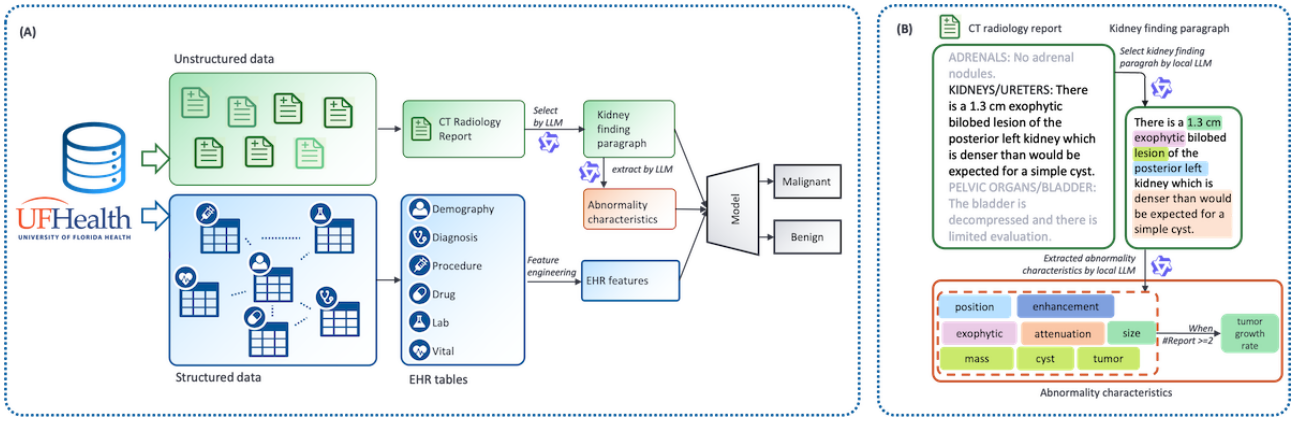
Cross-sectional imaging, particularly computed tomography (CT), plays a central role in the diagnosis and management of renal masses, and many imaging-based models (eg, radiomics or deep learning) have demonstrated promising predictive capabilities. For example, deep learning models applied to preoperative CT imaging have achieved the area under the receiver operating characteristic curve (AUC) of up to 0.87 in differentiating benign from malignant tumors [7-10], and up to approximately 0.86 in predicting RCC subtypes [11]. Prognostic models for Stage, Size, Grade, and Necrosis scores or survival outcomes have also shown concordance indices between 0.75 and 0.84 [12,13]. However, these approaches typically require access to raw imaging data and specialized computational infrastructure, limiting scalability in resource-constrained health care settings.

In contrast, electronic health records (EHRs) are widely available and contain rich, routinely collected data, such as demographics, comorbidities, medication histories, and clinical notes (eg, pathology reports and radiology reports), which can be harnessed to develop predictive models. Structured EHR data captures known RCC risk factors (eg, BMI, smoking history, cardiovascular disease, and diabetes) [14], and has been successfully used in risk stratification for various diseases [15,16]. Thus, incorporating EHR data into renal tumor prediction models offers a scalable, cost-effective alternative to image-based approaches.



While structured EHR data offers important clinical information, approximately 80% of health care information remains unstructured, such as narrative texts, images, and signals [17]. Tumor-specific details (eg, size, texture, and imaging descriptors) are often embedded in radiology reports rather than structured fields. In response, researchers have used natural language processing (NLP) techniques to extract granular tumor characteristics from free-text clinical documentation [18,19]. Rule-based NLP frameworks have demonstrated efficacy in retrieving tumor-related information from unstructured texts [20,21]; however, these approaches typically necessitate labor-intensive development, including manual rule crafting and domain-specific engineering, which constrains their scalability and cross-institutional applicability. In contrast, large language models (LLMs), such as GPT-4 [22] and LLaMA-2 [23], offer improved adaptability and scalability due to their deep contextual understanding acquired through extensive pretraining. Empirical evidence indicates that LLMs can extract structured oncologic information from narrative radiologic and pathologic reports with minimal manual intervention [24-28].

Building upon these advances, recent studies have explored the multimodal integration of structured EHR data with unstructured textual and imaging features to improve predictive modeling, particularly in oncology [29,30]. For example, Xi et al [31] developed a deep learning framework that combined routine magnetic resonance imaging with structured clinical variables to differentiate benign from malignant renal lesions. Similarly, Xu et al [32] integrated clinical data with radiomic features derived from CT to support tumor classification. In parallel, combining NLP-processed clinical narratives with structured data has been shown to boost predictive performance across diverse medical domains [33-35]. Although research specifically targeting renal tumors is still limited, evidence from related applications suggests strong translational potential.

In this study, we developed a multimodal pipeline that integrates structured EHR data with features extracted from unstructured radiology reports. An LLM was used to extract abnormality descriptors from free-text narratives, and additional engineered features were derived from tabular EHR data. Each information stream, structured clinical variables, kidney-specific findings, and abnormality characteristics, was encoded via a specialized architecture: Bidirectional Encoder Representations from Transformers (BERT) processed the textual kidney-related observations, while a multilayer perceptron (MLP) handled the structured clinical variables and engineered abnormality characteristics. The resulting embeddings were then combined through a fusion strategy designed to evaluate whether multimodal integration could enhance descriptive model performance for renal tumor prediction. Importantly, integrating structured and unstructured data not only enhances model performance but also enables the creation of more comprehensive patient profiles that could support more individualized assessment and better-informed clinical decisions. An overview of the pipeline is shown in Figure 1A.

Methods

Data Sources and Cohort Definition

Data were obtained from the University of Florida Health Integrated Data Repository, which houses its clinical content in the Observational Medical Outcomes Partnership Common Data Model. The structured dataset included demographics, diagnoses, medications, procedures, and laboratory results, while unstructured data comprised CT radiology report narratives. We retrospectively identified over 60,000 patients with renal-related conditions observed from December 2011 to August 2024. The study cohort included patients who met all of the following criteria: (1) had at least 2 distinct renal tumor diagnoses, recorded at different time points, based on *ICD* (*International Classification of Diseases*) codes, with the earliest diagnosis designated as the index date; (2) experienced at most 1 change in tumor classification (benign to malignant or malignant to benign), with the final status serving as the outcome label (patients with multiple reversals were excluded); and (3) had at least 1 renal CT report dated before the index date. A schematic illustrating the temporal ordering of imaging, diagnosis, outcome labeling, and surgical intervention is provided in Figure S9 in Multimedia Appendix 1.

Outcome Definition and Sensitivity Analyses

Benign vs malignant tumor status was derived from longitudinal EHR diagnosis codes, as pathology reports were not uniformly available. Patients were classified as benign or malignant if they had at least 2 corresponding *ICD* diagnosis codes recorded on distinct dates, with the final observed status used as the outcome label. To reduce label instability, patients with multiple benign-malignant reversals were excluded, and a 1-direction transition rule was applied.

To assess the robustness of the *ICD*-based outcome definition, sensitivity analyses were conducted in patient subsets with higher-specificity reference signals. These included (1) a pathology-confirmed subset identified from unstructured surgical pathology reports and (2) a nephrectomy subset, in which renal tumor diagnosis codes recorded after surgery were used as proxy reference labels. These analyses were used to evaluate the consistency of outcome labeling under more stringent definitions.

Data Preprocessing

We integrated structured EHR data with CT radiology report analyses to generate three feature sets for modeling: (1) structured EHR variables; (2) kidney-specific findings extracted from radiology reports; and (3) tumor characteristics derived from these findings. The detailed workflow for feature extraction from radiology reports is shown in Figure 1B.

Structured clinical variables were retrieved from tables containing patient demographics, diagnoses, procedures, medications, vital signs, and laboratory results. The observation window extended from the earliest available record up to the index date. Demographic variables (eg, age, sex, and race/ethnicity) were categorized, diagnoses were mapped using PheWAS (Phenome-Wide Association Study) Phecode groupings [36], and medications were aggregated at the ingredient level using Anatomical Therapeutic Chemical classification codes [37]. For vital signs and laboratory tests, the most recent values preceding the index date were selected. For blood pressure, the highest and lowest systolic and diastolic values recorded on the most recent measurement day were used as continuous summary features. Dialysis procedures were encoded as binary indicators. Categorical features were one-hot encoded, and continuous variables were standardized prior to modeling.

To isolate kidney-specific findings, the most recent radiology report within the observation window was selected. Given that abdominal CT reports often include findings for multiple organs, the LLM Qwen2.5-32B [38] was then used to isolate the paragraph exclusively detailing kidney-specific findings, yielding a consolidated narrative for downstream analysis. The model was hosted on premises to ensure patient confidentiality and maintain data integrity.

Abnormality characteristics were extracted from the kidney-specific narratives using an LLM to capture detailed lesion descriptors absent from structured data. Extracted features included abnormality presence, type (eg, cyst, mass, or tumor), lesion size, anatomical position (eg, left kidney or right kidney), exophytic status, CT attenuation, and contrast enhancement. For patients with multiple preindex renal CT examinations, tumor growth rate was calculated using only lesion size measurements obtained prior to the index date, defined as the earliest recorded renal tumor diagnosis. Specifically, when at

XSL•FO
RenderX

least 2 preindex imaging studies were available, growth rate was computed as the slope of lesion size change (cm per day) between the earliest and latest available preindex imaging studies.

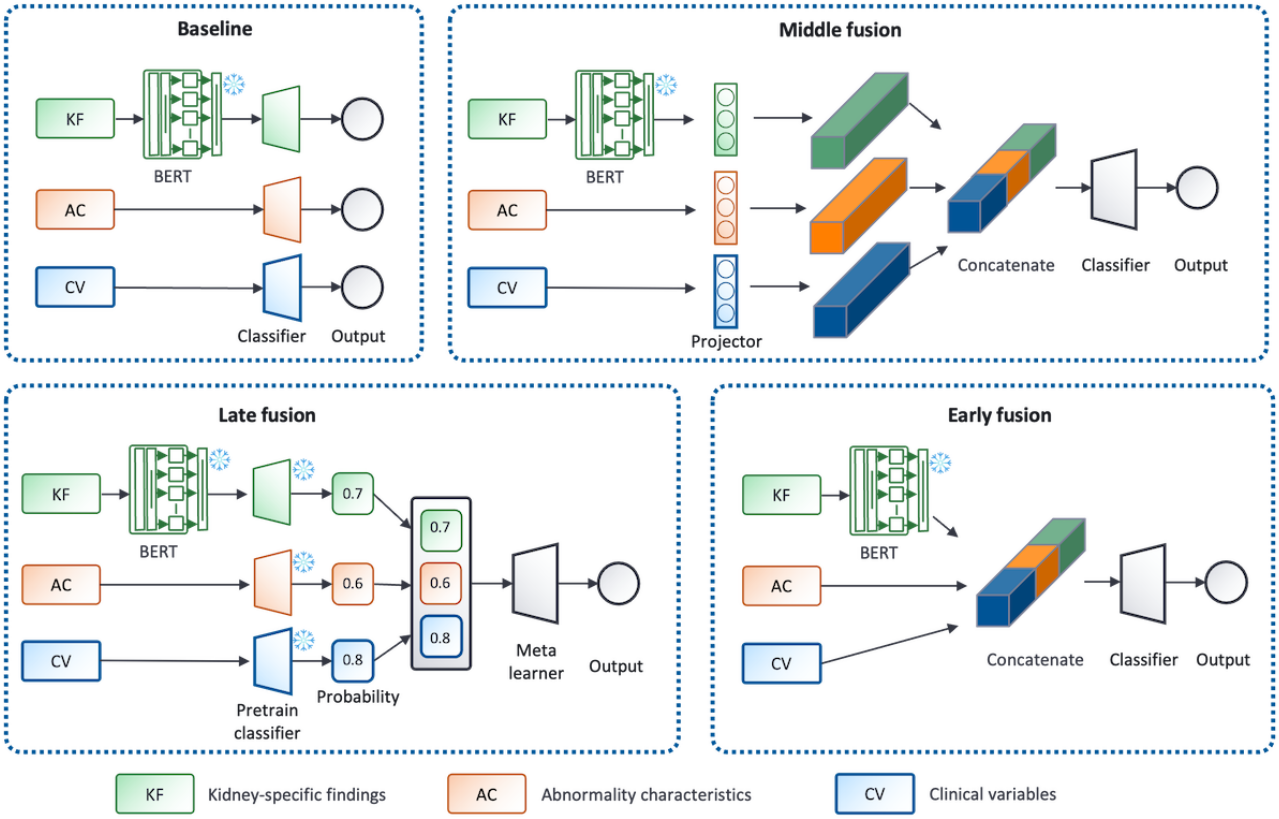
Missing values in structured EHR variables were handled using modality-specific strategies. Before imputation, laboratory variables with greater than 50% missingness were excluded from the structured clinical feature set. Continuous features (ie, laboratory measurements and vital signs) were imputed using mean values calculated from the full cohort, and categorical variables (ie, diagnosis and medication records) were processed via standard presence-absence encoding, with missing entries encoded as 0 (eg, absence of a diagnosis or medication record). For radiology-derived abnormality characteristics, categorical attributes were treated as "unknown" when not explicitly mentioned and encoded as a separate category. Continuous abnormality variables (eg, lesion size and tumor growth rate) were encoded using a 2-part sentinel representation. For cases where size information was unavailable, or where fewer than 2 preindex longitudinal imaging studies were present to compute a growth rate, the numeric value was imputed with a placeholder of zero. This value was paired with a corresponding binary missingness indicator to ensure the model could mathematically distinguish between missing measurements and true physiologic stability (eg, a measured growth rate of zero). Both the numeric placeholder and the binary indicator were included as independent features in the model input. Kidney-specific text findings were encoded using pretrained biomedical transformer models, producing fixed-length embeddings of 768 dimensions. More details can be found in Table S7 in Multimedia Appendix 1.

LLM Extraction Evaluation

To evaluate the performance of LLMs in extracting these abnormality characteristics, we manually annotated 500 independent radiology reports to establish a gold-standard dataset. The gold-standard annotations were created by 2 independent nonexpert annotators with biomedical research training, following detailed annotation guidelines developed in consultation with board-certified radiologists. Annotators independently labeled each of the 500 radiology reports, blinded to model outputs. Interrater reliability was assessed using Cohen κ for each abnormality attribute, with disagreements resolved through consensus discussion guided by a radiologist.

For automated extraction, the pipeline identifies kidney-related sentences, extracts lesions with their attributes as structured entries, validates outputs against a predefined schema, and ranks lesions by severity, prioritizing tumors over masses and cysts, and ordering within categories by size. Four locally deployed LLMs (Qwen2.5-7B [38], Qwen2.5-32B [38], LLaMA3-8B [39], and LLaMA3-70B [39]) were evaluated in inference-only mode under institutional data privacy constraints, without any task-specific model training.

To quantify extraction performance, 2 components of the pipeline were assessed. Kidney-specific paragraph retrieval was evaluated by comparing automatically retrieved paragraphs with manually annotated reference paragraphs using the Bilingual Evaluation Understudy-4 (BLEU-4) metric [40], which measures n-gram overlap between predicted and gold-standard text. Performance was summarized as the average of the BLEU-4 score and the percentage of samples achieving a BLEU-4 score greater than 0.5 across reports. A BLEU-4 score above 0.5 indicates good alignment between predicted and reference text in terms of vocabulary, phrase structure, and semantic content, and was considered acceptable for practical downstream use. Abnormality characteristic extraction was evaluated by computing per-attribute accuracy based on an exact match between model outputs and gold-standard annotations. All performance metrics were calculated on the same set of 500 annotated radiology reports.



Modeling Approach and Fusion Strategies

Overview

To integrate the 3 feature modalities, we implemented and compared 3 fusion strategies: early, intermediate (middle), and late fusion, alongside unimodal baseline models (Figure 2).

XSL•FO
RenderX

Figure 2. Detailed architecture of the multimodal prediction model.

Baseline Models

We independently evaluated structured clinical variables and radiology-derived tumor attributes using a range of machine learning algorithms, including least absolute shrinkage and selection operator regression [41], logistic regression [42], MLP [43], random forest (RF) [44], support vector machine (SVM) [45], and extreme gradient boosting [46]. For narrative kidney-specific findings, 4 pretrained biomedical transformer models (radiology BERT [RadBERT] [47], BERT pretrained on clinical text [ClinicalBERT] [48], biomedical BERT [BioBERT] [49], and BERT pretrained on PubMed text [PubMedBERT] [50]) were used to generate text embeddings. For structured clinical variables and engineered lesion features, model performance was assessed under different resampling strategies (no resampling, random undersampling, random oversampling) to address class imbalance. For the text modality, the 4 transformer models were directly compared to identify the most effective baseline embedding approach.

Early Fusion

This approach integrates all 3 modalities at the input stage. Kidney-specific findings were first encoded into dense vectors using the best-performing pretrained transformer model selected from the 4 candidates described above. These embeddings were then concatenated with structured clinical variables and radiology-derived tumor attributes to form a combined feature vector, which was classified using a shallow 2-layer MLP. To mitigate overfitting in this high-dimensional space, we used dropout (0.1) after each hidden layer and Adam with decoupled weight decay (AdamW) optimization with weight decay (0.01; excluding bias and LayerNorm weights), providing L2 regularization of trainable parameters.

Middle Fusion

In this architecture, each modality was independently projected into a latent embedding space before being merged and passed through a 2-layer MLP classifier. To evaluate the effect of embedding choice, early and intermediate fusion experiments were repeated using each of the 4 BERT variants. Specifically, modality-specific inputs were compressed into lower-dimensional representations through dedicated projection layers with rectified linear unit activation and dropout (0.1) prior to fusion, thereby reducing dimensionality and mitigating overfitting risk. Training was performed using AdamW optimization with weight decay (0.01; excluding bias and LayerNorm weights) to ensure consistent L2 regularization.

Late Fusion

Predicted probabilities from the unimodal base models were combined using a logistic-regression meta-learner [42]. To avoid bias from in-sample predictions, an out-of-fold (OOF) stacking strategy was applied. After splitting the dataset into an 80% training set and a 20% held-out test set, 5-fold cross-validation was conducted within the training set. Base models generated probabilities only for their validation folds, producing OOF predictions. For each fold, the meta-learner was trained using the concatenated OOF probabilities from the other folds and evaluated on the held-out test set using the corresponding fold-specific test probabilities. This procedure ensured that the meta-learner was trained only on predictions from samples not used to fit the base models.

XSL•FO
RenderX

Model Validation and Performance Metrics

Model performance was assessed using a stratified 80/20 train-test split. The 80% training partition was used for model development with 5-fold cross-validation. In each iteration, 1 fold was used for internal validation, and the remaining 4 folds were used for training. The resulting 5-fold–specific models were each evaluated on the same independent 20% held-out test set, which was not used for training, validation, resampling, or hyperparameter tuning. For the machine learning classifiers, hyperparameters were tuned via grid search, with model selection guided by the minimization of negative log-loss on the validation folds. In parallel, deep neural networks were trained using the AdamW optimizer and a linear learning rate scheduler with an initial warm-up phase, with cross-entropy loss serving as the selection criterion on validation subsets.

The primary evaluation metric was the AUC. Secondary metrics included overall accuracy, balanced accuracy, sensitivity (recall for the malignant class), specificity, precision (positive predictive value), and F_1-score, all reported as the mean and SD across 5-fold–specific models evaluated on the independent held-out test set. Balanced accuracy was included to provide a more representative assessment of the model's discriminative performance beyond class prevalence by equally weighting sensitivity and specificity in the presence of class imbalance. Decision thresholds for probability-based models were determined by maximizing the Youden J statistic. To address class imbalance, we compared 3 approaches: no resampling, random undersampling, and random oversampling. To prevent data leakage, all resampling procedures were performed strictly within the training partition of each cross-validation fold; validation folds and the held-out test set were preserved in their original class distributions.

Interpretability Analyses

We assessed the contribution of each modality to the best-performing multimodal fusion model using 2 complementary approaches.

Kidney-Specific Findings (Text Modality)

We assessed the contribution of individual tokens from the text modality by applying Captum's layer-integrated gradients to the BERT embedding layer of our best-performing multimodal fusion model. First, we encapsulated the pretrained model in a wrapper that returns class-probability outputs via a SoftMax over logits. Using the wrapped model and specifying the BERT word-embedding layer as the attribution target, we computed layer-integrated gradients for each test sample with 50 interpolation steps. For each test sample, we summed the absolute attributions over the embedding dimension to yield a scalar score per token, then merged WordPiece subtokens into full words by concatenating "##" continuations and averaging their scores. We filtered out trivial tokens (length ≤2), retained the top 15 highest-scoring words per sample, and accumulated counts and total scores across the dataset. Dividing total attribution by occurrence count produced an average-importance score for each word. To improve robustness, this analysis was performed for the best model from each of the 5 cross-validation folds; keyword importance scores were then averaged across folds, and the final top-15 keywords were selected based on the aggregated importance ranking.

Abnormality Characteristics and Clinical Variables Feature Analysis

To disentangle and measure the respective contributions of abnormality characteristics and clinical variables to the fusion model's outputs, we developed 2 dedicated input filters that retain only 1 modality at a time while nullifying all others and applied a gradient-based Shapley value explainer with a randomly selected reference set of up to 100 background samples. For each held-out sample, we computed local attributions for the positive class and derived the mean absolute contribution of each feature across the test cohort, thereby identifying the 15 most influential attributes. These results were summarized using a concise bar chart of mean absolute attributions and a beeswarm plot illustrating the polarity and variability of each feature's contribution.

Ethical Considerations

The study has been approved, and the requirement to obtain any informed consent has been waived by the University of Florida Institutional Review Board (protocol number IRB202100401). The research does not involve greater than minimal risk for participation. Analyses only involve the secondary analysis of data that are either limited data sets or deidentified. Our research team has no direct contact with human subjects. All methods were carried out in accordance with relevant guidelines and regulations.

Results

Cohort Characteristics

A total of 967 patients with renal tumors met the inclusion criteria. The mean age at initial diagnosis, whether benign or malignant, was 69 (SD 12.93) years, with approximately 60% of the cohort being male. Among these patients, 712 (73.6%) were diagnosed with malignant tumors. Comorbidities were common: over 90% (874/967) had disorders of the kidney and ureters, and 74% (719/967) had a documented history of hypertension. Smoking was reported in 15.51% (150/967) of patients, and the mean BMI was 30.07 (SD 7.08). Detailed baseline characteristics and comorbidity profiles are summarized in Table S1 in Multimedia Appendix 1. The median observation period was 34.43 (IQR 8.53-73.92) months. Surgical intervention was performed in 401 patients (41.47% of the cohort). Among these, 294 (30.40%) patients underwent partial nephrectomy and 250 (25.85%) patients underwent radical nephrectomy; 143 (14.79%) patients received both procedures. Tumor growth rate was available for 22.2% (215/967) of patients, reflecting those with at least 2 preindex surveillance CT examinations; the remaining cases were treated as missing for this feature.

Sensitivity Analyses for Outcome Definition

Surgical pathology reports containing renal tumor–related diagnostic statements were available for 89 patients (from 97 reports), of whom 81 (91.0%) were classified as malignant based on pathology text. In this pathology-confirmed subset, the

XSL•FO
RenderX

primary *ICD*-based outcome labels were fully concordant with pathology-derived malignancy status. In addition, 401 patients underwent nephrectomy, and among the 383 with postprocedure renal tumor diagnosis codes, 347 (90.6%) were malignant; outcome labels derived from *ICD* codes were fully concordant with postnephrectomy diagnostic coding.

LLM Extraction Evaluation

Interrater reliability for the manually annotated gold-standard dataset was substantial to near-perfect across abnormality attributes (Cohen κ=0.95-1.00) (Table S10 in Multimedia Appendix 1). Table 1 summarizes the performance of LLMs in kidney-specific paragraph retrieval and abnormality characteristic extraction from radiology reports. As shown in Table 1, Qwen2.5-32B and LLaMA3-70B demonstrated comparable performance in abnormality characteristic extraction. For kidney-specific paragraph retrieval, both models achieved high BLEU-4 scores, with more than 95% (475/500) of reports exceeding a BLEU-4 threshold of 0.5, indicating accurate identification of the relevant anatomical sections. However, accuracy alone does not adequately reflect model usability. Qwen2.5-7B and LLaMA3-8B failed to extract 10.4% (52/500) and 18.2% (91/500) cases, respectively, despite repeated attempts. Additionally, the standard LLaMA3 release was limited by its 8192-token context window, which hindered few-shot prompting with multiple examples. In contrast, Qwen2.5-32B demonstrated more reliable kidney-specific paragraph retrieval across long, heterogeneous radiology reports and supported stable local deployment under institutional data-privacy constraints. Considering paragraph retrieval fidelity, abnormality extraction accuracy, and robustness, Qwen2.5-32B was selected as the primary model for downstream lesion feature extraction.

Table 1. Performance comparison of large language models for kidney-specific paragraph retrieval and abnormality characteristic extraction from radiology reports.

	Qwen2.5-7B	Qwen2.5-32B	LLaMA3-8B	LLaMA3-70B
Kidney-specific findings

Modeling Results

The consolidated performance results for all modeling approaches are presented in Table 2. Table 2 reports performance on the independent 20% held-out test set. Values are summarized as mean and SD across 5-fold–specific models, each trained during cross-validation within the 80% training partition and then evaluated on the same held-out test set. In the unimodal analyses, the SVM model applied to structured clinical variables achieved the highest descriptive AUC among the 6 traditional algorithms, achieving an AUC of 0.758 and a balanced accuracy of 0.717, whereas the RF model achieved the highest F_1-score (0.833). For the engineered abnormality characteristics, logistic regression led the same set of models with an AUC of 0.716 and an F_1-score of 0.766. Ablation studies comparing undersampling, oversampling, and no-sampling strategies are provided in Table S2 in Multimedia Appendix 1 for the clinical variable models and Table S3 in Multimedia Appendix 1 for the LLM-engineered abnormality characteristic models. Among the 4 medically pretrained BERT variants evaluated on kidney-specific report findings, RadBERT achieved the highest descriptive performance, yielding an AUC of 0.746 and an F_1-score of 0.719. In addition to AUC and F_1-score, balanced accuracy was reported for all models to account for class imbalance (Table 2). Among fusion models, early fusion achieved the highest balanced accuracy (mean 0.775, SD 0.010), followed by late fusion (mean 0.749, SD 0.013), indicating consistent performance across malignant and benign classes rather than dominance by the majority malignant class.

[m]BioBERT: biomedical BERT.
[n]PubMedBERT: BERT pretrained on PubMed text.

Variability across cross-validation folds was observed in some configurations using ClinicalBERT and BioBERT embeddings. Because pretrained transformer embeddings are deterministic for fixed inputs, this variability reflects sensitivity of the downstream fusion classifier to specific training-validation splits in a high-dimensional setting rather than the instability of the embedding models themselves. For example, ClinicalBERT-based early fusion exhibited higher fold-level variance (overall accuracy: mean 0.661, SD 0.226; Table S4 in Multimedia Appendix 1), and BioBERT exhibited variability in middle fusion performance (F_1-score: mean 0.608, SD 0.344; Table S5 in Multimedia Appendix 1), indicating inconsistent fold-level behavior. In contrast, RadBERT-based models

XSL•FO
RenderX

demonstrated notably more stable performance across both early and middle fusion strategies.

Multimodal integration was associated with higher descriptive predictive discrimination than unimodal modeling. The middle fusion framework achieved an AUC of 0.782, which was higher than the best unimodal baseline AUC, while the early fusion configuration reached the highest AUC of 0.813 and the highest F_1-score of 0.809. The late fusion strategy, which combined predicted probabilities from top-performing unimodal models through a meta-learner, yielded a competitive AUC of 0.805, with precision and sensitivity values of 0.902 and 0.722, respectively. These results suggest that integrating structured and unstructured data modalities may provide complementary information for renal tumor malignancy prediction.

Ablation Studies

To quantify the contribution of each data modality, we performed an ablation analysis on each fusion architecture by systematically omitting one modality and measuring the resulting impact on model performance. For the 3 modalities, all pairwise combinations were evaluated and their metrics compared against those obtained using the full 3-modality setup. Detailed results are presented in Table 3. Mean (SD) of each evaluation metric across 5-fold cross-validation is reported. Balanced accuracy was also reported in ablation analyses (Table 3) to ensure that observed performance differences across modality combinations were not driven by class prevalence effects. Input modalities include kidney-specific findings, abnormality characteristics, and clinical variables. Because RadBERT achieved the best overall performance, all ablation results reported in Table 3 are based on models incorporating RadBERT (ie, late fusion combining RadBERT with RF). Ablation analyses for the other 3 BERT variants are provided in Table S4 in Multimedia Appendix 1 (ie, early fusion missing-modality) and Table S5 in Multimedia Appendix 1 (ie, middle fusion missing-modality).

Table 3. Ablation study results: effect of excluding individual modalities on fusion model performance.

Modality	overall accuracy	Balanced accuracy	Sensitivity	Specificity	Precision	F_1-score	AUC[a]

[a]AUC: area under the receiver operating characteristic curve.

[b]AC: abnormality characteristics.

[c]CV: clinical variables.

[d]KF: kidney-specific findings.

In late fusion experiments, all 24 combinations of 6 traditional machine learning classifiers and 4 pretrained BERT models were evaluated. Among these, RadBERT paired with RF emerged as the top-performing configuration (see Table S6 in Multimedia Appendix 1).

Omitting kidney-specific findings led to the greatest performance decline in both middle and late fusion configurations. In contrast, within the early fusion scheme, excluding clinical variables caused the most pronounced drop. Removal of abnormality characteristics had only a modest effect across all 3 fusion strategies, with early and late fusion approaches exhibiting robustness to their absence.

Interpretability Analyses on Fusion Model

Kidney-Specific Findings: Visualization and Interpretation

The interpretability analysis of the text modality revealed distinctive linguistic patterns associated with malignancy predictions. The average contribution scores, computed using layer-integrated gradients, were visualized as a ranked horizontal bar plot (Figure S11 in Multimedia Appendix 1). Each bar

XSL•FO
RenderX

represents a token, and bar length corresponds to the token's mean attribution score toward the model's positive-class predictions (larger values indicate stronger positive contribution). Representative high-impact terms from the kidney-specific findings notes are listed in Table 4. Tokens such as "greater," "irregularly," and "huge" exhibited the highest attribution scores, indicating a strong association with malignancy classification in the multimodal fusion framework.

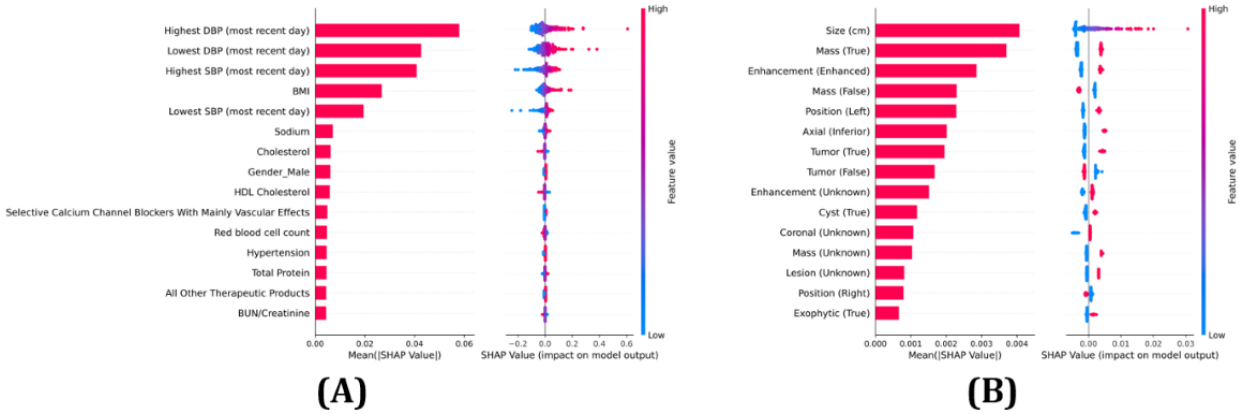

Table 4. Representative words from the kidney-specific findings notes.

Ground truth	Prediction	Kidney-specific findings
Malignant	Malignant	There is a 2.3 cm exophytic lesion on the inferior pole of the *right kidney*, with an attenuation *greater* than expected for simple cyst.
Malignant	Malignant	Within the right kidney posteriorly, there is an *irregularly* enhancing mass measuring approximately 2.7 x 2.7 cm.
Malignant	Malignant	*Huge* left renal mass is again partially *observed*.
Benign	Benign	There are multiple *unchanged* bilateral renal *simple* cysts.

Abnormality Characteristics and Clinical Variables Feature Analysis

For the structured clinical variables, feature importance rankings derived from gradient-based Shapley values (Figure 3A) indicated that diastolic and systolic blood pressures, BMI, along with serum sodium, were the most influential predictors. Among the abnormality characteristics, lesion size demonstrated the highest importance (Figure 3B), followed by the presence of a mass, with enhancement patterns furnishing critical discriminative information for differentiating benign from malignant lesions.

Figure 3. Shapley additive explanations (SHAP) summary plot showing (A) the top 15 clinical variables and (B) the top 15 abnormality characteristics contributing to model prediction. DBP: diastolic blood pressure; HDL: high-density lipoprotein; SBP: systolic blood pressure.

Discussion

Principal Results

Among the unimodal approaches, structured clinical variables showed the highest descriptive predictive performance. Specifically, an SVM classifier with undersampling achieved an AUC of 0.758 (Table 2; Table S2 in Multimedia Appendix 1). By comparison, logistic regression on abnormality characteristics, enhanced via oversampling, yielded an AUC of 0.716 (Table S3 in Multimedia Appendix 1), likely limited by extraction fidelity and feature granularity. Text embeddings from complete paragraph-level kidney-specific findings slightly outperformed the abnormality descriptors, achieving an AUC of 0.746 (Table 2) when encoded with RadBERT [47] (initialized from BioBERT [49] and fine-tuned on radiology reports). PubMedBERT [50], pretrained from scratch on PubMed abstracts and full-text articles, showed comparatively lower performance, likely due to its limited alignment with radiology-report semantics. All 3 multimodal fusion strategies demonstrated higher descriptive AUC values than the unimodal models (Table 2). Early fusion, concatenating feature representations from each modality prior to classification, produced the highest AUC (0.813) and F_1-score (0.809), potentially because it preserves complementary information across modalities. Middle fusion, which first projects each modality into a lower-dimensional latent space, performed slightly worse (AUC 0.782; F_1-score=0.791), possibly due to information loss during dimensionality reduction. Late fusion remained competitive, achieving an AUC of 0.805 and an F_1-score of 0.800, but did not surpass early fusion on any major metric. Overall, these findings indicate that early integration of multimodal information achieved the highest descriptive performance in this study, while late fusion still offered stable and competitive performance through an ensemble-based combination of unimodal predictors.

Although AUC values in the range of 0.8 are insufficient to support automated clinical decision-making, they may offer incremental value for preoperative risk stratification. For patients with indeterminate renal masses, a multimodal model could

XSL•FO
RenderX

complement radiologic interpretation by providing an additional quantitative estimate of malignancy risk to inform multidisciplinary discussion and clinical judgment. Such estimates are not intended to direct specific interventions but rather to contextualize imaging findings and patient characteristics within existing diagnostic workflows. Higher specificity, if confirmed in future validation studies, could potentially help reduce unnecessary interventions for benign lesions, an ongoing challenge in renal mass management. Overall, incremental gains in predictive performance may translate into practical support for clinical risk assessment when used alongside established evaluation processes.

Modality Contributions From Ablation Studies

To assess the contribution of each modality within the fusion architectures, we performed systematic ablation experiments. In the early fusion model, omitting structured clinical variables was associated with the largest decrease in AUC, from 0.813 to 0.755, indicating that clinical variables contributed the strongest predictive signal in this configuration. Removing kidney-specific findings led to a smaller decline in AUC to 0.779, whereas excluding radiologic abnormality characteristics had only a modest effect, with the AUC remaining 0.796. In the middle fusion model, the pattern differed slightly: omitting kidney-specific findings caused the greatest reduction in AUC, from 0.782 to 0.731, while excluding abnormality characteristics or clinical variables resulted in smaller decreases, to 0.749 and 0.747, respectively. In the late fusion model, removing kidney-specific findings caused the largest reduction in AUC, from 0.805 to 0.752, closely followed by omission of clinical variables, which reduced the AUC to 0.758; excluding abnormality characteristics resulted in only a modest decline, with the AUC remaining 0.794. Overall, these ablation results suggest that structured clinical variables were the dominant source of predictive information in the early fusion scheme, whereas kidney-specific text findings contributed most strongly in the middle and late fusion models. Across all 3 fusion strategies, removal of abnormality characteristics produced the smallest or among the smallest performance changes, suggesting that part of the radiologic information captured by these handcrafted features may already be represented in the kidney-specific text embeddings.

Interpretability Insights

Furthermore, we conducted an interpretability analysis on the optimal early fusion model by applying Captum's layer-integrated gradients to the kidney-specific text and Shapley additive explanations (SHAP) values to the abnormality characteristics and clinical variables. As illustrated in the horizontal bar plot visualization (Figure S11 in Multimedia Appendix 1) and exemplified in Table 4, tokens such as "huge," "irregularly," and "greater" attained relatively high integrated gradients attributions, suggesting a stronger contribution to malignancy predictions. This observation is in line with prior imaging research reporting that irregular tumor margins are associated with higher-grade clear cell RCC [51].

Quantitative SHAP analysis of clinical variables (Figure 3A) showed that higher systolic blood pressure, diastolic blood pressure, and BMI were associated with increased predicted probabilities of malignancy. These associations are consistent with previous epidemiological studies: individuals with diastolic pressure ≥100 mm Hg face more than a twofold higher risk of RCC compared to those with <80 mm Hg [52], and a dose-response meta-analysis demonstrates that each 1 kg/m^2 increase in BMI is linked to an approximately 6% higher incidence of KC [53]. For abnormality characteristics (Figure 3B), SHAP analysis identified tumor size as the most influential imaging feature, with contrast - enhancement also contributing meaningfully to the model's predictions. This finding aligns with prior evidence showing that each 1 cm increase in tumor diameter is associated with a ~30% higher likelihood of malignancy (effect size=1.3, 95% CI 1.22-1.43 per cm) [54]. Furthermore, established imaging guidelines indicate that postcontrast attenuation gains greater than 15 Hounsfield units may aid in distinguishing malignant renal lesions [55]. Collectively, these interpretability results suggest that our multimodal fusion framework captures and integrates clinically validated markers across multiple modalities.

Limitations

Despite these findings, several limitations should be acknowledged. First, this was a single-institution study, and no external validation was performed. Consequently, model performance may reflect institution-specific characteristics, including documentation practices, patient populations, and radiology reporting styles unique to our health care system. This is particularly relevant for NLP-based feature extraction, which can be sensitive to local language conventions. Second, the retrospective use of EHR data introduces inherent biases related to incomplete or inaccurately recorded information. Mean imputation was applied strictly to continuous variables, specifically laboratory measurements and vital signs. To reduce instability from extreme sparsity, laboratory variables with greater than 50% missingness were excluded before imputation. However, some retained variables, including cholesterol and high-density lipoprotein cholesterol, had missingness rates close to this threshold and remained subject to mean imputation. The missingness percentages for these variables are reported in Table S8 in Multimedia Appendix 1 to provide transparency regarding the extent of missing data. We acknowledge that this simplified strategy may attenuate physiological variance and fail to preserve correlations between related clinical measures, such as metabolic markers, potentially affecting model calibration, particularly for non–tree-based models used in the fusion strategies. In addition, continuous structured variables were imputed and standardized using cohort-level parameters rather than parameters estimated separately within each cross-validation training fold, which may introduce limited information leakage. Third, ground-truth tumor labels were not uniformly confirmed by surgical pathology. For the unoperated majority of the cohort, outcome labels were derived from longitudinal clinical diagnosis codes that may reflect radiologic interpretation rather than definitive tumor biology. This introduces a risk of diagnostic circularity, where the imaging features used for prediction overlap with those informing clinical labeling. While we mitigated this by requiring repeated concordant codes on distinct dates and performing sensitivity analyses on the pathology-confirmed subset, residual

XSL•FO
RenderX

misclassification and circularity may persist. To further assess potential temporal leakage from treatment-related terminology, we conducted a temporal audit of all radiology reports used for feature extraction. Among 1338 reports, only 17 (1.27%) contained the term "surgically," and none of these patients had nephrectomy or other renal procedural codes recorded prior to the index date, suggesting minimal risk of leakage from completed interventions. However, because explicit diagnostic terminology was not systematically removed from the radiology text, some NLP-derived features may partially reflect radiologists' diagnostic impressions rather than purely morphological descriptors, introducing a potential source of label leakage in the text-derived features. Although the updated interpretability analysis primarily highlighted descriptive terms such as "greater," "irregularly," and "huge," the broader possibility of diagnostic-language leakage remains a limitation of the current approach. Finally, the LLM-based extraction pipeline incurs nontrivial computational requirements. While models were used in inference-only mode, larger architectures like Qwen2.5-32B require high-memory GPU infrastructure for local deployment. Because processing a single radiology report requires several seconds in batch mode, the proposed framework is currently best suited for asynchronous deployment within institutional analytics pipelines rather than real-time clinical use in resource-constrained environments.

Future Work

Future work should focus on validating this multimodal approach across multiple health care institutions using larger and more diverse patient populations to ensure broad applicability. Although internal validation demonstrated consistent performance, multicenter external validation across heterogeneous health care systems is required to assess generalizability prior to clinical implementation. Prospective studies are also needed to evaluate clinical use and real-world effectiveness in live diagnostic workflows. Incorporating more robust missing data handling strategies, such as iterative imputation (eg, Multivariate Imputation by Chained Equations [56]), could more dynamically capture physiological dependencies among continuous clinical variables. Furthermore, integrating longitudinal patient data may allow the model to provide dynamic risk assessments as new clinical information becomes available over time. Additional research could explore deeper integration with imaging modalities, including advanced radiomic features or the direct use of raw imaging data, potentially enhancing diagnostic accuracy. Finally, improving scalability and computational efficiency through model compression techniques or cloud-based solutions could facilitate wider clinical adoption in resource-constrained clinical settings.

Conclusions

This study developed and evaluated a multimodal malignancy prediction pipeline that integrates structured EHR variables with radiology report–derived features, including LLM-extracted abnormality characteristics and transformer-based embeddings of kidney-specific findings. Across systematic comparisons of early, middle, and late fusion, multimodal models achieved higher descriptive performance than unimodal baselines, with early fusion yielding the highest AUC and F_1-score. Ablation and interpretability analyses indicated that structured clinical variables and kidney-specific report embeddings appeared to provide complementary predictive value: clinical variables provided the strongest signal in the early fusion setting, whereas kidney-specific text embeddings contributed most strongly in the middle and late fusion models. Together, these findings suggest that multimodal EHR modeling is a promising and scalable approach for supporting preoperative renal mass risk stratification, although external validation and formal statistical comparisons are needed before claims of superiority or clinical effectiveness can be made.

Acknowledgments

The authors also wish to acknowledge the developers of the large language models evaluated in this study, whose groundbreaking work made this research possible. While drafting this manuscript, the authors used ChatGPT (OpenAI) with the sole purpose of checking the grammar of the text.

Abstract

Background: Norwegian Child and Adolescent Mental Health Services (CAMHS) use the World Health Organization's (WHO) multiaxial diagnostic system based on the *International Classification of Diseases, Tenth Revision* (ICD-10); however, analysis of prescribing patterns among axes I-III is underexplored in electronic health records (EHRs) with intertwined patient, episode of care, and contact information.

Objective: This study aimed to develop and demonstrate an analytic pipeline for mining and mapping information from EHRs to facilitate understanding of clinical processes and support informed decision-making. This study used the Norwegian CAMHS EHR data to identify common diagnoses, comorbidities, and medication use across axes I-III per individual contact.

Methods: We extracted records of patients ≤19 years old with a primary mental health diagnosis on axes I-III and one or more medications per individual contact. Diagnoses were categorized according to ICD-10 and medications according to the Anatomical Therapeutic Chemical (ATC) classification system. Descriptive analyses quantified contact counts, diagnosis frequency, comorbidity rates, and medication frequency within each diagnostic category. Next, we mapped the medications used across all the contacts and noncomorbid contacts separately along each axis.

Results: Of 7214 prescribing contacts (axis I: n=7179, 99.51%; axis II: n=821, 11.38%; axis III: n=65, 0.90%), comorbidity was present in 12.06% (n=866) contacts in axis I, 96.10% (n=789) contacts in axis II, and 96.92% (n=63) contacts in axis III. Leading diagnoses were behavioral-emotional disorders (ICD-10 codes F90-F98) in axis I, school skills and learning difficulties (ICD-10 code F81) in axis II, and mild mental retardation (ICD-10 code F70) in axis III. Most observed comorbidities were F90-F98 with speech and language development disorder (ICD-10 code F80), ICD-10 code F81, and mixed specific skills development disorder (ICD-10 code F83). Psychostimulants predominated across all diagnosis axes, with methylphenidate being the most common. For other ATC categories, the most commonly prescribed medications were antidepressants (sertraline and fluoxetine), antipsychotics (risperidone and aripiprazole), hypnotics and sedatives (melatonin), antiepileptics (lamotrigine), anxiolytics (diazepam), and nonpsychotropics (laxatives, vitamins, and supplements). Medication profiles varied minimally by axis or comorbidity status.

Conclusions: We demonstrated a mining and mapping analytic pipeline for EHRs to analyze diagnoses, comorbidities, and prescribing practices at the individual contact level. In the Norwegian CAMHS, axis I diagnoses are common, often

XSL•FO
RenderX

behavioral-emotional disorders. Among the medications, psychostimulants and antidepressants are common. Beyond characterizing diagnoses and medication prescribing patterns, the study presents an approach for mining and mapping EHR data to analyze and provide service-level metrics, as well as clinical practice insights.

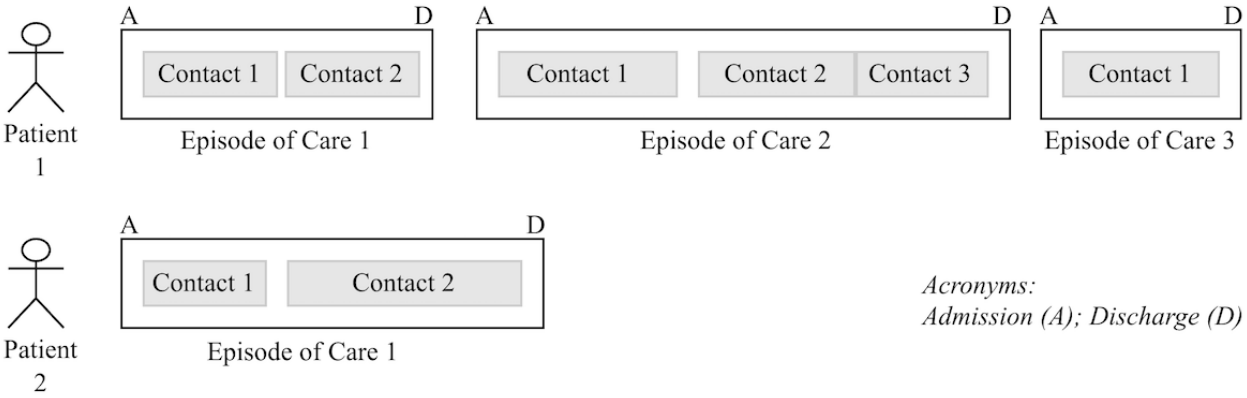
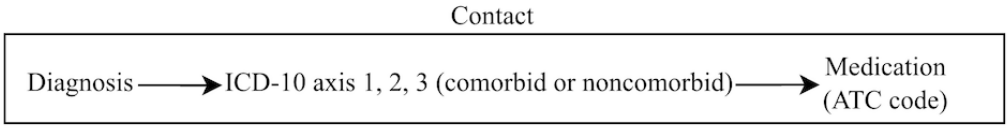
children; adolescents; mental health; data mining; electronic health records; medication; diagnosis; knowledge representation; clinical decision support

Introduction



Norwegian Child and Adolescent Mental Health Services (CAMHS), like many CAMHS worldwide, use the *International Classification of Diseases, Tenth Revision* (ICD-10) for diagnostic purposes [1]. Norwegian CAMHS use a national adaptation of the World Health Organization's (WHO) ICD-10 multiaxial framework, where different aspects are grouped to provide a useful and unambiguous view of the patient's disorder in CAMHS [2]. The axis for the psychosocial situation is coded with a locally relevant classification, and the function axis uses the Children's Global Assessment Scale (CGAS). Medication and prescriptions are coded using the Anatomical Therapeutic Chemical (ATC) classification system developed by the WHO [3]. In the WHO multiaxial framework, axis I covers clinical psychiatric syndromes, axis II covers specific developmental disorders, and axis III covers intellectual disability (mental retardation) [1,2,4]. This multiaxial framework aims to provide a clinically useful picture of mental health, distinguishing, for example, an expressive language disorder on axis II from a comorbid attention deficit/hyperactivity disorder (ADHD) on axis I or noting an intellectual disability (mental retardation) on axis III [1,2]. Such differentiation is clinically important, as it guides individualized treatment planning across psychiatric, developmental, and cognitive domains. However, despite its structural design, prescribing patterns and comorbidity profiles across WHO multiaxial axes I-III remain underexplored, and mining and mapping could provide insights into diagnostic patterns and clinical decision-making.

The ATC classification system organizes medications according to their anatomical site of action, therapeutic use, and pharmacological properties [3,5]. This allows mapping of psychotropic and nonpsychotropic medication categories and enables systematic analysis across diagnostic categories. Medications are pharmaceutical products, or drugs, intended for administration to patients, and the use of psychotropic medications in child and adolescent mental health care has expanded over the past two decades worldwide [6]. Previous international studies have reported an increase in the number of medication prescriptions, including stimulants for ADHD and antidepressants for adolescent mood/anxiety disorders [6]. For instance, from 2000 to 2019, stimulant use roughly doubled in England [7]. In Norway, and other Nordic countries, the diagnosis of ADHD and associated treatment involving stimulant medications has risen markedly in the 2000s [8,9]. It is estimated that around 7% of children aged 4-14 years in Norway have a diagnosable mental disorder, while about 1 in 5 adolescent girls and 1 in 10 boys report experiencing multiple psychological problems [10], and medications are now an important component of treatment for moderate-to-severe psychiatric conditions. Despite this general trend, the use of medication across different diagnostic categories in routine practice is not fully explored. Worldwide, most pharmacoepidemiological research in child and adolescent psychiatry focuses on single disorders in isolation or broad nationwide prescribing rates, rather than examining differences by diagnostic axis [7,11,12].



In Norwegian CAMHS electronic health records (EHRs), clinicians have historically recorded multiaxial diagnoses for each patient in line with the multiaxial classification system; however, research to date neither relies on secondary use of EHRs [13] nor uses such data to examine the use of psychotropic medications and comorbidities across the axes. For this study, a Norwegian CAMHS EHR [4,14] containing information at several interconnected levels about patients, their episodes of care, and individual contacts (encounters), capturing different aspects of clinical activity, was used [4]. In this study, an "episode of care" was a defined period during which a patient receives continuous mental health services for a specific issue by one responsible service unit (ie, hospital or clinic), starting with an accepted referral, followed by a decision to provide care or an acute admission, and ending with a formal discharge; no additional time window rule was used to merge or split episodes. Each episode of care included one or more contacts (encounters) with the patient (see Figure 1a). A contact was any single, recorded interaction between the patient and the care team within an episode of care (see Figure 1b), and each contact contained information about diagnosis, as well as prescribed medications. Diagnoses or prescriptions documented on separate contacts were retained as separate contact-level observations.

(a) Patients, episodes of care, and contacts

(b) A contact at CAMHS

Using the CAMHS EHR data described in the *Data Source and Study Cohort* section later, the analytic pipeline presented clinical insights and decision-making related to multiaxial diagnostic behavior and prescribing patterns. Specifically, we presented the demographic and clinical profiles of medicated children and adolescents by diagnostic axis, identified the proportions of diagnoses and prescribed medications, mapped medication prescriptions (by ATC category) to their corresponding diagnostic categories, and determined comorbid diagnoses across axes. The data pipeline extracted, preprocessed, mapped, and visualized diagnostic and medication proportions, with individual clinical contacts as the unit of analysis. The study focused on the following research questions (RQs):

- RQ1: What are the proportions of diagnoses and prescribed medications among patient contacts with a primary axis I, II, and III diagnosis?
- RQ2: Which comorbid conditions are observed among patient contacts with a primary axis I, II, and III diagnosis?
- RQ3: Which medications are prescribed among patient contacts for each primary axis I, II, and III diagnosis, both including and excluding comorbidities?

Methods

Data Source and Study Cohort

This study used EHR data from a part of the Central Norway Regional CAMHS, which include all specialist care inpatient and outpatient contacts. These specialized, publicly funded CAMHS clinics focus exclusively on the treatment of child and adolescent mental disorders. These regional EHR data do not include nationwide patient coverage. The available EHR contains a total of 22,643 patients, encompassing 30,938 episodes of care and 41,411 contacts with child and adolescent patients, with a "contact" being defined as the smallest record unit, corresponding to a single encounter between a patient and a service provider within an episode of care (as illustrated in Figure 1a). The EHR extract did not include free-text notes, behavioral narratives, and patient-reported data. For all 41,411 contacts, only 22.17% included a medication prescription. The EHR data contained episodes of care beginning in July 1982. For this study, we restricted the cohort to episodes of care that started and ended after 1995 because 1685 patients, with 897 contacts, were from before this date (including medicated and unmedicated), and applying the additional study filters would have further reduced that early cohort. This restriction allowed us to focus on the systematic, analytically stable portion of the available extract; it was not intended to be a representative sample of the population and did not include untreated or unmedicated CAMHS contacts as a comparison group. We acknowledge that these excluded episodes spanned the 1995 boundary or were still ongoing at the time of data extraction.

Accordingly, the study filtered child and adolescent contacts from the EHR that fulfilled all three inclusion criteria: (1) patients aged 19 years or younger at the time of episode start; (2) patient contacts with a recorded ICD-10-coded primary diagnosis on axis I, II, or III; and (3) at least one medication prescription associated with the patient contact. These inclusion criteria were used to preprocess the EHR records, in line with the RQs. The medicated contacts facilitated mapping medication use to diagnostic axes; consequently, the findings visualize prescribing practices and do not represent the broader prevalence of these conditions in the general or unmedicated CAMHS population.

We aggregated the data at the patient level for patients with multiple episodes and then extracted demographic summaries (ie, gender, language, father's and mother's ethnicity, and parent

XSL•FO
RenderX

relationship type), as these are permanent. This patient demographic information is specific to each patient. At the same time, medication prescriptions and diagnoses were analyzed at the individual contact level to capture the proportions of occurrences. Age was derived from the patient's date of birth and the start of the episode of care, which was available in the EHR (ie, at the episode level). The diagnosis and prescribed medication were linked to individual contacts; therefore, the overall analysis was based on the contact level, with the contact as the unit of analysis. Data extraction and processing were conducted to derive the dataset variables (see Multimedia Appendix 1) by joining and mapping information about the patient, episode of care, contact, medication, and diagnosis (see the database schema in Multimedia Appendix 2).

We concentrated on mental disorder diagnoses and the corresponding prescribed medications for treatment based on these diagnoses. The analysis was limited to axes I-III, with axes IV-VI excluded. This is because we did not have access to prescriptions or medication information originating outside the CAMHS clinic for disorders that axes IV-VI may cover. Somatic diseases coded on axis IV were often diagnosed and treated by health care professionals and services outside of CAMHS. Consequently, comorbidity in this study referred to co-recorded CAMHS mental health primary diagnoses within axes I-III and did not include somatic or other non-CAMHS conditions. The patients and their contacts were stratified into three groups by their primary diagnosis in each axis, following the WHO multiaxial framework [1,2] used in the Norwegian CAMHS, as follows:

- Axis I: clinical psychiatric syndromes (eg, depressive disorders, anxiety disorders, behavioral and hyperkinetic disorders, psychosis, typically corresponding to ICD-10 codes F03-F48, F50-F69, F84, F90-F99, R40-R46, and Z00-Z71)
- Axis II: specific developmental disorders (eg, developmental language disorder, school skills and learning difficulties, and other developmental disorders, typically corresponding to ICD-10 codes F80-F83 and F88-F89)
- Axis III: mental development disability or intellectual developmental disorders (eg, mild, moderate, or severe intellectual disability, typically corresponding to ICD-10 codes F70-F71 and F79).

We excluded diagnoses that did not represent actual clinical conditions after consultation with the CAMHS clinicians. In particular, diagnosis codes that could not be decoded or indicated administrative entries were excluded (codes 000 or 999 on all axes). We also excluded codes 1000 and 1999, as well as codes X6n, Z724, and F710 (rarely occurring and wrongly labeled; could not be verified as corresponding to ICD-10 axis III intellectual disability and appeared to represent administrative entries or invalid diagnoses) when they appeared as primary diagnoses in axis I; codes 2000 and 2999 in axis II; and codes 3000 and 3999, as well as CGAS codes 1-5, 9, and 99 in axis III (since these do not denote a confirmed disorder but rather CGAS scores). The exclusion applied only to code F710 when it was recorded as the primary diagnosis on axis I; legitimate code F71 entries recorded as the primary diagnosis on axis III were considered valid and retained. The CGAS codes exist in axis VI [1], but in our EHR data, when axis III contained CGAS codes 1-5, 9, and 99, these were also excluded. Codes Z00-Z71 (factors affecting health status and contact with the health service) and R40-R46 (symptoms and signs associated with cognition, perception, emotional state, and behavior) were used in practice when a child was under evaluation or for follow-up contact. A total of 7214 contacts (ie, 3415 patients) satisfied the filtering criteria (ie, age ~19 years or younger; episode-of-care starting and ending after 1995; recorded primary diagnosis on axis I, II, or III, excluding the aforementioned codes; and at least one prescribed medication) and hence were used in this study. The interventions in excluded contacts were outside the scope of this study.

Measures

Diagnoses

Diagnostic codes in the dataset were based on ICD-10 and assigned by CAMHS clinicians during clinical contact with patients, rather than by episode of care. Data were drawn from the clinician-maintained working record in the EHR. For each contact, we mapped the primary key linking the diagnosis. During each contact, one or more coded diagnoses could be recorded across the same or different axes. The structured extract available to us did not support reliable use of uncoded narrative information, so the analysis was limited to coded diagnoses linked to each contact. For the analysis, we focused on the primary diagnosis in each contact. If multiple primary diagnoses were found to be recorded within the same contact, we treated them as a comorbid contact. This operational definition reflects co-recorded CAMHS mental health diagnoses within the structured EHR and likely underestimates broader clinical comorbidity, including uncoded secondary diagnoses and somatic conditions outside axes I-III. If only one primary diagnosis was recorded within a contact, they were treated as a noncomorbid contact. Multiple primary diagnoses recorded within a contact across different axes (eg, an axis I disorder together with an axis II disorder) were classified as comorbid contacts. We grouped each diagnosis code in the CAMHS dataset by category (see Table 1) following the multiaxial framework used in the Norwegian CAMHS [1,2], tabulated the contact counts, identified and ranked the comorbid diagnosis categories, and mapped the corresponding prescribed medications.

Table 1. Observed and categorized ICD-10[a] codes occurring in the Norwegian CAMHS[b] dataset.

Axis and ICD-10 code/code range	Description
Axis I	
F03-F09	Organic, symptomatic
F10-F19	Psychoactive substances
F20-F29	Schizophrenia and paranoia
F30-F39	Affective/mood disorders
F40-F48	Neurotic and somatoform disorders
F50-F59	Behavioral syndromes
F60-F69	Personality and behavioral disorders
F84	Pervasive developmental disorders
F90-F98	Childhood behavioral and emotional disorders
F99	Unspecified mental disorder
R40-R46	Cognition and emotional signs
Z00-Z71	Health services contacts
Axis II	
F80	Speech and language development disorders
F81	School skills and learning difficulties
F82	Motor skills disorders
F83	Mixed specific skills developmental disorder
F88	Other psychological developmental disorders
F89	Unspecified psychological development
Axis III	
F70	Mild mental retardation
F71	Moderate mental retardation
F79	Unspecified mental retardation

[a]ICD-10: *International Classification of Diseases, Tenth Revision*.

[b]CAMHS: Child and Adolescent Mental Health Services.

Medications

The CAMHS clinic from which the EHR data originated used a diagnostic approach, as shown in Figure 1b, considering the diagnostic categories listed in Table 1.

We used primary keys linking the contact to the recorded diagnosis and medication. Medication information from outside, such as national prescription databases, was not available in the EHR extract. A single contact could contain one or multiple recorded medications, and all recorded medications were retained in the contact-level analysis. As mentioned in the *Introduction* section, medications recorded as prescriptions linked to each contact were based on the ATC classification system [3] and prescribed during the clinical contact with the patient. The presence of an ATC code in this study indicated a prescription or medication documentation event in the CAMHS EHR, but it did not confirm actual medication dispensing, patient adherence, dosage, or treatment duration. For mental health-related diagnoses, ATC nervous system category medications (ie, ATC code with the starting character "N") [15] were observed to be commonly prescribed in this dataset. Based on suggestions from clinicians, the ATC nervous system category encompasses mostly the psychotropic drugs used in psychiatric treatment. We extracted, preprocessed, and standardized ATC codes to categorize medications, as shown in Table 2, which uses psychotropic medication subcategories [15] and the rest of the nonpsychotropics [16] as a category. The other nonpsychotropic medications shown in Table 2 belong to a ATC nervous system category (N01, N02, N04, and N07), and those with starting ATC code "A" (alimentary tract and metabolism), "B" (blood and blood-forming organs), "C" (cardiovascular systems), "D" (dermatological), "G" (genitourinary system and sex hormones), "H" (systemic hormonal preparation, excluding sex hormones), "J" (anti-infective for systemic use), "M" (musculoskeletal system), "R" (respiratory system), and "S" (sensory organs). Psycholeptics and psychoanaleptics in combination (N06C) as well as antidementia medications (N06D) were not observed to be prescribed in any of the contacts; thus, we did not include these categories. For each contact, we identified medication ATC agent names from ATC code across the Table 2 categories.

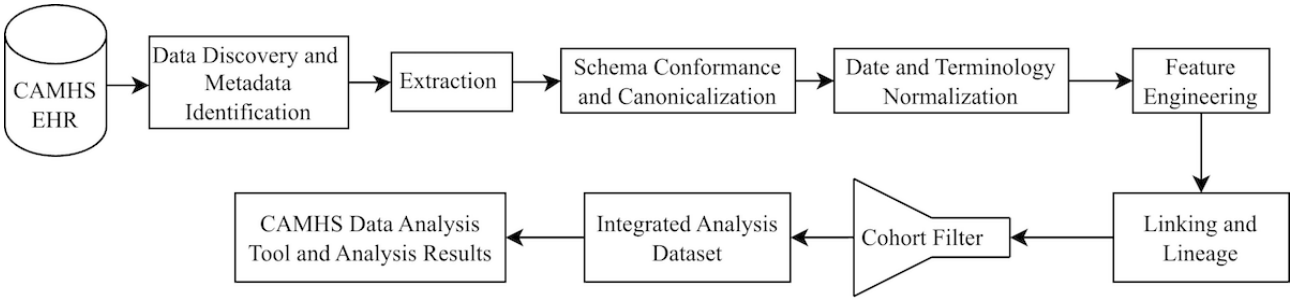
Table 2. Medication categories by ATC[a] code prefix.

ATC code	Medication category
N05A	Antipsychotics
N05B	Anxiolytics
N05C	Hypnotics and sedatives
N06A	Antidepressants
N06B	Psychostimulants, agents used for ADHD[b] and nootropics
N03	Antiepileptics
A, B, C, D, G, H, J, M, N01, N02, N04, N07, R, S	Other nonpsychotropics



[a]ATC: Anatomical Therapeutic Chemical.

[b]ADHD: attention deficit/hyperactivity disorder.

CAMHS Data Analysis Tool

Figure 2 illustrates the data pipeline, which uses rule-based extraction and linkage of patients, episodes, contacts, diagnoses, and medications using a structured schema, and its conformance. The pipeline begins with data discovery and metadata identification from the CAMHS EHR. The useful metadata and attributes are identified and exported as immutable raw extracts to a landing or raw zone within a secure analysis environment. These extracts undergo schema conformance, where data types are enforced, required fields are validated, and columns are renamed to canonical names. This is followed by data normalization, including parsing and standardizing dates, cleaning medication and ATC code terminology, and mapping their descriptions. Next, feature engineering is performed, deriving attributes such as age. Based on the three cohort-filtering conditions, we narrowed the data to the scope of this study. During lineage and linking, the pipeline assembles the medication chain; links patients to episodes and individual contacts; and integrates diagnoses, medications, and contacts to build a complete patient-episode-contact-medication-diagnosis dataset (ie, integrated analysis dataset). This consolidated analysis-ready dataset is consumed by the CAMHS data analysis tool.

Figure 2. Data pipeline for dataset preparation and analysis. CAMHS: Child and Adolescent Mental Health Services; EHR: electronic health record.

Our CAMHS data analysis tool is a web app developed and used to analyze and visualize the data in this study (see Multimedia Appendix 3). We developed and used the tool within a secure analysis environment. The tool was developed using Python, with the libraries *Streamlit* [17] for rapid web app development and *Plotly* [18] for creating interactive visualizations. The tool ingests the preprocessed dataset (ie, integrated analysis dataset) as Parquet files. To ensure data integrity, we mapped data as dictionaries, converting numeric codes (eg, 1 for female and 2 for male and similarly for family relationships and ethnicities). Similarly, the ATC and ICD-10 codes were mapped to corresponding descriptions in human-readable formats (ie, JavaScript Object Notation [JSON] files). We used this tool to obtain axes I, II, and III summaries and analyze patient and contact-level information. The tool offers the following functionality:

- Filtering: Users can filter patient records by ICD-10 codes (axis specific) or ATC codes. Optionally, the age and gender filters are implemented via checkboxes to include or exclude these criteria.
- Patient trajectory visualization: The patient trajectory displays each episode of care, consisting of individual contacts within it, spanning the episode's duration and including the patient's age at the start of the episode [19]. Hover annotations display information for each contact, including ICD-10 codes, ATC medication details, and demographic information. The tool supports randomized pagination, ensuring that a manageable subset of patient trajectories is displayed at any one time.
- Interactive visual analytics: Histograms and pie charts illustrate the distribution of demographics, while the patient trajectory provides a detailed view of information at the individual patient and the contact level (eg, medications and diagnoses given per contact).

Analyses

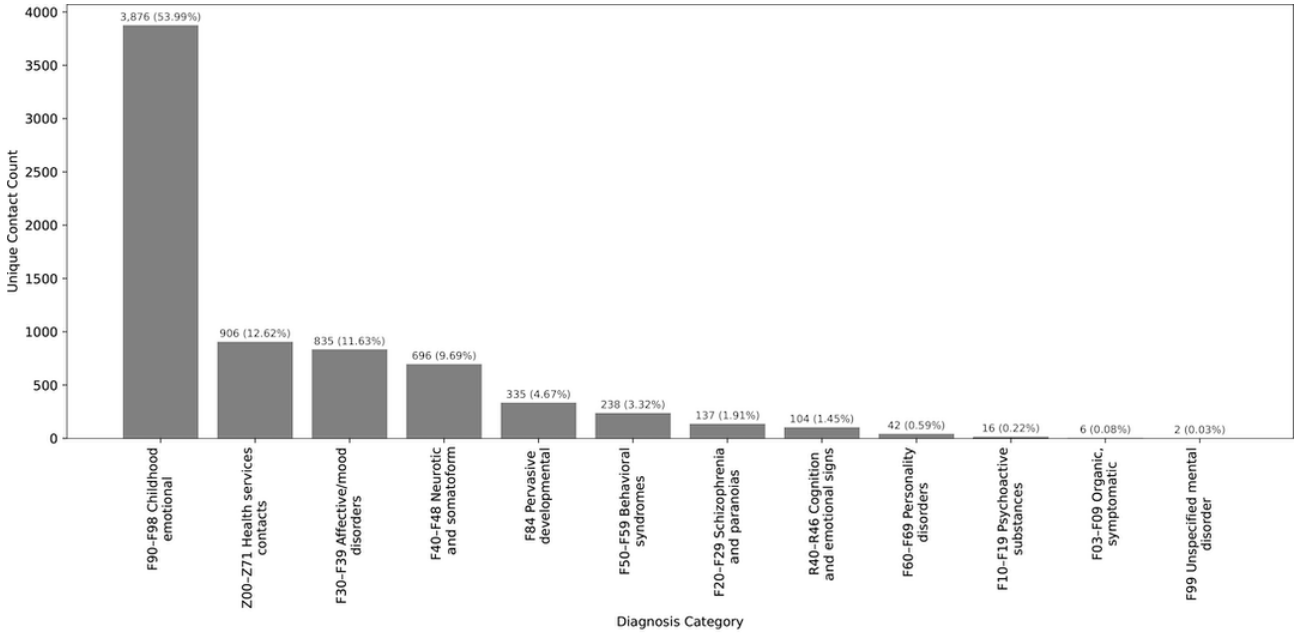
All analyses were conducted using Python, Structured Query Language, Microsoft Excel, and our CAMHS data analysis tool.

XSL•FO
RenderX

The analyses were descriptive and focused on patient contact events as the primary analytic unit. We did not perform inferential modeling or estimate patient-level prevalence from these data. As repeated contacts from the same patient are not independent, the reported percentages should be interpreted as descriptive contact-level proportions rather than inferential estimates. To accomplish this, we first generated a summary for each axis. Sociocultural analysis based on demographic fields was not assessed or interpreted in the study, as substantial missing data in fields, such as parental ethnicity and home language, limited the depth of sociocultural analysis.

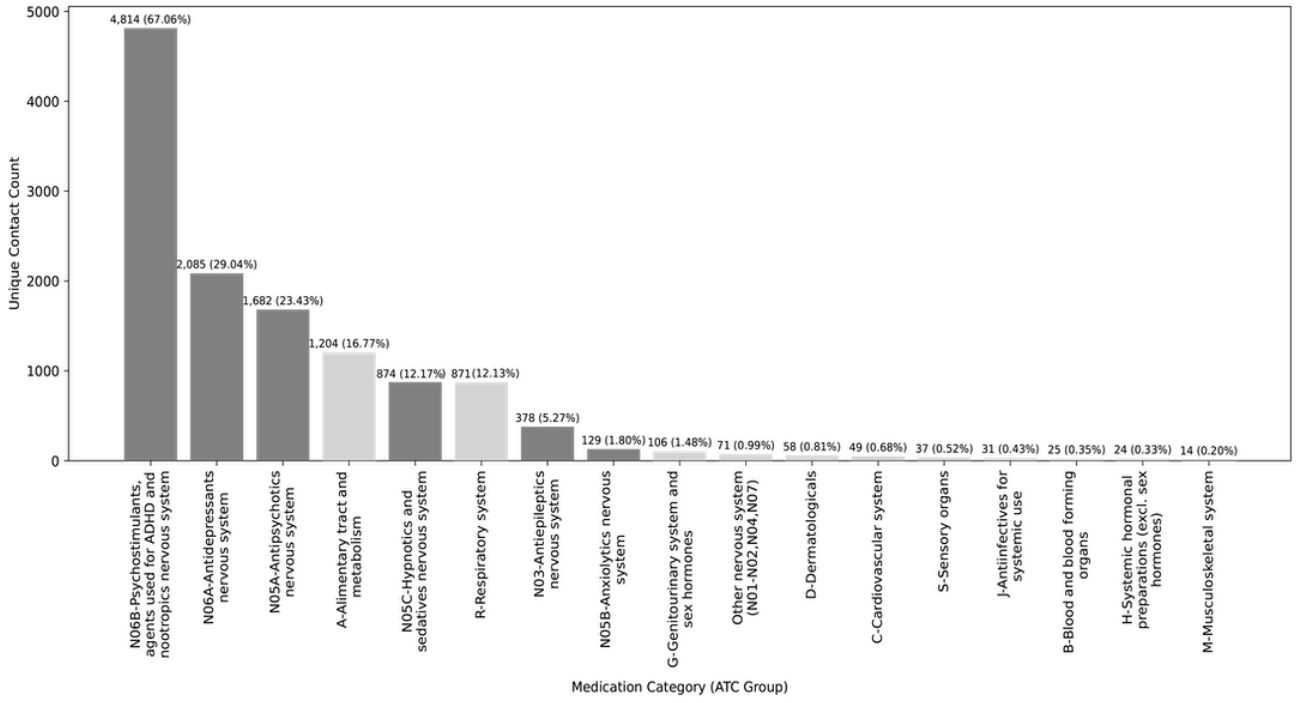
Ethical Considerations

The Individualised Digital DEcision Assist System (IDDEAS) project [20] was assessed by the Regional Committee for Medical and Health Research Ethics (REK Southeast, reference number 2018–2186), which determined that the project fell outside the scope of the Health Research Act and did not require formal ethics approval. Following the REK's recommendations, the Central Norway Regional Health Authority IT and the local data protection officer approved a risk analysis and data protection impact assessment (DPIA). Informed consent was obtained or waived, and all data were deidentified to ensure participant confidentiality. No compensation was provided, and no identifiable information is present in any images or supplementary materials.



Results

Research Question 1: Frequent Diagnoses and Medications in All Contacts



We calculated and identified the most common primary diagnoses and the most commonly prescribed medications per individual contact, represented in descending order. This was based on the frequency within each corresponding category in axes I, II, and III. The psychotropic medication categories (antipsychotics, anxiolytics, hypnotics and sedatives, antidepressants, psychostimulants, and antiepileptics) are represented by gray bars; other nonpsychotropic medications are represented by light-gray bars (see Figure 3, Multimedia Appendix 4, and Multimedia Appendix 5, respectively).

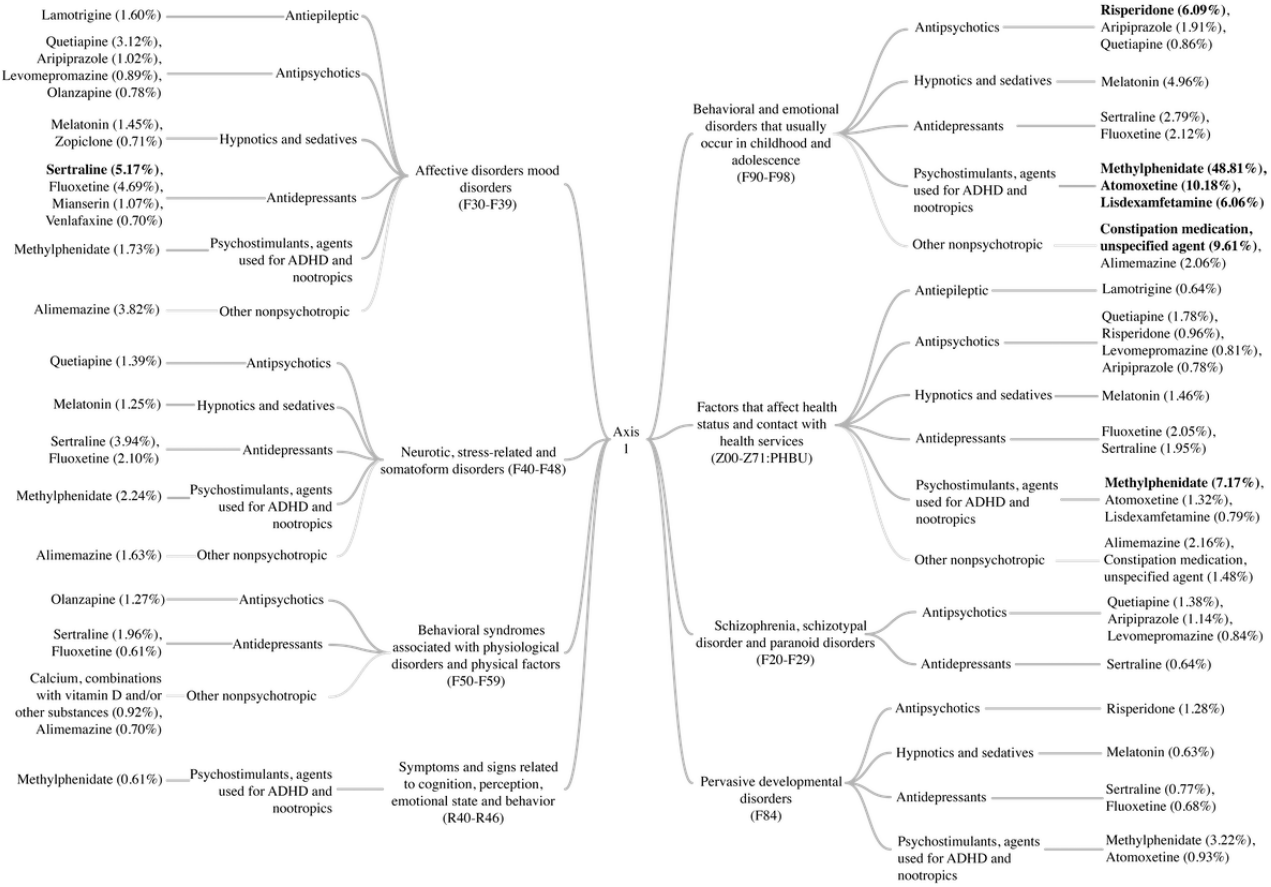
(a) Diagnoses

(b) Medications

Research Question 2: Comorbidities by Diagnosis in Comorbid Contacts

We identified and ranked the frequency of comorbidities across all diagnostic categories on all three axes based on the ratio of comorbid contacts in that diagnosis category to the total comorbid contacts in the axis. The distinction between comorbid and noncomorbid contacts helped pinpoint medication prescriptions for a specific diagnosis. This was necessary because in the EHR data, medication prescriptions are linked to the contact rather than to a specific diagnosis.

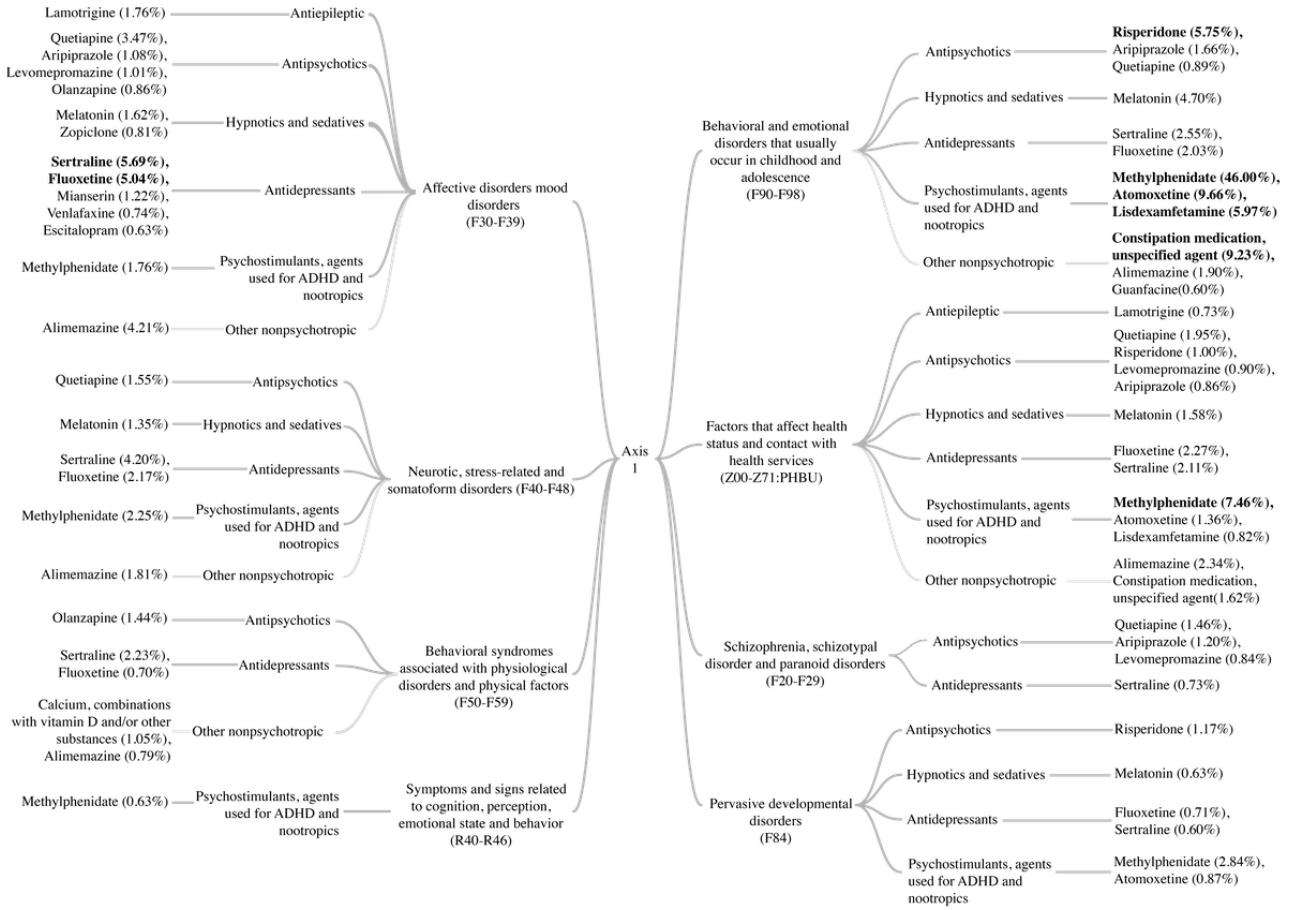
Research Question 3: Medication Patterns by Diagnosis in All Contacts and Excluding Comorbid Contacts



For each axis, we mapped the intersection of diagnoses and medications. We identified and listed all corresponding medications in each diagnosis category. These results are presented in the form of a mind map (see Figure 4 and Multimedia Appendices 6 and 7) for illustration and clarity. For the other nonpsychotropic medication category, we displayed only the five most frequently prescribed medications to maintain readability. As our focus was on the psychiatric medication categories shown in Table 2, the complete mappings, including

XSL•FO
RenderX

proportions, are provided in Multimedia Appendices 6, 7, and 8. Representing the mapping of medications and diagnoses in this way aimed to help the reader understand and navigate which medications were prescribed for which diagnosis categories. The ordering of medications is in descending order, based on the ratio of contacts involving observed medication use to the total number of contacts in the axis.



We separated noncomorbid contacts and examined the intersection of diagnoses and medications across the categories (see Figure 5 and Multimedia Appendices 9 and 10), showing the ratio of noncomorbid contacts involving observed medication use to the total noncomorbid contacts on the axis.

Figure 4. Categorized primary diagnoses and corresponding mapped medications for all axis I contacts (n=7179, 99.51%; percentages based on "n"). A single contact may include multiple mapped medications; therefore, medication percentages represent proportions of all axis I contacts, not prescribing rates within the corresponding diagnosis category. ADHD: attention deficit/hyperactivity disorder.

