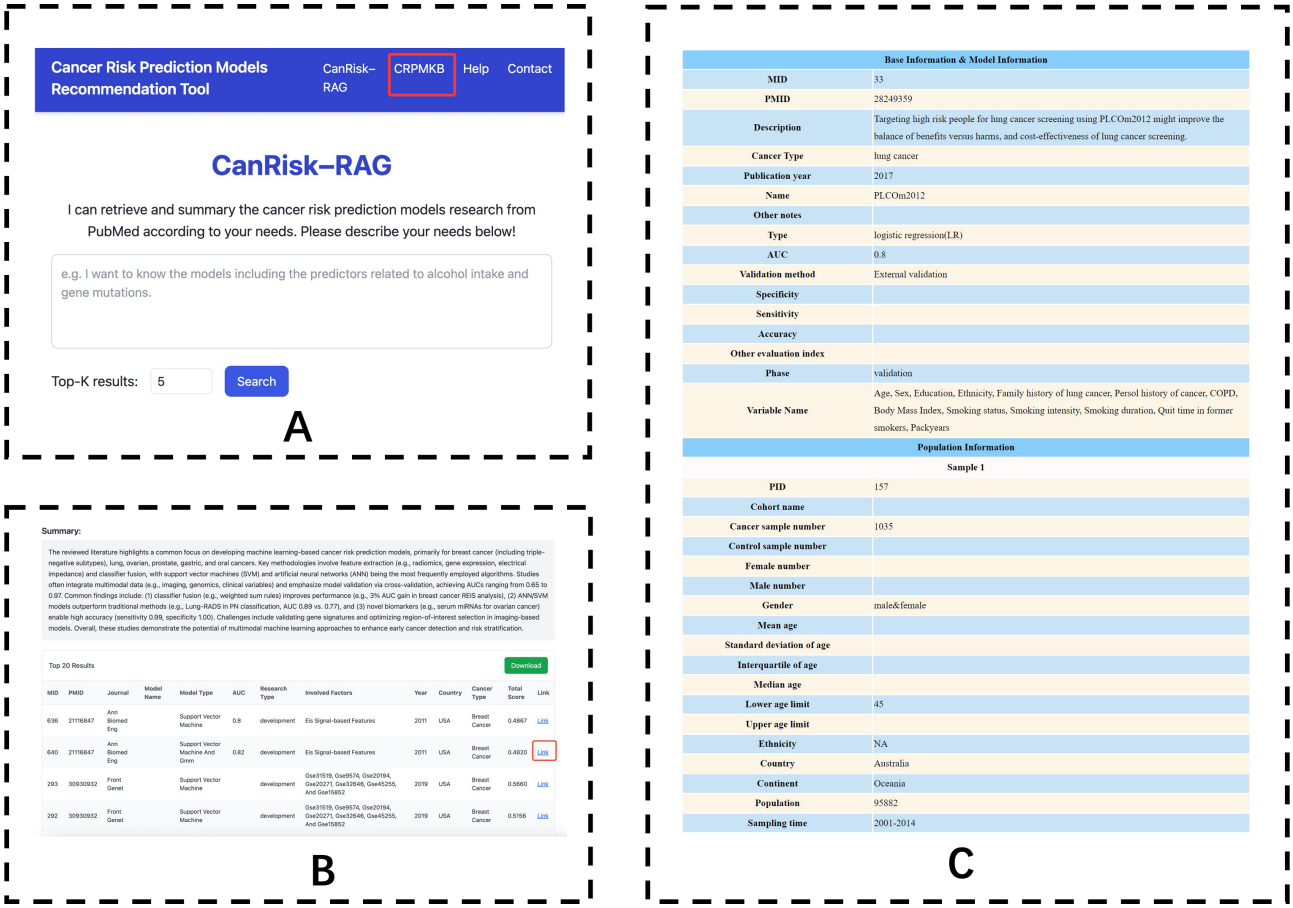
XSL•FO
RenderX

Statistical Analysis

The evaluation was conducted in 2 phases: first, the embedding models were assessed, then the 5 applications were evaluated. Descriptive statistics on the scores were given by the evaluators, including the mean and SD. To determine the consistency among evaluators for every metric assessed, we conducted a 2-way intraclass correlation coefficient analysis.

For the evaluation of different applications, the Shapiro-Wilk test was employed to determine whether the scores assigned by different evaluators for a specific metric followed a normal distribution. Due to the departure of the scores from normality, the Mann-Whitney *U* test was selected to compare the overall performance scores. To explore variations in performance across the five applications and various subthemes, the Kruskal-Wallis rank-sum test was employed. When significant differences were identified by the Kruskal-Wallis test, Dunn post hoc multiple comparisons test was used to evaluate the performance of the different baselines in relation to CanRisk-RAG. Cliff delta was reported for all pairwise comparisons. Multiplicity control across post hoc tests was handled using Benjamini–Hochberg adjustments (α=.05). A significance level of P<.05 was applied to all statistical tests. All statistical tests were performed using Python (version 3.12).

Ethical Considerations



This study did not involve human or animal subjects; therefore, an ethics review board assessment was not required in accordance with institutional and national guidelines of Sichuan University. All analyses were conducted on publicly available, nonidentifiable data, consistent with regional research ethics policies [51].

Results

Tool Interface

As shown in Figure 3, the homepage of CanRisk-RAG features an interactive input form (Figure 3A) that allows users to specify any retrieval criteria related to cancer risk prediction models. Users may define the desired number of recommended results through a customizable selection option. Additionally, users can directly access the data source associated with the homepage by clicking the “CRPMKB” link in the main navigation bar. After entering the desired model criteria in the input field and clicking the “Search” button, the system displays the results page (Figure 3B), which presents a list of recommended models retrieved based on the user’s specified conditions. In the table result, each recommended model is presented with detailed information, including attributes such as MID, PMID, Journal, Model Name, Model Type, AUC, Research Type, Involved Factors, Year, Country, Cancer Type, Total Score. Each model entry is hyperlinked to its corresponding detailed record (Figure 3C). Furthermore, for all recommended models, the tool automatically generates a summary of the corresponding research abstract (Figure 3B), providing a concise overview of these studies to support rapid understanding and comparison.

Model Recommendation Evaluation Results

Weight Configuration

We systematically evaluated eleven alternative weighting configurations (G1-G11) that varied the relative contributions of similarity (α), JIF (β), model AUC (γ), and publication timeliness (δ) (Table 3). Each configuration was tested on the same dataset of representative queries, and the average scores for relevance, reliability, and total performance were calculated.

A nonparametric Kruskal–Wallis *H* test revealed a statistically significant overall difference among the eleven configurations (H=47.916, P<6.430 × 10 , see Supplemental Information 2.3 in Multimedia Appendix 2).

The proposed configuration (G1: α=.85, β=.05, γ=0.05, δ=0.05) achieved the highest overall score, significantly outperforming variants such as SimOnly and Recency+ (P_{Holm}<.01). G1 consistently yielded higher scores across all configurations, demonstrating a robust performance on relevance and reliability.

Table . Performance comparison of different weighting configurations (mean [SD] for relevance, reliability, and total scores).

Group	Avg_Relevance, mean (SD)	Avg_Reliability, mean (D)	Avg_Total, mean (SD)
G1 (Proposed)	9.50 (0.78)	8.88 (0.85)	18.38 (1.44)
G8 (Similarity + JIF[a])	8.50 (0.66)	9.21 (0.78)	17.71 (1.16)
G7 (Similarity + AUC[b])	8.92 (0.97)	8.75 (0.85)	17.67 (1.55)
G6 (Similarity + Recency)	9.25 (0.74)	8.04 (0.81)	17.29 (1.12)
G3 (AUC+)	7.96 (0.96)	9.25 (0.90)	17.21 (1.59)
G5 (JIF+)	8.17 (0.92)	8.67 (0.96)	16.83 (1.37)
G10 (Similarity + Recency + JIF)	8.08 (0.78)	8.25 (0.79)	16.33 (0.87)
G9 (Similarity + Recency + AUC)	8.17 (1.05)	8.08 (0.93)	16.25 (1.51)
G11 (Similarity + AUC + JIF)	7.83 (0.64)	7.92 (0.72)	15.75 (0.79)
G2 (Similarity only)	9.42 (0.65)	5.46 (0.72)	14.88 (1.08)
G4 (Recency+)	7.33 (0.96)	7.08 (0.72)	14.42 (1.06)

[a]JIF: journal impact factor.

[b]AUC: area under the curve.

Performance Comparison of Applications

In the comparative evaluation across 5 applications, CanRisk-RAG consistently achieved the highest relevance and reliability across all 4 themes of the validation set (Table 4, see Supplemental Information 2.4 and 2.5 in Multimedia Appendix 2 for detailed statistics), delivering markedly superior retrieval precision compared with existing applications. For relevance, the average score was 8.30 (SD 0.59; 95% CI 8.02-8.58), indicating that the retrieved models closely matched the intended cancer types, modeling approaches, and predictive factors specified in the queries. In terms of reliability, the average score reached 7.62 (SD 0.76; 95% CI 7.27-7.98), reflecting strong consistency with authoritative and well-validated literature sources. These results confirm that, when applied to independent validation themes, CanRisk-RAG maintains robust generalization and stable interpretability, effectively extending to unseen data while preserving retrieval accuracy and quality consistency, thereby underscoring its scalability and real-world applicability. PubMed showed reasonable accuracy for straightforward cancer-type queries but struggled when tasks involved modeling approaches or specific predictive factors, often returning incomplete or no usable results. Scholar AI performed moderately in simpler recommendation tasks, but its accuracy dropped sharply for more complex, integrative queries. ChatGPT-4o occasionally retrieved relevant cancer-type models but frequently missed methodological or variable-level details. Gemini 1.5 Flash repeatedly failed to interpret user intent or generate sufficient recommendations, underscoring its limited capability for structured retrieval.

[b]Not applicable.

[c]Not significant.

As a structured and knowledge-grounded recommendation system, CanRisk-RAG achieved high performance in authenticity, data completeness, and consistency, and was therefore used as the benchmark for evaluating other applications (Figure 4). PubMed, while fully reliable in authenticity and consistency due to its literature-based retrieval, showed only moderate data completeness, particularly failing in the comprehensive recommendation task. The 3 LLM-based tools, Scholar AI, ChatGPT-4o, and Gemini 1.5 Flash, performed less reliably overall and often generated incomplete or inconsistent metadata (see Supplemental Information 2.6 in Multimedia Appendix 2). Scholar AI displayed partial strength across themes but still suffered from missing model details, while Gemini 1.5 Flash showed some consistency in recommending models based on cancer types and modeling approaches yet frequently fabricated or cited nonscientific sources such as blogs or online news (see relevant examples in Supplemental Informations 1.12 and 1.13 in Multimedia Appendix 1).

XSL•FO
RenderX

Figure 4. Comparative evaluation of authenticity, data completeness, and consistency among 4 baseline applications in cancer risk prediction model recommendation tasks.

Overall, these findings demonstrate that CanRisk-RAG effectively bridges structured domain knowledge with LLM-driven semantic reasoning, achieving both high retrieval precision and reproducibility. Across all evaluation metrics, CanRisk-RAG consistently outperformed PubMed, Scholar AI, ChatGPT-4o, and Gemini 1.5 Flash, attaining markedly higher relevance and reliability alongside near-perfect scores in authenticity, data completeness, and consistency. In contrast, the baseline systems frequently struggled with complex, multifactorial queries, often returning incomplete, inconsistent, or fabricated information.

Usability Evaluation Results

The usability scores are summarized in Supplemental Information 14 in Multimedia Appendix 1. On a 3-point scale, CanRisk-RAG achieved a mean score of 2.7 (SD 0.48) for user goal achievement, indicating that the system was generally effective in meeting users' personalized retrieval needs. In addition, the tool demonstrated good operative accessibility, with an average score of 2.5 (SD 0.53), suggesting that users found the interface and overall operation intuitive and easy to use. Taken together, these results indicate that CanRisk-RAG is user-friendly, enabling most users to accomplish their intended tasks efficiently with minimal operational burden.

Discussion

Principal Findings

The results highlight CanRisk-RAG's clear advantages in recommending cancer risk prediction models, outperforming general-purpose LLM tools and traditional systems like PubMed. By combining an organized knowledge base, which provides rich metadata including cancer types, modeling methods, and performance metrics with a RAG framework, CanRisk-RAG enables high-quality personalized recommendations and advances beyond keyword-based retrieval toward expert-level semantic recommendation. Unlike ChatGPT-4o, Scholar AI, and Gemini 1.5 Flash, which often hallucinate content or misinterpret domain-specific queries, CanRisk-RAG delivers accurate recommendations with structured information grounded in validated literature. It should be noted that as a peer-reviewed, specialized biomedical literature database, PubMed achieved near-perfect scores in authenticity and consistency, which should be interpreted as a reference baseline rather than an algorithmic achievement. While PubMed inherently ensures authenticity through direct literature indexing, it lacks the semantic parsing capabilities required for complex, multifactorial queries, thereby underscoring the value of domain-specific systems that integrate structured knowledge with semantic understanding. It should also be acknowledged that a degree of circularity exists between the system design of CanRisk-RAG and the reliability evaluation. Specifically, JIF is incorporated as a low-weight auxiliary signal in the ranking algorithm, while the reliability metric used in expert evaluation partially reflects publication in authoritative journals. Consequently, the high reliability scores achieved by CanRisk-RAG should be partly interpreted as evidence that the system adheres to its predefined design principles, namely prioritizing models supported by established, higher-reputation peer-reviewed sources, rather than being overinterpreted as direct indicators of clinical effectiveness.