XSL•FO
RenderX

Figure 5. Categorized primary diagnoses and corresponding mapped medications for all noncomorbid axis I contacts (n=6313, 87.94%; percentages based on "n"). A single contact may include multiple mapped medications; therefore, medication percentages represent proportions of all noncomorbid axis I contacts, not prescribing rates within the corresponding diagnosis category. ADHD: attention deficit/hyperactivity disorder.

Characteristics of Patients

Table 3 presents an overview of patients with an axis I diagnosis and their contacts, with analogous summaries for axes II and III provided in Multimedia Appendices 11 and 12, respectively. The analysis involved a total of 7214 contacts, with 7179 (99.51%) classified under axis I, 821 (11.38%) under axis II (Multimedia Appendix 11), and 65 (0.90%) under axis III (Multimedia Appendix 12); the comorbid contacts were classified under multiple axes. The majority of contacts were in axis I. Table 4 lists the diagnostic categories, along with corresponding comorbidity categories observed across axes I, II, and III, arranged in descending order by proportion (see Multimedia Appendix 13). Axis I had a comparatively lower comorbidity ratio: only 12.06% (n=866) of axis I contacts had a comorbid diagnosis. Notably, the comorbidity ratio in axis II was 96.10% (n=789), and axis III had a comorbidity ratio of 96.92% (n=63). The mapped diagnosis medication intersection showed prescribing patterns in all contacts (see Figure 4 and Multimedia Appendices 6 and 7) and those without comorbidity (see Figure 5 and Multimedia Appendices 9 and 10). The noncomorbid contacts included 6313 (87.94%) contacts in axis I, 32 (3.89%) in axis II, and only 2 (3.07%) in axis III.

[a]Percentages are at the contact level within clinical episodes. Comorbidities in the same category represent two distinct *International Classification of Diseases, Tenth Revision* (ICD-10) codes within the same primary category block.

[b]Not applicable.

Axis I: Clinical Psychiatric Syndrome

As shown in Figure 3a, axis I (n=7179, 99.51%) contacts exhibited childhood behavioral-emotional disorders (ICD-10 F900 [disturbance of activity] and F901 [hyperkinetic disorder]) as the most frequent disorders (F90-F98; n=3876, 53.99%), followed by health service contacts, potentially representing consecutive visits or follow-ups (Z codes; n=906, 12.62%), affective mood disorders (F30-F39; n=835, 11.63%), and neurotic disorders (F40-F48; n=696, 9.69%). Consistent with these diagnostic categories, psychostimulant medications (N06B; n=4814, 67.06%), followed by antidepressants (N06A; n=2085, 29.04%), were the most observed medications (Figure 3b). Table 4 shows that among the 866 (12.06%) comorbid contacts in axis I, in 41.11% (n=356), childhood behavioral emotional disorders (F90-F98) were comorbid with specific learning disorders (F81),

XSL•FO
RenderX

followed by speech/language disorder (F80; n=132; 15.24%), mixed specific skills development disorder (F83; n=71, 8.2%).

Figures 4 and 5 show the axis I diagnoses and mapped prescribed medications (see Multimedia Appendix 8), considering all contacts (Figure 4) and only noncomorbid contacts (Figure 5). Percentages are based on the total contact denominator used in the corresponding figure and should not be interpreted as within-diagnosis prescribing rates. For example, as shown in Figure 4 for childhood behavioral-emotional disorders (F90-F98), the most frequent medication was methylphenidate, observed in 48.81% (n=3504) of all contacts in axis I, followed by atomoxetine (n=731, 10.18%) and risperidone (n=435, 6.06%). As medication code A06BA04 could not be reliably mapped to a specific generic substance, and standard constipation drugs are classified under A06A, this medication was therefore labeled as "Constipation medications, unspecified agent." For affective disorders and mood disorders (F30-F39), sertraline (n=371, 5.17%) and fluoxetine (n=337, 4.69%) were frequent. For neurotic, stress-related, and somatoform disorders (F40-F48) also, sertraline (n=283, 3.94%) and fluoxetine (n=151, 2.10%) were frequent.

Figure 5 shows medications prescribed to noncomorbid contacts only. For example, in the absence of comorbidity for the same F90-F98 diagnoses category, methylphenidate was observed in 46% (n=2904) of axis I noncomorbid contacts, followed by atomoxetine (n=610, 9.66%), and lisdexamfetamine (n=377, 5.97%). For affective disorders and mood disorders (F30-F39), the antidepressants sertraline (n=359, 5.69%) and fluoxetine (n=318, 5.04%) were frequent. For neurotic, stress-related, and somatoform disorders (F40-F48) also, sertraline (n=265, 4.2%) and fluoxetine (n=137, 2.17%) were frequent.

Axis II: Specific Developmental Disorders

Axis II contacts (n=821, 11.38%) had specific developmental disorders of scholastic skill (F81; n=481, 58.59%), which in ICD-10 also include specific reading disorders and learning difficulties as the most common diagnosis, followed by speech/language issues (F80; n=173, 21.07%), mixed disorders (F83; n=102, 12.42%), and motor disorders (F82; n=59, 7.19%); see Multimedia Appendix 4. Axis II had lower medication exposure but substantial comorbidity with axis I. Among medications, overwhelmingly, psychostimulants (n=724, 88.19%), followed by antidepressants (n=138, 16.81%), were observed (see Multimedia Appendix 4). Other medication categories, such as alimentary tract and metabolism (n=127, 15.47%), included constipation medications and were often observed across all axes. The axis II comorbidities (n=789, 96.10%) shown in Table 4 also revealed that childhood behavioral-emotional disorders (F90-F98) were mostly comorbid with school skills and learning difficulties (F81; n=356, 45.12%), speech/language issues (F80; n=132, 16.73%), mixed specific skills development disorders (F83; n=71, 9.00%), and motor skills disorders (F82; n=43, 5.45%). Multimedia Appendices 6 and 9 show the mapped medications prescribed for axis II diagnosis categories, considering all contacts (Multimedia Appendix 6) and only noncomorbid contacts (Multimedia Appendix 9). They show the predominance of psychostimulant medications across diagnostic categories.

Axis III: Mental Developmental Disabilities

Axis III had only 65 (0.90%) contacts with mild, moderate, or unspecified retardation. The diagnosis was dominated by mild retardation (F70; see Multimedia Appendix 5), which in ICD-10 includes F700-F701 (mild behavioral retardation). The diagnosis also showed frequent comorbidity with, especially, childhood behavioral-emotional disorders (F90-F98; n=37, 58.73%) and other neurodevelopmental conditions (see Table 4). With 96.92% (n=63) comorbidity, axis III showed the use of antipsychotic and psychostimulant medications (see Multimedia Appendix 5). Axis III diagnoses and corresponding medication mapping (see Multimedia Appendices 7 and 10) showed that methylphenidate among psychostimulants and risperidone among antipsychotics were common; this is an observation of the small number of contacts in axis III, not a disorder-specific treatment pattern for intellectual disability in isolation or for epidemiological interpretation.

Discussion

Principal Findings

CAMHS EHR data extraction and preprocessing are complex because patient, episode-of-care, and contact-level records are integrated [4]. We extracted, transformed, and mapped 25 years of longitudinal CAMHS EHR data into a singular contact-level dataset, enabling multilevel analyses of patient demographics, diagnostic and comorbidity patterns, medication-prescribing patterns, and their interrelationships. To the best of our knowledge, this is the first study to extract, transform, mine, and map 25 years of CAMHS EHR data into a contact-level dataset for analyses of diagnostic and medication-prescribing patterns.

Using percentages for axis-specific contacts rather than patient-level prevalence estimates, we observed that among medicated contacts in specialist CAMHS, axis I clinical psychiatric syndromes were most common, particularly childhood behavioral-emotional disorders (F90-F98), which also consist of ADHD (53.99%), health service contacts (Z codes) representing follow-up contacts (12.62%), and affective mood disorders (11.63%). These contacts were dominated by psychostimulant medications, followed by antidepressants, usually corresponding to the treatment of ADHD and mood disorders [6,21]. The presence of risperidone, a second-generation antipsychotic, reflects targeted short-term use for severe behavioral dysregulation [22]. In noncomorbid axis I contacts, rates of methylphenidate remained high at 46.0% for childhood behavioral-emotional disorders (F90-F98), while selective serotonin reuptake inhibitor antidepressant (sertraline, 2.55%; fluoxetine, 2.03%), antipsychotics (risperidone, 5.75%; aripiprazole, 1.66%), hypnotics (melatonin, 4.70%), and nonpsychotropic medication (constipation medications: unspecified agent, 9.23%; alimemazine, 1.90%) were more evenly distributed, indicating more diversified pharmacotherapy when no secondary diagnoses are present. In addition, of the 866 comorbid contacts in axis I, for childhood behavioral-emotional disorders (F90-F98), 41.11% of contacts

XSL•FO
RenderX

were also comorbid with specific developmental disorders (F81), highlighting the potential benefits of screening children presenting with childhood behavioral-emotional disorders or ADHD symptoms for developmental disorders.

In axis II (developmental disorders), school skills and learning difficulties (58.59%) were the most frequently occurring diagnoses, followed by speech/language issues (21.07%), mixed specific skills development disorder (12.42%), and motor disorders (7.19%). The high comorbidity between axis I and II, as well as the use of psychostimulants and antidepressants, also points to the medications being prescribed for childhood behavioral-emotional disorder comorbidities, with melatonin and risperidone to address sleep disturbances and behavioral challenges [23]. The axis II noncomorbid contacts, which exhibit a decrease in psychostimulant use and a relative increase in nonpsychostimulant use, reflect more diversified pharmacotherapy and some monotherapy patterns when no secondary diagnoses were present.

Axis III contacts overwhelmingly involved mild intellectual disability (84.62%) and almost always included comorbid diagnoses. Accordingly, the observed methylphenidate and risperidone use in axis III contacts should not be interpreted as evidence of efficacy for intellectual disability itself [24,25]. Rather, these medications were recorded in highly comorbid contacts in which the prescribing indication was likely related to co-occurring behavioral or psychiatric symptoms.

The high comorbidity rates of axis II and axis III contacts with axis I contacts indicate how clinicians choose and use medications when managing patients with multiple comorbid conditions, and the medications may be prescribed to treat the comorbid diagnoses. Axes II and III exhibit a particularly pervasive overlap between neurodevelopmental and intellectual disabilities and childhood behavioral-emotional disorders (F90-F98), leading to frequent symptomatic methylphenidate/atomoxetine and risperidone use. The axis I cohort exhibiting lower comorbidity than axes II and III likely reflects the WHO multiaxial classification structure, which indicates that axis II and III codes capture long-term developmental or intellectual disorders commonly recorded alongside axis I behavioral and clinical conditions. Often, the axis I conditions are linked to medication use for treatment. This indicates that comorbid behavioral disorder likely drives clinical management and prescribing decisions, even when the intellectual disability is coded as the primary diagnosis.

The use of psychostimulants, antidepressants, hypnotics and sedatives, antipsychotics, and other medication categories in CAMHS indicates multifaceted pharmacological management in routine clinical practice settings. This highlights the need for integrated neurodevelopmental screening; coordinated care, including psychosocial interventions; and informed resource allocation to improve long-term prognosis [26]. The predominance of psychoanaleptic (N06A, N06B) medications underscores that stimulant and antidepressant therapies must be tailored alongside interventions for comorbid learning and speech disorders to optimize outcomes [27]. Medication-prescribing patterns characterized by psychostimulants for ADHD and antipsychotics for behavioral disorders broadly align with clinical practice but may raise concerns about the use of antipsychotics in individuals with mild and moderate intellectual disabilities [7,28]. These findings emphasize the importance of careful medication management, offering important implications for future clinical practice and policy enhancements. Policy initiatives should strengthen oversight and access to supportive therapies, and future research will evaluate long-term outcomes and refine evidence-based prescribing strategies to optimize safety and efficacy in these complex patient groups.

Medication approval dates in Norway (see all approval dates in Multimedia Appendix 14) provide a historical context for the available agents across the study period. For example, in the psychostimulants category, methylphenidate was mainly prescribed, followed by atomoxetine. The reason could be that although immediate-release methylphenidate was first approved in Norway in 1956 (see Multimedia Appendix 14) and extended-release methylphenidate was approved for use in Norway in 2002 [29], atomoxetine was not approved until 2004, and our data are from 1995. Therefore, the medication's approval date and release in Norway may have influenced its usage proportion. However, we did not formally model time trends, segmented changes, or policy effects across the 25-year window. Therefore, differences in observed medication frequencies should not be causally attributed to approval dates, organizational reforms, or guideline changes in this study. Future work should analyze prescribing patterns longitudinally by calendar period. The prescription of particular medications within each medication category also may have been influenced by the Norwegian government, CAMHS clinic policies, individual CAMHS physician preferences, or the preferences of other health care personnel. In addition, depending on the EHR system and the updates made to it over the years, certain information may not have been recorded.

Given that prescribing should follow evidence-based prescribing guidelines, the use of antipsychotics for intellectual disability especially may further indicate the need for monitoring, clear protocols, and integrated multidisciplinary care that enhance psychosocial and nonpharmacological interventions [30]. Policy efforts should focus on providing clear guidelines and monitoring frameworks for psychotropic use in developmental and intellectual disabilities, as well as ensuring access to nonpharmacological interventions, such as psychosocial first line of treatment, including behavioral therapy, educational, and speech support. The use of nonpharmacological interventions is evident, as we observed that of all of the 41,411 patient contacts, only 22.17% had a medication code, indicating that medication was not always the first and foremost choice. This could be potentially further explored from the text notes, behavioral narratives, or patient-reported outcomes.

Strengths and Limitations

The strength of our study lies in mapping a large-scale, long-term, real-world EHR at the individual contact level, visualizing the most fine-grained encounters involving diagnoses and medication prescriptions. We combined patient, episode, and contact-level information to provide longitudinal insights into diagnostic and prescribing patterns. We applied a systematic

XSL•FO
RenderX

WHO multiaxial diagnosis and ATC medication classification, used by the Norwegian CAMHS, to identify comorbid diagnoses and prescribed medications. All results were categorized using the same classification system and summarized in tables and graphics to enhance readability and accessibility. We acknowledge that the ICD-10 and multiaxial diagnosis axis classification provides a useful taxonomy; however, in clinical practice, these categories often overlap, and coding precision and practices may vary, meaning that the contact level may not always reflect clear-cut clinical distinctions.

We note that the medication codes in the EHR represent prescription events and do not confirm actual dispensing, patient adherence, or dosage; they serve, instead, as proxies for clinical treatment intention. The analysis is descriptive rather than inferential; repeated contacts from the same patient are not statistically independent. We acknowledge the following as potential sources of bias in this study: contact-based analysis, medicated-only sampling, missing demographic data, omission of axes IV-VI, unstructured data, and the small size of the axis III sample. As this was a descriptive study, we made these biases transparent and constrained our interpretation accordingly. Future studies could refine prescribing stratification, including contacts without medication prescription, analyze prescriptions based on progression of a disease over time, apply standardized comorbidity indices, focus on polypharmacy scores, and evaluate nonpharmacological alternatives to reduce the psychotropic burden in complex CAMHS populations. The analysis tool is a proof of concept designed to extract and visualize data from our specific EHR. However, it requires external validation in other EHR systems before it can be used elsewhere. As this study was descriptive and limited to contacts with medication prescriptions, conclusions about guideline adherence are not drawn.

Conclusion

This study demonstrated an analytic pipeline that enabled the mining and mapping of Norwegian CAMHS EHRs over a 25-year period, allowing analysis of diagnostic patterns, comorbidities, and medication-prescribing practices across axes I-III at the individual contact level. We observed that CAMHS prioritize psychosocial interventions, but among the medicated patients, they mostly encounter axis I diagnoses, mostly childhood behavioral-emotional disorders. The axis I diagnoses are predominantly linked to medication use, with axis II and III diagnoses frequently observed to be comorbid with axis I. This study presents a proof of concept in which extensive EHR data collected over decades can be mined and mapped, allowing users to transform complex, multiaxial/multidimensional records into interpretable formats for various purposes, such as understanding clinical decision-making, managing resource allocation, planning, and developing policies. Our methods transform EHRs from “black boxes” into readily accessible information that can be used to inform and improve clinical practice, service use, and ultimately patient outcomes.

Acknowledgments

We acknowledge the financial support provided by the Liaison Committee between the Central Norway Regional Health Authority and the Norwegian University of Science and Technology (project code 30233). The funding bodies had no role in the design of the study; collection, analysis, and interpretation of data; and writing of the manuscript.

Data Availability

This study used the *barne-og ungdomspsykiatri* data EHR managed by St Olavs Hospital in Trondheim, Norway. Due to the sensitive nature of the data, they cannot be made publicly available with the study. To request access, please contact Research Department, St Olavs Hospital, Trondheim, Norway. The applicant must comply with any requirements or guidelines provided by the head of the project, as well as any nondisclosure agreements, the Regional Committee for Medical and Health Research Ethics, the Data Access Committee, and the Helseundersøkelsen i Trøndelag Cloud. Breach of legal or formal requirements is punishable under Norwegian law. The code is available online [31].

Abstract

Background: Metabolic multimorbidity is prevalent in high-risk populations for diabetes and is linked to cardiovascular disease (CVD) and gut microbiota composition. The relationship between metabolic clusters (MCs), microbial age (MA), and metabolic markers remains poorly understood.

Objective: This study aimed to investigate the characteristics of MCs and MA in high-risk diabetic populations, focusing on their associations with gut microbiota, metabolic dysregulation, and CVD risk.

Methods: Using data from the NIH Integrative Human Microbiome Project, we performed metabolomic and microbiomic analyses. K-means clustering identified MCs, and redundancy analysis examined the relationship between metabolic variables and microbiota. A random forest (RF) model predicted MA and CVD risk, while the linear discriminant analysis effect size identified microbial species associated with MCs and MA. Co-occurrence network analysis explored microbial interactions.

Results: We included 103 high-risk individuals (56/103, 54.4% female, mean age 50.6, SD 54.6 years). In total, 3 MCs were identified: MC1 (high glucose or blood urea nitrogen), MC2 (relatively healthy), and MC3 (lipid dysregulation). Age explained 3% of gut microbiota variation (R^2=0.03; P=.006). The RF model predicting microbial age showed a strong correlation with chronological age in training data (ρ=0.97, root mean square error=3.33; P<.001) and moderate correlation in test data (ρ=0.35; P<.001). High microbial age was associated with elevated lipid markers (low-density lipoprotein and triglycerides; P<.001) and higher cardiovascular risk. The RF model for CVD risk prediction achieved excellent discrimination (area under the curve=0.95 for the low-risk and 0.95 for the high-risk groups).

Conclusions: This study highlights the relationship between MCs, MA, and gut microbiota, providing insights for early intervention and personalized treatment strategies for diabetes and related metabolic disorders.

KEYWORDS

metabolic multimorbidity; microbial age; gut microbiota; cardiovascular disease risk; diabetes

Introduction

According to the International Diabetes Federation (IDF), approximately 463 million adults worldwide had diabetes in 2019, and this number is expected to continue rising over the coming decades [1]. Diabetes is a metabolic disorder characterized by chronic hyperglycemia, typically accompanied by abnormalities in insulin secretion or action, or both. This persistent high blood glucose not only disrupts glucose metabolism but is also closely linked to severe complications such as cardiovascular disease (CVD), kidney disease, and neuropathy [2,3]. Early in the disease, patients with diabetes often have concurrent metabolic disorders, such as hypertension, obesity, and dyslipidemia, which collectively form metabolic clusters (MCs) [4,5]. These metabolic abnormalities interact

XSL•FO
RenderX

and exacerbate the condition, further increasing the CVD risk in patients with diabetes [6,7]. Thus, early identification of high-risk populations with diabetes is critical for personalized treatment and precision medicine.

In recent years, the gut microbiota, as a crucial microbial ecosystem in the human body, has been found to play a significant role in host metabolism, immunity, and neurological functions [8,9]. Extensive research has shown that the imbalance of the gut microbiota is closely related to metabolic disorders in diabetes and its complications. The gut microbiota influences the host's glucose, lipid metabolism, and inflammatory responses through metabolic products such as short-chain fatty acids (SCFAs) [10,11]. However, the mechanisms underlying the interaction between the gut microbiota and the host's metabolic functions remain incompletely understood. Nevertheless, growing evidence suggests that changes in the gut microbiota's composition are not only associated with the pathogenesis of diabetes but may also contribute to the comorbidity of other metabolic diseases, such as obesity, fatty liver disease, and hypertension, providing a biological basis for the formation of MCs [12,13].

The health of the gut microbiota is closely linked to the biological age of the host. The composition and function of the microbiota can reflect the host's biological age, a concept known as "microbial age" (MA) [14,15]. MA is a composite indicator inferred from the analysis of the gut microbiota's composition, metabolic products, and other factors. It is closely associated with the host's health status, metabolic function, and inflammation levels [16,17]. Research has shown that, with increasing host age, the gut microbiota undergoes natural aging, characterized by reduced microbial diversity and increased specific pathogens [18,19]. Therefore, as a potential biomarker, MA may provide new insights for early prediction and personalized intervention of metabolic diseases.

The potential application of MA in high-risk populations with diabetes has attracted growing attention. MCs and dysbiosis typically characterize these populations, and the interaction of these multiple factors may exacerbate disease progression and the onset of complications [20,21]. Existing studies have indicated that MA is associated with the onset of various diseases, including metabolic disorders, CVDs, and obesity. However, research on MA in high-risk diabetic populations remains limited [22,23]. CVD, one of the most common complications of diabetes, has become a leading cause of death in high-risk populations with diabetes [2,24]. Therefore, understanding the relationship between MCs, MA, and CVD is of significant clinical importance for developing personalized intervention strategies.

This study aims to explore the characteristics and interrelationships between MCs and MA in high-risk populations with diabetes through metabolomics and microbiome analysis and to reveal the potential impact of these factors on CVD risk. We will focus on analyzing the relationships between different metabolic subtypes and the gut microbiota in high-risk populations with diabetes, investigating the interactions between metabolic disorders and changes in the microbiota. Through systematic data analysis, we will uncover the potential role of MA in metabolic disorders and CVD risk and further identify key microbial species that may exhibit significant differences across different metabolic subtypes and MA groups, thereby influencing the host's metabolic health and disease risk. In addition, we will explore the synergistic interactions within the gut microbiota, further revealing how microbial communities contribute to the development of metabolic diseases through various mechanisms. This study will not only deepen our understanding of the complex relationship between metabolism and microbiota in high-risk populations with diabetes but also provide new scientific evidence and clinical perspectives for the early diagnosis, personalized treatment, and intervention of diabetes and related metabolic diseases.

Methods

Ethical Considerations

This study was a secondary analysis of publicly available, deidentified data from the NIH Integrative Human Microbiome Project (iHMP). The original studies were approved by the relevant institutional review boards, and all participants provided written informed consent at the time of data collection. As this analysis used only anonymized data and involved no direct contact with participants, additional ethical approval was not required and the study was considered exempt from further review. Participant privacy and confidentiality were fully protected. No compensation was provided for this secondary analysis.

Data Acquisition

This study was based on data from the NIH Integrative Human Microbiome Project (iHMP), focusing on individuals at high risk for diabetes. A total of 103 individuals were included in the study cohort, contributing longitudinal samples collected during infection (n=79) and healthy states (n=429) across multiple time points. To avoid the confounding effects of acute illness on metabolic and gut microbiome profiles, only samples from the healthy phase were selected for the main analyses, including metabolic subtype classification, MA prediction, and CVD risk evaluation. This selection ensured that results reflected stable metabolic characteristics and minimized biases introduced by transient infection.

The sample types consist of fecal samples (16S ribosomal RNA microbiome), clinical data (BMI, age), and laboratory metabolic data (glycated hemoglobin, albumin, blood urea nitrogen [BUN], calcium, cholesterol, high-density lipoprotein cholesterol, chloride, creatinine, estimated glomerular filtration rate, glucose, high-density lipoprotein [HDL], high-sensitivity C-reactive protein, insulin, potassium, low-density lipoprotein [LDL], sodium, non–high-density lipoprotein, triglycerides, and total protein).

Subjects from both the iHMP and subprojects, such as exercise, were included. Detailed demographic and metabolic characteristics are listed in Table S1 in Multimedia Appendix 1. Females made up approximately 54.4% (56/103) of the overall sample; the majority were White, with a minority being Black or mixed race. The average age was 50.6 (SD 54.6) years, and the median BMI was 26.7 (IQR 19.4 - 39.1) kg/m^2. Some

XSL•FO
RenderX

participants also had recorded steady-state plasma glucose levels and insulin resistance or sensitivity status, which were used for subsequent stratified analyses. This diverse cohort covered a range of metabolic statuses and population characteristics, providing a robust basis for investigating the relationship between metabolic subtypes and MA.

Construction of MCs

To characterize MCs, we applied an unsupervised K-means clustering algorithm to the metabolic data from the healthy phase, ensuring that short-term fluctuations due to infection did not affect the clustering outcomes. This approach improved the biological interpretability and robustness of the identified subtypes. Initially, metabolic data from individuals at high risk for diabetes were collected, standardized, and tested for various clustering numbers (K-values). The optimal number of clusters was determined by calculating the Davies-Bouldin index and using the NbClust function to compute the Kullback-Leibler index. Based on these results, K=3 was selected as the optimal number of clusters, and the data were partitioned into 3 clusters (MC1, MC2, and MC3) using the k-means algorithm. Principal component analysis was applied to visualize the clustering results and validate the distribution of each cluster. Additionally, heatmaps were generated to illustrate the distribution of variables across clusters. Data analysis and visualization were primarily performed using the R packages NbClust, clusterSim, and factoextra.

Redundancy Analysis

Redundancy analysis (RDA) was used to explore the relationship between the gut microbiome and metabolic variables. The RDA was performed using the RDA function from the R package Vegan, applied to both microbiome and metabolic data. Subsequently, the ANOVA function (with 999 permutations) was used to calculate each variable's contribution to the explained variance and identify significant results. The results were converted to percentages and displayed using bar plots to visually represent the explained variance for each metabolic variable.

Distance-Based Redundancy Analysis

To analyze the relationship between different MCs and gut microbiome composition, we performed distance-based redundancy analysis (dbRDA) using the R packages "ggrepel," "dplyr," and "vegan." First, the Bray-Curtis distance was used to compute a distance matrix for the microbiome data, with age and multiple metabolic indicators as independent variables. A dbRDA model was then constructed. To assess the differences in the microbiome composition between MCs, permutational multivariate ANOVA was applied, with 999 permutations to calculate the *P* values.

Random Forest Analysis

To explore the relationship between microbiome characteristics and host age, we used a random forest (RF) model with 5-fold cross-validation, implemented in the R packages "randomForest," "caret," and "tidyr," to predict MA. The microbiome data were combined with the corresponding metadata and split into 70% training and 30% test sets. The model parameters were optimized through 5-fold cross-validation, and the RF model was trained on the training set to predict MA. Model performance was evaluated on both the training and test sets using Spearman correlation and root mean square error (RMSE). The results were visualized with a correlation scatter plot, illustrating the relationship between actual and predicted ages. Additionally, uniform manifold approximation and projection dimensionality reduction was applied to display the distribution of different MCs and low microbial age (LMA) and high microbial age (HMA) in the reduced dimensional space, providing visual support for subsequent analyses. The model was constructed using 500 decision trees (ntree=500), with 5-fold cross-validation used to tune the mtry parameter (ranging from 2 to 6). A random seed of 123 was set to ensure reproducibility. All model training, cross-validation, and performance evaluation were conducted in R using standard packages, including randomForest, caret, and pROC.

Linear Discriminant Analysis Effect Size

To investigate the distribution of significantly different microbial species across different MCs and MA, linear discriminant analysis effect size (LEfSe) was used, with a threshold for linear discriminant analysis (LDA) effect size set at 2. The microbiome data were first standardized to ensure comparability in statistical analysis. LEfSe was then used to test the significance of microbial species in different MCs, identifying those with significant differences across groups. Nonparametric Kruskal-Wallis tests were conducted to assess species abundance differences between groups, followed by LDA to calculate the effect size for each significant species. Species with an LDA score greater than 2 were selected to quantify the intergroup differences.

Co-Occurrence Network Analysis

To reveal the co-occurrence patterns between different microbial populations or genes, we performed correlation analysis using the "propr" package in R (R Core Team). First, the microbial abundance data were standardized to minimize the impact of differences in data magnitude on the analysis. The "propr" package was then used to calculate the phi coefficient (ϕ) between populations, as this coefficient effectively handles high-dimensional zero-inflated data and reduces the impact of sparsity on correlation assessments. Based on the results, we selected significantly correlated pairs using a predefined significance threshold ($\phi \geq 0.3$; *P* value threshold=.05) to construct the co-occurrence network. Network nodes represent microbial populations or genes, and edges indicate significant correlations. Subsequently, modularity analysis was conducted to identify functionally related or synergistic microbial communities, and the modularity index was calculated to assess the quality of network clustering. The network structure was optimized using the Fruchterman-Reingold layout algorithm, with community modules indicated by different colors.

Framingham Risk Assessment

We used the Framingham risk score model to assess the study participants' CVD risk. Data, including age, sex, blood pressure, total cholesterol, low-density lipoprotein cholesterol, high-density lipoprotein cholesterol, and diabetes status, were

XSL•FO
RenderX

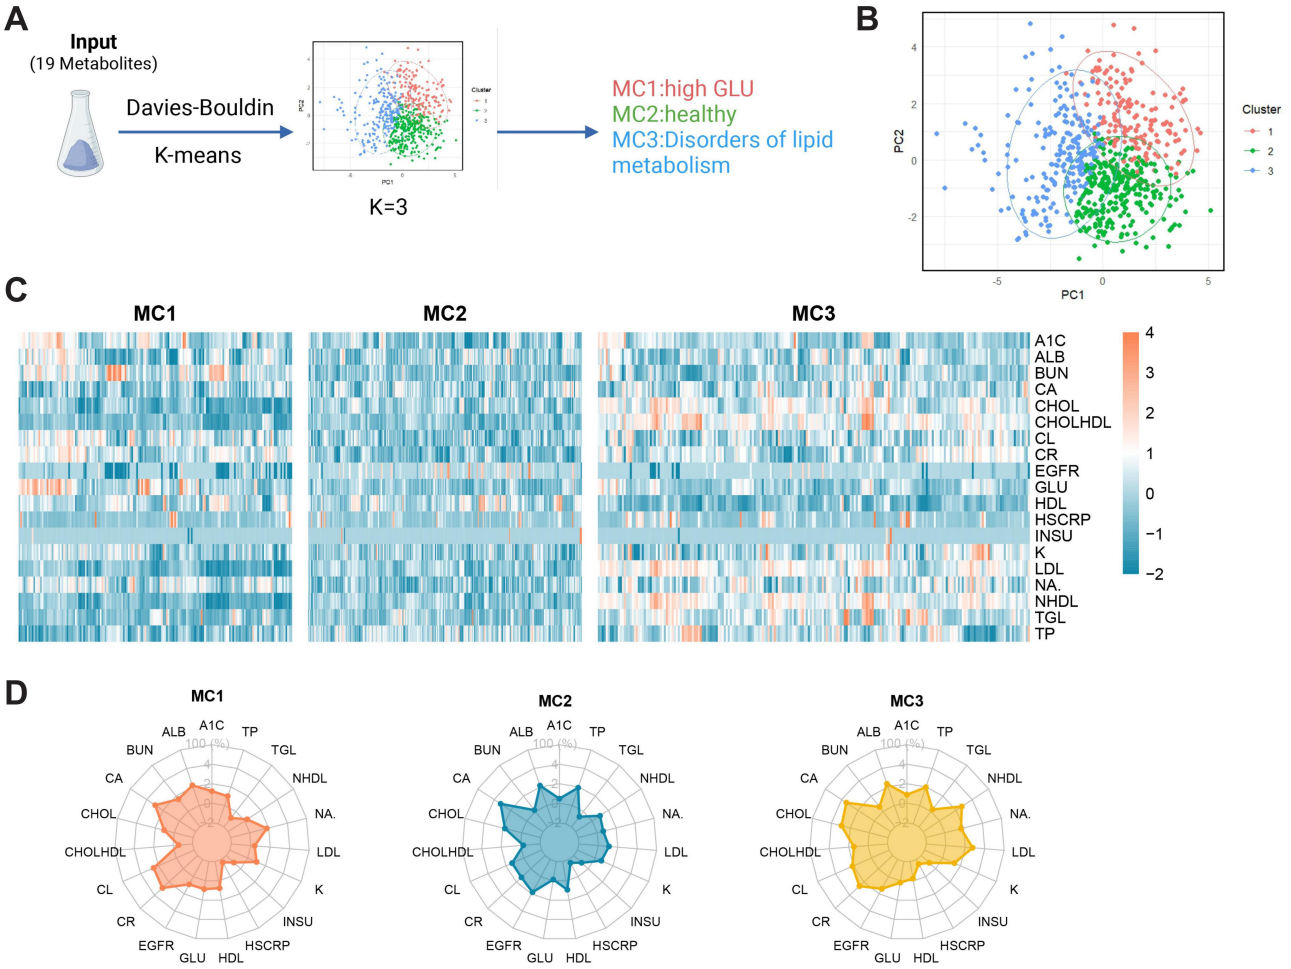
collected. Using the Framingham risk assessment formula, we calculated each participant's probability of developing CVD within the next 10 years. Based on the risk scores, participants were classified into low, medium, and high-risk groups, enabling an analysis of the relationship between different risk levels, gut microbiome composition, and MCs.

RF Model for Predicting CVD Risk

This study used an RF model to predict CVD risk, optimizing model performance through hyperparameter tuning. The dataset was split into 70% training and 30% test sets. We set the random seed to 123 to ensure reproducibility and used 5-fold cross-validation to optimize the mtry parameter (ranging from 2 to 6), training 500 decision trees. The model evaluation included the generation of a confusion matrix to assess classification accuracy and specificity, along with extracting feature importance scores to identify key metabolic indicators. To evaluate the RF model's performance in predicting CVD risk, we used the pROC package to generate ROC curves for each risk category (low, medium, and high) and calculated the corresponding area under the curve (AUC) values.

Results

Construction of MCs and Analysis of Gender Differences and Metabolic Characteristics



Diabetes is a metabolic disorder characterized by prolonged hyperglycemia, typically resulting from insufficient insulin secretion or impaired insulin action [25]. Increasing evidence suggests that the gut microbiome plays a crucial role in the onset and progression of diabetes. The gut microbiome, consisting of diverse microorganisms, including bacteria, fungi, and viruses, is essential for maintaining human health, digestion, absorption, and immune regulation. Recent studies have shown that the gut microbiome in individuals with diabetes exhibits distinct structural and functional characteristics compared to healthy individuals [26].

This study used an unsupervised k-means clustering algorithm to analyze 19 precisely measured metabolic variables and classified 103 participants (including data from both infection and healthy phases) into different metabolic MCs (Figure 1A). The optimal number of clusters was determined to be 3 based on the Davies-Bouldin index and the Kullback-Leibler index. Principal component analysis showed that the 3 clusters exhibited a certain degree of separation in the PC1 and PC2 space, although some sample overlap was observed in certain regions (Figure 1B). We believe that this overlap reflects the continuous spectrum nature of metabolic states in high-risk populations for diabetes, rather than strictly discrete pathological classifications. This may better resemble clinical reality, suggesting that some individuals are in transitional stages of metabolic states. These borderline samples between metabolic phenotypes may exhibit greater plasticity in disease progression and, therefore, warrant special attention in individualized risk assessment and intervention strategies. Moreover, since this study was based on a single cohort, the current clustering results have not yet been externally validated. In the future, we plan to incorporate independent, multicenter population data to further assess the stability and generalizability of the metabolic classification.

Each MC exhibited distinct metabolic subphenotypes: MC1 was characterized by elevated glucose and BUN levels; MC2 represented a relatively healthy metabolic profile; and MC3 was characterized by elevated cholesterol, high-density lipoprotein cholesterol, potassium, LDL, triglyceride, and total protein levels. MC1 may indicate glucose metabolism and kidney function issues, whereas MC3 may be associated with lipid metabolism disorders and potential cardiovascular risk. In contrast, MC2 displayed a more ideal metabolic state, potentially reflecting metabolic homeostasis or better overall health (Figure 1C and D).

XSL•FO
RenderX

Figure 1. Metabolic subphenotype classification and characterization based on k-means clustering. (A) Study workflow: based on 19 metabolic variables, k-means clustering was applied, with the optimal number of clusters determined to be 3 using the Davies-Bouldin index and Kullback-Leibler index. In total, 3 metabolic clusters were identified: MC1 (high glucose), MC2 (healthy metabolic profile), and MC3 (lipid metabolism dysregulation). (B) Principal component analysis of MCs: the distribution of the three clusters is shown in the PC1 and PC2 space, with colors representing MC1 (red), MC2 (green), and MC3 (blue). (C) Distribution of standardized metabolic variable values across different metabolic clusters, with color indicating the relative level of each metabolic variable (orange for higher, blue for lower). (D) Characteristic distribution of 19 metabolic indicators across different metabolic clusters. A1C: hemoglobin A_{1C}; ALB: albumin; BUN: blood urea nitrogen; CA: calcium; CHOL: cholesterol; CHOLHDL: high-density lipoprotein cholesterol; CL: chloride; CR: creatinine; EGFR: estimated glomerular filtration rate; GLU: glucose; HDL: high-density lipoprotein; HSCRP: high-sensitivity C-reactive protein; INSU: insulin; K: potassium; LDL: low-density lipoprotein; NA: sodium; NHDL: non–high-density lipoprotein cholesterol; TGL: triglyceride; TP: total protein.

To explore metabolic differences between genders and across MCs, we used k-means clustering analysis, principal component analysis, and *z*-score normalization methods (Figure 2A). The results showed that, overall, there were no significant gender differences in metabolic characteristics. However, women tended to exhibit higher metabolic levels for certain metabolites, particularly those related to carbohydrate and nitrogen metabolism (eg, BUN and glucose; Figure 2B–C). Moreover, there were notable differences in the distribution of MCs between males and females. While MC2 had the highest proportion in both groups, the proportion of females in MC2 (57%) was significantly higher than that of males (41%). Conversely, a higher proportion of males (29%) was found in MC3 compared to females (23%; Figure 2D). The gender differences in MC1 were minimal, showing typical metabolic characteristics. In MC2, there were small metabolic differences between genders, though the overall metabolic levels were low, possibly indicating a suboptimal health status. In the MC3 group, a clear sex difference was observed, with female participants showing more pronounced metabolic features, such as higher *z*-scores for cholesterol, high-sensitivity C-reactive protein, LDL, and non–high-density lipoprotein compared to males (Figure 2E). This may suggest a greater degree of lipid metabolism disorders and chronic inflammation among females in this group. This phenomenon could be closely related to the regulatory role of sex hormones, especially estrogen, in lipid metabolism. It may also be influenced by gender-differentiated factors such as lifestyle, social role distribution, and dietary behavior. Studies have shown that women, particularly during the perimenopausal period, are at increased risk of lipid metabolic imbalance due to hormonal changes, and the gut microbiota may also be involved in metabolic regulation through estrogen-related pathways [27]. Therefore, gender is a critical factor in both the composition of MCs and the mechanisms underlying MA. Future studies should consider incorporating variables such as hormone levels, menstrual cycle status, and dietary habits to better elucidate their roles in the differentiation of metabolic phenotypes.

XSL•FO
RenderX

Figure 2. Metabolic characteristics analysis based on gender and MCs. (A) Study workflow: metabolic clusters were identified using k-means clustering based on the values of 19 metabolites. *z*-score normalization was applied to analyze gender differences in metabolic characteristics across the metabolic clusters. (B) Distribution of metabolic variables in different genders and metabolic clusters (MC1, MC2, and MC3), with color representing the *z*-score of metabolic levels (orange for higher, blue for lower). (C) Distribution of metabolic clusters in the PC1 and PC2 space for males and females, with different colors indicating different metabolic clusters. (D) Proportional distribution of males and females in each metabolic cluster, with females showing a significantly higher proportion in MC2, while males have a higher proportion in MC3. (E) Comparison of *z*-scores of metabolic indicators between males and females across different MCs. A1C: hemoglobin A_{1C}; ALB: albumin; BUN: blood urea nitrogen; CA: calcium; CHOL: cholesterol; CHOLHDL: high-density lipoprotein cholesterol; CL: chloride; CR: creatinine; EGFR: estimated glomerular filtration rate; GLU: glucose; HDL: high-density lipoprotein; HSCRP: high-sensitivity C-reactive protein; INSU: insulin; K: potassium; LDL: low-density lipoprotein; NA: sodium; NHDL: non–high-density lipoprotein cholesterol; TGL: triglyceride; TP: total protein.

Associations Between Host Age, MCs, and Gut Microbiome

We obtained 16S ribosomal RNA data from gut samples to investigate the relationship between the gut microbiome and host and environmental factors (permutational multivariate ANOVA; Figure 3A). Redundancy analysis was performed to explore how 19 metabolic variables, age, and MCs contribute to the variation in microbiome composition. Notably, age emerged as the strongest host-associated variable affecting microbiome composition (R^2=3%). After accounting for age and other covariates, MCs and most MC-related variables also showed significant contributions. To further explore the relationship between age and gut microbiome composition, participants were divided into 2 groups: a younger group (<60 years) and an older group (≥60 years; Figure 3B). The dbRDA revealed significant associations between age, MCs, and the gut microbiome composition, with the first 2 axes explaining 61% of the total constrained variation. Statistically significant differences in microbial community structure were observed between the younger and older groups (*P*value threshold=05; Figure 3C). Additionally, significant differences in microbiome composition were found between the different MCs (MC1, MC2, and MC3; $P<.05$). The microbiome profiles of MC1, MC2, and MC3 showed distinct differences, reflecting the impact of metabolic status on gut microbiome structure (Figure 3D). Kruskal-Wallis and Dunn tests were used to identify gut microbes with significant abundance differences between MCs. The results revealed that the 2 most prominent phyla were Proteobacteria and Verrucomicrobia. The relative abundance of Proteobacteria showed only slight differences across MC1, MC2, and MC3, with significant variation observed only between MC1 and MC3 (*P* value threshold=.05). In contrast, Verrucomicrobia exhibited more pronounced differences between groups, with significant relative abundance differences found particularly between MC1 and MC2, as well as between MC1 and MC3 (*P* value threshold=.05; Figure 3E).

Figure 3. Association analysis of metabolic clusters, age, and gut microbiota composition. (A) Study workflow: gut microbiota data were obtained through 16S ribosomal RNA sequencing, and a dbRDA model was constructed, incorporating metabolic clusters and age. Permutational multivariate ANOVA was used to identify significant differences in microbiota composition. (B) Redundancy analysis of variable contributions: The explanatory contributions of age, metabolic clusters, and metabolic variables to gut microbiota changes are displayed, with age (R^2=3%) being the strongest covariate. (C) Age-related differences in gut microbiota composition: distance-based redundancy analysis axes CAP1 and CAP2 explained 61% of the compositional variation, with significant differences observed between younger and older groups in microbiota structure (permutational multivariate ANOVA; *P*=.006). (D) Gut microbiota differences among metabolic clusters: distance-based redundancy analysis revealed significant compositional differences between MC1, MC2, and MC3 (permutational multivariate ANOVA; *P*.001), with CAP1 explaining 48% of the variation. (E) Key differences in gut microbiota phylum-level abundances between different metabolic clusters: Kruskal-Wallis and Dunn tests identified significant abundance differences in Proteobacteria and Verrucomicrobia phyla across metabolic clusters. A1C: hemoglobin A_{1c}; ALB: albumin; BUN: blood urea nitrogen; CA: calcium; CHOL: cholesterol; CHOLHDL: high-density lipoprotein cholesterol; CL: chloride; CR: creatinine; dbRDA: distance-based redundancy analysis; EGFR: estimated glomerular filtration rate; GLU: glucose; HDL: high-density lipoprotein; HSCRP: high-sensitivity C-reactive protein; INSU: insulin; K: potassium; LDL: low-density lipoprotein; NA: sodium; NHDL: non–high-density lipoprotein cholesterol; TGL: triglyceride; TP: total protein; PERMANOVA: permutational multivariate ANOVA.

Construction and Validation of MA

We conducted a Kruskal-Wallis test to analyze the differences in microbial species abundance between different age groups (younger group:<60 years, older group:≥60 years) and identified microbial species that showed significant differences between these age groups. Based on 20 significantly different species, we constructed a five-fold cross-validation RF model to predict MA (Figure 4A). The model results showed a high correlation in the training set (ρ=0.97; *P* value threshold=.01) and a low RMSE of 3.33, indicating a strong relationship between age and MA within the training data. The model performed well on this dataset. In the test set, the model still showed a significant correlation (ρ=0.35; *P*=1.18e-05), suggesting an association between age and MA. Although the model demonstrated high predictive correlation in the training set (ρ=0.97; RMSE=3.33), its performance in the test set was relatively limited (ρ=0.35; RMSE=8.96), suggesting that the model's generalizability to unseen samples requires improvement (Figure 4B). In addition, the current MA model was built based solely on 20 differential microbial genera and did not incorporate microbial functions or metabolic products, which may oversimplify the complex microbiome features associated with age. Future work could reference related studies [28] to integrate metabolomics, functional genomics, or host-microbiome interaction data in order to develop a more comprehensive and robust MA prediction model and enhance its utility as a biomarker. After stratifying participants into LMA and HMA groups, we found that the microbial composition differences between the MA groups were significantly greater than the differences observed between the three MCs (Figure 4C). Additionally, the distribution of MCs was similar between the 2 MA groups. Notably, MC2 was the dominant cluster in the LMA group (51%), suggesting that MC2, representing a relatively healthy metabolic profile, predominates in individuals with LMA (Figure 4D). Next, we examined the differences in metabolic levels (measured in *z*-scores) between the LMA and HMA groups across different MCs (MC1, MC2, and MC3). The results showed that cholesterol, high-density lipoprotein cholesterol, LDL, non–high-density lipoprotein, and triglycerides were higher in MC3 than in MC1 and MC2, and higher in the HMA group compared to the LMA group. These findings suggest that MC3 is closely associated with lipid metabolism abnormalities, particularly in the HMA group, which exhibited higher levels of lipid metabolism dysregulation. This may indicate that higher MA is linked to disturbances in lipid metabolism (Figure 4E).

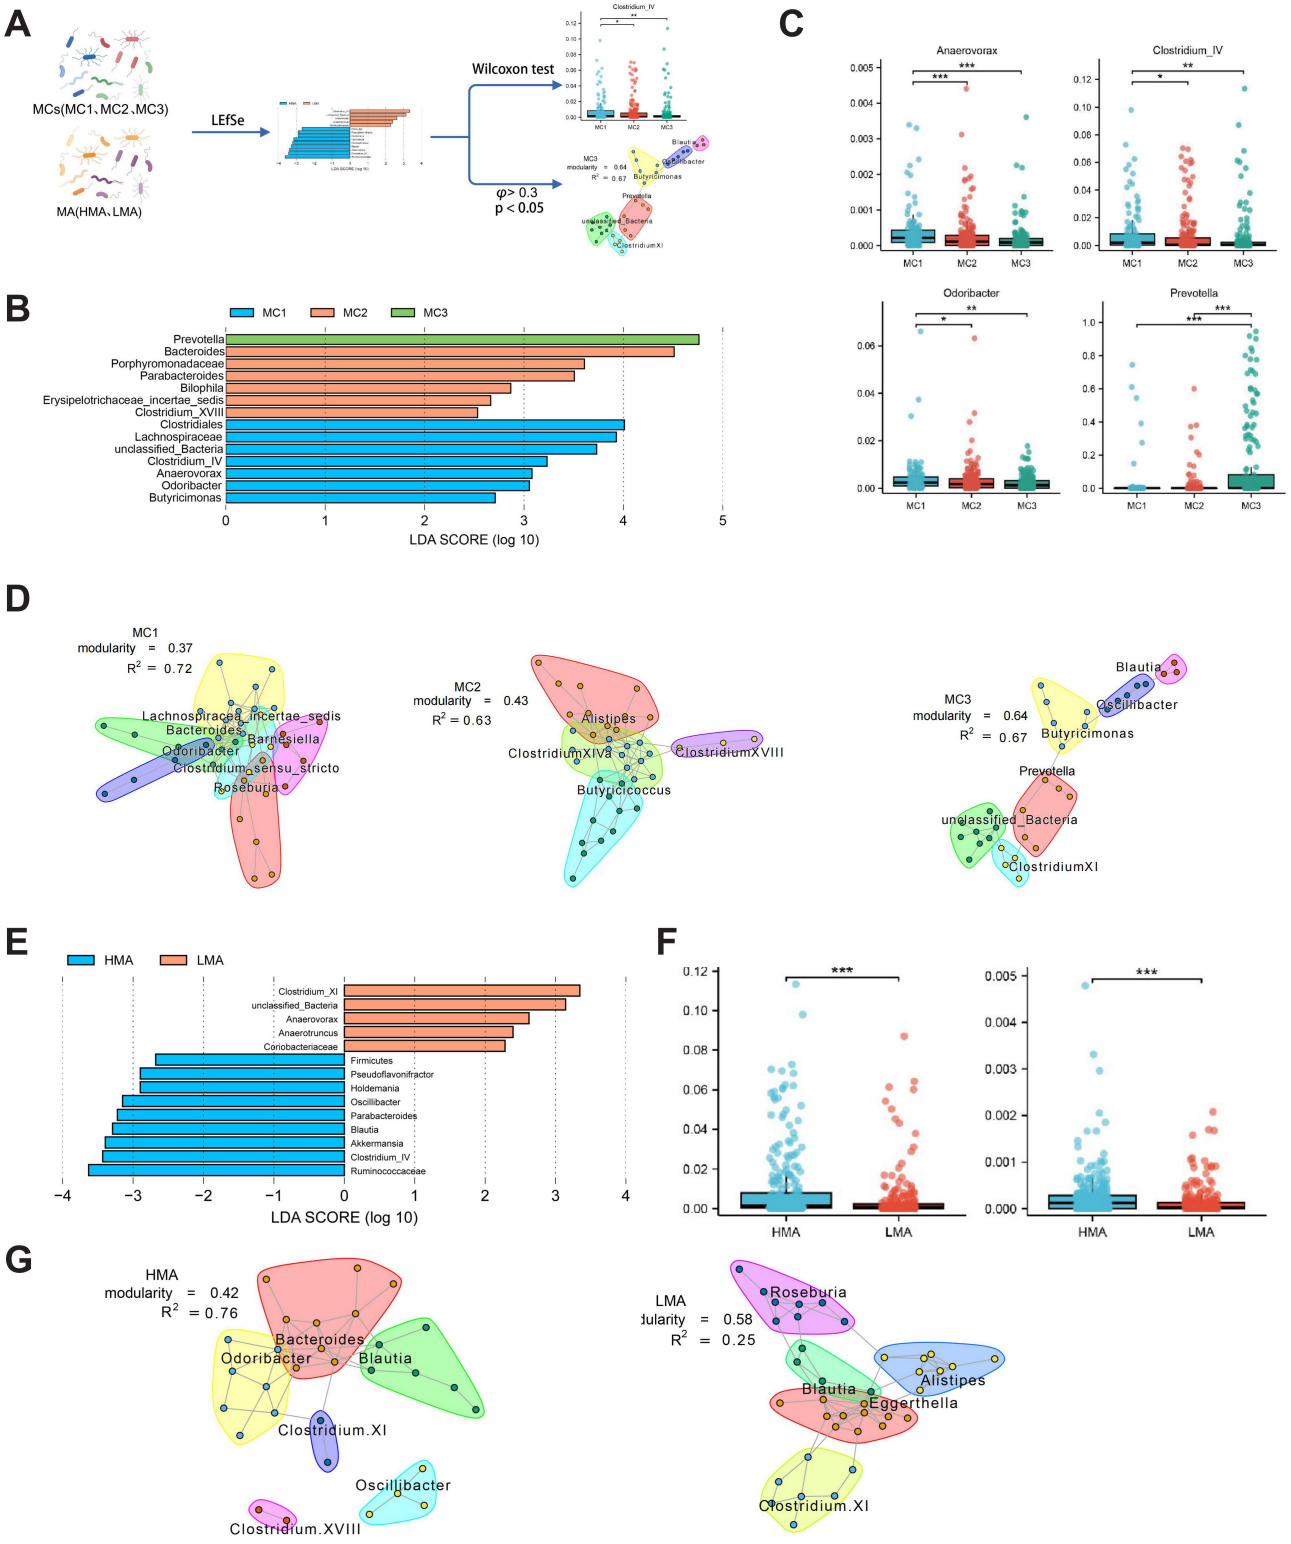
Microbial Community Differences in MCs and MA



Using gut microbiome data from different metabolic clusters (MC1, MC2, and MC3) and MA groups (HMA and LMA), we used LEfSe analysis to identify bacterial genera that differed significantly between groups, with a threshold of LDA score>2 and *P* value threshold=.05. The differences in microbial abundance were further validated using the Wilcoxon test (Figure 5A).

To explore the species-level microbial differences within the MCs (MC1, MC2, and MC3), LEfSe analysis statistically delineated community variances, revealing genera with significant intergroup differences. Subsequently, we compared the abundance of these distinct genera across metabolic groups. The results indicated that Akkermansia, *Clostridium IV*, and Oscillibacter had significantly higher relative abundance in MC1 compared to other groups, while *Prevotella* was most abundant in MC3. MC1 was enriched with *Clostridium IV*, *anaerovorax, and odoribacter*, potentially linked to metabolic traits associated with glucose metabolism and renal function [29,30]. MC2 predominantly contained *Bacteroides*, *Parabacteroides, and Bilophila*, known for their roles in maintaining intestinal health and metabolic balance, reflecting MC2's relatively healthy metabolic characteristics [31-33]. *Prevotella* was notably enriched in MC3, suggesting a close association with lipid metabolism disorders and potential cardiovascular risk [34]. These findings elucidate the differential distribution of microbial species across metabolic groups and their potential functional correlations (Figure 5B and C). The coexpression network characteristics and modular distribution of microbial species within the three MCs (MC1, MC2, and MC3) revealed microbial communities' synergy and clustering traits under different metabolic states. In the MC1 group, the modularity value of the microbial coexpression network was 0.37 with an R^2 value of 0.72, indicating a less modular structure but still discernible clustering characteristics within this metabolic group. The primary modules included *Achromobacter aceae incertae sedis*, *Bacteroides*, and *Roseburia*. In MC2, the modularity value increased to 0.43 with an R^2 value of 0.63, suggesting clearer microbial community segregation. The main modules consisted of *Clostridium XIVa*, *Alistipes*, and *Butyricicoccus*, implying more distinct synergistic relationships among different microbes in MC2. The MC3 group exhibited the most pronounced modular features, with a modularity value of 0.64 and an R^2 value of 0.67, indicating a more independent and stable microbial network structure. The principal modules included *Butyricimonas*, *Prevotella*, and *Clostridium XI*. The high modularity value reflects a more differentiated microbial ecosystem within MC3, potentially linked to its characteristic metabolic state related to lipid metabolism abnormalities (Figure 5D).

We used LEfSe analysis to assess the statistical differences in microbiome composition between the HMA and the LMA and to compare the relative abundance of significantly different genera between these MA groups. The results indicated that in the HMA group, genera significantly differing from the LMA group included *Firmicutes*, *Pseudoflavonifractor*, *Holdemania*, *Oscillibacter*, *Parabacteroides*, *Blautia*, *Akkermansia*, *Clostridium IV*, and *Ruminococcaceae*, which may be linked to the metabolic features of HMA. In contrast, the LMA group was significantly enriched with *Clostridium XI*, *Anaerovorax*, *Anaerotruncus*, *and Coriobacteriaceae* genera. Notably, the relative abundance of *Clostridium IV* and *Pseudoflavonifractor* was significantly higher in the HMA group compared to the LMA group (P<.001), suggesting that HMA is associated with the enrichment of specific genera. These differences highlight the significant impact of MA on microbiome structure and function (Figure 5E and F). For the HMA group, the modularity value of the coexpression network was 0.42, with an R^2 value of 0.76, indicating a moderately modular microbial network with strong correlations. Key modules included *Bacteroides*, *Odoribacter*, *Blautia*, and *Clostridium XI*, suggesting high synergy and functional connections among these genera in the HMA group. In contrast, the LMA group exhibited a higher modularity value of 0.58 but a lower overall network correlation (R^2=0.25). Major modules in the LMA group included *Roseburia*, *Blautia*, *Eggerthella*, and *Clostridium XI*, suggesting a more differentiated microbial distribution and the possible formation of independent ecological units. These differences reflect the varying effects of MA on microbial synergy and functional differentiation, with the HMA group exhibiting stronger metabolic functional co-ordination while the LMA group shows more differentiated ecological traits (Figure 5G).

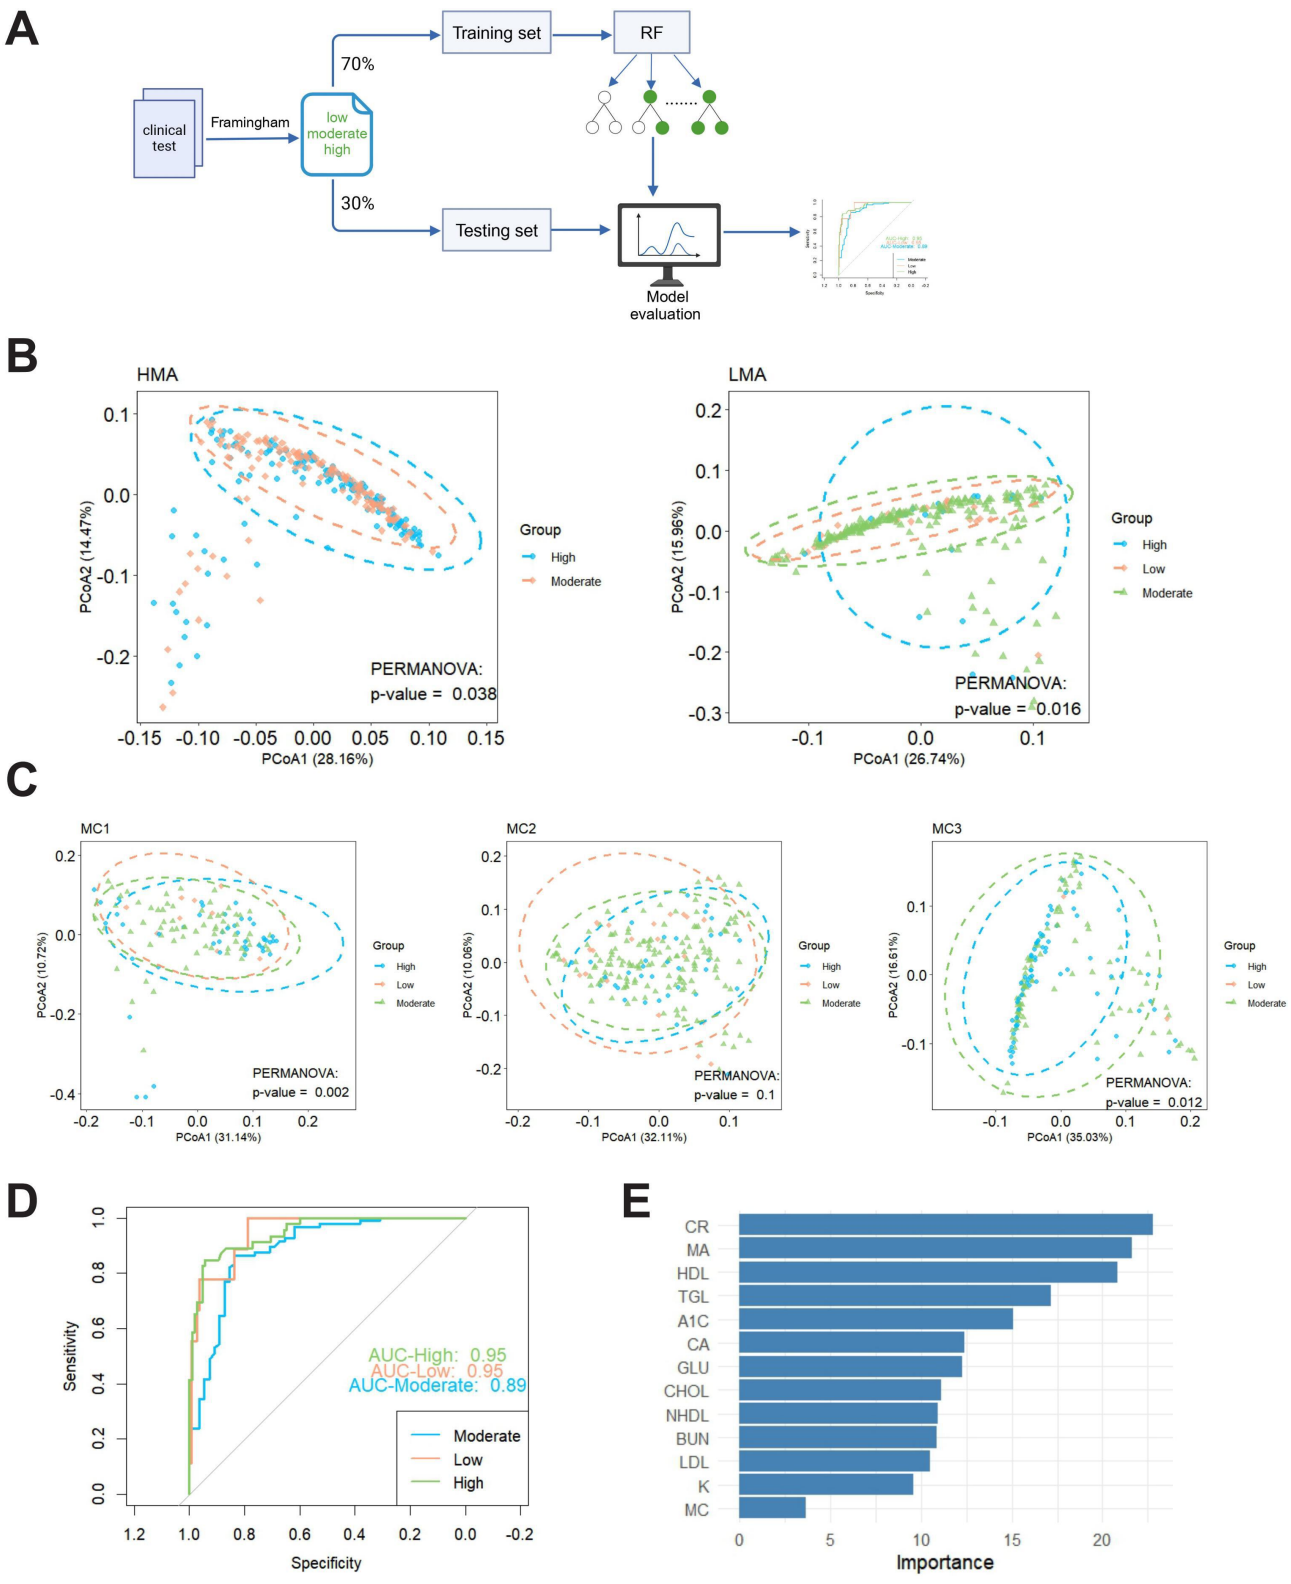
Figure 5. Gut microbial characteristics differences between metabolic clusters (MC1, MC2, and MC3) and microbial age groups (high microbial age and low microbial age). (A) Analysis workflow: Based on metabolic clusters and microbial age groups, linear discriminant analysis effect size analysis (linear discriminant analysis score>2, *P* value threshold=.05) and Wilcoxon tests were used to identify significantly different taxa, and co-occurrence network analysis was applied to reveal microbial community structure and functional characteristics. (B) Genera with statistically significant differences across metabolic subtypes (MC1-MC3) and microbial age groups (low microbial age and high microbial age) were identified using linear discriminant analysis effect size, with thresholds set at linear discriminant analysis score>2 and *P* value threshold=.05. (C) Box plots comparing the relative abundances of significantly different genera. (D) Genus coexpression networks: Nodes represent genera, node color indicates module membership, node size is proportional to mean abundance, and edge width reflects the strength of correlation (ϕ>0.3; *P* value threshold=.05). Modules were defined based on modularity maximization. (E) Linear discriminant analysis scores for microbial age groups. (F) Comparison of the abundance of significantly different taxa between high microbial age and low microbial age groups. (G) Co-occurrence network analysis for microbial age groups: microbial pairs were selected based on a ϕ coefficient>0.3 and *P* value threshold=.05; modules were defined using modularity maximization. Node color indicates functional modules, node size reflects relative abundance, and edge width indicates correlation strength. All significance tests were conducted using the Wilcoxon rank-sum test.

XSL•FO
RenderX

Association Between MA, MCs, and CVD Risk



Using the Framingham risk assessment, we evaluated the CVD risk of the study participants. Based on these risk scores (high, medium, and low), we analyzed differences in gut microbiome composition between the LMA and HMA groups. Principal Co-ordinates Analysis and permutational multivariate ANOVA were performed to reveal significant differences in microbiome composition across the different risk groups (Figure 6A). The results indicated that within both the HMA and LMA groups, significant differences in gut microbiome composition were observed across the high, medium, and low cardiovascular risk categories. Specifically, in the HMA group, there was a distinct difference in microbiome composition between the high-risk and medium-risk groups (value threshold=.05), while in the LMA group, significant differences were found across all three risk categories (low, medium, and high) (*P* value threshold=.05; Figure 6B). Next, we examined the microbiome distribution across the different cardiovascular risk groups (high, medium, and low) within each MC. The results showed that in the MC1 group, significant differences in microbiome composition were observed between the high-risk and medium-risk groups in the HMA group (*P* value threshold=.05). In the MC2 group, no statistically significant differences were found between the risk groups (*P* value threshold=.05). In contrast, in the MC3 group, the high-risk and medium-risk groups exhibited significant differences in microbiome composition (*P* value threshold=.05). These findings suggest that microbiome composition significantly differs across cardiovascular risk groups, particularly between the high-risk and medium-risk categories, indicating a potential association between gut microbiome composition and CVD risk status (Figure 6C).

We further constructed a multifactorial prediction model using the RF algorithm, incorporating variables such as MA, MCs, and metabolic indicators to assess their predictive power for CVD risk. The model demonstrated a strong ability to differentiate between risk groups. Specifically, the curve for the medium-risk group (blue) was close to the top left corner, with an AUC of 0.89, indicating good predictive ability. The curve for the low-risk group (orange) showed an AUC of 0.95, indicating excellent discriminatory ability for this group. Similarly, the high-risk group (green) displayed an AUC of 0.95, comparable to the low-risk group, suggesting the model's strong predictive power for both high and low-risk groups (Figure 6D). The importance of each variable in predicting CVD risk within the RF model was ranked. The results showed that creatinine had the highest importance score, indicating that CR contributed the most to the model's predictive ability. MA and HDL were the next most influential variables, significantly impacting CVD risk prediction. In contrast, the importance of MCs was lower, contributing less to the model's prediction. These findings suggest that the model primarily relies on key metabolic indicators (CR and HDL) and MA to predict CVD risk, with a relatively minor contribution from MCs (Figure 6E). These findings suggest that MA and MCs, as novel biomarkers, have not yet surpassed traditional indicators in predicting cardiovascular risk. Instead, they may serve as complementary factors to conventional markers or as tools for risk stratification in specific subpopulations. In the future, longitudinal data modeling, stratified analyses, or multimodal integration approaches should be employed to enhance their independent predictive power and explore their practical clinical value in informing early intervention strategies among high-risk populations.

Discussion

Principal Findings

This study reveals associations between different metabolic communities (MC1, MC2, and MC3) and gut microbiome composition while exploring the potential mechanistic links between the microbiome and metabolic health. LEfSe analysis identified key microbial taxa associated with specific metabolic features, emphasizing the complex interplay between host metabolism and gut microbiota.

MC1 is characterized by elevated glucose and BUN levels, suggesting potential insulin resistance, prediabetes, or diabetes. The microbiota in MC1 is significantly enriched with *Clostridium IV, Anaerovorax*, and *Odoribacter*, which may influence glucose metabolism through specific pathways. *Clostridium* species produce SCFAs, such as butyrate and acetate, critical in regulating insulin sensitivity [35,36]. Studies

XSL•FO
RenderX

have shown that SCFAs regulate insulin sensitivity by activating G-protein coupled receptors, thereby influencing insulin secretion and glucose homeostasis. However, it should be noted that the association observed in this study between *Clostridium IV* and glucose metabolism indicators has not yet been experimentally validated for causality. Future investigations using fecal microbiota transplantation, germ-free animal models, or in vitro coculture experiments could help elucidate the specific mechanistic role of *Clostridium IV*, thereby enhancing the biological interpretability of the observed microbiome–metabolism associations. In addition, SCFAs can modulate the secretion of gut hormones that influence appetite and energy metabolism, further improving insulin sensitivity [37,38]. The metabolic imbalance observed in the MC1 group (elevated glucose) may involve gut dysbiosis (enrichment of *Clostridium IV*), impaired intestinal barrier function, and increased systemic inflammation, which together exacerbate insulin resistance and trigger glucose metabolism disorders.

In contrast, MC2 represents a metabolically healthy state, with normal glucose, lipids, and nitrogen metabolism markers. Key microbial taxa enriched in MC2, including *Bacteroides*, *Parabacteroides*, and *Bilophila*, likely contribute to maintaining metabolic homeostasis. *Bacteroides* play a pivotal role in the secondary metabolism of bile acids, influencing the gut-liver axis and lipid metabolism while reducing inflammation [39]. *Parabacteroides* may help maintain gut microbiota balance by inhibiting pathogenic bacterial growth, thereby supporting metabolic health [32]. The healthy metabolic state in MC2 (normal metabolic markers) is supported by a balanced microbiome composition (*Bacteroides* enrichment), which maintains normal bile acid metabolism and homeostasis of the gut-liver axis.

The MC3 group is characterized by elevated levels of cholesterol, LDL, and triglycerides, indicating lipid metabolism disorders and potential cardiovascular risk. Prevotella was significantly enriched in MC3, suggesting that these genera may aggravate lipid metabolic disturbances through multiple pathways. The *Prevotella* genus may promote systemic inflammation by producing lipopolysaccharide, inhibit reverse cholesterol transport, and contribute to atherosclerosis [40]. Lipid metabolism disorders in the MC3 group (elevated cholesterol and LDL) may be associated with gut dysbiosis (enrichment of *Prevotella*), increased inflammation, and oxidative stress, collectively heightening cardiovascular risk. It is important to note that the 16S ribosomal RNA (rRNA) sequencing technology used in this study is limited to genus-level resolution and cannot distinguish between functionally heterogeneous microbial species. For example, although *Prevotella* was enriched in the MC3 group, previous research has shown that different *Prevotella* species may have significantly distinct roles in lipid metabolism—some may promote lipopolysaccharide production and inflammation, while others may have anti-inflammatory potential. Therefore, while 16S rRNA sequencing is suitable for preliminary screening of microbial community structure, it has limitations for functional mechanism studies. Future research should use higher-throughput methods such as metagenomic sequencing or metabolomics to improve the depth and accuracy of functional characterization, which is particularly important for elucidating microbial mechanisms related to lipid metabolic disorders [41,42].

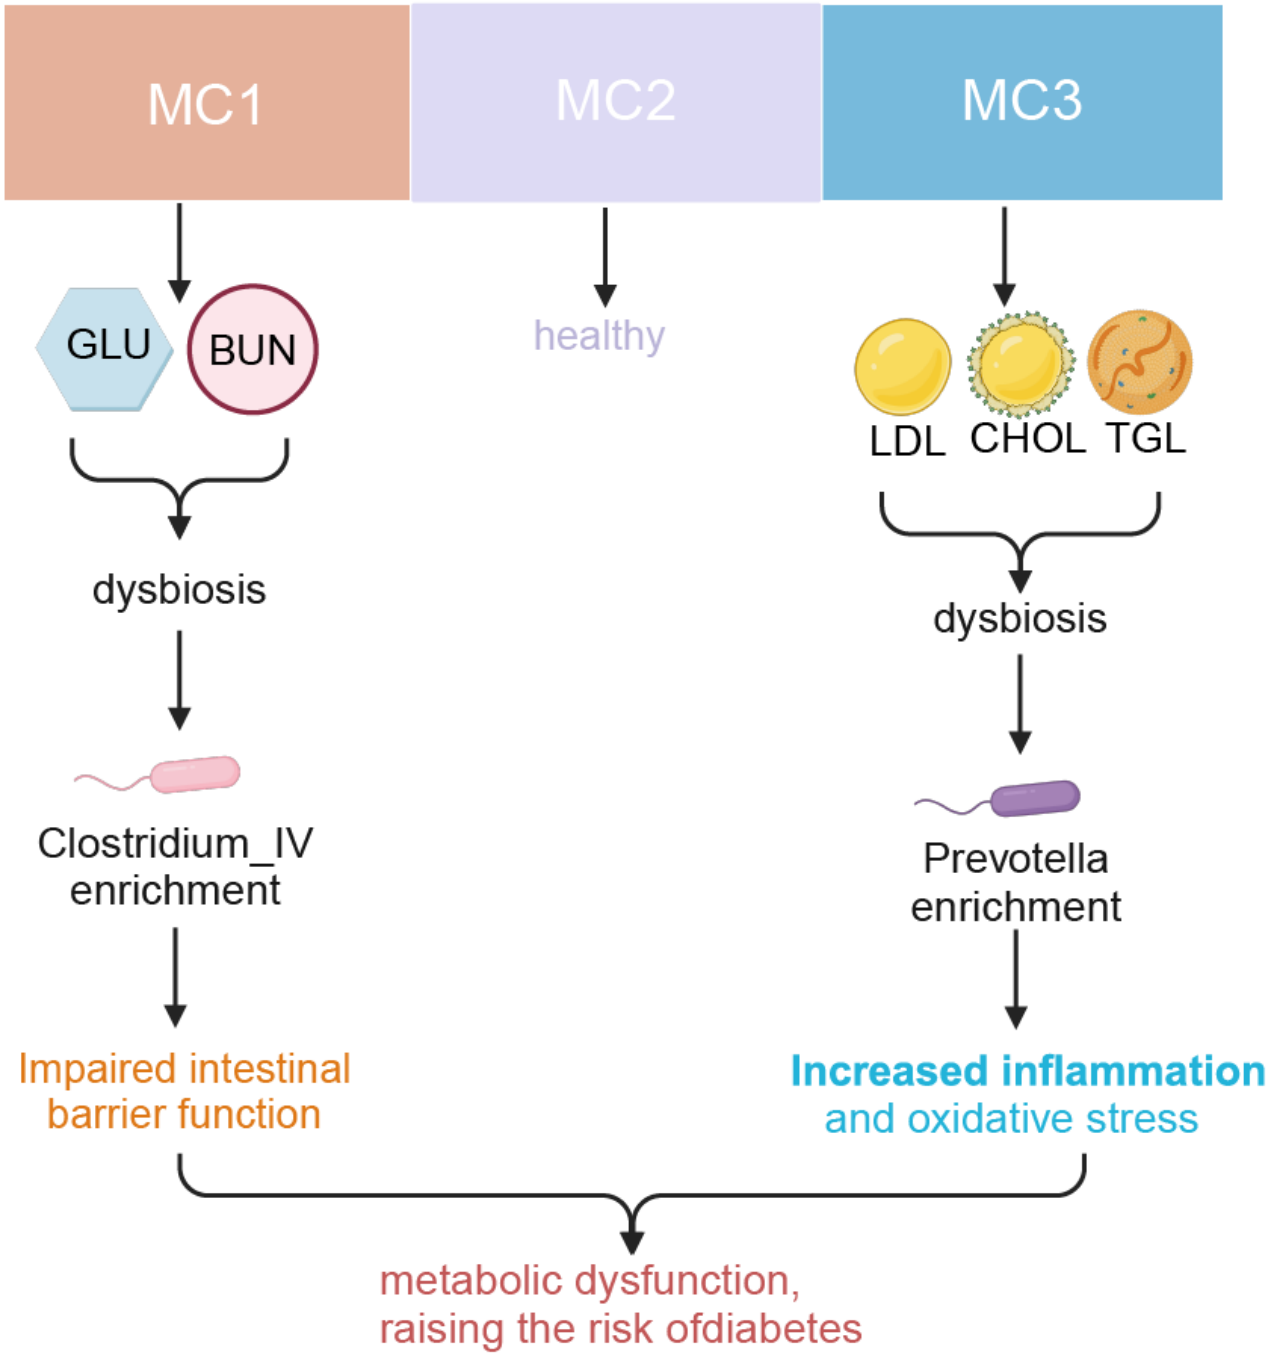
The microbiota enriched in the HMA group includes *Pseudoflavonifractor* and *Clostridium IV*. Studies indicate that *Pseudoflavonifractor* is a major producer of butyrate, which provides energy to the colonic mucosa and regulates host cell gene expression, inflammation, differentiation, and apoptosis [43]. *Clostridium IV* is also involved in butyrate production, a crucial metabolite for gut health that may influence energy metabolism and inflammatory responses [44]. This study observed significant associations between high MA and specific microbiome structures, enrichment of inflammation-related genera, and lipid metabolic abnormalities, suggesting a potential link between microbial aging and metabolic dysfunction. However, as this is a cross-sectional study, it is not possible to determine whether changes in MA temporally precede the onset of metabolic disorders, nor can causality be established. Thus, the proposed mechanistic explanations are based solely on correlation analyses and existing literature. Future studies should employ longitudinal follow-up or interventional designs to validate the temporal sequence and causal role of MA in the development of lipid disorders and cardiovascular risk.

Despite achieving meaningful results regarding the association between microbiological and metabolic characteristics in high-risk populations for diabetes, this study also has several limitations. First, the samples were collected during both infection and healthy phases. Although only healthy-phase samples were included in the primary analyses to minimize acute confounding, differences in physiological state may still have introduced potential biases in certain outcomes. We addressed this by applying data filtering, standardization, and sensitivity analyses to mitigate such biases as much as possible. Furthermore, although the study used large-scale iHMP data, the scope and sample size remain limited, potentially failing to capture the full diversity of high-risk diabetic populations globally. This limitation may be especially relevant when performing gender-stratified or subgroup analyses, which can result in reduced statistical power and an increased risk of type II error. Thus, some observed gender differences should be interpreted with caution, as they may be subject to bias or instability due to limited sample sizes. Future studies should aim to replicate and validate these findings using larger, multi-center datasets to strengthen the statistical reliability of subgroup analyses. Additionally, although the MA model offers a promising predictive tool, its accuracy requires further validation and optimization. The current MA model, based on 16S rRNA sequencing data, can identify genus-level microbial features but lacks the resolution to discern species-level functional heterogeneity or metabolic potential. This limits the model's explanatory power regarding microbial functional status. Future research should integrate multi-omics functional data, such as metagenomic sequencing to identify microbial species and functional genes, as well as metatranscriptomics and metabolomics to measure gene expression and metabolic outputs, in order to more accurately capture microbial functional states and improve the construction of the MA model. Moreover, this study's cross-sectional design prevents the establishment

XSL•FO
RenderX

of causal relationships between MA and the risks of diabetes and cardiovascular diseases. Longitudinal studies are needed to explore the causal links and underlying mechanisms among these variables. Finally, although the study used the iHMP platform, which provided relatively comprehensive clinical and microbiome data, several key lifestyle variables were either missing or inadequately documented. These variables include dietary intake, medication use (such as antidiabetic agents and statins), physical activity, and smoking status. As these factors are widely recognized to significantly influence gut microbiota and metabolic status, their absence may confound the observed associations between MA, metabolic subtypes, and cardiovascular risk.

Therefore, future research could advance in several key areas. On the one hand, given the complex interactions between metabolic dysregulation and the microbiota in diabetes and CVD, researchers could explore the functional differences of microbiota across different metabolic subtypes and their association with disease progression. By integrating high-throughput sequencing technologies and metabolomics, researchers could further elucidate how gut microbiota influences high-risk diabetic populations. On the other hand, with the ongoing advancement of artificial intelligence and machine learning technologies, future studies could enhance the predictive capability of MA about metabolic disorders and cardiovascular risk through multidimensional data integration. For instance, deep learning models based on multiomics data could more accurately identify potential biomarkers and assist in developing personalized clinical interventions. Furthermore, future interventional clinical trials will help verify the practical value of MA in the early prevention of diabetes and CVDs, thus advancing the clinical translation of precision medicine.



Conclusion

This study reveals significant features of MCs and MA in individuals at high risk for diabetes, exploring the complex relationships between these features, gut microbiota, metabolic indicators, and CVD risk (Graphic abstract). Using k-means clustering, we classified high-risk individuals into three distinct metabolic subtypes, each associated with glucose metabolism disturbances, metabolic homeostasis, and lipid metabolism abnormalities. RDA identified age as the primary covariate influencing gut microbiome composition, with significant differences observed between the microbiomes of the different metabolic subtypes. An RF model was employed to predict the relationship between MA and CVD risk, revealing a significant predictive correlation between MA and chronological age. LEfSe analysis further identified microbial taxa with significant differences across metabolic subtypes and MA groups. Ultimately, we found that the HMA group exhibited stronger lipid metabolism disturbances and CVD risk characteristics, suggesting that MA may serve as a potential biomarker for early assessment and intervention in high-risk diabetic populations.

The main contribution of this study lies in its systematic identification of the associations between MCs and MA, highlighting how these factors jointly influence metabolic disturbances and CVD risk in high-risk diabetes populations. This finding not only provides new insights into the complex pathophysiological mechanisms underlying diabetes and its complications but also offers a novel biological marker for personalized treatment and early intervention in high-risk diabetes individuals. As a potential predictor of metabolic dysfunction and CVD risk, MA holds significant clinical relevance. It may not only assist in predicting the onset of diabetes and CVD but also provide a new biological foundation for early intervention in high-risk groups. Thus, this study offers clinicians more precise risk assessment tools, facilitates the development of personalized medicine, and introduces new strategies for preventing and treating diabetes and CVDs (Figure 7).

Figure 7. Mechanistic diagram of the association between metabolic clusters, gut microbiota, and diabetes risk. MC1 and MC3 are characterized by impaired glucose and lipid metabolism, respectively. They are accompanied by gut microbiota dysbiosis enriched with *Clostridium IV* and *Prevotella*, which leads to compromised intestinal barrier function and increased inflammation and oxidative stress. BUN: blood urea nitrogen; CHOL: cholesterol; GLU: glucose; LDL: low-density lipoprotein; MC: metabolic cluster; TGL: triglyceride.

Data Availability

The data used in this study were obtained from the publicly accessible NIH Integrative Human Microbiome Project (iHMP) database and can be accessed at [45]. All analysis code used in this study, including data preprocessing, clustering analysis, microbial age modeling, and cardiovascular disease risk prediction, is available from the corresponding author upon reasonable academic request for the purposes of research replication.

Authors' Contributions

XL and HG contributed equally to this work and are considered co-first authors. XL conceptualized the study, conducted data analysis, and drafted the manuscript. HG participated in data collection, microbiome analysis, and manuscript editing. RL and XM were responsible for clinical data acquisition and contributed to the interpretation of cardiovascular outcomes. CC supervised the project, provided critical revisions, and approved the final version of the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Myocardial ischemia-reperfusion injury (MIRI) poses diagnostic challenges due to complex histopathological changes.