The system adopts a dual-embedding strategy that fuses tag-level semantic representations with embeddings of the original user query, allowing it to jointly capture structured domain constraints and broader user intent. This design enables effective semantic matching even in the absence of exact keyword overlap. Building on this representation, a multi-factor ranking algorithm integrates semantic similarity with complementary quality indicators—including JIF, model AUC, and publication recency—to enhance the credibility and practical usefulness of the recommended models. This is particularly beneficial for model comparison and systematic review scenarios, where both relevance and evidential strength are critical. In addition, our tag-extraction evaluation demonstrates that DeepSeek-V3 achieves high overall accuracy (micro-F_1=0.994), with only two omission cases observed in the 40-query test set. These rare errors were primarily attributable to implicit semantic descriptors or typographical issues rather than systematic extraction failures. Importantly, the fused embedding framework provides partial robustness to such upstream imperfections, as the original-query embedding channel can still encode missing concepts even when a structured tag is not completely extracted.

XSL•FO
RenderX

With respect to the comparative evaluation strategy, baseline LLM systems, namely ChatGPT-4o, ScholarAI, and Gemini 1.5 Flash, were evaluated using static zero-shot prompts to ensure standardized and reproducible conditions across tools. Although this design choice reduces prompt engineering bias and enhances fairness, it may underestimate the upper bound performance of general purpose LLMs, which can benefit from chain of thought prompting, multiround clarification, or interactive refinement. However, incorporating adaptive and tool-specific prompt optimization would compromise reproducibility and comparability, as performance would then depend on prompt engineering expertise rather than intrinsic system capability. Importantly, CanRisk-RAG does not rely on iterative user clarification. Instead, it embeds domain knowledge and semantic constraints directly into the retrieval pipeline, reflecting a distinct design philosophy that shifts cognitive and procedural burden from the user to the system. This property is particularly important in clinical and translational research settings. Moreover, unlike interactive LLM-based tools, CanRisk-RAG produces deterministic and reproducible outputs for identical inputs, which is essential for evidence-based model discovery and systematic research workflows.

Although the superior performance of CanRisk-RAG highlights the advantage of integrating structured domain knowledge with retrieval-augmented generation, its effectiveness largely depends on the built-in knowledge base, which supplies high-quality, expert-verified model information. Consequently, the "extensibility" of the framework depends on the sustainable expansion of such constructed resources. To address this scalability challenge, we developed a semiautomated update pipeline that combines automated literature retrieval, rule-based metadata extraction, and LLM-assisted knowledge extraction in a workflow [52]. This tool substantially improves data update efficiency while reducing manual workload. Nevertheless, essential human review and expert supplementation are retained to ensure the accuracy of curated content. The knowledge base is planned to be updated every six months to maintain both recency and reliability.

In addition, although currently focused on cancer risk prediction models, the CanRisk-RAG framework is adaptable to other disease domains and scenarios, including prognosis and treatment response models, underscoring its potential as a universal platform for the discovery and application of clinical prediction models.

Limitations

Despite the encouraging performance of CanRisk-RAG, several limitations should be acknowledged.

First, although CanRisk-RAG offers enhanced flexibility and effective retrieval, its performance is inevitably shaped by multiple structured layers of uncertainty spanning internal (algorithmic) and external (evidence-base) factors. Internally, reliance on semantic similarity may reduce field-level specificity; LLM-based tag extraction can over-generalize factors (eg, interpreting "family history of breast cancer" as "family history" or generalizing a specific genetic factor such as BRCA1/2 mutation into a broad category like "genetic risks") and changes in multi-factor weights (eg, raising "Recency" weight from 0.05 to 0.15) can alter rankings. These factors introduce algorithmic uncertainty, which we partially mitigated through ablation experiments and iterative weighting optimization. Externally, heterogeneity in study design, sample size, population, and reporting limits comparability and generalizability. For instance, lung cancer survival models from small regional cohorts may not generalize to multi-institutional datasets, and models trained on East Asian populations may underperform in Western populations due to demographic and healthcare-system differences. Even established models (eg, Gail) exhibit cohort-dependent AUC and calibration, highlighting cross-dataset variability as an important uncertainty layer. Future work will incorporate domain adaptation and uncertainty quantification methods to reduce these effects.

Second, the current ranking strategy relies on a limited set of quality-related indicators. JIF is included as a low-weight auxiliary signal and is normalized to mitigate its influence; however, it remains a coarse, venue-level metric that does not directly reflect study-level methodological rigor. Important indicators such as sample size, calibration reporting, and the extent of external validation are not yet uniformly available across the curated literature and therefore could not be systematically incorporated as first-class ranking features in the present version. As a result, residual bias may be introduced when finer-grained quality signals are missing or inconsistently reported, even though JIF is used only to refine the ordering among semantically similar candidates. In addition, the ranking strategy incorporates reported AUC values as a quantitative indicator of model performance without explicitly differentiating or weighting AUCs derived from model development versus external validation stages. This design choice may inadvertently favor development studies that report optimistic performance over rigorously validated models with stronger generalizability. Future versions of CanRisk-RAG will aim to integrate validation-aware performance stratification and explicit study-level quality indicators, such as cohort size, validation design, and calibration metrics, to better balance apparent accuracy with real-world applicability and progressively reduce reliance on venue-level signals.

Third, the present study relied on a single LLM (DeepSeek-V3) for semantic tag extraction and literature summarization. While this design choice ensured internal consistency and reproducibility across experiments, it inevitably limited robustness to model-specific variability and potential biases inherent to a single LLM. In addition, baseline comparisons with general-purpose LLMs were conducted under a static zero-shot prompting setting without access to external retrieval, web browsing, or tool invocation capabilities. As a result, these baselines were constrained to parametric-only knowledge, which may underestimate their performance in more interactive or retrieval-augmented configurations. In this context, the evaluation primarily highlights the hallucination risks and structural limitations of ungrounded LLM responses when external knowledge is unavailable, rather than serving as an exhaustive benchmark of the full capabilities of modern LLM ecosystems. Future work will extend this evaluation framework by incorporating multi-model ensemble strategies for tag extraction and summarization to enhance robustness and

XSL•FO
RenderX

stability. In parallel, more comprehensive comparisons will be conducted against LLM-based systems equipped with web browsing, tool use, or fully integrated RAG workflows, including multi-turn and interactive prompting strategies.

Fourth, expert scoring was performed manually, introducing subjectivity despite inter-rater consistency checks. Future studies will incorporate automated evaluation methods, such as rule-based matching and semantic alignment metrics, to improve reproducibility and reduce dependence on manual assessments.

Fifth, although CanRisk-RAG includes an LLM-based literature summarization module, the current evaluation is primarily centered on retrieval and recommendation performance. The adopted metrics assess the relevance and reliability of retrieved models and metadata but do not explicitly quantify the factual accuracy or hallucination rate of the generated summaries. The summarization component is intended to serve as an assistive tool for facilitating user comprehension and synthesizing key information from retrieved literature, rather than to provide precise quantitative data; future work will incorporate dedicated evaluation protocols to systematically assess the quality and faithfulness of the generative component.

Finally, a key limitation of the present study is that the CanRisk-RAG knowledge base was constructed using literature retrieved prior to December 2022, and therefore does not include cancer risk prediction models published from 2023 onward. This temporal constraint may temporarily place CanRisk-RAG at a relative disadvantage when compared with contemporary LLMs that potentially have access to more recent biomedical literature. Beyond general concerns regarding data currency, this cutoff has specific implications for users seeking state-of-the-art computational or deep learning–based cancer risk prediction models, as recent years have witnessed a rapid proliferation of AI-driven approaches incorporating deep neural networks and multimodal data integration. As a result, the current version of CanRisk-RAG may be less suitable for users whose primary objective is to identify the most recent model architectures. To address this limitation and enhance temporal coverage, we have developed a semiautomated update pipeline that integrates automated literature retrieval, rule-based metadata extraction, and LLM-assisted curation, while retaining expert review to ensure data quality. The knowledge base is planned to be updated on a semiannual basis. Future evaluations will incorporate newly published models to assess how expanded temporal coverage influences retrieval performance, and to enable more temporally aligned comparisons with evolving LLM-based systems, particularly in the context of rapidly advancing AI-driven cancer risk modeling.

Conclusion

This study introduced CanRisk-RAG, a knowledge-driven retrieval framework for cancer risk prediction models that integrates structured knowledge with semantic reasoning. Through systematic evaluation, CanRisk-RAG demonstrated superior performance in relevance, reliability, and data consistency compared with existing retrieval systems. These results indicate that combining structured knowledge representation with LLM-based reasoning can substantially improve the precision and transparency of model discovery in biomedical research, supporting reproducible and evidence-based applications in precision oncology.

Abstract

Background: Data linkage in pharmacoepidemiological research is commonly employed to ascertain exposures and outcomes or to obtain additional information on confounding variables. However, to protect patient confidentiality, unique patient identifiers are not provided, which makes data linkage across multiple sources challenging. The Saudi Real-World Evidence Network (SRWEN) aggregates electronic health records from various hospitals, which may require robust linkage techniques.

Objective: We aimed to evaluate and compare the performance of deterministic, probabilistic, and machine learning (ML) approaches for linking deidentified data of patients with multiple sclerosis (MS) from the SRWEN and Ministry of National Guard Health Affairs electronic health record systems.

Methods: A simulation-based validation framework was applied before linking real-world data sources. Deterministic linkage was based on predefined rules, whereas probabilistic linkage was based on a similarity score–based matching. For ML, both similarity score–based and classification approaches were applied using neural networks, logistic regression, and random forest models. The performance of each approach was assessed using confusion matrices, focusing on sensitivity, positive predictive value, F_1 score, and computational efficiency.

Results: The study included linked data of 2247 patients with MS from 2016 to 2023. The deterministic approach resulted in an average F_1 score of 97.2% in the simulation and demonstrated varying match rates in real-world linkage: 1046/2247 (46.6%) to 1946/2247 (86.6%). This linkage was computationally efficient, with run times of <1 second per rule. The probabilistic approach provided an average F_1 score of 93.9% in the simulation, with real-world match rates ranging from 1472/2247 (65.5%) to 2144/2247 (95.4%) and processing times ranging from approximately 0.1 to 5 seconds per rule. ML approaches achieved high performance (F_1 score reached 99.8%) but were computationally expensive. Processing times ranged from approximately 13 to 16,936 seconds for the classification-based approaches and from approximately 13 to 7467 seconds for the similarity score–based approaches. Real-world match rates from ML models were highly variable depending on the method used; the similarity score–based approach identified 789/2247 (35.1%) matched pairs, whereas the classification-based approach identified 2014/2247 (89.6%).

Conclusions: Probabilistic linkage offers high linkage capacity by recovering matches missed by deterministic methods and proved to be both flexible and efficient, particularly in real-world scenarios where unique identifiers are lacking. This method achieved a great balance between recall and precision, enabling better integration of various data sources that could be useful in MS research.

Introduction

Real-world data (RWD) derived from routine clinical care provide remarkable potential for generating pharmacoepidemiological studies related to medication safety, effectiveness, and utilization [1-4]. The recent emergence of electronic health records (EHRs) in the Kingdom of Saudi Arabia led to the foundation of the Saudi Real-world Evidence Network (SRWEN) by the Saudi Food and Drug Authority [5-8]. This central network plans to integrate and harmonize EHRs from various hospitals, primarily to maximize the efficacy

XSL•FO
RenderX

of RWD in contributing to drug regulatory policymaking and understanding disease dynamics in the Saudi population [6,7].

Common data models (CDMs), such as the observational medical outcomes partnership model, incorporate consolidated formats necessary for data standardization across multiple clinical data sources to perform large-scale observational studies [9-11]. CDMs enable researchers to pool multiple EHR datasets and perform federated data analyses through standardized data architectures, formats, and terminologies [10,11]. The observational medical outcomes partnership CDM, developed as part of the observational health data sciences and informatics, offers a systematic framework of clinical data across diverse subdomains such as demographics, diagnoses, medications, procedures, and laboratory results. It uses standardized terminologies, mitigating inherent variability, customized formats, or inconsistent coding in raw EHR data [9,11].

While CDMs are in place to standardize structures in collecting and evaluating clinical data, many are built on deidentified datasets that may not hold vital contextual information or complete patient histories [9-11]. Thus, restricting the ability to solve such limitations of CDM as incomplete data mapping, the lack of direct mappings for some clinical or medication concepts, laboratory or narrative data gaps, which necessitate going back to the data to retrieve context-specific information that may not be contained in the standardized model [9-11]. Therefore, EHR linkage offers a powerful solution addressing this limitation by enabling researchers to link patient records across various databases and reconstruct comprehensive longitudinal health trajectories [12-14]. Common linkage approaches are deterministic, probabilistic, and machine learning (ML) linkage, each with advantages and challenges [14-16]. For instance, the deterministic linkage is based on an exact matching across predefined variables, achieving high precision; however, sensitivity may be compromised in this case, particularly when matching data that contain errors in a given variable. Probabilistic linkage overcomes this weakness by using weighted matching, enhancing sensitivity at the cost of reduced precision in specific applications [12,13]. ML techniques, such as gradient boosting and neural networks (NNs), can achieve high levels of accuracy [12,13]. These models are particularly successful when integrating a dataset with large volumes of missing and errant data, identifying more links than deterministic and probabilistic approaches [16].