Objective: This study aimed to develop an intelligent framework for evaluating MIRI on hematoxylin-eosin–stained slides, to compare major deep learning architectures, and to determine the advantages of transformer models across multiple interventions and time points.

Methods: A total of 1280 whole-slide images (~62,000 tiles) from public datasets were analyzed across antioxidant, β-blocker, calcium channel blocker, and control groups at 6, 24, and 72 hours. Seven model families (convolutional neural networks, recurrent neural networks, long short-term memory networks, autoencoders, graph convolutional networks, variational autoencoders, and transformers) were trained under unified preprocessing, with generative adversarial networks used exclusively for leakage-free augmentation. Weak supervision used a clustering-constrained attention multiple-instance learning strategy, and segmentation applied a Transformer-UNet. Data were split into 8:1:1 at the subject level, with 5-fold cross-validation.

Results: The transformer achieved the best performance (accuracy=0.942; area under the curve=0.982; and F_1-score=0.958). Segmentation Dice scores were 0.847 (necrosis) and 0.821 (apoptosis). Predictions strongly agreed with expert measurements (r=0.886; Bland-Altman limits +5% or −5%), and attention maps aligned with necrotic borders and inflammatory foci. Temporal trends matched biological expectations, with the antioxidant group showing the most stable improvement.

Conclusions: Transformer-based pathology offers accurate, robust, and interpretable assessment of MIRI and provides a scalable framework for dynamic injury quantification and therapeutic evaluation.

Introduction

Myocardial infarction (MI) is one of the leading causes of disability and mortality worldwide [1]. The widespread adoption of reperfusion therapies, including thrombolysis and percutaneous coronary intervention, has enabled a growing proportion of patients with acute myocardial ischemia to receive timely treatment [2]. However, although reperfusion can salvage ischemic myocardial tissue, it may also trigger additional tissue injury under certain conditions, a phenomenon known as myocardial ischemia-reperfusion injury (MIRI) [1,3]. The pathogenesis of MIRI involves multiple interacting mechanisms, including oxidative stress, calcium overload, inflammatory activation, mitochondrial dysfunction, and programmed cell death, all of which contribute to cardiomyocyte apoptosis and necrosis [4,5]. Secondary injury caused by MIRI reduces the therapeutic benefit of reperfusion and promotes adverse cardiac remodeling and progression to heart failure, ultimately affecting long-term clinical outcomes. Therefore, early identification and dynamic monitoring of MIRI at the tissue level have become critical challenges in basic and clinical cardiovascular research.

Hematoxylin and eosin (H&E)–stained tissue sections remain the diagnostic gold standard for assessing myocardial morphological changes and evaluating cellular injury in both clinical and experimental research. MI lesions identified by

H&E staining typically show increased cytoplasmic eosinophilia, loss of cross-striations, and nuclear pyknosis or karyolysis, which indicate coagulative necrosis. These alterations are followed by inflammatory cell infiltration, disruption of myocardial structure, and subsequent fibrosis [6]. Although these histopathological features can be clearly recognized under light microscopy, manual slide evaluation is affected by staining variability, background artifacts, and tissue heterogeneity. These factors reduce analytic efficiency and introduce considerable observer subjectivity [7,8]. Reliance on expert pathological experience further limits the consistency and scalability of H&E slide interpretation, particularly in studies involving large sample sizes, multiple interventions, or multiple time points [9]. Therefore, there is an urgent need for an efficient, objective, and reproducible intelligent method to replace or to assist traditional manual histopathological review (Multimedia Appendix 1).

Artificial intelligence (AI), particularly deep learning, has achieved remarkable advances in medical image analysis in recent years. Convolutional neural networks (CNNs) have been widely applied to the automatic recognition of pathological images in diseases such as breast and lung cancer, demonstrating performance that matches or even exceeds that of human experts [10,11]. Recurrent neural networks (RNNs) and long short-term memory networks (LSTMs) have also shown superior capabilities in handling time series and dynamic medical images [12]. Generative adversarial networks (GANs) provide powerful tools for image augmentation, modality conversion, and synthetic data generation, which effectively mitigate the limitations posed by small training cohorts [13].

Recent systematic analyses have emphasized the expanding role of AI in medical image interpretation, and multiple reviews have noted that deep learning shows considerable potential in pathology, imaging, and multimodal data integration [14,15]. However, most current research remains focused on domains such as tumor image recognition or pulmonary computed tomography analysis. Efforts related to the identification of myocardial reperfusion injury based on histological or imaging data remain limited. Comprehensive studies that integrate multiple models and cross-modality evaluation are still lacking [16]. In addition, the interpretability of model outputs and their alignment with underlying biological mechanisms are still inadequate, further constraining the broad clinical translation of AI technologies in myocardial pathological diagnosis.

Transformer-based models have recently achieved strong performance in natural language processing and image segmentation and are increasingly applied to pathological image interpretation. Their global attention mechanisms enable the capture of long-range pixel dependencies, offering a theoretical advantage in analyzing complex tissue architectures and indistinct boundaries in histological images [17,18]. Generative models such as GANs contribute to data augmentation, rare structure reconstruction, and synthetic sample generation, thereby improving model robustness and generalizability [19]. A systematic comparison of major deep learning architectures for the analysis of H&E-stained sections in MIRI has not yet been established. Relevant architectures include CNNs, RNNs, LSTMs, autoencoders, graph convolutional networks (GCNs), variational autoencoders (VAEs), transformers, and GANs. Studies that analyze dynamic histopathological trends across multiple time points and treatment conditions also remain limited [20]. Current research is further constrained by incomplete dataset construction and inadequate quality control of annotation labels.

A detailed review of current AI applications in medical image recognition provides the basis for the analytical framework developed in this study for MIRI. The framework integrates multiple models, time points, and treatment groups. Eight deep learning architectures are systematically evaluated to identify apoptotic and necrotic regions in H&E-stained myocardial tissue images. These architectures include CNNs, RNNs, LSTMs, autoencoders, GCNs, VAEs, transformers, and GANs. Particular emphasis is placed on the capacity of the transformer architecture to capture dynamic tissue alterations and biologically relevant features. GAN-based models are used for data augmentation and image completion to enhance model generalizability. All training data are sourced from publicly available databases and are reannotated by experienced cardiovascular pathologists to ensure label consistency and dataset reliability. Additionally, we construct a time series dataset of pathological sections to quantitatively track myocardial tissue recovery across different treatment strategies at 6, 24, and 72 hours after reperfusion, thereby providing a novel technical pathway for mechanistic studies and therapeutic evaluation.

In summary, this study aimed to apply deep learning as the central analytical approach to evaluate its ability to perform intelligent recognition and dynamic monitoring of histopathological images in myocardial reperfusion injury. An interpretable AI evaluation framework was established by integrating image, temporal, annotation, and intervention information. Innovation is reflected in both model design and application. The integration of the transformer architecture with GAN models enables automated analysis of H&E-stained images and supports quantitative assessment of myocardial injury progression under different therapeutic strategies. The results provide a high-throughput image analysis tool for basic research and offer clinicians a quantitative decision support system for treatment planning and evaluation. Furthermore, the proposed framework demonstrates strong scalability and can be extended to histopathological analyses of other tissue injury conditions (eg, cerebral infarction, hepatic injury, and pulmonary fibrosis). The approach establishes both the technical and conceptual foundation for developing multimodal, multiscale, and interpretable medical AI platforms with scientific and clinical relevance.

Methods

Study Subjects and Sample Acquisition

All myocardial H&E-stained histological images used in this study were obtained from publicly accessible medical image repositories, primarily the BioImage Archive (dataset accession: S-EPMC9426742) and a dataset related to MI and MIRI models released by researchers on Zenodo [21]. The combined dataset comprised a total of 1280 whole-slide images (WSIs) of

XSL•FO
RenderX

myocardial HE-stained sections, including 640 human-derived samples (50%) and 640 animal model samples (50%), mainly from Sprague-Dawley rats and C57BL/6 mice. All WSIs were acquired through standardized digital slide scanning procedures and were subsequently processed using a unified tissue detection and image tiling pipeline to generate image patches for model training. Detailed scanning parameters and tiling strategies are described in the subsection "Image Types, Scanning, and Tiling Strategy" below.

Both human myocardial samples and sections from classical murine MIRI models were included in this study based on the well-established evidence that MIRI exhibits highly consistent histopathological end points across species. Previous studies have demonstrated that key pathological features induced by MIRI, such as coagulative necrosis, apoptosis-associated nuclear alterations, and inflammatory cell infiltration, show strong morphological comparability between humans and commonly used rodent models. Moreover, pathological diagnosis of these lesions relies primarily on histological architecture rather than species-specific markers. Accordingly, the inclusion of animal model sections helps to broaden the diversity of pathological morphologies and enhances the robustness of the model to variations in staining protocols, scanning conditions, and tissue heterogeneity. To mitigate potential domain shift arising from cross-species data integration, stratified control was applied during dataset partitioning with respect to species, intervention groups, and time points, and uniform color normalization and quality control procedures were implemented across all samples. It should be emphasized that clinical interpretation and conclusions in this study are primarily based on observations from human-derived samples, while animal samples are mainly used to support model learning of generalizable pathological phenotypes of myocardial reperfusion injury and to evaluate its generalization capability.

All images originated from deidentified public datasets and required no additional ethical approval. No human or animal experiments were performed in this study. Images were included based on the following criteria: (1) H&E-stained sections from clinically confirmed MIRI cases or validated animal models; (2) high image quality with consistent staining and minimal artifacts; (3) presence of typical morphological indicators of myocardial apoptosis or necrosis; (4) availability of multiple reperfusion time points, including 6, 24, and 72 hours; (5) availability of intervention information, including antioxidant, beta-blocker, calcium channel blocker, and control groups; and (6) presence of lesion annotations or descriptive pathological documentation in the original dataset.

To ensure reproducibility and balanced representation, data partitioning was performed at the patient or animal subject level and divided into training, validation, and test subsets in an 8:1:1 ratio. Images from the same subject appeared in only one subset. Stratified sampling across intervention groups and reperfusion time points maintained proportional distributions across subsets.

In addition, the study team invited 2 senior cardiovascular pathology experts, each with more than 15 years of professional experience, to perform secondary validation and fine-grained annotation of key regions on a subset of samples. These annotations were used to calibrate the original labels and improve overall labeling consistency. In cases of disagreement between the 2 experts, arbitration was conducted by a third senior pathologist. The mean overall interannotator agreement, measured by Cohen κ, reached 0.92 (SD 0.03). To clearly present the composition of the dataset, Multimedia Appendix 2 summarizes the category distributions across different treatment groups, time points, and pathological states. According to the expert annotations, the distribution of tissue states was normal:apoptosis:necrosis of 2.1:1.0:1.3, indicating a mild class imbalance. During model training, class weighting and a focal loss–based weighting strategy were applied to mitigate potential bias introduced by this imbalance.

Image Types, Scanning, and Tiling Strategy

All samples were obtained from the publicly accessible MIRI-Histo v1 database (BioImage Archive, S-EPMC9426742; Zenodo[34], which contains H&E-stained myocardial tissue sections from both human subjects and animal models. A total of 1280 WSIs were included in this study, comprising 640 human-derived samples and 640 animal model samples, primarily from Sprague-Dawley rats and C57BL/6 mice. Human myocardial sections were digitized using an Aperio AT2 scanner at 40× magnification, corresponding to a spatial resolution of 0.25 µm per pixel, whereas animal tissue sections were scanned using a Hamamatsu NanoZoomer S360 scanner at 20× magnification, with a spatial resolution of 0.50 µm per pixel. All images were stored in TIFF or SVS formats and underwent rigorous quality control procedures. Only slides with intact tissue architecture, homogeneous staining, and no evident scanning artifacts were retained for subsequent analysis.

To standardize model inputs and improve training efficiency, a unified tissue region detection and image tiling pipeline was applied to each WSI. First, tissue regions were identified using Otsu thresholding combined with morphological operations to remove background areas. Fragmented regions with an area smaller than 10,000 µm² were excluded. Subsequently, a sliding window strategy was used within the valid tissue regions to generate image tiles, with a tile size of 512×512 pixels and a stride of 256 pixels. Tiles with a tissue occupancy of less than 40% were discarded, retaining only regions with high tissue density. After this procedure, each WSI yielded an average of approximately 50.1 (SD 4.8) valid image tiles.

To further ensure data quality, all image tiles underwent additional screening for sharpness and staining consistency. Image sharpness was assessed using the variance of the Laplacian method, while brightness and chromaticity histograms were used to exclude overexposed images or tiles with abnormal staining. Ultimately, approximately 62,000 high-quality image tiles were obtained. These tiles were partitioned at the subject level into a training set (approximately 49,600 tiles, 80%), a validation set (approximately 6200 tiles, 10%), and a test set (approximately 6200 tiles, 10%), ensuring that images from the same subject appeared in only one subset.

Image Preprocessing and Data Augmentation

Prior to model training, all image tiles underwent a unified color normalization and preprocessing pipeline. The Macenko

XSL•FO
RenderX

algorithm was applied to normalize the color distribution of H&E-stained images, thereby reducing batch effects introduced by variations in experimental conditions and scanning devices. All images were preserved in 3-channel RGB format and processed within the sRGB color space.

To enhance the robustness of the model to variations in tissue morphology and image acquisition conditions, data augmentation strategies were applied exclusively to the training set. These included random rotations (+20° or −20°), horizontal and vertical flipping, brightness adjustments (+10% or −10%), affine transformations, and mild Gaussian blurring. These augmentations were used only during the training phase and were not applied to the validation or test sets.

All image processing procedures were implemented in a Python 3.9 (Python Software Foundation) environment, primarily using OpenCV (OpenCV.org), NumPy (NumFOCUS), Pillow (Pillow Contributors), SimpleITK (Insight Software Consortium), and Albumentations (Albumentations Team) image processing libraries.

Filtering Validation and Weakly Supervised Label Generation

An identical image filtering workflow was applied across all experimental groups and classification tasks to avoid preprocessing-related bias. Before input into the transformer architecture, each image underwent standardized color normalization, smoothing, and edge enhancement. Gaussian filtering (σ=1.2) was used to reduce scanner noise, and Laplacian operators were applied to sharpen local tissue boundaries. Validation on an independent dataset yielded a mean structural similarity index (SSIM) of 0.982 (SD 0.007) and a mean edge preservation index of 0.963 (SD 0.011) between preprocessed and original images, indicating enhanced textural contrast without significant alterations in cellular boundaries or nuclear density (P>.05). Transformer models trained on filtered and unfiltered data showed comparable validation performance: area under the curve (AUC; 0.979 vs 0.982) and F_1-score (0.957 vs 0.958), confirming the neutrality of the filtering procedures.

Several datasets contained expert-annotated lesion regions, from which region of interest (ROI) masks were extracted and spatially aligned using a hybrid registration pipeline based on OpenCV and SimpleITK, consisting of rigid, affine, and B-spline transformations. For datasets lacking manual annotations, a weakly supervised method based on clustering-constrained attention multiple-instance learning (CLAM) was implemented in PyTorch (version 1.13) to generate pseudo-ROIs. Through attention-based learning, the model identified high-contribution regions at the slide level, which were designated as pseudo-ROIs. These pseudo-ROIs were subsequently integrated with expert-annotated samples during feature pretraining and fine-tuning to enhance label consistency and improve model robustness.

Label Sources and Quality Control

The labeling framework integrated both strong and weak supervision. Pixel-level strong supervision was applied to human samples (n=640), and slide-level weak supervision was used for animal samples (n=640). All annotations originated from the metadata provided in the public databases and were further validated by the research team. The original annotation files contained polygon masks delineating apoptotic regions, necrotic areas, and normal myocardium, generated by expert pathologists at the time of dataset submission and stored in standardized JSON and XML formats.

To ensure label accuracy and consistency, 3 senior cardiovascular pathologists with ≥10 years of diagnostic experience independently reevaluated all slides. A double-blind and randomized review process was conducted in which each expert reinterpreted the slides and confirmed or refined regional annotations based on established histopathological criteria, including apoptosis, necrosis, inflammatory infiltration, and fibrosis. When all reviewers agreed, the annotation was accepted. In cases of disagreement, a consensus was reached by majority vote after adjudication by the third pathologist. Following verification, a total of 12,460 high confidence annotated regions (defined as ≥80% expert agreement) were obtained, corresponding to 62,000 image tiles.

Annotation reliability was assessed using the Cohen κ and Fleiss κ statistics. Pixel-level annotations demonstrated a mean κ of 0.92 (95% CI 0.90 - 0.94), while slide-level weak supervision yielded κ of 0.87 (95% CI 0.84 - 0.89), indicating excellent interrater agreement. All annotation files underwent logical integrity and spatial consistency checks, including mask-boundary smoothing, hole filling, and area normalization implemented in OpenCV, ensuring cross-format and cross-resolution compatibility.

For weakly supervised samples, a multiple-instance learning (MIL) strategy was used, with global injury scores (0 - 1) assigned at the slide level as supervisory labels during model training. The final labeling schema consisted of 3 primary classes (ie, normal myocardium, apoptotic region, and necrotic region) and 2 auxiliary classes (ie, inflammatory infiltration and fibrosis, used only for interpretability analysis and heatmap validation).

Dataset Splitting and Leakage Prevention

To ensure training independence and reproducibility, all data were divided into training, validation, and independent test sets at an 8:1:1 ratio. Splitting was performed at the subject level (patient or animal level) rather than the patch level to prevent images from the same specimen from appearing in different subsets. The final allocation included 1024 WSIs in the training set (≈49,600 patches), 128 in the validation set (≈6200 patches), and 128 in the test set (≈6200 patches). Each subset was distributionally balanced across species (human or animal), treatment groups (antioxidant, β-blockers, calcium channel blockers, and control groups), and reperfusion time points (6, 24, and 72 h) to ensure comparability in downstream statistical analyses. All splitting procedures were performed using a fixed random seed (seed=42) and repeated 5 times to minimize stochastic bias, with results reported as the average outcome.

Multiple safeguards were used to prevent data leakage during model training and validation. Subject-level splitting ensured that all WSIs and derived patches from a given individual were

XSL•FO
RenderX

restricted to a single subset. Temporal independence was maintained by assigning samples from different reperfusion time points (6, 24, and 72 h) independently within each treatment group. Data augmentation procedures, including rotation, flipping, brightness adjustment, blurring, and affine transformation, were applied only to the training set; the validation and test sets remained unchanged. File trace integrity was ensured by assigning each WSI a unique identifier during indexing, and SHA-256 hash verification confirmed that no file or patch appeared in more than one subset. Five-fold cross-validation was additionally performed to evaluate model robustness, and model performance was further validated using an independent external dataset.

The independent test set consisted of 64 human WSIs and 64 animal WSIs, covering all 4 treatment interventions and 3 reperfusion time points. This dataset was used both for quantitative performance evaluation and comparison with expert pathological assessments. All labels in the test set remained completely hidden during model development and tuning and were only accessed after model freezing for inference and final performance assessment, ensuring objectivity and fairness.

Model Architecture and Training Protocol

Overview

All models were developed and optimized within a unified experimental framework to ensure reproducibility. The primary architecture was a ViT-Base/16 model (patch size=16, hidden dimension=768, 12 heads/blocks), using RGB image patches resized from 512×512 to 224×224 pixels as input. Benchmark models included Swin-T, ResNet-50, RNNs or LSTMs, GCNs, autoencoder, VAE, and a GAN-based module used exclusively for synthetic augmentation rather than final classification. Leakage prevention at the slice and subject levels, as well as batch and staining stratification, followed the procedures described in the sections “Label Sources and Quality Control” and “Dataset Splitting and Leakage Prevention.”

Sampling Strategy

Each WSI was tiled into 512×512 patches (stride=256) based on tissue masks. Class-balanced sampling (positive:negative=1:1) was applied during training, while validation and test sets followed the natural class distribution. To limit batch variance, no more than 120 patches were randomly sampled from each WSI during each training iteration.

Color Processing and Augmentation

Macenko stain normalization was performed prior to modeling. Data augmentation included random rotation (+20° or −20°), horizontal or vertical flipping, ColorJitter (brightness/contrast/saturation/hue=0.2/0.2/0.2/0.05), Gaussian blur (σ=1.0), and elastic deformation (α=15; σ=4), each applied with a probability of .5. Validation and test sets underwent only resizing and center cropping.

Optimization and Scheduling

Models were trained using AdamW (learning rate=3×10^{-4}, betas=0.9/0.999, weight decay=0.05) with CosineAnnealingLR (T_max=100, min_lr=1×10^{-6}). Training parameters included batch size=32, a maximum of 100 epochs, and early stopping based on validation AUC (patience=12, ΔAUC $\geq1\times10^{-3}$). Automatic mixed precision (FP16) and gradient clipping (max-norm=1.0) were enabled.

Loss Functions and Weighting

Multiclass cross-entropy served as the primary loss function. Class-balanced weighting based on effective sample number was applied when class imbalance exceeded 1.5:1. For weakly supervised branches, Focal loss (γ=2.0; α=.25) was used for pseudo-ROI refinement. Segmentation tasks used a composite Dice+BCE objective (λ_Dice=0.7; λ_BCE=0.3).

Label Definitions

According to histopathological criteria, each patch was categorized into noninjured, apoptotic, or necrotic myocardium. Reperfusion time points and treatment groups were used only for stratified or subgroup analyses and were not included as supervised labels.

Randomization and Hardware

Deterministic execution was enforced using fixed random seeds {2023, 2024, 2025, 1337, 3407}. Five independent runs were conducted, and results are reported as mean (SD). All training procedures were performed on a single NVIDIA A100 (40 GB) GPU with 256 GB system memory.

Reproducibility Materials

Complete YAML configurations, training scripts, and data inventories, including WSI-to-patch mapping and train/val/test lists, are provided in Multimedia Appendix 3.

Model Selection and Construction

Eight representative deep learning architectures were constructed and compared to evaluate their performance in classifying and recognizing H&E-stained myocardial tissue images following MIRI. The evaluated models included CNNs, RNNs, LSTMs, autoencoders, GANs, GCNs, transformers, and VAEs (Multimedia Appendix 4). CNNs, autoencoders, and GCNs were used mainly for feature extraction and region-level classification in static images. RNNs and LSTMs were designed to process time series labels or sequential image data. Transformers, equipped with global attention mechanisms, demonstrated the ability to model both image and sequential features and offered advantages in medical image interpretation.

Given the relatively limited dataset size, a data augmentation module based on the Deep Convolutional Generative Adversarial Network (DCGAN) framework [22] was constructed to generate high-quality synthetic myocardial H&E images. The GAN architecture consisted of a generator that learned underlying textural patterns and a discriminator that evaluated the authenticity of generated images. The “classification accuracy” reported in Multimedia Appendix 4 reflected only the discriminator’s ability to distinguish real from synthetic samples and served as an indicator of generator convergence. GAN training was restricted to the training set to maintain dataset independence and prevent leakage. After quality filtering, a total of 6250 of 49,600 (12.6%) images in the training set were augmented (synthetically generated). These augmented images

XSL•FO
RenderX

were used exclusively during the model training phase to enhance data diversity and improve generalization performance, and they were not included in the validation or test set performance evaluation.

All models were implemented within a unified PyTorch framework, initialized through transfer learning, and optimized using architecture-specific optimizers and learning rate schedulers. Input consisted of preprocessed H&E tiles, and outputs included categorical predictions of myocardial status (normal, apoptotic, and necrotic) or regional annotation maps. Multiple loss functions, including cross-entropy, Dice coefficient, and Focal loss, were applied during training to address class imbalance and subtle histological boundaries. Model performance was evaluated using cross-validation and an independent external test set, assessing accuracy, sensitivity, specificity, robustness, and task-specific metrics for classification, localization, and segmentation tasks. These evaluations enabled the identification of the most suitable architecture for H&E-based myocardial tissue analysis.

GAN-Based Augmentation Strategy and Leakage Prevention

A StyleGAN2-ADA-based generative adversarial network was incorporated during data augmentation to increase sample diversity and improve model generalization. The generator operated at 512×512 resolution with a 512-dimensional latent space, an 8-layer mapping network, and R1 regularization. The discriminator used adaptive discriminator augmentation to reduce domain shift caused by limited data. GAN training was performed exclusively on real tiles from the training set, following subject-level and slide-level partitioning. The Adam optimizer (β_1 =.0; β_2 =.99) with an initial learning rate of 2×10^{-3} and exponential decay scheduling was applied. Training continued until convergence criteria were met, corresponding to ~1.2 million real-sample views (kimg ≈ 1200), and stopped early when Fréchet Inception Distance or inception score (IS) stabilization indicated discriminator equilibrium.

During classification and segmentation model training, synthetic GAN-generated samples contributed no more than 10% of input data (real:synthetic ≈9:1). A curriculum mixing strategy was applied, with no synthetic samples during the first 5 epochs, 5% synthetic inclusion during epochs 6 to 10, and 10% thereafter. Synthetic images were excluded from validation and test sets. Leakage prevention followed a strict "split-before-generate" protocol in which dataset partitioning was completed before GAN training, and the generator accessed only the training subset. Real and synthetic samples were stored in separate directories with a syn_ filename prefix, and the dataloader automatically filtered out syn_ files in nontraining modes. Quality control for synthetic images included structural similarity filtering (SSIM ≥0.90), IS thresholds, and near-duplicate detection using perceptual hashing (pHash ≥12) and LPIPS (≥0.20), ensuring removal of synthetic samples that closely resembled real images.

Ablation experiments demonstrated small but consistent improvements with GAN augmentation. For the transformer classifier, the test accuracy increased from 0.942 to 0.944, the AUC from 0.982 to 0.983, and the F_1-score from 0.958 to 0.959. For Transformer-UNet, Dice coefficients for necrosis and apoptosis improved from 0.847 to 0.851 and 0.821 to 0.824, respectively, without statistically significant differences. These results indicate that GAN augmentation slightly improves robustness while preserving evaluation integrity and avoiding synthetic content during validation or testing.

Evaluation and Validation of GAN-Generated Samples

Quantitative and qualitative assessments were performed to evaluate the data augmentation utility and visual fidelity of synthetic H&E images generated using the DCGAN framework. IS and SSIM were first computed, yielding mean IS of 2.81 (SD 0.17) and mean SSIM of 0.936 (SD 0.012). These results indicated that the synthetic images closely matched real tissue samples in morphological texture and staining distribution. In addition, 100 synthetic and 100 real patches were randomly selected for blinded review by 2 independent pathology experts. Expert identification accuracy was 47.3%, approximating random guessing and confirming the visual realism of the generated images.

The impact of GAN-based augmentation on model performance was further evaluated by training transformer models under identical conditions, with and without synthetic patches. Incorporation of GAN-generated samples increased the validation AUC from 0.978 to 0.982 and improved the F_1-score from 0.956 to 0.958, although neither difference reached statistical significance (P>.05). These findings suggest that GAN augmentation provides stable and modest gains in generalization performance without affecting core model conclusions. Overall, the GAN component supports the feasibility of synthetic H&E images as a complementary data expansion strategy and contributes supplementary benefits while not determining the primary analytical outcomes of the study.

Deep Learning Model Architecture and Implementation Details

Eight mainstream deep learning architectures were implemented within a unified PyTorch (version 1.13) framework to ensure architectural transparency and methodological reproducibility. The evaluated models included CNN, RNN, LSTM, autoencoder, GAN, GCN, VAE, and transformer. All architectures were constructed according to their original seminal publications [22-29] and adapted for the MIRI histopathology classification task using 224×224 RGB H&E image tiles. Standardized, preprocessed patches served as model inputs, and outputs corresponded to 3 tissue categories: normal myocardium, apoptosis, and necrosis. The CNN architecture used a 5-layer convolutional backbone with ReLU activation and max pooling, followed by fully connected layers (512-128-3) and dropout (0.4) to reduce overfitting. RNN and LSTM models were designed for sequential tile modeling, with the LSTM implemented as a bidirectional 2-layer network (hidden size=128 and dropout=0.3). Autoencoders and VAEs performed feature compression and reconstruction with latent dimensions of 128 and 64, respectively; VAE training incorporated a KL divergence regularization term (weight=0.005). The GAN module followed the DCGAN

XSL•FO
RenderX

architecture and was applied exclusively for synthetic data augmentation. The GCN treated tile-level features as graph nodes, modeling spatial adjacency to capture microstructural relationships. The core transformer model was built upon the Vision Transformer (ViT-Base) backbone (12 self-attention heads, embedding dimension=768, patch size=16×16) and integrated the CLAM framework to support attention-based weakly supervised MIL, enabling slide-level classification and pseudo-ROI generation. Model-specific loss functions and hyperparameters were selected according to architectural characteristics. Cross-entropy loss was applied to CNN, RNN, LSTM, and GCN models, with additional L2 regularization used for LSTM. Combined mean squared error and SSIM losses were used for autoencoder and VAE models, with KL divergence included for VAE. GAN training used adversarial and discriminator cross-entropy objectives. Class-weighted cross-entropy was adopted for transformer models to address class imbalance. Optimization was performed using Adam or AdamW (learning rate=1×10^{-4}; β_1=0.9; β_2=0.999), while the transformer used a 3×10^{-5} learning rate with cosine annealing scheduling. Batch sizes ranged from 8 to 64 depending on model complexity. Early stopping (patience=10) was applied to prevent overfitting, and fixed random seeds ensured reproducibility. All models were executed under identical hardware and software environments using publicly available codebases to maintain comparability across architectures.

Model Training and Evaluation

All deep learning models were trained and evaluated using the preprocessed H&E-stained myocardial tissue images, following a unified data partitioning strategy and standardized training pipeline to ensure comparability across architectures. The dataset was divided into training, validation, and test sets in an 8:1:1 ratio, with balanced representation of cardiomyocyte states (normal, apoptotic, and necrotic) in each subset. Model training was conducted in an NVIDIA GPU–accelerated environment using Adam or RMSProp optimizers. Adaptive learning rates and batch sizes were configured according to the requirements of each model. Early stopping and learning rate scheduling were applied to prevent overfitting during optimization.

Model performance was assessed using accuracy, sensitivity, specificity, precision, F_1-score, the AUC, and Dice coefficient to evaluate both classification and segmentation tasks. For multiclass classification, all metrics were calculated using the weighted macro-average method to ensure balanced contributions across classes. In segmentation tasks, particular emphasis was placed on the identification of boundary regions and small lesions. Dice loss and focal loss were used to improve sensitivity to target structures.

Transfer validation was conducted using multiple independent external datasets to further evaluate model generalizability. Model predictions were compared with expert-annotated labels, and agreement between the AI model and clinical experts was quantified using the Cohen κ coefficient. For images generated by GANs, objective assessments of image quality were performed using the SSIM and IS to validate the effectiveness of GANs in data augmentation. On the basis of combined performance across validation and test sets, the suitability of all 8 models for myocardial injury detection was assessed. Special attention was given to the best-performing transformer-based model, particularly its stability and advantages across multiple time points, injury categories, and regions characterized by blurred pathological boundaries.

Comparative Analysis of Therapeutic Strategies

MIRI samples with known treatment backgrounds were selected from the publicly available BioImage Archive database. The dataset included several representative intervention strategies: antioxidant therapy, calcium channel blockade, β-adrenergic receptor inhibition, and an untreated control group. Each group contained H&E-stained tissue sections corresponding to multiple reperfusion time points (eg, 6, 24, and 72 h), providing the temporal coverage required for longitudinal evaluation. Using the best-performing transformer model, an automated recognition pipeline was constructed to extract key pathological indicators at each time point, including the proportion of apoptotic cells, necrotic area ratio, and tissue integrity scores. These indicators served as primary metrics for evaluating therapeutic efficacy.

During AI-based analysis, the model received preprocessed H&E-stained images and learned to identify characteristic morphological patterns of injury, including nuclear pyknosis, cytoplasmic homogenization, myofiber disruption, and blurred cellular boundaries. Multidimensional quantitative outputs were generated for each sample. Cross-validation and external test sets were used to evaluate model generalizability across treatment groups, ensuring objectivity and reproducibility. Conventional pathological scoring systems were incorporated as reference standards to compare and validate model predictions.

By establishing a closed-loop workflow encompassing "treatment strategy → image input → AI analysis → extraction of injury metrics," this study enables an intelligent, quantitative assessment of different therapeutic interventions. The proposed framework lays a methodological foundation for future treatment optimization and mechanistic exploration.

Temporal Evaluation of Posttreatment Effects

To assess the dynamic therapeutic effects of different interventions during the recovery phase of MIRI, we performed a longitudinal analysis using the best-performing transformer model. All treatment groups were analyzed using H&E-stained myocardial tissue sections obtained at multiple reperfusion time points (eg, 6, 24, and 72 h). The model automatically identified key pathological features, including apoptotic cells, necrotic regions, and structural disorganization, and quantified them into interpretable metrics, such as necrosis area ratio, apoptosis proportion, and tissue integrity score. These outputs were used to construct temporal progression curves of myocardial injury.

We analyzed the temporal dynamics of tissue recovery for the intervention group with the most significant treatment effect to explore the time window in which early intervention alleviates pathological changes. The time series results of the other treatment groups were also identified synchronously by the model as comparative data, further validating the broad

XSL•FO
RenderX

applicability of AI-based recognition in dynamic efficacy evaluation.

All time series images were strictly aligned during training to ensure consistency in image regions, tissue layers, and lesion areas. The model's output results were used to generate trend curves through linear fitting or locally estimated scatterplot smoothing, and the statistical significance of changes across different time points was assessed using ANOVA and repeated measures *t* tests. These analyses provide image-based support for understanding the timeliness and reversibility of treatment responses following reperfusion injury.

Statistical Analysis

All statistical analyses were performed using R software (version 4.2.2) and SPSS (version 26.0; IBM Corp). For continuous variables derived from model outputs, including the proportion of apoptotic regions, necrotic area percentage, and tissue structure scores, descriptive statistics were calculated as mean (SD) or median as appropriate. Comparisons among multiple groups were conducted using one-way ANOVA. When significant differences were detected, post hoc pairwise comparisons were performed using either the Least Significant Difference test or Tukey's Honest Significant Difference test. For data with a temporal structure (eg, pretreatment, 6, 24, and 72 h post treatment), repeated measures ANOVA was used to assess the effects of time, treatment, and their interaction on tissue injury parameters. When necessary, paired *t* tests were used for within-group comparisons.

For the evaluation metrics of AI model classification tasks (such as accuracy, sensitivity, specificity, F_1-score, and AUC), the average values from cross-validation were used for summary, along with calculating their 95% CIs. The DeLong test was used to assess performance differences between models for statistical comparison of receiver operating characteristic (ROC) curves. In image segmentation tasks, the Dice coefficient and intersection over union are used to evaluate the consistency between predictions and expert annotations, while Cohen κ coefficient is used to further quantify the correlation between AI and human recognition results.

All statistical tests were 2-tailed unless otherwise specified, and a *P* value of <.05 was considered statistically significant. The results of these analyses were used to support model evaluation, intergroup treatment comparisons, and the assessment of time-dependent changes, ensuring statistical rigor and reproducibility of the study findings.

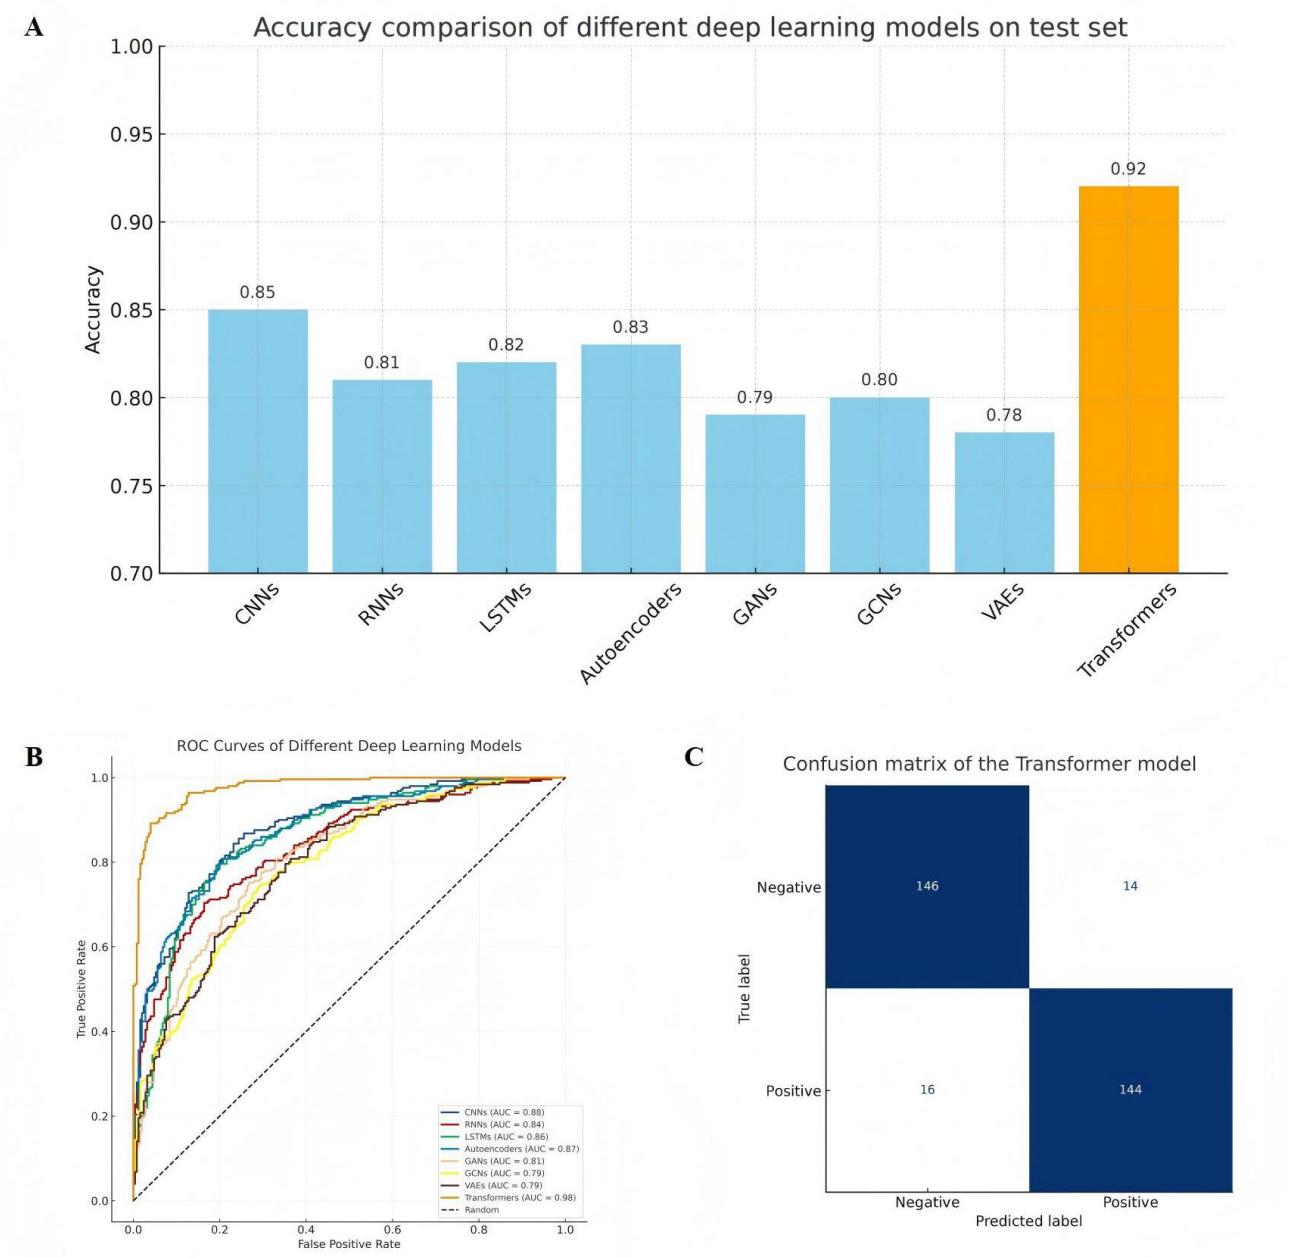
Ethical Considerations

All myocardial H&E-stained histopathological images used in this study were obtained exclusively from publicly accessible data repositories, and no new human or animal experiments were conducted. The primary dataset, MIRI-Histo v1, is available through the BioImage Archive (accession: S-EPMC9426742) and the Zenodo data sharing platform [34].

All images were fully deidentified, and the original annotation files (JSON and mask formats) are provided to support reproducibility and secondary analysis. Model training was performed in a Python 3.9 environment using open-source libraries, including PyTorch, OpenCV, NumPy, Pillow, and Albumentations. All source code necessary to reproduce the results will be released publicly upon formal publication.

As this study exclusively used publicly available, deidentified medical imaging datasets, no additional institutional review board or ethics committee approval was required. Data collection and sharing procedures for the original datasets complied with institutional ethics standards and data protection regulations, including the European General Data Protection Regulation and policies of the BioImage Archive. The research team was not involved in any direct acquisition of human or animal specimens, and all data usage adhered to international standards for ethical research and responsible data stewardship.

Results



Transformer Model Demonstrates Superior Overall Recognition Performance

A total of 1280 myocardial H&E WSIs and approximately 62,000 high-quality tissue patches were included in the analysis. The dataset was evenly distributed across 4 therapeutic intervention groups (antioxidant, β-blockers, calcium channel blockers, and untreated controls) and 3 reperfusion time points (6, 24, and 72 h), with balanced representation of human and animal samples. This dataset constituted the foundation for training, validation, and testing of all 8 deep learning models.

Eight representative deep learning architectures were implemented to systematically evaluate computational performance in identifying MIRI patterns on H&E-stained histopathology images. The models included CNNs, RNNs, LSTMs, autoencoders, GANs, GCNs, VAEs, and transformers (Figure 1A).

XSL•FO
RenderX

Figure 1. Comparative performance of different deep learning models in the recognition of MIRI on H&E-stained histological images. (A) Classification accuracy of 8 representative deep learning models on the test set. The transformer model outperforms all others in overall accuracy. (B) Receiver operating characteristic (ROC) curves for each model. The transformer model achieves the highest AUC value of 0.963. (C) Confusion matrix of the transformer model, demonstrating the lowest false-positive and false-negative rates among all models, indicating superior classification consistency and boundary recognition capability. CNN: convolutional neural network; GAN: generative adversarial network; GCN: graph convolutional network; LSTM: long short-term memory; RNN: recurrent neural network; VAEs: variational autoencoders.

All models were evaluated using the same data split and assessed with 5 complementary metrics: accuracy, precision, recall, F_1-score, and AUC. The transformer model demonstrated the strongest overall performance, achieving a mean cross-validation accuracy of 0.920 (SD 0.011) and a mean final independent test accuracy of 0.942 (SD 0.008), with a mean AUC of 0.982 (SD 0.004), outperforming all comparator architectures (Figure 1B). Confusion matrix analysis further revealed markedly reduced false-positive and false-negative rates (Figure 1C), indicating superior sensitivity, specificity, and robustness in myocardial tissue classification.

Quantitative Performance Statistics

To ensure reproducibility and enable cross-study comparison, the classification performance of all 8 model architectures was evaluated using an identical dataset split and a unified assessment protocol. Table 1 reports point estimates and 95% CIs for accuracy, AUC, F_1-score, precision, and recall, calculated using nonparametric bootstrapping (n=1000). Consistent with the overall findings, the transformer model achieved the strongest performance across all evaluation metrics. Both the 5-fold cross-validation mean accuracy (0.920) and the independent held-out test accuracy (0.942) are presented to

XSL•FO
RenderX

reflect model behavior under different statistical evaluation schemes.

Table . Classification metrics across models (5-fold CV[a] mean [95% CI]) and hold-out test[b].

Model	Accuracy (CV)	AUC[c] (CV)	F_1-score (CV)	Precision (CV)	Recall (CV)	Accuracy (test)
Transformer	0.920 [0.912 - 0.928]	0.963 [0.956 - 0.970]	0.958 [0.951 - 0.964]	0.955 [0.947 - 0.962]	0.962 [0.955 - 0.969]	0.942
CNN[d]	0.889 [0.879 - 0.899]	0.935 [0.926 - 0.944]	0.927 [0.918 - 0.936]	0.918 [0.908 - 0.928]	0.937 [0.928 - 0.946]	0.908
LSTM[e]	0.874 [0.864 - 0.885]	0.922 [0.912 - 0.933]	0.913 [0.903 - 0.924]	0.905 [0.893 - 0.916]	0.922 [0.912 - 0.933]	0.895
RNN[f]	0.862 [0.851 - 0.873]	0.913 [0.902 - 0.925]	0.902 [0.890 - 0.913]	0.894 [0.881 - 0.906]	0.911 [0.899 - 0.923]	0.882
Autoencoder	0.848 [0.836 - 0.860]	0.902 [0.889 - 0.915]	0.889 [0.877 - 0.901]	0.882 [0.868 - 0.895]	0.897 [0.885 - 0.910]	0.871
GCN[g]	0.857 [0.845 - 0.869]	0.909 [0.897 - 0.921]	0.897 [0.885 - 0.909]	0.890 [0.877 - 0.903]	0.904 [0.892 - 0.916]	0.879
VAE[h]	0.842 [0.830 - 0.855]	0.898 [0.885 - 0.911]	0.885 [0.872 - 0.898]	0.877 [0.863 - 0.891]	0.893 [0.880 - 0.906]	0.868
GAN[i]	0.801 [0.787 - 0.815]	0.861 [0.847 - 0.875]	0.846 [0.832 - 0.860]	0.839 [0.824 - 0.854]	0.854 [0.840 - 0.869]	0.829

[a]CV: cross-validation.

[b]This table summarizes the classification performance of 8 deep learning models (CNN, RNN, LSTM, Autoencoder, GAN, GCN, VAE, and transformer) on 5-fold cross-validation and the independent test set. Evaluation metrics include accuracy, area under the curve (AUC), F_1-score, precision, and recall, with 95% CIs calculated using 1000 bootstrap iterations. The results show that the transformer model achieves the best performance across all metrics, demonstrating high stability and strong generalization capability.

[c]AUC: area under the curve.

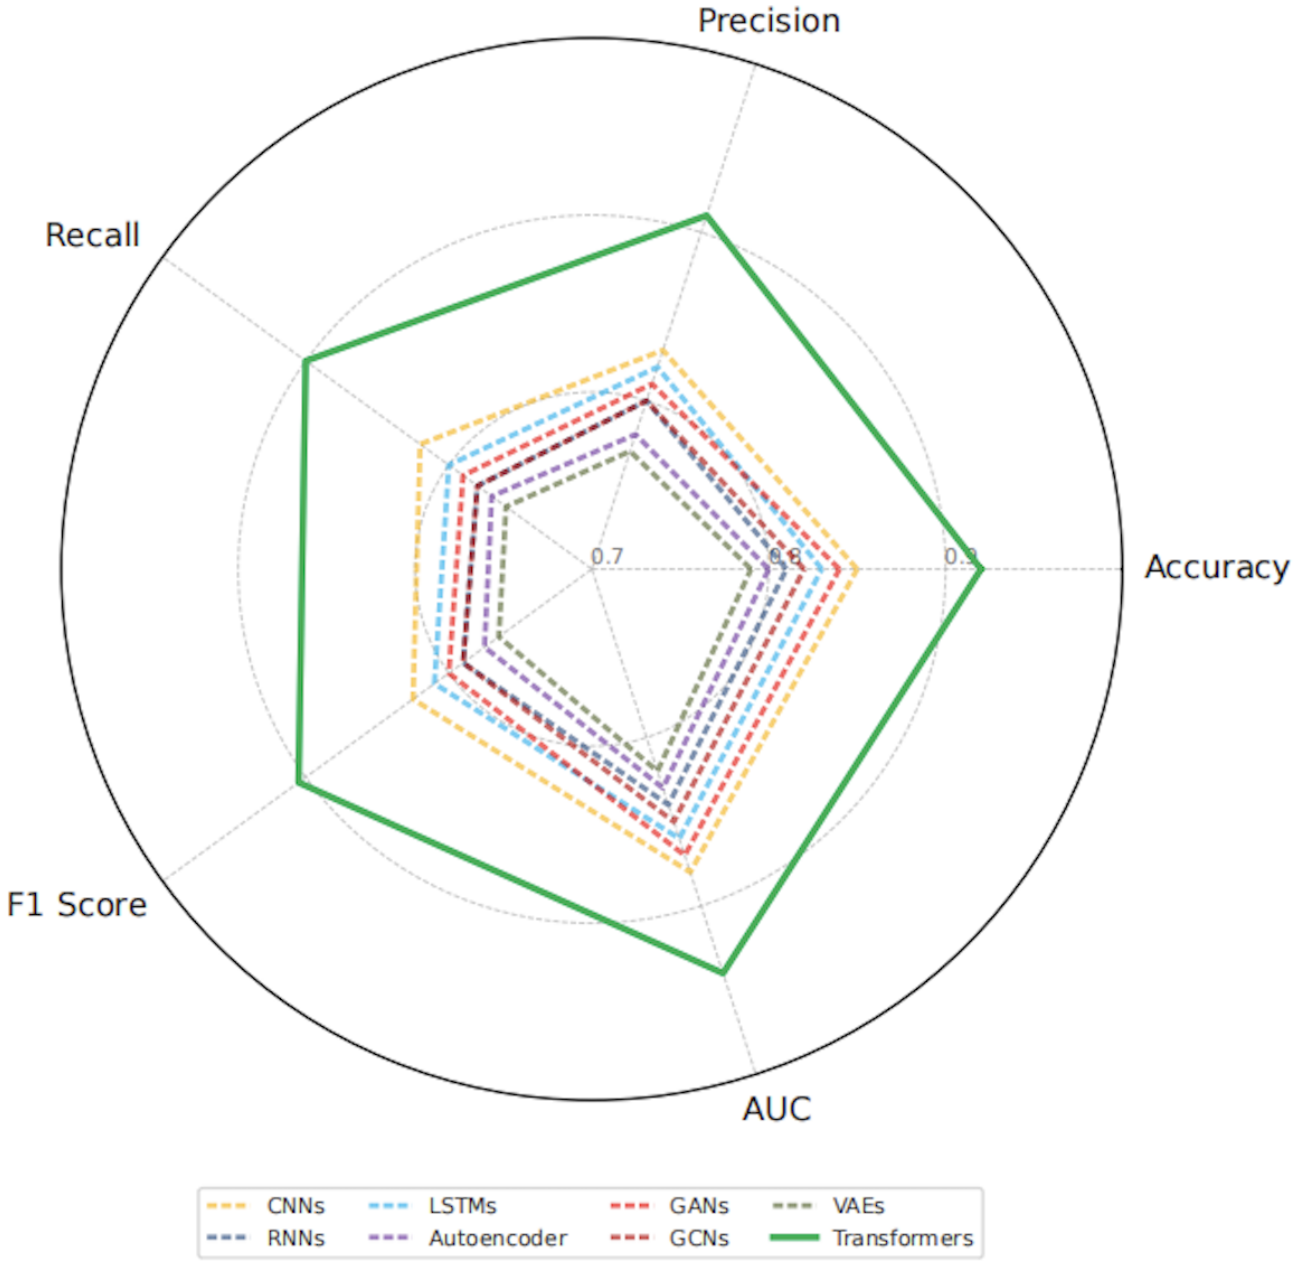
[d]CNN: convolutional neural network.

[e]LSTM: long short-term memory.

[f]RNN: recurrent neural network.

[g]GCN: graph convolutional network.

[h]VAE: variational autoencoder.



[i]GAN: generative adversarial network.

Quantitative Evaluation and Comparative Assessment of Classification Performance

In the aggregated comparison of classification performance, the transformer model ranked first across all 5 evaluation metrics, including accuracy, F_1-score, AUC, precision, and recall. A mean test set accuracy of 94.2% (P<.01) demonstrated significantly superior performance relative to all other architectures (Figure 2). Strong robustness was observed in challenging histopathological conditions, including blurred tissue boundaries, disorganized myocardial structures, and heterogeneous lesion patterns. Supplementary analyses further indicated shorter inference time and faster convergence during training, supporting the feasibility of the transformer architecture for practical deployment.

XSL•FO
RenderX

Figure 2. Transformers achieve the best overall performance across 5 key metrics. Radar plot showing the aggregated performance of all deep learning models across 5 evaluation metrics—accuracy, precision, recall, F_1-score, and area under the curve (AUC). The transformer architecture outperforms all other models across every dimension, demonstrating superior discriminatory power and generalizability, particularly for complex tissue structures and highly heterogeneous lesion patterns. CNN: convolutional neural network; GAN: generative adversarial network; GCN: graph convolutional network; LSTM: long short-term memory; RNN: recurrent neural network; VAEs: variational autoencoders.

Although GANs were not used as primary classifiers, they contributed indirectly by supplying high-quality synthetic augmentation samples, thereby enhancing downstream discriminative model stability and generalization capacity. Dual-metric evaluation using the IS and SSIM confirmed that GAN-generated images achieved high diversity and structural fidelity, reinforcing their value as an auxiliary data enhancement strategy.

To further characterize differences in computational efficiency and deployment readiness, additional quantitative indicators were recorded, including training loss fluctuation, the number of epochs required for convergence, and mean per-image inference latency. Detailed values are reported in Multimedia Appendix 5. Overall, the transformer model retained the highest accuracy while exhibiting favorable convergence behavior and strong generalization consistency. Although training loss variability (SD 0.184) was slightly greater than that of lighter architectures, stable validation curves, absence of overfitting, and reasonable inference speed underscore its potential for clinical integration and scalable biomedical imaging applications.

Segmentation Performance and Consistency Validation

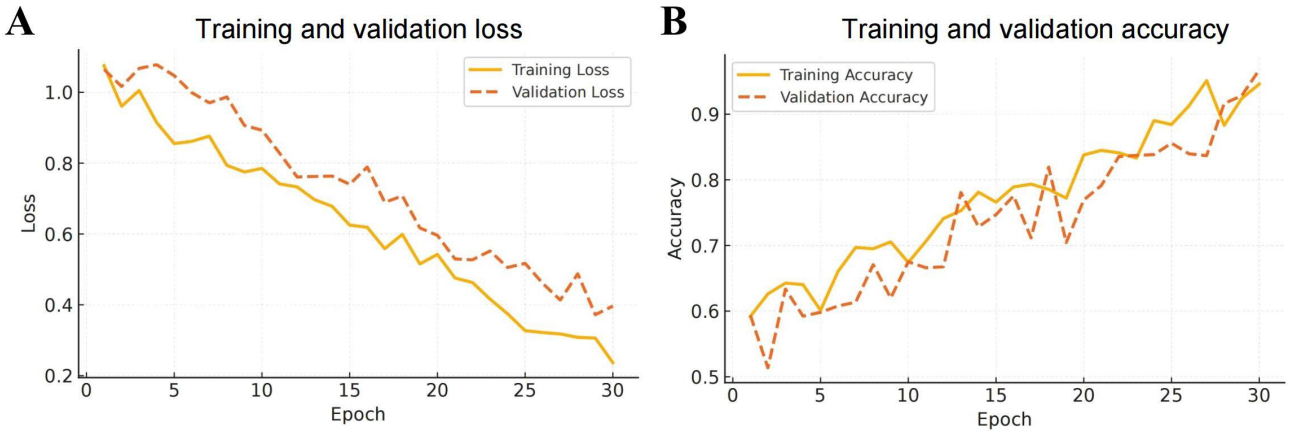
Segmentation performance for necrotic and apoptotic myocardial regions was evaluated using the Dice coefficient and Intersection over Union. Consistent with the classification results, the Transformer-UNet architecture achieved the highest agreement with expert annotations across both mask types (Table 2). All values are reported as mean (SD) on the held-out test set.

XSL•FO
RenderX

Table . Segmentation performance by lesion type[a].

Model (segmentation)	Dice (necrosis), mean (SD)	IoU[b] (necrosis), mean (SD)	Sensitivity (necrosis), mean (SD)	Specificity (necrosis), mean (SD)	Dice (apoptosis), mean (SD)	IoU (apoptosis), mean (SD)	Sensitivity (apoptosis), mean (SD)	Specificity (apoptosis), mean (SD)
Transformer-UNet	0.847 (0.032)	0.740 (0.038)	0.861 (0.035)	0.973 (0.010)	0.821 (0.036)	0.696 (0.041)	0.838 (0.041)	0.968 (0.012)
CNN-UNet	0.812 (0.037)	0.683 (0.043)	0.829 (0.042)	0.965 (0.013)	0.788 (0.041)	0.653 (0.046)	0.808 (0.047)	0.960 (0.014)

[a]The table presents the main quantitative performance metrics of Transformer-UNet and CNN-UNet in the task of segmenting myocardial ischemia-reperfusion injury regions, including Dice coefficients, IoU, sensitivity, and specificity for necrotic and apoptotic areas. Agreement analysis between model predictions and manual annotations (Cohen κ) is reported separately in the main text.



[b]IoU: intersection over union.

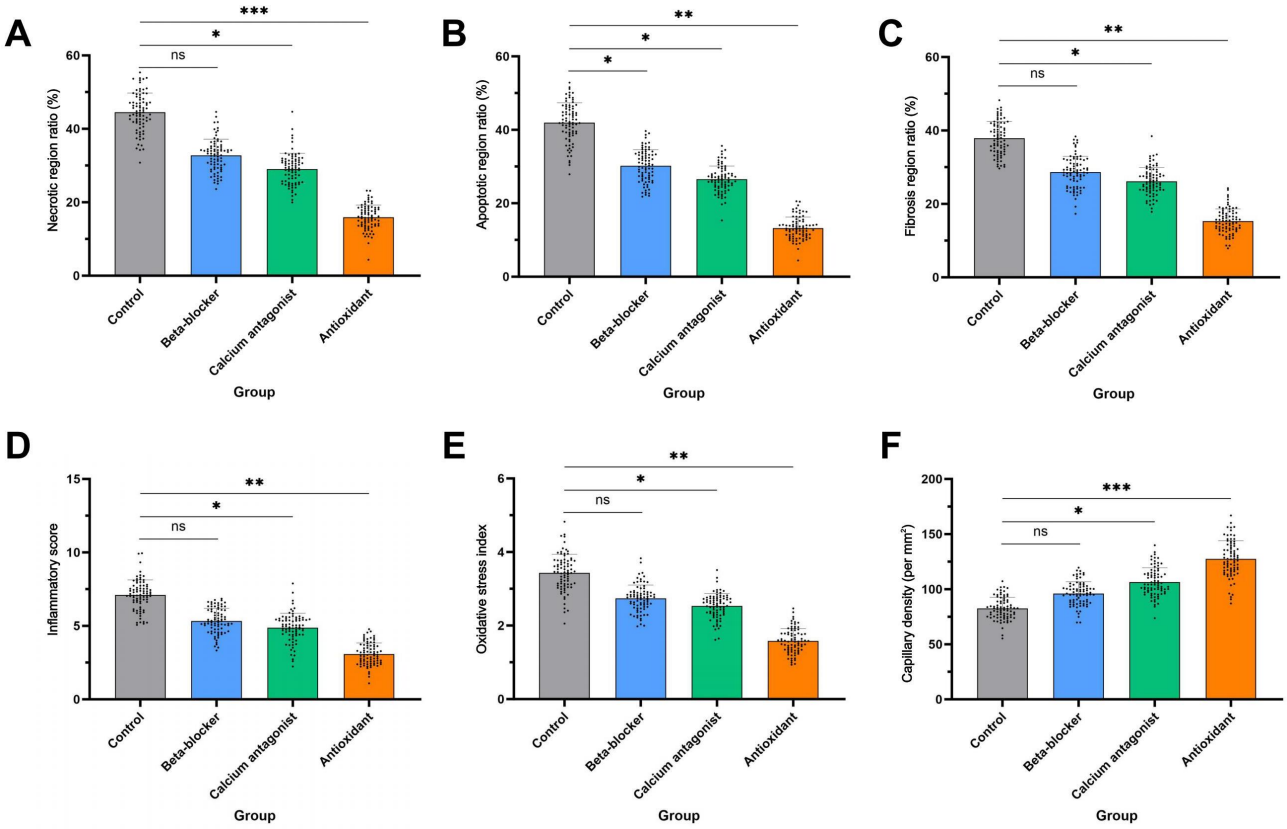
To further quantify agreement between model predictions and human experts, we computed Cohen κ. The overall κ was 0.86 (95% CI 0.83 - 0.89), indicating strong agreement. Stratified analyses across reperfusion time points showed progressively increasing consistency, with mean values of 0.83 (SD 0.02) at 6 hours, 0.86 (SD 0.02) at 24 hours, and 0.88 (SD 0.01) at 72 hours, suggesting that pathological regions became more distinguishable over time. For comparison, interexpert agreement between the 2 board-certified cardiovascular pathologists reached a κ of 0.88 (95% CI 0.85 - 0.91), demonstrating high stability of the reference standard. The close similarity between model-expert and expert-expert κ values supports the reliability, interpretability, and clinical applicability of the segmentation model.

Transformer Model Exhibits Stable Convergence and Strong Generalization During Training

Training process analysis demonstrated that the transformer model displayed a continuous decrease in loss for both the training and validation sets, accompanied by steadily increasing accuracy and no evidence of overfitting (Figure 3A). The learning trajectory remained smooth, and convergence was stable across training epochs, reflecting reliable optimization behavior. Strong generalization performance was observed on the validation set, with consistent accuracy maintained across different dataset partitions. The results indicate that the transformer architecture effectively learns pathological image features and provides robust, transferable performance in myocardial tissue recognition tasks (Figure 3B).

Figure 3. Training dynamics of the transformer model showing loss reduction and accuracy improvement. (A) Loss function curves for the training and validation sets, showing that the model gradually converged during training without oscillation or overfitting. (B) The accuracy of the training and validation sets increased progressively with the number of iterations, indicating that the model had a stable learning process and good generalization ability.

Comparison of Structural and Functional Pathological Features Across Treatment Groups



After confirming the superior classification performance of the transformer model for myocardial H&E-stained images, the model was applied to automatically identify and quantitatively assess pathological alterations across different treatment groups to evaluate the tissue repair effects of various interventions in MIRI.

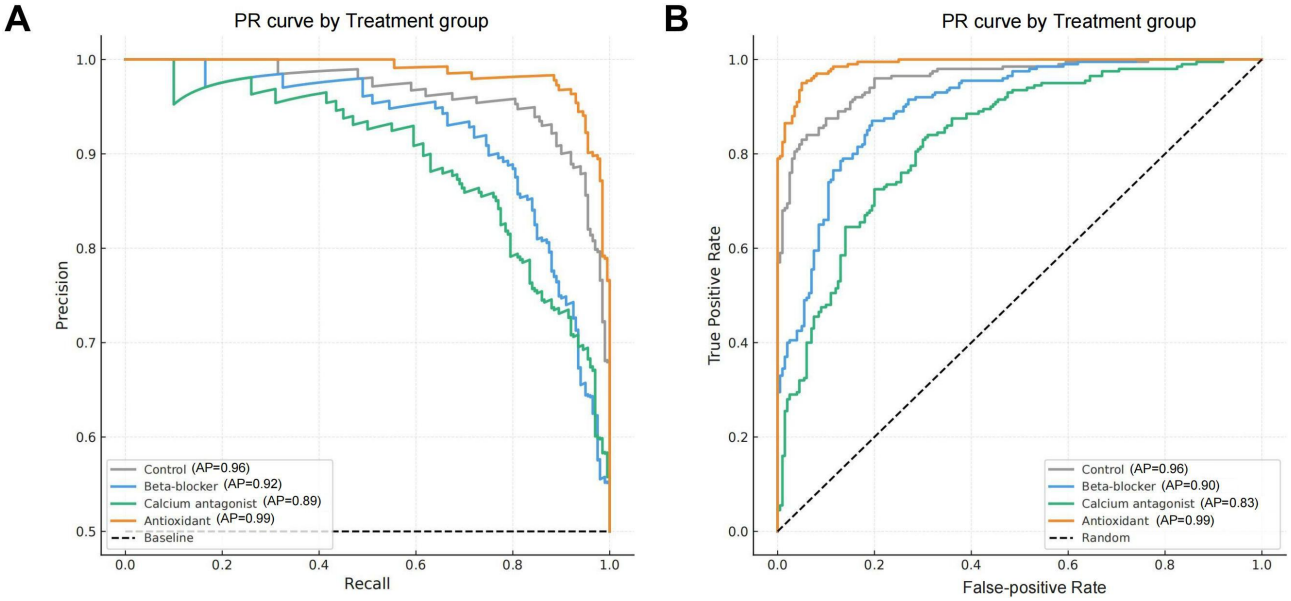
For structural damage, the antioxidant-treated group exhibited the most pronounced reduction in necrotic and apoptotic regions, indicating better preservation of membrane integrity and more effective suppression of programmed cell death. The control group showed the highest proportions of necrosis and apoptosis, reflecting the most severe tissue injury. The β-blocker group demonstrated a stronger inhibitory effect on apoptosis, whereas the calcium channel blocker group showed modest antifibrotic potential during structural remodeling (Figures 4A-4C).

For functional pathological markers, the antioxidant group displayed the lowest inflammatory response scores and oxidative stress index values, suggesting a broad protective effect potentially mediated through modulation of immune activity and reduction of free radical accumulation. Increased capillary density scores further indicated improved microvascular integrity, which may have contributed to more stable tissue repair progression (Figures 4D-4F).

XSL•FO
RenderX

Figure 4. Evaluation of the effects of multiple therapeutic interventions on structural and functional tissue parameters following myocardial ischemia-reperfusion injury. (A-C) Comparisons of necrotic area percentage, apoptotic area percentage, and fibrosis scores among treatment groups indicate that the antioxidant group shows the most significant structural protection. (D-F) Group comparisons of inflammation scores, oxidative stress indices, and capillary density reveal that the antioxidant group performs better in modulating immune responses, providing antioxidant protection, and maintaining microcirculation. Statistical significance was assessed using one-way ANOVA followed by post hoc multiple comparisons. *P<.05; **P<.01; ***P<.001; ns: no significant difference.

Discriminative Accuracy Performance of the Transformer Model in Myocardial Injury Images Across Multiple Intervention Groups



To further evaluate the transformer model's image discrimination capability under different treatment interventions, this study plotted precision-recall (PR) curves and ROC curves for 4 treatment groups (antioxidant, β-blockers, calcium channel blockers, and control group) to quantitatively assess the model's classification accuracy and discriminative power in a complex multigroup setting (Figures 5A and 5B).

The results showed that the Transformer model achieved the strongest performance in the antioxidant group, reaching an average precision and a mean AUC of 0.99 (SD 0.003) and 0.99 (SD 0.004), respectively. These values indicate highly reliable recognition of subtle repair trends and boundary features within antioxidant-treated samples. The control group ranked second, with AP of 0.96 (SD 0.006), and the AUC was also 0.96 (SD 0.005). Strong performance in this group was expected, as the classification task was less challenging due to the consistent and severe tissue damage, which provided clearer morphological cues.

Performance in the β-blocker and calcium channel blocker groups was lower, with mean AUC values of 0.90 (SD 0.011) and 0.83 (SD 0.015), respectively, accompanied by modest PR metrics. Increased morphological heterogeneity and less distinct lesion boundaries in these groups likely contributed to the reduced discriminative accuracy by creating more complex recognition conditions for the model. Overall, the transformer model demonstrated particular strength in processing images with pronounced structural continuity and clear repair dynamics, such as those observed in the antioxidant group, highlighting its advantage in global feature modeling and contextual pattern perception.

XSL•FO
RenderX

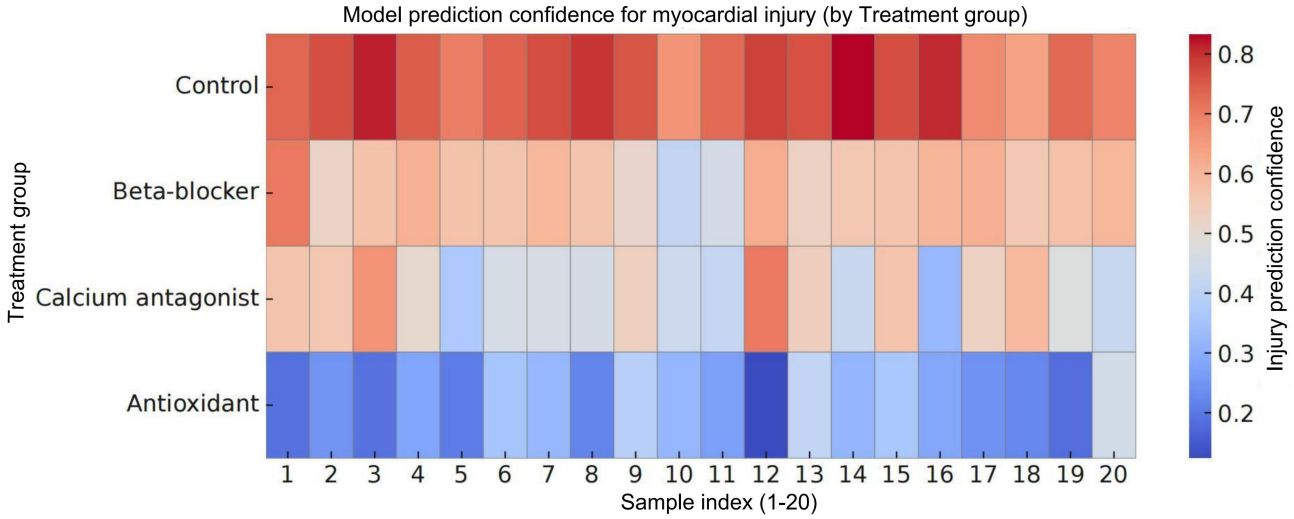


Figure 5. Evaluation of transformer model performance under 4 therapeutic interventions. (A) The precision-recall (PR) curves of the 4 treatment groups demonstrate the model's classification accuracy under different intervention conditions, with the antioxidant group showing the highest average precision (AP) value, indicating the strongest sensitivity of the model in this group. (B) The corresponding receiver operating characteristic (ROC) curves indicate that the antioxidant group also has the highest area under the curve (AUC), suggesting optimal model discriminative power for this image category. The calcium channel blocker group shows the weakest performance, implying that the complexity of its image features may pose greater challenges for the model.

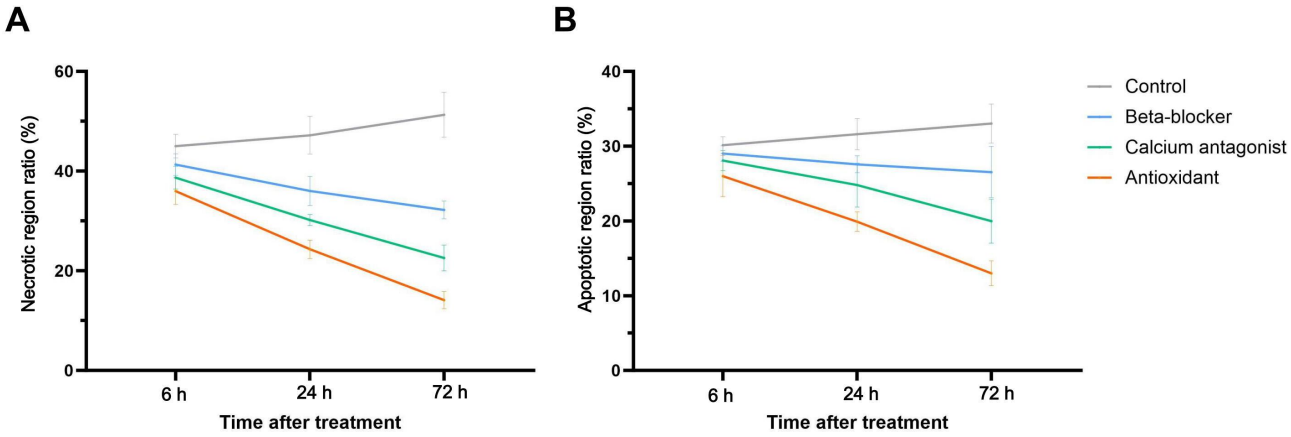
Analysis of Multigroup Image Recognition Stability and Model Discriminative Power Based on Confidence Scores

To further explore the prediction stability and confidence distribution patterns of the transformer model in classifying myocardial injury images under different therapeutic conditions, we generated a 2D heatmap based on model output confidence scores (Figure 6). Each treatment group included 20 samples. The vertical axis represents the treatment categories, and the horizontal axis denotes individual sample identifiers. The color gradient extends from blue to red, corresponding to low and high predicted probabilities for the tissue injury label, respectively.

Figure 6. Heatmap of tissue damage prediction confidence by the transformer model across treatment groups. The heatmap illustrates the distribution of damage prediction confidence scores for 20 myocardial hematoxylin and eosin–stained image samples per group under 4 treatment conditions. The color gradient ranges from blue (low confidence) to red (high confidence), indicating the model's predicted probability of tissue damage. Samples from the control group are predominantly concentrated in high confidence regions (red), while those from the antioxidant group are primarily located in low-confidence areas (blue), reflecting the model's discriminative sensitivity and stratification stability across different treatment backgrounds.

The results showed that samples from the control group exhibit consistently high confidence in predicted injury status, with the heatmap largely distributed in the red region. This indicates pronounced tissue damage and strong prediction consistency across control samples. In contrast, the antioxidant group predominantly displays low-confidence scores (mostly blue), suggesting that the model identifies milder tissue alterations or a tendency toward repair, with predictions leaning toward "no or mild injury."

The β-blocker and calcium antagonist groups demonstrated intermediate confidence distributions, characterized by



XSL•FO
RenderX

noticeable individual variability and gradual color transitions. These patterns may reflect heterogeneous tissue responses to the respective therapeutic interventions. Overall, the confidence scores showed clear stratification across treatment groups, confirming strong discriminative capability and stable performance of the model in multiclass classification. The confidence-based visualization further supported biological plausibility and enhanced the interpretability of the predictions.

Temporal Evolution of Myocardial Injury Under Different Treatment Strategies

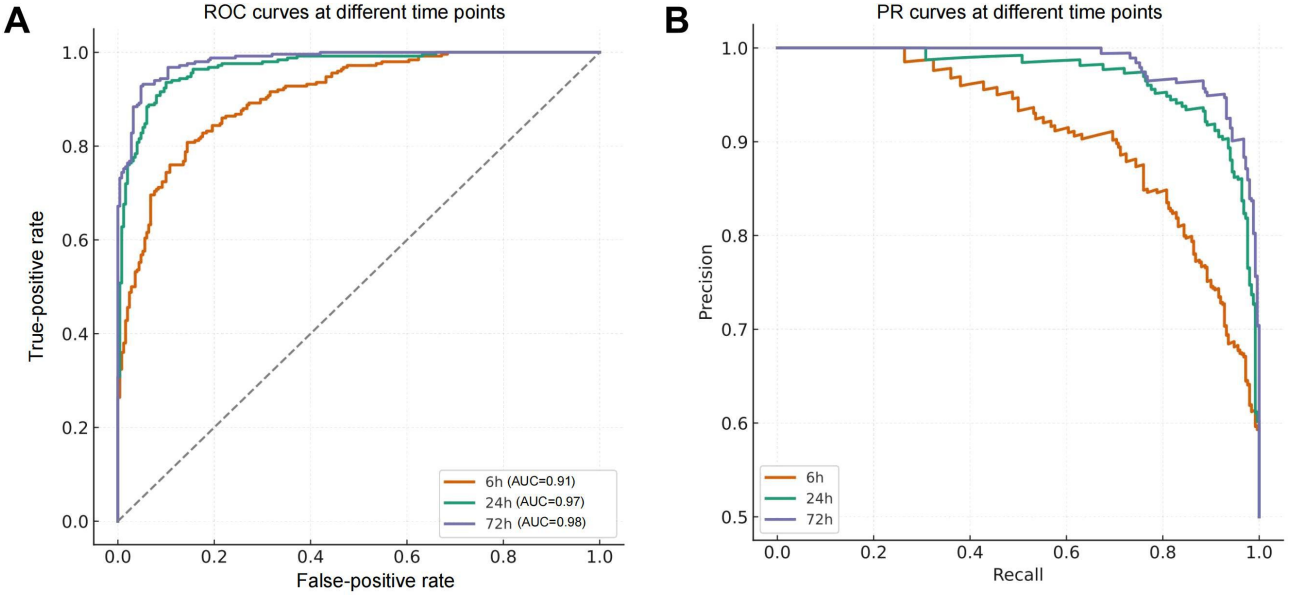
To evaluate the discriminative performance of the transformer-based model on time series images, 3 key time points after myocardial reperfusion—6, 24, and 72 hours—were selected. On the basis of the model's automated identification results, dynamic changes in 2 primary injury-related indicators were analyzed across different treatment groups: the proportion of necrosis-related patches and the proportion of apoptosis-related patches (Figures 7A and 7B). All proportions were calculated as the number of patches classified by the model as injured divided by the total number of patches within the corresponding group at each time point.

Figure 7. Dynamic trends of key myocardial injury indicators at 3 time points across different treatment groups. (A) The necrotic area ratio over time shows the most substantial reduction in the antioxidant group by 72 h, indicating a strong tissue-protective effect. In contrast, the control group exhibits a continuous upward trend, suggesting progressive damage without intervention. (B) A similar trend is observed for the apoptotic area ratio, with the antioxidant group showing the most significant decline, while other groups demonstrate only mild decreases, and the control group slightly increases. Error bars represent each group's SD.

The results showed that the antioxidant-treated group exhibited a significant and sustained downward trend in both indicators. Specifically, the proportion of necrosis-related patches decreased from 461 of 1282 (36.0%) at 6 hours to 311 of 1279 (24.3%) at 24 hours, and further declined to 183 of 1295 (14.1%) at 72 hours (Figure 7A). A consistent trend was observed for apoptosis-related patches, with proportions decreasing from 334 of 1285 (26.0%) at 6 hours to 256 of 1286 (19.9%) at 24 hours, and reaching 168 of 1292 (13.0%) at 72 hours (Figure 7B). These findings indicate that antioxidant intervention exerts a pronounced tissue-protective effect as early as the initial phase of reperfusion, and that this protective effect progressively strengthens over the follow-up period.

In contrast, the β-adrenergic blocker group and the calcium channel blocker group showed a certain degree of injury attenuation at the 24-hour time point, but the overall downward trend plateaued after 72 hours. In the β-adrenergic blocker group, the proportion of necrosis-related patches decreased from 524 of 1269 (41.3%) at 6 hours to 458 of 1271 (36.0%) at 24 hours and was 414 of 1286 (32.2%) at 72 hours. The corresponding proportions of apoptosis-related patches were 368 of 1269 (29.0%), 351 of 1273 (27.6%), and 342 of 1289 (26.5%), respectively. A similar pattern was observed in the calcium channel blocker group, where the proportion of necrosis-related patches declined from 489 of 1265 (38.7%) at 6 hours to 384 of 1272 (30.2%) at 24 hours, and further to 292 of 1294 (22.6%) at 72 hours; the corresponding apoptosis-related patch proportions were 356 of 1268 (28.1%), 316 of 1275 (24.8%), and 258 of 1292 (20.0%). These findings suggest that both interventions confer a moderate protective effect during the intermediate phase, but their capacity to promote long-term tissue repair is relatively limited.

In contrast, the control group exhibited a progressive worsening over time in both injury-related indicators. The proportion of necrosis-related patches increased from 587 of 1304 (45.0%) at 6 hours to 620 of 1314 (47.2%) at 24 hours and further rose to 677 of 1320 (51.3%) at 72 hours. Similarly, the proportion of apoptosis-related patches increased from 394 of 1307 (30.1%) to 416 of 1316 (31.6%), reaching 437 of 1323 (33.0%) at 72 hours. These results indicate that, in the absence of therapeutic intervention, myocardial tissue injury continues to progress with reperfusion time, with no clear evidence of spontaneous repair.



Overall, distinct treatment strategies exhibit pronounced time-dependent differences in the histopathological evolution of MIRI. The transformer-based model is able to stably and sensitively capture these dynamic changes at the patch level, supporting its potential utility in mechanistic studies of reperfusion injury and in stage-wise evaluation of therapeutic efficacy.

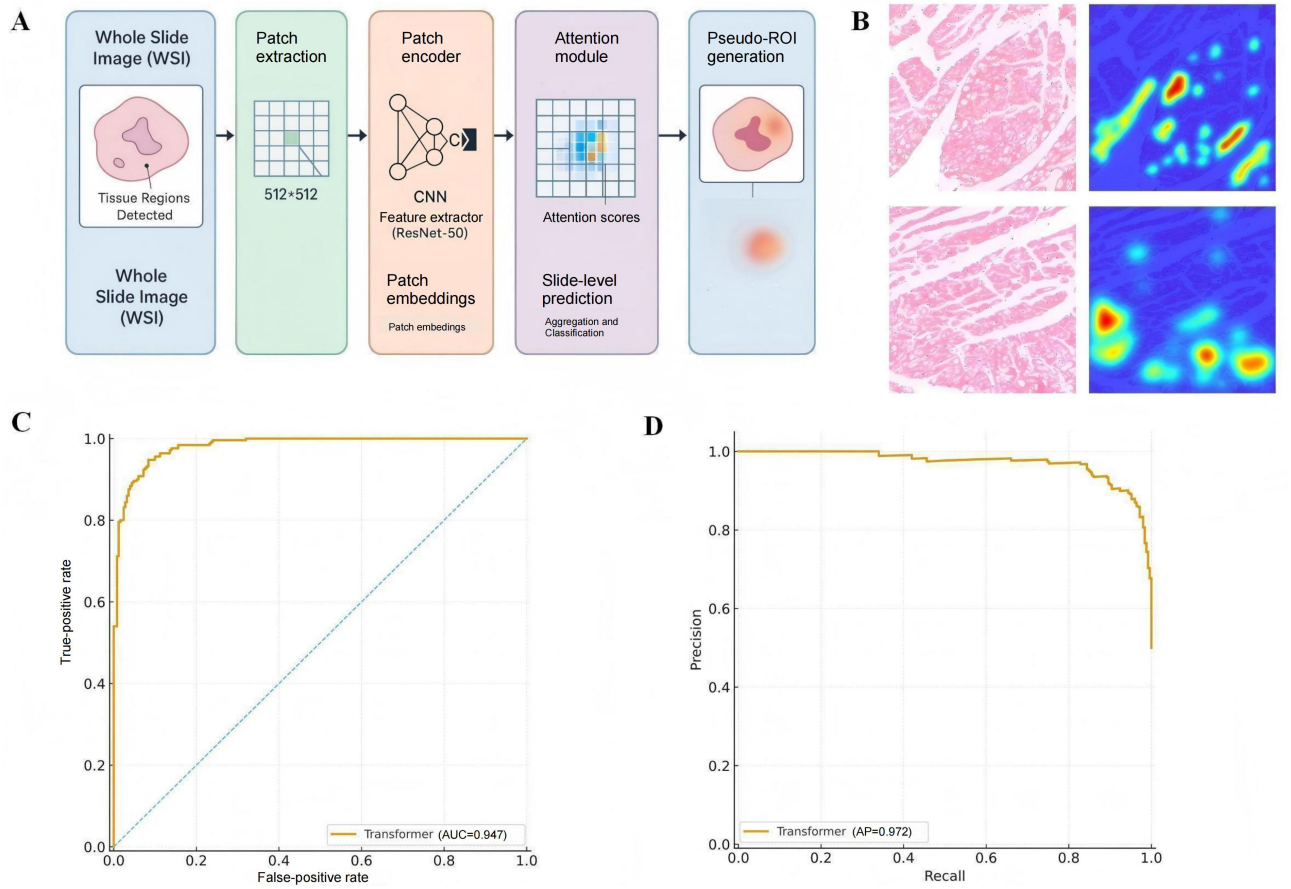
RenderX

Evaluation of the Discriminative Performance of Transformer Models Across Different Epochs

To validate the transformer model's classification performance across different postreperfusion stages, we generated ROC and PR curves for 3 key time points: 6 hours, 24 hours, and 72 hours (Figures 8A and 8B). The results demonstrate that the model achieved its strongest performance at 72 hours, with a mean AUC of 0.98 (SD 0.003). The distribution of the PR curve approached the ideal upper bound, indicating effective identification of subtle injury regions during late-stage tissue repair.