With a growing number of multiple sclerosis (MS) cases among the Saudi population—from 25 per 100,000 in 1998 to 40.4 per 100,000 in 2020—the linkage of data pertaining to MS is of priority, especially given the complexity of MS treatment management, both within Saudi Arabia and globally [17]. SRWEN contains a complex variety of data sources, reference standards, and case definitions, highlighting the intrinsic complexity associated with the reliability of RWD in health care settings [7]. Therefore, accurate linkage of EHRs is paramount for addressing the complexities associated with defining patient outcomes with MS, such as disease progression, relapse rate, and treatment response. This analysis requires frequent validation by clinical expertise and enhancement of the validity and robustness of the SRWEN[17]. To achieve this, we compared different EHR linkage methods, including deterministic, probabilistic, and ML approaches. The findings from this study may have implications for the value and design of future longitudinal studies using linked MS data.

Methods

Ethical Considerations

This study was approved by the institutional review board of Saudi Food and Drug Authority with approval number 2024_17 and by the King Abdullah International Medical Research Center with approval number ROMJ/WE/WS/059/2023. Because the data were extracted from the EHR system as part of routine clinical care, patients are required to provide consent to receive treatment within the institution. Separate study-specific consent was considered waived in accordance with institutional policies. Patient privacy and confidentiality were granted through de-identification of all records prior to data exchange, such that no direct identifiers were available to the research team.

Study Population and Data Sources

In this study, we used 2 datasets from 2 different sources. First, we included SRWEN data of patients with MS between 2016 and 2023. The SRWEN functions as a repository of longitudinal health care information and incorporates diverse EHR data, such as demographics, medical history, medication use, laboratory outcomes, hospitalizations, and clinical outcomes. Information is gathered from diverse EHRs from multiple hospitals in Saudi Arabia, including the Ministry of National Guard Health Affairs (MNGHA). Subsequently, these collected data are standardized through a CDM to ensure consistency and streamline analysis [6]. Furthermore, an anonymization process is implemented prior to exchanging data to ensure patient privacy [6]. For the purposes of this study, we focused exclusively on extracting and analyzing MNGHA data within SRWEN.

Similarly, we collected MNGHA EHR data from King Abdullah International Medical Research Center, identifying patients with MS using the International Classification of Diseases 10th version (*ICD10*: G35) for the same period of (2016 - 2023). MNGHA EHRs contain routinely collected data, including patient characteristics, diagnostic history, medications history, and visit records (ie, admissions, outpatient clinical visits, or emergency visits; Table S1 in Multimedia Appendix 1).

While SRWEN collects data already from the MNGHA, the benefit of the direct link between these 2 entities is advantageous. Data within SRWEN are organized and standardized within a CDM, providing for multi-institutional data analysis at the risk of some loss in source detail. By linking the primary MNGHA EHRs to their corresponding RERN representations, we were able to recover additional clinical granularity from narrative diagnosis notes and reports. This linkage also allowed validation of data consistency between SRWEN and its original source, resulting in a larger and more accurate longitudinal profile of patients with MS.

XSL•FO

Simulation-Based Validation

Overview

We first cloned and deidentified the original dataset to address the challenge of linking deidentified records from the targeted database (ie, SRWEN) with original records (ie, MNGHA EHRs). This process ensured a realistic framework testing and that the dataset resembled the deidentified target dataset. Simulating the conditions of the intended linkage objective, we linked records to themselves using these deidentified cloned records, employing deterministic, probabilistic, and ML approaches. Following this self-linkage phase, we assessed each approach's performance using computational efficiency metrics. Consequently, the best-performing linkage method was used to link the original records to the target dataset, thereby maximizing the accuracy and reliability of the final linkage. This methodology enabled a rigorous, performance-based selection of the optimal linkage approach for secure and accurate record linkage of deidentified datasets [13].

Deterministic Approach

Deterministic EHR linkage is a rule-based approach that relies on exact matches between specific patient identifiers across different EHR systems [12,14,15,18]. Given the lack of patient identifiers in SRWEN, we implemented multiple matching criteria (ie, rules) based on a range of available variables, each considered both independently and in unique combinations (Table S2 in Multimedia Appendix 1). We explored different variable groupings in some detail to determine how various linkage methods perform under conditions with differing degrees of completeness and complexity of data encountered in real-world settings. This approach generates pairs of records classified as match or nonmatches. For each pair, we included multiple linkage variables, including demographic characteristics (eg, gender, date of birth, nationality, eligibility), and health care–related fields (eg, *ICD-10* codes, diagnosis description and date, medication order details, visit type and date, and facility information) [12,14,15,18]. Additional derived variables were generated from these data elements, including coverage, which was derived from eligibility and indicated a patient's treatment eligibility, the first MS diagnosis date, derived from the diagnosis data, and inpatient admission status, derived from visit records.

Probabilistic Approach

In this approach, patient records were grouped into blocks based on shared variables (eg, date of birth, initial MS diagnosis date, received medications, or admission events) to reduce the number of pairwise comparisons required for linkage [12,14,19]. Subsequently, each record pair within a block was compared across diverse fields, including gender, coverage (ie, eligibility), region, nationality, facility name, or diagnostic codes other than MS [12,14,19]. A similarity score was assigned to each record pair corresponding to the level of agreement on predefined variables. Variable weights were estimated as match probabilities (ie, m-probability)—the probability that two field values match, given that the records refer to the same individual—and unmatch probability (ie, u-probability)—the probability that 2 field values match given that the records refer to different individuals. These probabilities were computed using the expectation-maximization algorithm [12-14,19]. An overall similarity score for each pair was computed by summing the weighted scores across all variables [12,14,19].

Pairs were categorized as matches or nonmatches using a one-to-one linkage approach. This method was implemented using the "select_n_to_m" function from the rclin package, which maximizes total similarity score under the constraint that each record is linked only once [20]. This probabilistic approach incorporates imperfect matches caused by inaccuracies or missing data, thereby enhancing the quality and reliability of linked EHR datasets in clinical studies [19].

ML Approach

In the ML approach, record linkage was performed in 2 methods. First, we generated pairs of records using common variables in the cloned data to limit the number of comparisons, creating a grouped set of pairs [20] Similarity scores were computed for each pair across different selected variables 20[]. Pairs were labeled as matches or nonmatches for training using the known true matches. The pairs were then fed into different models for training, and we fitted the model on variables that had the higher impact based on each variable similarity score, allowing the model to learn patterns that accurately identify true matches [20].

Second, a classification-based ML approach was implemented by training models on a labeled training dataset comprising 75% of all possible record pairs derived from the original dataset. Match and nonmatch labels were derived from the reference dataset. The remaining 25% of the record pairs were used for the testing dataset to evaluate the classifier performance [16].

Four ML algorithms—K-nearest neighbor, logistic regression (LR), NN, and random forest (RF)—were used in both methods to evaluate their linkage accuracy [16]. Internal validation was reinforced using a 100-replication bootstrap approach in each method for more robust performance estimates and to ensure stability across repeated sampling iterations [16]

Real-World Record Linkage

In the real-world matching scenario, we linked data from SRWEN and MNGHA to identify patients diagnosed with MS between 2016 and 2023. Because the SRWEN and MNGHA datasets lack a unique common identifier, no reference standard was available to evaluate the performance of each matching algorithm [13]. Therefore, model performance was compared based on the number of matched record pairs identified.

Statistical Analysis

Descriptive analyses of both datasets, including diseases, demographics, and facilities, were tabulated and presented by counts and percentages. Using original identifiers as the reference standard, accurate matches and true nonmatches were defined for the simulation [13]. True matches were record pairs agreeing on identifiers, whereas true nonmatches were record pairs conflicting on identifiers [13]. Sensitivity and positive predictive value (PPV) were calculated along with their corresponding 95% CI. Additionally, the F_1 score was calculated as a measure of balanced accuracy between sensitivity and PPV

XSL•FO

(equation 1) [19]. Computational time required by the ML model to complete the record linkage process.

(1)F1score=2×Sensitivity×PPVSensitivity+PPV

Results

Descriptive Analysis

The MNGHA dataset contained 2642 patients with MS, whereas 2247 were identified from SRWEN. Because only MNGHA-related dataset within SRWEN was used, 395/2642 (14.9%) patients with MS from the original MNGHA dataset were not captured in the SRWEN data. The distribution of demographic data between the 2 data sources was comparable. For instance, the mean age of patients in the MNGHA dataset was 34.4 (SD 11) years, which was similar to the mean age of 34.6 (SD 11.3) years in SRWEN.

Deterministic Approach

The highest number of pairwise comparisons (3,854,740) was observed in the "sex" variable, compared with a significant precise pairwise comparisons (6212) using the "date of birth (DOB)" or "nationality" variables. Sensitivity was consistent with a perfect score across the variables. However, the specificity rate varied, with the highest (99.9%) observed using "DOB" and the lowest (5%) observed using "nationality." Conversely, precision was considerably low across different variables, with the highest (42.5%) observed using "DOB." Moreover, both "DOB" and "MS Date" had relatively high F_1 scores of 59.7% and 48.8%, respectively (Table 1).

Table . Results of deterministic matching in % based on an individual variable.

Metric	Sex	DOB[a]	Nationality	Coverage	Facility	Region	MS[b] date[c]	Admissions	Other diagnoses	Medications
Accuracy	44.45	99.95	5.09	69	62.92	58.06	99.92	88.15	64.37	99.73
Sensitivity (recall)	100	100	100	100	100	100	100	100	100	100
Specificity	44.43	99.95	5.05	68.99	62.91	58.04	99.92	88.14	64.36	99.73
PPV[d] (precision)	0.07	42.53	0.04	0.12	0.10	0.09	32.28	0.32	0.11	12.45
F_1 score	0.14	59.68	0.08	0.25	0.21	0.18	48.81	0.64	0.21	22.14

[a]DOB: date of birth.

[b]MS: multiple sclerosis.

[c]MS date: first multiple sclerosis diagnosis.

[d]PPV: positive predictive value.

A sequence of deterministic linkage rules was applied to evaluate data matching using a set of variables instead of a single variable (Table 1). The number of correctly matched pairs remained consistent across most rules, with 2642 pairs correctly matched for each rule. Likewise, almost all of the linkage rules resulted in a nearly perfect score across the metrics. The average F_1 score for the deterministic approach was 97.2% (Table S3 in Multimedia Appendix 1). In terms of computing time, deterministic linkage was completed in less than one second for each criterion (Table S3 in Multimedia Appendix 1).

Probabilistic Approach

To ensure a manageable dataset for analysis, we first reduced the number of comparisons by blocking records based on exact matches on DOB (6212 pairs). Precision remained consistently perfect regardless of the variables used across diverse combinations of matching criteria in the probabilistic approach. Both specificity and sensitivity increased with more variables, as the combination of sex, nationality, and coverage was 76%. Further, adding the facility name and the MS diagnosis date led to a perfect score. A similar observation was found for the F_1 score, which began at 69.9% with sex only, increased to 94.6% after adding facility name and region, and reached a perfect score of 100% with the inclusion of MS diagnosis date.

By using a combination of the best-performing variables derived from the deterministic approach to improve match accuracy further, in addition to examining different blocking criteria, precision was constantly at 100%. Sensitivity and specificity rates were high, considerably assisted by combining specific clinical variables. Likewise, the F_1 score ranged from 82% to 99.9% (Table S3 in Multimedia Appendix 1). In terms of computing time, probabilistic linkage required 0.1 to 5 seconds for each criterion (Table S3 in Multimedia Appendix 1).

Using this probabilistic approach with the one-to-one linkage (ie, select_n_to_m from the reclin package) matching criterion, the linkage models achieved perfect performance for all the metrics evaluated. In addition, m-probabilities and u-probabilities were compared across the variables under different matching criteria (Table S4 in Multimedia Appendix 1).

ML Approach

In the similarity-score method, models trained on combinations of DOB, MS diagnosis date, and medications, after being blocked (ie, exact match) on admission, performed best overall. NN, RF, and LR models demonstrated comparable performance, with slightly higher accuracy using NN (99.37% vs 99.36%). However, computational time analysis showed that LR presented a combination of high performance and acceptable processing time (15 - 766 s). In contrast, both RF and NN, while having

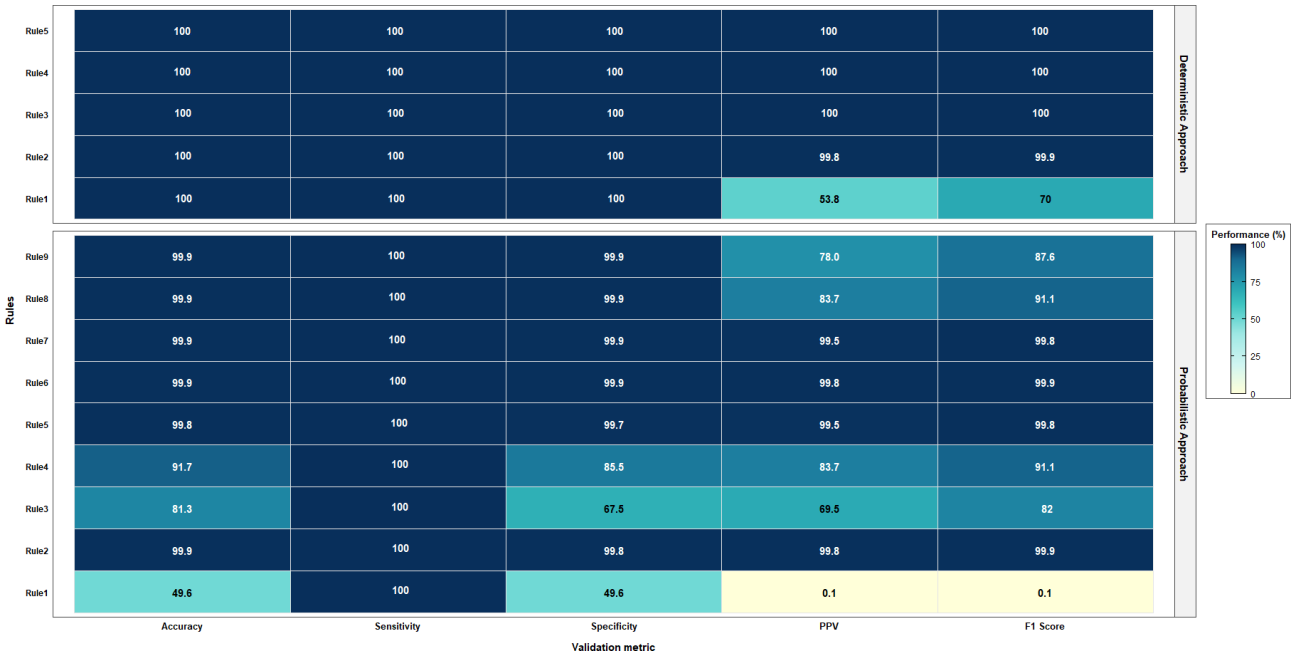
XSL•FO
RenderX

comparable results to LR, were less practical for large-scale linkage tasks due to their longer training times (15 - 7467 s) associated with their complexity (Table S5 in Multimedia Appendix 1).

In the classification approach, despite the blocking variable or combination of matching criteria, performance was constantly high among the three models, ranging from 91.7% to 100%, while computational efficiency varied depending on the blocking strategy and applied comparison criteria. Moreover, the classification is usually more computationally expensive (13 - 16,936 s) compared with the similarity-score approach, affecting scalability for larger datasets. However, K-nearest neighbor demonstrated an excellent trade-off between computational efficiency and linkage performance (Table S5 in Multimedia Appendix 1).

Record Linkage

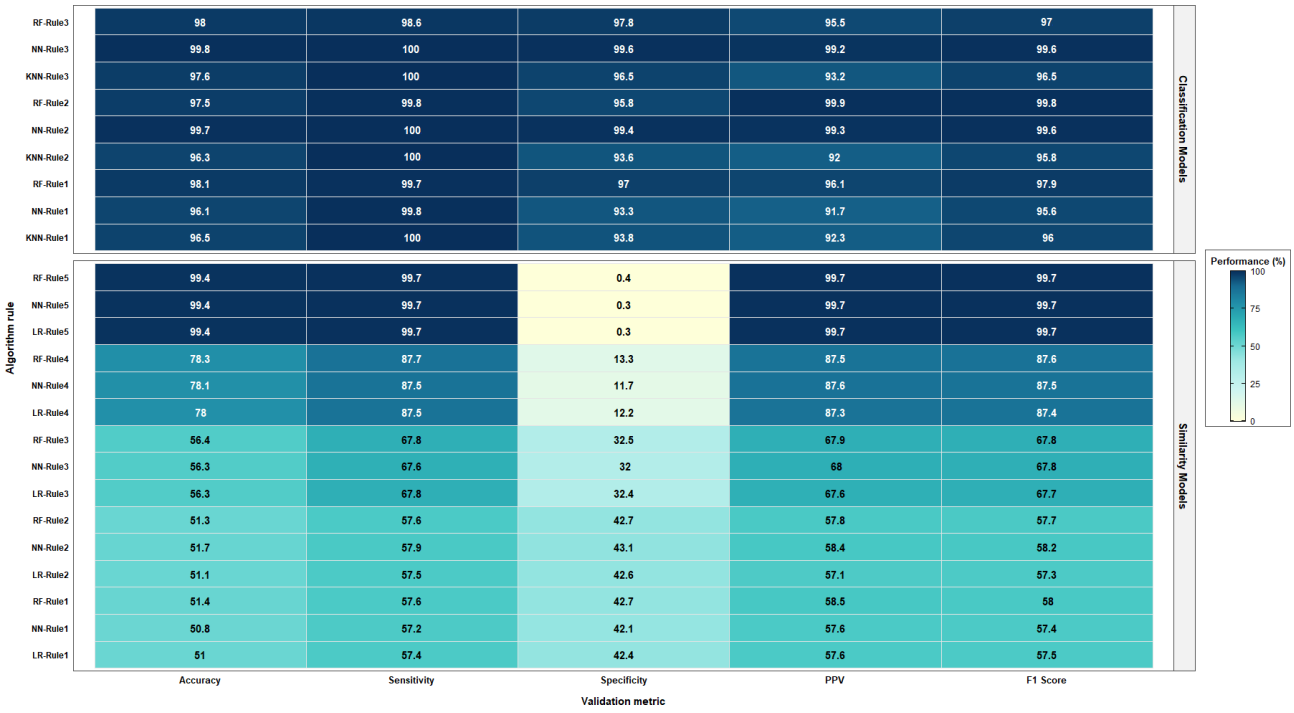
The deterministic approach produced the fewest matched pairs. Increasing the number of variables (eg, adding admissions or medications) made the linkage criteria stricter, resulting in gradually fewer matched pairs, ranging from 1046/2247 (46.6%) to 1946/2247 (86.6%). The probabilistic approach achieved more pairs ranging from 1472/2247 (65.5%) to 2144/2247 (95.4%) based on the combination of variables. The ML approach, using similarity scoring or classification with an NN model, generated 789/2247 (35.1%) pairs and 2014/2247 (89.6%) pairs, respectively (Table S5 in Multimedia Appendix 1).



Discussion

Principal Results

Through the simulated scenario and after using a mixture of variables without identifiers, we determined that the deterministic method was the most efficient data linkage algorithm. Although this approach had limited generality, it accomplished 100% scores across all metrics without incurring high computational times. Therefore, the deterministic approach is practical when we need absolute certainty in matched pairs. In contrast, the probabilistic method also demonstrated efficient performance with a similar mixture of variables. Initially, the recall and specificity metrics exhibited low performances. However, when we applied one-to-one linkages, the performance of the probabilistic method improved significantly, yielding a 100% score. Furthermore, the core benefit of this approach is retrieving a higher number of matched pairs, signifying its advantage when maximum generalization and thorough data retrieval are required. In the case of ML methods like NN models, we attained perfect performance scores at the expense of higher computational costs, limiting their feasibility in real-world scenarios. Among all methods, the probabilistic approach provided the highest number of patients, signifying its flexibility in real-world healthcare scenarios. These outcomes give a reproducible framework for appropriate EHR record linkages, underscoring its efficacy in practical patient care situations.



Considering the average F_1 score for the different models in each approach, the deterministic approach achieved the highest average (97.2%), followed by the probabilistic approach (93.9%). Noteworthy, the probabilistic approach using one-to-one linkage achieved an average of 100%, and in both probabilistic and ML approaches, an initial blocking step based on exact matching was performed. Examining the criteria without applying any blocking led to poor performance in the probabilistic method and was infeasible for ML. Figure 1 shows a comparison between deterministic and probabilistic approaches, while Figure 2 shows a comparison between similarity score and classification ML approaches.

Comparison with Prior Work

Despite the application of a straightforward deterministic algorithm requiring exact matching among all variables of linkage rule, our deterministic solution outperformed the probabilistic method, in contrast to findings from previous studies [21,22]. For instance, Gomatam et al [21] used a forward stepwise deterministic method to evaluate variables independently before constructing matching rules. We used a similar approach and observed high specificity and recall, achieving a perfect score, using this method [21]. The probabilistic linkage was implemented similarly to prior research, and we only allowed for exact matches in the deterministic approach. However, unlike previous studies' findings where probabilistic linkage outperformed deterministic linkage in most scenarios, our results are comparable, with slightly better performance of the deterministic approach when linkage rules (rather than individual variables) were employed [19,21-23]. Implementing a one-to-one linkage method proposed by the reclin package further improved the probabilistic approach to exceed the performance of the deterministic approach when using similar matching rules [20]. Compared with Röchner et al [16], our ML approach exhibited a lower performance than the deterministic approach using a similar combination of rules. Furthermore, even though NN in the classification method achieved a near-perfect score, it required significantly more computational time than the deterministic approach. Nonetheless, we reached a similar finding to Röchner et al [16] in identifying the NN as the highest-performing algorithm in record linkage.

Computational benchmarking was performed on a standard workstation featuring an Intel Core i7 processor, 16 GB of RAM, and 2 GB of GPU (64-bit Windows OS). From a computational perspective, the most efficient method of linkage was the deterministic approach: each run finished in under one second, F_1 scores were between 70% and 100%, and memory requirements were low (<2 GB). The probabilistic approach required 0.1 to 4.88 seconds (F_1 score 82% - 99.9%), while maintaining moderate memory requirements (<8 GB) and achieving excellent accuracy. In contrast, machine-learning-based methodologies were very computationally intensive requiring: 12 to 7467 seconds (~0.2 - 124 min; F_1 score 57.3% - 99.7%, similarity-based models), and 13 to 16,936 seconds (~0.2 - 282 min; F_1 score 95% - 99.8%, classification-based models), both at a maximum memory requirement of 12 to 14 GB. These data demonstrate that the deterministic and probabilistic approaches are ideal for large scale and routine linkage tasks where the computational efficiency of the method is crucial, while ML-based methods, though highly accurate, demand greater resources and are better suited for smaller or high-value analytic linkages where accuracy outweighs runtime considerations.

Clinical and Regulatory Implications

Beyond demonstrating methodological aspects, this study supports the assertion that EHR linkage of original sources with their standardized mapping has clinical importance of linking the fragmented data of MS into a multi-institutional timeline that supports relapse reconstruction, mapping of treatment trajectories, and assessment of long-term outcomes. Importantly, this linkage addresses the challenges of RWD in MS by enabling the validation of deidentified records and matching the structured components (diagnoses, labs, prescriptions, utilization) with unstructured data (notes by physicians and radiology reports) to improve phenotype definition when ICD codes are ineffectively applied. The linked dataset supports earlier case identification (using utilization surrogates as proxies when standard scales are not available), risk stratification and

XSL•FO
RenderX

compliance monitoring across care sites, and provides more frequent and expandable data for pharmacoepidemiologic and safety surveillance that will be more robust than values obtained from trial groups. At the same time, addressing challenges related to the lack of data sufficiency, burdens related to the gaining of patient-reported outcomes data, evolving criteria for diagnosis, and the need for consistent harmonization and resourcing across systems. This linkage produces an analytically reproducible and available dataset for the practical and generalizable studies related to MS and in support of decisions concerning it, changing otherwise unstructured clinical data into actionable knowledge connecting to clinicians, regulators, and health-system leaders.

With the growing availability of large-scale clinical datasets, opportunities to create more comprehensive patient care pathways through data linkage are expanding. The findings of this study suggest that probabilistic linkage of anonymized datasets using indirect identifiers can substantially improve linkage capacity, minimize computational cost, and maintain patient privacy. Probabilistic linkage has demonstrated a greater ability to recover more pairs that may be missed by deterministic methods (1472-2144 vs 1046-1946) due to its flexibility, highlighting its potential as a complementary method to deterministic linkage. Furthermore, to ensure transparency, we examined the contributions of each linkage variable before developing the matching criteria. This approach allowed us to identify the most influential variables for effective linkage. More particularly, the date of birth and first MS diagnosis date achieved F_1 scores of 59.7% and 48.8%, respectively, suggesting strong linkage capabilities with balanced precision and recall. Moreover, incorporating both variables in the matching rules of the deterministic approach resulted in a perfect record linkage across all performance metrics. This improved linkage capability is beneficial for patients with MS by enabling data integration across different providers and supports an even more unified and comprehensive record of each patient's journey. Such a broad linkage helps researchers and clinicians track the progression of diseases over time, evaluate treatment effects on symptoms, and track long-term health outcomes.

The study findings are significant for regulatory requirements, especially when conducting policymaking and postmarketing surveillance. The low computational costs of the deterministic approach enable the regulators to evaluate its treatment outcomes and specify any safety issues, whereas the flexibility and open-ended retrieval of the probabilistic approach is remarkable, especially in the case of comprehensive data retrieval from anonymized records. Therefore, using both deterministic and probabilistic approaches is significant for creating a comprehensive clinical data source for policymaking, postmarketing assessments, and monitoring of the healthcare industry. Ultimately, a combination of these approaches can lead to excellent patient outcomes regarding safety and treatment accuracy.

Limitations

Several limitations must be acknowledged in this study. First, our selection of methods was affected by computational constraints, which highlighted the need for advanced optimization and more powerful hardware for ML models. Discrepancies in patient records count between datasets could also affect generalizability, highlighting the importance of complete data capture in future studies. In our linkage of RWD, we standardized both datasets in terms of variable names and value structure, perhaps influencing the performance of algorithms when linking across different data quality in a real-world application. Furthermore, one patient in SRWEN had an inaccurate date of birth, while 4 patients in both data sets had an unknown nationality. Also, 44 patients in MNGHA and 11 patients in SRWEN had an unknown coverage status. Variables such as other diagnoses, admissions (visits), and medications contain null values (no value), but we believe that these nulls refer to the absence of a clinical event rather than missing entries. Lastly, the lack of an identifier limited our ability to validate the results against a reference standard for the real-world linkage section. Consequently, we could not accurately evaluate the retrieval of matched pairs. Therefore, we used the number of matches solely to describe the linkage performance in real-world linkage.

Conclusion

The findings of this study demonstrate how probabilistic linkage with indirect identifiers can enhance data integration, particularly for MS research and patient care. In real-world situations where we lack unique identifiers, probabilistic linkage proved to be both flexible and efficient as a complement to traditional approaches. These results provide a more holistic overview of patients with MS care and afford researchers access to an inclusive dataset for studying disease progression, treatment outcomes, and monitoring medication safety. In conclusion, applying probabilistic linkage techniques can be expected to facilitate more informed, data-driven clinical and research practices in managing MS.