Figure 8. Evaluation of classification performance of the transformer model on myocardial injury images at 3 time points. (A) The receiver operating characteristic (ROC) curve comparison indicates that the model achieves the highest area under the curve (AUC) of 0.98 at 72 h, demonstrating excellent sensitivity to mild late-stage injury. The AUC values at 24 and 6 h are 0.97 and 0.91, respectively, confirming the model's stable performance in identifying acute-phase lesions. (B) The precision-recall (PR) curve demonstrates that the model achieves the highest balance between precision and recall at 72 h, confirming its generalization capability across time and consistent performance in early- and late-stage recognition.

At the 24-hour time point, the model maintained strong classification capability with a mean AUC of 0.97 (SD 0.005), indicating high generalizability for evaluating early therapeutic responses. Even during the acute injury phase at 6 hours, the model demonstrated robust discrimination, achieving a mean AUC of 0.91 (SD 0.012) and consistently high precision in the PR curve. This implies that the transformer is effective at identifying typical necrotic and apoptotic features even in early-stage pathology.



Overall, the model exhibited stable classification performance across all 3 time points, supporting its applicability to both static image discrimination and the analysis of complex morphological variations across different stages of time series tasks.

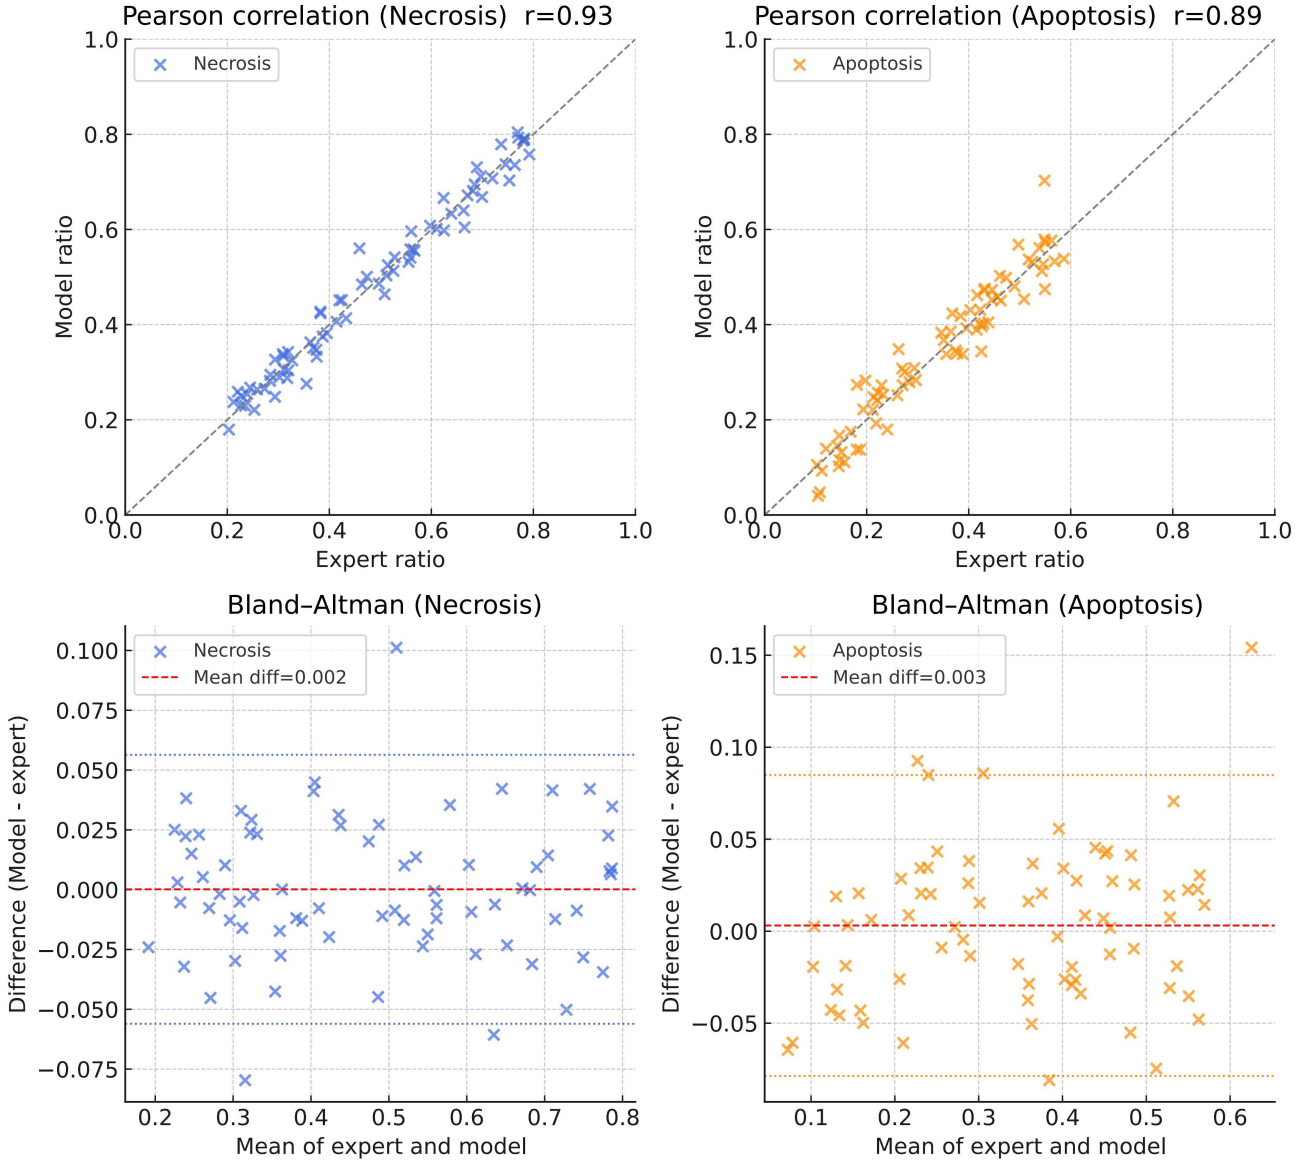
Model Interpretability and Biological Consistency of Attention Maps

To further evaluate the interpretability and biological plausibility of the transformer model in histopathological image classification, we conducted a weakly supervised analysis based on an MIL framework (Figure 9). Specifically, we adopted the CLAM architecture, in which each myocardial H&E WSI was partitioned into 512×512 pixel patches and trained under weak supervision using reperfusion time points and treatment group labels. Through its attention mechanism, the model automatically generated pseudo-ROIs, highlighting diagnostically relevant areas without requiring pixel-level annotations.

XSL•FO
RenderX

Figure 9. Workflow and performance of the MIL-based weakly supervised framework. (A) Schematic diagram of the weakly supervised learning pipeline. Whole-slide images (WSIs) are partitioned into 512×512-pixel tiles and assigned slide-level labels based on treatment group and reperfusion time. Using the CLAM framework, the model applies an attention mechanism to automatically generate pseudo-regions of interest (ROIs) and learn pathological discriminative features. (B) Representative H&E image overlaid with the attention heatmap. Red regions denote high-importance areas identified by the model. (C) Receiver operating characteristic (ROC) curve of the weakly supervised transformer classifier, showing an area under the curve (AUC) of 0.947. (D) Precision-recall (PR) curve illustrating the balance between precision and recall across varying thresholds. The attention-derived pseudo-ROIs generated from this workflow are subsequently used to guide model pretraining.

The resulting attention heatmaps showed high spatial concordance with key histopathological regions, including necrotic border zones and inflammatory infiltration areas. Highly weighted red regions consistently aligned with structurally compromised zones or areas with dense inflammatory cell accumulation, indicating that the features learned by the model carried clear biological meaning (Figure 9B). The weakly supervised transformer classifier demonstrated strong performance on the held-out test set, achieving a mean AUC of 0.947 (SD 0.006) on the ROC curve (Figure 9C), and its precision-recall curve showed balanced high precision and recall (Figure 9D).



Collectively, these results demonstrate that the transformer model not only outperforms other deep learning architectures in quantitative metrics but also provides intrinsically interpretable outputs. The attention mechanism consistently identified pathologically relevant structures, enhancing transparency, supporting biological consistency, and strengthening the translational potential of transformer-based models in medical histopathology.

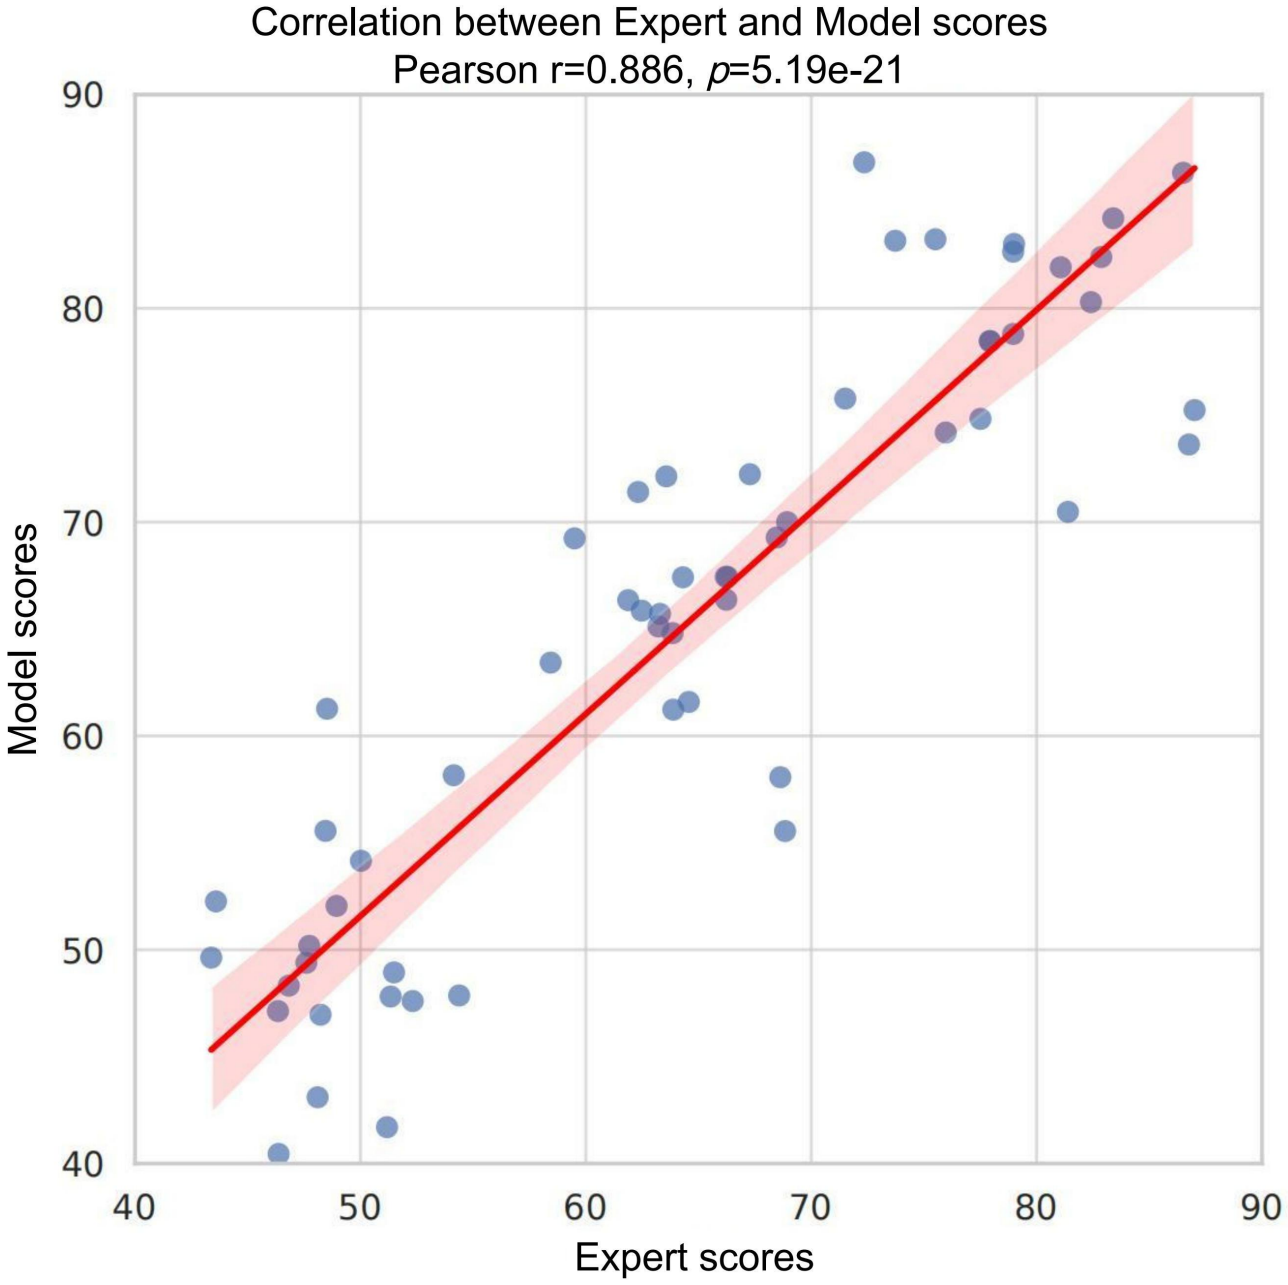
Model Validation and Consistency Analysis

To evaluate the reliability of the transformer model in detecting dynamic tissue changes associated with MIRI, we conducted expert pathological review and statistical consistency analyses using an independent dataset (Figure 10). Two senior cardiovascular pathologists independently measured the proportions of necrotic and apoptotic areas under blinded conditions (25 images per time point). These manual measurements were then compared with model-derived outputs. The results demonstrated strong concordance between human assessments and model predictions. The mean Pearson correlation coefficients (r) for necrotic and apoptotic area ratios were 0.93 (SD 0.02) and 0.89 (SD 0.03), respectively (both P<.001), indicating a high degree of alignment. Bland-Altman analyses further supported this agreement, with mean differences of 0.002 for necrotic regions and 0.003 for apoptotic regions, 95% limits of agreement confined within +5% and −5%, and no evidence of systematic bias.

XSL•FO
RenderX

Figure 10. Consistency analysis between model outputs and pathologist measurements for necrotic and apoptotic regions. Top row: Pearson correlation analyses comparing model-predicted necrotic and apoptotic areas with manual measurements by expert pathologists. Strong linear positive correlations were observed for both necrosis (r=0.93) and apoptosis (r=0.89), with all P<.001. The dashed line represents the line of perfect agreement. Bottom row: Bland-Altman plots assessing agreement between model predictions and expert annotations. The mean differences were 0.002 for necrotic regions and 0.003 for apoptotic regions, with 95% limits of agreement within +5% and −5% and no systematic bias detected. Blue and orange points represent necrotic and apoptotic samples, respectively. These results demonstrate a high degree of concordance between the transformer model and expert assessments, confirming the model's reliability and clinical consistency in identifying myocardial injury regions.

The model's temporal recognition capability was further validated using the independent BioImage Archive dataset (S-EPMC9426742). The temporal trajectories of necrotic and apoptotic area reduction across reperfusion time points closely matched the patterns observed in the local validation cohort. These results confirm that the transformer model reliably captures biologically meaningful, time-dependent tissue changes following reperfusion. The dynamic differences detected by the model reflect authentic pathological progression rather than algorithmic artifacts, underscoring its stability, interpretability, and suitability for longitudinal histopathological assessment.



Concordance Analysis Between Model Outputs and Expert Annotations

To further validate the reliability and interpretability of the transformer model in recognizing myocardial tissue injury, we performed a pairwise comparison between model-generated scores and pathologist-assigned expert scores, and visualized the results using a correlation scatter plot (Figure 11). Statistical analysis revealed a significant positive linear correlation between the 2 sets of scores (mean Pearson correlation coefficient r=0.886, SD 0.018; P=5.19×10^{-21}). The regression line exhibited a stable slope with a narrow 95% CI, indicating a high level of agreement between the model outputs and expert assessments.

The results confirm the reliability of the model predictions from a statistical perspective and demonstrate strong trend-level consistency with expert assessments from a clinical standpoint. The findings further support the potential of the transformer model as an auxiliary evaluation tool in practical applications by providing a structured and quantifiable basis for interpreting the severity of myocardial injury.

XSL•FO
RenderX

Figure 11. Linear correlation between model predictions and expert pathological scores. The scatter plot illustrates the correspondence between transformer model predictions and expert manual assessments. The red line represents the linear regression trend, with the shaded area indicating the 95% CI. The Pearson correlation coefficient is 0.886 with a *P* value of 5.19×10^{-21}, indicating a strong positive correlation and validating the model's consistency and reliability in assessing tissue injury severity.

Discussion

MIRI represents a critical pathological process in the treatment of cardiovascular diseases and is typically characterized by marked cardiomyocyte apoptosis and necrosis, which directly influence the efficacy of clinical interventions and patient prognosis [30,31]. Traditional pathological assessment depends heavily on manual slide interpretation and is limited by subjectivity, low efficiency, and poor reproducibility. In recent years, rapid advances in AI, particularly deep learning–based medical image recognition, have highlighted the potential of automated H&E-stained tissue analysis to improve the quality and consistency of histopathological evaluation. In this context, this study constructed a large-scale H&E image dataset encompassing multiple intervention groups and reperfusion time points. Performance comparisons across 8 mainstream deep learning models for myocardial injury recognition identified the transformer-based architecture as the optimal option. An integrated framework for AI-assisted histopathological assessment was also established, combining image recognition, trend quantification, and visual output. The framework provides a novel technical pathway to support clinical interpretation of myocardial pathology and offers a foundation for more standardized and quantitative evaluation in translational cardiovascular research.

Deep learning has seen increasing application in cardiovascular pathology image analysis in recent years. However, most studies remain focused on static image recognition simultaneously,

XSL•FO
RenderX

with typical tasks including apoptotic cell detection, fibrotic region segmentation, or immunohistochemical image classification. These investigations predominantly rely on CNN-based models or their variants, focusing on local feature extraction capabilities [32]. Some studies have explored the use of GANs for image augmentation or used LSTMs for processing temporal data, but spatiotemporal integration at the tissue level remains largely underdeveloped [33,34]. In contrast, this study incorporates diverse therapeutic contexts and systematically introduces the temporal dimension. By leveraging the strengths of the transformer architecture in spatial representation and long-range dependency modeling, high-precision recognition of histopathological progression across multiple reperfusion time points was achieved. Model outputs are further validated against expert annotations to ensure interpretability and clinical consistency. The proposed approach addresses limitations of prior work that emphasized classification accuracy without adequate clinical benchmarking and advances the application of AI from static image recognition toward dynamic pathological interpretation.

In this study, both human-derived and classical rodent MIRI sections were incorporated during the model training phase, primarily based on the fact that this pathological process exhibits highly consistent histological endpoint features across different species. Nevertheless, interpretations related to clinical relevance in this work are primarily grounded in the model's performance on human samples. Animal-derived samples are mainly leveraged to enhance the model's ability to learn generalizable pathological phenotypes of myocardial reperfusion injury and to improve its robustness and stability of generalization.

It is worth noting that the strong performance of the transformer model in this study arises not only from its global receptive field and robust spatial modeling capacity but also from its compatibility with the complex spatial textures and gradual color transitions that frequently characterize myocardial injury images. Although some studies report that GANs perform well in image augmentation and feature completion, the results show that GANs yield only modest performance gains in this task, suggesting greater utility in contexts involving severe class imbalance or limited sample availability. Heatmap analysis further demonstrates a high degree of correspondence between the attention regions generated by the transformer model and the pathological zones of interest. In the antioxidant treatment group in particular, low activation intensity in blue aligns with reduced apoptosis and necrosis, reflecting strong agreement with histopathological findings. Such spatial concordance strengthens model interpretability and provides empirical support for the concept of biological consistency, in which AI outputs correspond to biologically meaningful patterns. These findings collectively highlight the potential of deep learning to assist with mechanistic inference in MIRI.

From a clinical perspective, the proposed AI framework demonstrates broad adaptability and strong potential for translation into routine practice. Integration into digital pathology platforms enables automated identification and quantitative assessment of MIRI on histological sections, thereby supporting pathologists in interpretation, particularly in high-throughput or repetitive evaluation environments. The framework also provides a quantitative basis for drug screening, therapeutic efficacy assessment, and prognostic evaluation, offering standardized and objective data that can enhance cardiovascular research. Visual outputs generated by the model, including heatmaps and temporal trend plots, can be applied in research, training, and educational settings to improve understanding of pathological progression among junior clinicians and investigators. Given the model's high classification accuracy across treatment groups and its ability to characterize temporal dynamics, broader adoption in preclinical studies and clinical research is recommended to support mechanistic investigation and to improve the efficiency and quality of precision medicine in cardiovascular disease.

Although the study has produced meaningful findings, several limitations remain. First, model training and validation relied on publicly available datasets. These datasets offer relatively large sample sizes and stable quality, yet they do not fully capture common clinical challenges, such as sectioning artifacts, staining variability, or scanning-induced noise, which may affect generalizability in routine clinical environments. Second, this analysis is restricted to static histopathological images and has not incorporated multimodal information from serial tissue sections, biochemical indicators, electrocardiogram data, or other physiological time series measurements. As a result, the relationship between microscopic pathology and macroscopic physiological processes has not been comprehensively explored. Third, although the transformer architecture achieves high classification accuracy, its substantial parameter count and slower inference speed require considerable computational resources, which may hinder real-time deployment on edge devices or remote platforms. These limitations indicate that future research should aim to enhance dataset diversity, develop lightweight models suitable for broader deployment, and promote deeper integration of multimodal clinical information.

Future research can progress in several directions. First, expanding the dataset to incorporate clinical samples from multiple hospitals, imaging platforms, and slide preparation protocols will strengthen cross-center robustness and improve generalizability. Second, integrating histological image data with multiomics biomarkers, including genomic, transcriptomic, and serological information, may support the development of end-to-end AI systems with deeper mechanistic relevance. Third, incorporating explainable AI techniques to investigate the causal links between model attention regions and pathological alterations will promote greater verifiability, interpretability, and clinical trust. Fourth, in terms of model optimization, approaches such as model compression and knowledge distillation may enhance computational efficiency and facilitate deployment in edge computing environments or real-time clinical workflows. In addition, the current framework can be extended to the analysis of other tissue injury contexts, including cerebral ischemia, liver fibrosis, and pulmonary damage, thereby contributing to the construction of a broader AI framework for histopathological evaluation across diverse disease domains.

In conclusion, the study constructs a large-scale dataset of myocardial H&E-stained images and provides a systematic comparison of 8 deep learning models for recognizing reperfusion injury. The results show that transformer-based

XSL•FO
RenderX

models consistently achieve superior performance, with clear advantages in interpreting dynamic pathological changes and evaluating treatment responses. The findings broaden the application of AI in myocardial injury analysis and establish a scalable AI-assisted evaluation framework. With high classification accuracy, strong temporal trend tracking, and close agreement with expert assessments, the proposed approach demonstrates both scientific value and clinical applicability. Although certain technical and methodological limitations remain, the study provides a solid foundation for the development of standardized, high-throughput, and mechanism-oriented AI systems in digital pathology and offers robust technological support for future advances in precision medicine (Multimedia Appendix 6).

Funding

This study was supported by General Science and Technology Project of the Zhejiang Provincial Department of Education (Y202249201), Foundation of TCM Science and Technology Project of Zhejiang Province (2023ZF185), and Jinhua City Science and Technology Project (2024-4-309).

Data Availability

All data generated or analyzed during this study are included in this article and/or its supplementary material files. Further inquiries can be directed to the corresponding author.

Authors' Contributions

CL designed the study, performed data preprocessing and model development, and drafted the initial manuscript. MX contributed to histopathological data curation, annotation, and validation of experimental results. YL assisted in dataset organization, pharmacological grouping verification, and statistical analysis. ZZ supported model training, optimization, and visualization of attention and segmentation outputs. YP supervised the project, provided methodological guidance, and critically revised the manuscript. YW conceived the study, coordinated clinical and pathological resources, oversaw overall research direction, and finalized the manuscript. All authors reviewed and approved the final version of the manuscript.

Abstract

Background: Adult-type diffuse glioma (ADG) is the most common primary malignant tumor of the central nervous system. Its highly invasive nature, marked heterogeneity, and resistance to therapy contribute to a high risk of recurrence and poor prognosis. At present, the lack of reliable prognostic tools poses a significant barrier to the development of individualized treatment strategies.

Objective: This study aimed to develop an effective prognostic model for ADG by integrating multiple machine learning algorithms, in order to enhance the precision of individualized clinical decision-making.

Methods: In this retrospective study, 160 newly diagnosed patients with ADG who underwent surgical resection and histopathological confirmation at our institution between June 2019 and September 2021 were included. A total of 32 variables, including clinical characteristics, molecular biomarkers, and preoperative hematological indicators, were collected. Overall survival (OS) and progression-free survival (PFS) were defined as the study endpoints. Feature selection was performed using least absolute shrinkage and selection operator regression, extreme gradient boosting, and random forest algorithms. Kaplan-Meier survival curves and log-rank tests were used for survival analysis. Multivariate Cox proportional hazards models were constructed to identify independent prognostic factors, and nomograms were developed accordingly. The model's discriminative ability, calibration, and clinical utility were evaluated using the concordance index, area under the receiver operating characteristic curve (area under the curve), calibration plots, and Kaplan-Meier analysis.

Results: Age, neutrophil percentage–to-albumin ratio (NPAR), and platelet-to-mean platelet volume ratio were identified as independent prognostic factors for OS, while age and NPAR were independent predictors for PFS (all $P<.001$). The prognostic models based on these variables demonstrated good predictive performance, with concordance index values of 0.731 and 0.763 for the training and validation cohorts in the OS model, respectively. The PFS model also showed robust performance. Area under the curve values and calibration curves further supported the models' accuracy and stability. Risk stratification analysis revealed clear survival differences between risk groups (all $P<.05$), indicating strong clinical applicability.

Conclusions: This study is the first to identify preoperative NPAR as a significant prognostic biomarker for ADG using machine learning approaches. The prognostic model incorporating NPAR, platelet-to-mean platelet volume ratio, and age demonstrated favorable predictive performance, offering a novel perspective for accurate risk stratification and personalized treatment in patients with ADG.

KEYWORDS

adult-type diffuse glioma; machine learning; neutrophil percentage-to-albumin ratio; NPAR; prediction model; prognosis

Introduction

Glioma is the most common primary malignant tumor of the central nervous system, with an annual incidence of approximately 4.5 per 100,000 individuals [1]. Among its subtypes, adult-type diffuse glioma (ADG) constitutes the predominant pathological category, characterized by high invasiveness, frequent postoperative recurrence, and poor overall survival (OS) [2]. Epidemiological data indicate that ADG incidence exhibits age and sex specificity, with the highest prevalence observed in individuals aged 45-70 years (peak incidence at age 65-75 years) and a male predominance (male-to-female ratio: 1.3-1.6:1) [3].

Despite advances in multimodal treatment—including maximal surgical resection combined with radiochemotherapy—ADG survival outcomes have shown limited improvement over the past decade [4,5]. Novel therapies such as immune checkpoint inhibitors (eg, anti–PD-1 monoclonal antibodies) and targeted agents (eg, epidermal growth factor receptor inhibitors) offer promise, but their clinical benefits are restricted to specific molecular subgroups and are frequently accompanied by immune-related adverse events, such as pneumonitis (reported in 15%-20% of cases) and acquired resistance [6]. As such, there remains an urgent need for precise prognostic tools to identify treatment-sensitive subpopulations and guide individualized therapeutic decision-making.

Currently, prognostic evaluation of ADG largely depends on traditional clinicopathological parameters, including age, isocitrate dehydrogenase 1 (IDH1) mutation status, and O6-methylguanine-DNA methyltransferase (MGMT) promoter methylation [7,8]. However, these markers alone exhibit limited predictive accuracy for treatment response or survival. Emerging evidence suggests that inflammation within the tumor microenvironment (TME) plays a critical role in glioma progression by promoting angiogenesis and suppressing antitumor immune activity [9]. Peripheral blood–derived inflammatory biomarkers, such as the neutrophil-to-lymphocyte ratio (NLR), lymphocyte-to-monocyte ratio (LMR), and platelet-to-lymphocyte ratio (PLR), have demonstrated prognostic relevance in several malignancies, including breast and colorectal cancer [10,11]. However, their utility in ADG remains underinvestigated.

Recently, the neutrophil percentage-to-albumin ratio (NPAR)—a composite marker integrating systemic inflammation and nutritional status—has been proposed as a novel prognostic indicator in solid tumors [12]. Nevertheless, its prognostic value in ADG, particularly in the context of long-term survival and treatment response, remains unclear.

Moreover, most existing prognostic models in gliomas are based on conventional Cox regression analysis, which is limited in handling high-dimensional data and complex nonlinear interactions [13,14]. In contrast, machine learning algorithms such as least absolute shrinkage and selection operator (LASSO) regression, extreme gradient boosting (XGBoost), and random forest (RF) have shown superior performance in variable selection and pattern recognition [15-18]. However, no studies to date have integrated these 3 algorithms to enhance the robustness of prognostic modeling in ADG.

Therefore, this study proposes an innovative machine learning–based approach that integrates LASSO regression (for feature selection), XGBoost (a gradient-boosted decision tree method), and RF (an ensemble learning model) to develop a multidimensional prognostic tool based on clinical, molecular, and inflammatory parameters. The objective is to improve predictive accuracy and provide refined support for clinical decision-making in patients with ADG.

Methods

Ethical Considerations

This retrospective study was conducted in accordance with the Declaration of Helsinki and was approved by the Ethics Committee of The First Affiliated Hospital of Zhengzhou University (Approval No 2023-KY-0223-002). Given the retrospective nature of this study, the requirement for informed consent was waived by the ethics committee. All patient data were anonymized and deidentified prior to analysis. Personal identifiers were removed, and each patient was assigned a unique study code to ensure confidentiality throughout the research process. No financial compensation was provided to the participants.

Study Population

This retrospective study enrolled 160 treatment-naïve patients with ADG who underwent maximal safe surgical resection with histopathological confirmation at our institution between June 2019 and September 2021. The postoperative treatment regimen followed the standard protocol, consisting of concurrent chemoradiotherapy followed by adjuvant temozolomide chemotherapy. In cases of disease progression, targeted therapies such as bevacizumab or BRAF (B-Raf proto-oncogene, serine/threonine kinase) inhibitors (eg, for tumors harboring the BRAF V600E mutation) were administered based on clinical indications [19].

Inclusion criteria were as follows: (1) age ≥18 years, diagnosis of ADG in accordance with the 5th edition of the *WHO Classification of Tumors of the Central Nervous System* (World Health Organization [WHO] grade 3-4); (2) completion of preoperative magnetic resonance imaging or computed tomography evaluation; (3) no prior antitumor therapy; (4) receipt of standard treatment protocol; (5) availability of complete clinical data, including general characteristics, preoperative blood tests, cardiac, hepatic, and renal function assessments, as well as postoperative immunohistochemistry and molecular profiling; and (6) complete follow-up records.

Exclusion criteria were (1) postoperative mortality within 30 days due to surgical complications or nonneoplastic causes; (2) presence of severe systemic disease or active infection

XSL•FO
RenderX

potentially affecting study outcomes; (3) diagnosis of other concurrent malignancies; (4) significant cardiac, hepatic, or renal dysfunction; and (5) history of prior cranial surgery.

Postoperative follow-up included clinical and radiological evaluations every 3 months during the first year and every 6 months thereafter, until October 1, 2024. Progression-free survival (PFS) was defined as the time from diagnosis to radiographic or clinical disease progression or death from any cause. OS was defined as the time from diagnosis to death or the last follow-up.

Study Variables

Clinical data were collected from patients with ADG who met the inclusion and exclusion criteria. The variables analyzed in this study included: clinical characteristics, molecular biomarkers, genetic alteration markers, preoperative peripheral hematological indicators, and inflammation-related ratios.

Clinical Characteristics

Age, gender, preoperative tumor location, extent of tumor resection, maximum tumor diameter, and midline shift.

Molecular Biomarkers

Immunohistochemical markers included P53 protein (P53), oligodendrocyte transcription factor 2 (Olig-2), S100 calcium-binding protein (S100), epithelial membrane antigen (EMA), synuclein (SYN), alpha-thalassemia/mental retardation syndrome X-linked (ATRX), cluster of differentiation 34 (CD34), neuronal nuclei (NeuN), glial fibrillary acidic protein (GFAP), and proliferation cell nuclear antigen-67 (Ki-67).

Genetic Alteration Markers

IDH1 immunophenotype, telomerase reverse transcriptase (TERT) promoter region mutation, BRAF V600E point mutation, epidermal growth factor receptor (EGFR) amplification, MGMT promoter methylation status, 1p loss of heterozygosity (1pLOH), and 19q loss of heterozygosity (19qLOH).

Preoperative Peripheral Hematological Indicators

White blood cell (WBC), platelet (PLT), neutrophil (Neut), monocyte (Mono), lymphocyte (Lym), prothrombin time (PT), activated partial thromboplastin time (APTT), lactate dehydrogenase (LDH), and serum albumin (ALB). All preoperative peripheral hematological indicators, including NPAR, were measured from blood samples collected within 1 week prior to surgery, before the administration of any corticosteroids or other interventions that could significantly alter these values.

Inflammation-Related Ratios

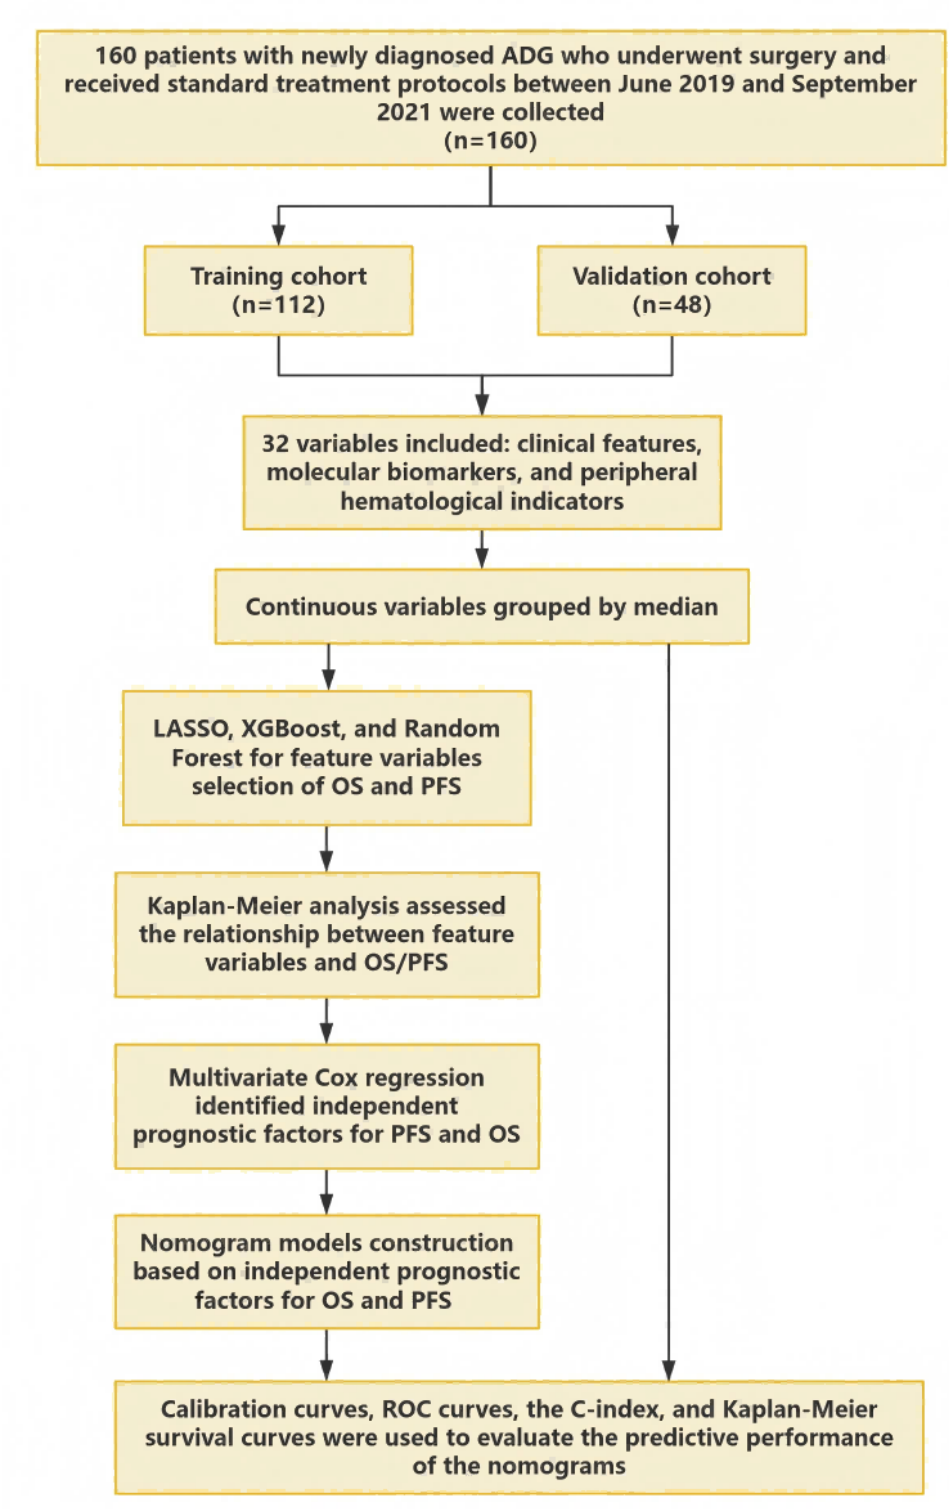
According to international standards for inflammatory biomarkers, the following parameters were calculated and defined: PLR = PLT/Neut, NLR = Neut/Lym, LMR = Lym/Mono, monocyte-to-lymphocyte ratio (MLR) = Mono/Lym, prognostic nutritional index (PNI) = ALB + 5 × Lym, systemic inflammation response index (SIRI) = (Neut × Mono)/Lym, systemic immune-inflammation index (SII) = (PLT × Neut)/Lym, aggregate index of systemic inflammation (AISI) = (Neut × PLT × Mono)/Lym, NPAR = (Neut/WBC%)/ALB, neutrophil-lymphocyte-platelet ratio (NLPR) = Neut/(Lym × PLT).

Study Design and Statistical Analysis

The study design is illustrated in Figure 1.

A random seed was set to divide the 160 cases into a training cohort (n=112) and a validation cohort (n=48) at a 7:3 ratio. The primary endpoint was OS, and the secondary endpoint was PFS. A total of 32 variables were included, encompassing clinical characteristics (age, gender, tumor location, etc), molecular biomarkers (Ki-67, IDH1, R132H, etc), and inflammatory indicators (NPAR, NLR, etc).

Continuous variables were dichotomized using the median as the cutoff. This approach was chosen to simplify the clinical interpretation of the model and to facilitate risk stratification, while also mitigating the impact of potential outliers and meeting the model's assumption of proportional hazards for categorical predictors. Categorical variables were expressed as frequencies (percentages), and group comparisons were conducted using the chi-square test (expected frequency ≥5) or Fisher exact test (expected frequency <5). The Shapiro-Wilk test was used to assess the normality of continuous variables. For normally distributed data, comparisons between groups were performed using the 2-tailed independent-samples *t* test (2 groups) or 1-way ANOVA (3 or more groups), with data presented as mean (SD). For nonnormally distributed data, comparisons were performed using the Mann-Whitney *U* test (2 groups) or the Kruskal-Wallis H test (3 or more groups), with post hoc pairwise comparisons adjusted using the Bonferroni method. These data were reported as median (IQR). A 2-tailed *P* value <.05 was considered statistically significant for all analyses.



A total of 3 machine learning algorithms were applied: LASSO regression (using the *glmnet* package with 10-fold cross-validation to optimize λ), XGBoost (using the *xgboost* package with max depth=6 and learning rate=0.01), and RF (using the *randomForest* package with *ntree*=1000). Venn diagrams were used to identify overlapping important variables selected by all 3 algorithms. Survival differences between groups were visualized using Kaplan-Meier (KM) curves and compared using the log-rank test.

A Cox proportional hazards regression model was constructed to estimate hazard ratios (HRs) and 95% CIs. Based on multivariate Cox results, a nomogram was developed using the *rms* package. Time-dependent receiver operating characteristic (ROC) curves were generated, and the area under the curve (AUC) at 1, 3, and 5 years was calculated. The concordance index (C-index) was used to evaluate the model's discrimination ability. Calibration was assessed using calibration curves based on 1000 bootstrap resamples. KM survival analysis based on the median nomogram score was performed to evaluate clinical utility. The validation cohort was used to assess the model's predictive performance.

All statistical analyses were conducted using R software (version 4.4.1; R Foundation for Statistical Computing). A 2-sided *P* value <.05 was considered statistically significant.

Results

Survival Outcomes

Among the 160 patients included in this study, a total of 132 (82.5%) experienced death events, and 152 (95%) experienced disease progression. The median OS was 23.0 months (IQR 15.0-38.3 months), while the median PFS was 10.5 months (IQR 6.8-17.5 months). The 1-, 3-, and 5-year OS rates were 85.6%, 27.1%, and 12.8%, respectively. The corresponding 1-, 3-, and 5-year PFS rates were 40.0%, 6.5%, and 3.4%, respectively. KM survival curves are presented in Figure 2.

XSL•FO
RenderX

Figure 2. Postoperative survival curves of 160 patients with adult-type diffuse glioma: (A) overall survival (OS) and (B) progression-free survival (PFS).

Baseline Characteristics

A total of 160 patients were included in this study, with a male-to-female ratio of approximately 1.4:1. The mean age was 51.3 (SD 13.6) years, and the median age was 53 (IQR 44-61) years. The maximum tumor diameter ranged from 1.0 to 9.5 cm, with a mean of 4.7 (SD 1.7) cm and a median of 5.0 cm (IQR 3.4-5.9 cm). Tumors were predominantly unilateral, with 76 cases (47.5%) on the left, 80 (50%) on the right, and 2 (2.5%) involving both sides. Midline shift was observed in 59.4% (95/160) of patients. All cases were classified as WHO grade 3-4. No significant differences in baseline characteristics were found between the training and validation cohorts (all P>.05). Detailed information is provided in Table 1.

[b]Indicates Fisher exact test.

Differences in PFS and OS Between Groups

Since the measurement data did not meet the assumption of normality according to the Shapiro-Wilk test, the nonparametric Wilcoxon rank-sum test was applied to evaluate the impact of different clinical characteristics on PFS and OS. Data are presented as median (IQR).

Using PFS as the outcome variable, significant differences (all $P<.05$) were observed in the following 10 variables: age ($P<.001$), tumor location ($P=.03$), NPAR ($P=.002$), NLR ($P=.002$), PNI ($P=.01$), SYN ($P=.003$), MGMT promoter methylation ($P=.004$), IDH1 R132 ($P<.001$), 1pLOH ($P=.04$), and 19qLOH ($P<.001$).

Using OS as the outcome variable, a total of 12 variables showed significant associations (all $P<.05$): age ($P<.001$), NPAR ($P<.001$), LMR ($P=.03$), NLR ($P=.02$), MLR ($P=.03$), PNI ($P=.01$), LDH ($P=.04$), SYN ($P=.009$), MGMT ($P=.04$), IDH1 R132 ($P<.001$), 1pLOH ($P=.003$), and 19qLOH ($P<.001$). Detailed results are presented in Table 2.

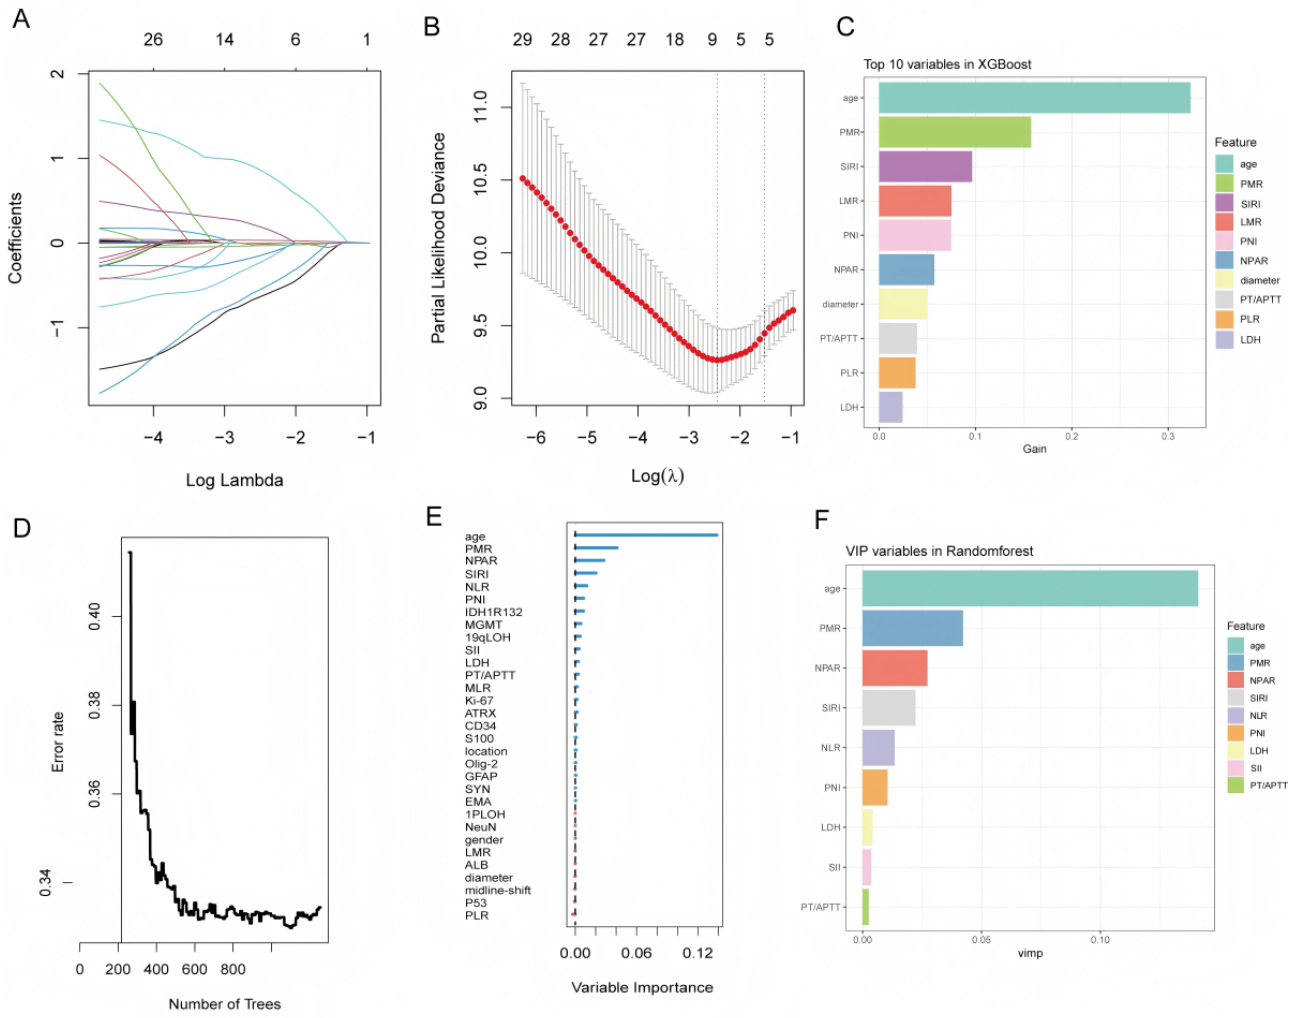
Construction and Validation of an OS-Based Prediction Model

Feature Variable Selection

Using OS as the outcome variable, a total of 3 machine learning algorithms—LASSO regression, XGBoost, and RF—were used to screen feature variables.



LASSO regression: based on the minimum λ value (λ_min), a total of 9 variables with nonzero coefficients were selected, including age, NPAR, platelet-to-mean platelet volume ratio (PMR), CD34 expression, SYN expression, EMA expression, IDH1 R132, 19qLOH, and MGMT promoter methylation (Figures 3A and B).

XGBoost model: according to feature importance scores, a total of 10 variables were selected, including age, PMR, SIRI, LMR, PNI, NPAR, maximum tumor diameter, PT/APTT, PLR, and LDH (Figure 3C).

RF: based on the mean decrease in Gini index, a total of 9 variables were selected, including age, PMR, NPAR, SIRI, NLR, PNI, LDH, SII, and PT/APTT (Figures 3D-F).

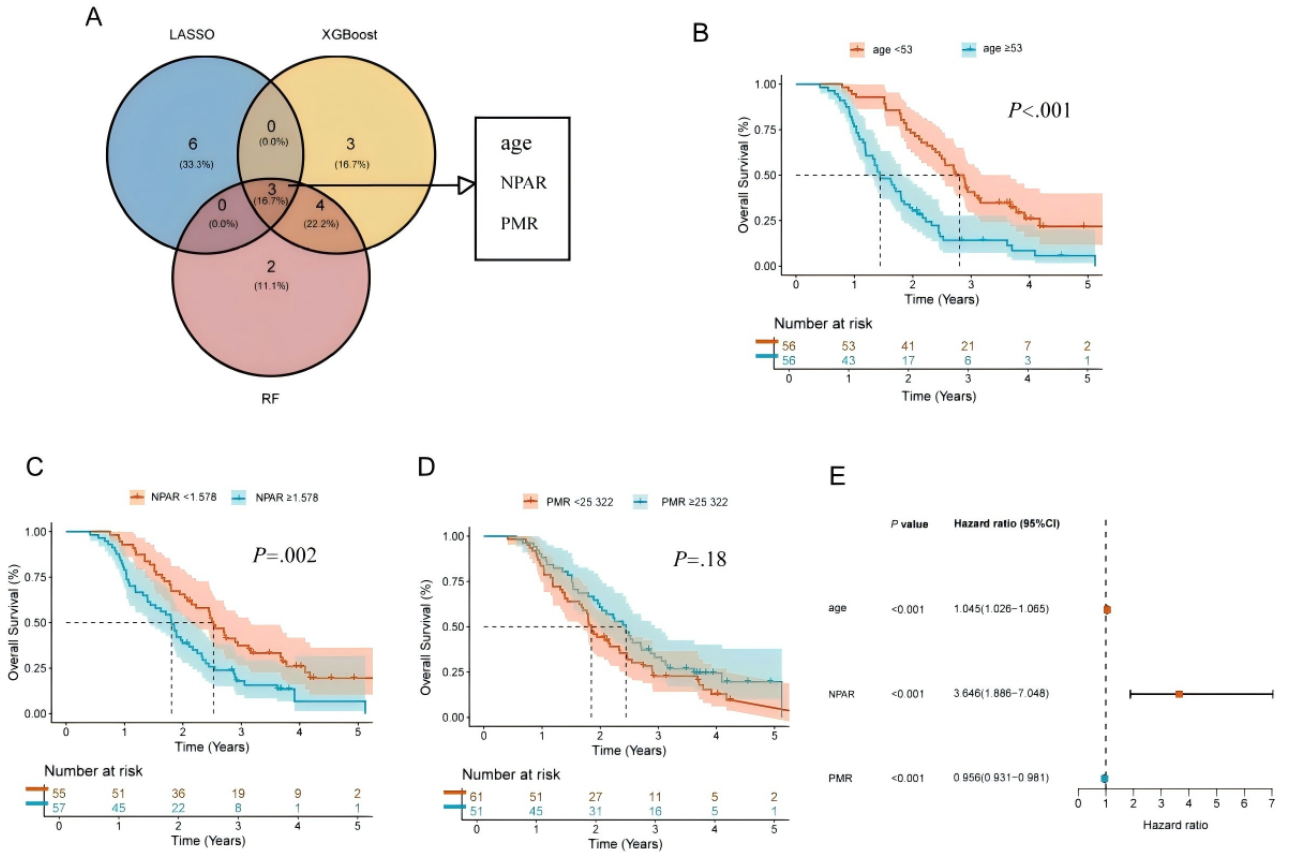
Survival Analysis



Based on the combined screening results from LASSO, XGBoost, and RF, Venn diagram intersection analysis identified age, NPAR, and PMR as key factors influencing OS (Figure 4A).

The prognostic impact of each individual variable was assessed using KM survival analysis (Figures 4B-D). Log-rank test results indicated that patients aged <53 years had significantly longer OS compared to those aged ≥53 years (P<.001), patients with NPAR <1.578 had significantly better OS than those with NPAR ≥1.578 (P<.001), while no significant difference in OS was observed between patients with PMR <25.322 and those with PMR ≥25.322 (P=.18).

Multivariate Cox proportional hazards regression analysis identified age (HR 1.05, 95% CI 1.03-1.07; P<.001), NPAR (HR 3.65, 95% CI 1.89-7.05; P<.001), and PMR (HR 0.96, 95% CI 0.93-0.98; P<.001) as independent prognostic factors for OS.

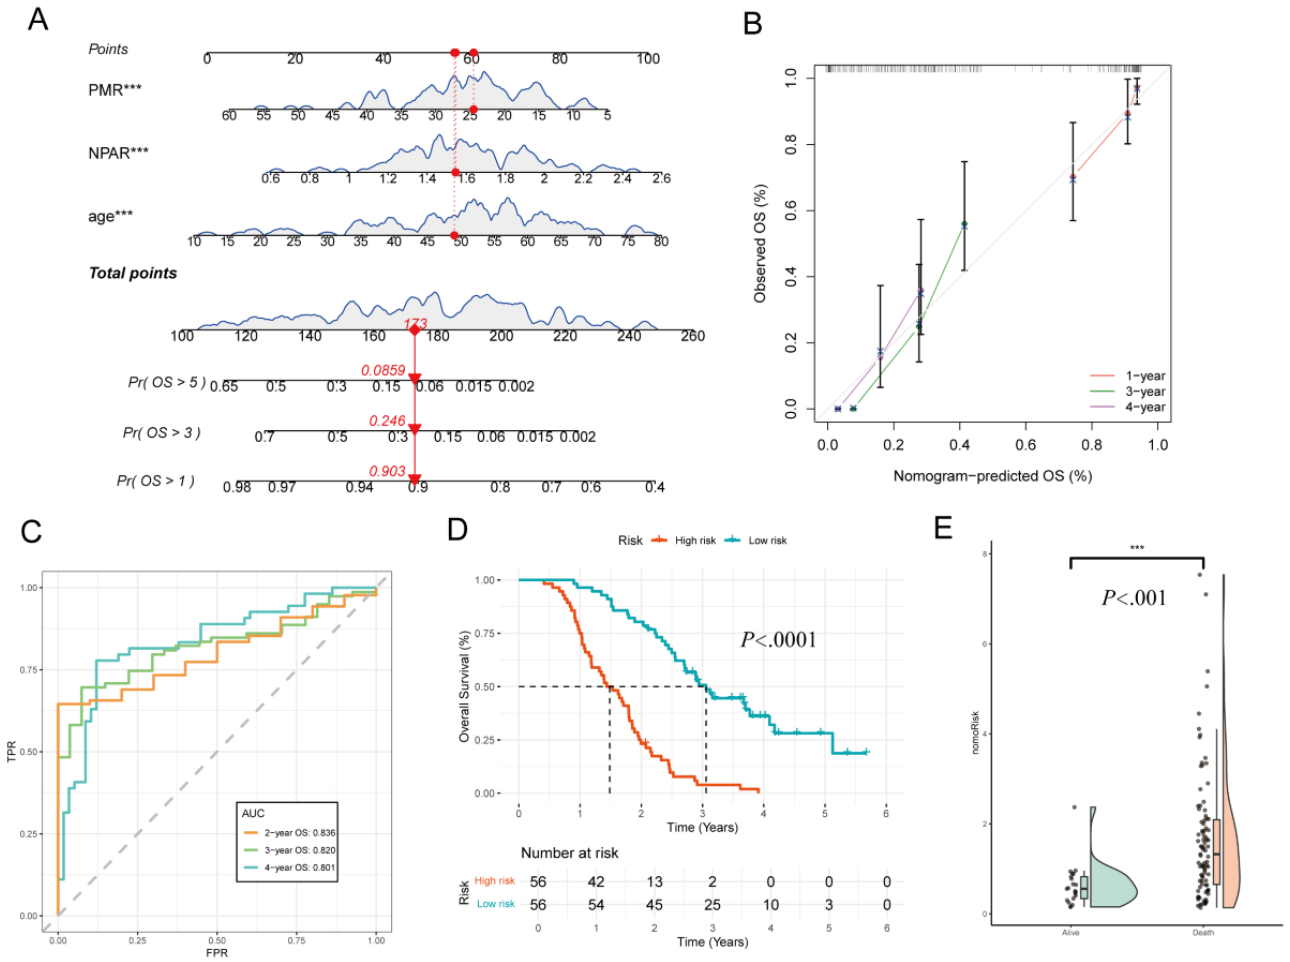
Figure 4. Identification of independent prognostic factors for overall survival (OS): (A) intersection analysis of feature variables from 3 models, (B) impact of age group on patient OS, (C) impact of neutrophil percentage-to-albumin ratio (NPAR) level on patient OS, (D) impact of platelet-to-mean platelet volume ratio (PMR) level on patient OS, and (E) forest plot of multivariate Cox regression analysis for OS. LASSO: least absolute shrinkage and selection operator.

Construction and Validation of the OS Nomogram

Based on the multivariate Cox regression analysis, age, NPAR, and PMR were identified as independent prognostic factors for OS. A nomogram was constructed using these variables to predict 1-, 3-, and 5-year OS probabilities. Each variable was assigned a corresponding risk score, and the total score was used to estimate individual survival probability (Figure 5A). The calibration curve showed good agreement between the predicted and observed 1-, 3-, and 5-year OS rates (Figure 5B). Time-dependent ROC analysis demonstrated that the AUCs for 2-, 3-, and 4-year OS in the training cohort were 0.836, 0.820, and 0.801, respectively, indicating strong predictive performance across multiple timepoints (Figure 5C).



Patients were stratified into high- and low-risk groups based on the median nomogram score. KM survival analysis revealed that the high-risk group had significantly poorer OS compared with the low-risk group (P<.001), supporting the nomogram's utility in risk stratification (Figure 5D).

To further evaluate the discriminative ability of the nomogram score, a raincloud plot was used to visualize the score distribution between the survival and death groups. This plot, which integrates a density plot, box plot, and scatter plot, clearly illustrated the differences in score distribution, providing additional evidence of the nomogram's effectiveness in prognostic assessment (Figure 5E).

The calibration curve in the validation group indicated good predictive accuracy of the model for 1-, 2-, and 3-year survival in patients with ADG (Figure 6A). Time-dependent ROC analysis showed that the AUCs for 1-, 3-, and 4-year OS were 0.822, 0.797, and 0.722, respectively (Figure 6B). Risk stratification based on the nomogram score revealed a significant difference in score distribution between survivors and nonsurvivors. Patients in the high-risk group had significantly poorer OS compared with those in the low-risk group (P<.01), supporting the prognostic discriminatory power of the nomogram (Figure 6C). The C-index remained high in both the training and validation sets, suggesting robust and consistent predictive performance (Figure 6D).

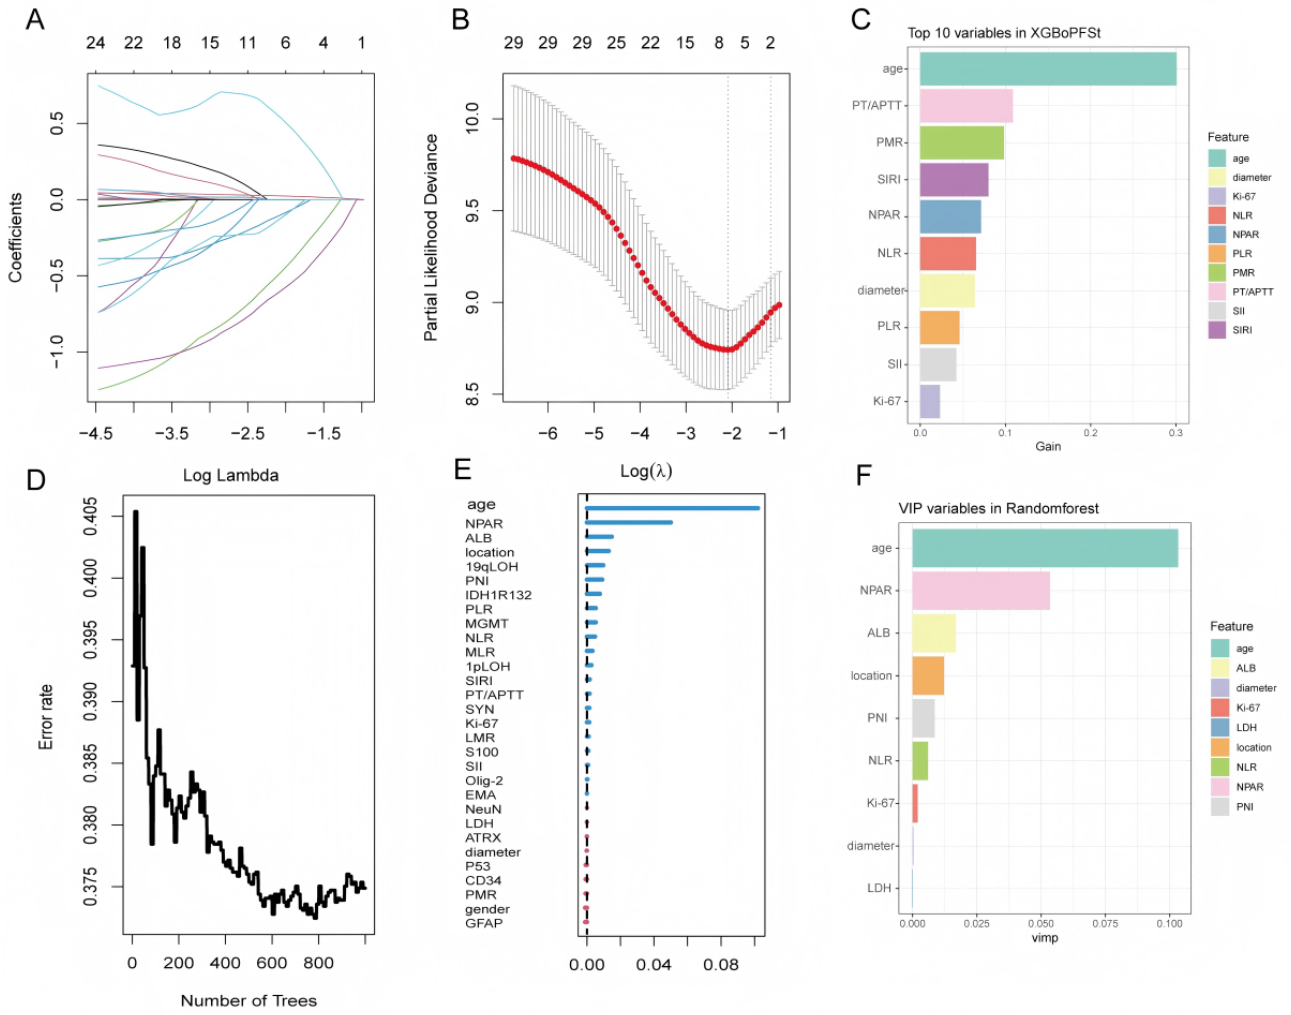
Construction and Validation of the PFS Prediction Model for ADG

Feature Variable Selection

Using PFS as the outcome variable, 3 machine learning algorithms—LASSO regression, XGBoost, and RF—were used to screen feature variables.



LASSO regression: based on the minimum λ value (λ_min), a total of 6 nonzero coefficient variables were selected, including age, NPAR, MLR, MGMT methylation, 1pLOH, and 19qLOH (Figure 7A and B).

XGBoost model: based on feature importance scores, a total of 10 variables were selected, including age, PT/APTT, PMR, SIRI, NPAR, NLR, maximum tumor diameter, PLR, SII, and Ki-67 expression (Figure 7C).

RF: based on the mean decrease in Gini index, a total of 9 variables were selected, including age, NPAR, ALB, tumor location, PNI, NLR, Ki-67, maximum tumor diameter, and LDH (Figures 7D and E).

XSL•FO

Survival Analysis

Based on the important variables screened by LASSO, XGBoost, and RF, Venn diagram intersection analysis identified age and NPAR as key factors influencing PFS (Figure 8A). The impact of each single factor on prognosis was assessed using KM survival analysis (Figures 8B and C). Log-rank test results showed that patients in the age <53 years group had significantly longer PFS than those in the age ≥53 years group (P<.001); patients in the NPAR <1.578 group had significantly longer PFS than those in the NPAR ≥1.578 group (P<.001). Multivariate Cox proportional hazards regression analysis revealed that age (HR 1.04, 95% CI 1.02-1.05; P<.001) and NPAR (HR 3.04, 95% CI 1.58-5.86; P<.001) were independent prognostic factors for PFS (Figure 8D).

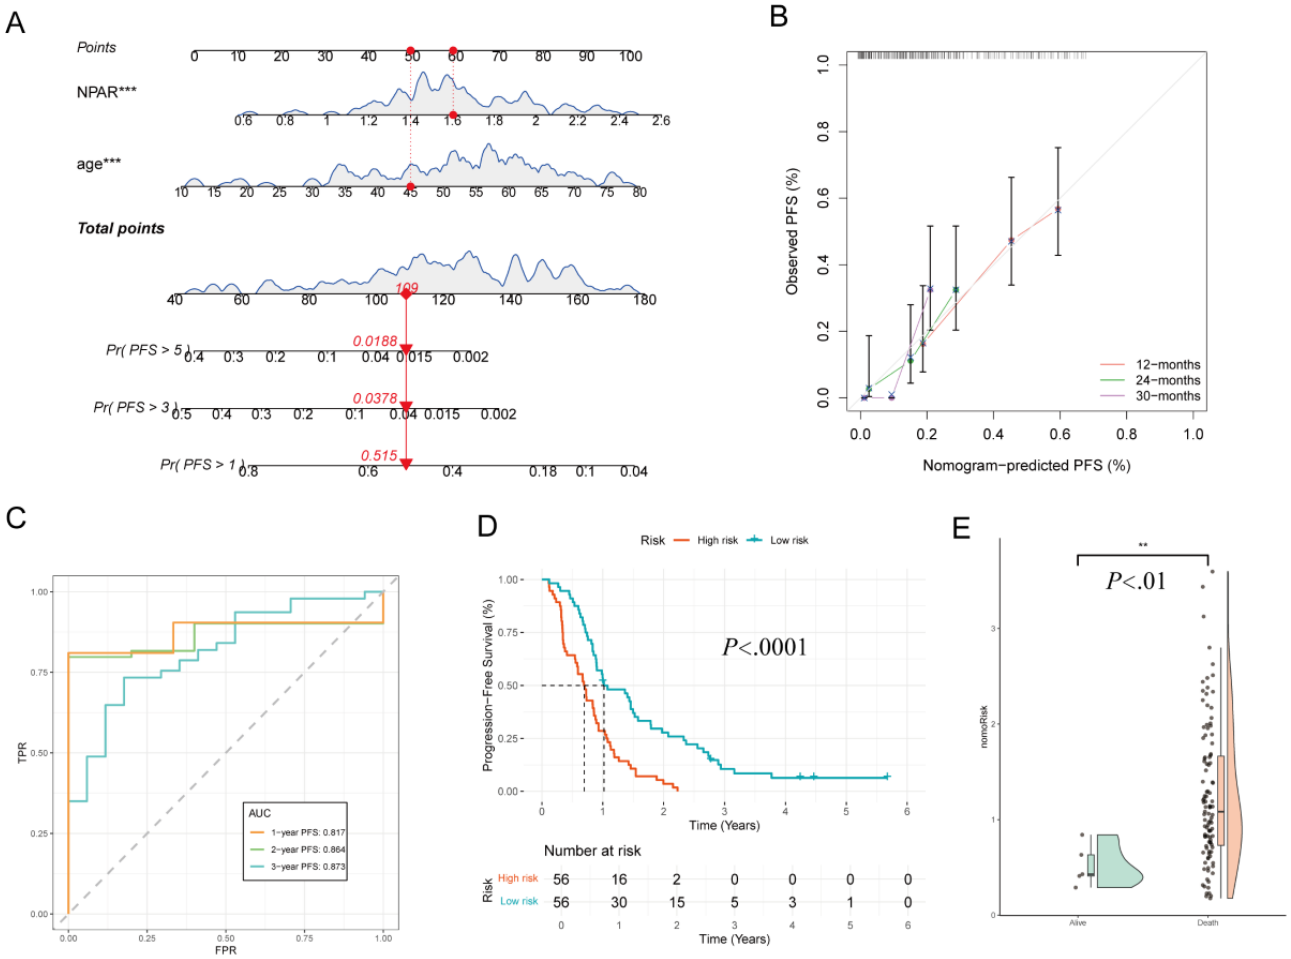
XSL•FO
RenderX

Figure 8. Identification of independent prognostic factors for progression-free survival (PFS): (A) intersection analysis of feature variables from 3 models, (B) impact of age group on patient PFS, (C) impact of neutrophil percentage-to-albumin ratio (NPAR) level on patient PFS, and (D) forest plot of multivariate Cox regression analysis for PFS. LASSO: least absolute shrinkage and selection operator.

Construction and Validation of the PFS Nomogram

Based on multivariate Cox regression analysis, age and NPAR were identified as independent prognostic factors for PFS. A nomogram was constructed using these variables to predict 1-, 3-, and 5-year PFS rates. Each predictive variable was assigned a corresponding risk score, and the total score estimated the patient's probability of disease progression (Figure 9A).

The calibration curve demonstrated good agreement between the model-predicted and observed 12-, 24-, and 30-month PFS rates (Figure 9B). Time-dependent ROC curve analysis showed that the AUC for 1-, 2-, and 3-year PFS in the training group was 0.817, 0.864, and 0.873, respectively, indicating high predictive accuracy of the model at different timepoints (Figure 9C). Patients were divided into high-risk and low-risk groups based on the median nomogram score. KM survival curves revealed that the high-risk group had significantly lower PFS than the low-risk group (P<.001), demonstrating that the nomogram score effectively stratified patients' prognostic risk (Figure 9D).



The raincloud plot provides a visual representation of the score distribution differences between the 2 groups and further supporting the effectiveness of the nomogram score in prognostic assessment (Figure 9E).

Due to the high risk of patient recurrence, the calibration curve for the validation group demonstrated good predictive performance for 6-, 12-, and 18-month disease progression risk in patients with ADG (Figure 10A). Time-dependent ROC curve analysis showed that the AUC for 1-, 3-, and 5-year PFS in the validation group was 0.709, 0.843, and 0.953, respectively (Figure 10B). Based on the median nomogram score, patients in the validation group were divided into high-risk and low-risk groups. KM survival curves revealed significant differences in OS between the 2 groups (P<.05), further validating the prognostic discriminative ability of the nomogram score (Figure 10C).

The C-index of the model was excellent in both the training and validation groups, indicating stable predictive performance across different datasets (Figure 10D).

Discussion

Principal Results

ADG, characterized by high malignancy and strong invasiveness, accounts for 45% of all gliomas [20,21]. The tumor heterogeneity and infiltrative growth patterns of ADG often lead to progressive neurological impairment, posing significant challenges for clinical management [9,22]. This study demonstrated that standardized comprehensive treatment (surgery combined with concurrent chemoradiotherapy and temozolomide) extended the median overall survival (mOS) to 23.0 (IQR 15.0-38.3) months, which is superior to the approximately 15 months reported in previous studies [2,23,24]. However, 95% (152/160) of patients experienced postoperative recurrence, with a median progression-free survival (mPFS) of only 10.8 months and a 5-year PFS rate of merely 1.9% (3/160). Moreover, the long-term prognosis remains poor, with a 5-year OS rate of just 12.8% (20/160) [25]. Therefore, it is of great significance to further explore the key prognostic factors affecting patients with ADG, establish novel prognostic models, and develop effective preventive strategies.

The key methodological advance of our work lies in the robust feature selection achieved by integrating 3 distinct machine learning algorithms (LASSO, XGBoost, and RF) [26]. This integrative approach circumvents the inherent pitfalls of relying on a single method, be it traditional Cox regression or an

XSL•FO
RenderX

individual machine learning model [13,14]. Consequently, it ensures that the identified prognostic factors (age, NPAR, and PMR) are consistently salient across different modeling paradigms, thereby significantly strengthening the credibility of our results.

Compared to existing prognostic models for ADG, our model demonstrates superior predictive performance. While Kim et al [27] reported a C-index of 0.70 using a single machine learning approach, the OS model in this study achieved C-indices of 0.731 and 0.763 in the training and validation cohorts, respectively. Furthermore, the model maintained high time-dependent AUC values at multiple timepoints (AUCs of 0.836, 0.820, and 0.801 for 2-, 3-, and 4-year OS, respectively) along with favorable calibration. Importantly, our model innovatively incorporates readily accessible hematological biomarkers (NPAR and PMR). This provides a more cost-effective and clinically feasible prognostic assessment tool compared to traditional models that rely solely on clinical and molecular parameters [7,8].

Analysis of 32 variables showed that longer survival was observed in patients with canonical molecular markers such as IDH1 mutation and MGMT promoter methylation, implicating them as potential prognostic factors. IDH1 mutations play a critical role in suppressing tumor metabolism and proliferation [28,29]. Patients with IDH1-mutant astrocytoma included had an mOS of 40.0 (IQR 33.6–NA, NA is censored data—some patients remained alive at follow-up cutoff, so the upper quartile was not observed) months, markedly better than the 22.2 (IQR 14.4–34.7) months observed in IDH1 wild-type patients. Similarly, MGMT methylation enhances sensitivity of tumor cells to alkylating agents such as temozolomide by inhibiting MGMT transcription and reducing DNA repair capacity, thereby significantly prolonging both PFS and OS [29-31]. In this study, a 30-year-old patient with IDH-mutant astrocytoma and MGMT methylation achieved a survival period exceeding 64 months, demonstrating significant survival benefit [32].

Furthermore, by integrating multiple machine learning methods, the study systematically identified age, the inflammation-nutrition marker NPAR, and the platelet quantity and function marker PMR as independent prognostic factors for patients with ADG [16]. These variables demonstrated significant predictive power in forecasting the prognosis of patients with ADG [33,34].

Age was confirmed as a key prognostic factor in our model. Patients aged ≥53 years had a higher risk of disease progression and significantly shorter survival time compared with those aged <53 years. This finding aligns with previous research trends regarding the prognosis of older adults with ADG, which may be related to reduced treatment tolerance and alterations in tumor biological characteristics in older individuals. It suggests that clinicians should pay attention to age stratification and develop personalized treatment plans accordingly [28].

This study is the first to identify NPAR as an independent prognostic factor for ADG. Patients with high NPAR levels had significantly shorter mOS and mPFS, along with a markedly increased risk of disease recurrence and worse prognosis. As a novel indicator that comprehensively reflects systemic inflammation and nutritional status, the NPAR has increasingly been recognized for its prognostic value in various cancers such as pancreatic and urological cancers in recent years. The NPAR integrates both systemic inflammation (reflected by neutrophil percentage) and nutritional status (reflected by serum ALB), 2 key pathophysiological processes known to influence cancer prognosis. Neutrophils can impair immune surveillance by suppressing natural killer cell function and promote tumor cell proliferation and metastasis [12,35]. Serum ALB levels not only reflect the body's protein metabolic status but are also closely associated with immune dysfunction [36]. The prognostic value of NPAR may stem from its correlation with systemic inflammatory responses mediated by proinflammatory cytokines in the TME. This pathophysiological cascade can accelerate the progression of cachexia and facilitate the evolution of malignant tumor phenotypes by modulating the TME [37,38].

The prognostic value of NPAR stems from its integration of 2 pivotal pathophysiological pathways: protumor inflammation and host nutritional status. The neutrophil component reflects systemic inflammation. Within the glioma TME, neutrophils are polarized into tumor-associated neutrophils (TANs), which facilitate tumor progression by secreting matrix metalloproteinases to enhance invasion, releasing proangiogenic factors like vascular endothelial growth factor, and contributing to T-cell dysfunction [39]. Emerging evidence specifically links this protumorigenic neutrophil activity to glioma progression [40]. Conversely, hypoalbuminemia, indicative of poor nutritional status and diminished physiological reserve, is a well-established marker of impaired immune competence and poorer outcomes in patients with cancer [41]. Thus, NPAR comprehensively captures this detrimental interplay between a proinflammatory TME and a compromised host state.

Furthermore, this study identified a higher PMR as an independent prognostic factor for prolonged overall survival in patients with ADG. This finding is consistent with a study on angiosarcoma, which also reported that a high mean platelet volume–to–platelet count ratio served as an independent risk factor for patient mortality [42]. This consistent pattern across malignancies highlights the biological significance of composite indices based on platelet count and volume.

While studies have established that platelets can facilitate glioma progression by releasing factors like platelet-derived growth factor to stimulate proliferation [43] and by modulating the immune microenvironment to promote an M2 phenotype and immune escape [44], our discovery of PMR as a protective factor suggests a more nuanced role. We hypothesize that an elevated PMR reflects a distinct platelet phenotype characterized by a lower mean platelet volume which is generally associated with diminished platelet reactivity. Consequently, a high PMR may indicate a reduced capacity of platelets to engage in these documented protumorigenic processes, thereby explaining its association with improved survival in ADG.

The prognostic nomogram developed from the aforementioned factors demonstrates significant translational potential. This tool can be integrated into electronic medical record systems to enable automated risk stratification at the time of diagnosis. Consequently, high-risk patients could be considered for more

XSL•FO
RenderX

aggressive treatment strategies—such as intensified chemoradiation following maximal safe resection—or more intensive follow-up (eg, neuroimaging every 2-3 months), and even enrollment in novel clinical trials. Conversely, low-risk patients may be suitable candidates for treatment de-escalation, such as shortened adjuvant chemotherapy cycles or reduced radiation doses, aiming to preserve oncological control while enhancing quality of life. This nomogram-based decision-making model represents a constructive step toward precision neuro-oncology.

Limitations

This study is subject to several limitations, including its single-center retrospective design, which may limit generalizability, and a variable-to-sample size ratio that raises concerns about overfitting despite internal validation. These limitations underscore the necessity for external validation in independent multicenter cohorts as an essential next step. Moreover, the molecular mechanisms linking NPAR and PMR to glioma prognosis are not fully understood. To address these points and advance this research, future work must focus on multicenter prospective validation, augmenting the model's power through the integration of radiomics and genomics, and leveraging single-cell and multi-omics technologies to decipher the functional roles of these circulating biomarkers in glioma pathogenesis.

Conclusion

In conclusion, this study significantly improved the robustness of prognostic biomarkers through a multimodel cross-validation strategy. Among the numerous factors, age, the preoperative inflammation-nutrition composite indicator NPAR, and platelet quantity and function marker PMR were key prognostic factors. Patients with ADG with younger age and lower NPAR values had a lower risk of disease progression and better prognosis; meanwhile, patients with higher PMR exhibited longer survival. These biomarkers are not only easily accessible and cost-effective but also highly beneficial, offering a new perspective for personalized treatment of ADG.

Abstract

Background: The clinical outcomes of diffuse large B-cell lymphoma (DLBCL) are highly heterogeneous. While clinical indices like the international prognostic index (IPI) are widely used, their predictive accuracy remains limited. The integration of molecular features with clinical characteristics holds promise for developing more precise prognostic models to improve risk stratification and personalize treatment strategies.

Objective: This study aimed to systematically identify key factors influencing overall survival (OS) and relapse in patients with DLBCL by leveraging publicly available transcriptomic data and clinical information. The goal was to construct and validate a high-precision risk-prediction model by using machine learning methods to aid in individualized clinical decision-making.

Methods: We curated clinical and transcriptomic data from the GSE31312 cohort. A baseline clinical model was first constructed using multivariate Cox regression. Key genes associated with prognosis were identified through univariate Cox and survival analyses. Subsequently, 3 machine learning survival models, namely, fast survival support vector machine (FastSurvivalSVM), gradient boosting survival analysis (GBSurvival), and random survival forest (RSF), were trained and evaluated using 5-fold cross-validation. The interpretability of the optimal model was further elucidated using Shapley Additive Explanations (SHAP) methodology.

Results: The baseline clinical model confirmed age, elevated lactate dehydrogenase, Eastern Cooperative Oncology Group score, Ann Arbor stage, and B symptoms as independent risk factors for OS and relapse-free survival, with a C-index of 0.65-0.67. At the molecular level, genes such as *PSMG4* and *CRY1* were significantly associated with poor OS, while *TMEM182* and *SPIRE1* were prominent in relapse prediction. Among the machine learning models, FastSurvivalSVM demonstrated the best overall performance, achieving an area under the curve of 0.791 for 1-year OS prediction and 0.774 for 1-year relapse prediction. SHAP analysis revealed that both clinical (eg, IPI and age) and molecular (eg, *PSMG4* and *SPIRE1*) features were critical drivers of the model's predictions.

Conclusions: This study successfully developed a multidimensional risk prediction model that integrates clinical and molecular characteristics for DLBCL. The FastSurvivalSVM model showed superior performance in predicting mortality and relapse risks. The interpretability analysis uncovered key prognostic factors, providing a valuable tool for personalized risk management and new theoretical insights for future mechanistic research.

Introduction

Diffuse large B-cell lymphoma (DLBCL) is one of the most prevalent subtypes of non-Hodgkin lymphoma, accounting for more than 30% to 40% of cases globally [1,2]. With the widespread adoption of immunochemotherapy regimens such as rituximab, cyclophosphamide, hydroxydaunorubicin (doxorubicin), oncovin (vincristine), and prednisone or prednisolone, the overall survival (OS) rate of patients has significantly improved compared to the past. However, approximately one-third of patients experience relapse or refractory disease, leading to an extremely poor prognosis [3,4]. The median survival time for these patients is often less than a year, posing a major challenge in clinical treatment [5,6]. Despite recent advancements in novel targeted therapies and immunotherapies, accurately identifying which patients will experience relapse or mortality remains highly challenging. Achieving effective risk stratification at the initial diagnosis to predict individualized risks of death and recurrence, thereby providing a reliable basis for selecting clinical treatment strategies and monitoring therapeutic efficacy, has become a core scientific issue in the field of DLBCL.