Abstract

Background: The occurrence of sepsis in patients with heart failure (HF) has received less attention in research; yet, it poses a significant clinical challenge due to the complex interplay between chronic cardiac dysfunction and acute systemic inflammation. The stress hyperglycemia ratio (SHR) has emerged as an independent risk factor in various cardiovascular diseases and patients with sepsis, but its role in predicting sepsis risk in patients with HF remains underexplored.

Objective: This study investigates the association between SHR and sepsis occurrence in patients with HF and explores the potential mediating role of inflammatory indicators.

Methods: This retrospective cohort study used data from the Medical Information Mart for Intensive Care-IV (version 3.0) database, encompassing patients with HF from critical care units. SHR was calculated based on initial blood glucose and glycated hemoglobin A_{1c} levels. The analysis population was divided into 4 groups based on the quartiles of the SHR. The primary end point was 7-day sepsis incidence, which was diagnosed following Sepsis-3 criteria.

Results: Within the 1205-patient cohort (male: 764/1205, 63.4%; median 71.51, IQR 62.45-79.47), a total of 162 (13.4%) patients with HF experienced sepsis within 7 days. In the fully adjusted model, a per-unit SHR increase was linked to an 18% higher sepsis risk (hazard ratio 1.18, 95% CI 1.01 - 1.38; *P*=.04). Restricted cubic splines analysis showed a nonlinear saturation effect association (*P* for nonlinearity=.02), which was consistent in the diabetic subgroup (*P* for nonlinearity=.01). After adjusting for 7-day mortality as a competing event using the Fine-Gray model, SHR was independently associated with an increased risk of sepsis (*P*=.01). The association between SHR and sepsis was significantly modified by diabetes mellitus, BMI, and insulin use (all *P* for interaction<.05). Furthermore, mediation analysis indicated that several inflammatory indices, including the systemic immune-inflammation index, neutrophil-to-lymphocyte ratio, platelet-to-neutrophil ratio, systemic inflammation response index, and monocyte-neutrophil-to-lymphocyte ratio, significantly mediated the association in critically ill patients with HF.

Conclusions: In critically ill patients with HF, an elevated SHR was associated with heightened 7-day sepsis risk, especially for those combined with diabetes. Furthermore, systemic inflammatory indices partially mediated this association in the overall population, implicating inflammation as a potential mechanistic link between SHR and sepsis.

KEYWORDS

stress hyperglycemia ratio; heart failure; sepsis; diabetes; mediation analysis

Introduction

Heart failure (HF), a prevalent but serious disease, has seen a 29% global prevalence increase from 2010 to 2019 [1], with a 30% - 50% risk of mortality or rehospitalization within the acute phase [2].

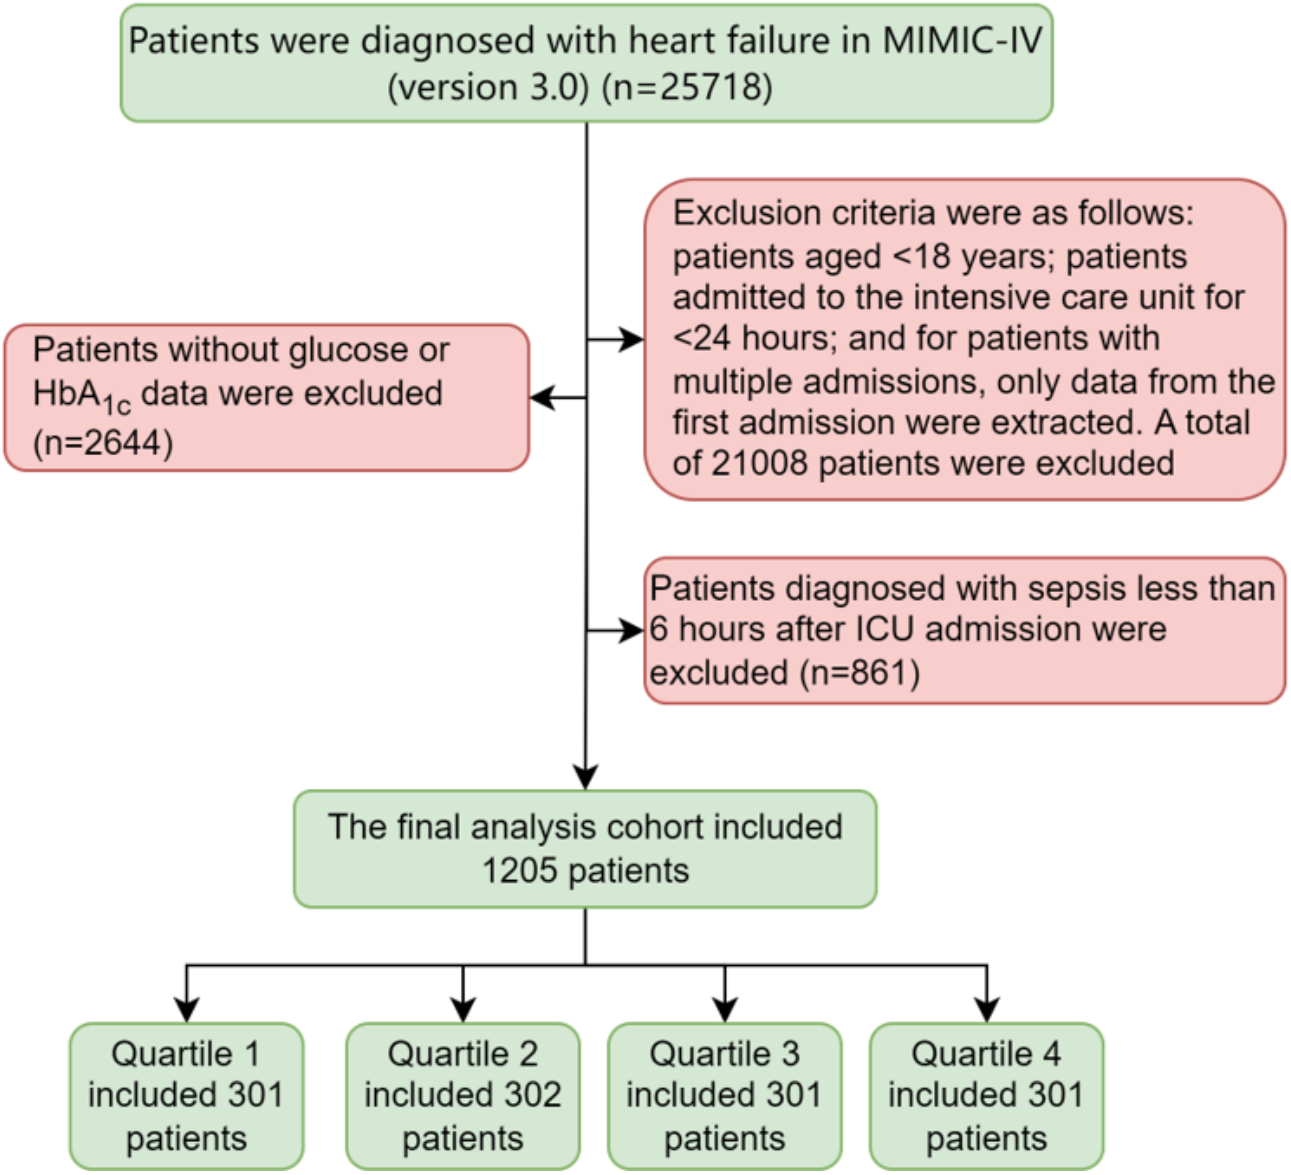
The critically ill patients with HF are particularly vulnerable to sepsis, which may be related to immune dysfunction [3], cardiac remodeling [4], or bacterial translocation [5]. It was reported that the mortality rate reach 90% in those combined cardiac dysfunction and sepsis [6], and the recurrence rate of sepsis in patients with HF is 3-fold higher than those without HF [7].

XSL•FO
RenderX

Thus, identifying modifiable risk factors for sepsis occurrence is crucial for global public health and prevention strategies. The pathogenesis of sepsis in critical illness is multifactorial, with emerging evidence suggesting that hyperglycemia, especially under stress, may contribute to the development and prognosis of sepsis involving immune dysregulation, inflammatory activation, and organ impairment [8-10]. Stress hyperglycemia ratio (SHR) has emerged as a novel and potentially valuable metric in the assessment of acute glycemic levels, which is calculated by comparing admission blood glucose levels to glycated hemoglobin (HbA_{1c}), distinguishing an acute stress-induced hyperglycemia from preexisting poor glycemic control [11]. Multiple studies have demonstrated that higher SHR levels were associated with poorer prognosis in patients diagnosed with acute coronary syndrome [12], acute HF [13], and sepsis [14]. However, the relationship between SHR and the occurrence of sepsis among patients with HF remains unclear. Inflammatory markers such as neutrophil-to-lymphocyte ratio (NLR), platelet-to-lymphocyte ratio, monocyte-to-lymphocyte ratio, neutrophil-to-platelet ratio (NPR), neutrophil-monocyte-to-lymphocyte ratio (NMLR), systemic immune-inflammation index (SII), and systemic inflammation response index (SIRI) have been investigated in patients with sepsis and show promise as prognostic indicators [15-20]. Given the intricate interplay between hyperglycemia and inflammation [21], and the well-documented role of inflammatory processes in the pathogenesis of sepsis, we hypothesize that inflammation may serve as a mediating factor in the association between SHR and sepsis occurrence. Therefore, this study aims to fill this critical gap by investigating the association of SHR and the risk of sepsis among critically ill patients with HF, based on data from the Medical Information Mart for Intensive Care-IV (MIMIC-IV) database. Furthermore, we explored whether inflammation acts as a potential mediator in this relationship.

Methods

Ethical Considerations



This study was a retrospective observational design with publicly available data from the MIMIC-IV database, which includes information on critically ill patients admitted to the intensive care units (ICUs) at Beth Israel Deaconess Medical Center from 2008 to 2022 [22]. The data acquisition process adhered to all relevant regulations. Author BY obtained a Collaborative Institutional Training Initiative license (Record ID 12861338) and the necessary permissions to extract data from the MIMIC-IV database. The project was approved by the institutional review boards of both the Massachusetts Institute of Technology and Beth Israel Deaconess Medical Center and followed the Strengthening the Reporting of Cohort Studies in Surgery guidelines [23]. Our research was conducted in accordance with the Declaration of Helsinki. Since the MIMIC-IV database includes fully anonymous or deidentified patient records and all protected health information has been removed in accordance with Health Insurance Portability and Accountability Act (HIPAA) privacy standards, participants or the participants' legal guardians or next of kin consent for publication is not applicable to this study. This study did not involve any ethical conflict issues.

Study Design and Participants

This is a retrospective observational study based on a large-scale critical care database, which included the ICU patients who were diagnosed with HF based on the *International Classification of Diseases, Ninth Revision* (ICD-9) and *International Classification of Diseases, Tenth Revision* (ICD-10) codes (Table S1 in Multimedia Appendix 1). We excluded (1) patients younger than 18 years of age; (2) patients with an ICU stay duration less than 24 hours; (3) for patients with multiple ICU admissions, only data from the first hospitalization were included; (4) patients lacked data of blood glucose or HbA_{1c}; and (5) patients diagnosed with sepsis [24] less than 6 hours after ICU admission. Finally, a total of 1205 patients were enrolled in the study cohort and divided into 4 groups based on SHR quartile (Figure 1). Quartile 4 representing the highest SHR was consistent with previously published studies [25].

Figure 1. Patient selection flowchart. Flowchart illustrating the inclusion and exclusion criteria for patient selection in a retrospective cohort study investigating the association between the stress hyperglycemia ratio and 7-day sepsis risk among critically ill patients with heart failure. Data were derived from the MIMIC-IV database, Beth Israel Deaconess Medical Center (Boston, MA, United States), encompassing admissions from 2008 to 2022. A total of 1205 patients were included in the final analysis. Inclusion and exclusion criteria are detailed. HbA_{1c}: glycated hemoglobin; ICU: intensive care unit; MIMIC-IV: Medical Information Mart for Intensive Care-IV.

Definition of Sepsis

Sepsis was defined according to Sepsis-3 criteria [3]. The time of sepsis onset (T_{sepsis}) was determined as the earlier of the first clinical suspicion of infection ($T_{suspicion}$) and the first time the Sequential Organ Failure Assessment (SOFA) score increased by ≥2 points (T_{SOFA}), provided that T_{SOFA} occurred no more than 24 hours before or 12 hours after $T_{suspicion}$ according to published literature [24]. To specifically capture new-onset sepsis developing during the ICU stay and to minimize the inclusion of infections likely present at admission, we excluded all patients for whom T_{sepsis} occurred within the first 6 hours after ICU admission in our primary analysis.

Inflammation Biomarkers

Inflammatory biomarkers included NLR, platelet-to-lymphocyte ratio, monocyte-to-lymphocyte ratio, NPR, NMLR, SII, and SIRI. Detailed calculation methods are provided in Table S2 in Multimedia Appendix 1.

Data Collection

The SHR was calculated using the formula: SHR=admission blood glucose (mg/dL)/ (28.7×HbA_{1c} (%)−46.7) [11]. Blood glucose and HbA_{1c} values were sourced from the initial records after ICU admission. The baseline variables were chosen on the bases of their possible influence on sepsis risk and cardiovascular risk of the individuals and followed six categories: (1) demographics (sex, age, race, and BMI), (2) vital signs (heart rate, systolic blood pressure, diastolic blood pressure, mean blood pressure, respiratory rate, temperature, and 6-hour fluid intake), (3) laboratory parameters (hemoglobin, white blood cell, platelet, blood urea nitrogen, creatinine, glucose, HbA_{1c}, etc), (4) comorbidities (diabetes, hypertension, shock, etc), (5) disease severity scores (Charlson comorbidity

XSL•FO
RenderX

index, Acute Physiology Score III, systemic inflammatory response syndrome score, SOFA score, etc), and (6) medication (angiotensin-converting enzyme inhibitors/angiotensin receptor blockers, diuretics, antibiotics drugs, insulin, glucocorticoid, oral hypoglycemic drugs, etc). For all baseline variables, the first recorded value within the initial 6 hours after ICU admission was extracted using PostgreSQL (version 13.7.1; PostgreSQL Global Development Group) and Navicat Premium (version 17; PremiumSoft CyberTech Ltd) and used in the analysis. This study adhered to the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guidelines for observational studies [26]. Variables with a missing rate ≤25% were imputed using the Multivariate Imputation by Chained Equations method, generating 20 imputed datasets, applying predictive mean matching for continuous variables and logistic regression for categorical variables. The imputation model included all baseline variables used in the analysis. Variables with a missing rate >25% were excluded to avoid bias. Further details are provided in Table S3 in Multimedia Appendix 1.

Definition of Outcomes

The primary outcome was the occurrence of sepsis within 7 days after ICU admission, which was defined based on the acute disease distribution patterns observed in our dataset (Figure S1 in Multimedia Appendix 1) and was consistent with the early prediction window commonly adopted in prior studies focusing on acute sepsis in ICU settings [27]. Secondary outcomes included 7-day mortality, a composite outcome of sepsis occurrence or mortality within 7 days, 28-day mortality, and in-hospital mortality.

Statistical Analysis

Continuous variables were described using median (IQR) or mean (SD), and comparisons between groups were performed using the Kruskal-Wallis test or ANOVA, as appropriate. Whereas categorical variables were expressed as frequency (%) and were analyzed using the Fisher exact test or the Pearson chi-square test. The Kaplan-Meier survival analysis was used to estimate the occurrence of primary outcomes among groups according to the log-rank test. To assess the impact of SHR on sepsis occurrence, the multivariate proportional hazard regression models (Cox regression models) were used to assess the hazard ratio (HR) and 95% CI for event occurrence. Specifically, model 1 was unadjusted for covariates, and model 2 further adjusted sex, age, and BMI. Considering the impacts of patient general condition, vital signs, SOFA scores, and steroid use on outcomes, based on model 2, model 3 incorporated acute HF, diabetes, shock, SOFA score, antibiotic, insulin, and glucocorticoid. To explore the potential dose-response relationship between SHR and the risk of sepsis occurrence, restricted cubic splines (RCS) analysis was performed and adjusted by the same models in model 3. Furthermore, subgroup analyses were conducted to delve deeper into the data, stratifying outcomes based on sex, age, BMI, diabetes, acute HF, and insulin use. These subgroup analyses were performed using comprehensive regression models adjusted for potential confounding factors. To test whether diabetes status modifies the relationship between SHR and sepsis risk, we introduced an interaction term between SHR (as a continuous variable) and diabetes status (yes or no) within the Cox regression model, which was also adjusted for the same covariates as in the fully adjusted model (model 3). Moreover, to rigorously evaluate the robustness of our main findings, sensitivity analyses were performed by logistic regression, Fine-Gray, and competing risk Cox models. In addition, we extended the exclusion window for incident sepsis from the original 6 hours to 12, 24, 36, and 48 hours after ICU admission, respectively, and repeated the Cox proportional hazards regression models.

To determine whether inflammatory indices (such as NLR and SII) mediate the association between SHR and sepsis occurrence, we used the Cox model in the *CMAverse* package in R (R Foundation for Statistical Computing). We performed 1000 bootstrap simulations to estimate each mediator's effect and calculate the mediation proportion. The average direct effect represents the impact of SHR on sepsis without mediation, while the average causal mediation effect indicates the effect of SHR on sepsis occurrence via mediators. The mediation proportion was calculated by dividing the average causal mediation effect by the total effect. All statistical analyses were executed using R software (version 4.4.1), with statistical significance set as a 2-sided *P* value of less than .05.

Results

Baseline Characteristics

A total of 25,718 patients with HF from the ICU were consecutively recruited. Following certain exclusion criteria, 1205 patients were ultimately included, of whom 63.4% (n=764) were male, and had a median age of 71.51 (IQR 62.45 - 79.47) years. Table 1 presents the baseline characteristics. There were 297 (24.6%) patients with hypertension, 564 (46.8%) patients with diabetes, 855 (71%) patients with acute HF, and 595 (49.4%) patients with pneumonia.

[a]Baseline demographic, clinical, laboratory, and treatment characteristics of 1205 critically ill patients with HF, stratified by quartiles of the stress hyperglycemia ratio. Data were derived from the Medical Information Mart for Intensive Care-IV database (Boston, MA, United States; 2008 - 2022). *P* values were calculated using the Kruskal-Wallis test for continuous variables and the Pearson chi-square or Fisher exact test for categorical variables.

[b]SHR quartiles: Q1: <0.8490; Q2: 0.8490-1.0331; Q3: 1.0331-1.3177; Q4: >1.3177.

[c]HbA_{1c}: glycated hemoglobin.

[d]SBP: systolic blood pressure.

[e]DBP: diastolic blood pressure.

[f]MBP: mean blood pressure.

[g]HCT: hematocrit.

[h]BUN: blood urea nitrogen.

[i]PT: prothrombin time.

[j]APTT: activated partial thromboplastin time.

[k]HF: heart failure.

[l]AMI: acute myocardial infarction.

[m]COPD: chronic obstructive pulmonary disease.

[n]APSIII: Acute Physiology Score III.

[o]SAPSII: Simplified Acute Physiology Score II.

[p]SIRS: systemic inflammatory response syndrome.

[q]SOFA: Sequential Organ Failure Assessment.

[r]ACEI/ARB: angiotensin-converting enzyme inhibitor/angiotensin receptor blocker.

[s]NSAID: nonsteroidal anti-inflammatory drug.

All participants were stratified into 4 groups (Q1-4) based on SHR quartiles: Q1: <0.8490 (n=301); Q2: 0.8490 - 1.0331 (n=302); Q3: 1.0331 - 1.3177 (n=301); and Q4: >1.3177 (n=301). The highest SHR group (Q4) exhibited increased vital signs, including respiratory rate and diastolic blood pressure, alongside elevated laboratory values such as platelet count and serum potassium levels. They had a higher burden of comorbidities (eg, coronary heart disease) and disease severity scores (Charlson index and Simplified Acute Physiology Score II), but lower antibiotic use. In contrast, the lowest SHR group (Q1) had higher HbA_{1c}, diabetes prevalence, and insulin use. However, parameters such as age, BMI, and race levels showed no significant variation across SHR groups.

Furthermore, for clinical outcome, Table S4 in Multimedia Appendix 1 provides a comparison of baseline characteristics between patients with sepsis and those without sepsis within 7 days after admitted to the ICU. Compared to patients without sepsis, those with sepsis exhibited significantly elevated levels of SHR (median 1.13, IQR 0.92 - 1.46 vs median 1.02, IQR 0.84 - 1.29; *P*=.001) and higher inflammation infection.

Considering SHR be associated with diabetes status, compared to patients without diabetes, those with diabetes had higher BMI (28.96 vs 27.90 kg/m²) and no significant difference in SHR (*P*=.79; Table S5 in Multimedia Appendix 1).

Relationship Between SHR and Parameters Related to Sepsis Diagnosis

Figures S2 and S3 in Multimedia Appendix 1 illustrate the relationship between SHR and markers of sepsis. The association between SHR and antibiotic use (defined as administration during the entire ICU stay) was assessed using the point-biserial correlation coefficient, yielding a weak negative correlation ($r=-0.196$). The Mann-Whitney *U* test further confirmed a difference (*P*<.001). In contrast, the linear relationship between SHR and SOFA score was evaluated using Spearman correlation and was not statistically significant ($r=0.056$; *P*=.05).

Clinical Outcomes According to SHR Levels

In this study, sepsis occurred in 162 (13.4%) patients with HF, among whom, the Q4 (SHR >1.3177) exhibited the highest sepsis occurrence at 17.3%, thus being chosen as the reference group, and Q1 to Q4 showed progressively higher risks (9.6% vs 11.3% vs 15.6% vs 17.3%). Notably, the Q4 group exhibited a significantly higher mortality rate of 17.3% (52/301) and a

XSL•FO
RenderX

composite outcome rate of 34.2% (103/301) compared with all other groups (both *P*<.001; S6 in Multimedia Appendix 1).

The Kaplan-Meier curves illustrated that patients with the highest SHR (Q4) exhibited the highest 7-day all-cause mortality across different SHR levels (*P*=.02; log-rank *P*<.001; Figure S4 in Multimedia Appendix 1). Specifically, although the association was nonsignificant in the diabetes subgroup (*P*=.17) and the nondiabetes subgroup (*P*=.07), the Q4 had relatively the highest 7-day all-cause mortality in the diabetes subgroup, while in the nondiabetes subgroup, patients in Q3 and Q4 groups had higher 7-day all-cause mortality than other groups (Figures S5 and S6 in Multimedia Appendix 1).

Association of SHR Index With Sepsis Occurrence

To explore the independent relationship of SHR index with the occurrence of sepsis, we constructed 3 Cox regression models (Table 2), and significant values were all found in models 1 - 3. When SHR emerged as a continuous variable, in the fully adjusted model 3, per 1-unit higher SHR index was associated with an 18% higher risk of sepsis occurrence (HR 1.18, 95% CI 1.01 - 1.38; *P*=.04). Additionally, similar trends were observed when patients were grouped according to quartiles of the SHR index. Taking the highest quartile of the SHR index (Q4) as the reference, the occurrence risk of sepsis in other groups showed a gradual upward trend of Q1 <Q2 <Q4 (HR 0.52, 95% CI 0.32 - 0.82; *P*=.005 vs HR 0.62, 95% CI 0.40 - 0.97; *P*=.04), while compared to Q4, Q3 showed no significant difference (HR 0.96, 95% CI 0.65 - 1.43; *P*=.85), indicating a dose-response relationship between SHR levels and sepsis risk. However, the trend test indicated a significant upward trend in sepsis risk with increasing quartiles (*P* for trends=.001).

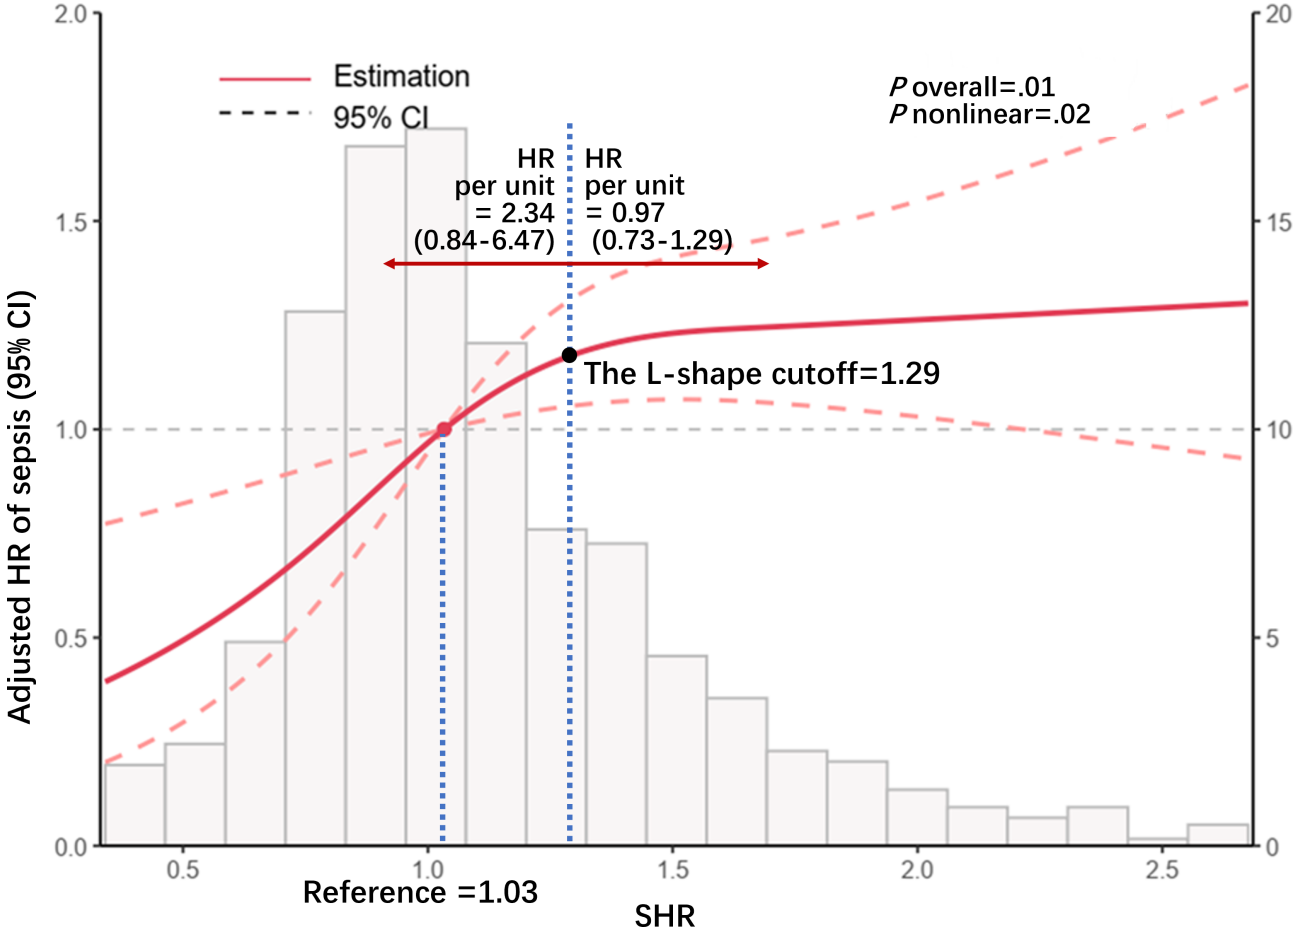
[a]Multivariable Cox proportional hazards regression model evaluating the association between the SHR (both as a continuous variable and by quartiles) and the risk of sepsis within 7 days of intensive care unit admission among 1205 critically ill patients with heart failure. Data were derived from the Medical Information Mart for Intensive Care-IV database (Boston, MA, United States; 2008 - 2022).