Traditional clinical prognostic tools have played a significant role in the risk assessment of DLBCL [7]. The international prognostic index (IPI), introduced in the 1990s, has been widely used in clinical practice. It incorporates factors such as age, clinical stage, Eastern Cooperative Oncology Group (ECOG) performance status, lactate dehydrogenase (LDH) levels, and the number of extranodal sites to stratify patient prognosis [8,9]. However, with advancements in treatment modalities, the predictive accuracy of IPI has gradually declined, making it challenging to effectively differentiate between high-risk and low-risk populations in certain patient groups [10]. Additionally, while immunophenotype-based molecular markers (such as *CD10*, B-cell lymphoma 6 [*BCL6*], Multiple Myeloma Oncogene 1 [*MUM1*], and Forkhead box protein P1 [*FOXP1*]) and molecular subtyping (Germinal Center B-cell-like/Activated B-cell-like subtypes) hold some value in clinical applications, individual markers often have limited predictive power and fail to capture the complex biological heterogeneity of DLBCL [11]. These limitations result in some high-risk patients not being promptly identified at initial diagnosis and pose a risk of overtreatment among low-risk patients.

With the rapid advancement of multiomics and high-throughput sequencing technologies, numerous studies have unveiled significant differences at the transcriptomic, gene mutation, and signaling pathway levels in patients with DLBCL [12,13]. Evidence indicates that aberrant expression of specific genes is closely associated with patient survival. For instance, molecules involved in cell-cycle regulation, metabolic reprogramming, and immune evasion may serve as critical drivers affecting the risk of relapse and mortality [14,15]. Compared to traditional clinical indicators, molecular characteristics can reflect tumor biological behavior at a more refined level, offering new perspectives for risk prediction [16-18]. However, the predictive power of individual genes is limited, and results across different studies often lack consistency. This inconsistency can be attributed to insufficient sample sizes, heterogeneity in statistical methods, and biological complexity [19]. A pressing scientific challenge is to systematically integrate clinical features with multigene characteristics to construct robust, comprehensive predictive models.

The advancement of artificial intelligence and machine learning has opened new avenues for risk modeling in complex diseases [20,21]. Compared with conventional Cox regression models, machine learning approaches are better suited to handle high-dimensional data and to capture nonlinear relationships and higher-order interactions among variables [22,23]. In recent years, methods such as random survival forest (RSF), gradient boosting survival (GBSurvival), and fast survival support vector machine have been increasingly applied to prognostic studies across multiple cancer types, demonstrating superior discriminative ability and stability over traditional approaches [24,25]. At the same time, interpretability techniques such as Shapley Additive Explanations (SHAP) provide insights into the key determinants underlying model predictions, thereby enhancing their translational potential in clinical practice [26,27]. Although these strategies have been reported in breast cancer, lung cancer, and leukemia, systematic investigations into their use for dual prediction of mortality and relapse risk in patients with DLBCL remain scarce [24,28].

Existing research remains limited in several respects. Most studies focus primarily on OS in DLBCL, with insufficient attention to systematic assessment of relapse risk and a lack of dual-modeling frameworks capable of simultaneously predicting mortality and relapse outcomes [29,30]. In addition, many models are restricted to clinical variables or single molecular features, failing to achieve true integration of clinical information with transcriptomic data, thereby constraining their discriminative power and robustness [31,32]. More critically, methodological shortcomings in interpretability hinder the clinical acceptance and applicability of these models. Developing a machine learning model that integrates both clinical and molecular characteristics, enables concurrent prediction of mortality and relapse risk, and provides transparent interpretability is therefore of considerable clinical and scientific significance for the individualized management of DLBCL.

Building on these considerations, this study uses the large-scale DLBCL cohort from the publicly available GSE31312 database to integrate clinical characteristics with transcriptomic data and to construct and compare multiple survival prediction models, including FastSurvivalSVM, GBSurvival, and RSF. We first established a clinical baseline model using Cox regression and identified candidate genes closely associated with survival. We then systematically evaluated the performance of the machine learning models in predicting both mortality and relapse risk, while applying SHAP to dissect the contributions of key features and to elucidate the synergistic effects of clinical and molecular determinants in prognostic prediction. The proposed framework not only offers a robust multidimensional strategy for risk modeling but also provides new perspectives for individualized risk stratification, precision therapeutic decision-making, and the exploration of potential molecular mechanisms in DLBCL, underscoring its translational and clinical relevance.

Methods

Data Sources and Inclusion Criteria

Expression profile data from the GSE31312 cohort were obtained using the Affymetrix Human Genome U133 Plus 2.0 Array (GPL570). Raw cell expression language files were downloaded from the Gene Expression Omnibus database and uniformly preprocessed in the R/Bioconductor environment. Specifically, the robust multiarray average pipeline was applied to perform background correction, quantile normalization, and probe set-level summarization, yielding a gene expression matrix on the $\log_2$ scale. Probe annotation was conducted using the official annotation package or files corresponding to GPL570 to map probe sets to gene symbols. Probe sets that could not be reliably mapped or that corresponded to multiple gene symbols were excluded from further analysis. For genes represented by multiple probe sets, a predefined "representative probe" selection strategy was used to ensure reproducibility and avoid selection bias. Within the training dataset, expression variability for each probe set across samples was calculated, and the probe set with the highest variability was selected as the representative probe for that gene. In sensitivity analyses, alternative probe-collapsing strategies—namely, taking the median or mean expression values across probe sets corresponding to the same gene—were also applied, and the results were confirmed to be consistent.

During data acquisition, the research team downloaded raw CEL files and corresponding clinical information from the Gene Expression Omnibus platform. All samples were cross-validated using unique patient identifiers to eliminate duplicate cases. The final cohort included cases with complete transcriptomic data, OS outcome information, and key clinical variables such as Age, ECOG score, LDH levels, Ann Arbor stage (AAS), B symptoms, and Gene Expression Profiling (GEP) subtype. OS was defined as the duration from diagnosis to death; for those still alive at last follow-up, data were censored accordingly.

In selecting study subjects, cases meeting the pathological diagnosis of DLBCL with comprehensive follow-up and core clinical information were included in the analysis; cases lacking key outcome indicators or core variables were excluded. Additionally, samples with significant outliers that could not be corrected upon review were also omitted from final analyses. These quality control measures ensured the scientific validity and reliability of data analysis. The study's data are entirely based on publicly accessible databases; all analyses were conducted under ethical compliance and data-sharing principles. Relevant data and analytical procedures will be made publicly available post-publication to ensure transparency and reproducibility.

Batch Effect Assessment and Correction

Quality control of the normalized expression matrix was performed using principal component analysis (PCA), hierarchical clustering, and density distribution plots, in conjunction with available technical metadata (eg, study center, batch, or processing date) to assess potential batch-driven clustering patterns. When pronounced batch effects were detected, ComBat (implemented in the sva package) was applied to the training dataset for batch correction, and the resulting adjustment parameters were subsequently transferred to the corresponding validation dataset. In cases where no substantial batch-driven structure was observed, batch correction was not enforced. Nevertheless, ComBat-based sensitivity analyses were conducted and reported to demonstrate the robustness of the study conclusions.

Preprocessing of Clinical Variables

In the process of organizing clinical features, age is treated as a continuous variable (measured in years) and directly included in the analysis. The ECOG performance status score is retained in its original ordinal scale from 0 to 4 and entered into subsequent models as a continuous ordinal variable to reflect the linear trend of functional status. LDH levels are categorized into high and normal groups based on test results, processed as a binary variable. B symptoms are also dichotomized to capture their adverse impact on disease progression. The AAS system is set as an ordinal categorical variable and converted into numerical values (I=1, II=2, III=3, and IV=4) to ensure comparability in regression and machine learning models. The IPI, a well-established prognostic stratification tool, is directly input into the model in integer form, ranging from 0 to 5, for performance comparison with newly developed modeling tools.

At the molecular phenotype level, GEP subtypes are classified into Activated B-cell-like, Germinal Center B-cell-like, and unclassified (UC) categories based on previous classification standards, using one-hot encoding during modeling with UC as the reference class to ensure statistical interpretability. Other molecular markers, such as *CD10*, *BCL6*, *FOXP1*, and *MUM1*, are recorded continuously rather than dichotomously to retain detailed expression level information. The number of extranodal involvements (N_extran) is input as a count variable that can be used for continuous variable modeling or binned in sensitivity analyses (eg, 0, 1, and ≥2) to verify stability. All clinical variables underwent missing value detection prior to inclusion in the analysis; when missing rates were low, median or mode imputation was used, with sensitivity analyses conducted during model validation to assess the impact of imputation methods on outcomes. These preprocessing steps ensure consistency and robustness of clinical features in subsequent Cox regression and machine learning models.

Transcriptomic Gene Screening

During the candidate gene screening process, transcriptomic data across the entire genome are initially prescreened using univariate Cox regression. This involves calculating each gene's hazard ratio (HR), 95% CI, and raw *P* value, followed by ranking the candidate genes based on statistical significance. To enhance the robustness of the selection process, regularization selection is performed using Cox regression with an elastic net penalty (implemented via CoxnetSurvivalAnalysis from the scikit-survival package) before entering multivariable modeling. During parameter tuning, the l1_ratio is set at 1.0, 0.8, and 0.5, respectively, combined with alpha_min_ratio values of 0.1, 0.2, and 0.5 for grid search. Each parameter set undergoes performance evaluation under a 5-fold cross-validation framework, using Harrell C-index as an indicator of model discrimination ability. This process identifies the optimal

combination of regularization parameters, with the corresponding average C-index serving as a benchmark to select the best-performing alpha value for subsequent modeling.

In the stability selection phase, bootstrap resampling is conducted 200 times; each time fitting a Coxnet model on the training set and recording the frequency at which each gene is selected in the model. Genes selected in more than 60% of iterations are considered core stable features, while those selected between 50% and 60% form a reserve set. If stability selection results are insufficient to construct a final feature set of 20 genes, penalty strength is reduced to refit the model to capture additional potential signals. Should gaps still exist, high-weight genes are supplemented according to absolute regression coefficients from the full model to ensure a complete feature set of 20 genes.

The final set of 20 genes integrates results from both univariate Cox regression screening and multivariable penalized regression stability selection while ensuring completeness and interpretability through a multitier fallback mechanism. The screening process was conducted in a Python environment using scikit-survival and scikit-learn libraries. All output results, including univariate Cox regression statistics tables, stability selection frequency tables, and the final gene set, are preserved to ensure transparency and reproducibility of the analytical workflow.

Handling of Missing Data

Prior to inclusion in the analysis, a comprehensive assessment and documentation of missing values for all clinical and molecular characteristics were conducted. The proportion of missing data was explicitly reported, and its potential biasing effect on modeling was evaluated. For continuous variables, such as age and the number of extranodal sites, mean or median imputation was used when the missing proportion was low. Additionally, a missing indicator variable was added to capture potential information loss in cases where the missing proportion was relatively high or involved critical variables; multiple imputation by chained equations was used. This method generated several imputed datasets through iterative regression chains, and their estimates were combined in subsequent analyses to ensure robustness of the estimators. For categorical variables like B symptoms, LDH status, and GEP subtype, missing values were uniformly filled using the mode of the variable to minimize information bias due to random missingness. All imputation steps were completed before model fitting, and sensitivity analyses were conducted subsequently to examine the impact of different imputation strategies on result robustness.

Construction and Evaluation of a Clinical Baseline Model

In constructing a clinical baseline model, univariate Cox proportional hazards regression analysis is initially performed on all candidate clinical and molecular variables, using OS and relapse-free survival (RFS) as endpoints. The HR, 95% CI values, and corresponding *P* values are calculated. Variables with $P<.10$ are selected for subsequent multivariate modeling, while certain recognized key factors, such as ECOG performance status and AAS, are forcibly included based on prior clinical knowledge.

In the multivariate Cox model, core variables ultimately included are age, LDH status, ECOG performance status, AAS, B symptoms, and GEP subtype. Immunophenotypic markers (*CD10*, *BCL6*, *FOXP1*, and *MUM1*) are also incorporated when necessary. During model fitting, the Schoenfeld residual test is used to verify the proportional hazards assumption, with sensitivity analysis through time interaction terms further validating model stability. If the proportional hazards assumption is violated, stratified Cox regression or time-dependent covariates are used for correction. To avoid model instability, all included variables undergo variance inflation factor testing, with variance inflation factor<5 set as the reference standard for the absence of severe multicollinearity. Model results are reported in terms of HRs, 95% CIs, and *P* values and visualized using forest plots on a logarithmic scale with T-shaped error bars indicating estimated CIs.

To further validate the clinical baseline model's capacity for risk stratification, individualized risk scores are generated based on weighted regression coefficients and survival comparisons conducted using different grouping methods. In the dichotomous approach, patients are divided into high-risk and low-risk groups based on the median risk score; in the tertile approach, they are categorized into low-, medium-, and high-risk subgroups according to tertiles of risk scores. Survival differences among groups are illustrated using Kaplan-Meier survival curves and statistically evaluated via log-rank tests. This methodology systematically verifies the applicability and discriminative power of the clinical baseline model in prognostic assessment for patients with DLBCL.

Gene-Level Association Analysis

To investigate the relationship between gene expression levels and patient prognosis, we selected 20 genes from a candidate set for individual analysis. Initially, we fitted a univariate Cox proportional hazards regression model for each gene, using OS and RFS as outcome measures. We calculated the HR, 95% CI, and corresponding *P* value for each gene. When necessary, we applied the Benjamini-Hochberg method to adjust for false discovery rate (FDR) to control for errors arising from multiple testing.

Subsequently, patients were stratified into high and low expression groups based on the median expression of each gene in the cohort. We used the Kaplan-Meier method to plot survival curves and used log-rank tests to evaluate differences between groups. This approach visually illustrates potential associations between gene expression levels and survival outcomes.

For visualization, all results from single-gene Cox analyses were presented as forest plots. These plots used a logarithmic scale with T-shaped error bars to display 95% CIs clearly, facilitating an understanding of effect sizes and their CIs. Additionally, Kaplan-Meier survival curves were presented in small multiples format, and where necessary, composite layouts were used to systematically display survival differences across varying expression levels of the 20 genes. This comprehensive

XSL•FO
RenderX

analysis ensures that the gene-level association results are statistically robust and visually interpretable.

Construction of Machine Learning Models

To enhance the accuracy of prognostic predictions, three types of machine learning-based survival models were developed: FastSurvivalSVM, GBSurvival, and RSF. Regarding feature inputs, all models integrate core clinical variables with the expression levels of candidate genes, ensuring a comprehensive consideration of both traditional prognostic factors and molecular-level information. To prevent data leakage, numerical variables were imputed and standardized using a column transformer during the modeling process. Categorical variables were binarized or one-hot encoded. The preprocessing and modeling stages were connected through a pipeline structure to achieve full automation and consistency throughout the process.

Cross-Validation Framework and Control of Information Leakage

To prevent potential information leakage during high-dimensional transcriptomic feature selection and model training, a nested 5-fold cross-validation framework was implemented. The outer loop was used for independent evaluation of model performance, in which one fold was held out as the outer validation set while the remaining four folds constituted the outer training set. The outer validation fold was strictly excluded from all gene selection procedures, stability selection, and hyperparameter tuning within that iteration. Within each outer training set, the complete internal modeling workflow was repeated in the inner loop, including: (1) genome-wide univariate Cox regression–based prescreening conducted exclusively within the training folds; (2) regularized feature selection and parameter optimization using elastic net-penalized Cox regression (Coxnet); (3) bootstrap-based stability selection to identify a stable set of prognostic genes; and (4) training and hyperparameter tuning of FastSurvivalSVM, gradient boosting survival models (GBSurvival), and random survival forest models. For the FastSurvivalSVM model, calibration of the risk score direction (decision margin direction) was also performed solely within the training folds and subsequently fixed and applied to the corresponding outer validation fold. Through this strictly nested procedure, all steps, from feature discovery and parameter optimization to model fitting, were confined to the training data only, thereby effectively preventing information leakage and ensuring objective and reliable performance evaluation.

Cross-Validation and Parameter Tuning

Model training and hyperparameter optimization were performed within a nested 5-fold cross-validation framework. The outer cross-validation loop was used for model performance evaluation, whereas the inner cross-validation loop was used for feature selection, hyperparameter tuning, and model training. Parameter tuning used a random search strategy (ParameterSampler), evaluating combinations drawn from a predefined candidate parameter space. For FastSurvivalSVM, the primary search focused on an alpha range from 1×10 to 1×10^2 (log-uniform distribution), with rank_ratio set at 0.2, 0.5, and 1.0. For GBSurvival, the search space included learning_rate (0.01–0.2), max_depth (1-3), n_estimators (200-1000), and subsample (0.6-1.0). For RSF, parameters ranged across n_estimators (500-1500), max_features ($\sqrt{p}$, $\log_2(p)$, or 0.3-0.8), and min_samples_leaf (1-10). Within each training fold, risk direction was further examined; if the model's risk scores contradicted the actual event direction, margin direction was adjusted accordingly and consistently applied during validation folds and full data training phases.

Model Evaluation Metrics

In terms of performance evaluation, Harrell C-index is initially used to assess the model's discriminative ability, with results reported for each fold along with the median and IQR values. Subsequently, cumulative_dynamic_auc is used to calculate the time-dependent receiver operating characteristic (ROC) curves and corresponding area under the curve (AUC) values at 1-year, 3-year, and 5-year intervals. CIs are estimated using the bootstrap method (≥1000 resamples). Calibration assessment is based on deciles or groupings of risk scores, comparing predicted probabilities with Kaplan-Meier observed rates at target time points. Calibration curves are plotted, and the calibration slope and intercept are calculated. Clinical benefit is evaluated through decision curve analysis (DCA), comparing the net benefit of the model across different threshold probabilities against "treat none" and "treat all" strategies. The model's risk stratification capability is visually demonstrated through risk score distributions and survival status strip charts. Additionally, Kaplan-Meier curves are plotted based on dichotomous and trichotomous methods, with log-rank tests used to assess differences between groups.

Interpretability Analysis Using SHAP

In terms of interpretability, FastSurvivalSVM is selected as the primary subject of analysis. The SVM decision function margin serves as the target for interpretation, and the Kernel SHAP method is used to approximate the contribution of each feature to risk prediction. To ensure robustness, 100 samples are randomly selected from the entire dataset as a background set for computation. Sensitivity analysis involves adjusting the background set size (ranging from 50 to 200) to test stability. The output includes global feature importance bar charts (featuring the top-ranked features by mean |SHAP|) and beeswarm plots, which visually depict the relationship between feature values and the direction of risk prediction. By integrating these interpretative results, we further elucidate the synergistic contribution patterns of clinical features (such as IPI score, AAS, age, ECOG score, and number of extranodal involvements) and molecular features (such as *PSMG4*, *CRY1*, *LENEP*, *SPIRE1*, *CKS1B*, and *TMEM182*; Figure S1 in Multimedia Appendix 1).

Statistical Analysis

All statistical tests were conducted as 2-sided tests, with a significance threshold set at $P<.05$. When necessary, the FDR was adjusted using the Benjamini-Hochberg method. CIs for all estimates were based on 95% CIs, and those for AUC and C-index were calculated via bootstrapping (≥1000 iterations). Data analysis and model construction were performed in a Python environment (versions 3.9/3.10), using key libraries

XSL•FO
RenderX

such as lifelines, scikit-survival, scikit-learn, pandas, numpy, matplotlib, and shap. Supplementary analyses and graphical representations were completed in an R environment (R Core Team) using the survival and survminer packages. To ensure reproducibility, a fixed random seed was set throughout the analysis process, with details of the computational environment and software versions documented.

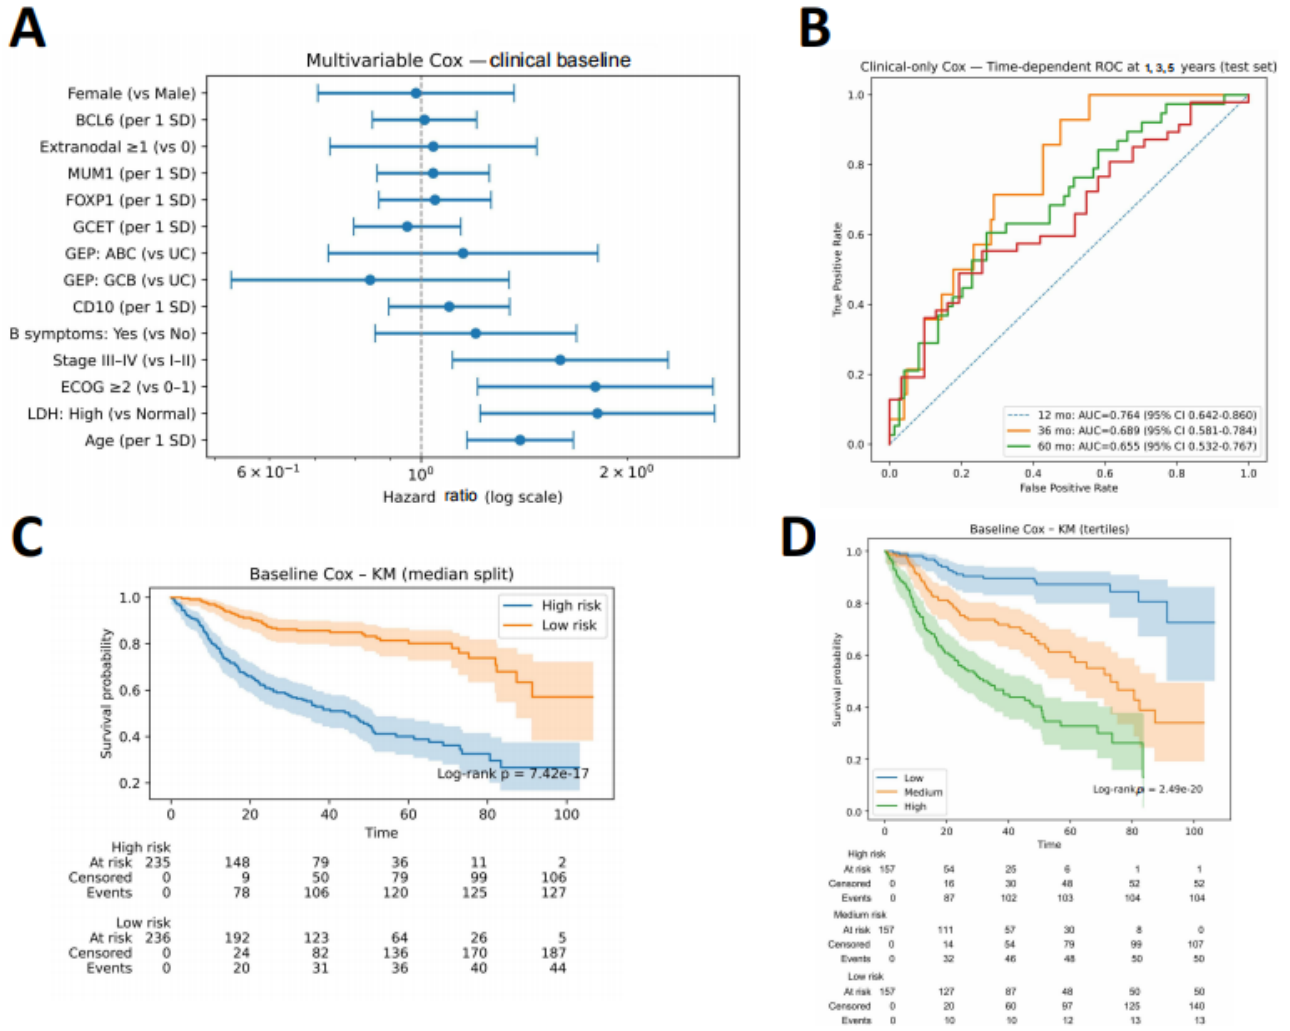
Ethical Considerations

This research constitutes a secondary analysis based on public databases, fully adhering to database usage terms and the ethical principles of the Declaration of Helsinki, thus not requiring additional ethical approval.

This study is a secondary analysis based on publicly available data from the Gene Expression Omnibus (GEO) database (accession number: GSE31312). All data used in this study are de-identified and publicly accessible, and therefore do not involve direct human participant interaction or identifiable personal information. According to institutional and international guidelines, including the Declaration of Helsinki, research based on publicly available, anonymized datasets does not require formal approval from an institutional review board or ethics committee. Therefore, ethics approval and informed consent were not required for this study. All procedures were conducted in accordance with relevant data usage policies and regulations.

Results

Application of Clinical Baseline Models in Mortality Risk Prediction



The clinical characteristics of the included patients are summarized in Multimedia Appendix 2.

To evaluate the prognostic predictive capacity of clinical features, we initially developed a clinical baseline model based on multivariate Cox regression. The results indicated that factors such as age, elevated LDH, an ECOG score of ≥2, and AAS III-IV were closely associated with poor survival outcomes (Figure 1A; Multimedia Appendix 3). The model achieved a C-index of 0.674 in the overall cohort, suggesting a moderate level of discrimination for patient mortality risk. Further time-dependent ROC analysis demonstrated that the model had an AUC of 0.764 (95% CI 0.642-0.860) at 1 year, 0.689 (95% CI 0.581-0.784) at 3 years, and 0.655 (95% CI 0.532-0.767) at 5 years (Figure 1B), indicating better performance in short-term prognostic prediction, with a decline in long-term predictive ability. In the OS analysis, a total of 471 patients with DLBCL were included. Among them, 167 out of 471 (35.5%) patients experienced events, while 304 out of 471 (64.5%) patients were censored at the end of follow-up due to the absence of observed events. The median follow-up duration was 35 (IQR 17.3-56.7) months. Meanwhile, Kaplan-Meier analysis showed that the model effectively differentiated patient survival differences whether risk scores were dichotomized or trichotomized. Patients in the high-risk group exhibited a significantly lower OS rate compared to the low-risk group, and the survival curves of the low, intermediate, and high-risk groups displayed a clear stepwise distribution, with statistically significant differences (log-rank P<.001; Figure 1C and D).

In summary, the clinical baseline model can effectively predict the survival risk of patients with DLBCL, providing a reference for subsequent integrative analysis of molecular characteristics.

Association Analysis of Genomic-Level Mortality Risk Prediction

Building upon genome-wide Cox regression screening, we further conducted univariate Cox regression analysis on 20 candidate genes. To facilitate comprehension of the gene selection and feature construction process, we supplemented the study with a schematic diagram. This diagram visually illustrates the step-by-step construction process from genome-wide screening, univariate Cox regression, stability selection, to the final 20-gene feature set (Figure S2A in Multimedia Appendix 1 and Multimedia Appendix 4). The results indicate that alterations in transcription levels of most genes are significantly associated with patients' OS. Specifically, genes such as *CERS6*, *HIC1*, *CRAT*, *COPE*, *CTBP2*, *MT2A*, *GBP2*, *ABCD2*, *INPP4B*, *BBS9*, *KPNA5*, *AAK1*, *FYB*, *HHEX*, *CASC9*, *CRY1*, *PSMG4*, and *CRTAM* exhibit consistent risk effects in the model, with some HR significantly deviating from 1, suggesting their potential independent prognostic value (Figure S2B in Multimedia Appendix 1).

Further Kaplan-Meier survival analysis aligns with the Cox regression findings. Patients with higher expression levels of genes such as *PSMG4*, *CRY1*, *CRTAM*, *CTBP2*, *HHEX*, and *CASC9* demonstrate notably poorer survival outcomes, with survival curves distinctly separating (Figure S2C in Multimedia Appendix 1). For instance, the median survival of the high-expression group of *PSMG4* is markedly reduced, and similarly, high expression of *CRY1* and *CRTAM* indicates adverse prognosis. Conversely, some genes, such as *CERS6*, *FYB*, and *KPNA5*, although statistically significant in univariate Cox regression, show weaker separation in their Kaplan-Meier curves. Overall, these findings suggest that the aforementioned genes may play a crucial role in mortality risk among patients with DLBCL and provide a potential molecular basis for subsequent multivariate modeling.

Comparative Analysis of Predictive Performance in Mortality Risk Forecasting Machine Learning Models

To enhance the accuracy of prognostic predictions, we developed three machine learning survival models based on clinical and genetic features: FastSurvivalSVM, GBSurvival, and RSF. During the external validation by 5-fold cross-validation, all 3 models demonstrated stable predictive capabilities, albeit with varying degrees of discrimination. To clearly present the modeling approach and evaluation process, we supplemented our study with a flowchart systematically illustrating the entire process, from the input of clinical and transcriptomic data, model construction, and parameter tuning to cross-validation and performance assessment (Figure 2A).

The results from the 5-fold cross-validation indicated that the C-index distributions of the three models were similar, all maintaining around a level of 0.7, suggesting comparable discrimination in patient survival risk (Figure 2B). Time-dependent ROC analysis further corroborated these findings. The FastSurvivalSVM model achieved AUCs of 0.791 (95% CI 0.751-0.818), 0.758 (95% CI 0.726-0.787), and 0.769 (95% CI 0.731-0.792) for 1-year, 3-year, and 5-year predictions, respectively, indicating high stability in both short-term and long-term forecasts (Figure 2C). In comparison, the GBSurvival model yielded AUCs of 0.752 (95% CI 0.697-0.802), 0.751 (95% CI 0.703-0.799), and 0.749 (95% CI 0.703-0.793) for the same periods, showing similar but slightly lower performance (Figure 2D); the RSF model presented AUCs of 0.736 (95% CI 0.671-0.796), 0.740 (95% CI 0.689-0.788), and 0.759 (95% CI 0.711-0.802), with overall predictive performance akin to GBSurvival but marginally inferior to FastSurvivalSVM in short-term predictions (Figure 2E).

In conclusion, all three machine learning models effectively differentiated high-risk and low-risk groups among patients with DLBCL, with the FastSurvivalSVM model exhibiting the best overall performance. Consequently, it was selected as the primary modeling tool for subsequent analyses.

Figure 2. Benchmark comparison of three machine learning survival models for OS prediction. (A) Workflow schematic of machine learning modeling integrating clinical and transcriptomic features. (B) Distribution of C-index values for GBSurvival, random survival forest, and FastSurvivalSVM, all approximating 0.7. (C) Time-dependent receiver operating characteristic curves of the FastSurvivalSVM yield area under the curve values of 0.791, 0.758, and 0.769 at 1, 3, and 5 years. (D) Time-dependent receiver operating characteristic curves of the GBSurvival model show area under the curve values of 0.752, 0.751, and 0.749 at 1, 3, and 5 years. (E) Time-dependent receiver operating characteristic curves of the random survival forest model present area under the curve values of 0.736, 0.740, and 0.759 at 1, 3, and 5 years. FastSurvivalSVM: fast survival support vector machine; GBSurvival: gradient boosting survival; GBSA: Gradient Boosting Survival Analysis; RSF: random survival forest; SVM: support vector machine; ROC: receiver operating characteristic; OOF: Out-of-Fold.

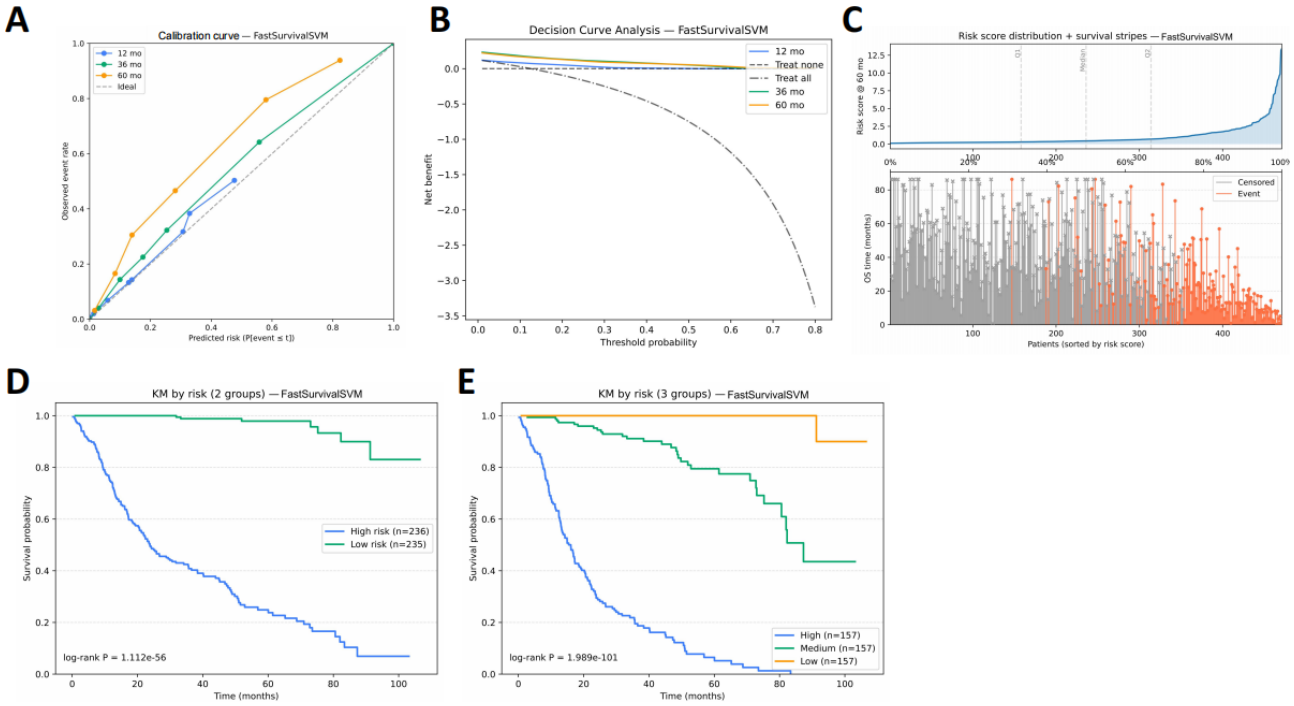
RenderX



Clinical Predictive Value of the FastSurvivalSVM Model for Mortality Risk Prediction

In further evaluating the clinical applicability of the FastSurvivalSVM model, calibration curves indicate that the model exhibits excellent fit at 1-year, 3-year, and 5-year intervals. The predicted probabilities are highly consistent with the actual observed event rates, suggesting robust reliability of the model (Figure 3A). DCA further demonstrates that at various threshold probabilities, the model consistently provides high net benefits, showing a significant advantage over the "treat none" and "treat all" strategies (Figure 3B).

The distribution of risk scores and survival status strip charts reveals that as risk scores increase, mortality events are significantly concentrated at the high-risk end, indicating the effectiveness of the model's risk stratification (Figure 3C). Kaplan-Meier survival analysis further corroborates this finding. Grouping based on median scores shows notably lower OS rates in the high-risk group compared with the low-risk group (Figure 3D), while tertile grouping similarly exhibits a stepwise survival difference among low, medium, and high-risk groups, further validating the model's robustness in risk stratification (Figure 3E).

In conclusion, the FastSurvivalSVM model not only demonstrates stable overall predictive performance but also achieves excellent calibration and clinical decision value. It effectively distinguishes between different risk levels, providing a reliable tool for individualized prognosis assessment in DLBCL.

Figure 3. Clinical use and risk stratification performance of the fast survival support vector machine model for overall survival. (A) Calibration curves at 1, 3, and 5 years demonstrate good agreement between predicted and observed survival. (B) Decision-curve analysis shows consistently higher net benefit of the model compared with treat-none and treat-all strategies across a range of threshold probabilities. (C) Risk score distribution and survival status plots indicate that mortality events are concentrated in the high-risk group. (D) Kaplan-Meier curves stratified by median risk score reveal significantly reduced survival in the high-risk cohort. (E) Kaplan-Meier curves stratified by tertiles of risk score display a clear stepwise separation of low-, intermediate-, and high-risk groups. KM: Kaplan-Meier; OS: overall survival.

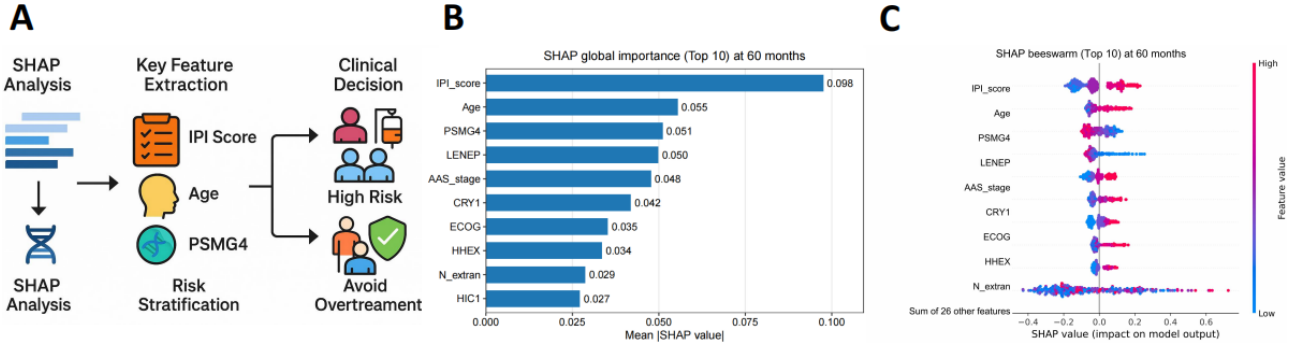
Supplementary Validation of GBSurvival and RSF Models for Mortality Risk Prediction

To further assess the predictive value of other machine learning models, we conducted an independent validation of the GBSurvival and RSF models. Calibration curves demonstrated that the predictions made by both models at 1, 3, and 5 years aligned closely with the actual observed outcomes, indicating good calibration (Figure S3A and S3B in Multimedia Appendix 1). DCA further illustrated that both GBSurvival and RSF models provided higher net benefits across various threshold probabilities compared to the "treat none" and "treat all" strategies, thereby affirming their potential use in clinical decision-making (Figure S3C and S3D in Multimedia Appendix 1).

The distribution of risk scores and survival status strip charts further elucidated the models' performance in patient stratification. The RSF model distinguished clearly between high and low-risk patients, whereas the GBSurvival model, although capable of identifying clusters of high-risk events, showed relatively weaker overall differentiation (Figure S4A and S4B in Multimedia Appendix 1). Kaplan-Meier analysis results supported this conclusion. The GBSurvival model effectively differentiated patient survival outcomes in both binary and tertiary groupings (Figure S4C and S4D in Multimedia Appendix 1); similarly, the RSF model demonstrated significant stepwise survival differences in these stratifications, underscoring its reliability in risk stratification (Figure S4E and S4F in Multimedia Appendix 1).

XSL•FO
RenderX

In summary, although the overall predictive performance of GBSurvival and RSF models shows limited differences with the FastSurvivalSVM model, they exhibit commendable calibration, clinical benefit, and risk stratification capabilities. These models offer diversified modeling options for individualized prognostic assessment of patients with DLBCL.



Analysis of Feature Importance and Interpretability in FastSurvivalSVM Model for Mortality Risk Prediction

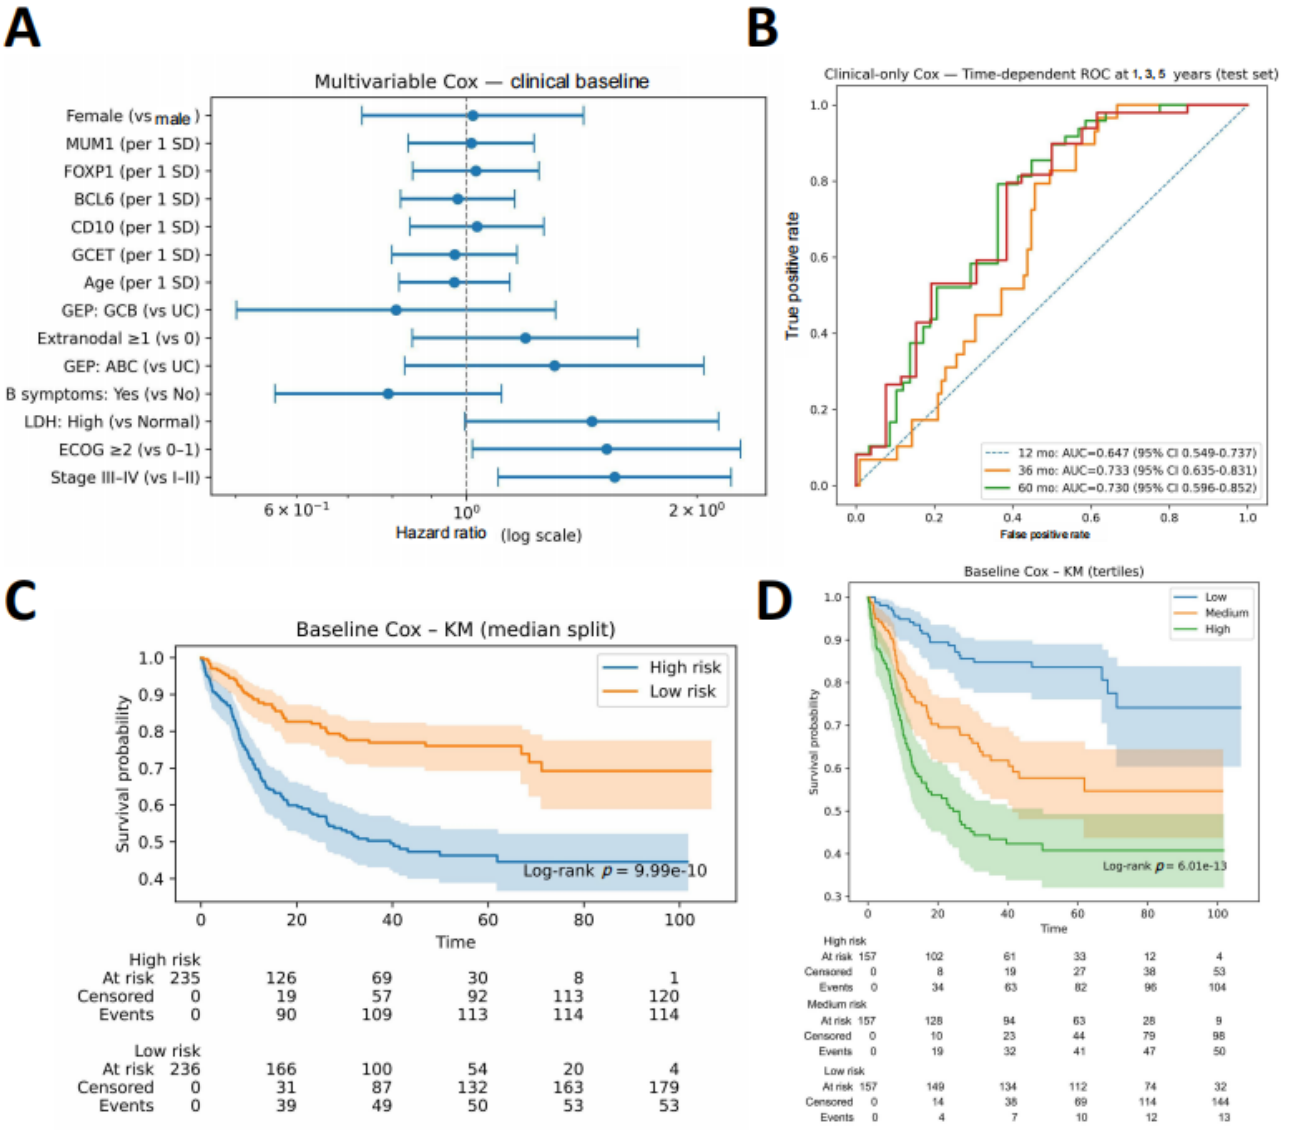
This study uses SHAP methodology to elucidate the predictive basis of the FastSurvivalSVM model, focusing on feature importance and interpretability analysis. The aim is to identify key clinical and molecular features that significantly influence model predictions. To illustrate how the model's interpretative outcomes can be applied in clinical practice, we provide a process diagram that visually outlines the entire procedure–from extracting critical features via SHAP analysis to achieving patient risk stratification, ultimately guiding clinical decision-making (Figure 4A). Both clinical and molecular features play pivotal roles in the model's prediction, with IPI score, age, *PSMG4*, *LENEP*, AAS_stage, *CRY1*, ECOG score, *HHEX*, N_extran, and *HIC1* being among the top 10 contributing features.

The feature importance bar chart indicates that IPI score and age are ranked highest in terms of overall contribution, underscoring the central role of clinical indicators in assessing the prognosis of DLBCL. Concurrently, molecular features such as *PSMG4*, *LENEP*, and *CRY1* hold significant weight in the model, suggesting that abnormal molecular expression is closely related to patient survival risk (Figure 4B). The beeswarm plot further reveals how different feature values influence the direction of risk prediction: higher expression of *PSMG4*, *CRY1*, and *LENEP* is associated with poor outcomes, whereas lower IPI scores and younger patients correlate with better survival outcomes (Figure 4C).

In summary, the SurvivalSVM model effectively integrates clinical and molecular features, identifying the most influential variables for prognosis prediction. SHAP interpretability analysis provides transparency in model decision-making, offering a reliable foundation for risk stratification and mechanism understanding in patients with DLBCL.

Figure 4. Model interpretability and key prognostic features identified by fast survival support vector machine for overall survival. (A) Schematic representation of Shapley Additive Explanations analysis for feature extraction and potential clinical translation. (B) Shapley Additive Explanations summary bar plot identifies the top 10 features, including international prognostic index score, age, PSMG4, LENEP, Ann Arbor stage, CRY1, Eastern Cooperative Oncology Group, HHEX, number of extranodal sites, and HIC1. (C) Beeswarm plot illustrates that high expression of PSMG4, CRY1, and LENEP is associated with poor outcomes, whereas low international prognostic index scores and younger age indicate favorable prognosis. AAS: Ann Arbor stage; ECOG: Eastern Cooperative Oncology Group; IPI: international prognostic index; SHAP: Shapley Additive Explanations.

Application of Clinical Baseline Model in Recurrence Risk Prediction



In the context of recurrence risk prediction, we initially developed a clinical baseline model based on a multivariate Cox regression analysis. The results indicated a significant association between recurrence risk and factors such as AAS III-IV, an ECOG score of ≥2, and elevated LDH levels (Figure 5A; Multimedia Appendix 5). The overall model demonstrated a C-index of 0.653, indicating a moderate discriminative ability in predicting patient recurrence risk. Time-dependent ROC analysis revealed that the model's AUC for predictions at 1, 3, and 5 years were 0.647 (95% CI 0.549-0.737), 0.733 (95% CI 0.635-0.831), and 0.730 (95% CI 0.596-0.852), respectively (Figure 5B), suggesting stable performance in long-term recurrence risk prediction.

Further validation of the clinical baseline model's risk stratification capability was conducted through Kaplan-Meier survival analysis. Median-based dichotomous analysis demonstrated a significantly higher recurrence rate in high-risk patients compared to low-risk patients (Figure 5C). Meanwhile, in the tertile analysis, the survival curves for low, medium, and high-risk groups exhibited a clear stepwise distribution, with differences being highly statistically significant (Figure 5D).

In summary, the clinical baseline model provides a degree of differentiation in recurrence risk among patients with DLBCL, offering a reference point for subsequent integration with molecular characteristics and machine learning modeling.

Association Analysis of Gene-Level Recurrence Risk Prediction

Based on a comprehensive genome-wide screening, we conducted univariate Cox regression analysis on 20 candidate genes to evaluate their independent prognostic value in predicting recurrence risk. The findings revealed that the expression levels of certain genes were significantly associated with recurrence risk. Specifically, the HR of genes such as *TMEM182*, *SPIRE1*, *CKS1B*, *MIR30D*, *MDK*, *DLEU1*, *MIR532*, and *ARIH2* were significantly divergent from 1, suggesting their potential independent prognostic role in recurrence event prediction (Figure S5A; Multimedia Appendix 6).

Further validation through Kaplan-Meier analysis confirmed these observations. High expression levels of genes such as *TMEM182*, *SPIRE1*, MIR30D, *CKS1B*, and *MDK* were associated with shorter RFS times (log-rank P<.05), with survival curves clearly separating between high and low expression groups. In contrast, although the Cox analysis indicated potential effects for some genes like *IBSP*, *NLRP11*, *DIP2A*, and *EFS*, no significant differences were evident in their survival curves (Figure S5B in Multimedia Appendix 1).

In summary, these findings indicate that numerous molecular characteristics play pivotal roles in recurrence risk, with several key genes potentially acting as driving factors in the progression of DLBCL recurrence. These insights provide candidate features for the development of comprehensive predictive models.

Comparative Performance Analysis of Multiple Models in Recurrence Risk Prediction

In the context of recurrence risk prediction, we conducted a comparative analysis of the predictive performance of three machine learning models: GBSurvival, RSF, and FastSurvivalSVM. During cross-validation for recurrence risk prediction, all three models demonstrated relatively stable discrimination capabilities. The C-index distribution for GBSurvival, RSF, and FastSurvivalSVM was generally concentrated between 0.70 and 0.78, with median performances across different folds showing no significant advantage for any model (Figure 6A). This finding indicates that all three models consistently provide robust discrimination in recurrence or progression risk prediction.

Time-dependent ROC analysis further elucidated the predictive performance of different models at various time points. The FastSurvivalSVM model achieved AUC values of 0.774 (95% CI 0.754-0.815), 0.757 (95% CI 0.739-0.773), and 0.757 (95% CI 0.727-0.777) at 1, 3, and 5 years, respectively, indicating stable overall performance (Figure 6B). The RSF model's AUCs at the corresponding time points were 0.713 (95% CI 0.659-0.763), 0.706 (95% CI 0.660-0.753), and 0.693 (95% CI 0.644-0.746), suggesting a short-term predictive advantage (Figure 6C). In contrast, the AUCs for the GBSurvival model were 0.698 (95% CI 0.645-0.749), 0.697 (95% CI 0.649-0.745), and 0.683 (95% CI 0.629-0.736), slightly lower overall compared to the other two methods (Figure 6D).

In summary, all three machine learning models effectively predict the recurrence risk of DLBCL, with FastSurvivalSVM exhibiting superior overall stability, while the RSF model shows certain competitive strengths in short-term predictions.

Figure 6. Comparative performance of three machine learning models in relapse-free survival prediction. (A) The distributions of C-index values for the three models are comparable, ranging from 0.70 to 0.78. (B) The fast survival support vector machine model achieves area under the curve values of 0.774, 0.757, and 0.757 at 1, 3, and 5 years, respectively. (C) The corresponding area under the curve values of the random survival forest model are 0.713, 0.706, and 0.693 at 1, 3, and 5 years. (D) The gradient boosting survival model yields area under the curve values of 0.698, 0.697, and 0.683 at 1, 3, and 5 years. Validation of the Clinical Use of the FastSurvivalSVM Model in Predicting Recurrence Risk

Upon further evaluation of the clinical applicability of the FastSurvivalSVM model in predicting recurrence risk, the calibration curve results indicate a high concordance between the model's predicted probabilities at 1, 3, and 5 years and the observed recurrence rates, demonstrating excellent predictive reliability and calibration (Figure 7A). DCA further reveals that across different threshold probabilities, the net benefit of using this model surpasses both the "treat none" and "treat all" strategies, highlighting its significant advantage in clinical decision-making (Figure 7B).

The distribution of risk scores and survival status stripes shows that recurrence events are markedly concentrated in patients with high-risk scores, suggesting that the model effectively identifies high-risk subgroups (Figure 7C). Kaplan-Meier survival analysis further corroborates the model's risk stratification capability. Results from median-based dichotomization indicate that the recurrence and progression probability is significantly higher in the high-risk group compared to the low-risk group (log-rank P=7.67×10 ; Figure 7D). Additionally, the tercile analysis reveals a pronounced stepwise difference among low, intermediate, and high-risk patients, with extremely high statistical significance (log-rank P=6.29×10 ¹ ; Figure 7E).

In summary, the FastSurvivalSVM model not only demonstrates robust overall predictive accuracy but also exhibits superior calibration, clinical decision value, and risk stratification capabilities, providing a powerful tool for assessing recurrence risk and facilitating personalized management in patients with DLBCL.

Figure 7. Clinical use and risk stratification of the fast survival support vector machine model for relapse-free survival. (A) Calibration curves at 1, 3, and 5 years show close agreement between predicted and observed outcomes. (B) Decision-curve analysis demonstrates clear net benefit across a wide range of threshold probabilities. (C) Risk score distribution and survival status plots indicate that relapse events cluster at the high-risk end. (D) Kaplan-Meier curves stratified by median risk score reveal significantly higher relapse rates in the high-risk group. (E) Kaplan-Meier curves stratified by tertiles of risk score display highly significant stepwise separation among low-, intermediate-, and high-risk groups.

Supplementary Validation of GBSurvival and RSF Models in Recurrence Risk Prediction

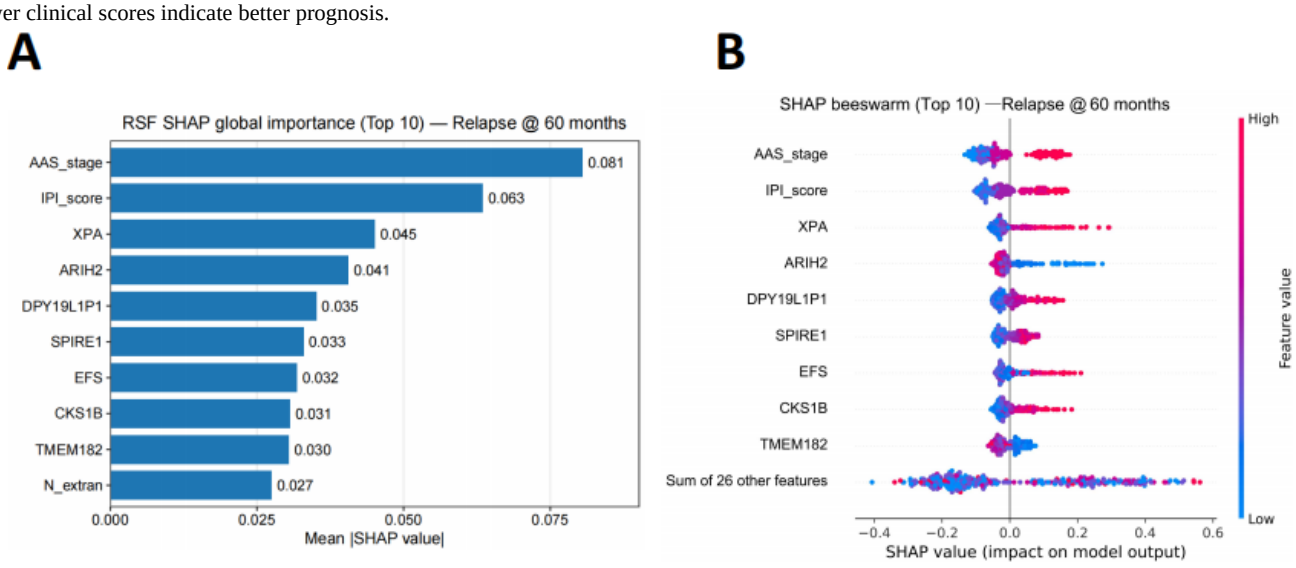
In the context of recurrence risk prediction, both GBSurvival and RSF models demonstrate commendable predictive capabilities. Calibration curves indicate that the predicted probabilities at 1, 3, and 5 years align closely with the observed recurrence rates, suggesting robust model fit and calibration (Figure S6A and S6B in Multimedia Appendix 1). DCA further reveals that both models yield a higher net benefit across various threshold probabilities compared to the "treat none" and "treat all" strategies, confirming their potential clinical applicability (Figure S6C and S6D in Multimedia Appendix 1).

The distribution of recurrence risk scores and survival status strip charts further elucidates the models' stratification performance. The RSF model achieves clear separation between high- and low-risk patients, while the GBSurvival model, although capable of identifying clusters of high-risk events, exhibits relatively weaker overall discrimination (Figure S7A and S7B in Multimedia Appendix 1). Kaplan-Meier analysis corroborates this conclusion. The GBSurvival model effectively distinguishes patients' recurrence OR progression risk in both binary and ternary groupings, with log-rank test results of P=9.32×10 ² and P=1.74×10 ³ , respectively (Figure S7C and S7D in Multimedia Appendix 1). The RSF model demonstrates even more pronounced survival curve separation in its binary and ternary groupings (log-rank P=5.11×10 and

XSL•FO
RenderX

P=1.99×10 ^{13}), with differences reaching high statistical significance (Figure S7E and S7F in Multimedia Appendix 1).

In summary, both GBSurvival and RSF models exhibit excellent calibration, clinical benefit, and stratification capabilities in recurrence risk prediction. They complement the FastSurvivalSVM model, collectively underscoring the value of integrating clinical and molecular characteristics in DLBCL recurrence risk assessment.



Feature Importance and Interpretability Analysis of FastSurvivalSVM Model in Recurrence Risk Prediction

To further elucidate the decision-making basis of the FastSurvivalSVM model in predicting recurrence risk, we conducted an analysis of feature importance and interpretability using the SHAP method. The findings indicate that both clinical variables and molecular features play pivotal roles in the model's predictions. Among the top 10 contributing features are AAS, IPI score, *XPA*, *ARIH2*, *DPY19L1P1*, *SPIRE1*, *EFS*, *CKS1B*, *TMEM182*, and N_extran.

The bar chart of feature importance demonstrates that AAS stage and IPI score hold the highest weights in model predictions, underscoring the central role of clinical characteristics in stratifying recurrence risk. Concurrently, molecular features such as the genes *XPA*, *ARIH2*, *SPIRE1*, *CKS1B*, and *TMEM182* also exhibit significant contributions, suggesting their potential driving role in the recurrence mechanisms of DLBCL (Figure 8A). The beeswarm plot further reveals the relationship between feature values and the direction of model predictions: higher AAS stage, IPI score, and elevated expression of *SPIRE1*, *CKS1B*, and *TMEM182* are closely associated with adverse recurrence outcomes, while lower clinical scores or feature levels suggest better event-free survival (Figure 8B).

In summary, the SHAP analysis of the FastSurvivalSVM model indicates that the model effectively captures the primary drivers of recurrence risk, highlighting the synergistic interaction between clinical features and key molecular markers. This provides crucial insights for the precise prediction of DLBCL recurrence risk and the exploration of potential biological mechanisms.

Figure 8. Shapley Additive Explanations–based interpretability analysis of the FastSurvivalSVM model for relapse-free survival. (A) Shapley Additive Explanations summary bar plot identifies Ann Arbor stage, international prognostic index score, XPA, ARIH2, DPY19L1P1, SPIRE1, EFS, CKS1B, TMEM182, and number of extranodal sites as the top 10 contributing features. (B) Shapley Additive Explanations beeswarm plot shows that high Ann Arbor stage, international prognostic index score, SPIRE1, CKS1B, and TMEM182 expression are associated with unfavorable relapse risk, whereas lower clinical scores indicate better prognosis.

Discussion

This study systematically evaluated the role of clinical and transcriptomic characteristics in prognostic prediction for DLBCL and developed various machine learning models to simultaneously predict patient mortality and recurrence risk. Through a comprehensive comparison of methods such as FastSurvivalSVM, GBSurvival, and RSF, we found that FastSurvivalSVM demonstrated superior performance in terms of model discrimination, calibration, and stability, particularly maintaining consistent accuracy in both short-term and long-term predictions. Notably, this study not only confirmed the value of clinical baseline models in prognostic assessment but also further revealed the complementary significance of molecular characteristics in risk stratification. Through SHAP interpretability analysis, the synergistic role of clinical and molecular factors within the model was elucidated. These findings provide a more comprehensive and transparent modeling framework for risk management in DLBCL.

The model developed in this study demonstrates superior discriminatory power compared to traditional clinical prediction tools. Indices such as the IPI, AAS, and ECOG performance status have long been used for risk stratification in DLBCL. However, these tools predominantly rely on a limited number of clinical variables, which inadequately capture the molecular heterogeneity among patients [7,33]. The findings of this study indicate that while clinical baseline models possess some efficacy in short-term risk prediction, their predictive capability diminishes over time. By incorporating transcriptomic features and using machine learning techniques, the model's performance

XSL•FO
RenderX

is significantly enhanced. This enhancement is evident not only in improved C-index and AUC values but also in the model's refined ability to accurately identify high-risk groups, suggesting that the integrated model effectively addresses the limitations of traditional methods in heterogeneous diseases.

In the genomic analysis, we identified several candidate genes that are significantly associated with patients' OS and recurrence risk. This study integrates 20 genes that showed statistical significance in univariate Cox analysis and further validates their prognostic value through stability selection and machine learning modeling. Notably, genes such as *PSMG4*, *CRY1*, *SPIRE1*, and *CKS1B* consistently appeared across multiple models, demonstrating uniform risk directionality, suggesting that they may be critical drivers in the prognosis of DLBCL. Unlike previous studies that focused solely on individual genes, this research emphasizes the stability and reproducibility of gene sets, enhancing the reliability of the results. Additionally, this study uncovered several potential molecular biomarkers that have been rarely reported before, providing new candidate targets for subsequent mechanistic research.

This study provides a clear comparison of various machine learning methods, highlighting the characteristics and applicability of different algorithms. The RSF model demonstrates certain advantages in short-term predictions, while GBSurvival exhibits balanced performance across multiple time points. FastSurvivalSVM stands out overall, aligning with findings from some hematologic malignancy prognosis studies that suggest support vector machines are advantageous in scenarios involving moderate-sized samples and high-dimensional features. This research further validates the rationale for algorithm selection, ensuring model robustness and generalizability through methods such as cross-validation and risk direction correction. These findings not only elucidate suitable contexts for different models but also offer significant technical references for future studies.

This study notably emphasizes the importance of model interpretability. Traditional machine learning models are often perceived as "black boxes," which limits their acceptance in clinical practice [34,35]. By incorporating the SHAP method, this research clearly demonstrates the direction and magnitude of each feature's contribution to model predictions. For instance, clinical indicators such as IPI score, AAS, and ECOG score continue to play a central role in the model, while molecular features like *PSMG4*, *CRY1*, and *LENEP* provide additional discriminative power. Through bar charts and beeswarm plots, we can intuitively understand how different feature values impact prediction outcomes, thereby enhancing the model's transparency and clinical credibility. This methodological innovation ensures that machine learning predictions are not only accurate but also interpretable, which is crucial for advancing their clinical application.

In the realm of mortality risk prediction, the findings of this study align closely with existing literature. Traditional clinical factors such as age, LDH levels, ECOG performance status, and AAS remain significant in the multivariable Cox model, reaffirming their stability as fundamental prognostic indicators. However, by integrating molecular characteristics, the model's efficacy in stratifying mortality risk is significantly enhanced, particularly in distinguishing between intermediate- and high-risk patients. This suggests that molecular abnormalities can complement clinical indicators, facilitate earlier identification of high-risk populations, and thereby provide a basis for intensified treatment or personalized follow-up strategies.

This study makes a significant contribution to the prediction of relapse risk. Previous research has predominantly focused on mortality outcomes, with insufficient systematic modeling of relapse or progression risk [36]. By integrating transcriptomic features, this study develops various relapse risk prediction models and demonstrates the superiority of FastSurvivalSVM. The analysis reveals that the drivers of relapse risk differ partly from those of mortality risk; for instance, genes such as *TMEM182*, *SPIRE1*, and *CKS1B* play a more prominent role in predicting relapse. This finding suggests that mortality and relapse in DLBCL may be driven by distinct molecular mechanisms, underscoring the necessity of dual prediction models. It also provides new insights for early intervention strategies targeting high-risk populations for relapse.

The findings of this study hold potential value for clinical translation. The model's consistent performance in both short-term and long-term predictions suggests its use in aiding risk stratification and therapeutic decision-making at the initial diagnosis stage for patients. Particularly, the precise identification of high-risk patients can inform the selection of more aggressive treatment strategies, such as intensified immunotherapy or novel targeted drugs. Conversely, identifying low-risk patients can help avoid overtreatment and the associated toxic burden. Additionally, the visualization of risk scores facilitates clinicians in explaining prognostic outcomes to patients and their families during clinical consultations, thereby enhancing treatment adherence and the efficiency of follow-up management.

From a scientific research perspective, this study is closely linked to precision medicine and integrative multiomics research. In recent years, integrative analyses based on multiomics have increasingly become a crucial approach for elucidating complex disease mechanisms and achieving personalized management [37,38]. This study establishes a transferable framework for DLBCL risk prediction by integrating clinical data with transcriptomic features. This not only provides a tool for clinical risk assessment but also offers a set of candidate genes for exploring the molecular mechanisms of DLBCL. Future research could build upon this foundation by incorporating proteomics, immunomics, or spatial transcriptomics data to develop a more comprehensive and multidimensional risk prediction system.

In conjunction with the key genes identified by the model, this study also offers insights into potential biological mechanisms. For instance, *SMG4* (PAC4) is a proteasome 20S core particle assembly chaperone that participates in proteasome biogenesis and may therefore contribute to tumor-associated protein degradation by regulating proteostasis and stress adaptation [39]. *TMEM182* has been reported to be associated with tumor cell motility and migration in certain solid tumors, and

XSL•FO
RenderX

accumulating evidence also suggests its involvement in differentiation programs and metabolic phenotype alterations [40,41]. These findings imply that *TMEM182* may contribute to the progression of DLBCL by modulating tumor cell adaptability or interactions with the tumor microenvironment.

Despite the systematic results obtained in prognostic modeling and interpretability analysis for DLBCL, several nonnegligible limitations of this study should be acknowledged. First, the analyses were conducted based on a single publicly available transcriptomic dataset (GSE31312). Although this cohort is relatively large, well-annotated with clinical information, and processed using a unified analytical pipeline, its single-source nature may still introduce potential selection bias and limit population heterogeneity. Consequently, the external generalizability of the proposed models may be constrained. The robustness and clinical applicability of these models across diverse populations and real-world settings, therefore, warrant further validation using independent external cohorts and multicenter prospective studies. Second, while multiple candidate genes significantly associated with overall survival and relapse risk were identified, their specific biological functions and molecular mechanisms in DLBCL pathogenesis and progression have not yet been experimentally validated. Future studies integrating Clustered Regularly Interspaced Short Palindromic Repeats-Cas9-mediated gene editing or RNA interference approaches in both in vitro and in vivo models could systematically evaluate the roles of these genes in tumor proliferation, invasion, and therapeutic response, thereby facilitating the translation of statistically associated biomarkers into potential functional targets. Finally, although rigorous modeling strategies, including cross-validation, robust feature selection, and multimodel comparisons, were used to mitigate overfitting, the predictive performance of machine learning models remains inherently dependent on the quality and dimensionality of the input data. Future work would benefit from incorporating additional multi-omics layers (such as somatic mutation profiles, copy number variations, and epigenetic features), as well as dynamic clinical variables related to treatment response and longitudinal follow-up. Such integration may enable the development of more comprehensive and dynamic risk stratification frameworks with improved predictive accuracy and clinical relevance.

In summary, this study systematically constructed and compared mortality and relapse risk prediction models for patients with DLBCL by integrating clinical features with transcriptomic data using various machine learning methods. The results demonstrated that FastSurvivalSVM exhibited superior overall performance and was capable of identifying key driving factors and clinical-molecular interactions through the SHAP method. Scientifically, this study proposes a robust multidimensional modeling framework, providing new evidence for understanding the biological heterogeneity of DLBCL. Clinically, it offers potential tools for individualized risk assessment, treatment decision-making, and follow-up management of patients. Despite limitations such as insufficient sample sources and external validation, this study lays the groundwork for future validation based on multicenter prospective data and the deep integration of multiomics data. With the continuous advancement of artificial intelligence and precision medicine, interpretable machine learning models are expected to play an increasingly important role in risk prediction and personalized management of lymphoma and other complex tumors.

Abstract

Background: Blockchain technologies have revolutionized the financial sector through their ability to generate immutable, cryptographically secure records. Clinical trials and health care data possess several synergies with those of the financial sector, specifically pertaining to the importance of tamper-resistant recording of processes. The evolution of blockchain to autonomously execute tasks contingent upon predefined contractual terms via smart contracts (SCs) allows a dynamic chain of interlinked events to unfold independently and in sequence, with time-stamped records. In recent years, mistrust in clinical trial data has grown significantly. Recording the entire clinical trial lifecycle from application, registration, recruitment to conduct, finance management, statistical analysis, and reporting in an immutable, cryptographically secure ledger with SC execution of trial processes could limit the potential for human intervention and tampering. This would produce a time-stamped record of all events within the trial lifecycle. Leveraging the capabilities of SCs could alleviate recruitment challenges and address ongoing concerns regarding data transparency, ownership, and integrity that currently undermine clinical trial processes.

Objective: This study aimed to review the existing literature on SC applications in clinical trials and propose a system architecture for using SCs to automate key processes throughout the clinical trial lifecycle.

Methods: A systematic search was conducted in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines, identifying peer-reviewed studies and open-source repositories pertaining to the implementation of SCs in clinical trials. Data were extracted specific to the stage of the trial lifecycle described, SC architecture, and technical specifications for real-world implementation. Data were synthesized to propose an architecture for automating clinical trial processes within the lifecycle using SCs.

Results: A total of 144 records were screened; 10 studies met the inclusion criteria. Most implementations used private Ethereum-based networks (7/10, 70%). Reported applications included automated patient matching (5/10, 50%), consent management with dynamic permissioning (6/10, 60%), protocol enforcement and time-stamped audit logs (9/10, 90%), adverse event reporting (3/10, 30%), and financial or workflow automation (3/10, 30%). SC-based recruitment systems demonstrated rapid matching performance (eg, 6000 simulated patients matched in 2.13 s). However, all included systems were prototypes or simulations, and none were tested in real-world regulatory settings. Scalability, interoperability limitations, regulatory ambiguity (eg, General Data Protection Regulation right-to-erasure conflicts), and high infrastructural complexity were common gaps noted across studies.

Conclusions: Current evidence suggests that SCs can enhance transparency, traceability, and automation throughout the clinical trial lifecycle. However, the literature remains dominated by simulation-based prototypes, primarily Ethereum-dependent architectures, and lacks analyses of cost-effectiveness, governance, and integration with institutional workflows. Future research should evaluate hybrid architectures, develop interoperability standards, and assess regulatory and ethical implications in real deployments.

Introduction

The successful execution of clinical trials presents numerous challenges, particularly in patient recruitment, incentivization, and data integrity [1]. Traditional trial infrastructures rely heavily on centralized data management systems that are vulnerable to breaches, human error, and manipulation—undermining the credibility of clinical outcomes [2]. Furthermore, low public awareness, privacy concerns, and fragmented health records impede the identification and recruitment of eligible participants, while nontransparent reimbursement mechanisms and burdensome administrative procedures contribute to poor retention rates [3].

Simultaneously, data transparency remains a core concern. Inconsistent documentation, delayed reporting, and limited traceability can erode trust among regulators, sponsors, investigators, and patients [4]. These operational and ethical concerns highlight the need for secure, automated, and transparent systems to support clinical research.

Blockchain technology offers a compelling solution to these challenges. As a decentralized, cryptographically secure ledger, blockchain enables transparent, tamper-resistant record-keeping across distributed networks. Once data are entered into the blockchain, it becomes immutable, ensuring the authenticity of records such as trial protocols, consent logs, and clinical outcomes [5].

A powerful feature of blockchain systems is the use of smart contracts (SCs), self-executing agreements coded with predefined conditions [6]. In the context of clinical trials, SCs can automate critical processes such as patient matching, consent acquisition, data permissioning, trial monitoring, and stakeholder coordination [7,8]. Their ability to enforce protocol adherence, timestamp events, and track user activity without intermediaries reduces administrative burdens while improving trust, traceability, and auditability.

This review explores the role of blockchain SCs in enhancing transparency, security, and efficiency across the clinical trial lifecycle. Through a systematic evaluation of peer-reviewed publications, preprints, and open-source implementations, we identify key use cases and architectural patterns in SC-based clinical trial systems. Specifically, we examine how SCs have been applied to optimize patient recruitment, streamline consent workflows, improve data sharing and permissions, automate trial governance, and uphold regulatory compliance.

By analyzing a diverse set of implementations, from academic prototypes to open-source repositories, this review highlights both the potential and the limitations of current blockchain applications in clinical research. In doing so, it offers a foundation for future innovations that leverage SCs to build more trustworthy, efficient, and patient-centric clinical trial ecosystems.

Methods

Search Strategy

A systematic literature review was conducted in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) [9] guidelines to identify peer-reviewed studies and open-source implementations relevant to the use of blockchain SCs in clinical trials. Two independent reviewers (ZS and GS) reviewed all eligible articles across 3 main sources: PubMed, arXiv, and GitHub, yielding 144 articles for screening, as well as manual cross-referencing of reference lists of screened papers. Conflicts were resolved through discussion. Only articles available in the English language were included. Studies were imported into the Covidence systematic review software.

Eligibility Criteria

Studies were included if they reported on the use of blockchain technology in SCs within any stage of the clinical trial lifecycle. Examples of eligible studies included but were not limited to patient recruitment, consent acquisition, protocol adherence, interinstitutional data sharing, and outcome reporting. Both academic publications and open-source repositories were eligible for inclusion if they contained sufficient technical detail on system architecture, deployment, or simulation. Studies were excluded if they lacked detail on SCs, had inadequate clinical trial relevance, failed to detail implementation methodology, or reported on nonclinical applications.

Data Extraction

Data were extracted from each included study using a standardized framework to capture study characteristics, blockchain platform, SC structure and function, use of off-chain storage systems, and targeted stage of the clinical trial cycle. Additional technical parameters such as programming language (eg, Solidity), performance simulation outcomes, stakeholder roles, and system testing (where reported) were also recorded. For GitHub repositories, associated documentation, proposals, and code structure were also reviewed.

Outcomes and Definitions

The primary outcome was the identification and synthesis of architectural and functional use cases for SCs in clinical trial management. These included applications in trial setup, patient matching, consent and permissions, protocol enforcement, data integrity, real-time monitoring, and reporting. Data were synthesized to develop a system architecture for the integration of SCs into the clinical trial lifecycle.

Study Quality

Academic studies were appraised for methodological rigor based on descriptive completeness, technical transparency, and real-world relevance. For open-source implementations, code completeness, versioning, accompanying documentation, and alignment with described functionality were assessed. Evaluation was performed independently by 2 reviewers (ZS and GS) and cross-checked for consistency. All final inclusions were agreed upon through consensus.

Results

Overview

In total, 144 records were identified using the search strategy (PubMed=80, GitHub=43, and arXiv=21). Following title and abstract screening, 20 publications (PubMed and arXiv) underwent full-text screening. From this, 6 publications met the inclusion criteria. Following reference screening, a further 2 publications were identified for full-text screening, and one met eligibility criteria. Of the 43 data repositories identified on GitHub, 5 repositories were evaluated after screening, and one was associated with a publication which was included in the final analysis. One further repository detailing the SC code, with an accompanying proposal document, was included in the final analysis. The full search strategy is included in the PRISMA flowchart for study inclusion, shown in Figure 1.

Studies detailed several stages of the trial process which could be optimized using SCs. The majority implemented private Ethereum-based blockchains, using Solidity, a programming language specifically designed for writing SCs in Ethereum [10]. One used Quorum, an Ethereum-based blockchain platform, and another used Hyperledger Fabric. Across studies, SCs facilitated trial application [2], patient recruitment [3], consent [4], and dynamic data permissions, allowing patients to grant or revoke access to data [2] (Table 1). SCs were also used to randomize patients [1], set up trial protocols [3], and ensure data transparency [5]. Other applications included trial workflow management [5], reporting of serious adverse events (SAEs) [3], statistical analysis and final reporting [4], data exchange between institutions, and financial management [1]. Several studies [5] described a multilayer architecture with multiple SCs for different stages of clinical trial management (Table 2). Extracted data were synthesized to develop a novel system architecture for the integration of SCs in all aspects of the clinical trial lifecycle (Figure 2).

Patient Recruitment

Recruitment for clinical trials is frequently challenging, often constrained by bureaucratic processes, multisite coordination requirements, and reliance on site-based recruiters. These inefficiencies hinder enrollment, delay trial timelines, and raise study costs. Patient enrollment is also hindered by a lack of awareness regarding available trials, exacerbated by inadequate outreach and poor trial visibility. Moreover, the necessity of additional hospital visits to discuss trial protocols can act as a further deterrent to participation.

SCs can be used to “auto-match” eligible patients to suitable clinical trials, thereby streamlining the recruitment process. Zhuang et al [7] propose a 2-tier blockchain architecture consisting of a Master Smart Contract and multiple Trial Contracts. The Master Smart Contract is managed by a trusted authority, such as the US Food and Drug Administration (FDA), and is designed to match patients to clinical trials based on predefined inclusion and exclusion criteria. To ensure trial authenticity and regulatory compliance, each sponsor is required to submit a transaction to the authority. This transaction includes a National Clinical Trial identifier and supporting trial information for validation. Once the authority has verified the sponsor’s identity and authenticity of the trial, it can execute the master smart contract, based on inclusion or exclusion criteria submitted by the sponsor. Patient information is inputted

XSL•FO
RenderX

by clinical sites for patients who have opted in for consideration of trial participation. This enables the system to automatically match eligible patients to appropriate trials.

Once a patient is matched, they are notified by the authority that there is a clinical trial they may be eligible to participate in. Patient authorization is subsequently required to permit sponsor access to electronic health records (EHRs). Sponsors can then verify that the patient information supplied to the authority matches their clinical records and precise matching can be performed by the clinical site. If patients fully match, the sponsor can send the patient a transaction to enroll in the trial which can be authenticated using an eSignature. Patient records are then stored in the trial contract. Trial-specific contracts also contain information on trial protocols, sponsor details, and other relevant documentation. Importantly, trial contracts are only accessible to individuals who have agreed to participate in the trial.

The authors simulate the use of the master contract, demonstrating the ability to auto-match 1145 of 6000 patients to a trial in 2.13 seconds. Once patients have enrolled using a trial-specific contract, the sponsor can access data on the geographical location of patients and choose clinical trial sites convenient to the majority of subjects. This significantly attenuates the time and resources associated with patient screening processes, widening accessibility and trial awareness.

Data Permissions and Consent

Lack of transparency on how health care data are used can lead to mistrust in the clinical trial process. Blocktrial, a web-based application developed by Maslove et al [12], is a simple patient SC that enables patients to specify data sharing permissions. These permissions can be changed through an "editPermissions" feature on the patient SC, allowing patients to control who has access to their data. Once consent to data sharing is edited, an immutable record is generated on the blockchain. SCs allowing real-time editing of data sharing permissions promote patient autonomy and agency, and may enhance trust and transparency in how patient data are used.

Protocol Compliance and Data Transparency

While patient-centric models offer valuable enhancements to consent management, broader systemic trust requires secure, verifiable collaboration between institutions involved in clinical trials. To this end, Nugent et al [8] propose a private, permissioned Ethereum-based blockchain network jointly maintained by regulatory bodies (eg, Medicines and Healthcare products Regulatory Agency and FDA), pharmaceutical companies, and contract research organizations (CROs) [8]. This network is intended to operate alongside traditional clinical data management systems, serving as a transactional, interorganizational record-keeping system. The authors illustrate that SCs can function as trusted administrative agents, enhancing transparency in clinical trial reporting by immutably recording key elements prone to manipulation, such as trial registration, protocols, subject enrollment, and clinical measurements. Within this architecture, Nugent et al [8] outline a hierarchical SC model comprising two core types:

1. Regulator contract: this SC maintains a data structure that holds Clinical Trial Authorization details. It is controlled and updated by regulatory authorities such as the Medicines and Healthcare products Regulatory Agency or the FDA, based on off-chain licensing agreements. The contract also includes a container to store individual trial contracts.
2. Trial contract: this is executed by the CROs through a function in the regulator contract; this contract's deployment is governed by permissioning logic tied to the Clinical Trial Authorization data. It holds a data structure for storing the trial protocol, leveraging the interplanetary file system (IPFS) or Ethereum's Swarm protocol for large file storage. The contract enforces rules requiring the protocol to be deposited and trial endpoints defined before subject data can be added to the associated container.

Finally, a trial report is generated, reading all data from the blockchain, with details of each subject and data points that have been added with timestamping. Such systems can strengthen trust in clinical data integrity and improve the credibility of trial outcomes, ultimately enabling more informed medical decisions while helping to reduce patient risk and the financial burden caused by data manipulation.

By leveraging the cryptographic security of modern blockchain protocols, the system extends beyond simple proof-of-existence to support complex, tamper-resistant data handling. This work illustrates how SCs on the Ethereum blockchain can enhance transparency in clinical trial data management.

As part of their evaluation, Nugent et al [8] deployed SCs on a private Ethereum blockchain to record synthetic data simulating clinical trials for Tamiflu, a medication stockpiled by the British government at a cost of US $575 million, despite 60% of the trial data being unpublished at the time. This test demonstrated the system's ability to provide real-time access to trial data, including participant numbers, number of trials, transaction addresses (linked to a CRO), and timestamps, while the blockchain's immutability allowed for retrieval of historical data, confirming the viability of using SCs to maintain transparent, verifiable records in clinical trials.

Similarly, Omar et al [15] propose a blockchain-based clinical trial framework using Ethereum SCs and IPFS to enhance transparency, traceability, and automation in trial data management. IPFS is used to store trial documents, such as protocols, consent, SAE reports, and lab results, while their cryptographic hashes are securely linked to the blockchain via SCs. These SCs automate critical tasks at each stage of the trial process, such as Investigational New Drug submission, trial initiation, patient enrollment, monitoring, and SAE occurrence. At the end of the trial, the sponsor is required to submit an analysis to the SC, following which the FDA can approve the final outcome.

Each stakeholder (eg, FDA, institutional review board, sponsor, and physician) is assigned a unique Ethereum address, enabling secure, permissioned interactions with the contract's specific functions, such as submitting data or accessing trial updates. The contracts enforce role-based access controls, ensuring that only authorized individuals can perform actions within the system. Events, such as patient enrollment or trial stage

XSL•FO
RenderX

completion, trigger real-time notifications to the relevant stakeholders, enhancing communication and transparency throughout the trial lifecycle. By automating these processes, SCs reduce administrative bottlenecks, improve data integrity, and ensure the auditability of every action taken in the clinical trial.

The authors successfully tested this SC framework across various scenarios in the clinical trial process. At each stage, from Investigational New Drug submission to final analysis, the system correctly executed role-specific tasks with access controls in place to prevent unauthorized actions. If an unauthorized action was attempted, the SC triggered an error, ensuring that only valid operations could be performed. Additionally, real-time notifications were generated for stakeholders at key points, such as patient enrollment or SAE reporting. The framework also enabled the retrieval of patient monitoring data per visit and correctly managed patient dropouts by preventing further data updates for removed participants. SAEs were reported by the principal investigator, reviewed by the institutional review board, and the final decisions were broadcast to all stakeholders through blockchain events. The simulated trial concludes with the FDA issuing a decision based on the final report, triggering an event that informs all stakeholders of the outcome, further demonstrating the ability of Ethereum SCs to manage clinical trials in a secure, transparent, and auditable manner.

SCs in Vaccine Development

Mistrust in vaccine development, driven by concerns over data transparency and trial integrity, remains a major challenge to public confidence. Sendin et al [14] attempt to address this through vaccine supply chain (VaccSC), using SCs to securely automate and coordinate key stages of a phase III vaccine trial while preserving double-blind conditions.