[b]Model 1: unadjusted.

[c]Model 2: adjusted for sex, age, and BMI.

[d]Model 3: adjusted for sex, age, BMI, acute heart failure, diabetes, shock, Sequential Organ Failure Assessment score, antibiotic use, insulin use, and glucocorticoid use.

[e]HR: hazard ratio.



[f]Not available.

The interaction analysis between SHR and diabetes was statistically significant (HR 1.96, 95% CI 1.23 - 3.14; *P*=.005), indicating that the association between SHR and sepsis was stronger in patients with diabetes. Similarly, a significant interaction was also observed with insulin use (HR 0.48, 95% CI 0.30 - 0.77; *P*=.002), whereas interactions with BMI (both continuous and categorized) were not statistically significant (*P*=.17 and *P*=.07, respectively; Table S7 in Multimedia Appendix 1).

Additionally, multivariable adjusted RCS analysis was used to provide a comprehensive examination of the continuous relationship between SHR and the occurrence of sepsis. Relationship showed a nonlinear saturation effect as SHR increased, with the specific turning point of 1.29 (*P* for nonlinearity=.02; Figure 2). Specifically, sepsis risk increased steeply with SHR up to 1.29, after which the risk curve plateaued.

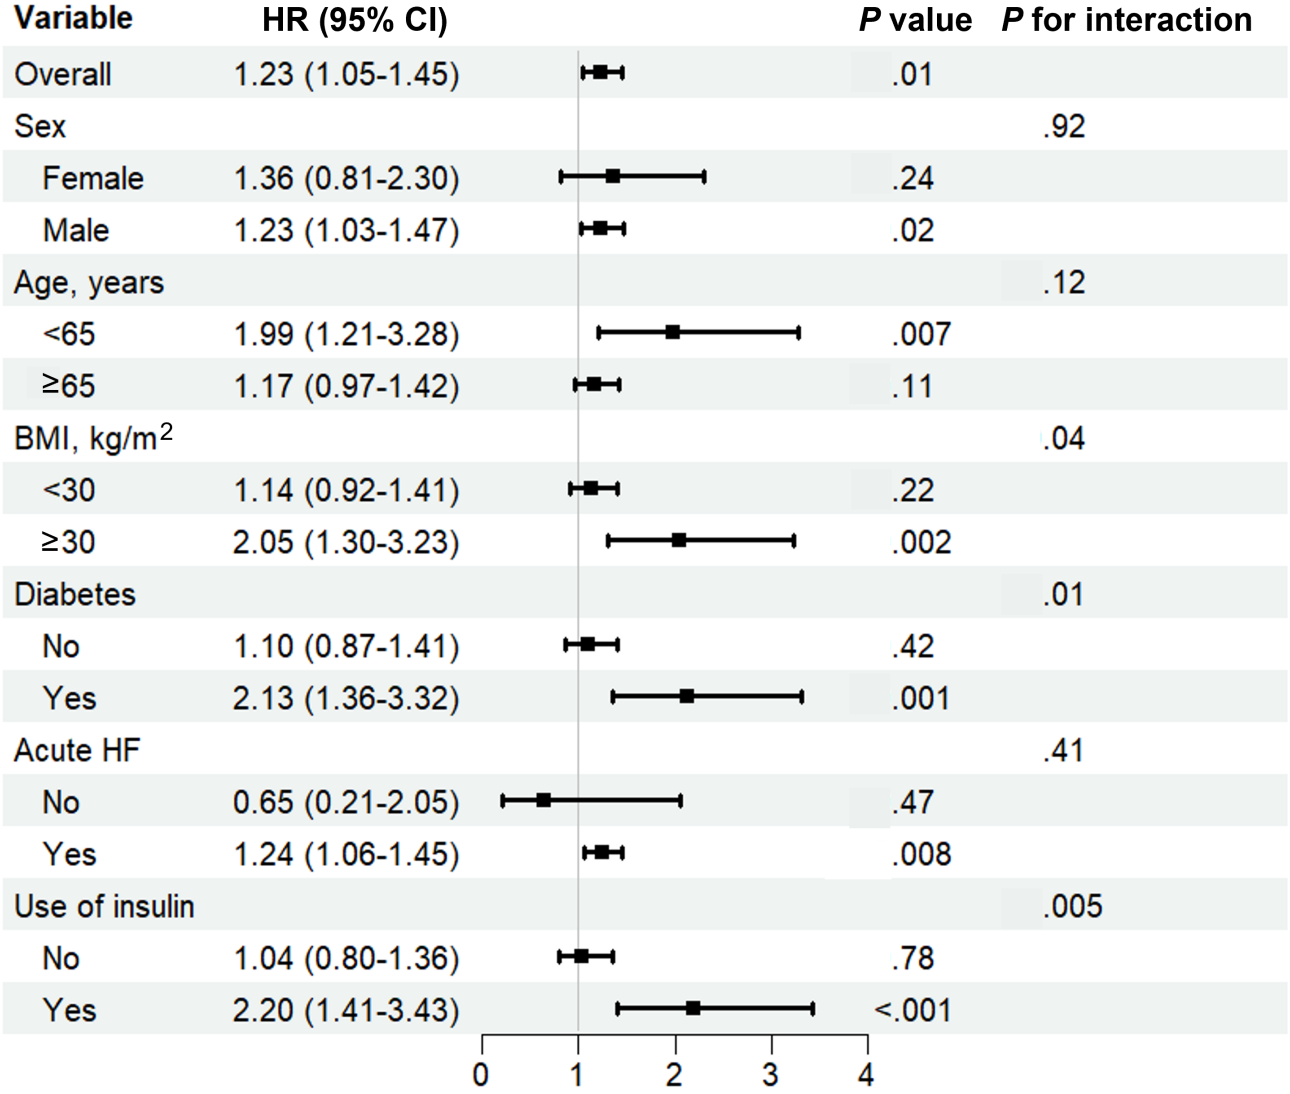
RenderX

Figure 2. Restricted cubic spline analysis of the association between SHR and 7-day sepsis risk. Restricted cubic spline curve depicting the dose-response relationship between the SHR (as a continuous variable) and the adjusted HR for 7-day sepsis occurrence among 1205 critically ill patients with heart failure. Data were derived from the MIMIC-IV database (Boston, MA, United States; 2008 - 2022). The model was adjusted for sex, age, BMI, acute heart failure, diabetes, shock, Sequential Organ Failure Assessment score, antibiotic use, insulin use, and glucocorticoid use. The curve demonstrates a nonlinear saturation effect, with an inflection point at SHR=1.29 (*P* for nonlinearity=.02). The horizontal dashed line represents an HR of 1.0. The shaded area represents the 95% CI. HR: hazard ratio; MIMIC-IV: Medical Information Mart for Intensive Care-IV; SHR: stress hyperglycemia ratio.



Subgroup Analysis

Subsequently, the subgroup analyses were stratified by sex (male and female), age (<65 and ≥65 years), BMI (<30 and ≥30 kg/m^2), diabetes (yes and no), acute HF (yes and no), and insulin use (yes and no). No significant interactions were observed for sex, age, or acute HF subgroups (*P* for interaction>.05). Notably, significant interactions were detected between SHR and BMI (*P*=.04), diabetes (*P*=.01), and insulin use (*P*=.005; Figure 3), thus prompting further RCS analyses within these subgroups. Results indicated that in the subgroups with diabetes, insulin use, and BMI ≥30 kg/m^2, a linear association was observed between SHR and sepsis incidence (all *P* overall<.05; *P* nonlinear>.05). In contrast, a U-shaped relationship was identified in the subgroup with BMI <30 kg/m^2, with the inflection point at 1.03 (*P* overall=.01; *P* nonlinear=.09). No significant associations were found in the remaining subgroups (*P* overall>.05; Figures S7-S9 in Multimedia Appendix 1).

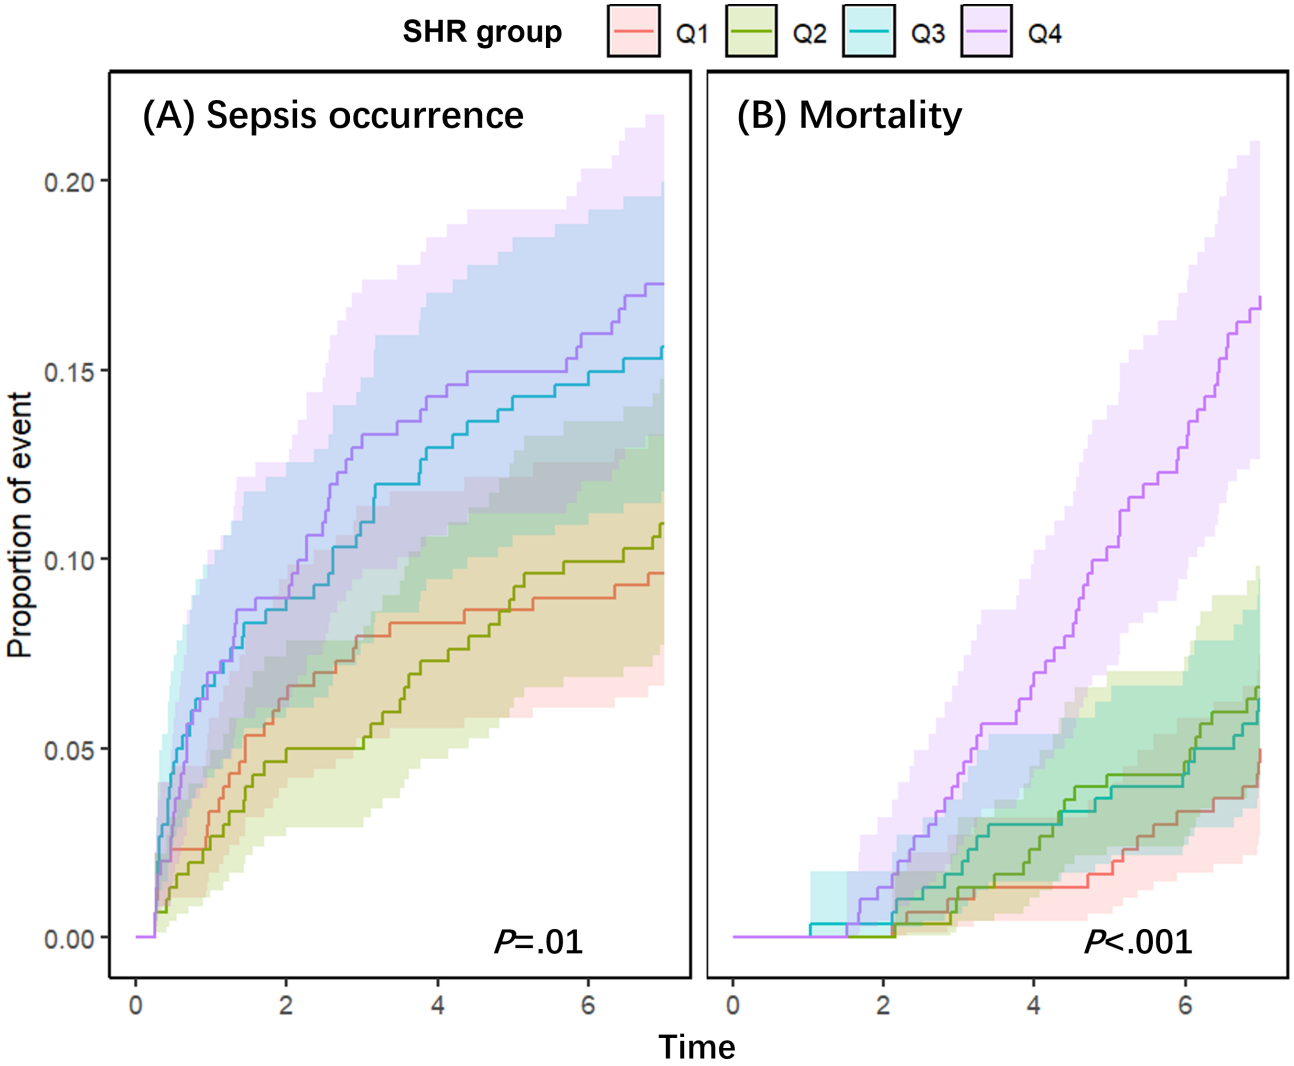
Figure 3. Subgroup analysis forest plot. Forest plot summarizing subgroup analyses of the association between the stress hyperglycemia ratio (as a continuous variable) and 7-day sepsis risk among 1205 critically ill patients with HF. Data were derived from the MIMIC-IV database (Boston, MA, United States; 2008 - 2022). Subgroups were stratified by sex, age (<65 vs ≥65 years), BMI (<30 vs ≥30 kg/m^2), diabetes status, acute HF, and insulin use. HRs and 95% CIs were adjusted for sex, age, BMI, acute HF, diabetes, and insulin use. *P* values for interaction are displayed to assess effect modification. HF: heart failure; HR: hazard ratio; MIMIC-IV: Medical Information Mart for Intensive Care-IV.