VaccSC leverages SCs on the Ethereum blockchain to automate randomization and requires the developer to specify the number of participants, the infected threshold (number of patients infected before allocations are revealed), minimum vaccine efficacy for approval, and the Ethereum address of clinics administering the vaccine in the SC before deployment. Once deployed by the vaccine developer, the SC governs the entire trial workflow. First, the developer distributes vaccine and placebo shots to clinics and records their association on-chain. Randomization is achieved through private number generation by the patient and the clinic; both numbers are then committed to the SC and combined to give a unique number, assigning a shot to the patient. Clinics then administer the shots and link unique shot identifiers to each patient within the contract, which the patient confirms. If a patient becomes ill, they report this directly to the contract. When a predefined infection threshold is met, the SC emits an event notifying the vaccine developer that the trial is complete. Using Ethereum addresses, the developer submits which patients received the control, allowing the contract to calculate how many received the actual vaccine. The contract then computes vaccine efficacy and approval status based on previously defined thresholds, making the results publicly accessible. By immutably capturing each step, from shot distribution, randomization, infection rates, and efficacy calculations, VaccSC uses SCs not only as a secure data ledger but also as an autonomous, unbiased administrator, reducing the risk of data manipulation and making the process transparent and accessible to the public. This methodology can be replicated in other drug development settings.

Multilayered SC Architectures for Comprehensive Trial Oversight

Several studies describe a multilayered approach to clinical trial management. Zhuang et al [11] initially proposed a 3-level architecture, consisting of a transaction, interface, and application layer. The transaction layer consists of 2 SCs, the EHR manager and the user manager. The EHR system automatically extracts patient ID, hospital ID, patient name, and a dataset related to patient health care use as an execution function of the SC on receiving a new EHR from a health institution. This data are then submitted to the blockchain. The user manager enables patients to grant institutions access to their metadata. Once access permission is verified, the blockchain adaptor will automatically retrieve the patient's metadata from the EHR manager, request the encrypted EHR dataset from the remote health facility in which it is stored, retrieve the encrypted data using dataset location information from the EHR metadata, and decrypt the data.

The interfacing layer enables secure data exchange between institutions through 4 functions. These include accessing external data, storing encrypted data off-chain, posting metadata and access requests to the blockchain via SCs, and transmitting encrypted data to authorized recipients. It retrieves metadata from the blockchain, verifies data integrity, and decrypts off-chain data as needed. The data retrieval and permission setting application programming interface calls on the SCs in the transaction layer to retrieve metadata from the blockchain and set access policies.

The application layer relies on the transaction SCs and interfacing layer to securely access data applications, which can be developed to interact with the preceding layers, such as data analytic tools to match patients to relevant trials or for patients to grant or revoke access to their records and track how they are being used.

Building on their earlier 3-layer architecture, the authors outline a more granular SC-based framework spanning five phases of the clinical trial process: (1) study planning, using a transparent electronic trial master file for protocol development; (2) study start-up, including patient recruitment and enrollment; (3) study conduct, supporting electronic data capture and monitoring of treatment safety and efficacy; (4) study closeout, incorporating statistical tools for reproducible analytics reporting; and (5) study finance, which leverages blockchain's cryptocurrency capabilities for payment and reimbursement [13].

The study planning stage uses SCs to control access to electronic documents relevant to the trial, validate file consistency, and manage collaboration in electronic trial master file development, and the IPFS network is used for file storage and file indexing. Trial master file documents are identified in the SC at the start of the trial, and sponsors are required to add the blockchain account of users who are permitted to work on the file. The SC

XSL•FO
RenderX

only permits 1 user at a time to work on a document, ensuring traceability and auditability of any modifications to trial documents. Once a user has finished working on a document, the blockchain adaptor will encrypt the document with a random new set of keys.

The study start-up phase builds on earlier work using SCs to automate matching and enhance recruitment. During the conduct phase, patient data are entered on an electronic case report form following each clinic visit; these are automatically hashed and stored in the IPFS. The SC determines whether a trial site has permission to store a patient's data. Once verified, the SC will send a visit ID and decryption key through the Quorum blockchain's private transaction. The sponsor will receive the decryption key and hash from the blockchain, and the blockchain adaptor will automatically decrypt and hash the records to compare with the hash stored on the blockchain, thereby identifying hash mismatches and data inconsistencies. Mismatches trigger alerts for investigation. The blockchain's immutability prevents overwriting erroneous data; instead, linking it to previous record hashes for validation.

The closeout phase involves encoding statistical analysis methods into an SC, with both the analyzed data and methods stored on the blockchain for reproducibility and result authentication. The final component pertains to finances, encoding a list of payable entities and predefined rates into an SC at the start of the study. This standardization reduces the risk of hidden fees during the trial and can be customized to the trial site to accommodate different rates. Encoding payables into the SCs can expedite the validation process. Furthermore, all financial transactions are recorded and time-stamped on the blockchain, allowing transparency around trial finances.

Discussion

Principal Findings

In recent years, public confidence in the validity of clinical research has been challenged, with multiple reports documenting that a substantial proportion of published studies contain methodological flaws or, in some cases, fabricated data [2]. This erosion of trust has intensified interest in technologies capable of enhancing transparency, auditability, and accountability across the clinical trial lifecycle. Since Satoshi Nakamoto's [18] 2008 white paper introduced a decentralized, time-stamped ledger for peer-to-peer financial exchange, blockchain technology has transformed the financial sector and has increasingly been explored for its potential applications in health care data management [19]. The fundamental properties of decentralized data storage, cryptographic integrity, and tamper-resistant audit trails have drawn attention as possible mechanisms for strengthening trust in clinical trials.

The emergence of SCs extends these capabilities from static, "proof-of-existence" records to programmable logic, capable of automating key operational processes. SCs can function as autonomous administrators of trial workflows, implementing predefined rules, and eliminating opportunities for retrospective alteration. This embodies Lawrence Lessig's idea that "code is law," such that the software logic itself becomes the governing framework for how stakeholders interact. Within the context of clinical trials, this has motivated the development of prototype systems that automate tasks ranging from eligibility screening and recruitment to dynamic consent management, protocol enforcement, data access tracking, and even automated reporting of results.

The studies included in this review demonstrate that many such applications are technically feasible in controlled environments. For example, SC-based recruitment workflows have been shown to match large numbers of simulated participants to trial criteria within seconds, and immutable audit trails can capture the entire sequence of procedural steps across the trial lifecycle. Dynamic data permissioning enabled by SCs may strengthen patient autonomy by allowing individuals to regulate access to their data in real time. The Ethereum blockchain, used in the majority of reviewed studies, has proven well-suited to these prototypes due to its mature SC infrastructure and developer ecosystem.

However, the findings also reveal a substantial gap between technical promise and real-world readiness. All identified implementations were prototypes or simulations, with no evidence of deployment in actual regulated trials. Assertions that clinical trial processes could be fully automated should therefore be interpreted with caution. Although the reviewed systems demonstrate the potential of SCs to automate constrained, deterministic processes, they do not address the complexities of real-world trial environments, such as the need for human judgment, protocol deviations, unstructured clinical data, and the heterogeneity of institutional workflows. Furthermore, Ethereum's dominance in the literature introduces platform bias, and few studies critically examine its well-known limitations, including fluctuating transaction costs, constraints on throughput, and the absence of built-in privacy protections.

Regulatory and legal challenges present even greater obstacles. The immutability of blockchain data conflicts with requirements under frameworks such as the General Data Protection Regulation, which grant individuals the right to erasure or correction of their personal data. While hybrid on-chain or off-chain architectures offer partial solutions, they also reintroduce trust dependencies that undermine decentralization. In addition, governments may impose abrupt regulatory changes or restrictions on blockchain platforms, as demonstrated by cryptocurrency bans in China and other jurisdictions. Such policy shifts pose risks to any clinical trial infrastructure built on blockchain technology. Adoption will therefore require not only technical adaptation but also careful consideration of governance, compliance, and stakeholder engagement.

Another critical gap in the current literature is the lack of evidence regarding stakeholder perspectives. No included study evaluated how patients, investigators, regulators, data monitors, or ethics committees perceive blockchain-based systems. The introduction of SCs could alter roles, responsibilities, and liabilities within clinical trials, and resistance to such changes may limit adoption. Moreover, the reviewed studies did not assess cost-effectiveness, integration with existing EHR or clinical trial management systems, or long-term sustainability, all of which are essential for real-world implementation.

XSL•FO
RenderX

Taken together, the findings indicate that blockchain SCs offer meaningful conceptual advantages, particularly in transparency, auditability, and automation, but their practical value remains unproven. Future progress will require a shift from idealized prototypes to rigorous evaluation within real clinical and regulatory environments, informed by legal expertise, operational realities, and stakeholder acceptance. The transition to blockchain-enabled clinical trials, if it occurs, will not be a purely technical transformation but a broader organizational and regulatory evolution involving new models of data governance and oversight.

Limitations

This review is subject to several limitations. First, the number of eligible studies was small, and all relied on prototype or simulation-based evaluations, which limits the generalizability of the findings. Second, given the technical nature of the field, important developments may exist outside traditional academic publishing channels. Although GitHub repositories were included, some relevant implementations may not have met the inclusion criteria due to insufficient documentation. Third, the heterogeneity of study designs, blockchain platforms, and evaluation methods precluded quantitative synthesis and necessitated a qualitative approach. Fourth, because the field is evolving rapidly, newer implementations may have emerged after the final search date. Fifth, no study included direct engagement with regulators, trial sponsors, investigators, or patient groups, meaning the review could not assess acceptability or practical feasibility from a stakeholder perspective. These limitations reflect the early stage of this research area and reinforce the need for more comprehensive, empirically grounded studies.

Future Directions

Future research should prioritize real-world pilot implementations that integrate SCs within existing clinical trial infrastructures, including EHRs, electronic data capture systems, and regulatory submission platforms. Development of privacy-preserving blockchain technologies, such as zero-knowledge proofs, secure multiparty computation, or trusted execution environments, will be essential for reconciling immutability with data protection requirements. Comparative studies evaluating different blockchain platforms, including permissioned and permissionless architectures, would help determine appropriate use cases and clarify the trade-offs between privacy, performance, and decentralization.

Hybrid systems that combine blockchain components with traditional clinical trial management frameworks offer a promising compromise and warrant further exploration. Researchers should also examine governance models for blockchain-enabled trials, ensuring that the encoded logic reflects clinical, ethical, and regulatory expectations. Economic evaluations will be essential to determine whether SC systems can deliver cost savings or improved efficiency relative to conventional solutions. Finally, engagement with stakeholders, including regulators, ethics committees, clinicians, patients, and data managers, will be vital to understand practical adoption barriers and align technical development with real-world priorities.

Conclusions

Blockchain-based SCs have the potential to revolutionize the way clinical trials are operated, audited, and disseminated. Through unrealized resources and finance efficiencies, recruitment to trials, trial timelines, and conduct could be optimized. The immutable core of the blockchain ledger, greater data decentralization, and patient data ownership could lead to greater trust and transparency in the body of scientific work produced. This review demonstrates that nearly all elements of a clinical trial could be efficiently executed using SC and blockchain technologies.

Abstract

Background: Screening for atherosclerosis is essential for early intervention, but conventional screening methods are often invasive and resource-intensive. As a result, there is growing interest in leveraging AI with noninvasive tools such as retinal fundus imaging to enable opportunistic cardiovascular risk assessment. The deep-learning funduscopic atherosclerosis score (DL-FAS) is an AI-derived biomarker, generated by a deep learning model, that was developed in a previous study to reflect the likelihood of carotid artery atherosclerosis from retinal fundus images.

Objective: This study aimed to externally validate DL-FAS in a multicenter health checkup population and investigate its association with coronary artery calcification to gain deeper insights into its ability to reflect the broader systemic atherosclerotic burden.

Methods: We used data from 108,982 participants in a Korean health checkup population who underwent retinal fundus imaging and at least one of either carotid artery sonography or coronary artery calcium scoring across 5 health-promotion centers operated by the Korea Association of Health Promotion between 2018 and 2021. Carotid atherosclerosis was defined by increased intima-media thickness (≥ 0.9 mm), atheroma, or stenosis. A coronary artery calcium score >0 indicated the presence of coronary artery calcification. DL-FAS (range 0 - 1) was generated for each fundus image, and the average score from both eyes was used as the final DL-FAS when available. The discriminative performance of DL-FAS for carotid atherosclerosis was assessed using the area under the receiver operating characteristic curve. We performed multivariable logistic regression, adjusted for the Pooled Cohort Equations (PCE) 10-year cardiovascular risk score, to quantify the associations between DL-FAS and both outcomes.

Results: The area under the receiver operating characteristic curve for detecting carotid atherosclerosis was 0.700 (95% CI 0.697 - 0.703), confirming the generalizability of DL-FAS across multiple centers. In multivariable logistic regression adjusted for the PCE score, a 10% absolute increase in DL-FAS was associated with both carotid atherosclerosis (odds ratio 1.29, 95% CI 1.28 - 1.31) and coronary artery calcification (odds ratio 1.29, 95% CI 1.24 - 1.33). These associations remained significant among participants aged <60 years, as well as within the PCE-defined low- and moderate-risk subgroups, highlighting the potential utility of DL-FAS in populations that may benefit most from early detection and intervention.

Conclusions: DL-FAS was externally validated in a large, multicenter health checkup dataset and was significantly associated with both carotid atherosclerosis and coronary artery calcification. These findings highlight its potential as a noninvasive biomarker associated with systemic atherosclerotic burden and cardiovascular risk stratification, particularly in the context of opportunistic screening.

KEYWORDS

retinal fundus image; AI; deep learning; carotid artery atherosclerosis; coronary artery calcification; opportunistic screening

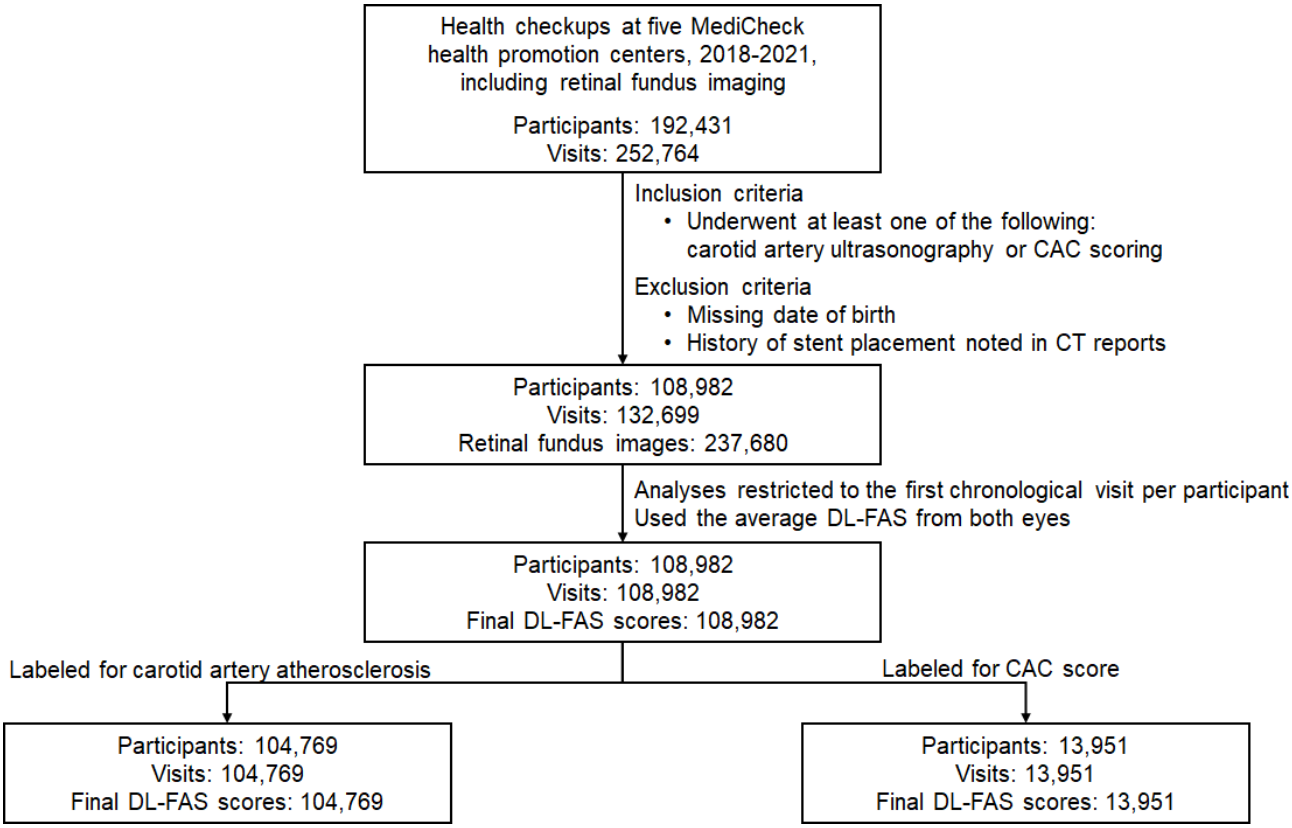
Introduction

Cardiovascular disease (CVD) remains the leading cause of mortality worldwide, imposing a substantial burden on health care systems and individuals [1,2]. Screening for atherosclerosis is crucial for timely intervention and risk stratification, yet traditional screening methods often require specialized equipment, invasive procedures, and significant health care resources [3,4]. Given these limitations, there is a growing interest in leveraging AI to enable opportunistic screening—identifying at-risk individuals using readily available medical data collected for other purposes [5,6].

One promising avenue for AI-driven opportunistic risk assessment is retinal fundus imaging, a noninvasive and widely accessible modality that uniquely allows direct visualization of blood vessels and is used primarily for ophthalmic evaluations. The retina offers a unique window into systemic vascular health, as its microvasculature shares pathophysiological similarities with the cerebral, coronary, and carotid circulations [7-9]. Recent advancements in deep learning have enabled the extraction of vascular biomarkers from retinal images, providing novel insights into cardiovascular risk beyond traditional clinical assessments [10-13].

In this context, a previous study by Chang et al (2020) [14] demonstrated that AI applied to retinal fundus imaging can predict carotid artery atherosclerosis, and they termed this AI-derived score the deep-learning funduscopic atherosclerosis score (DL-FAS). This study is evidence that AI can recognize atherosclerosis-related features in the retinal microvasculature [14]. As carotid atherosclerosis typically reflects systemic atherosclerotic burden [15-18]—often coexisting with coronary and peripheral atherosclerotic lesions—the association between DL-FAS and other markers of atherosclerosis warrants further investigation. One such marker is coronary artery calcium (CAC), a well-established indicator of coronary atherosclerosis and one of the strongest predictors of atherosclerotic cardiovascular disease (ASCVD) events [19,20]. Exploring whether DL-FAS is associated with CAC could provide deeper insights into its ability to reflect the broader coronary-cerebrovascular atherosclerotic burden.

In this study, we externally validated DL-FAS, the AI-derived score developed by Chang et al (2020) [14], using multicenter health checkup data to assess its reliability and generalizability in predicting carotid artery atherosclerosis. Additionally, we evaluated whether DL-FAS is associated with CAC, aiming to further elucidate its potential role in noninvasive cardiovascular risk stratification.



Methods

Study Participants and Data Collection

The data for this study were obtained from participants who had undergone regular health checkups at 5 health-promotion centers operated by the Korea Association of Health Promotion (MediCheck) in 3 cities in Korea—Seoul (3 centers), Suwon, and Incheon—between 2018 and 2021 (Figure 1). MediCheck offers elective medical health examinations, including surveys, physical examinations, laboratory tests, and medical imaging. Participants must subscribe to one of several available medical examination packages, which are not offered based on any specific indication. Carotid artery sonography and CAC scoring via computed tomography (CT) are included in the more expensive packages.

XSL•FO
RenderX

Figure 1. Participant flow diagram. CAC: coronary artery calcium; CT: computed tomography; DL-FAS: deep-learning funduscopic atherosclerosis score.

Among these participants, we included individuals who had undergone retinal fundus imaging and at least one of the following examinations: carotid artery sonography or CAC scoring. Individuals with detected stents in their CT reports were excluded. All analyses were restricted to the first chronological health checkup visit per participant.

We extracted retinal fundus images from both eyes and the carotid artery sonography findings. At all participating centers, only retinal fundus images deemed clinically interpretable by on-site technicians were registered in the database. Images of insufficient quality for clinical interpretation (eg, due to severe artifacts or media opacity) were not stored and therefore were not included in this study. No additional AI-based image quality filtering was applied. Carotid artery atherosclerosis was defined as the presence of any of the following: increased carotid intima-media thickness (CIMT; ≥0.9 mm), atheroma, or stenosis. We extracted CAC scores from CT reports using regular expressions. Additionally, other data collected during the health checkups were extracted, comprising demographic information including age and sex, blood test results including lipid profile, physical examination measurements including weight, height, and blood pressure, and survey responses including medical and medication history and smoking status.

Brief Overview of DL-FAS

The AI model that generates DL-FAS was developed in a previous study to predict carotid artery atherosclerosis using retinal fundus images [14]. It was trained on 15,408 images from the Health Promotion Center of Seoul National University Hospital, using the Xception architecture [21], with weights initialized from pretrained weights learned from ImageNet [22], followed by transfer learning. DL-FAS achieved an area under the receiver operating characteristic curve (AUROC) of 0.713 in detecting carotid artery atherosclerosis. Carotid artery atherosclerosis was defined as either a CIMT of ≥0.9 mm or the presence of carotid artery plaque detected via ultrasonography. In a retrospective cohort of 32,227 participants with a median follow-up of 7.6 years, DL-FAS was independently associated with cardiovascular mortality, with individuals in the highest tertile (DL-FAS range 0.67 - 1.00) having an 8.83-fold increased risk of CVD death compared to those in the lowest tertile (DL-FAS range 0.00 - 0.33). The score provided incremental predictive value beyond the Framingham Risk Score. These findings suggest that DL-FAS can serve as a noninvasive biomarker for cardiovascular risk stratification. DL-FAS has been approved by the Korean Ministry of Food and Drug Safety as a software medical device for cardiovascular risk assessment (product name: XAIMED Retina AI DL-FAS; model: XAIFN2211; approval no. 24 - 436; approval date: July 1, 2024).

DL-FAS Acquisition

The AI model was applied to the retinal fundus images obtained from MediCheck to generate DL-FAS. The model analyzes each eye separately, producing a score for each image. The model was used in its locked form, with weights fully frozen before application to the current cohort and without any updating, recalibration, or retraining during the validation process. As in the previous study [14], if fundus images from both eyes were available, the average of the 2 scores was used as the final DL-FAS, and DL-FAS was categorized into risk groups using thresholds of 0.33 and 0.67. For participants with

XSL•FO
RenderX

a clinically interpretable or available fundus image from only one eye, the single-eye score was used as the final DL-FAS; this applied to 20,942 of 108,982 participants.

External Validation and Regression Analyses

We externally validated the performance of DL-FAS in detecting carotid artery atherosclerosis: AUROC and average precision (AP) were calculated; accuracy, sensitivity, specificity, positive predictive value (PPV), negative predictive value, F_1-score, and number needed to screen (NNS) were assessed using a DL-FAS threshold of 0.368, which was determined in a previous study to maximize the F_1-score [14]. In addition, the performance of DL-FAS was evaluated at an operating point corresponding to approximately 80% specificity, with the threshold identified in this present study. As sensitivity analyses, we further evaluated model performance using alternative carotid end points, including atheroma or stenosis vs normal and stenosis vs normal. As the primary end point included increased CIMT to maintain consistency with the original model development study, whereas CIMT is less directly reflective of clinically established plaque burden than plaque- or stenosis-based disease, these additional analyses allowed us to assess robustness across different definitions of carotid atherosclerosis while also evaluating performance for end points more directly reflective of established plaque burden. Additionally, AUROC was evaluated for CAC across multiple thresholds (CAC score >0, >100, and >400).

To assess the association between DL-FAS and each carotid artery atherosclerosis and the presence of CAC (CAC score >0), we conducted multivariable logistic regression analyses for each outcome, with secondary analyses additionally evaluating associations with higher CAC burden using thresholds of CAC score >100 and CAC score >400. Adjusted odds ratios (ORs) were calculated after controlling for the Pooled Cohort Equations (PCE) score, a widely used estimate of 10-year CVD risk developed by the ACC/AHA (American College of Cardiology/American Heart Association) [23,24]. Individuals with missing data required for PCE score calculation—including age, sex, diabetes mellitus, hypertension, smoking status, total cholesterol, high-density lipoprotein cholesterol, and systolic blood pressure—were excluded from the regression analyses.

Subgroup analyses were conducted by sex, age group (<60 and ≥60 y), and PCE-based cardiovascular risk categories (low <7.5%, intermediate 7.5% - 20%, and high ≥20%). We further performed analyses in the subgroup of participants who underwent both carotid ultrasonography and CAC scoring to evaluate the association of DL-FAS with dual-labeled outcomes, providing additional evidence for systemic atherosclerotic burden.

As the PCE require race classification as White or African American and do not include a specific category for East Asian populations, all participants were coded as White for the primary PCE calculation, consistent with the recommended use of the White equation for individuals not classified as African American, while recognizing the need for further research to refine risk estimation in such populations [23]. To assess the potential influence of race coding on PCE-based analyses, we performed a sensitivity analysis in which the PCE was recalculated by coding all participants as African American. Moreover, as a sensitivity analysis, we repeated the multivariable logistic regression models using the Korean Coronary Heart Disease Risk Score, a population-specific cardiovascular risk model calibrated for Korean cohorts, instead of the PCE [25].

As a sensitivity analysis to assess the robustness of the complete-case results to missing data, we performed multiple imputation by chained equations for missing covariates used in the regression models. Imputation was conducted separately within each outcome-specific cohort (carotid atherosclerosis and CAC), including all variables used in the analytic models as well as outcome variables and study center indicators in the imputation model. A total of 20 imputed datasets were generated, and continuous variables were imputed using predictive mean matching, while binary variables were imputed using logistic regression models. PCE scores were subsequently recalculated within each imputed dataset before regression analysis. For each imputed dataset, the multivariable logistic regression analyses were repeated using the same model specifications as in the complete-case analysis. The pooled estimates of ORs and 95% CIs were obtained using Rubin rules.

As additional sensitivity analyses, we repeated the primary multivariable logistic regression models with study center included as a categorical covariate to assess whether the associations between DL-FAS and atherosclerotic outcomes were robust to intercenter heterogeneity. We also compared DL-FAS score distributions and AUROC values between participants with bilateral fundus images, for whom the average score from both eyes was used, and those with a single available fundus image, for whom the single-eye score was used.

To assess the incremental value of DL-FAS in reclassification beyond traditional risk factors, we evaluated the category-free net reclassification improvement (NRI) for carotid artery atherosclerosis by comparing a baseline logistic regression model including only PCE variables with an extended model that additionally incorporated DL-FAS.

Clinical Workflow Integration Evaluation

The 2018 ACC/AHA Guideline on the Management of Blood Cholesterol incorporated the CAC score as a decision aid for statin therapy in primary prevention of CVD when uncertainty remains after standard risk assessment [24]. Specifically, the guideline indicates that CAC measurement may be considered in selected adults in the borderline- to intermediate-risk categories when the decision about statin therapy remains uncertain [24]. Therefore, we evaluated how DL-FAS-based risk classification, following the initial PCE-based CVD risk classification, altered CAC prevalence within each PCE risk category to explore its potential role in CAC risk enrichment.

Statistical Analyses

The normality of continuous variables was assessed using the Shapiro-Wilk test. For normally distributed variables, ANOVA was used to compare 3 or more groups, while the Kruskal-Wallis test was applied for nonnormally distributed variables. For comparisons between 2 groups, the Mann-Whitney *U* test was

XSL•FO
RenderX

used for nonnormally distributed continuous variables. Categorical variables were compared using the chi-square test. The results are reported as mean (SD) for normally distributed variables and median (IQR) for nonnormally distributed variables. Model calibration was assessed using calibration plots constructed by grouping participants into deciles based on predicted DL-FAS values, and calibration error was quantified using the expected calibration error. The correlation between DL-FAS and CAC scores was assessed using the Spearman rank correlation coefficient. To assess potential selection bias arising from the use of complete case analysis in the logistic regression models, we compared baseline characteristics between participants included in and excluded from the regression analyses using standardized mean differences (SMDs). The 95% CI of the AUROC was determined using the DeLong method (paired, 2-sided) [26]. For the NRI, 95% CIs were estimated using 2000 bootstrap resamples with replacement, reporting the 2.5th and 97.5th percentiles. Statistical significance was defined as $P<.05$.

To clarify the role of each DL-FAS threshold used in this study, the 0.368 threshold was a predefined F_1-score–optimized operating point from the original DL-FAS study, and the 0.565 threshold was identified in the present dataset to illustrate performance at approximately 80% specificity; these thresholds were used to characterize potential clinical operating points. In contrast, the tertile-based cutoffs of 0.33 and 0.67 were used for exploratory risk categorization adopted from the original study, and the midpoint threshold of 0.5 was used for an additional exploratory workflow analysis.

The model developer was involved in initial dataset construction and preliminary analyses. All statistical analyses reported in this paper, including model performance evaluation, regression analyses, subgroup and sensitivity analyses, workflow-integration analyses, reclassification analyses, and the revised analyses conducted during peer review, were performed by an investigator affiliated with Seoul National University and unaffiliated with the model-developing company, using the finalized analytic dataset. No material discrepancies affecting the interpretation of the findings were observed compared with the preliminary analyses.

Ethical Considerations

This retrospective study was reviewed and approved by the institutional review boards of the Korea Association of Health Promotion (130750 - 2022 HR-008) and Seoul National University Hospital (D-2311-163-1488). The requirement for informed consent was waived by both institutional review boards because this study involved secondary analyses of previously collected clinical data. All study data were deidentified before analysis in accordance with institutional anonymization procedures, and no personally identifiable information was accessible to the investigators. Data usage was restricted to the approved study period and purposes. As this study was based on retrospective deidentified data without direct participant involvement, no financial or other compensation was provided to participants. No images or supplementary materials included in this paper contain information that could identify individual participants.

Results

Participant Characteristics

Among 252,764 health checkup visits (from 192,431 individuals) conducted between 2018 and 2021 at all 5 health-promotion centers of MediCheck that included retinal fundus imaging, 132,699 visits with at least one of either carotid artery sonography or CAC scoring were initially identified, after which analyses were restricted to the first chronological visit per participant, yielding a final analytic cohort of 108,982 participants (Figure 1). Of these, 104,769 DL-FAS cases were labeled for carotid artery atherosclerosis based on carotid artery sonography conducted during the same visit, and 13,951 DL-FAS cases were labeled based on CAC scoring conducted during the same visit. The locations and sample sizes of the 5 centers are provided in Table S1 in Multimedia Appendix 1.

The distribution of DL-FAS scores was as follows (Table 1): 20,566 of 108,982 (18.9%) cases in the 0.00 - 0.33 range, 75,748 of 108,982 (69.5%) cases in the 0.33 - 0.67 range, and 12,668 of 108,892 (11.6%) cases in the 0.67 - 1.00 range. Compared to the previous study [14], in which 13,057 of 32,227 (40.5%) cases had DL-FAS scores in the 0.00 - 0.33 range, 18,310 of 32,227 (56.8%) cases in the 0.33 - 0.67 range, and 860 of 32,227 (2.7%) cases in the 0.67 - 1.00 range, the present external validation study had a higher proportion of participants in the higher-risk group ($P<.001$).

[a]DL-FAS: deep-learning funduscopic atherosclerosis score.

[b]N/A: not applicable.

[c]HDL: high-density lipoprotein.

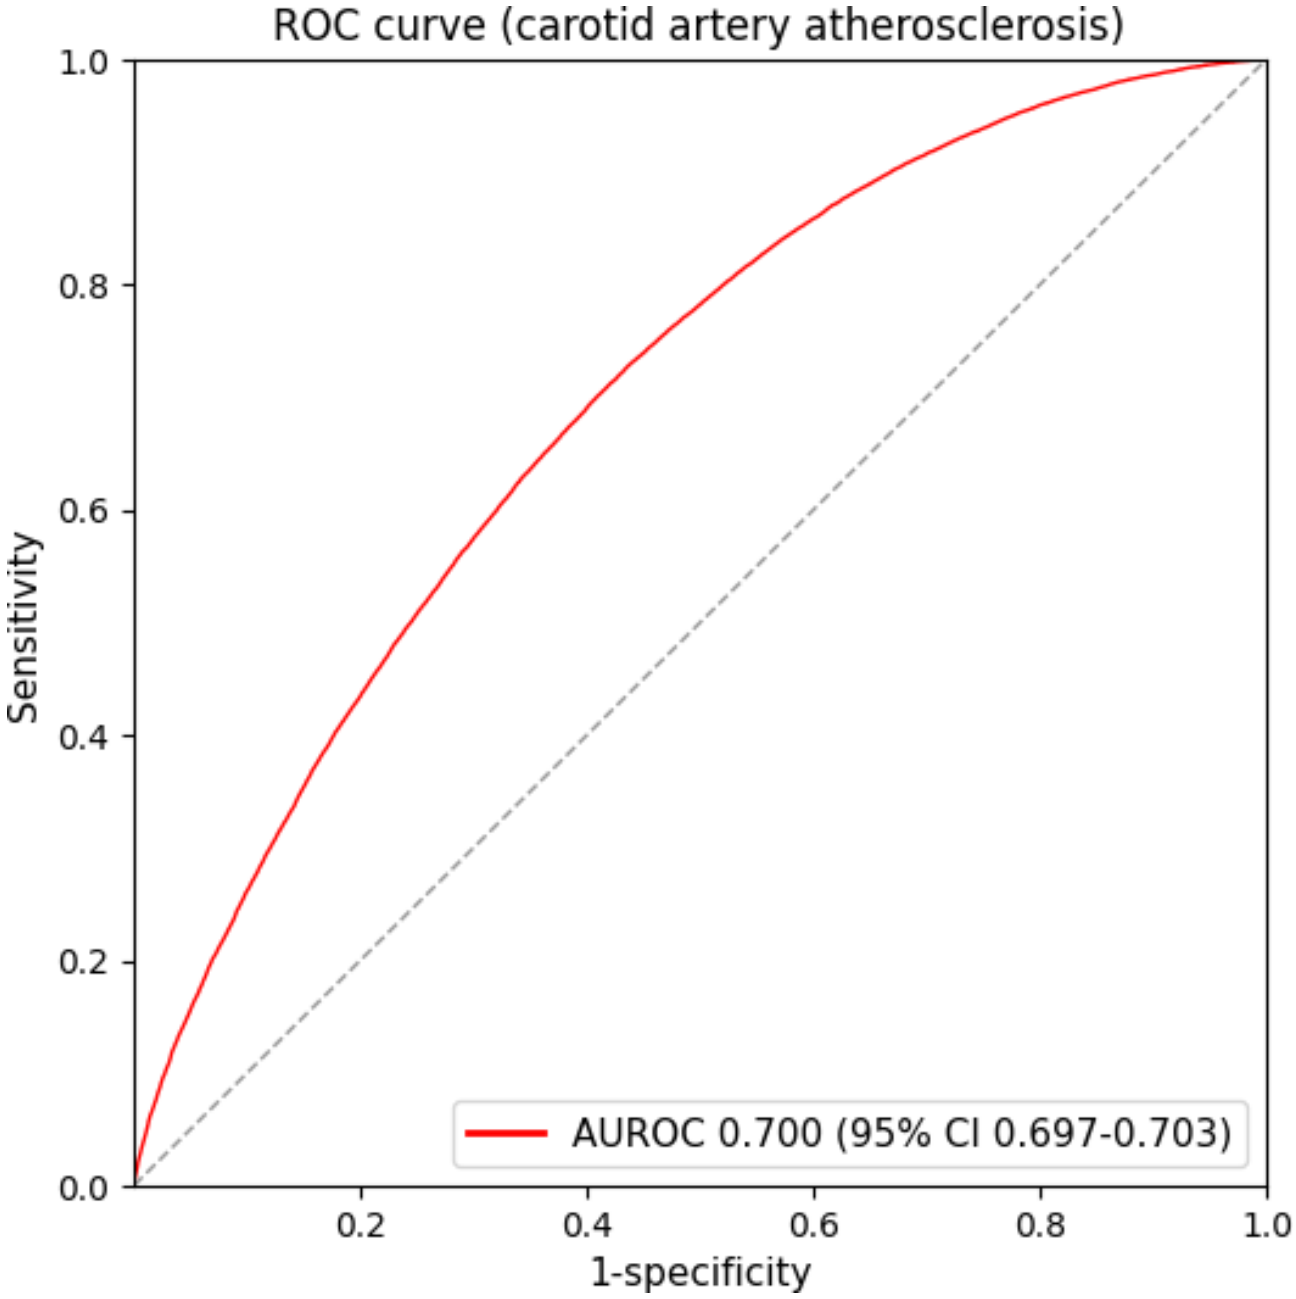
[d]CAC: coronary artery calcium.

[e]PCE: Pooled Cohort Equations.

[f]KRS: Korean Coronary Heart Disease Risk Score.

Individuals in the higher DL-FAS risk group represented a more at-risk spectrum (Table 1), with older age (median 37, IQR 31-44, to 52, IQR 44-60, to 64, IQR 57-69, y, *P*<.001), a higher proportion of males (10,770/20,566, 52.4%, to 45,275/75,748, 59.8%, to 8112/12,668, 64%, *P*<.001), and increased prevalence of diabetes mellitus (316/14,069, 2.2%, to 4555/54,537, 8.4%,

XSL•FO
RenderX



to 1699/9354, 18.2%, *P*<.001) and hypertension (886/14,069, 6.3%, to 11,512/54,537, 21.1%, to 3652/9354, 39%, *P*<.001), along with higher PCE scores (mean 2%, SD 3.9%, to 6.5%, SD 8.1%, to 14.9%, SD 13%, *P*<.001). Additionally, individuals in the higher DL-FAS risk group had a greater prevalence of carotid artery atherosclerosis (3924/19,601, 20%, to 37,339/72,868, 51.2% to 9001/12,300, 73.2%, *P*<.001), higher CAC scores (mean 18, SD 175, to 61, SD 265, to 167, SD 444, *P*<.001), and a greater proportion of CAC >400 cases (24/2279, 1.1%, to 399/9757, 4.1%, to 226/1915, 11.8%, *P*<.001). Baseline characteristics of participants across the 5 MediCheck health-promotion centers are presented in Table S2 in Multimedia Appendix 1.

Model Performance

DL-FAS demonstrated an AUROC of 0.700 (95% CI 0.697 - 0.703) for carotid artery atherosclerosis in external validation (Figure 2). Across the 5 MediCheck health-promotion centers, AUROC values ranged from 0.671 (95% CI 0.660 - 0.681) to 0.765 (95% CI 0.758 - 0.771; Table S3 in Multimedia Appendix 1). At a threshold of 0.368, which was determined in the previous study to maximize the F_1-score [14], DL-FAS demonstrated a sensitivity of 0.882, specificity of 0.364, PPV of 0.561, and NNS of 1.782 (Table S4 in Multimedia Appendix 1). At an operating point corresponding to approximately 80% specificity (threshold=0.565), DL-FAS achieved a sensitivity of 0.435, PPV of 0.667, and NNS of 1.499. DL-FAS demonstrated good calibration for carotid artery atherosclerosis, with close agreement between predicted risk and observed prevalence across deciles (Figure S1 in Multimedia Appendix 1, expected calibration error=0.022). For the subset without missing data required for PCE calculation (n=74,818), the AUROC of the PCE for carotid artery atherosclerosis was 0.788 (95% CI 0.785 - 0.791).

XSL•FO
RenderX

Figure 2. ROC curve showing overall external validation performance of deep-learning funduscopic atherosclerosis score for carotid artery atherosclerosis. AUROC: area under the receiver operating characteristic curve; ROC: receiver operating characteristic.

The median and IQR of DL-FAS progressively increased with the severity of carotid artery findings, from normal to increased CIMT, atheroma, and stenosis (Figure S2 in Multimedia Appendix 1). DL-FAS was also positively correlated with CAC scores (Spearman rank correlation coefficient=0.34, *P*<.001), with its median and IQR progressively increasing across higher CAC score categories.

In sensitivity analyses separating the composite carotid end point, DL-FAS demonstrated progressively higher discriminative performance when restricting outcomes to established atherosclerotic lesions (Figure S3 in Multimedia Appendix 1, AUROC 0.700, 95% CI 0.697-0.703, for the composite definition including CIMT thickening, 0.708, 95% CI 0.705-0.712, for atheroma or stenosis, and 0.778, 95% CI, 0.768-0.787 for carotid stenosis alone). In the corresponding precision-recall analyses, AP was 0.658 (95% CI 0.653-0.662) for the composite definition, 0.631 (95% CI 0.626-0.636) for atheroma or stenosis, and 0.135 (95% CI 0.124-0.147) for carotid stenosis alone. In the sensitivity analysis comparing single-eye and bilateral-average DL-FAS scores, differences were observed in both the AUROC (0.691, 95% CI 0.684-0.697, vs 0.711, 95% CI 0.708-0.715, *P*<.001) and the median DL-FAS score (0.526, IQR 0.392-0.642, vs 0.477, IQR 0.366-0.580, *P*<.001) between the 2 subgroups (Table S5 in Multimedia Appendix 1).

For CAC prediction, AUROC was 0.701 (95% CI 0.692 - 0.710) for CAC score >0, 0.709 (95% CI 0.696 - 0.721) for CAC score >100, and 0.713 (95% CI 0.694 - 0.732) for CAC score >400 (Figure S4 in Multimedia Appendix 1).

Regression Analyses Results

Among the 104,769 DL-FAS cases labeled for carotid artery atherosclerosis and the 13,951 DL-FAS cases labeled with CAC scores, a total of 74,818 and 9636 cases, respectively, had complete data with no missing values and were included in the regression analyses. Most baseline characteristics showed small SMDs between included and excluded participants (Table S6 and S7 in Multimedia Appendix 1). Moderate SMDs were observed for some variables, particularly those with substantial missingness resulting in smaller available sample sizes for comparison.

Tables 2 and 3 present the results of the logistic regression analyses. To facilitate more intuitive interpretation, the DL-FAS, originally scaled from 0 to 1, was rescaled to a range of 0 to 10 by multiplying by ten. This adjustment allows the ORs displayed in Tables 2 and 3 to represent the change in odds associated with a 10% absolute increase in the DL-FAS after accounting for other relevant clinical variables.

Table . Adjusted odds ratios of DL-FAS[a]*10 for carotid artery atherosclerosis. To facilitate a more intuitive interpretation, the DL-FAS, originally scaled from 0 to 1, was rescaled to a 0 - 10 scale by multiplying by 10. Accordingly, the reported odds ratios represent the change in odds for carotid artery atherosclerosis associated with a 10% absolute increase in DL-FAS, after adjustment for the PCE[b] score.

After adjusting for the PCE score, a 10% absolute increase in the DL-FAS was associated with an OR of 1.29 (95% CI 1.28 - 1.31, *P*<.001) for carotid artery atherosclerosis (Table 2). The association between DL-FAS and carotid artery atherosclerosis remained significant in several subgroups: a 10% absolute increase in the DL-FAS was associated with an OR of 1.25 (95% CI 1.23 - 1.27; *P*<.001) in the PCE low-risk group, 1.09 (95% CI 1.06 - 1.13; *P*<.001) in the PCE moderate-risk group, 1.29 (95% CI 1.27 - 1.31; *P*<.001) among participants aged <60 years, 1.30 (95% CI 1.28 - 1.33; *P*<.001) in females, and 1.27 (95% CI 1.25 - 1.29; *P*<.001) in males. No significant association was observed in the PCE high-risk group (*P*=.58) or among participants aged ≥60 years (*P*=.14). ORs for all covariates are provided in Table S8 in Multimedia Appendix 1.

When DL-FAS was added to a logistic regression model including the PCE variables, the category-free NRI for carotid artery atherosclerosis was 0.082 (95% CI 0.068 - 0.097), driven by improvements in both event reclassification (event NRI=0.020, 95% CI 0.010 - 0.031) and nonevent reclassification (nonevent NRI=0.062, 95% CI 0.052 - 0.072; Table S9 in Multimedia Appendix 1).

After adjusting for the PCE score, a 10% absolute increase in the DL-FAS was associated with an OR of 1.29 (95% CI 1.24 - 1.33, *P*<.001) for CAC score >0 (Table 3). The association between DL-FAS and CAC score >0 remained significant in several subgroups: a 10% absolute increase in the DL-FAS was associated with an OR of 1.17 (95% CI 1.11 - 1.24; *P*<.001) in the low-risk group, 1.10 (95% CI 1.02 - 1.17; *P*=.01) in the moderate-risk group, 1.30 (95% CI 1.23 - 1.37; *P*<.001) among participants aged <60 years, 1.27 (95% CI 1.19 - 1.35; *P*<.001) in females, and 1.30 (95% CI 1.24 - 1.37; *P*<.001) in males. No significant association was observed in the high-risk group (*P*=.89) or among participants aged ≥60 years (*P*=.79). ORs for all covariates are provided in Table S10 in Multimedia Appendix 1.

We additionally conducted analyses using higher CAC score thresholds. After adjusting for the PCE score, a 10% absolute increase in the DL-FAS was associated with a higher adjusted OR of 1.31 (95% CI 1.24 - 1.38; *P*<.001) for CAC score >100 in the overall cohort (Table S11 in Multimedia Appendix 1). The association was even stronger for CAC score >400, with an adjusted OR of 1.34 (95% CI 1.24 - 1.44; *P*<.001; Table S12 in Multimedia Appendix 1). Similar associations were observed across subgroups, particularly among participants with low and moderate PCE-based CVD risk, those aged <60 years, and both sexes.

Among the 108,982 participants who underwent at least one of either carotid ultrasonography or CAC scoring, 9738 received both examinations, of whom 6700 had complete data and were included in the dual-labeled subgroup regression analyses. In this subgroup, DL-FAS remained significantly associated with carotid artery atherosclerosis, CAC presence, and higher CAC burden (Table S13 in Multimedia Appendix 1). Consistent associations were also observed for composite outcomes defined as either carotid artery atherosclerosis or CAC >0, as well as for the concurrent presence of both conditions, further supporting that DL-FAS reflects systemic atherosclerotic burden across multiple vascular territories.

Sensitivity analyses recalculating the PCE by coding all participants as African American yielded results materially consistent with the primary PCE-adjusted analyses, confirming that the overall associations were preserved (Table S14 in Multimedia Appendix 1, carotid artery atherosclerosis: adjusted OR 1.27, 95% CI 1.26 - 1.29; CAC score >0: adjusted OR 1.24, 95% CI 1.20 - 1.29; CAC score >100: adjusted OR 1.28, 95% CI 1.22 - 1.36; CAC score >400: adjusted OR 1.31, 95% CI 1.21 - 1.42). Using the Korean Coronary Heart Disease Risk Score for adjustment yielded consistent associations between DL-FAS and all outcomes, confirming that the overall associations were preserved despite the use of a population-specific risk model (Table S15 in Multimedia Appendix 1, carotid artery atherosclerosis: adjusted OR 1.34, 95% CI 1.32 - 1.36; CAC score >0: adjusted OR 1.36, 95% CI 1.31 - 1.41; CAC score >100: adjusted OR 1.41, 95% CI 1.34 - 1.48; CAC score >400: adjusted OR 1.45, 95% CI 1.35 - 1.57). Multiple imputation analyses yielded results that were materially consistent with those from the complete-case analyses for both carotid artery atherosclerosis and CAC (Tables S16 and S17 in Multimedia Appendix 1). Additional adjustment for examination center yielded DL-FAS associations that were materially consistent with the primary PCE-adjusted analyses (Tables S18 and S19 in Multimedia Appendix 1, carotid artery atherosclerosis: adjusted OR 1.38, 95% CI 1.36 - 1.40; CAC score >0: adjusted OR 1.34, 95% CI 1.29 - 1.40). Although significant between-center differences in outcome odds were observed relative to the reference center, the DL-FAS association remained robust after accounting for this variation.

Clinical Workflow Integration Evaluation

In the PCE low-risk group, 32.2% (117/363) of those labeled high-risk by DL-FAS (0.67 - 1 range) had CAC, exceeding the overall CAC >0 proportion in the PCE low-risk group (1101/6183, 17.8%, *P*<.001; Figure S5A in Multimedia Appendix 1). In the PCE moderate-risk group, DL-FAS risk categorization did not significantly alter the proportion of individuals with CAC >0. As an additional exploratory analysis, we also dichotomized DL-FAS at the prespecified midpoint threshold of 0.5. Individuals in the PCE low-risk group with a DL-FAS of 0.5 - 1.0 had a significantly higher CAC >0 proportion than the overall PCE low-risk group (576/2293, 25.1%, vs 1101/6183, 17.8%, *P*<.001; Figure S5B in Multimedia Appendix 1). Sensitivity analyses using alternative PCE race coding showed that the overall findings of the workflow-integration analysis were preserved, with CAC enrichment observed in the recalculated PCE low-risk group (Figure S6 in Multimedia Appendix 1).

Discussion

Principal Findings

This study externally validated DL-FAS, an AI-derived score for carotid artery atherosclerosis generated from retinal fundus images, using multicenter health checkup data and demonstrated its generalizability. Despite being developed specifically for carotid atherosclerosis detection, DL-FAS was significantly

XSL•FO
RenderX

associated with both carotid artery atherosclerosis and coronary artery calcification, suggesting its potential as a noninvasive marker associated with systemic atherosclerotic burden and cardiovascular risk stratification.

Clinical Implications

The ability to assess atherosclerosis risk noninvasively using AI applied to retinal fundus images represents a transformative shift in preventive cardiology. Given that both CAC and CIMT are established predictors of ASCVD events [19,20,27,28], early detection of atherosclerosis is critical for initiating timely preventive measures. Although current strategies—such as the PCE followed by selective CAC scoring [24]—are well established for cardiovascular risk stratification, CAC measurement and carotid ultrasonography are not routinely performed at the population level because of accessibility constraints, cost considerations, limited insurance coverage [29,30], and, in the case of CAC, radiation exposure. In this context, retinal fundus imaging offers a noninvasive, low-cost, and widely available alternative that is already integrated into ophthalmologic practice and general health screenings, with increasing availability through portable and mobile devices even outside traditional clinical settings [31]. In this study, DL-FAS was independently associated with both carotid atherosclerosis and CAC, and showed a modest correlation with CAC, suggesting its role as an adjunctive risk marker rather than a direct surrogate. By leveraging routinely acquired retinal images, DL-FAS may help extend cardiovascular risk assessment to broader populations and support earlier identification of individuals at elevated risk, thereby informing prevention strategies and improving long-term cardiovascular outcomes.

DL-FAS showed a significant association with both carotid atherosclerosis and CAC even among individuals in the PCE low- and moderate-risk groups and those younger than the age of 60 years. In these subgroups, conventional risk calculators may underestimate the presence of asymptomatic vascular disease, leading to missed opportunities for timely intervention [32]. Detecting early vascular pathology in younger individuals is especially impactful, as it offers a longer window for preventive action and may alter the trajectory of disease progression. The observed association of DL-FAS with both carotid atherosclerosis and CAC in these populations suggests its utility as an additional, noninvasive tool to enhance cardiovascular risk assessment. In contrast, in this validation cohort, DL-FAS showed no detectable independent signal for either carotid atherosclerosis or CAC among adults aged ≥60 years after adjustment. This pattern may partly reflect a ceiling effect, whereby baseline cardiovascular risk and outcome prevalence are already high, limiting incremental discrimination by DL-FAS for cross-sectional atherosclerosis markers in older adults. It is also plausible that a substantial component of the model signal reflects general vascular aging rather than specific atherosclerotic pathology independent of age. As current preventive cardiology workflows often focus on older adults, the absence of a detectable independent signal among participants aged ≥60 years limits the role of DL-FAS as a standalone marker for cross-sectional atherosclerosis enrichment in this population. In this validation cohort, its potential role may therefore be more relevant to opportunistic enrichment of systemic vascular risk in younger or conventionally lower-risk individuals. However, this finding should not be interpreted as excluding the potential relevance of DL-FAS for longitudinal cardiovascular outcomes in older adults. In the original DL-FAS cohort study by Chang et al (2020) [14], DL-FAS was independently associated with cardiovascular mortality, including among participants aged ≥50 years (age ≥50 years subgroup: middle vs lowest tertile, adjusted hazard ratio 2.66, 95% CI 1.15 - 6.17; highest vs lowest tertile, adjusted hazard ratio 5.09, 95% CI 2.25 - 11.6; *P* for trend <.001). Therefore, further longitudinal studies are needed to determine whether DL-FAS remains associated with longitudinal cardiovascular outcomes in older populations, even when its adjusted association with cross-sectional carotid atherosclerosis or CAC is limited in this validation cohort.

In addition, we explored how DL-FAS may potentially be integrated into clinical workflows by evaluating its role in guiding targeted CAC screening. In our analysis, DL-FAS enriched CAC detection within the PCE low-risk group. Current cholesterol management guidelines primarily recommend CAC measurement for selected borderline- to intermediate-risk individuals when the decision about statin therapy remains uncertain, whereas routine CAC scoring is not recommended for PCE low-risk individuals [24]. Therefore, using DL-FAS to guide targeted CAC screening among PCE low-risk individuals would represent a potential extension beyond current guideline-defined indications. Nevertheless, our findings suggest that DL-FAS may help opportunistically identify, within the PCE low-risk population, a subgroup with a higher likelihood of CAC that might otherwise be missed under usual care. In such individuals, detection of CAC could inform more intensive preventive management, including consideration of statin therapy, although this proposed approach would require prospective validation before clinical implementation. Regardless of whether a DL-FAS threshold of 0.67 or 0.5 was applied, individuals in the PCE low-risk group above the threshold had a significantly higher CAC >0 proportion than the overall PCE low-risk group. Lowering the threshold from 0.67 to 0.5 captured a substantially larger subgroup, suggesting that the operating threshold may be adjusted depending on the intended balance between CAC enrichment and population coverage. However, expanding CAC screening to PCE low-risk individuals on the basis of DL-FAS would need to be weighed carefully against the potential increase in downstream testing, radiation exposure, costs, and false-positive burden in a lower-prevalence population. We also evaluated the incremental improvement in risk reclassification using the category-free NRI, which was statistically significant but modest in magnitude. Although this suggests that the impact of DL-FAS on individual-level risk reclassification may be limited, even modest improvements may be meaningful in the context of large-scale opportunistic screening—particularly given that retinal fundus imaging is already routinely performed in many health checkup settings—where such gains can accumulate at the population level without requiring additional testing.

The clinical relevance of DL-FAS may be better assessed by whether it provides additive information beyond conventional

XSL•FO
RenderX

risk assessment, rather than by whether it outperforms a composite clinical risk score built from multiple established risk factors. Indeed, in the subset with complete data, the standalone discrimination of DL-FAS for carotid atherosclerosis was lower than that of the PCE. Nevertheless, as discussed above, DL-FAS remained significantly associated with carotid atherosclerosis after adjustment for the PCE score, identified subgroups within the PCE low-risk population with a higher prevalence of CAC than the overall low-risk group, and yielded a statistically significant category-free NRI when added to a model including the PCE variables. Accordingly, DL-FAS may be best positioned as an adjunctive tool to complement existing risk assessment frameworks rather than as a standalone decision-making tool.

Potential Mechanisms

The ability of an AI model trained on retinal fundus images to predict carotid atherosclerosis—and its association with CAC—raises intriguing questions about the underlying pathophysiology captured by the deep learning model. One plausible explanation is the shared vascular pathology between the retinal, carotid, and coronary circulations [7-9]. Atherosclerosis is a systemic disease affecting multiple vascular territories, including the coronary, carotid, and peripheral arteries [15-18]. The retina provides a noninvasive window into the systemic vasculature, with its microvasculature reflecting early atherosclerotic changes that parallel those occurring in larger arteries [33-35]. AI may be detecting subtle vascular features, such as microvascular remodeling [36,37], vessel caliber [38-41], or vessel tortuosity [42], which are indicative of systemic atherosclerosis but not readily quantifiable by human observers. Another possibility is that AI leverages global image patterns beyond visible vascular features, capturing complex structural and textural characteristics that correlate with systemic atherosclerotic burden. Prior studies have shown that retinal imaging can predict systemic biomarkers such as demographic information (age and sex), anthropometric measures (eg, height, weight, and muscle mass), blood pressure, serum creatinine, hemoglobin, and red blood cell count [10,11,43]. Our findings further extend this concept, suggesting that AI can extract complex patterns and features from retinal images that may reflect aspects of systemic vascular changes related to atherosclerosis.

Strengths of This Study

This study has several strengths. First, it represents a large-scale external validation of DL-FAS using multicenter health checkup data, leveraging data from 108,982 participants across 5 centers, ensuring its generalizability across diverse regions and health care settings. Second, because health checkups embody the principles of preventive medicine—primarily targeting asymptomatic individuals to proactively detect early-stage diseases and implement primary prevention when necessary—this study validated DL-FAS in a population where the identification of cardiovascular risk factors yields the greatest clinical benefit. Third, this study provides novel insights by linking DL-FAS to CAC, expanding its clinical implications beyond carotid atherosclerosis. Fourth, the robustness of the findings was further supported by sensitivity analyses using a Korean population-calibrated cardiovascular risk model, addressing potential concerns related to the applicability of Western population-derived risk equations. Fifth, sensitivity analyses separating CIMT thickening from plaque-based carotid endpoints demonstrated that DL-FAS showed higher AUROC for established atherosclerotic lesions, suggesting stronger rank-order discrimination for more advanced disease. This finding should be interpreted together with the precision-recall analysis: although AP for the stenosis-only endpoint was low in absolute terms, it was substantially higher than the prevalence-anchored baseline, with an AP of 0.135 compared with a baseline prevalence of 3.6%, indicating performance above random expectation but still limited positive predictive performance for this rare endpoint. Sixth, despite external validation in a multicenter cohort, DL-FAS exhibited favorable calibration, supporting its generalizability and potential clinical applicability.

Limitations and Future Directions

This study's findings should be interpreted in light of the following limitations. First, this study was conducted in a South Korean elective health checkup cohort, which may limit generalizability to populations with different ethnic or racial backgrounds, baseline cardiovascular risk profiles, and disease prevalence. As carotid atherosclerosis prevalence was relatively high in our cohort, the PPVs observed here may be more optimistic than those expected in general primary care or broader screening settings with lower prevalence. Accordingly, the real-world false-positive burden associated with a given DL-FAS threshold may be greater than implied by our results. Future studies should include validation in more diverse international and lower-prevalence populations to better establish generalizability and clinical utility. Second, we observed intercenter heterogeneity in DL-FAS score distributions and threshold-based risk categorization across the 5 MediCheck centers. The differences in the proportion of participants classified as high risk suggest that fixed DL-FAS thresholds may be sensitive to site-specific factors, including differences in fundus camera hardware, illumination conditions, image acquisition protocols, operator expertise, and image quality assessment practices. As image quality control relied on subjective assessments of clinical interpretability at each center without standardized criteria, additional center-specific variability and selection bias may also have been introduced. Accordingly, DL-FAS score distributions and threshold-based classifications may not be directly transportable across imaging environments without adjustment. These findings suggest that DL-FAS should not be considered a device-agnostic tool for immediate uniform deployment and that site-specific calibration, standardized or automated image quality control, and prospective validation may be necessary to ensure reproducibility, safety, and generalizability in real-world clinical practice. Third, we did not evaluate whether DL-FAS predicts actual cardiovascular events, which requires further longitudinal datasets. Fourth, individuals with stents identified on CT reports were excluded to better reflect the intended DL-FAS screening context among individuals without clearly documented established ASCVD. However, this may introduce spectrum bias and limit generalizability to populations with established

XSL•FO
RenderX

CVD. As the available medical history and medication information lacked sufficient granularity, other forms of prior ASCVD could not be reliably identified; therefore, participants with prior ASCVD other than CT-documented stents may have been retained. Accordingly, the findings should be interpreted as reflecting a health checkup population excluding clearly documented stent cases, rather than a cohort definitively free of established ASCVD. Fifth, although the F_1-score–optimized threshold provides high sensitivity, its low specificity may increase false positives in opportunistic screening. We therefore additionally reported performance at a higher-specificity operating point to illustrate sensitivity-specificity trade-offs. In practice, threshold selection should depend on clinical context, highlighting the need for flexible operating points rather than a single fixed cutoff. Sixth, although most baseline characteristics were well balanced between participants included in vs excluded from the regression analyses, moderate differences were observed for some variables with substantial missingness, leading to smaller effective sample sizes for comparison. Accordingly, some degree of selection bias from complete-case analysis cannot be excluded, and this should be considered when interpreting the regression results. In addition, although we performed multiple imputation by chained equations as a sensitivity analysis, this method assumes that data are missing at random. Given the elective health-checkup setting, this assumption may not fully hold, as missingness may have been related to unmeasured factors such as socioeconomic status or health literacy, and some residual bias may therefore remain despite the use of multiple imputation, potentially affecting the precision or magnitude of the estimated associations. Seventh, we did not provide interpretability for DL-FAS predictions, limiting insight into the features driving model outputs. In addition, due to data access restrictions, the original retinal images are no longer accessible, precluding post hoc interpretability analyses or independent verification. Future work should incorporate visual interpretability methods, such as class activation mapping, to verify that predictions are driven by clinically relevant retinal vascular features. Eighth, the operating threshold (≈80% specificity) was derived and evaluated within the same validation dataset, which may introduce optimistic bias due to data leakage. This threshold was intended to illustrate clinically relevant trade-offs rather than to define a fixed cutoff. Future studies using independent datasets or cross-validation are needed to establish more robust thresholds. Ninth, although we adjusted the regression models using the PCE score as a summary measure of conventional cardiovascular risk, the PCE was originally developed to predict longitudinal 10-year cardiovascular events rather than cross-sectional atherosclerotic outcomes. Accordingly, this approach may not fully account for confounding in the present analytic context. Tenth, the single-eye subgroup showed slightly lower AUROC and higher median DL-FAS score than the bilateral-average subgroup. However, this finding may partly reflect potential selection bias related to single-eye image availability, rather than a limitation that invalidates the use of single-eye DL-FAS values. Moreover, because averaging bilateral eye-specific scores can reduce score variance, applying the same fixed thresholds to single-eye and bilateral-average scores may partly affect risk-group assignment independent of biological signal. Lastly, involvement of the model developer in the initial dataset construction and preliminary analyses may raise concerns regarding the perceived objectivity of the external validation. Although all statistical analyses reported in this paper were performed by an investigator affiliated with Seoul National University and unaffiliated with the model-developing company, full independence of the validation process was not ensured. Future studies conducted by fully independent investigators using independently curated datasets are warranted to further confirm robustness and objectivity.

Conclusions

In conclusion, this study externally validated the AI-based funduscopic carotid atherosclerosis score using a large, multicenter health checkup dataset and demonstrated its association with both carotid artery atherosclerosis and coronary artery calcification. These findings highlight its potential as a noninvasive biomarker associated with systemic atherosclerotic burden and cardiovascular risk stratification, particularly in the context of opportunistic screening.

Acknowledgments

The authors confirm that no generative AI tools were used in this paper's generation.

Funding

This study was supported by a contract research project commissioned by XAIMED Co, Ltd, to Seoul National University Hospital (0620240830). This research was supported by a grant of the Korea Health Technology R&D Project through the Korea Health Industry Development Institute (KHIDI), funded by the Ministry of Health & Welfare, Republic of Korea (RS-2022-KH129902). The funder had no involvement in this study’s design, data collection, analysis, interpretation, or the writing of this paper.

Data Availability

Data are available from the institutional review boards of the Korea Association of Health Promotion and Seoul National University Hospital only to researchers who meet the criteria for accessing confidential data. This restriction is in place because the data contain potentially identifying or sensitive patient information, and distributing them without proper regulation could breach patient confidentiality. Authors' Contributions

CH and JC had full access to all of the data in this study and take responsibility for the integrity of the data and the accuracy of the data analysis.
Concept and design: CH, JC, SMP
Acquisition, analysis, or interpretation of data: JC, CH
Drafting of the manuscript: CH
Critical review of the manuscript for important intellectual content: SC, HK, SK, KHK, JK, HL
Statistical analysis: CH, JC
Obtained funding: KHK
Administrative, technical, or material support: SMP, KHK
Supervision: SMP

Conflicts of Interest

This study used the deep-learning funduscopic atherosclerosis score (DL-FAS), an AI model developed by XAIMED Co, Ltd. SMP is the chief executive officer and holds ownership of XAIMED Co, Ltd, and JC is the Chief Technology Officer of XAIMED Co, Ltd. JC had full access to this study's data and contributed to the statistical analysis. The authors disclose this involvement to ensure transparency regarding the external validation process. All other authors declare no competing interests.

Abstract

Background: Advances in medical imaging have led to massive archives, yet navigating these datasets remains challenging due to the limitations of traditional text-based search engines. While content-based medical image retrieval (CBMIR) offers a visual feature–based solution to enhance clinical workflows and research, its operational integration into picture archiving and communication systems (PACS) remains a significant bottleneck. Despite the progress in deep learning for feature extraction, CBMIR tools are rarely integrated and effectively implemented within existing radiology information systems due to complex protocol barriers.

Objective: To address these challenges, this study develops a CBMIR system meticulously designed to cater to 7 distinct types of brain tumors as seen in brain magnetic resonance images. Our system is tailored to assist radiologists and health care professionals in efficiently retrieving pertinent historical medical images, thereby providing quantitative decision support for radiologists and facilitating evidence-based case comparison, with the potential to improve retrieval efficiency and clinical workflow, rather than directly enhancing diagnostic accuracy.

Methods: The dataset used in this study was collected from a single medical center and is not publicly available. The core innovation is a state-of-the-art deep learning–based feature extraction algorithm specifically engineered for the CBMIR system. We use GoogLeNet as the primary architecture, incorporating generalized mean pooling to capture nuanced local features and an embedding layer for dimension reduction. Crucially, we address the integration gap by harmonizing 2 open-source projects to successfully embed the CBMIR system into a functional PACS environment via standard protocols.

Results: The image dataset contains 658 participants with 15,873 images collected from 2000 to 2017. The empirical findings of our research demonstrate the performance and robustness of the proposed CBMIR system. Our system achieves a remarkable mean average precision score of 89.16% and an equally impressive Precision@10 score of 94.08%. These metrics affirm the system's efficacy in retrieving relevant medical images. Furthermore, we successfully integrate the CBMIR system into a PACS by successfully harmonizing 2 open-source projects.

Conclusions: This study presents the design and implementation of a PACS-integrated CBMIR system for brain magnetic resonance imaging, and the experimental results demonstrate that the system can achieve efficient and accurate image retrieval within a clinical workflow.

Introduction

Background

Advances and rapid growth in medical imaging technology have led to the emergence of massive medical image archives. Effective image retrieval is crucial for both research and clinical applications, yet navigating these large-scale archives remains a time-consuming task, often limited by traditional text-based search engines [1]. Radiologists, in particular, face the challenge of interpreting cross-sectional studies composed of thousands of images retrieved from picture archiving and communication systems (PACS) [2].

PACS is a health care IT system that manages the storage, retrieval, distribution, and presentation of medical digital images within a hospital. It works closely with the DICOM (Digital Imaging and Communications in Medicine) standard, which ensures that medical images and related data are stored and transmitted in a consistent format across different machines and systems. To integrate a third-party system, it must interface directly with the PACS via the DICOM protocol. This integration is critical as it allows health care providers to successfully access and share patient images within their workflows, enabling the content-based medical image retrieval (CBMIR) system to function effectively as a clinical decision support tool.

CBMIR offers a more efficient solution by enabling image searches based on the visual features of source images. CBMIR systems have the potential to significantly enhance clinical imaging workflows, delivering meaningful improvements across multiple areas, including medical education, research, and clinical diagnostics [3].

Röhrich et al [4] found that integrating CBMIR into medical imaging reduced image interpretation time by 31.3% for both junior and senior radiologists, while also helping them access more valuable consultative resources. When combined with an intelligent interactive visual browser, CBMIR could further enhance medical education, research, and clinical care by improving both image navigation and diagnostic outcomes [1]. Müller et al [5] highlighted the usefulness of CBMIR in academic settings, particularly for lecturers and students who can visually explore educational image repositories, facilitating more engaging and insightful learning experiences.

The retrieval principle encompasses several key aspects that collectively contribute to the effective retrieval of information. In particular, intricate processes are involved, such as analyzing and converting user requisites into queries suitable for retrieving data from indexed databases. In the process of CBMIR operation, the features of the images, relying on captions, visual words [6], preannotations [7], and image attributes [8], are first extracted and stored in a database. A distance metric summarizing information about image features measures the similarity between any given pair of images [9,10]. During CBMIR development, the key components are feature extraction and similarity determination [8], with feature extraction being the crucial step. In the past, CBMIR techniques have focused on semantic content matching of images, for example, analyzing and retrieving images based on their color, texture, and layout. Ponciano-Silva and colleagues [11] addressed the limitations of past CBMIR systems that typically used only a single perceptual parameter (ie, feature extraction and distance function), thus restricting such systems to a single search space.

In recent years, the rapid development of artificial intelligence (AI) technology and significant improvements in image processing capabilities have led to the application of AI technology to enhance CBMIR performance. The powerful algorithmic capabilities of deep learning have also been applied to CBMIR systems. Maji et al [12] compared the accuracy of various AI pretrained models, such as DenseNet [13], InceptionResNetV2 [14], InceptionV4 [14], MobileNetV2 [15], ResNet50 [16], and VGG19 (Visual Geometry Group model 19) [17]. They concluded that InceptionResNetV2 exhibited the highest accuracy and chose it as the feature extraction model. They further proposed using principal component analysis and clustering methods to increase retrieval speed by at least a factor of 2.

Rashad et al [18] adopted pretrained deep learning models to extract additional high-level features from medical images to improve the accuracy of the retrieved results in extracting compact, deep, and high-level features. Cheng and colleagues [19] tackled the limited texture representation of brain tumor images in traditional image processing methods. They used the Fisher Vector to aggregate local features into a single vector and used closed-form metric learning to effectively measure similarity between 2 given images. They achieved a mean average precision (mAP) of 94.8%. While this method achieved excellent accuracy, the concatenation of feature vectors from various subregions led to a high dimensionality of up to 24,576, potentially resulting in decreased query speed.

Qayyum et al [20] collected a diverse medical image dataset encompassing 24 anatomical regions and various imaging modalities. They used deep learning to train and build an 8-layer model whose architecture transforms 4096 features into a probability distribution over 24 categories. The average accuracy achieved in classification was 99.76%. They found that without prior classification and querying, mAP reached a mere 53%, while performing classification before querying improved mAP to 69%. Swati et al [21] focused on a contrast-enhanced magnetic resonance imaging brain tumor dataset [22] and used the pretrained VGG19 model (Visual Geometry Group model 19) for fine-tuning transfer learning (TL). Their study applied deep learning by using the last fully connected layer to extract the features, which is the input of the closed-form metric learning for contrast-enhanced magnetic resonance imaging to achieve a mAP of 96.13% [21]. Deepak and Ameer [23] evaluated various pretrained model architectures in terms of classification accuracy, training time, and feature extraction time. They selected GoogLeNet as the basis for their deep learning architecture, requiring a 2-stage training process; the achieved mAP was 97.64%.

Vision Transformer (ViT)–based models have demonstrated significant advantages when dealing with large datasets, enabling them to attend to critical image features, superior capacity for global feature modeling and context awareness,

XSL•FO
RenderX

and thereby improve medical image classification performance [24]. For instance, Anupama and Anitha [25] developed a ViT-based CBMIR system that reliably and precisely extracts pertinent medical images. The predicted results, particularly for magnetic resonance imaging data, confirm the model's capability to manage intricate imaging characteristics and provide precise outcomes [25]. Furthermore, studies by Sunday et al [26] highlight the use of the DINOv2 self-supervised framework to enhance anatomical structure visibility and reduce image noise. This demonstrates the potential of general-purpose self-supervised models in CBMIR, offering high transferability and robustness to varying image quality without requiring extensive domain adaptation [26]. In related work, Sarıateş and Özbay [27] used a TL framework to successfully classify melanoma images and enhance the efficiency of their content-based image retrieval systems.

However, due to technological bottlenecks that have yet to be overcome, CBMIR is rarely used in existing PACS and radiology information systems [1]. CBMIR could greatly benefit researchers and physicians in PACS [28-31]. Valente et al [32] used the open-source PACS software Dicoogle (University of Aveiro) as the development base for CBMIR for clinical applications. Besides general image, they focused on a mammography profile specifying the mammography features, allowing users to access CBMIR features integrated with a PACS to ensure high scalability.

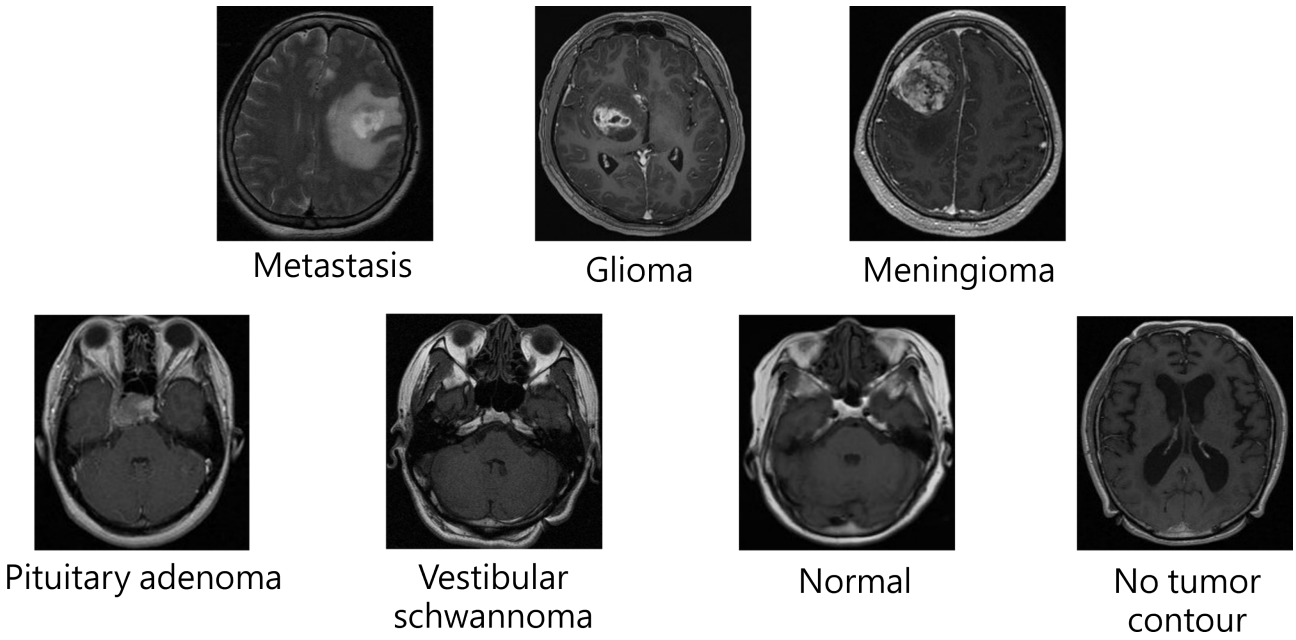
Our Contributions

Our primary contributions are summarized as follows: This study proposes an innovative CBMIR approach using ArcFace Loss [33] to enhance the understanding of image feature similarity and replaces the pooling layer with generalized mean (GeM) pooling. This allows the model to focus on key regions while preserving overall image information. This strategy strengthens the feature space's discriminability, resulting in significantly improved retrieval accuracy (mAP). We developed a robust CBMIR system successfully integrated with open-source DICOM viewer named BlueLight [34], achieving real-time clinical applicability by enabling rapid consultation of structurally similar cases.

Methods

Dataset

We gathered from Taipei Veterans General Hospital (TVGH) a comprehensive collection of brain magnetic resonance (MR) images formatted in DICOM. This image dataset was retrospectively collected and features a wide array of neurological conditions. These conditions have been categorized into 7 distinct groups: metastasis, glioma, meningioma, pituitary adenoma, vestibular schwannoma, and categories for images with no tumor contour and those representing normal brain scans.



All classes of tumors were delineated by neurosurgeons and validated by neuroradiologists from the TVGH, referred to as "ground truth." Table 1 provides statistics regarding the classes of tumors in the dataset. The image dataset, comprising 658 participants, was divided into training (70%, 461 participants, 11,207 images) and test (30%, 197 participants, 4666 images) subsets collected from 2000 to 2017. The median age was 56.4 years. Gender distribution was 57% (375/658) male and 43% (283/658) female. The distribution of image laterality was 52% left and 48% right. The median tumor volume, excluding normal images, was 2.02 mL, calculated from manual segmentation of lesions in MR images. Some patients underwent Gamma Knife radiosurgery that contains both pre–radiation therapy images and follow-up images. No patient overlapped between the training and test sets. Data in the test subset were not augmented. Examples of all classes of tumors are shown in Figure 1.

Table . Classification of tumors in the dataset.

Class	Training set	Test set	Total
Metastasis	1479	651	2130
Glioma	1484	633	2117
Meningioma	1466	632	2098
Pituitary adenoma	1520	629	2149
Vestibular schwannoma	1492	645	2137
No contour	2387	884	3271
Normal brain	1379	592	1971
Overall	11,207	4666	15,873

XSL•FO
RenderX

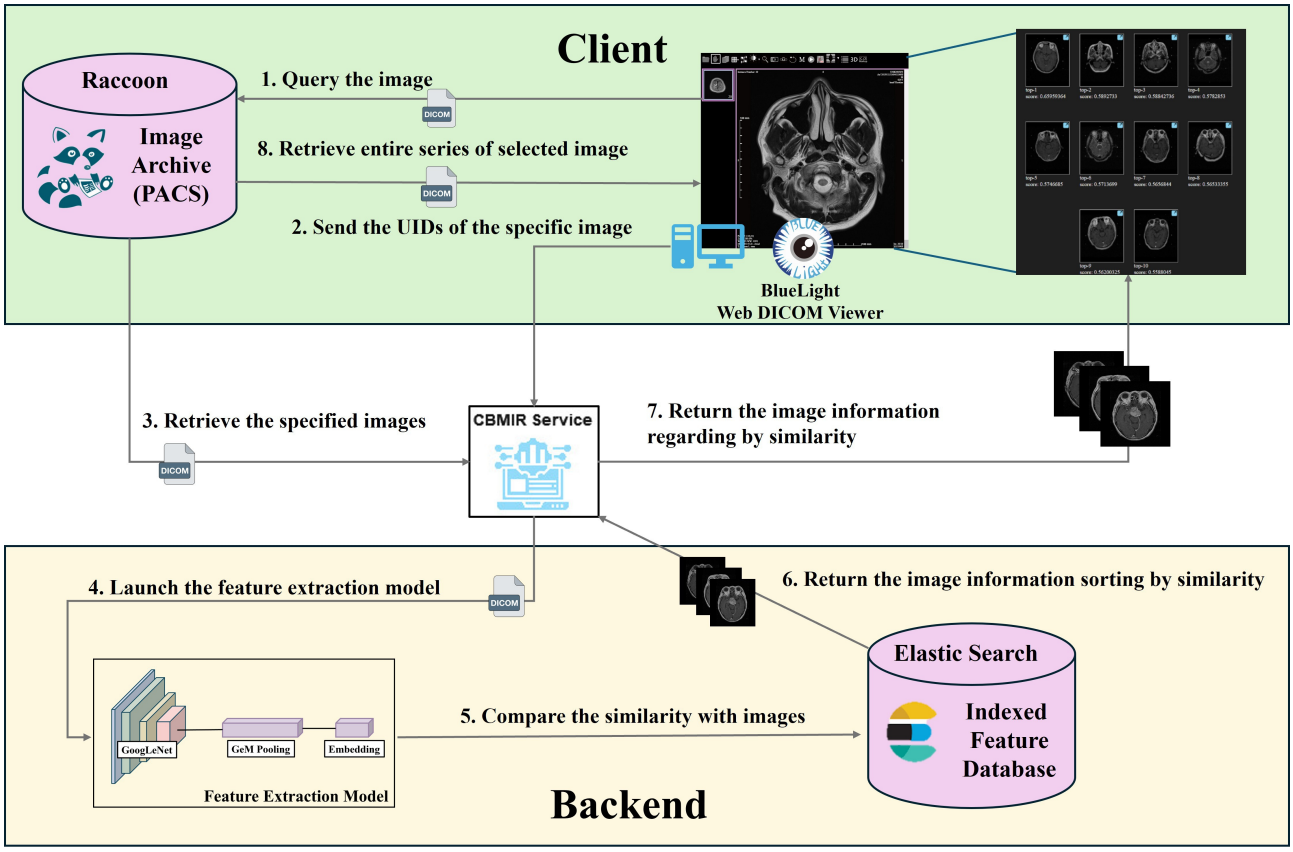
Figure 1. Examples of all tumor classes.

A brain image is inherently composed of a series of image slices, constituting a set that encompasses images both with and without tumor contours. In real-world clinical scenarios, such a dual presence of image types is a common occurrence. Focusing solely on images displaying tumors would inadvertently result in the exclusion of those lacking tumor contours, thereby impeding the accurate extraction of the latter. To mitigate this challenge, we implemented a strategy to segregate such images into a distinct category labeled “no tumor contour.” This deliberate classification enables us to effectively handle and differentiate images without tumor contours, thereby enhancing the comprehensiveness of our dataset and ensuring a more accurate analysis.

Imaging Parameters

All images were acquired using consistent imaging acquisition protocols, detailed as follows. MR scans were obtained using 1.5T parametric MR scanners from manufacturers General Equipment and Philips. Each image had a spatial resolution of 512×512 pixels, with 16-bit depth per pixel, and a slice thickness of 3 mm. The imaging protocols included both T1-weighted (T1W) and T2-weighted (T2W) sequences. These sequences were conducted as follows: (1) T1W+C: acquired using axial 2D spin echo (repetition time = 416 ms, echo time = 9 ms, flip angle = 90°). (2) T2W: acquired using axial 2D spin echo (repetition time = 4050 ms, echo time = 109 ms, flip angle = 90°).

Image Preprocessing and Augmentation



The original 512×512-pixel single-channel DICOM images were resized to 224×224 pixels using bilinear interpolation. Although the GoogLeNet backbone, integrated with GeM pooling, supports variable spatial dimensions, this specific scale was selected to align with the ImageNet pretraining distribution. Such standardization optimizes the balance between representation learning and computational efficiency, significantly reducing graphics processing unit memory footprint and inference latency. To leverage pretrained weights without altering the input layer, the resulting grayscale images were stacked into 3 identical channels (red-green-blue). Finally, while the training set underwent data augmentation (including random rotation, flipping, and scaling) to enhance robustness, the test set remained nonaugmented to ensure an evaluation reflective of clinical practice. This choice represents a practical trade-off between computational efficiency and spatial resolution, which is appropriate for large-scale similarity retrieval rather than pixel-level diagnosis.

System Architecture

The CBMIR system, including the feature extraction model, is illustrated in Figure 2. As seen therein, radiologists can select the images they wish to query for the CBMIR system within the web DICOM viewer. Upon selection, the query image is initially input into a pretrained AI model for feature extraction. Subsequently, CBMIR takes these feature vectors and matches them against the database, retrieving images with similar feature vectors from the database. For each search, the user sends a single query request containing 3 DICOM UIDs: the Study Instance UID, Series Instance UID, and SOP Instance UID. In response, the CBMIR system retrieves the specified image from the PACS and sends it to the feature extraction model. After processing, the retrieved images are then presented in the web DICOM viewer. Finally, the user can select the most closely related image and retrieve the entire study from the PACS server.

Feature Extraction Model

The foundational network of the feature extraction model architecture is based on GoogLeNet, with a modification replacing the original global average pooling with GeM pooling [35] to obtain more generalized features. Finally, an embedding layer is added to reduce the feature dimensions from 1024 to 256, compressing the data for improved computational efficiency. An explanation of each of the components of the model follows in the subsections, including (1) GoogLeNet, (2) GeM pooling, (3) embedding, and (4) the loss function.

1. *GoogLeNet layer*: The primary design core is the inception architecture, which uses 1×1 convolutional layer to reduce dimensionality, thereby lowering computational complexity. The inception architecture also splits the input into various sizes for parallel processing and subsequently aggregates them to extract features at various scales. The choice of GoogLeNet as the network backbone in this study is influenced by a previous study [23]. According to their results, GoogLeNet demonstrates several advantages over other potential network backbones, including lower computational complexity (number of operations), minimal memory consumption (parameter count), higher validation accuracy, shorter training time, and faster feature extraction. Furthermore, although ResNet50 exhibits higher accuracy, its training time is approximately 3 times that of GoogLeNet. Therefore, ResNet50 was not considered for this study due to our preference for efficient computation.

2. *GeM pooling layer*: GeM pooling was proposed by Ponciano-Silva et al [11] as a method that uses a universal formula to replace traditional global max pooling, that is,

$$(1) f(m)=f1(m)\ldots fkm\ldots fK(m)\ ,fkm=\max x\in Xkx,$$

and global average pooling, that is,

$$(2) f(a)=[f1(a)\ldots fk(a)\ldots fK(a)]\ ,fk(a)=1|Xk|\sum x\in Xkx$$

Formula equation (3) shows the process of GeM pooling, which uses a 3D tensor x with dimensions $W \times H \times K$ as input to compute the result, represented as the f vector.

$$(3) f(g)=[f1(g)\ldots fk(g)\ldots fK(g)]\ ,fk(g)=(1|Xk|\sum x\in Xkxpk)1pk$$

In this formula, pk is a parameter that determines the norm level. When $pk\to\infty$, GeM pooling becomes equivalent to max pooling; when $pk=1$, it simplifies to average pooling. Although pk can be treated as a trainable parameter, in this study, it was fixed to $pk = 3$ for all experiments, following prior image retrieval benchmarks [35]. This design choice ensures a stable and reproducible feature embedding space across all evaluations.

By maintaining pk as a constant rather than a trainable parameter, we ensure a stable feature embedding space, particularly when processing domain-specific medical images. This approach contributes to improved accuracy and consistency in image retrieval tasks.

- 3. *Embedding layer*: The embedding layer exists primarily to reduce the dimensionality of the output from the global pooling layer. In this study, we used an embedding structure [33,36] that consists of a sequence of FC (fully connected) − BN (BatchNorm) − PReLU (parametric rectified linear

XSL•FO
RenderX

unit) layers. The FC layer maps the original 1024-dimensional features to 256 dimensions while attempting to preserve the original features as much as possible. The BN layer normalizes the values to mitigate the problem of vanishing gradients, and the PReLU layer adds nonlinearity to the model.

- 4. *Loss function*: This study uses the ArcFace loss function [33], as represented in formula equation 4.

$$(4) L=-1b\log es(\cos(\theta yi+m))es(\cos(\theta yi+m))+\sum j=1,j\neq yines\cos\theta j$$

In this formula, *b* represents the batch size, *s* corresponds to the fixed feature values after L2-normalization,θyi represents the weight and angle between the correct class and feature, and *m* controls the additional angle for separating different classes. The primary objective of this loss function is to ensure that embedding features from different classes are pushed as far apart as possible while keeping embedding features from the same class close together.

Enhanced Feature Discriminability and Aggregation Strategy

In our feature extraction model, 2 key techniques were used to optimize the quality and representativeness of the feature vectors.

ArcFace loss significantly increases the quality and purity of the feature clusters. This robust separation ensures that when the system queries an image, the retrieved results are demonstrably and reliably from the most similar cluster, thus leading to higher retrieval accuracy and confidence.

GeM Pooling allows the network to intelligently decide where to focus its attention for feature extraction. It enables the model to effectively highlight the most relevant regional features (like specific pathological textures) while retaining sufficient global structural context for comprehensive retrieval, making the resulting feature vector more representative of the entire image.

Indexed Features

We use Elasticsearch as the indexing database due to its native support for high-dimensional vector storage that supports a data type for feature vectors and can perform similarity evaluations on vectors that enable retrieval of data results sorted by similarity. The features are 1024-dimensional embeddings extracted from the GoogLeNet backbone. To enhance searching performance, the indexing phase involves the following steps:

For the core similarity calculation between feature vectors (per image), we adopt the Euclidean Distance defined in formula equation 5. This metric calculates the straight-line geometric distance between 2 feature vectors in the high-dimensional space. The retrieval results are then precisely ranked based on this distance, where a smaller distance signifies higher similarity.

To significantly enhance retrieval efficiency, we used a precalculation strategy. During the indexing phase, we precalculate and store the similarity difference values between each image and all other images in the database. Each image record is uniquely identified by 3 UIDs: Study instance UID, Series instance UID, and SOP instance UID. When a new image is queried, the system calculates its distance to the query and uses this preestablished similarity difference lookup table for comparison, which avoids the traditional method of sequentially searching and calculating every single entry.

It should be noted that this precalculation strategy is primarily designed for intradatabase browsing and retrospective analysis and applies only to images that have already been indexed. For new query images not included in the database, similarity computation is performed on the fly using the Hierarchical Navigable Small World (HNSW) algorithm, which is the default vector search method provided by Elasticsearch. Specifically, when a new query image is submitted, its feature vector is extracted and compared against the indexed feature vectors using HNSW-based approximate nearest neighbor search.

Similarity Calculation

The similarity between feature vectors of different samples is typically measured using distance metrics to gauge the closeness or dissimilarity of each sample. In this study, we used the Euclidean distance, as represented in formula equation 5.

$$(5) D(p,q)=(p1-q1)2+(p2-q2)2+\ldots+(pn-qn)2 Similarity sore(p,q)=1D(p,q)$$

Here, *p* represents the feature vector of the image that the user wishes to query, and *q* represents the feature vector of the image stored in the database. The Euclidean distance measures the real distance between any 2 elements in an *n*-dimensional space. While a smaller Euclidean distance mathematically signifies higher feature-level similarity, we transformed these raw distances into "Similarity Scores" via an inverse distance mapping for display within the CBMIR interface. This ensures that higher scores directly reflect closer visual matches, thereby aligning the computational output with standard clinical assessment logic. This design choice aligns with the study's objectives by leveraging the capacity of deep learning models to encode semantic relationships as geometric distances within a high-dimensional feature space, while ensuring that the retrieval outputs are presented in a format intuitive for clinical practitioners.

Evaluation Factors

Once the CBMIR system is developed, objective evaluation metrics are essential to assess its performance. In this context, mAP and Precision@10 are commonly used evaluation measures [19,21,23]. mAP is extended from precision and average precision (AP). Precision is a fundamental metric and is defined as

$$(6) Precision=Relevant images\frown Retrieved images Retrieved images.$$

Precision is often computed as Precision@k for various values of *k*, where *k* is typically set to 10, 20, or 30. This computation helps determine the performance of the retrieval results when a certain number of images are returned. However, precision provides insight into performance only at a specific rank. AP extends precision by considering all ranks of retrieved images. AP is defined as

$$(7) AP=\sum k=1nPrecision(k)\times rel(k)Relevant images rel(k)=\{1, if image is relevant image 0, otherwise$$

Here, *rel*(*k*) is a binary indicator, assuming a value of 1 if the image at rank *k* is relevant and 0 otherwise. AP provides a more comprehensive view of retrieval performance than ordinary precision. However, AP is typically used for a single query; to

XSL•FO
RenderX

assess retrieval performance across multiple queries, mAP is used. mAP is defined as

(8)mAP=∑q=1nAP(q)Q.

Here, *Q* represents the total number of queries, and *q* denotes the current query number. mAP gives an aggregate performance measure across multiple queries, providing a more comprehensive evaluation of the CBMIR system's effectiveness than ordinary precision measures could provide.

Ethical Considerations

This study was conducted according to the guidelines of the Declaration of Helsinki and approved by the Institutional Review Board (1) of TVGH (protocol code 021-05-0005CC; approval date: March 14, 2023). Informed consent was waived because of the retrospective nature of the study and the use of deidentified clinical data.

Results

Overview

In this study, the image dataset contains 658 participants with 15,873 images collected from 2000 to 2017. The experimental environment for this study used the following hardware specifications: an AMD Ryzen 3 PRO 4200G CPU, 24 GB of DDR4 memory, and a dedicated Nvidia GeForce RTX 3060 Ti Graphics Card. The graphics processing unit features 4864 CUDA cores and 8 GB of GDDR6 video memory. The operating system used was Linux Ubuntu (version 22.04; Canonical). For software development, the primary Integrated Development Environment used was PyCharm (JetBrains). The programming language was Python (Python Software Foundation), and the deep learning framework used for code development was PyTorch (PyTorch Foundation).

Evaluation of AI Models for Feature Extraction Model

In evaluating the base feature extraction model for the CBMIR system, our core focus was centered on balancing model performance with clinical use and efficiency. To ensure that the system delivers fast, effective retrieval services within a real-world clinical workflow, we conducted a comprehensive comparative analysis of several state-of-the-art AI models when evaluated on the dataset. This comparison was intended to assess how modern, large-scale ViT architectures perform on the dataset relative to established CNNs (Convolutional Neural Networks).

For consistency and to leverage learned feature representations, TL was applied for all models. Each model was initialized with ImageNet pretrained weights and subsequently fine-tuned on our dataset. To explicitly examine the trade-off between model capacity and dataset size, we evaluated both base-scale ViT architectures (Swin-Base and DinoV2-Base) and their lightweight variants (Swin-Tiny and DinoV2-Small). The comparative results incorporating 95% CIs are shown in Table 2.

The results indicate that, under this TL setting and dataset scale, ViT-based models exhibit higher computational complexity and do not achieve superior retrieval performance compared with the CNN-based approach. In contrast, GoogLeNet demonstrates consistent and robust superiority across accuracy, mAP, F_1-score, and computational efficiency. As evidenced by the clearly separated CIs in Table 2, GoogLeNet (95.9% accuracy) substantially outperforms the second-best architectures (upper bound 87.1%), supporting that its performance advantage is stable and unlikely to result from sampling variability. Therefore, within the context of TL on a specific clinical magnetic resonance imaging dataset, GoogLeNet was selected as the backbone feature extractor for the proposed CBMIR system.

Performance Evaluation for Feature Extraction Model

The feature extraction model underwent training for 150,000 iterations. To evaluate its performance, feature extraction was first applied to all images in both the training and test datasets. Next, the feature vectors from the test dataset were individually compared and ranked against those from the training dataset to measure the similarity between the respective images. Notably, an image was considered relevant (with rel(k)=1 in AP) if its category matched that of the query image.

A summary of the evaluation metrics, including mAP and Precision@10, is shown in Table 3 for each image class. These metrics assess the performance and retrieval quality of the model for each image class as well as overall. The overall mAP for the study was 89.16%, with a Precision@10 of 94.08%. The best performance was observed in the normal brain category, achieving a mAP of 94.95% (95% CI 94.32 - 95.58) and a Precision@10 of 97.57% (95% CI 97.13 - 98.01), indicating high reliability in identifying normal tissues.

The results show that the overall classification performance of this model was excellent, but its mAP for CBMIR was only 89.16%. This disparity highlights the difference between classification and image retrieval in practical terms. In classification, the main training objective of the AI model is to identify the tumor class to which the current image belongs. However, in image retrieval, the training objective must consider the similarity (distance relationship) between the current image and other images to learn the relationships between the features of each image in the pair of images. These are 2 conceptually distinct tasks.

[b]mAP: mean average precision.

Performance Evaluation for Tumor Classification

The main purpose of this study was to use an AI model to extract feature vectors for image retrieval. To realize this purpose, we chose to extend the ArcFace loss function, which is based on the softmax loss function, using a margin of 38 and a scale of 64, as the classification for a model that can theoretically be used for image classification. Therefore, this study also investigated the performance of the AI model for classification tasks. Table 4 shows the precision, recall, and F_1-score for each class, while Figure 3 provides the confusion matrix for each tumor class.

Table . Classification performance evaluation for each tumor class.

Tumor class	Precision, %	Recall, %	F_1-score, %
Metastasis	91.75	94.01	92.87
Glioma	98.17	93.36	95.71
Meningioma	99.02	96.36	97.67
Pituitary adenoma	99.68	97.93	98.80
Vestibular schwannoma	94.62	95.50	95.06
No tumor contour	88.79	89.59	89.19

Performance Comparison at Various Embedding Dimensions

In our study, ArcFace loss was used not merely for classification but as a feature embedding mechanism to ensure that images belonging to the same tumor class are mapped closer together in the embedding space, while those from different classes are more widely separated. This results in well-clustered and discriminative feature vectors, which form the necessary basis for our similarity-based retrieval. Hence, although these are distinct tasks, they are synergistically integrated within the same CBMIR system: classification helps structure the embedding space, thereby significantly enhancing the discriminative power and ultimately the retrieval performance of the system.

We initially drew inspiration from a study [37] in which the optimal embedding dimension for their specific objective of facial recognition was determined to be 128. However, we recognize that this dimension may not necessarily be optimal for brain tumor classification. Consequently, we undertook a comprehensive comparison of various embedding dimensions, as outlined in Table 5. The findings of this analysis unequivocally indicated that 256 dimensions yielded the highest performance for our retrieval task.

Furthermore, we note that the disparities in performance across dimensions, ranging from 64 to 512, were relatively marginal. This observation is particularly significant when considering the cost-effectiveness of deploying the model on devices with limited computational capabilities. Opting for a dimensionality of 64 can substantially curtail computational overheads while still maintaining respectable performance levels.

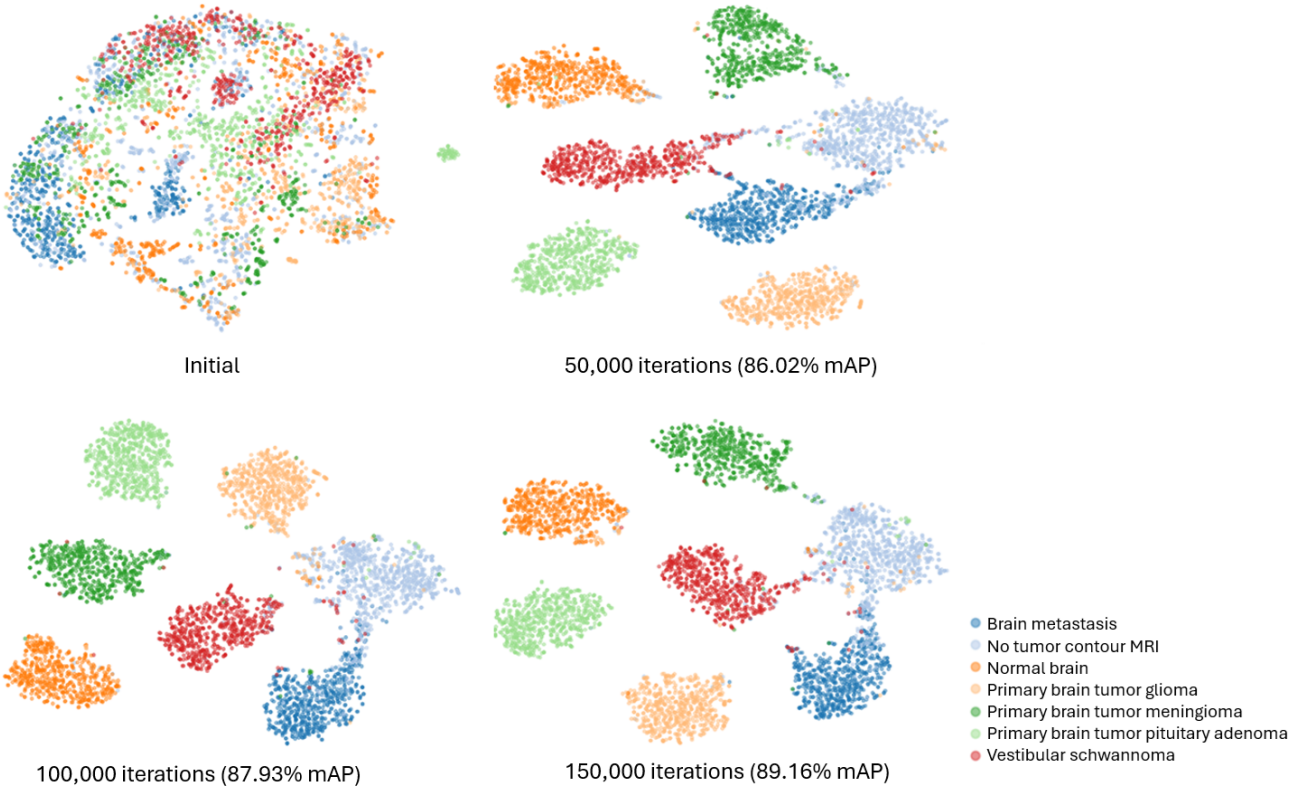
Table . Performance comparison of different embedding dimensions.

Embedding size	Overall mAP, %
64	88.16
128	88.76
256	89.16[a]
512	89.14



[a]Indicates the best performance in different various embedding dimensions.

Feature Vector Projection

Our methodology consolidated similar feature vectors while actively distancing dissimilar ones. While mAP serves as a useful indirect metric for assessing effectiveness, the feature vector coherence can be qualitatively assessed through projection. To qualitatively visualize the evolution of feature representations during training, we used t-distributed Stochastic Neighbor Embedding to project high-dimensional feature vectors into a lower-dimensional space. As a stochastic dimensionality reduction method, t-distributed Stochastic Neighbor Embedding is sensitive to parameter settings and is used here solely for qualitative inspection of learning trends rather than as quantitative evidence of feature space cohesion or class separability. The visual representation of feature vector projection is illustrated in Figure 4.

Figure 4 illustrates that the initially untrained feature vectors, denoted as "Initial," exhibit a scattered pattern with minimal cohesion among different classes. However, as training progresses through 50,000, 100,000, and 150,000 iterations, we observe a gradual convergence of feature vectors within each class, reflecting increasing cohesion. Concurrently, an observable qualitative visual separation implies that feature vectors from different classes become more distantly grouped, highlighting the model's progressive learning and adaptability.

Figure 4. Visual representation of feature vector projection using t-distributed Stochastic Neighbor Embedding across various training iterations. The projection was implemented with 3 components, a perplexity of 30, 1000 iterations, and the Euclidean metric. This visualization is intended to illustrate trends in feature learning rather than to provide quantitative evidence of class separation. mAP, mean average precision; MRI, magnetic resonance imaging.

System Integration With PACS

Our system operates as follows. Users can initiate image queries from the PACS and subsequently retrieve and display these images within BlueLight via the QIDO (query based on ID for DICOM Objects) and WADO (web access to DICOM objects) protocols, respectively. To use the CBMIR functionality, users provide the StudyInstanceUID, SeriesInstanceUID, and SOPInstanceUID for the specific DICOM image they require.

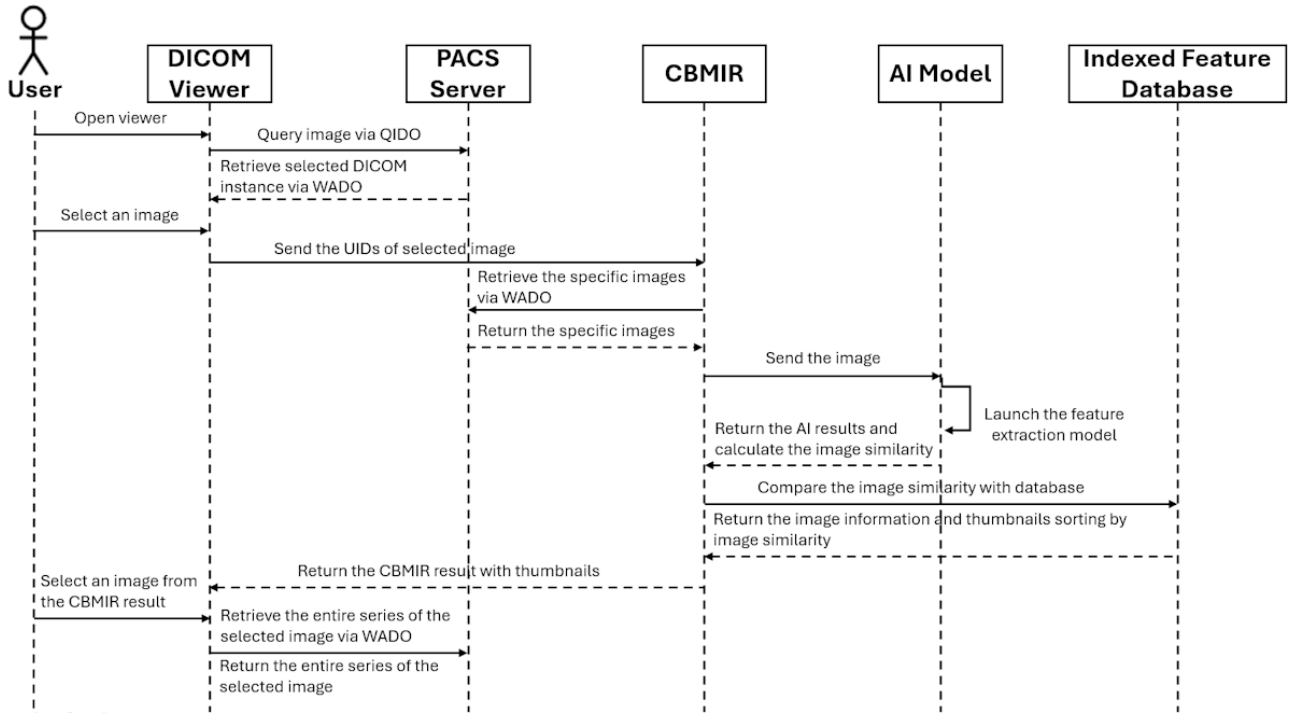
Once these details are specified, the CBMIR system retrieves the corresponding DICOM image from the PACS using WADO and then processes this image to calculate the CBMIR results, returning the top 10 images that bear the highest similarity to

XSL•FO
RenderX

the input image. The operational process and data workflow are depicted in Figure 5.

A demonstration video is provided in Multimedia Appendix 1, and a screenshot of the user interface of the CBMIR client prior to executing a search is shown in Figure 6A. To enhance the successful integration of our CBMIR system into clinical workflows, we integrated it with an open-source DICOM viewer known as BlueLight [34] and the DICOM server Raccoon [38]. This client application communicated with a PACS-supporting DICOMweb, significantly simplifying user access to and interpretation of brain tumor images, including the display of top retrieval results ordered by similarity scores (Figure 6B). Moreover, considering that brain images are inherently 3D, a single image may not always convey the complete information for a whole series of images. The system's workflow ensures that the entire series of images associated with a case is retrieved from the PACS, rather than just a single instance (Figure 6C).

Figure 5. Sequence diagram for the integration of content-based medical image retrieval with a picture archiving and communication system. AI: artificial intelligence; CBMIR: content-based medical image retrieval; DICOM: Digital Imaging and Communications in Medicine; PACS: picture archiving and communication system; UIDs: unique identifiers.



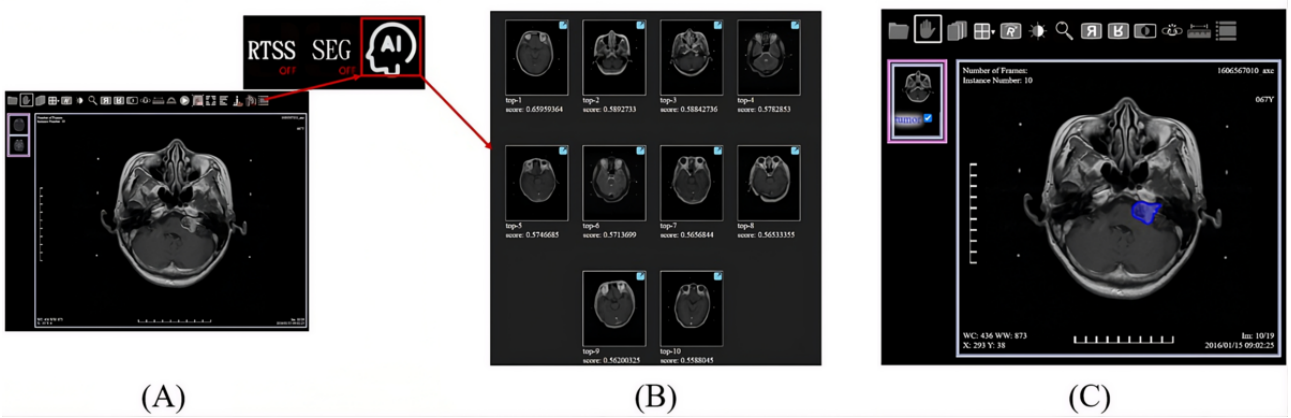


Figure 6. The user interface of the content-based medical image retrieval (CBMIR) services is integrated into a web Digital Imaging and Communications in Medicine viewer. (A) Before performing the CBMIR system; (B) Top 10 retrieval results ordered by descending similarity scores. A higher score denotes greater visual similarity between the query and the retrieved images; (C) Retrieve the selected whole series of images from picture archiving and communication system.

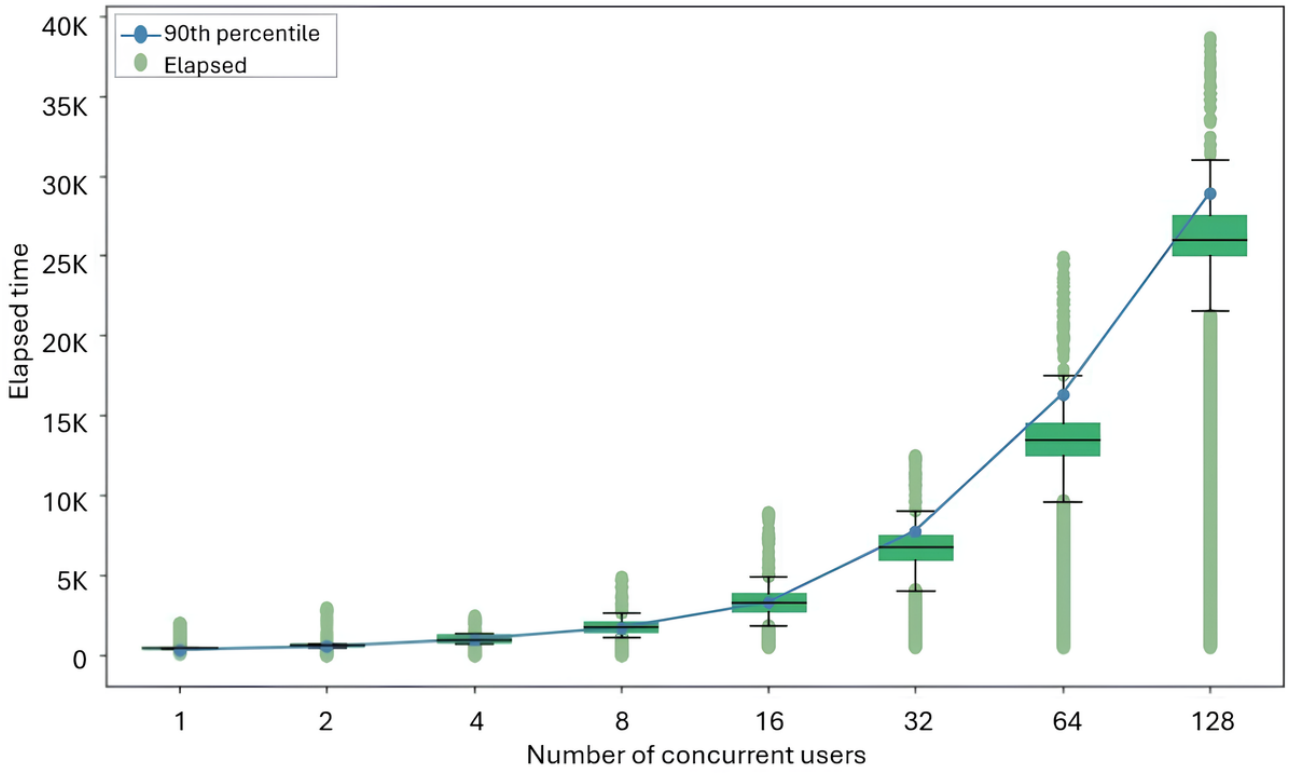
Performance of CBMIR System

During the usage of the CBMIR system, the "time" and "stability" of querying for similar images can significantly impact the overall operational process. Therefore, this study conducted a performance evaluation of the CBMIR system. The response time represents the end-to-end round trip for image retrieval, including WADO communication, database execution, and network transfer latency. The overall response time evaluation involved the following steps: (1) sending image to the CBMIR system, (2) retrieving images from PACS, (3) extracting image feature vectors using the CBMIR AI model,

XSL•FO
RenderX

(4) indexing image feature vectors into the database, (5) querying for similar images within the database, and (6) assessing the response time back to the user.



The stability assessment involved simulations with 2^*n* users, ranging up to 256 concurrent users, using the CBMIR system. The evaluation results are shown in Table 6; a box-and-whisker plot depicting the evaluation results is shown in Figure 7.

Additionally, as no system crashes or errors were observed for user counts ranging from 1 to 128, this study conducted further testing, revealing that when more than 256 users simultaneously used the system, all requests began to experience 30-second time-outs, the default value of request time-out for all web browsers, thereby all requests failed. The results demonstrate that as the number of concurrent users increases, the response time exhibits a nonlinear growth. Specifically, under extreme stress testing conditions (exceeding 64 simultaneous users), the variability in response time expands significantly. When the concurrent load surpasses 256 users, the system reaches its current architectural capacity limit, resulting in request time-outs (exceeding 30 seconds). These findings delineate the operational boundaries of the current implementation, indicating that while the system is stable for routine, low-concurrency clinical usage, high-concurrency scenarios impose a significant load that impacts real-time stability.

Table . Response time results under various user loads.

Users	Response time, ms		
	Average	Maximum	90th percentile
1	273.98	1373	333.00
2	434.48	2696	531.00
4	918.89	2233	1187.00
8	1758.38	4423	2219.00
16	3225.49	8230	3903.10
32	6432.68	12,541	7775.40
64	13629.18	24,391	16337.40
128	25672.47	39,196	28909.10

Figure 7. Relationship between the elapsed response time and the number of concurrent users in the content-based medical image retrieval system evaluation. The green box-and-whisker plots and scatter points display the statistical distribution of the response time (median, quartiles, and extreme values), while the blue line graph indicates the 90th percentile response time.

Discussion

Principal Findings

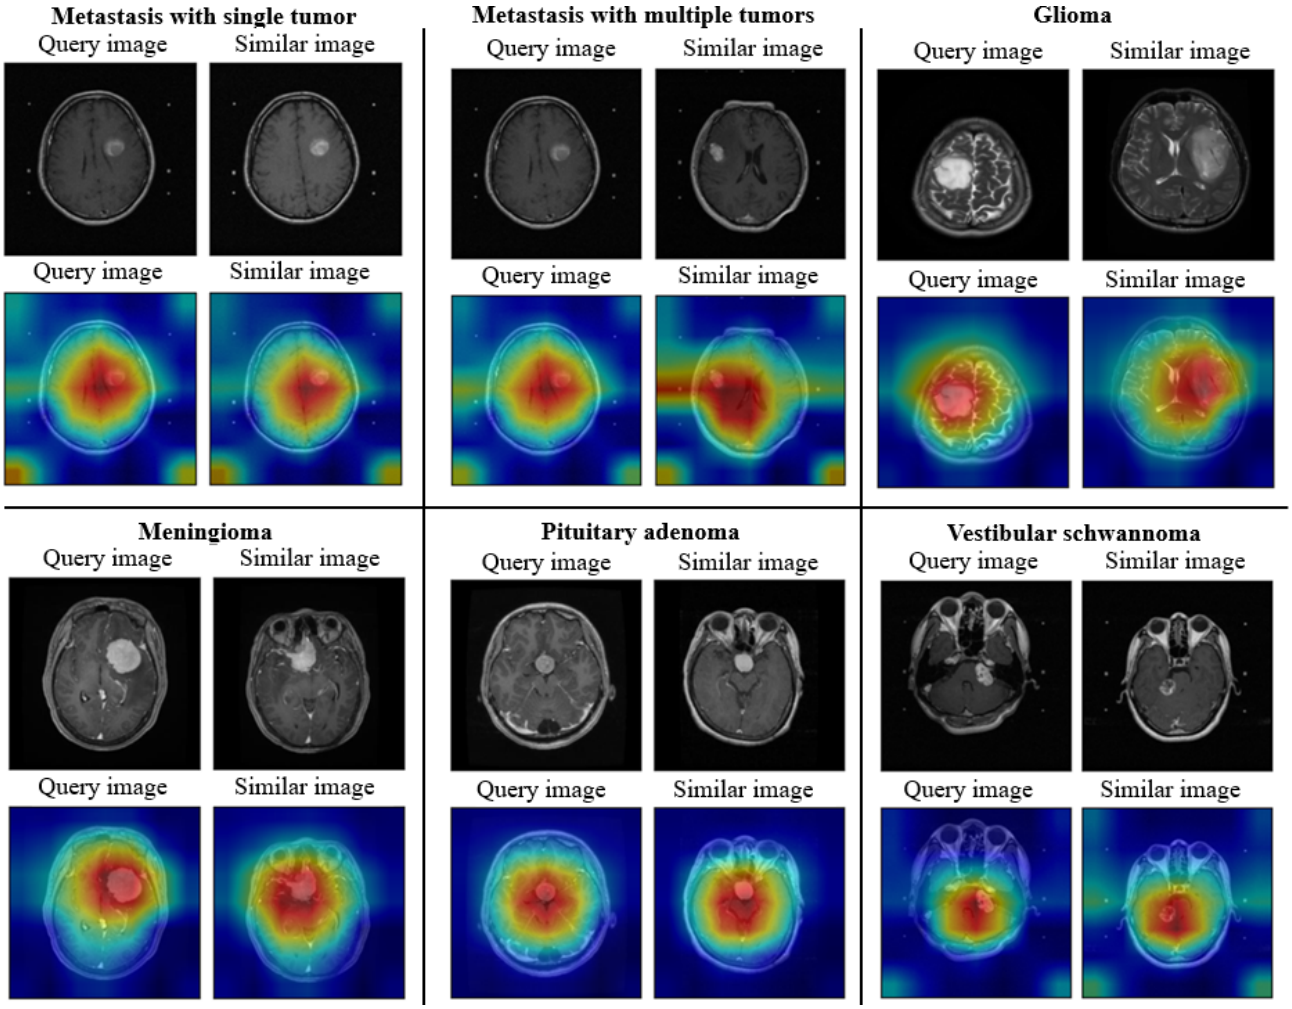
We developed and evaluated a CBMIR system tailored for brain tumor detection within a PACS environment. The results demonstrate a substantial improvement in retrieval accuracy enabled by the innovative deep learning architecture, enhancing feature discriminability. By integrating our AI model with 2 open-source tools—Raccoon for backend DICOM management and BlueLight for frontend web-based image viewing—our CBMIR system provides seamless, real-time decision support directly within the clinician's workflow. This practical integration helps bridge the gap between advanced AI retrieval techniques and routine clinical practice. This achievement represents an important step toward establishing the CBMIR system as a valuable tool for both clinical diagnosis support and medical research.

Rationale for GoogLeNet Selection

We selected GoogLeNet as the backbone feature extractor for our CBMIR system due to its demonstrated optimal balance between clinical use and overall performance.

1. *Performance versus computational cost*: As Table 2 illustrates, while ViT-based and deeper CNN architectures are state of the art in many domains, their performance metrics on our specific medical imaging task are significantly lower than those achieved by GoogLeNet. This discrepancy is likely influenced by the interaction between model complexity and the relatively homogeneous characteristics of the dataset. In contrast, GoogLeNet's moderate depth and multiscale receptive fields appear to facilitate more stable embedding learning and improved generalization in similarity-based retrieval scenarios.
2. *Overwhelming computational advantage*: GoogLeNet demonstrates a massive advantage in efficiency. Its Floating Point Operations are nearly one-tenth that of Swin (1.51 G vs 15.17 G), and its parameter count is approximately one-tenth that of the ViT models (6.8 M vs ≈85 M). Furthermore, its training time is significantly shorter (57 minutes vs ≈500 minutes).
3. *Critical clinical deployment consideration*: Given that a CBMIR system must be lightweight and support low-latency retrieval for real-time clinical use, efficiency is paramount. GoogLeNet provides a high mAP of 89.16% while maintaining minimal computational demands. Therefore, GoogLeNet was chosen as it achieves the best balance among accuracy, model compactness, and deployment efficiency, making it the superior foundation for our CBMIR architecture.

Heatmaps of Image Similarity



To provide interpretability for our CBMIR model's retrieval decisions, we used a visualization technique based on Gradient-weighted Class Activation Mapping, adapted for deep similarity networks following the approach introduced by Stylianou et al [39].

Our heatmaps aim to quantify the degree of feature matching between 2 images. Our methodology integrates Gradient-weighted Class Activation Mapping with the calculation of distances between the final convolutional layer and the pooling layer to gauge the level of attention or similarity across different regions within the images. In the visualization, regions exhibiting high similarity are represented in red, while those with lower similarity are depicted in blue. Figure 8 shows 5 examples of brain tumors, illustrating our primary goal of identifying images of brain tumors that share similarities. The ensuing sections showcase detailed heatmaps for each of the tumor classes.

For all tumor classes presented in Figure 8, except for the case of multiple tumors in metastasis, the examples used contain only a single tumor within the image. This choice was deliberate to ensure that the heatmaps clearly illustrate that retrieval similarity is based on matching the pathological features of the tumor (where the hot spot is located), rather than simply reflecting class probabilities as in a classification task. The high feature consistency observed between the query and retrieved images across these single-lesion cases strongly supports this interpretation. However, it is essential to note that while this analysis explains the underlying mechanism, the study does not draw definitive clinical conclusions regarding these results. It should be emphasized that these heatmaps are presented for qualitative illustration only. Determining whether such activation patterns correspond to meaningful anatomical features or to nonanatomical factors would require systematic image-by-image analysis, which is beyond the scope of this study.

XSL•FO
RenderX

Figure 8. Heatmaps of similar images for various tumor classes: query image and retrieved similar image with corresponding heatmaps.

Single Versus Multiple Tumors (Metastasis Cases)

We included metastasis cases with both single and multiple tumors within a single image. The heatmaps illustrate visually different activation patterns between these 2 scenarios. However, the primary focus of our analysis remains the observed differences in image similarity behavior between metastasis cases with multiple tumors and single-tumor cases, rather than the anatomical interpretation of activation maps.

1. *Single tumor*: In single-tumor cases, the query image heatmap shows a visually concentrated activation region (red or yellow) localized around the dominant lesion. The corresponding retrieved image exhibits a similarly localized activation pattern. This observation reflects a spatially focused activation pattern in both the query and retrieved images.
2. *Multiple tumors*: In multiple-tumor cases, the activation patterns appear more spatially distributed. While high-activation regions remain present near individual lesions, the heatmaps often extend into broader areas of the image. The similarity image heatmap exhibits horizontally distributed activation patterns or band-like structures. These patterns indicate a more dispersed activation distribution in images containing multiple lesions.

Clinical Considerations for Cross-Class Image Similarity

Our heatmap analysis differs from traditional methods, which often focus only on areas of interest within a single image for classification. Our objective is to describe and quantify the similarity between 2 images in terms of mutual focus on specific regions, an understanding pivotal for elucidating the model's retrieval effectiveness. Considering clinical evaluation, 2 radiologists (KHK and WYG) used the hospital's DICOM viewer to cross-validate brain tumor cases and assess the correctness of similarity scores between different tumor classes.

We acknowledge that highly similar images from the query results may not always belong to the same tumor class. Indeed, in some instances, the similarity score may be substantially higher for images assigned to other tumor classes. These cases indicate a significant degree of visual and structural image similarity, even if the retrieved image's classification label may not be totally accurate. The similarity score is calculated for the entire image. While a partial score calculated from the tumor lesion may result in a high score, it is worth noting that when 2 images share a similar location in an axial brain slice, the similarity of surrounding organs and structures may yield a higher final score than that of the tumor lesion alone.

This result shows a clinical potential use in identifying shared characteristics among images across tumor classes. However, it must be emphasized that definitive conclusions regarding

XSL•FO
RenderX

these results were not drawn in this study. To mitigate this potential disparity, the user interface has been thoughtfully crafted to label these images accordingly, providing a clear notification to the user regarding this outcome.

Normal Brain Versus No Tumor Contour

From a clinical perspective, the "Normal Brain" class represents images from patients without a brain tumor diagnosis, whereas the "No Tumor Contour" class consists of image slices acquired from patients with known brain tumors in which no visible lesion is present on the specific slice. Although these 2 classes may appear visually similar at the slice level, they differ fundamentally at the case level, which explains the observed confusion in similarity-based retrieval. Specifically, while the "Normal Brain" class achieves a high mAP of 94.95%, the "No Tumor Contour" class yields a lower mAP of 87.39%, which is below the overall average of 89.16%.

This confusion reflects a realistic diagnostic scenario in routine clinical practice, where individual slices without visible lesions may be indistinguishable from normal brain images. This observation highlights the system's ability to handle visually overlapping categories in routine clinical practice. The inclusion of these classes underscores the system's ability to handle visual overlaps based on deep feature embeddings learned from pixel-level representations, rather than pathology-specific descriptors. Consequently, the reported mAP reflects the global coherence of the learned visual embedding space across diverse clinical categories.

It should be noted that this behavior does not imply a false-negative diagnostic result, as the proposed CBMIR system is designed for similarity-based image retrieval rather than automated diagnosis. Instead, it underscores the necessity of contextual interpretation at the case or series level when reviewing retrieved images. To mitigate potential clinical misunderstanding, the system retrieves the complete image series rather than a single slice, allowing clinicians to examine adjacent slices where lesions may be present. The interface further indicates that tumor annotations exist elsewhere within the retrieved series.

Limitations

While this study successfully developed a high-performing CBMIR system and integrated it into PACS, there are limitations regarding dataset characteristics, system scalability, and model interpretability. First, regarding the dataset characteristics and partitioning, this study used a dataset spanning a long retrospective period (2000 - 2017) from a single medical center, acquired primarily on 1.5T scanners. Although this provided consistency in clinical protocols and image quality, it may limit the model's generalizability. In particular, robustness across different scanner manufacturers, field strengths (eg, 3T), and heterogeneous acquisition protocols remains to be systematically validated. Given the increasing prevalence of 3T scanning in modern neuro-oncology, the model's performance on higher-resolution and advanced acquisition protocols warrants further investigation, especially in multicenter clinical settings.

To ensure balanced class distributions for benchmarking, we used a random split strategy. Unlike a prospective temporal split, this approach introduces a potential for "future leakage" and may not fully simulate clinical deployment timelines. A temporal split, in which earlier data are used for training and later data for testing, may better reflect real-world clinical deployment scenarios and provide a more stringent evaluation of generalization across time. However, such a design requires strict longitudinal harmonization of acquisition protocols, and scanner variations could provide a more stringent assessment of real-world generalization and will be a potential improvement in future studies.

Second, regarding system latency and scalability, although GoogLeNet was selected for its relatively low computational cost, the processes of calculating feature vectors and similarity computation create a computational bottleneck under heavy workloads. Our stress testing demonstrates that response time increases substantially under high concurrency, exceeding 13 seconds for 64 simultaneous users and approaching 26 seconds for 128 users. Such latency is incompatible with real-time clinical workflows and therefore represents a critical limitation of the current implementation.

Third, regarding the analysis of metastasis cases with multiple tumors, we observed distinct horizontal bands of high activation in the heatmaps. While these patterns may suggest distributed feature attention, we cannot definitively rule out the possibility that they represent acquisition or reconstruction artifacts (eg, motion or noise). Consequently, this ambiguity serves as a limitation regarding the model's focus and explainability in complex, multilesion scenarios.

Fourth, to accommodate the input requirements of the pretrained GoogLeNet architecture, the original 512×512 pixels images were resized to 224×224 pixels before feature extraction. This downsampling inevitably reduces spatial resolution and may obscure fine-grained texture details that could be relevant for differentiating certain tumor subtypes. While the loss of fine-grained texture information may affect the representation of subtle local patterns, the system is designed to capture global and midlevel feature similarities that are sufficient for retrieval tasks within the intended clinical workflow. Nonetheless, this resolution reduction is a limitation of the current implementation.

Fifth, similarity in our CBMIR system does not rely on predefined morphological or pathological criteria (eg, tumor size, location, and texture). Instead, it is quantified by computing the Euclidean distance between high-dimensional deep embeddings derived directly from pixel-level representations. Consequently, similarity ranking is fundamentally driven by pixel-derived feature distances, rather than by pathological labels or manually defined structural attributes.

Finally, the retrieval performance metrics reported in this study were computed using Euclidean distance across the full test set to provide standardized and reproducible benchmarking. In contrast, the deployed CBMIR system uses an approximate nearest neighbor search strategy based on HNSW graphs to ensure low-latency, real-time responses and system scalability. The use of HNSW enables efficient similarity search for unseen queries without requiring their prior inclusion in a precalculated distance matrix. While this approximate nature may lead to

XSL•FO
RenderX

minor deviations in retrieval precision or recall compared with an exhaustive search, such a trade-off is essential for practical clinical usability, effectively balancing theoretical accuracy with the demands of real-time medical decision support.

Future Work

Building upon the current findings and addressing the identified limitations, we propose the following three main directions for future research:

1. *Expansion to multicenter dataset validation*: Future work will prioritize incorporating image data from diverse health care institutions to test and fine-tune the model's robustness. Training and validating the system on multicenter datasets will significantly enhance the model's generalizability and practical usefulness.
2. *Exploration of modern AI model*: Although preliminary experiments showed modern AI models, for example, Swin and DinoV2, to be less computationally efficient for our specific task, their inherent strength in capturing long-range dependencies warrants further investigation. Future research may explore methods to optimize or prune these AI models to harness their superior feature learning capabilities without unduly sacrificing computational efficiency.
3. *Integration of multimodal retrieval*: The current system relies solely on visual features. In clinical practice, structured and unstructured radiology reports provide critical contextual information. Future work may explore multimodal deep learning models to combine image features with textual features, enabling more comprehensive and accurate multimodal retrieval functionality.

Conclusions

This study represents the design, implementation, and evaluation of a CBMIR tailored for the classification and retrieval of brain MR images. We successfully developed a CBMIR system focusing on structured tumor classification and incorporating deep learning–based feature extraction, including GoogLeNet combined with ArcFace Loss to enhance the discrimination of image similarities and differences, thereby improving retrieval relevance. In addition, GeM pooling was used as the feature aggregation strategy and evaluated in comparison with conventional average pooling and maximum pooling methods. These results indicate that GeM pooling provides a more refined representative embedding of image features, contributing to improved retrieval accuracy and robustness in the CBMIR system. To facilitate practical deployment, the training workflow was designed as a streamlined, single-stage process, reducing complexity and enabling efficient model preparation. The system was trained using a dataset that includes both tumor-positive and tumor-negative brain MR images, reflecting the diversity of cases encountered in routine clinical practice. Finally, the proposed CBMIR system was successfully integrated with the open-source web DICOM viewer BlueLight with a PACS. The retrieved results were able to be communicated with a PACS to retrieve corresponding medical images for display in a web DICOM viewer, demonstrating the feasibility of integrating CBMIR functionality into existing clinical imaging workflows.

Abstract

Background: The rising global incidence of renal tumors necessitates precise diagnostic interventions. Accurate segmentation of computed tomography (CT) scans is essential for nephron-sparing surgery and radiotherapy. However, conventional manual delineation is labor-intensive and prone to significant interobserver variability due to tumor morphological heterogeneity. There is an urgent clinical demand for robust, automated segmentation solutions.

Objective: This study aims to develop and validate GAM-DeepLabV3+, an automated framework designed to address boundary ambiguity and high false-positive rates in complex renal imaging scenarios.

Methods: We propose an optimized encoder-decoder architecture specifically tailored for renal mass detection. The framework incorporates three key innovations: (1) a lightweight MobileNetV2 backbone to minimize computational overhead for clinical deployment; (2) an Atrous Spatial Pyramid Pooling (ASPP) module to capture multiscale contextual information; and (3) a Global Attention Mechanism (GAM) in the decoder to enhance channel-spatial interactions, thereby refining boundary delineation by suppressing background noise. The model was rigorously evaluated on a private clinical dataset (n=218) and the KiTS19 benchmark (n=210).

Results: GAM-DeepLabV3+ consistently outperformed state-of-the-art baselines. On the private dataset, the model achieved a mean Dice similarity coefficient (DSC) of 0.939 (SD 0.008), significantly surpassing feature pyramid network (FPN; mean 0.893, SD 0.008; $P<.001$) and no-new-Net (nnU-Net; 2D, custom; mean 0.908, SD 0.013; $P<.001$). It also achieved a mean 95% Hausdorff distance (HD95) of 1.485 (SD 0.522) pixels. On the KiTS19 dataset, it maintained a mean robust DSC of 0.928 (SD 0.006). To facilitate clinical translation, a demonstration-only online platform was developed.

Conclusions: The GAM-DeepLabV3+ framework provides an accurate, efficient, and fully automated solution for renal tumor segmentation. By overcoming boundary ambiguity and optimizing feature fusion, this approach shows potential as a decision-support aid, pending future validation with 3D reconstruction.

(JMIR Med Inform 2026;14:e78523) doi:10.2196/78523

KEYWORDS

kidney tumor segmentation; CT images; DeepLabV3+; global attention mechanism; deep learning; KiTS19

Introduction

The kidney is a parenchymal organ situated bilaterally along the spinal column beneath the costal arches, encapsulated by a thin layer of connective tissue and adipose tissue. It plays essential physiological roles in excreting metabolic waste products, maintaining water-electrolyte homeostasis, and secreting critical hormones, including erythropoietin and renin. Against the backdrop of a continuously rising global burden of malignant disease, kidney tumors [1,2] have emerged as one of the most prevalent malignancies of the urinary system. Epidemiologically, their incidence ranks second only to bladder cancer among urological tumors. In 2020 alone, more than 430,000 new cases of kidney cancer were diagnosed worldwide, and the incidence continues to rise with advances in diagnostic technology and accelerating population aging, posing formidable challenges to kidney cancer prevention and treatment across diverse health care settings [3]. The World Health Organization

XSL•FO
RenderX

(WHO) has formally designated kidney tumors as a critical global public health priority [4].

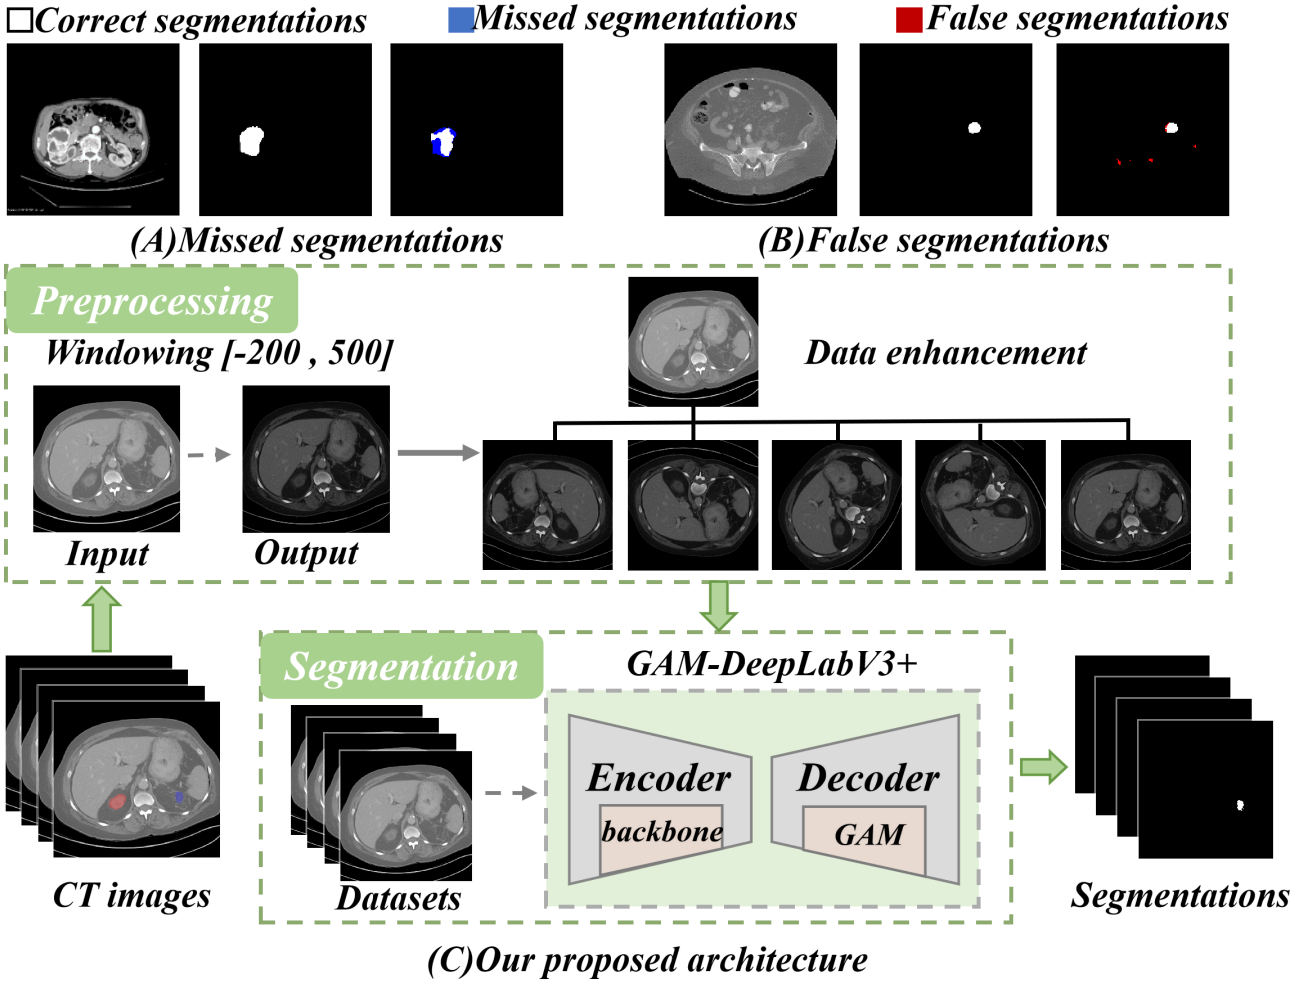
Kidney tumors encompass 3 principal histological categories [5]: clear cell renal cell carcinoma (ccRCC), Wilms tumor, and transitional cell carcinoma of the renal pelvis. ccRCC, originating from the proximal tubular epithelium of the kidney, constitutes the most common primary renal malignancy in adults, accounting for approximately 80% - 85% of all cases. Wilms tumor predominantly affects pediatric populations, whereas transitional cell carcinoma of the renal pelvis arises at the pelvicalyceal junction and is characterized by urothelial differentiation. At the molecular pathological level, ccRCC—the predominant subtype of renal cell carcinoma—is closely associated with mutations in the von Hippel-Lindau (VHL) gene [6,7]. In current clinical practice, computed tomography (CT) [8], magnetic resonance imaging, and ultrasonography [9,10] constitute the principal imaging modalities for evaluating renal lesions. Because most patients with kidney tumors lack specific early symptoms and are frequently diagnosed at an advanced stage, early detection and accurate imaging-based diagnosis are of paramount clinical importance. However, visual lesion detection alone is insufficient to guide complex therapeutic decision-making. Following confirmed or highly suspected diagnosis, precise 3D reconstruction [11] and quantitative analysis of the tumor region are fundamental prerequisites for surgical planning, treatment response assessment, and prognostication. Yet conventional clinical workflows rely on manual tumor delineation by radiologists—a process that is not only time-consuming and labor-intensive, but also susceptible to interobserver variability arising from subjective interpretation, potentially compromising the consistency and accuracy of treatment planning. Accordingly, the development of automated segmentation technology holds substantial significance for improving diagnostic efficiency, guiding surgical planning, and optimizing therapeutic strategies.

Early landmark contributions in this field focused primarily on enhancing feature extraction capability through architectural innovation. Yu et al [12] proposed Crossbar-Net, which introduced crossbar-shaped patch sampling and a cascaded training strategy to strengthen the capture of local textural features, achieving a Dice similarity coefficient (DSC) of 0.91 on kidney tumor segmentation tasks. To address organ boundary ambiguity in arterial-phase 3D CT scans, Myronenko and Hatamizadeh [13] designed a boundary-aware fully convolutional network that incorporated explicit edge supervision signals, elevating the joint kidney-tumor segmentation DSC to above 0.89 and establishing the importance of boundary constraints in fine-grained segmentation. This trajectory was further substantiated by studies in the KiTS challenge series: Heller et al [14] and Zhao et al [15] demonstrated, through ensemble optimization strategies and multiscale supervised U-Net (MSS U-Net), respectively, that multiscale contextual information is critical for overcoming tumor morphological heterogeneity, with kidney and tumor DSC on the KiTS19 dataset consistently exceeding 0.97 and 0.80.

To address the persistent challenge of detecting small positive regions under limited supervision, subsequent research integrated residual connections with attention mechanisms. Guo et al [16] proposed residual and attention U-Net (RAU-Net), and Zhao et al [17] introduced boundary attention U-Net (BAU-Net), both of which used main-auxiliary branch synergy and weighted loss functions to substantially improve model sensitivity to small lesions. Notably, BAU-Net achieved kidney DSC of 0.98 and tumor DSC of 0.84 in the KiTS2021 challenge, marking the maturation of boundary attention mechanisms. More recent research has converged on 2 emerging directions. The first addresses the efficiency-interpretability trade-offs, exemplified by UNet-PWP developed by Rao et al [18], which reduces computational complexity through pretrained weight transfer and adaptive partitioning while incorporating explainable AI to enhance clinical trustworthiness. Along this line, recent studies have incorporated Grad-CAM and attention-based visualization techniques within EfficientNetV2-based frameworks to provide interpretable segmentation results across both clinical and public datasets [19]. Furthermore, combining Vision Transformers (ViTs) with conditional random fields (CRFs) has been shown to enhance boundary refinement while maintaining model transparency, offering a promising direction for explainable segmentation systems [20]. The second direction centers on global context modeling, as demonstrated by the simplified UNETR developed by Choi et al [21], which leverages the long-range dependency capture of Transformer architectures and integrates organ-level prior information for simultaneous segmentation, confirming that anatomical context integration significantly improves tumor localization accuracy [22]. Recent advances have further explored hybrid architectures that combine convolutional neural networks (CNNs) with ViTs to leverage both local feature extraction and global context modeling. For instance, multiscale fusion strategies integrated with UNet and Transformer backbones have demonstrated superior performance in capturing heterogeneous tumor structures [23]. In addition, cascaded Transformer frameworks incorporating mechanisms such as Gumbel-Softmax have been proposed to improve multiclass segmentation by enhancing feature selection and stage-wise refinement [24]. Analogous findings in brain tumor segmentation have demonstrated that backbone selection critically influences detection accuracy [25], and that integrating DeepLabV3+ with attention mechanisms yields consistent improvements across both public benchmarks and private clinical datasets [26], further supporting the design rationale of this study.

Despite impressive benchmark performance reported by these methods [27,28], their clinical translation remains substantially constrained. Prevailing high-performance approaches predominantly rely on 3D cascaded architectures or heavyweight Transformer models. Although 3D convolutions fully exploit volumetric spatial continuity, their substantial graphics processing unit (GPU) memory requirements and high computational overhead introduce considerable inference latency, precluding real-time deployment on standard clinical workstations or in time-critical emergency settings. Furthermore, complex cascaded pipelines increase system instability and maintenance burden. In response to this accuracy-efficiency dilemma, Lin et al [29] proposed an efficient 2D segmentation framework designed to transcend the prevailing 3D paradigm

XSL•FO
RenderX



by optimizing receptive field design and feature aggregation in 2D CNNs, thereby substantially reducing computational complexity while preserving high segmentation accuracy for small and morphologically complex kidney tumors.

Notwithstanding the accuracy benchmarks established by the aforementioned 3D and hybrid architectures, their high computational cost and complex deployment pipelines remain primary barriers to clinical translation. Specifically, existing mainstream methods exhibit several key limitations: first, the prohibitive GPU memory demands of 3D convolutions restrict real-time inference on standard medical hardware [30], rendering them incompatible with the low-latency requirements of emergency care or intraoperative navigation; second, heavyweight Transformer models [31] often require large-scale pretraining data and have been reported to be more susceptible to missed detections of small lesions under oversmoothing or receptive field mismatch [32]; third, most methods fail to fully exploit deep semantic context at the 2D slice level during feature fusion, resulting in insufficiently sharp segmentation boundaries in challenging scenarios characterized by low tumor-to-background contrast and indistinct margins.

This study presents GAM-DeepLabV3+, a framework based on DeepLabV3+ for automated renal tumor segmentation (Figure 1), designed to reconcile the trade-off between accuracy and efficiency and to enhance the segmentation of small, low-contrast tumors. The system enhances the capture of semantic contextual information in tumor regions through backbone network refinement and the introduction of a global attention module. A targeted feature fusion strategy is further devised with the aim of improving tumor boundary delineation in complex backgrounds, including challenging cases such as small kidney tumors. The specific contributions of this work are as follows:

1. To reduce model parameter count, a lightweight enhanced MobileNetV2 is adopted as the backbone network, thereby strengthening the low-level feature extraction capability of GAM-DeepLabV3+.
2. Two Global Attention Mechanism (GAM) modules are introduced at key positions within the decoder: one is placed after a 1×1 convolution and prior to feature concatenation, while the other is embedded within the upsampling pathway. This configuration enables efficient fusion of deep and shallow features, enhancing the representation of salient information while suppressing background noise.
3. A BCEDiceLoss function is used to simultaneously mitigate class imbalance and refine boundary detail optimization. The proposed method achieves a mean Dice coefficient of 0.939 (SD 0.008) and 0.928 (SD 0.006) on a private dataset and the KiTS19 preoperative CT dataset, respectively, demonstrating its capacity for accurate renal tumor segmentation.

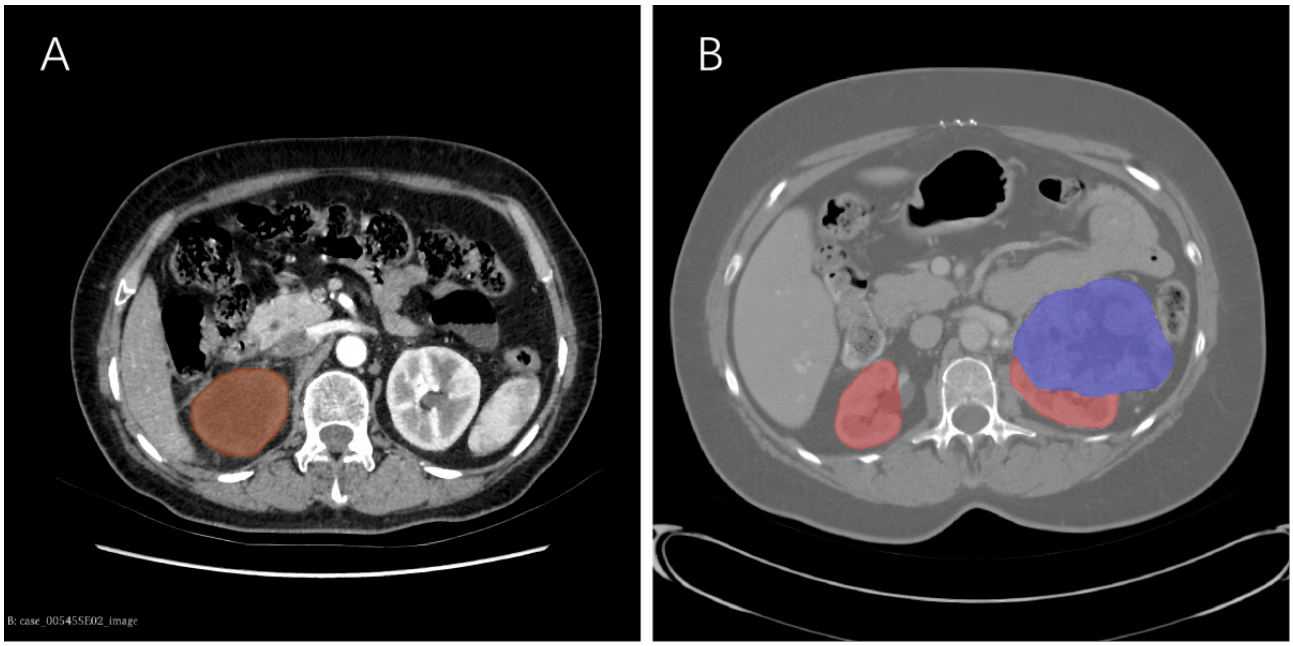
Methods



Overview

This section systematically presents a 2D segmentation method for renal tumors based on CT images. First, we provide a detailed description of the construction of the experimental dataset and the standardized preprocessing pipeline. Subsequently, we comprehensively describe the design and implementation of the DeepLabV3+ framework along with its novel modules.

Description of Experimental Data

In this study, we conducted a retrospective analysis using a private dataset obtained from the Lanzhou University Second Hospital. The dataset comprises 3D CT renal tumor images from 218 patients who were treated between 2016 and 2022. Data collection for this study was conducted over the 6-month period beginning on October 28, 2022. Notably, the dataset used in this study does not include any personal identifying information of the patients. The dataset is provided in Neuroimaging Informatics Technology Initiative (NIfTI) format with corresponding segmentation labels. In addition to CT imaging data, it encompasses various histological subtypes of renal tumors, including ccRCC, papillary renal cell carcinoma (pRCC), and chromophobe renal cell carcinoma (chRCC). The tumors were precisely classified into stages I, II, III, and IV based on the international TNM staging system. Moreover, the dataset contains fundamental clinical attributes such as patient age and gender; however, these clinical variables were collected but not used in the current segmentation algorithm, which operates solely on 2D CT images. The segmentation annotations were manually performed by experienced radiologists based on surgical pathology results to guarantee accurate tumor localization. Nontumor cystic lesions were strictly excluded to enhance the dataset's quality. The annotations include 2 categories: background and renal tumor, as illustrated in Figure 2A.

Figure 2. An example cross-sectional image showing the annotations of organs and tumors in our dataset: in the private dataset, renal tumors are highlighted in orange (A), while in the public dataset, kidneys are marked in red and renal tumors in blue (B).

Additionally, experiments were conducted on the publicly available KiTS19 dataset from the 2019 Kidney and Kidney Tumor Segmentation Challenge [33]. This dataset comprises original abdominal CT images and manually annotated label images by physicians, with annotation classes for background, kidney, and renal tumor, as illustrated in Figure 2B. To enhance data complexity and diversity, and to create a more challenging training environment for the network, we incorporated diverse cases from 210 patients. Notably, this dataset is publicly available on GitHub [34] and has been approved by the Institutional Review Board of the University of Minnesota. Throughout this study, we strictly complied with the terms of the KiTS19 license [33].

The private dataset and the public KiTS19 dataset exhibit complementary characteristics in terms of data construction, collectively offering diverse perspectives for evaluating model performance. The private dataset was meticulously annotated on a per-case basis by experienced radiologists, and a single representative slice was extracted for each patient using dedicated software from 3D volumetric NIfTI-format data. In contrast, the KiTS19 dataset was preprocessed using the official pipeline, generating a series of continuous slices from the raw volumetric scans. To comprehensively assess the generalizability of the proposed model, we conducted experiments on both datasets, thereby validating its robustness and adaptability across different data acquisition and annotation protocols.

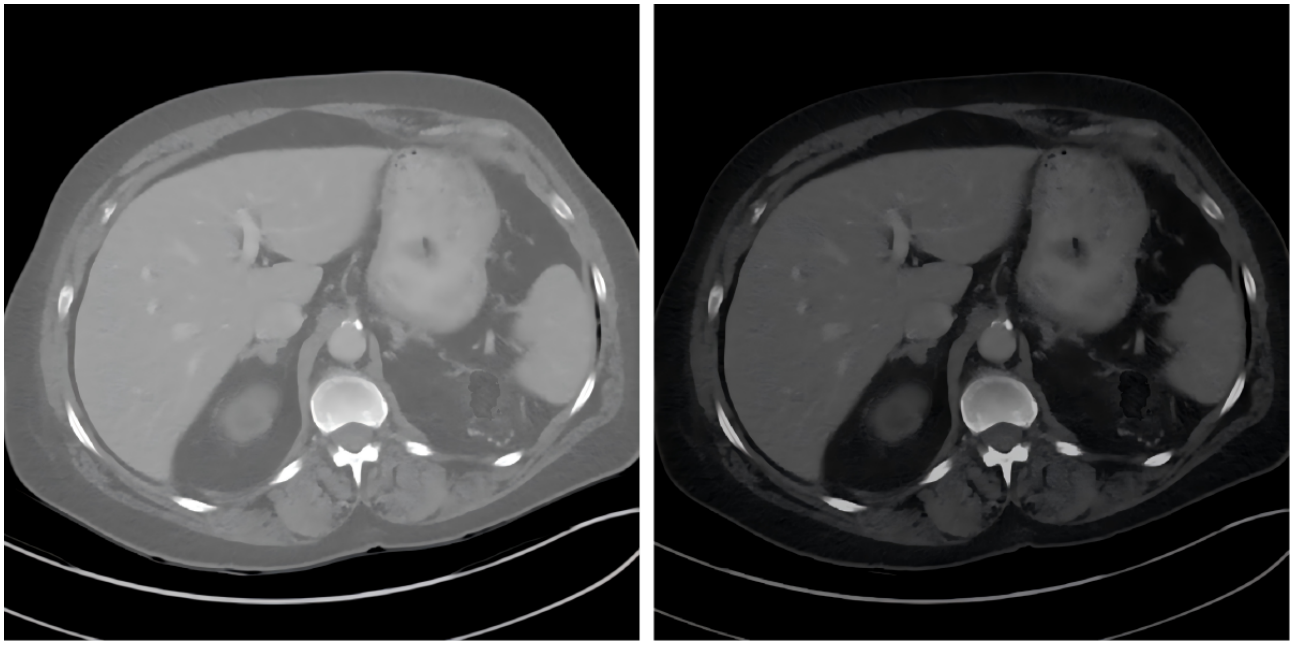
Ethical Considerations

This study was approved by the Ethics Committee of the Second Hospital of Lanzhou University (approval number: 2022A-575), ensuring compliance with medical ethical standards. Given the retrospective nature of the study and the use of deidentified data, the requirement for informed consent was waived by the ethics committee. All imaging data were fully anonymized prior

XSL•FO
RenderX

to analysis, and no direct or indirect patient identifiers were accessible to the research team. No financial or material compensation was provided to participants for their inclusion in this study. No images included in the paper or supplementary materials contain identifiable information of individual participants.

Data Preprocessing



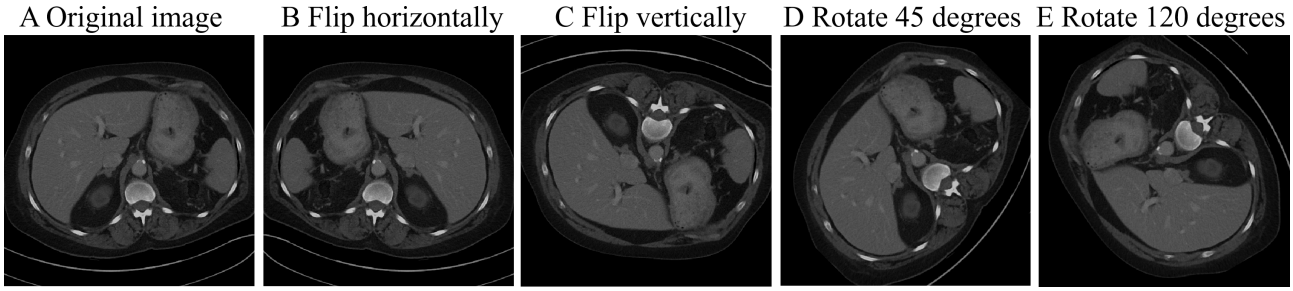
Overview

In the data preprocessing stage, we use a variety of strategies—including image slicing, window width and level adjustment, data augmentation, and label binarization—to enhance both the quality of the training dataset and the efficiency of the deep learning network training. These measures enable the model to better adapt to the feature distribution of the training data. Through data augmentation, not only can more diverse and complex training samples be generated, but the model's generalization ability is also significantly improved, effectively preventing overfitting [35]. Furthermore, to ensure consistency in data processing, all images are uniformly preprocessed to a resolution of 512×512 pixels for input.

Windowing

Since the experimental dataset consists of 3D medical imaging data, while our segmentation network operates on a 2D architecture, it is necessary to first convert the data from 3D to 2D. For the private dataset, we used the widely used 3D Slicer software to precisely extract renal tumor slices. Meanwhile, for the KiTS19 public dataset, we used the official open-source script provided by the competition organizers to perform automated batch slicing. Only 2D CT slices containing renal tumors were retained. For the KiTS19 dataset, labels were converted to a binary schema: the kidney label (class 1) was merged into the background (class 0), retaining only background and renal tumor (class 2) categories, consistent with the annotation schema of the private dataset, while those without labeled tumors were discarded. After preprocessing, the private dataset and KiTS19 dataset yielded 218 and 4800 renal tumor images, respectively. To enhance the visibility of target tissues, we adjusted the window width (WW) and window level (WL) during the slicing process. First, we applied a dual-threshold truncation method to constrain CT values within [−200, 500] HU, effectively reducing the impact of extreme values. This range was selected to preserve contextual anatomical information from surrounding structures, which assists in localizing the kidney and tumor relative to adjacent tissues, and is consistent with preprocessing choices in prior KiTS19 studies. Next, we determined a dynamic effective grayscale range based on the 0.5% - 99.5% quantiles and applied a Gaussian kernel filter to suppress high-frequency noise. Finally, each CT volume was standardized using *z*-score normalization by subtracting the volume mean and dividing by the SD. Min-max scaling was then applied to rescale the pixel values to the range [0,1] for network input. These preprocessing steps significantly improved the deep network's ability to extract meaningful features, as shown in Figure 3.

Figure 3. Comparison diagram for window width and window level adjustments.



Data Enhancements

To mitigate overfitting and enhance the model's generalization ability, we used various data augmentation techniques, including flipping and rotation. By skillfully leveraging artificial expansion, we significantly enriched the diversity of the training data, thereby effectively reducing the adverse impact of data scarcity on model performance, as illustrated in Figure 4. During training, dynamic data augmentation is applied to each CT image using random flipping and multiangle rotations. Moreover, these transformations are randomly applied to all images with a 50% probability to ensure that the augmented data generated are sufficiently diverse and representative.

Kidney Tumor Segmentation

This section provides a detailed description of the overall architecture for automatic segmentation of renal tumors in CT images. First, in the "GAM-DeepLabV3+ Modeling" section, we introduce the overall system design and elaborate on the implementation details of the encoder and decoder, respectively; next, in the "MobileNetV2 Module" section, we focus on the lightweight improvements made to the MobileNetV2 network structure; finally, in the "GAM Module" section, we delve into the design principles and functional mechanisms of the GAM module.

GAM-DeepLabV3+ Modeling

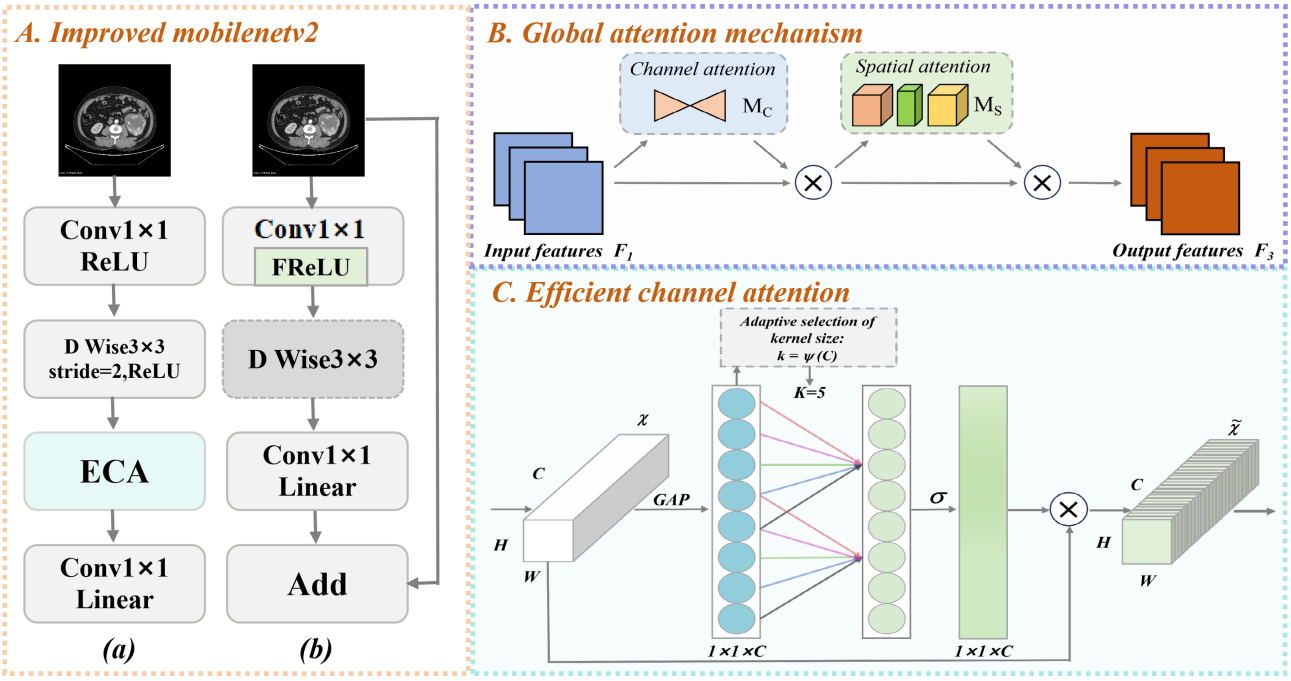
The proposed GAM-DeepLabV3+ integrates three key components, each addressing a specific limitation of the standard DeepLabV3+: (1) the improved MobileNetV2 backbone with Efficient Channel Attention (ECA) reduces model parameters while enhancing low-level feature extraction; (2) the GAM modules in the decoder improve multiscale feature fusion and suppress background interference; and (3) the BCEDiceLoss function addresses class imbalance while optimizing boundary delineation. In recent years, DeepLabV3+ has demonstrated outstanding performance in multiscale feature extraction and fusion [36]. Its encoder-decoder structure is particularly effective in segmentation tasks. However, the traditional DeepLabV3+ encoder suffers from missing small targets, while its decoder is suboptimal in capturing global information, allocating feature weights, and resisting noise, which to some extent limits segmentation accuracy. To address these limitations, we propose an improved segmentation algorithm, GAM-DeepLabV3+, the architecture of which is depicted in Figure 5.

Figure 5. GAM-DeepLabV3+ architecture. ASPP: Atrous Spatial Pyramid Pooling; Conv: convolution; GAM: Global Attention Mechanism.

Specifically, in the encoder section, a CT image with dimensions of 512×512×3 is first processed by the backbone network for preliminary feature extraction. In contrast to the conventional use of the Xception network [37], we introduce a lightweight MobileNetV2 network [38] to extract both shallow and deep features. This replacement significantly reduces the computational burden while further optimizing the feature extraction process through depthwise separable convolutions, inverted residual structures, and linear bottleneck designs, which are particularly effective in preserving fine-grained information and improving the detection of small targets. Subsequently, the high-level features are fed into the Atrous Spatial Pyramid Pooling (ASPP) module [39]. The ASPP module, composed of 4 convolutional layers with dilation rates of 1, 6, 12, and 18, respectively, along with a global average pooling operation, effectively integrates contextual information from different receptive fields, providing a rich and precise feature foundation for the subsequent decoder stage.

In the decoder, we introduce GAM modules at 2 critical locations (as shown in Figure 5) to enhance the fusion and selection of multiscale features. First, features obtained from the encoder's lower layers are compressed via a 1×1 convolution

XSL•FO
RenderX



and initially fused with high-level features; after upsampling, they are input to the first GAM module [40] to highlight key information and suppress background noise. Subsequently, these attention-optimized features are merged with another set of high-level features in the second GAM module, and the results are integrated with earlier processed features via concatenation. Finally, the fused features undergo a 3×3 convolution and further upsampling to progressively restore resolution, ultimately producing segmentation results that match the original image dimensions. By introducing GAM modules at these 2 positions, the network is designed to better attend to edge details and to exploit global and local information at different resolutions, thereby aiming to improve segmentation accuracy and robustness while maintaining a lightweight model.

MobileNetV2 Module

Overview

Addressing the dual requirements of network lightweight design and effective feature extraction for high-resolution medical image segmentation tasks, we adopt MobileNetV2 as the backbone encoder and optimize it accordingly. Based on depthwise separable convolutions and inverted residual blocks, MobileNetV2 implements an "expansion–extraction–projection" feature processing paradigm that balances computational complexity and feature representation, as illustrated in Figure 6. Initially, a 1×1 convolution expands the low-dimensional input into a high-dimensional feature space; then, a 3×3 depthwise convolution extracts spatial features; finally, a 1×1 convolution projects the features back to a lower dimension. In contrast to traditional residual structures with nonlinear transformations, MobileNetV2 introduces a linear bottleneck in its inverted residual blocks, which suppresses redundant nonlinear activations in high-dimensional features. This not only ensures stable gradient propagation but also provides a structural basis for preserving fine feature details.

Figure 6. Detailed architectures of key modules in the proposed GAM-DeepLabV3+ framework. Conv: convolution; ECA: Efficient Channel Attention; FReLU: free rectified linear unit; GAP: Global Average Pooling; ReLU: rectified linear unit.