Sensitivity Analyses

We performed different sensitivity tests to validate the robustness of our results. First, considering 7-day all-cause mortality as a competing event, the Fine-Gray competing risk model was used. In the univariable-adjusted Fine-Gray model, the cumulative occurrence of sepsis increased from Q1 to Q4 (*P*=.01), maintaining significance even when accounting for the competing risk of all-cause mortality (*P*<.001; Figure 4).

XSL•FO
RenderX

Figure 4. Cumulative incidence curves from Fine-Gray competing risk models, illustrating the impact of SHR quartiles on (A) the cumulative incidence of sepsis within 7 days and (B) the cumulative incidence of 7-day all-cause mortality, with each considered a competing event for the other. The analysis is based on a retrospective cohort of 1205 critically ill patients with heart failure from the MIMIC-IV database (Boston, MA, United States; 2008-2022). SHR quartiles: Q1 (<0.849); Q2 (0.849 - 1.033); Q3 (1.033 - 1.318); Q4 (>1.318). MIMIC-IV: Medical Information Mart for Intensive Care-IV; SHR: stress hyperglycemia ratio.

In the multivariable-adjusted Fine-Gray model, SHR, as a categorical variable (quartiles), revealed a significant overall difference in sepsis incidence across groups (*P*=.01). When modeled as a continuous variable in the fully adjusted model, the association was positive but not statistically significant (HR 1.18, 95% CI 0.96 - 1.44; *P*=.11). There was a significant positive trend in sepsis risk across increasing SHR quartiles, indicating a dose-response relationship (*P* for trend<.001 in the fully adjusted model; Table S8 in Multimedia Appendix 1).

Second, the logistic regression was also made to show a significant positive association between SHR and sepsis risk (model 3: odds ratio 1.03, 95% CI 1.01 - 1.05; *P*<.001), with sepsis risk increasing significantly across SHR quartiles (*P* for trend <.001; Table S9 in Multimedia Appendix 1).

Third, when the sepsis exclusion window was extended to 12, 24, 36, and 48 hours, the overall association remained consistent. However, the association was not significant when the exposure was modeled continuously in the fully adjusted model (all *P*>.05; Table S10 in Multimedia Appendix 1).

Mediation Analysis

Table 3 shows the mediation value of inflammatory indices between SHR and sepsis occurrence.

NMLR[l]	807	1.03 (1.00 to 1.09)	.04	1.93 (1.23 to 2.98)	.004	0.06 (0.00 to 0.23)	.04	1.99 (1.28 to 3.04)	<.001

[a]Mediation analysis estimating the ACMEs, ADEs, PM, and TEs of systemic inflammatory indices in the association between the stress hyperglycemia ratio and 7-day sepsis occurrence. Analysis was performed among 807 patients with complete inflammatory biomarker data from the Medical Information Mart for Intensive Care-IV database (Boston, MA, United States; 2008 - 2022). Estimates were derived from a fully adjusted Cox regression model using 1000 bootstrap resamplings. The mediation effects presented in the table are estimated based on the fully adjusted model, which accounts for adjustments including sex, age, BMI, acute heart failure, diabetes, shock, Sequential Organ Failure Assessment score, antibiotic use, insulin use, and glucocorticoid use.

[b]ACME: average causal mediation effect (indirect effect).

[c]ADE: average direct effect.

[d]PE: proportion mediated.

[e]TE: total effect.

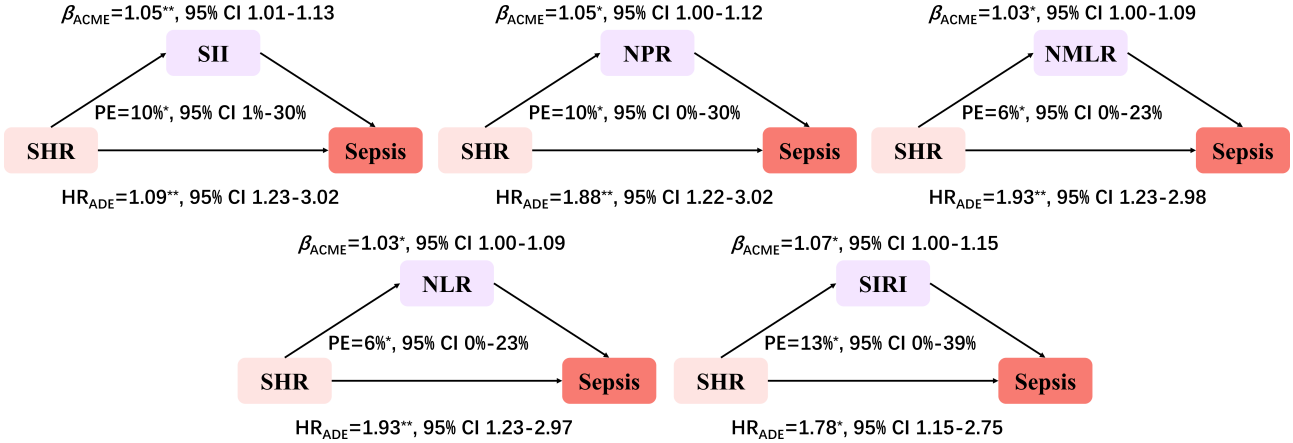
[f]SII: systemic immune-inflammation index.

[g]NLR: neutrophil-to-lymphocyte ratio.

[h]PLR: platelet-to-lymphocyte ratio.

[i]MLR: monocyte-to-lymphocyte ratio.

[j]NPR: neutrophil-to-platelet ratio.



[k]SIRI: systemic inflammation response index.

[l]NMLR: neutrophil-monocyte-to-lymphocyte ratio.

The mediation analysis indicates that, for the general population, the estimated proportions of the association mediated by NLR, NPR, NMLR, SIRI, and SII were 6% (95% CI 0.00% - 23%), 10% (95% CI 0.00% - 30%), 6% (95% CI 0.00% - 23%), 13% (95% CI 0.00% - 39%), and 10% (95% CI 1% - 30%), respectively (Figure 5).

XSL•FO
RenderX

Figure 5. Mediation analysis (adjusted for sex, age, BMI, acute heart failure, diabetes, shock, Sequential Organ Failure Assessment score, antibiotic use, insulin use, and glucocorticoid use). ACME: average causal mediation effect; ADE: average direct effect; HR: hazard ratio; NLR: neutrophil-to-lymphocyte ratio; NMLR: neutrophil-monocyte-to-lymphocyte ratio; NPR: neutrophil-to-platelet ratio; PE: proportion mediated; SHR: stress hyperglycemia ratio; SII: systemic immune-inflammation index; SIRI: systemic inflammation response index. *P<.05; **P≤.01.

For the diabetes subpopulation, no significant exposure mediator interaction effects were observed (all P>.05; Table S11 in Multimedia Appendix 1). Additionally, mediation analysis in the nondiabetic subgroup was underpowered due to limited sample size, resulting in unstable estimates with wide CIs (Table S12 in Multimedia Appendix 1).

Discussion

Principal Findings

In this study, we first demonstrated that a higher SHR was significantly associated with a higher risk of sepsis occurrence after fully adjusting for potential confounders in critically ill patients with HF based on the MIMIC-IV database, with an evidently positive linear relationship in the diabetes and BMI ≥30 kg/m^2 subgroup. The association between SHR and sepsis occurrence in the RCS analysis after adjusting confounders further showed a nonlinear pattern, where risk increased up to an SHR threshold (1.29) and then plateaued. Furthermore, systemic inflammatory indices partially mediated this relationship, implicating inflammation as a potential mechanistic link.

Comparison to Prior Work

The concept of SHR highlights a relative acute rise in glycemia compared to the individual's previous glycemic status in response to a stress reaction or critical illness [11], which was triggered by the release of stress hormones (eg, adrenaline and cortisol), immune responses, neural activity, and insulin resistance [28].

Extensive research has shown that SHR was associated with adverse outcomes across various diseases. Consistent with our findings, elevated SHR has been linked to poorer prognosis in patients with acute coronary syndrome [12], acute HF [13], and sepsis [14,29,30]. However, while several studies have demonstrated a U-shaped association between SHR and mortality in various cardiovascular and metabolic diseases, including HF [13], acute myocardial infarction [31], and cardiovascular-kidney-metabolic syndrome [32], the relationship between SHR and the occurrence of sepsis in critically ill patients with HF remains underexplored. Our study revealed a positive, nonlinear saturation effect between SHR and sepsis occurrence in critically ill patients with HF. However, a U-shaped association between SHR and the occurrence of acute kidney injury in patients with congestive heart failure was observed in a study by Li et al [33], which contrasts with our finding of a plateauing effect. This discrepancy may be attributable to differences in the outcomes studied (sepsis vs acute kidney injury) and the competing risk of early mortality in patients with extreme SHR values, which was addressed in our sensitivity analyses using the Fine-Gray model.

The steep increase in risk below the SHR threshold of 1.29 in our study underscores a dose-dependent hazard, which likely reflects the cumulative, detrimental effects of acute hyperglycemia on immune dysfunction [8,9] and endothelial activation [34], making patients progressively more susceptible to infection. Several biological mechanisms may explain this association. First, critical illness activates the hypothalamic-pituitary-adrenal axis, leading to stress hyperglycemia [28], which impairs immune responses such as adhesion, chemotaxis, phagocytosis, and bacterial killing by immune cells [8], thus increasing susceptibility to infection. Second, stress hyperglycemia may cause endothelial dysfunction by increasing mitochondrial reactive oxygen species production [9], leading to upregulation of adhesion molecules and enhanced leukocyte recruitment [34], thereby amplifying the inflammatory cascade. Finally, hyperglycemia-driven reactive oxygen species generation can cause myocardial inflammation and dysfunction [35], worsening HF and indirectly elevating sepsis risk.

Our subgroup analyses further revealed that the association between SHR and sepsis was significantly modified by diabetes mellitus, BMI, and insulin use. RCS analysis showed a nonlinear saturation effect in the overall population, which was consistent in the diabetic subgroup. Specifically, in the diabetic subgroup, as SHR increased, the risk of sepsis increased linearly, a finding that aligns with previous studies, demonstrating that the long-term hyperglycemic state of patients with diabetes impairs immune cell function, including adhesion, chemotaxis, phagocytosis, and bacterial killing, thereby increasing susceptibility to sepsis [10,36]. The resulting chronic low-grade

XSL•FO
RenderX

inflammation and vascular endothelial activation, typical in diabetes, also overlap with sepsis pathology [14,29], explaining why patients with HF and diabetes exhibited higher sepsis occurrence in our study.

While there is no definitive research to explain the risk plateau after SHR exceeds 1.29, we hypothesize the following potential factors. First, there is a significant competing risk of early mortality, given that patients with the highest SHR had the greatest 7-day mortality, potentially precluding the diagnosis of sepsis. Second, these patients likely receive more aggressive clinical management (eg, insulin therapy and broader-spectrum antibiotics), which may attenuate the observable sepsis risk. Therefore, an SHR >1.29 might be a stronger indicator of overall critical illness severity and metabolic derangement.

After adjusting for 7-day mortality as a competing event using the Fine-Gray model, SHR remained independently associated with an increased risk of sepsis. The subsequent sensitivity analysis further corroborated this finding, confirming the robustness of our results. Specifically, although the association was nonsignificant in the diabetes subgroup and nondiabetes subgroup when examined separately, the Q4 had the relatively highest 7-day all-cause mortality in the diabetes subgroup, while in the nondiabetes subgroup, patients in Q3 and Q4 groups had higher 7-day all-cause mortality than other groups.

Additionally, our study is the first to explore the mediating role of systemic inflammation in the SHR-sepsis association. We found that NLR, NPR, NMLR, SIRI, and SII significantly mediated this relationship, with mediation proportions ranging from 6% to 13%. This provides a new prospective between the proinflammatory effects of hyperglycemia [21,37-39] and the pathogenesis of sepsis [40], offering a mechanistic insight that has not been previously reported in this specific population. The potential mechanisms might be as follows: SHR underscores an individual's acute glycemic response to stress, and the increased blood glucose further promotes monocyte and macrophage aggregation, leading to the release of additional proinflammatory cytokines [37-39], which contributes to inflammation, tissue damage, and impaired immune function.

Sepsis is a systemic inflammatory response syndrome caused by infection [3], wherein monocytes, neutrophils, and other innate immune cells release proinflammatory cytokines to induce infection [40]. Therefore, comprehensive inflammation indices might have certain mediation value for sepsis onset and prognosis, which is consistent with our findings. Chronic hyperglycemia in patients with diabetes may lead to adaptive changes in insulin signaling and glucose transporter expression, which can attenuate the acute inflammatory response [41]. Moreover, hospitalized individuals with diabetes typically receive stricter glucose management, potentially mitigating the detrimental impact of stress-induced hyperglycemia on sepsis risk and obscuring the role of inflammation mediation [42].

From a clinical perspective, these findings highlight that even moderate elevations in SHR (well below 1.29) might carry increased risk for sepsis, thus suggesting that it could serve as a dynamic and sensitive marker for early risk stratification. The identified threshold of 1.29 could serve as a practical tool for sepsis risk stratification, enabling earlier identification of high-risk patients for intensified monitoring and early treatment intervention based on this cutoff. From a public health perspective, SHR offers a low-cost, accessible biomarker for risk stratification, particularly in resource-limited settings. The finding that inflammatory indices mediate this relationship suggests that anti-inflammatory strategies, alongside strict glycemic control, might be beneficial in mitigating sepsis risk in this vulnerable population.

Limitations