Although MobileNetV2 exhibits efficiency in feature extraction, there remains room for improvement in the semantic discrimination of channel dimensions. To address this, we propose a hierarchical optimization strategy. In the low-level feature extraction stage, an ECA module [41] is embedded after the depthwise separable convolution to enhance the expression of fundamental features such as edges and textures through adaptive channel weighting. Then, in the high-level feature processing stage, an improved free rectified linear unit (FReLU) activation function combined with a residual connection is used to optimize the gradient propagation path while preserving the integrity of the original information. This hierarchical enhancement strategy creates a complementary effect: the former calibrates channel semantics to improve local detail representation, and the latter strengthens global semantic modeling through improved nonlinear transformations. Together, they construct a hierarchical fine-grained feature expression system that maintains the network's lightweight advantage. The subsequent sections will discuss these 2 improvement mechanisms in detail.

Low-Level Feature Improvement: Embedding of ECA Modules

In the inverted residual blocks of MobileNetV2, low-level features are typically extracted using 3×3 depthwise separable convolutions. However, this process primarily relies on local operations within each channel and lacks global modeling of interchannel relationships. To address this limitation, we introduce an ECA module between the 3×3 depthwise convolution (Dw Conv) and the subsequent 1×1 projection convolution. The purpose is to perform adaptive reweighting

XSL•FO
RenderX

of channel information, thereby enhancing the network's ability to capture critical low-level features such as edges and textures.

The ECA module is designed to capture cross-channel dependencies through a lightweight attention mechanism, thus improving the discriminative power of feature representations. The detailed computational process of the ECA module is illustrated in Figure 6. For an input feature mapX∈ RC×H×W, the ECA first compresses the spatial information into a channel descriptor vector g∈ RCvia Global Average Pooling (GAP):

(1)

Subsequently, this descriptor vector is fed into a 1D convolution (Conv1D) over the channel dimension. The kernel size *k* is adaptively determined according to the channel number *C* as k=ψ(c) , where ψ(c) denotes the nearest odd integer to |(log2(c)+b)/γ|, with γ=2 and b=1 in our implementation. This adaptive Conv1D captures local cross-channel interactions, and a Sigmoid activation function is then applied to generate channel attention weights w∈ RC:

(2)w=σ(Conv1D(g;k))

Finally, these weights are multiplied with the original feature map on a per-channel basis, yielding the enhanced feature representation:

(3)X′=w⊗X

Here, ⊗ denotes element-wise multiplication across channels. In this formulation, X∈ RC×H×W denotes the input feature map with *C* channels, spatial height *H*, and width *W*; g∈ RC is the channel descriptor vector obtained via global average pooling; w∈ RC represents the learned channel attention weights generated by the Conv1D and Sigmoid operations; and *X*' is the channel-recalibrated output feature map. This mechanism eliminates the need for an explicit fully connected layer, thereby reducing the number of parameters while maintaining computational efficiency. Moreover, the fine-grained channel reweighting effectively enhances the model's responsiveness to key information.

Advanced Feature Improvement: FReLU Activation and Residual Connection

In the high-level feature extraction stage, to further enhance nonlinear expressive capability and ensure stable information propagation, we adopt an improved activation function, FReLU, and incorporate residual connections within the inverted residual blocks. Unlike the traditional rectified linear unit (ReLU) activation, which truncates negative information, FReLU uses local spatial information to generate a nonlinear mapping, thereby increasing the flexibility of feature expression. Its specific formulation can be expressed as follows:

(4)FReLU(x)=max{x,φ(x)}

Here, φ(x) generated by the local convolution operation adaptively captures local feature information. In this way, not only is the positive information of the original input *x* preserved, but auxiliary information derived from local spatial awareness is also introduced. Furthermore, the residual connection in the inverted residual block adds the input feature *X* to the output *F*(*X*) obtained after a series of convolution and activation operations. This ensures stable gradient propagation and effectively preserves the initial feature information:

(5)

Here, *X* denotes the input feature map of the inverted residual block; *F*(*X*) represents the transformed feature obtained through a series of convolution, normalization, and activation operations; and *H*(*X*) denotes the residual output obtained by adding the original input *X* to the transformed feature *F*(*X*). This residual formulation preserves the original feature information while facilitating gradient propagation, thereby alleviating the gradient vanishing problem in deep networks. As a result, high-level features can retain richer semantic information after multiple nonlinear transformations, which is expected to support fine-grained segmentation.

GAM Module

In renal tumor segmentation tasks, models in the decoder stage are often affected by inconsistent fusion of features from different resolutions and noise interference, which may result in misclassification of some critical features and ultimately compromise segmentation performance. To address this issue, we introduce the GAM module to enhance focus on target regions during feature fusion, as shown in Figure 6. Given that both channel and spatial information are essential for refining and restoring resolution, the GAM module is incorporated at 2 critical locations within the decoder, following the 1×1 convolution and during the 4× upsampling. This placement enables the extraction of both channel and spatial features from the image.

The design inspiration for the GAM module comes from the remarkable performance of attention mechanisms in information filtering. Its structure mainly comprises 3 components: a channel attention branch, a spatial attention branch, and a residual connection, which together enable the collaborative modeling of global semantic information and local detail.

In the channel attention branch, the module first applies global average pooling to the input feature map to obtain global response information for each channel. In our implementation, the channel attention branch uses a multilayer perceptron (MLP) structure with a channel reduction ratio of 4 to model interchannel dependencies and generate importance weights for each channel. These weights reflect the contribution of each channel to the segmentation task and are multiplied element-wise with the original feature map *F* to obtain the channel-enhanced feature map Fc, thereby reinforcing critical channel information and suppressing redundant features:

(6)Fc=Mc⊗F

Meanwhile, the spatial attention branch focuses on capturing local contextual information at each spatial location of the feature map. In our implementation, this branch consists of 2 successive 7×7 convolutional layers with padding of 3. The first convolution reduces the channel dimension from C to C/4, followed by batch normalization and ReLU activation, while the second convolution restores the channel dimension from C/4 to C and is followed by batch normalization. The channel reduction ratio in the spatial attention branch was set to 4. After these convolution and normalization operations, the spatial

XSL•FO
RenderX

attention branch produces a spatial weight map Ms that matches the dimensions of the input feature map. This spatial weight map is then multiplied element-wise with F_C to obtain the spatially enhanced feature map F_S. Through dynamic adjustment of features at different spatial positions, the saliency of the target region is further enhanced:

(7)Fs=Ms⊗Fc

Finally, to ensure stable propagation of features during the attention processing, the GAM module incorporates a residual connection. After the channel and spatial attention processing, the optimized features are added to the original input features, achieving shortcut information transmission. This design not only helps mitigate the gradient vanishing problem in deep networks but also preserves key information from the original features, ensuring that the introduction of the attention mechanism does not result in loss of information, thereby enhancing the overall robustness of feature representation. The schematic of this structure is shown in Figure 6.

Overall, by jointly applying channel and spatial attention mechanisms, the GAM module adaptively weights the input feature map, significantly enhancing focus on the target region and improving the quality of feature fusion while maintaining a lightweight model. Its flexible and efficient architecture not only boosts the model's capability to extract fine-grained information but also provides robust theoretical support and technical assurance for segmentation in complex scenarios.

Evaluation Metrics

Fundamentally, image segmentation can be viewed as a pixel-level classification problem, where each pixel is classified as either background or target. For segmentation tasks, it is ideal for the network to correctly predict target pixels as true positives (TP) and background pixels as true negatives (TN), whereas misclassifying background pixels as target or vice versa results in false positives (FP) and false negatives (FN), respectively. In this study, the performance of the proposed GAM-DeepLabV3+ network in renal tumor segmentation is quantitatively evaluated using 6 metrics: intersection over union (IoU), Dice, recall, precision, accuracy, and 95% Hausdorff distance (HD95). IoU is a widely used metric in image segmentation that calculates the ratio of the intersection to the union of the predicted segmentation and the ground truth, as given by the following formula:

(8)IoU=TPTP+FP+FN

The Dice coefficient, which measures the similarity between 2 samples on a scale from 0 to 1 (with values closer to 1 indicating better performance), is calculated as follows:

(9)DSC=2TP2TP+FP+FN

Recall is defined as the proportion of TP pixels correctly identified by the model relative to all actual positive pixels in the ground truth, computed as:

(10)Recall=TPTP+FN

Precision refers to the ratio of TP pixels among all pixels predicted as positive by the model, computed as:

(11)Precision=TPTP+FP

Accuracy denotes the proportion of all pixels that are correctly classified by the model, measuring the overall prediction accuracy with the formula:

(12)ACC=TP+TNTP+FP+FN+TN

HD95 refers to the 95th percentile Hausdorff distance between the predicted segmentation boundary and the ground-truth boundary. It is less sensitive to extreme outliers than the maximum Hausdorff distance and was used to evaluate boundary accuracy. It is calculated as follows:

(13)HD95(A,B)=max{P95(d(A,B)), P95(d(B,A))}

where d(A,B)={min{ ‖ b−a ‖ 2:a∈A}} and d(B,A)={min{ ‖ b−a ‖ 2:b∈B}}. Here, A and B denote the boundary point sets of the predicted segmentation and ground-truth mask, respectively. In this study, HD95 was reported in pixels.

Our proposed loss function is a combination of binary cross-entropy (BCE) loss and Dice loss, referred to as BCEDiceLoss. BCE loss, a special case of cross-entropy loss suitable for binary classification problems, is computed as follows:

(14)BCE=−[ylog(p)+(1−y)log(1−p)]

Here, y represents the ground truth label (0 or 1), and p denotes the model's predicted probability. The BCE loss function quantifies the discrepancy between the ground truth and the predicted probabilities.

By combining BCE loss with Dice loss, both classification accuracy and segmentation detail can be simultaneously optimized during training. Specifically, the total loss can be computed using the following formula:

(15)BCEDiceLoss=BCE+λ(1−Dice)

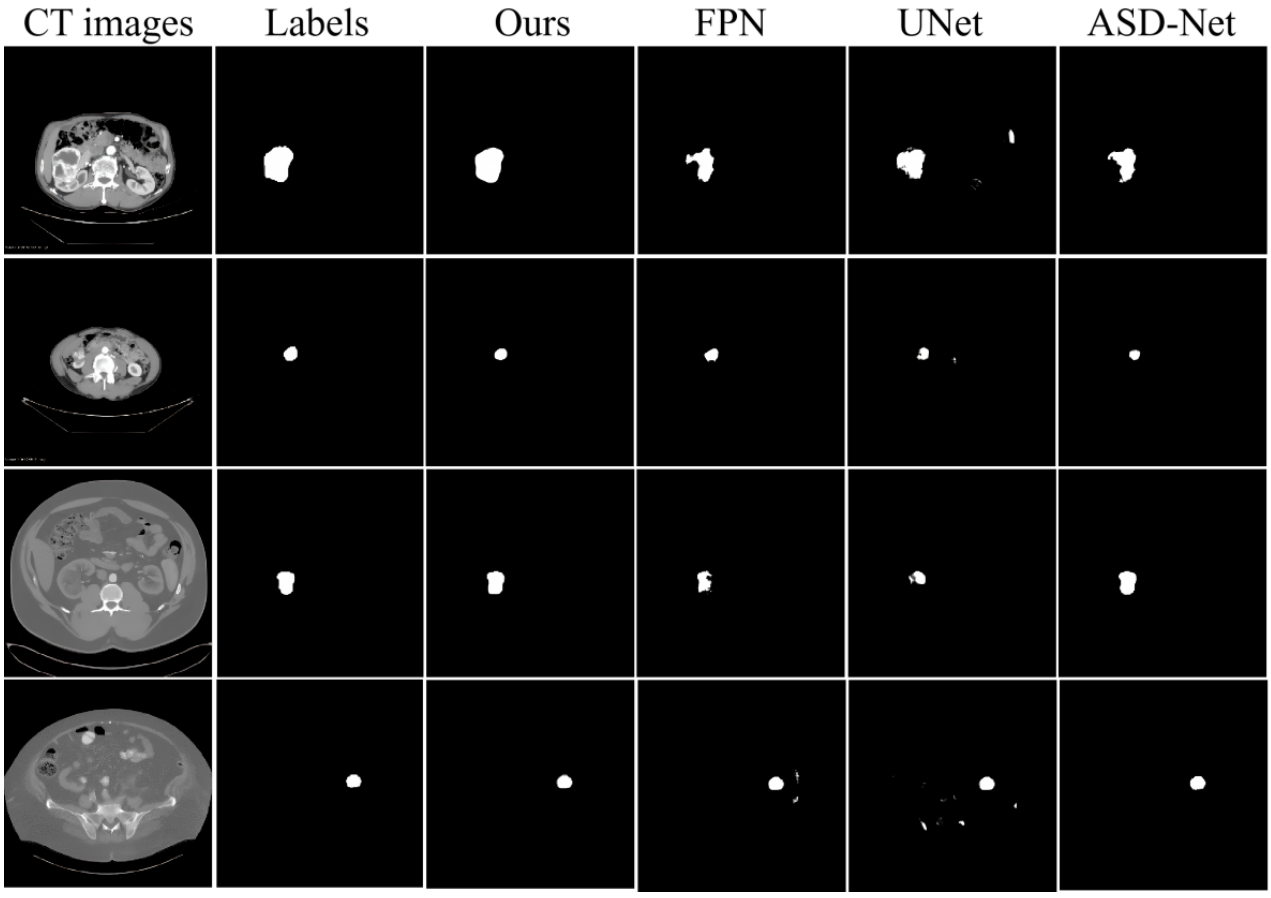
Here, BCE refers to the binary cross-entropy loss, and Dice denotes the Dice coefficient (computed with a smoothing term), so that the term (1 − Dice) constitutes the Dice loss and a higher Dice coefficient yields a lower loss. λ is a hyperparameter used to balance the contributions of the 2 loss terms, which was empirically set to 2 in all experiments. During training, the model optimizes both BCE and Dice objectives concurrently, thereby improving its overall performance.

By integrating the metrics, we can comprehensively and objectively evaluate the model's performance under various conditions, thereby providing robust data support for subsequent model optimization and clinical applications.

Results

Experimental Settings

In our experiments, we used the CT data described in the data preparation section and established the deep learning environment using Python 3.8 (Python Software Foundation) and PyTorch 1.11.0 (PyTorch Foundation, The Linux Foundation) on Ubuntu 20.04 (Canonical Ltd). The hardware configuration included an AMD EPYC 9754 processor and an RTX 4090D GPU with 24 GB of memory. During training, the batch size was set to 8 and the maximum number of epochs was



XSL•FO
RenderX

set to 200, with validation performed at the end of each epoch. An early stopping strategy was used to prevent overfitting. The Adam optimizer was adopted with an initial learning rate of 1×10^{-4}, a weight decay of 1×10^{-4}, β1 of .9, and a minimum learning rate of 1×10^{-5}. To ensure reproducibility and assess result stability, all compared models were trained and evaluated 5 times using different random seeds (42, 123, 456, 789, and 1024), and the results are reported as mean (SD). All dataset splits were performed at the patient level to prevent data leakage. For the private dataset, 218 patients were divided into 153 training, 43 validation, and 22 testing cases, with one representative slice extracted per patient. For the KiTS19 dataset, 210 patients were divided into 147 training, 42 validation, and 21 testing cases; each patient contributed multiple continuous slices containing tumor regions, resulting in 4800 slices for training and evaluation. All backbone networks used in the ablation experiments were initialized with ImageNet pretrained weights. For the no-new-Net (nnU-Net) baseline, we adopted a 2D nnU-Net implementation and trained it under the same unified experimental protocol as the other baseline models. The complete self-configuring nnU-Net pipeline, including automated experiment planning, preprocessing, configuration selection, and postprocessing, was not used. To assess statistical significance, paired *t* tests were conducted across the 5 independent runs for Dice scores between the proposed method and baseline models, with statistical significance defined as $P<.001$.

Visualization Results

During the evaluation of the proposed GAM-DeepLabV3+ model, training and testing were performed on both a private dataset and the public KiTS19 dataset. All splits were performed at the patient level, with 70% for training, 20% for validation, and 10% for testing, with identical hyperparameter settings and training strategies used to objectively compare the model's performance across different data sources. The proposed model converged stably within 200 epochs on both datasets, with no signs of overfitting observed under the patient-level experimental setup. Figure 7 presents the final segmentation visualization results.

Figure 7. Visualization of the segmentation results of the proposed model and their comparison. CT: computed tomography; FPN: feature pyramid network.

We randomly selected 2 groups of CT image predictions from the test sets of both the private dataset and the KiTS19 dataset for comparative analysis, as shown in Figure 7. This visual comparison demonstrates the segmentation results of different network models on renal tumors, with the white regions representing the tumor segmentation. It can be observed that traditional classic networks such as U-Net and feature pyramid network (FPN) produce relatively coarse segmentation boundaries for complex-shaped and small-volume tumor targets, often leading to segmentation errors due to insufficient deep feature extraction, which results in the failure to capture certain detailed regions. In contrast, the proposed GAM-DeepLabV3+ network performs well in segmenting small and irregular lesion areas. Compared with other classical networks, it reduces both

XSL•FO
RenderX

undersegmentation and oversegmentation issues, primarily because the network is able to filter channels that contain critical information through dual attention modules, thereby reducing feature loss and enhancing overall accuracy. Consequently, it can, to a certain extent, resolve the separation between small tumor regions and the kidney, and compensate for missegmentation or omission errors observed in other networks, thereby providing valuable assistance for clinical diagnosis of renal tumors.

Experimental Results

Overview

In our experiments, we compared the performance of the proposed network with several classical segmentation models (including U-Net, Attention-UNet, U-Net++, and ResUNet) on segmentation tasks using both a private dataset and the public KiTS19 dataset. Tables 1 and 2 present the detailed results of each model across various metrics.

[a]The nnU-Net baseline in this table was implemented as a 2D nnU-Net model and trained under the same unified experimental protocol as the other baseline models. Because our study used 2D slice-level binary tumor segmentation, patient-level data splits, tumor-containing slice selection, and a different evaluation protocol, these results should not be directly compared with the official KiTS19 challenge leaderboard or the tumor Dice score reported by Heller et al [33].

[b]IoU: intersection over union.

[c]HD95: 95% Hausdorff distance.

[d]FPN: feature pyramid network.

[e]nnU-Net: no-new-Net.

XSL•FO
RenderX

Note that the high accuracy value observed on the private dataset is expected because renal tumor segmentation is highly class-imbalanced, with background pixels occupying the vast majority of each CT slice. Therefore, accuracy may be inflated by correctly classified background pixels, and overlap-based metrics such as Dice and IoU provide more informative evaluation of tumor segmentation performance.

As can be seen from the data, our proposed GAM-DeepLabV3+ network achieved the best overall performance among the compared methods, particularly in terms of IoU, Dice, and HD95. Specifically, the IoU and Dice coefficients of our method on the renal tumor test set reached 92.8% and 93.9%, respectively, representing improvements of 6.2% and 4.6% over FPN. Moreover, compared with the baseline DeepLabV3+, our method achieved increases of 2.2% and 2.8% in IoU and Dice coefficients, respectively. Paired *t* tests based on the 5 independent runs showed that the Dice improvements of GAM-DeepLabV3+ over all compared baseline models on the private dataset were statistically significant (all $P<.001$).

Similarly, as shown in Table 2, our method outperforms the other models on the public KiTS19 dataset. Paired *t* tests based on the 5 independent runs showed that the Dice improvements of GAM-DeepLabV3+ over all compared baseline models on the KiTS19 dataset were statistically significant (all $P<.01$). On the test set, the IoU and Dice coefficients reached 90.2% and 92.8%, respectively, outperforming all compared baseline models on the KiTS19 external validation set, further demonstrating the strong generalizability of the proposed approach.

As shown in Table 3, GAM-DeepLabV3+ achieved a lower per-slice inference latency than the standard DeepLabV3+ on both the private and the public KiTS19 datasets, corresponding to a speed-up of approximately 1.5× on both datasets (private: from 21.8 to 14.2 ms/slice; KiTS19: from 21.8 to 14.4 ms/slice). These results highlight the efficiency and lightweight characteristics of the enhanced MobileNetV2 architecture. The experimental findings presented in the “Experimental Results” section systematically validate the effectiveness and practical value of the proposed method in terms of both segmentation accuracy and computational performance.

Table . Per-slice inference latency (ms; mean, SD over 5 runs; RTX 4090D; batch size 1).

Model	Private dataset (ms), mean (SD)	KiTS19 (ms), mean (SD)
DeepLabV3+	21.8 (0.4)	21.8 (0.8)
GAM-DeepLabV3+	14.2 (0.4)	14.4 (0.5)

All results are reported as mean (SD) over 5 runs. Inference time refers to pure model forward-pass computation, excluding data loading and preprocessing.

Ablation Experiment

In this section, we conducted a series of experiments to investigate the impact of different modules on the model’s performance, mainly examining how various backbone networks and attention mechanisms integrated within the DeepLabV3+ framework affect segmentation outcomes. Our experiments aim to verify the feasibility and effectiveness of the improved MobileNetV2 network and GAM module in enhancing renal tumor segmentation performance. To this end, all backbone networks (MobileNetV2, Xception, and ResNet101) were initialized with ImageNet-pretrained weights to ensure a fair comparison and avoid performance differences attributable to training-from-scratch instability on the small private dataset. We compared the performance of each variant using quantitative metrics. The results indicate that incorporating the GAM module on top of the lightweight, improved MobileNetV2 backbone significantly enhances overall segmentation accuracy; specific data are presented in Table 4.

[a]ECA: Efficient Channel Attention.

[b]CBAM: Convolutional Block Attention Module.

[c]GAM: Global Attention Mechanism.

[d]IoU: intersection over union.

[e]HD95: 95% Hausdorff distance.

[f]Component included in the model configuration.

From the table, it can be observed that the lightweight backbone network MobileNetV2 offers advantages in model compactness and parameter efficiency while maintaining competitive accuracy. Its accuracy and robustness are slightly superior to the other backbone networks. Specifically, the IoU coefficient of MobileNetV2 is 0.4% and 1.8% higher than that of Xception and ResNet101, respectively, while its Dice coefficient exceeds those of Xception and ResNet101 by 0.5% and 1.2%, respectively. Building upon this foundation, the incorporation of the GAM further enhances model performance. After introducing GAM, the Dice coefficient and IoU improved significantly, increasing by 0.8% and 1.0%, respectively. Moreover, compared to the Convolutional Block Attention Module (CBAM) integrated at the same position, GAM achieves an additional 1.4% increase in IoU and 1.1% in the Dice coefficient. These results indicate that GAM is more effective in feature extraction and weight allocation, enabling the model to better focus on key information within the kidney tumor region. Furthermore, a comparative analysis of the evaluation metrics in the table reveals that the GAM module not only maintains a balance between precision and recall but also preserves overall segmentation accuracy. This fully validates the effectiveness and generalization capability of the GAM in kidney tumor segmentation tasks.

Discussion

Principal Findings

This study introduced GAM-DeepLabV3+, a lightweight, automated framework for renal tumor segmentation, and validated its efficacy on both a single-center clinical dataset and the multicenter KiTS19 benchmark. Our primary finding is that the proposed model achieves superior segmentation precision while maintaining high computational efficiency. On the private dataset, the model yielded a mean DSC of 0.939 (SD 0.008) and a mean HD95 of 1.485 (SD 0.522) pixels, consistently outperforming baseline architectures such as the standard DeepLabV3+ (DSC: mean 0.911, SD 0.008). The robust performance on the KiTS19 external validation set (DSC: mean 0.928, SD 0.006; HD95: mean 2.536, SD 0.742 pixels) further demonstrates the framework's strong generalizability across heterogeneous data acquisition protocols and varying annotation standards.

Ablation analysis systematically quantified the contributions of the individual architectural innovations (Table 4). Transitioning from an Xception to an enhanced MobileNetV2 backbone provided a 0.5% increase in DSC (from 0.917 to 0.922), confirming that a lightweight backbone can preserve, and even refine, feature representation while significantly reducing computational complexity. Most notably, the substitution of CBAM with the GAM resulted in the most substantial gains, improving the DSC by 1.1% over the CBAM-integrated version. This suggests that the sequential channel-spatial attention design of GAM contributes to suppressing background noise and refining boundary delineation; however, because our evaluation did not include a tumor size–stratified analysis, a specific benefit for small renal lesions remains to be confirmed quantitatively. Furthermore, the reduction in per-slice inference latency (from 21.8 to 14.2 ms/slice on the private dataset, an approximately 1.5× speed-up) indicates improved computational efficiency, although real-time clinical use would require further validation.

Comparison With Prior Work

The performance metrics in Table 5 illustrate the advantages of the proposed approach relative to previously reported methods on the KiTS19 dataset. Early CNN-based approaches provided a foundation for automated renal tumor segmentation but faced

XSL•FO
RenderX

inherent limitations in handling morphological complexity. Yang et al [42] achieved a Dice of 82.6% using a CNN architecture with a 3-stage augmentation strategy; while this result demonstrated the promise of deep learning for this task, the approach encountered difficulties with structurally complex tumor presentations. da Cruz et al [43] advanced the field by introducing a 2.5D DeepLabV3+ model with cross-plane feature fusion, reaching a Dice of 85.17%. Ji et al [44] introduced ASD-Net, a U-Net variant incorporating asymmetric spatial-channel convolution modules, achieving a Dice of 85.22%. In the same period, Ruan et al [45] proposed MB-FSGAN, a multiscale bipath generative adversarial network that reached 85.9%, although its feature extraction remained less sensitive to small lesions.

Table . Comparison of segmentation metrics of the proposed method versus other state-of-the-art models (KiTS19)[a].

Work	Methods	Dice	Accuracy
Yang et al [42]	CNNs[b]	0.826	—[c]
da Cruz et al [43]	DeepLabv3+2.5D	0.852	0.997
Ji et al [44]	ASD-Net	0.852	—
Ruan et al [45]	MB-FSGAN	0.859	0.957
Türk et al [46]	Hybrid V-Net	0.865	—
Sun et al [47]	2.5D MFFAU-Net	0.875	—
Jackson et al [48]	3D CNNs	0.885	—
Sun et al [49]	FR2PAttU-Net	0.911	—
This paper	GAM-DeepLabV3+	0.928	0.992

[a]External Dice values are tumor-class scores from the original 3-class KiTS19 task (background, kidney, and tumor); the proposed method uses a binary tumor-versus-background task with the kidney merged into the background, so the comparison is indicative rather than strictly controlled.

[b]CNN: convolutional neural network.

[c]Component not included in the model configuration.

The growing interest in 3D architectures subsequently opened new directions for performance improvement. Türk et al [46] combined residual connections with dense block structures in a hybrid V-Net, achieving a Dice of 86.5%; however, this came at the cost of substantially increased model parameters and computational overhead. Sun et al [47] balanced computational cost against accuracy through a multiscale feature fusion strategy in their 2.5D MFFAU-Net, reaching 87.5%. Jackson et al [48] demonstrated that a 3D CNN augmented with data augmentation could attain a Dice of 88.5%, though the shallow architecture constrained the model's capacity to represent heterogeneous small-tumor features. More recently, attention mechanisms have driven further performance gains: Sun et al [49] proposed FR2PAttU-Net with a dual-path feature refinement module and pyramid attention unit, achieving a Dice of 91.1%, albeit with a 32% increase in parameter count attributable to its cascaded module design. Notably, the external scores in Table 5 are tumor-class Dice from the original 3-class KiTS19 task (background, kidney, and tumor), whereas our model adopts a binary tumor-versus-background formulation with the kidney merged into the background; the comparison is thus indicative rather than strictly controlled. Moreover, merging the kidney into the background does not necessarily simplify tumor delineation, as the renal parenchyma is the tissue most readily confused with tumor.

The proposed GAM-DeepLabV3+ framework achieved a Dice of 92.8% on the KiTS19 test set, which is numerically higher than the 91.1% Dice reported for FR2PAttU-Net [49], while maintaining an accuracy of 99.2% and a more favorable computational profile. As noted in the footnote to Table 5, this comparison is indicative rather than a strictly controlled head-to-head result, because the external KiTS19 scores derive from the original 3-class task whereas our model adopts a binary tumor-versus-background formulation. On the private dataset, GAM-DeepLabV3+ outperformed both ASD-Net (Dice: 0.876, IoU: 0.810) and DeepLabV3+2.5D (Dice: 0.888, IoU: 0.806), achieving a mean Dice of 0.939 (SD 0.008) and a mean IoU of 0.928 (SD 0.012; Table 6). These results collectively support the effectiveness of combining global context modeling through the GAM module with a lightweight MobileNetV2 encoder for renal tumor segmentation under both data-rich and data-limited conditions. We note that these 2 comparators were reimplemented in-house and evaluated as single-run reference comparisons on the private test set, rather than under the multiseed protocol used for the other baselines in Table 1; they are therefore reported as single-point values.

XSL•FO

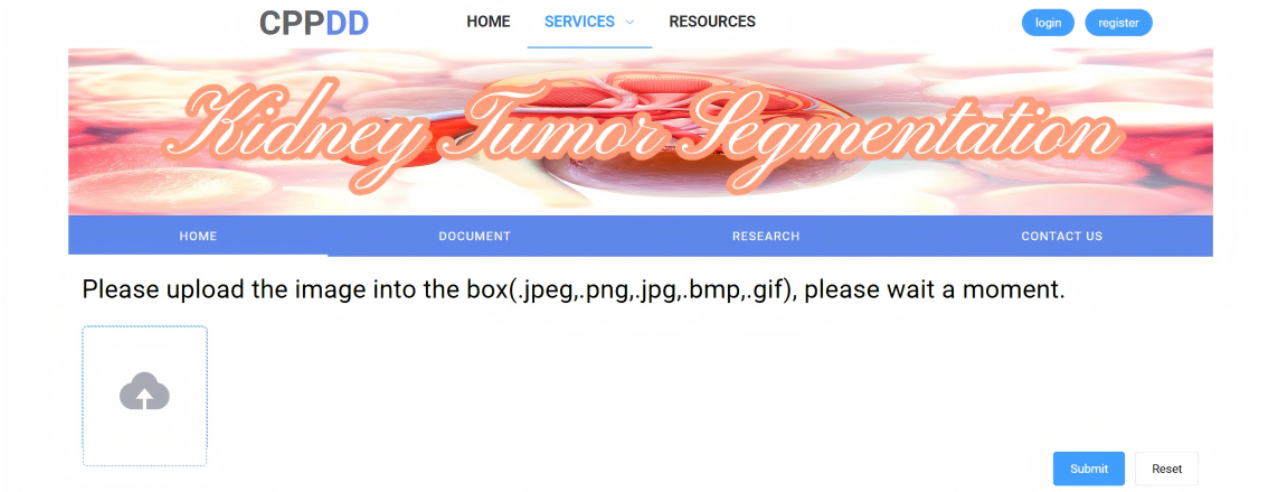
Table . Comparison of segmentation metrics of the proposed method versus other state-of-the-art models (private dataset)[a].

Methods	IoU[b]	Dice	Recall	Precision	Accuracy	HD95[c]
ASD-Net	0.810	0.876	0.869	0.924	0.998	—[d]
DeepLabV3+ 2.5D	0.806	0.888	0.869	0.920	0.998	—
GAM-DeepLabV3+, mean (SD)	0.928 (0.012)	0.939 (0.008)	0.941 (0.007)	0.943 (0.006)	0.999 (0.000)	1.485 (0.522)

[a]ASD-Net (Ji et al [44]) and DeepLabV3+ 2.5D were reimplemented by us and evaluated on the private test set as single-run reference comparisons; they were not run under the multiseed protocol used for the Table 1 baselines and are therefore reported as single-point values without SDs or HD95. The ASD-Net predictions shown in Figure 7 were produced by this reimplementation; the same reimplementation was also applied to the KiTS19 slices displayed in Figure 7 for qualitative comparison, whereas the quantitative ASD-Net results in this table correspond to the private test set only.



[b]IoU: intersection over union.

[c]HD95: 95% Hausdorff distance.

[d]Not available.

An online demonstration platform based on GAM-DeepLabV3+ has been made freely accessible at CPPDD [50] (for demonstration purposes only; not intended for upload of real patient data), as illustrated in Figure 8. The platform is intended for research-context demonstration only and is not validated for clinical use.

Figure 8. Homepage of the renal tumor segmentation network server.

Limitations

This study has several limitations that warrant consideration. The private dataset comprised 218 patients from a single center, with one representative 2D slice extracted per patient. Although this strategy is consistent with the 2D segmentation paradigm adopted here, it discards volumetric continuity information and may not fully reflect the spatial heterogeneity of renal tumors across contiguous axial slices. The relatively high performance metrics observed on the private test set may in part reflect the representative nature of the selected slices rather than the full spectrum of imaging variability encountered in clinical practice. To partially address this, external validation was performed on the KiTS19 dataset, which includes multiple consecutive slices per patient and data from multiple centers, providing a more challenging and diverse evaluation environment. The model achieved a mean HD95 of 1.485 (SD 0.522) pixels on the private test set and a mean HD95 of 2.536 (SD 0.742) pixels on KiTS19, suggesting reasonable spatial consistency of the 2D predictions; nevertheless, formal 3D reconstruction validation—including volumetric Surface Dice and 3D HD95 computed across the full *z*-axis stack—to confirm the absence of stacking artifacts remains an important direction for future investigation. This constitutes a key limitation of the current work. In addition, because the external KiTS19 results in Table 5 were obtained under different task definitions (3-class vs binary), preprocessing, and evaluation protocols, the numerical differences reflect contextual competitiveness rather than a controlled demonstration of superiority. Finally, although the architecture is motivated in part by the difficulty of small renal tumors, no tumor size–stratified evaluation was performed; the corresponding claims are therefore qualitative, and a volume-stratified analysis of small-lesion performance is left for future work. Furthermore, because only 2D slices containing annotated renal tumors were retained and tumor-free (negative) slices were discarded during dataset construction, the model's false-positive behavior on normal, tumor-free tissue and its performance on complete patient volumes that include negative slices were not evaluated in this study; assessment on full CT volumes therefore remains an important direction for future work.

XSL•FO
RenderX

Although nnU-Net was included as a baseline, only its 2D implementation was evaluated under our unified experimental protocol. This baseline therefore represents a custom adaptation that may underestimate the true capability of the nnU-Net framework. The complete self-configuring nnU-Net pipeline and whole-volume 3D evaluation were not explored, which should be addressed in future work. Likewise, modern ViT baselines were not included in our comparative experiments, and a direct experimental comparison against Transformer-based architectures remains future work. In addition, because of the retrospective design and limited dataset scale, the reported results should be interpreted as indicating promising accuracy for research and assistive purposes rather than as evidence of validated clinical utility. The private test set included only 22 patients, which may limit the statistical power to detect significant performance differences between methods. The heterogeneous nature of renal tumors across stages and histological subtypes, combined with the single-institution data source, may limit the generalizability of the current findings. Prospective multicenter studies with larger and more diverse patient cohorts are needed before conclusions regarding clinical deployment can be made with confidence.

Conclusions

In summary, this study proposed GAM-DeepLabV3+, a CT renal tumor segmentation model built on an improved DeepLabV3+ framework incorporating a lightweight MobileNetV2 encoder, an ASPP module, and a GAM attention mechanism in the decoder. The model demonstrated promising segmentation accuracy on both the private dataset (Dice: mean 0.939, SD 0.008; IoU: mean 0.928, SD 0.012; HD95: mean 1.485, SD 0.522 pixels) and the public KiTS19 dataset (Dice: mean 0.928, SD 0.006; IoU: mean 0.902, SD 0.008; HD95: mean 2.536, SD 0.742 pixels), while offering improved inference speed relative to standard DeepLabV3+. By integrating lightweight backbone design with global-local attention feature fusion, the proposed approach is designed to address several challenges in renal tumor CT segmentation, such as blurred tumor boundaries and class imbalance; a dedicated, tumor size–stratified evaluation of small-lesion performance remains an avenue for future work. These findings support the potential of GAM-DeepLabV3+ as a research tool and a basis for further development toward clinically assistive automated segmentation systems. Prospective validation on larger, multicenter datasets will be an essential next step in assessing broader clinical applicability.

Abstract

Background: Quantitative magnetic resonance imaging (MRI) is an advanced technique that can map the physical properties (T1, T2, and proton density [PD]) of different tissues, offering crucial insights for disease diagnosis. Nonetheless, the practical application of this technology is indeed constrained by several factors, with the most notable being the protracted scanning duration.

Objective: This study aimed to explore whether deep learning (DL)–based superresolution reconstruction of ultrafast whole brain synthetic MRI can obtain quantitative T1/T2/PD maps that are closely approximated to those from routine clinical scans, while substantially shortening scan time and preserving diagnostic image quality.

Methods: A total of 151 healthy adults and 7 individuals with different pathologies were prospectively enrolled. Each individual was examined twice on a 3.0T scanner using routine and fast synthetic MRI protocols. The routine scans (acquisition matrix: 320×256) were interpolated to 512 by 512 for clinical display and served as reference images. The fast scans (acquisition matrix: 192×128) were preprocessed to 256 by 256 and used as inputs to a superresolution generative adversarial network (SRGAN), which reconstructed them to the same 512 by 512 interpolated resolution as the reference. For each quantitative chart, 120 (75.95%) healthy individuals' images were used for training, and 38 (24.05%) individuals' images (healthy individuals: n=31, 19.62%; patients: n=7, 4.43%) were used for testing. Agreement was assessed with a paired *t* test, two 1-sided tests, Bland-Altman analysis, and coefficients of variation.

Results: DL reconstructed and reference T1/T2/PD values were strongly correlated (T1: R^2=0.98; T2: R^2=0.97; and PD: R^2=0.99). The slopes of the linear regression were near 1.0 both for T1 (0.9418) and PD (0.9946), whereas T2 values were moderate, as the slope of the linear regression was 0.8057. Additionally, the average biases of T1, T2, and PD values were small (0.93%, −0.85%, and 0.31%, respectively). The intra- and intergroup coefficient of variation for most of the brain regions stayed below 5%, especially for PD values, and after DL reconstruction, it still has quantitative accuracy for lesions. Quantitative and qualitative analyses of image quality also indicate that SRGAN markedly suppressed noise and artifacts in fast acquisitions, restoring structural fidelity (structural similarity image measure) and signal fidelity (peak signal-to-noise ratio) close to the level of routine scans while substantially improving perceptual naturalness over fast scans (as measured by the naturalness image quality evaluator), although not yet matching that of routine imaging.

Conclusions: SRGAN superresolution applied to ultrafast synthetic MRI yields whole brain T1, T2, and PD maps that show strong correlation with routine synthetic MRI while halving acquisition time and maintaining diagnostic image quality. Although T1 and PD values exhibit near-ideal agreement, and T2 values demonstrate a moderate systematic underestimation, this approach represents a promising step toward accelerating clinical deployment of quantitative brain imaging.

KEYWORDS

magnetic resonance imaging; qMRI; fast MRI; deep learning; brain imaging

Introduction

Quantitative magnetic resonance imaging (qMRI) can reflect the inherent properties of human tissue relaxation times and proton density (PD), providing valuable support for verifying visual assessments of structures and tissues against a normal quantitative standard, thereby holding significant clinical diagnostic value [1]. Nevertheless, the extended scan time of qMRI imposes limitations on its practical use. Synthetic MRI, based on multidynamic, multiecho sequences, can provide multiple quantitative information and multicontrast images in a single scan, enabling fast qMRI scans [2,3]. It has been proven to have comparable diagnostic value to conventional scanning methods, with the generated quantitative data being valuable for disease identification [4-7]. However, the single scan time of this imaging method still typically ranges from 4 to 7 minutes, particularly for brain MRI imaging, which can lead to individual discomfort and potentially impact image quality. Therefore, improving the imaging speed of synthetic MRI is the key to realizing ultrafast qMRI.

It is also crucial to ensure the quality of qMRI and the reliability of quantitative values while accelerating imaging. Usually, fast imaging methods such as parallel acquisition and compressed sensing may result in a loss of image quality [8]. The reconstruction technology based on deep learning (DL) has been applied in various medical image reconstruction tasks, and its development makes it possible to solve the trade-off between image quality and scan time. Generative adversarial networks, renowned for generating high-fidelity superresolution images, have been successfully used in MRI [9]. Many researchers have implemented the concept of generative adversarial networks for MRI image reconstruction, achieving high-quality reconstruction from highly undersampled data [10-14]. In addition, the generative adversarial approach can be used for tasks, such as artifact correction and denoising in MRI [15,16]. In clinical practice, in addition to focusing on image quality, it is more important to determine whether the DL-based reconstruction method can provide less bias and consistent quantitative data [17].

To shorten synthetic MRI quantitative acquisitions and increase clinical throughput, we hypothesized that DL superresolution can generate T1/T2/PD maps that are close to routine long acquisition quantitative values while maintaining image quality, thereby providing faster yet equally reliable neuroimaging and ultimately enhancing diagnostic precision and patient comfort.

Methods

Participants

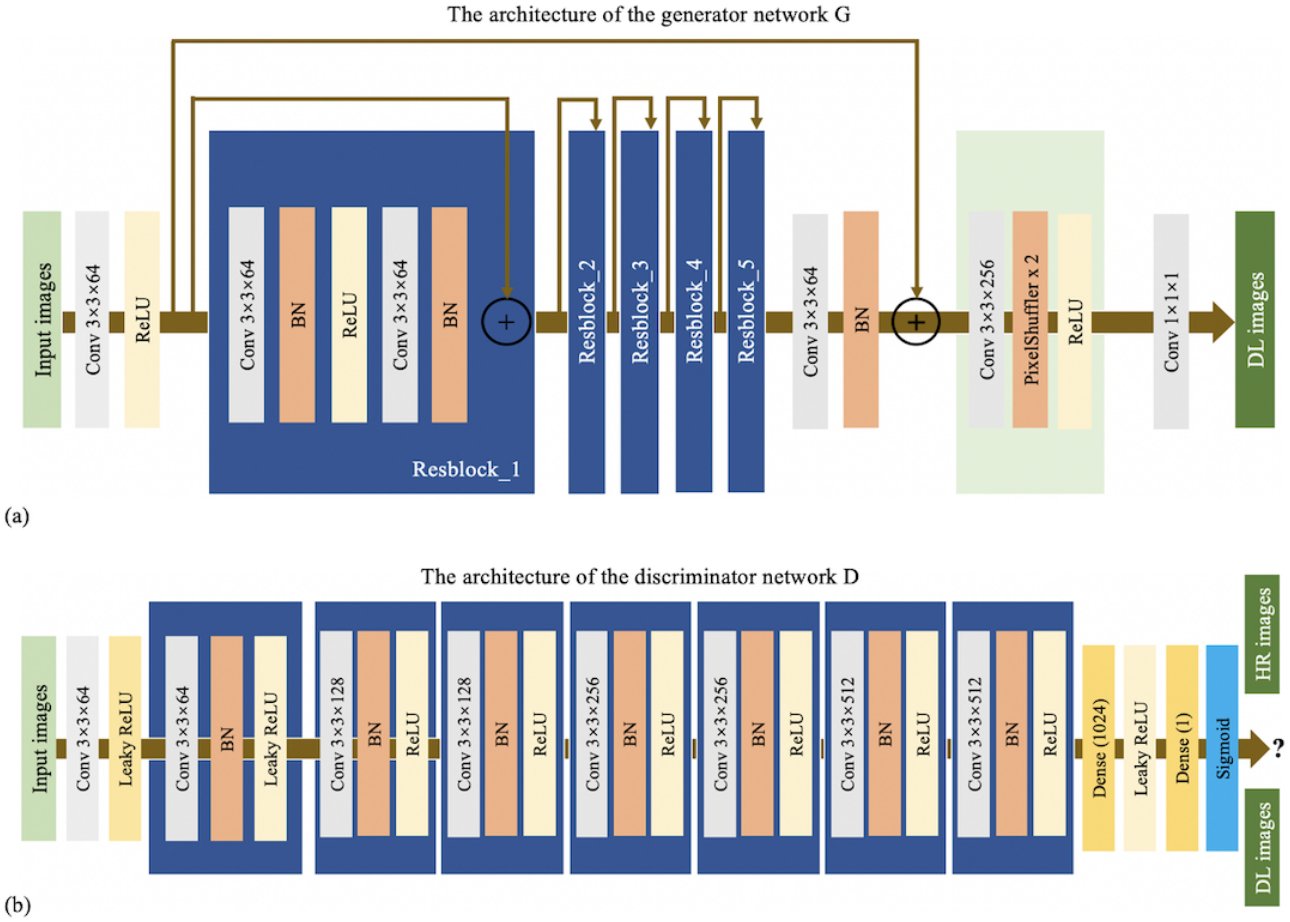
This study was approved by the Medical Research Ethics Committees of the Beijing Friendship Hospital, Capital Medical University (2020-P2-122-02). Written informed consent was obtained from all participants prior to enrollment. A total of 151 healthy individuals were prospectively recruited at 1 institution for this study. The inclusion criteria were as follows: (1) the age of the individual was greater than or equal to 18 years, (2) the individual showed no structural changes or signs of disease in brain MRI, and (3) the individual showed no contraindications or adverse reactions to MRI examination. The exclusion criteria were as follows: (1) there were obvious artifacts in the images, and (2) the individual failed to complete all MRI examinations. In addition, we also collected images from 7 individuals with different pathologies (white matter [WM] hyperintensities, cerebral infarcts, and encephalomalacia) to evaluate the potential for clinical application.

Synthetic MRI Acquisition

All MRI examinations were performed using a SIGNA Pioneer 3.0 T MRI scanner (GE Healthcare). All individuals underwent two synthetic MRI scans using the multidynamic multiecho sequence (MDME sequence, named MAGiC in the GE scanner): a routine scan protocol and a fast scan protocol. The routine scan uses commonly used clinical acquisition parameters: TR=4000 ms; TE1=18.3 ms; TE2=91.4 ms; TI=28.2 ms; thickness=5 mm; FOV=220×220 mm; acquisition matrix=320×256; echo-train length=16; bandwidth=31.25 kHz; delay times=170, 670, 1840, and 3840 ms; and acceleration factors=2, 24 slices, with a pixel size of 0.7×0.8 and an acquisition time of 4 minutes 55 seconds. Fast scan modifies the acquisition matrix and acceleration factor, which affect the acquisition time, by changing the acquisition matrix to 192×128 and the acceleration factor to 3. The remaining parameters remained the same as those of the routine scan, with a pixel size of 1.1×1.7 and an acquisition time of 1 minute 52 seconds.

Data Preprocessing

The same method was used to retrieve the quantitative maps (T1 maps, T2 maps, and PD maps) as mentioned in a previous study [18]. In this study, quantitative maps from the routine scan (reconstruction matrix=512×512, 0.43×0.43 mm² pixel) served as the high-resolution (HR) reference, whereas those from the fast scan (reconstruction matrix=256×256, 0.86×0.86 mm² pixel) were used as low-resolution (LR) inputs. DICOM images were directly read and prepared for network training. It should be noted that the maximum image intensities of T1 maps, T2 maps, and PD maps are 43,000, 20,000, and 1600, respectively, which correspond to 10 times the actual values. This scaling is due to the rescaling slope value of 0.1 specified in the DICOM header file.



Network Architecture

The detailed generator network structure is shown in Figure 1A. It starts with a 9 by 9 convolutional filter and connects to 5 residual blocks, each of which consists of two 3 by 3 convolutional layers alternating with batch normalization layers, and activation is performed using a rectified linear unit (ReLU) function. After the residual network, a 3 by 3 convolution and a 1 by 1 convolution are connected, and a subpixel convolutional

XSL•FO
RenderX

layer is used to upsample the image. In the generator network, except for the last layer that uses tanh as the activation function, all other layers use ReLU as the activation function. The discriminator network structure is shown in Figure 1B. In the discriminator network D, our model first uses an architecture comprising eight 3×3 convolutional layers and Leaky ReLU function activation. All convolutional layers except the first have batch normalization layers. The Sigmoid activation function is applied to the last fully connected layer, which outputs the probability of discriminating whether the input HR image is a real HR image or an image generated by the generator. The network architecture includes a pretrained VGG-19 network, which is used for feature extraction and loss function calculation.

Figure 1. The architecture of the superresolution generative adversarial network. BN: batch normalization; DL: deep learning; HR: high resolution; ReLU: rectified linear unit.

Loss Function

The pixel-by-pixel error method used is the L1 loss function, also known as the mean absolute error, which is calculated using equation 1. Although SRGAN completely discards the pixel-by-pixel error, we still add this error in a certain proportion during the actual training process to amplify the difference and guide the optimization of the model. The cross-entropy loss function of the discriminator is used as the adversarial error of the network, and the calculation method is expressed using equation 2. In addition to using the adversarial error, SRGAN also uses a content error, which is defined as the Euclidean distance between the superresolved image and the feature map of the reference image, and the calculation method is expressed using equation 3. The content error is used to align the content of LR images and HR images, which plays the same role as the mean square error. In this network, the pretrained VGG-19 network is used to extract the feature parameter map. Therefore, the loss function for the generator in this network is described using equation 4.

$$(1) L_{mae} = \frac{1}{CHW}\sum_{i,j,k} |I_{i,j,k}^{DL} - I_{i,j,k}^{GT}|$$

where I^{DL} is the output image of the generator and I^{GT} is the input reference image.

$$(2) L_{gan} = -\sum_{i} \log D(G(I^{DL}))$$

where G and D are the generative network and the discriminative network, respectively.

$$(3) L_{VGG} = \frac{1}{C_j H_j W_j}\sum_{x=1}^{W_j}\sum_{y=1}^{H_j}\sum_{c=1}^{C_j}(\phi_j(G(I^{DL}))_{x,y,c} - \phi_j(G(I^{GT}))_{x,y,c})^2$$

where $(\varnothing j)$ is the feature map obtained from the jth convolutional layer of the VGG-19 network, C_j, H_j, and W_j are the number of channels and height and width of the feature map, respectively, I^{DL} is the output image of the generator, and I^{GT} is the input reference image.

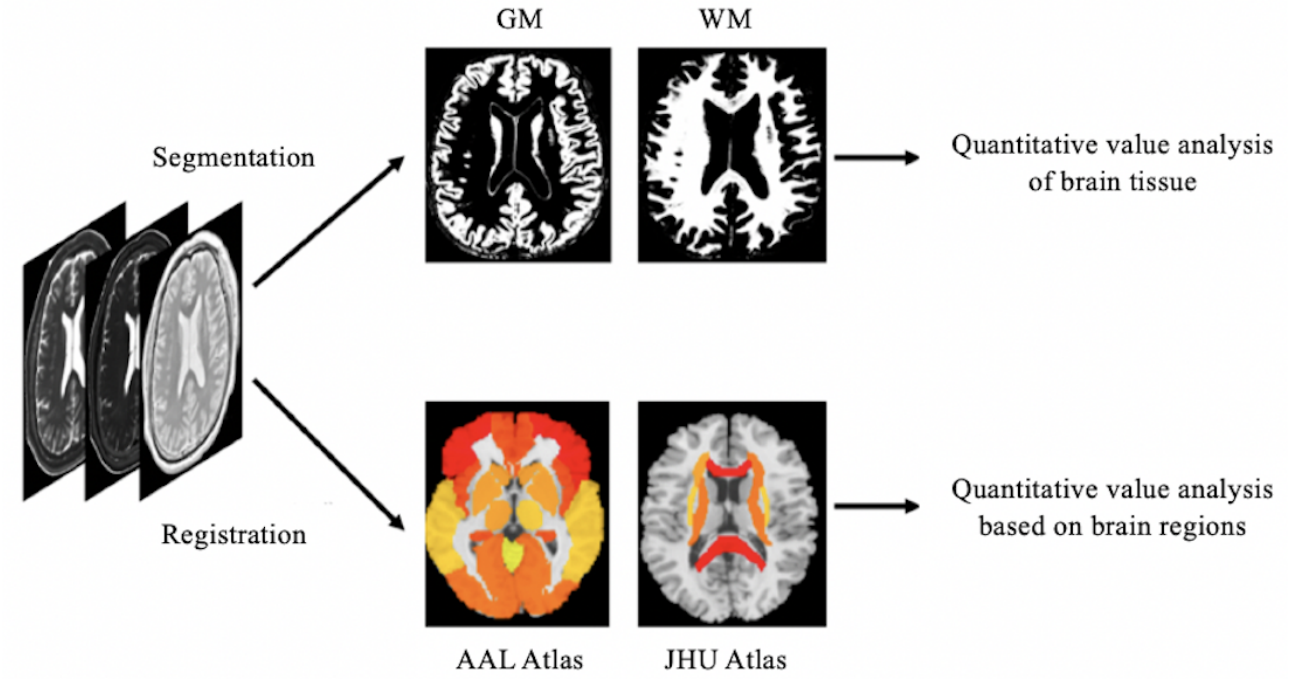
$$(4) L_{total} = L_{mae} + 10^{-3} L_{gan} + 2 \times 10^{-6} L_{VGG}$$

Implementation

Approximately 80% (120 healthy individuals) of the dataset were allocated to training, and the remaining individuals (healthy individuals: 31, 19.62%; and patients: 7, 4.43%) were used for

XSL•FO
RenderX

testing. Slices from each individual were pooled and randomly shuffled within their respective sets to prevent any sequential bias and improve the performance of the model. Before training, all quantitative maps (T1, T2, and PD) underwent intensity normalization to match the output range of the generator network, that is, imagenorm=(pixelvalue/normalizepara)×2−1, where normalize_para is set to 45,000, 22,000, and 1800 for T1, T2, and PD maps, respectively.



The DL models for T1, T2, and PD maps were trained separately but with identical hyperparameters. Each model was implemented using the TensorLayer framework [19] and optimized via the adaptive moment estimation (Adam) optimizer with a learning rate of 1×10^{3} and step-wise decay every 1000 iterations. Training was performed on an NVIDIA Tesla V100 GPU with a batch size of 8 and a total of 200 epochs. All other parameters were kept at their default settings.

Quantitative Value Measurements

The flowchart illustrating the process of quantitative value measurements is presented in Figure 2.

For healthy participants, quantitative value analysis of brain tissue and brain regions was conducted. First, brain tissue segmentation was performed on each individual's quantitative map using the New Segment tool within SPM [20] software. Then, quantitative value extraction of gray matter (GM) and WM was performed using self-written programs in the MATLAB (The MathWorks Inc.) platform.

Figure 2. The process of quantitative value measurements for healthy participants. AAL: anatomical automatic labeling; GM: gray matter; JHU: Johns Hopkins University; WM: white matter.

In addition to analyzing quantitative values for both GM and WM tissue, analysis was also performed by different brain regions for clinical evaluation and application. Using the anatomical automatic labeling atlas of the Montreal Neurological Institute (MNI), 10 GM regions of interest (ROIs) were created on anatomical structures, including frontal cortex, temporal cortex, parietal cortex, occipital cortex, insula, hippocampus, caudate nucleus, putamen, pallidum, and thalamus. Additionally, using the JHU-WhiteMatter-48 atlas, 9 WM ROIs were generated, including the middle cerebellar peduncle, genu of corpus callosum, splenium of corpus callosum, cerebral peduncle, internal capsule, anterior corona radiata, superior corona radiata, posterior corona radiata, and external capsule [21]. In all analyses, right and left quantitative data were averaged. The quantitative value of the corresponding brain region in the quantitative map reconstructed by DL and from routine scans was obtained for each individual for subsequent statistical analysis.

For the images of individuals with pathologies, an experienced radiologist used the ITK-SNAP software (version 3.8.0; [22]) to delineate the ROI of typical lesions manually and acquired the mean value of the signal in the ROI. To ensure paired comparison, identical ROI size and location were replicated on the DL reconstructed and reference routine scan images. A total of 12 ROIs were obtained from 7 (4.43%) patients (individual 3: 3 ROIs, individual 5: 3 ROIs, individual 7: 2 ROIs, and the remaining 4 individuals: 1 ROI each).

Image Quality Evaluation

Two full-reference evaluation indices—peak signal-to-noise ratio (PSNR) and structural similarity image measure (SSIM)—were used in this study for image quality assessment [23]. The larger the value of the 2 indices, the better the image quality. The PSNR was defined by equation 5:

$$MSE=\sum_{m=1}^{M}\sum_{n=1}^{N}[R(m,n)-I(m,n)]^{2}M\times N$$

$$(5)PSNR=20\log L^{2}MSE$$

The calculation method of SSIM is given by equation 6:

$$,$$

$$(6)SSIM(X,Y)=(2\mu_X\mu_Y+C1)(2\sigma XY+C2)(\mu X2+\mu Y2+C1)(\sigma X2+\sigma Y2+C2)$$

XSL•FO
RenderX

$C1=(K1L)2, C2=(K2L)2$

where μ and μ, σ and σ, and σ are the local means, SDs, and cross-covariance for the DL quantitative images and routine scans, respectively, and C1 and C2 are 2 quantities used to stabilize the division in the case of a weak denominator, with L=65,535, K1 = 0.01, and K2= 0.03.

In addition, a no-reference image quality assessment method, the naturalness image quality evaluator (NIQE), was used to evaluate the quality of quantitative images reconstructed by DL, with fast scan and with routine scan, respectively [24]. Unlike PSNR and SSIM, the lower the value of NIQE, the less distortion and higher image quality.

Statistical Analysis

For the quantitative analysis of brain tissue in healthy participants, Paired *t*-test was used to compare the differences in quantitative values between DL and routine scans, and equivalence was confirmed using two one-sided tests (TOST). Linear regression analysis and Bland-Altman analysis were used in the study, and we combined GM and WM to comprehensively evaluate overall bias. This method captures the overall trends and variability of different tissue types, which is crucial for evaluating the performance of DL reconstruction in clinically relevant contexts. For the region-based quantitative value analysis in healthy participants, coefficients of variation (CVs) were calculated within each imaging method (intragroup CV) and across each imaging method (intergroup CV). Intergroup CV was calculated using the average of the quantitative values from each method. For the images of individuals with pathologies, Paired *t*-test was used to compare quantitative values in different ROIs between groups. All statistical analyses were performed using SPSS 22.0 and GraphPad Prism 9. A *P* value <.05 was considered statistically significant.

Ethical Considerations

This study was approved by the Medical Research Ethics Committees of Beijing Friendship Hospital, Capital Medical University (2020-P2-122-02). All participants provided informed consent before participating. Participants' privacy and confidentiality were protected, with all data being deidentified during analysis. No compensation was provided for participation. No identifiable information of participants was included in the paper or supplementary materials in Multimedia Appendix 1. All procedures adhered to ethical guidelines for participant autonomy, safety, and confidentiality.

Results

Time Consumption

The average whole brain acquisition time was 4 minutes 55 seconds for routine scans, with an additional 1 minute for vendor postprocessing. Fast scans were completed in 1 minute 52 seconds; applying the SRGAN network trained in this study then reconstructed, the 512 by 512 quantitative T1/T2/PD maps were completed in approximately 1 second. Thus, the combined acquisition and reconstruction time was reduced from 5 minutes 55 seconds to 1 minute 53 seconds, promoting the wider clinical application of quantitative neuroimaging and synthetic MRI.

Quantitative Value Accuracy

A paired *t* test showed significant differences in GM tissue values between DL and fast scans (T1: *P*<.001, PD: *P*=.002), while there was no significant difference in GM tissue values between DL and routine scans at T1 (*P*=.66) and PD (*P*=.18). However, compared with routine scans, T2 values still showed significant differences after DL (*P*<.001). For WM, compared with routine scans, there was no significant difference in T2 after DL (*P*=.11). Although there were still significant differences in T1 and PD, the differences were reduced compared with fast scans (Table 1).

Table . The quantitative value of brain tissue obtained by fast scan, deep learning (DL), and routine scan.

	Fast, mean (SD)	DL, mean (SD)	Routine, mean (SD)	*P* value[a]	*P* value[b]
GM[c]					
T1 (ms)	1200.03 (36.01)	1230.17 (34.12)	1232.65 (34.98)	<.001	.66
T2 (ms)	97.87 (2.07)	91.36 (2.60)	93.33 (3.50)	<.001	<.001
PD (%)	79.69 (2.35)	80.29 (1.51)	80.11 (1.23)	.002	.18
WM[d]					
T1 (ms)	814.88 (35.78)	855.06 (32.12)	837.86 (35.88)	<.001	<.001
T2 (ms)	84.57 (2.17)	80.23 (1.61)	79.92 (2.05)	<.001	.11
PD (%)	67.55 (1.94)	68.49 (1.44)	68.21 (1.29)	<.001	.01

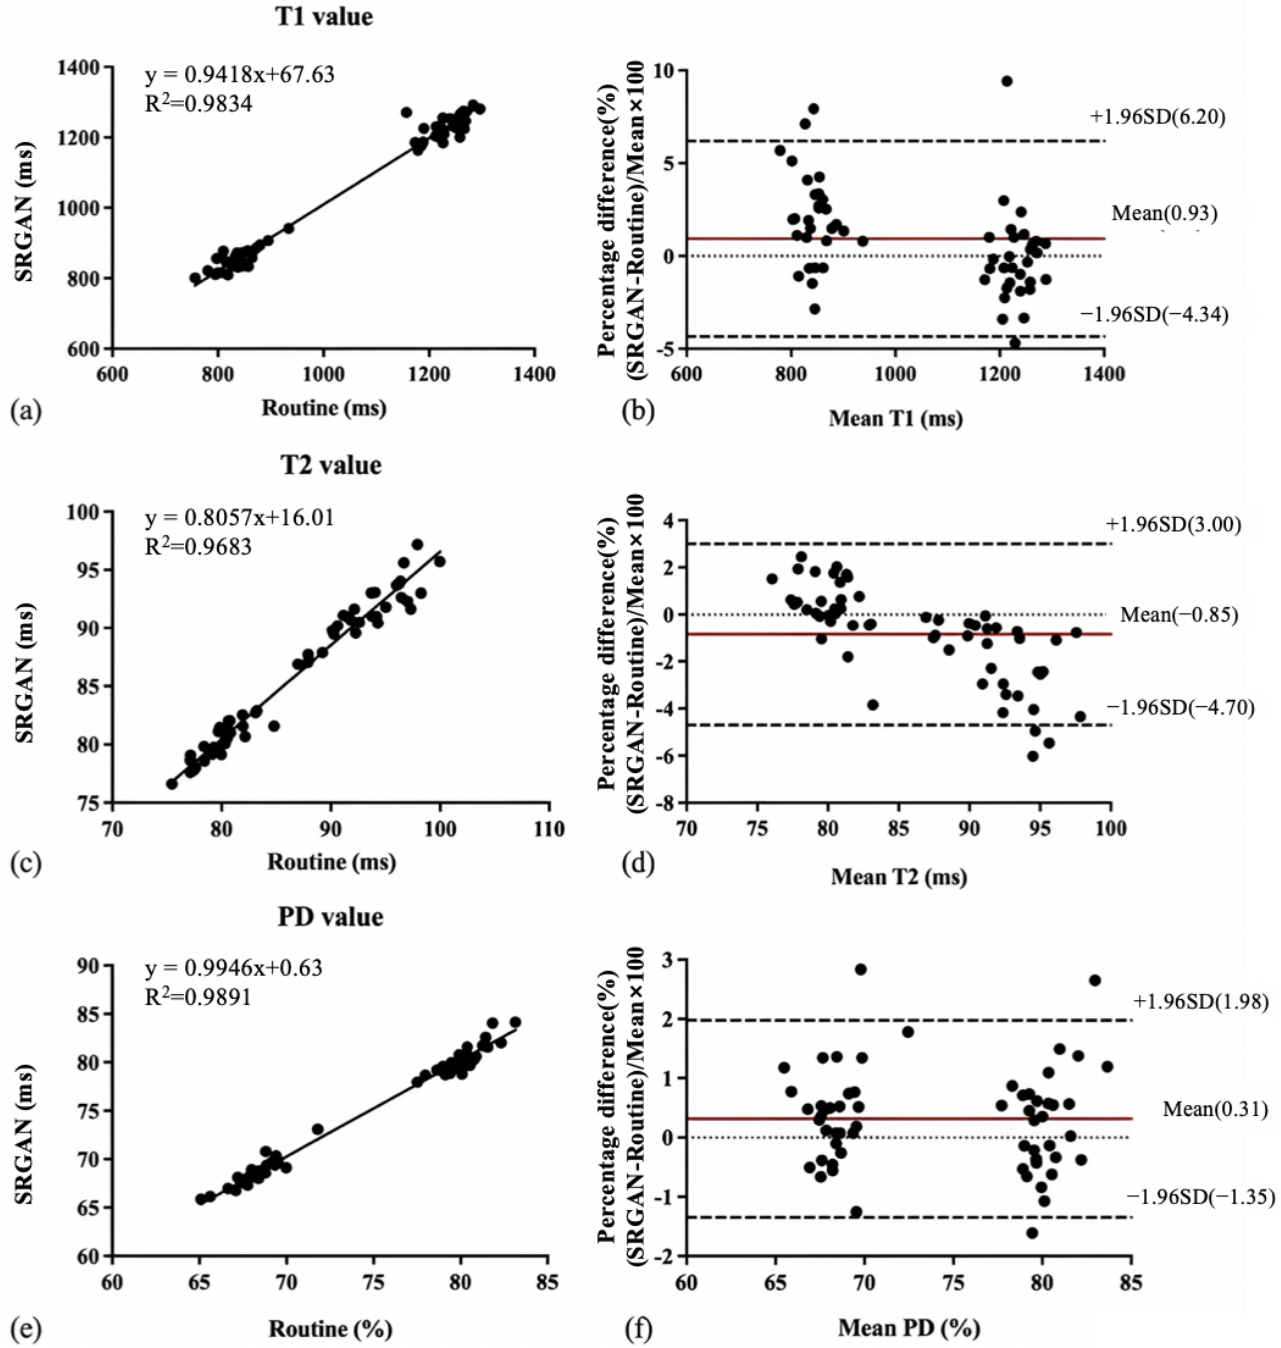
Setting the clinically acceptable brain tissue quantification value limit to ±5% of the mean values from the routine scans (T1_GM epsilon: 61.63 ms, T2_GM epsilon: 4.67 ms, PD_GM epsilon: 4.01%, T1_WM epsilon: 41.89 ms, T2_GM epsilon: 4.00 ms, and PD_WM epsilon: 3.41%), the 90% TOST CI for the brain tissue in 3 quantitative maps (T1_GM: −11.88 to 6.91, T2_GM:



XSL•FO
RenderX

−2.48 to−1.46, PD_GM: −0.04 to 0.41, T1_WM: 10.94 to 23.46, T2_WM: −0.01 to 0.03, and PD_WM: 0.10 to 0.45) were all within the predefined margins (P<.001).

Figure 3 shows the relationship and Bland-Altman plots between the T1, T2, and PD values obtained by DL and routine scans (reference). The correlations to the reference value were excellent, as the R^2 for the T1, T2, and PD values of DL compared to the reference value was 0.98, 0.97, and 0.99, respectively. The slopes of the linear regression were near 1.0 both for T1 (0.9418) and PD (0.9946). In contrast, the T2 values were moderate, as the slope of the linear regression was 0.8057 (Figure 3A,C,E). In addition, the average percentage bias for T1, T2, and PD was 0.93%, −0.85%, and 0.31%, respectively. The 95% limits of agreement were 6.20% to −4.34% for T1, 3.00% to −4.70% for T2, and 1.98% to −1.35% for PD (Figure 3B,D,F). Similarly, Figure 4 shows the relationship and Bland-Altman plots of the T1, T2, and PD acquired by DL and fast scans. The results of linear regression analysis also showed a strong correlation between the 2 methods in T1 and PD (T1: R^2=0.99 and PD: R^2=0.98), with a slightly lower correlation in T2 (R^2=0.80). The slopes of the linear regression were near 1.0 both for T1 (0.9680) and PD (0.9381). In contrast, the T2 values were moderate, as the slope of the linear regression was 0.7755 (Figure 4A,C,E). The results of the bias trend of T1, T2, and PD between these 2 methods also showed similar results, that is, the mean percentage difference for T1 and PD was smaller (3.66% and 1.09%, respectively), whereas the mean percentage difference for T2 was slightly higher (−6.32%) (Figure 4B,D,F).

Bland-Altman plots show mean percentage differences (solid red line) and the 95% CIs (dashed black line). SRGAN: superresolution generative adversarial network.

Table 2 presents the intragroup CV and intergroup CV of brain regions' quantitative values acquired by DL and routine scans. The intragroup variability of the quantitative values obtained by these 2 methods is small, as the intragroup CV for the routine scan's PD values ranges from 1.64% to 6.44%, and the PD values for DL range from 1.98% to 5.84%. The highest intragroup CV of T1 and T2 values was noted in the pallidum (T1: 18.77% vs 17.25%; and T2: 17.00% vs 16.33%). The intergroup CV was lower than the intragroup CV for all brain regions. For intergroup CV, there were no significant differences in the quantitative values of T1, T2, and PD for the WM region after DL reconstruction. However, significant differences in T2 values were observed in the GM regions, including the frontal cortex, temporal cortex, parietal cortex, occipital cortex, insula, and hippocampus.

Table 3 presents the quantitative values in ROI of typical lesions acquired by DL and routine scans. Compared with the quantitative values under routine scans, there were no significant differences in the quantitative values reconstructed by deep learning (T1, *P*=.67; T2, *P*=.73; and PD, *P*=.75).

Table . The naturalness image quality evaluator of quantitative maps under fast scan, deep learning (DL), and routine scan.

	Fast scan, mean (SD)	DL, mean (SD)	Routine, mean (SD)
T1 maps	29.46 (6.42)	13.36 (1.88)	10.90 (1.84)
T2 maps	30.56 (5.57)	18.79 (1.46)	15.21 (1.78)
PD[a] maps	34.66 (2.99)	11.74 (2.17)	10.85 (2.53)

[a]PD: proton density.

Discussion

Principal Findings

In this paper, we trained an SRGAN network to reconstruct whole brain T1, T2, and PD maps from accelerated synthetic MRI data. Experimental results show that the application of DL for reconstruction can generate quantitative maps from fast scans with a 50% reduction in acquisition time. The quantitative instability caused by LR acquisition is reduced, with no significant difference between the reconstructed and routine scan values, and intra- and inter-CVs are small in most brain regions. Our study also found that the resulting maps still allow clear visual detection of common pathologies, thereby helping to shorten clinical scanning time.

Comparison With Prior Work

In previous studies, the use of commercial algorithms for fast image reconstruction resulted in a total brain acquisition time exceeding 3 minutes [25]. Our research further reduces the collection time to less than 2 minutes while maintaining accuracy. DICOM raw data were used as input and output for

XSL•FO
RenderX

the network, which conforms to the standard practice of DICOM image processing, where metadata (including rescaled slopes) are crucial for accurate image analysis and quantitative measurement. By adhering to these specifications, the study maintains the integrity of the qMRI data, facilitating a reliable evaluation of the DL reconstruction techniques' impact on the accuracy of quantitative brain tissue values.

The MDME sequence was used to acquire the quantitative maps, and several studies have investigated the repeatability and reproducibility of quantitative values using this sequence. In this study, we applied multiple quantitative metrics and statistical methods to analyze differences among DL reconstructed, fast scan, and routine scan values. The results of our study, as indicated by the paired *t* tests, provide valuable insights into the performance of DL reconstruction and demonstrate that it improves the accuracy of fast quantitative MRI scans, bringing tissue-specific T1, T2, and PD values closer to those of routine clinical acquisitions. In GM, the method achieved no statistically significant difference compared to routine scans. However, a small but statistically significant underestimation in T2 remained. A previous study examining the influence of parameter modifications on MDME-derived quantitative values reported that alterations in acquisition matrix or acceleration factor induced negligible variance in measured constants, with the exception of CSF T2 estimation [26,27]. Notably, this investigation was performed on an isolated, homogeneous phantom; consequently, partial volume effects and other anatomical confounders were absent. The present fast scan protocol, in contrast, simultaneously varies both matrix size and acceleration factor without a commensurate increase in the number of echo times. This divergence in experimental design may compromise the accuracy of T2 mapping—particularly through reduced sampling density in echo space—thereby introducing systematic bias into the fitted relaxation constants. However, TOST analysis further indicates that the 90% CIs of all brain tissue parameters in the 3 quantitative maps are within clinically acceptable ranges, providing the possibility for the clinical applications of DL quantitative reconstruction.

In our quantitative analysis, the linear regression slope for T2 values (DL vs routine) was 0.8057, which deviates from the ideal value of 1.0. Clinically, this may affect the diagnostic accuracy of high T2 lesions, leading to misdiagnosis or delayed intervention. Most of the samples in this study were healthy volunteers, and the accuracy of DL for T2 values under specific pathological manifestations was not validated. Such bias may arise primarily from the L1 loss component, which enforces pixel-wise fidelity at the expense of high-frequency details and can lead to oversmoothing—particularly in regions with high tissue contrast or rapid T2 decay. Consequently, although the average T2 error across healthy tissue may satisfy TOST criteria, it may reduce the accuracy of this method in extreme cases of dynamic range that often occur in pathology. Despite this limitation, the SRGAN model demonstrated good performance in overall image quality metrics, indicating its practicality in routine clinical workflows, although it requires appropriate attention.

Linear regression and Bland-Altman plots also demonstrated that the vast majority of quantitative parameters exhibited high correlation and agreement between the DL and routine scans, with 95% of data points lying within the limits of agreement, which is in line with previous research [28,29]. In contrast, T2 estimates derived from the DL exhibited a marked bias relative to the reference (Figure 3 vs Figure 4). These findings indicate that the DL model successfully compensates for systematic errors introduced by the fast scan, yielding quantitative values that closely approximate those obtained under routine scans. Such error mitigation directly supports the primary objective of this study: to establish the feasibility of using DL for accurate, ultrafast quantitative MR reconstruction.

In addition to measuring the quantitative values of gray and WM, the study also applied classic atlases from brain science analysis: the anatomical automatic labeling and the Johns Hopkins University atlases [30]. These atlases divide the brain into regions based on structure or function, which allows for a more comprehensive characterization of the accuracy and reliability of the quantitative values. Generally, the intragroup CV should ideally be below 10%, and the intergroup CV should remain under 15%, yet a significant intragroup CV was observed in deep GM nucleus regions, such as pallidum. This may be due to the inhomogeneity of B1 and differences in data acquisition parameters or variations in the age and gender of the individuals, which have also been shown and analyzed in previous studies [31-33]. Additionally, these numerical disparities may stem from spatial registration errors between individual quantitative maps and brain region templates, potentially affecting the extraction of quantitative values. Our study also observed significant differences in the T2 CVs between DL and routine scans in some GM brain regions. This difference indicates that although the SRGAN model has good consistency at the overall organizational level, it may introduce variability at the regional scale, which may be due to the model's sensitivity to local texture or noise, potentially limiting its practicality in precise quantitative neuroimaging applications. However, the intra- and inter-group CV for the remaining brain regions remained below 5%, especially for PD values, which show minimal intragroup and intergroup variation across all brain regions. This implies that T2 is relatively sensitive in quantitative analysis and should be a key focus in disease analysis.

The outlined lesion areas in the study are predominantly distributed in the WM. The average T1, T2, and PD quantitative values within these lesion areas exceed 1000 milliseconds, 100 milliseconds, and 80 milliseconds, respectively, which are higher than the ranges observed in the healthy participants' quantitative values. Furthermore, different types of lesions exhibit distinct quantitative values. WM hyperintensities and acute-phase cerebral infarction have similar quantitative values. In contrast, the quantitative values in encephalomalacia are significantly higher than those in the other 2 types of lesions, particularly the T1 values within encephalomalacia (approaching 4000 ms), which are similar to the T1 value of cerebrospinal fluid because the components of encephalomalacia are similar to cerebrospinal fluid. These findings align with clinical knowledge, indicating that lesion areas generally have longer T1 and T2 relaxation

XSL•FO
RenderX

times. Importantly, the quantitative values obtained through DL still maintain diagnostic efficacy. Through careful examination of quantitative values, it was found that with a small amount of lesion data, although the difference in quantitative values between DL and routine scans did not reach statistical significance, 5 reconstructed T2 values were lower than those of the routine scan in 7 WMH and infarct ROIs. Given that these lesions have already exhibited high T2 relaxation times (usually >100 ms), any systematic underestimation may weaken their abnormal manifestations. This may be because superresolution networks are only trained on quantitative images of healthy adults and do not include any pathological cases. Therefore, the model has not yet learned the characteristic diastolic curves of common brain injuries, such as significant prolongation of WM hyperintensities on T2. This lack of exposure may lead to the network interpreting high T2 values in lesions as outliers or reconstruction artifacts, thereby regressing these values to the healthy tissue distribution. Therefore, the sample size will continue to be expanded in the future to verify the quantitative accuracy of DL reconstruction in various neurological diseases.

While the DL maps have basically met the predefined quantitative equivalence margins, the no-reference NIQE metric reveals a residual perceptual gap: compared with fast scanning, the DL image quality has significantly improved (as indicated by a decreased NIQE score), but compared with routine scans, the NIQE scores of the 3-parameter images are slightly higher. This suggests that the current model ensures the accuracy of clinical quantification and significantly improves accuracy on the basis of fast scans, but further improvement is needed to achieve complete perceptual equality with routine HR imaging.

Limitations

This study still has some limitations. First, the study adopted the widely validated SRGAN framework and focused on quantitative agreement and image quality comparison; however, emerging architectures such as ESRGAN or SwinIR were not compared, nor were traditional non-DL upsampling methods used as baselines. Second, the network was trained exclusively on data acquired with a GE 3.0 T scanner and entirely on normal-appearing brain tissue (only 7 patients with 3 common lesion types were used for testing), so the performance of the method on pathological tissue is a preliminary proof of concept rather than evidence of clinical equivalence. The small number of pathology cases limits statistical power and generalizability to diverse or high-contrast lesions, which may pose a barrier to routine clinical deployment. Third, based on the current amount of data, using the training set and testing set with a single subject-level split of 8:2 may prevent data leakage from related slices but may not fully capture the variability between multiple random partitions. Due to limited training data, the model runs on 2D slices instead of 3D volumes, which may result in a loss of spatial continuity between slices. Fourth, acceleration was limited to an R of 3, reconstruction was performed on postprocessed quantitative maps, raw k-space data were not used, and weighted images generated from the quantitative maps were not evaluated. Additionally, the ground truth images have been reconstructed from a matrix of 320 by 256 to a matrix of 512 by 512, and thus, the model learns to reproduce the interpolated image content rather than recovering genuine high-frequency details that would be present in a natively HR acquisition. Finally, evaluation was performed based on quantitative metrics without introducing a qualitative visual assessment by radiologists.

Future Directions

Future research should focus on the following improvements: systematically compare the current SRGAN implementation with newer superresolution networks and quantify the individual contributions of perceptual and adversarial losses to quantitative accuracy, and compare them with non-DL baseline reconstruction methods to better illustrate the benefits of DL. A prospective cohort including demyelinating disease, tumor edema, and microhemorrhages will be enrolled, and the model will be fine-tuned or retrained if necessary before wider clinical deployment. To improve robustness, we will collect both k-space and image-domain data and develop a dual-domain joint reconstruction framework. Future work will explore 3D or slice-aware architectures based on richer training data and computing resources and attempt to use different data partitioning methods to validate generalization further. Finally, the weighted images derived from the superresolved quantitative maps will be generated and assessed for diagnostic quality.

Conclusions

In conclusion, accelerating synthetic MRI is pivotal for its broader clinical adoption in neuroimaging. In this study, we undertook the optimization and enhancement of images acquired through fast synthetic MRI via DL-based reconstruction techniques. Our efforts may result in a remarkable 50% reduction in clinical scan time, all the while achieving better image quality. Importantly, reconstructed T1 and PD maps show excellent agreement with reference scans, supporting their potential for reliable quantification, although T2 values exhibit a consistent underestimation at higher intensities. Despite this limitation, the overall strong correlations and low average biases suggest that using DL methods to mitigate biases in quantitative values is feasible. Furthermore, the shortened scan time not only enhances patient comfort but also reduces the likelihood of motion artifacts. This optimization streamlines the scanning workflow, minimizes redundancy, and maximizes the efficient use of MRI machines.

Abstract

Background: Supraspinatus tendon pathologies are common causes of shoulder pain. Magnetic resonance imaging (MRI) is the reference imaging method but requires expert interpretation. Automated classification may improve diagnostic consistency and support musculoskeletal imaging workflows.

Objective: This study aimed to develop and evaluate a hierarchical deep learning model to classify supraspinatus tendon status as intact tendons, tendinopathy/partial-thickness tears, or full-thickness tears.

Methods: A total of 1192 shoulder MRI scans were analyzed. The hierarchical system consisted of a left-right orientation classifier, a full-thickness tear detector (model F), and a classifier for distinguishing intact tendons from tendinopathy/partial-thickness tears (model ITP). A flat 3-class model served as a baseline comparator. Performance was evaluated on both an internal test set and an independent external cohort.

Results: On the internal test set, the hierarchical system achieved a system-level sensitivity of 68.1% for tendinopathy/partial-thickness tears, outperforming the flat baseline (57.4%) while maintaining comparable sensitivity for full-thickness tears (hierarchical vs flat: 94.1% vs 95.1%). On the independent external cohort, the sensitivity for tendinopathy/partial-thickness tears was 45.5% for the hierarchical model and 18.2% for the flat baseline. The hierarchical model also showed a numerically higher balanced accuracy (hierarchical vs flat: 68.1% vs 64.5%), macro F_1-score, and macro area under the curve, although its overall accuracy was lower (76.4% vs 79.8%).

Conclusions: A hierarchical deep learning approach that mirrors clinical diagnostic reasoning may improve the recognition of tendinopathy and partial-thickness tears, a challenging category for nonspecialist readers. Given the overlapping CIs, these findings should be interpreted as indicative of a trend rather than definitive improvement. External validation supports feasibility across different MRI sources, though the predominance of data from a single institution limits generalizability and warrants further prospective evaluation.

Introduction

Supraspinatus tendon abnormalities, including tendinopathy and partial- and full-thickness tears, refer to rotator cuff disorders resulting from stress injury, overuse, or age-associated changes. These rotator cuff disorders are leading causes of shoulder pain and functional limitation, affecting approximately 20% of the general population at some point during their lifetime [1]. Among the 4 rotator cuff tendons, the supraspinatus tendon is the most frequently affected, particularly in older adults [2]. Epidemiological studies suggest that nearly half of adults aged older than 60 years exhibit at least partial-thickness supraspinatus tears [3,4]. Supraspinatus tendon abnormalities have a profound impact on patients' quality of life and the use of health care resources [5].

Magnetic resonance imaging (MRI), particularly with coronal T2-weighted sequences, is widely regarded as the imaging modality of choice for evaluating rotator cuff pathology [6]. Its superior soft-tissue contrast allows detailed visualization of tendon integrity, tear morphology, and associated joint abnormalities [7]. Clinicians rely heavily on MRI findings to assess the presence, extent, and severity of supraspinatus tendon pathology to directly inform treatment decisions. While full-thickness tears often necessitate surgical intervention to restore shoulder biomechanics, conservative measures (eg, physical therapy, modifying physical activity, and corticosteroid injections) are typically used to manage tendinopathy and partial-thickness tears [8].

Artificial intelligence (AI), particularly deep learning techniques, can automate complex pattern recognition tasks and support radiologic decision-making [9,10]. However, many early AI models for rotator cuff evaluation lacked demonstrated generalizability, primarily because they were trained on single-institution datasets or homogeneous imaging protocols [11,12]. In addition, prior studies varied considerably in class definitions, input strategies (eg, single-plane vs multisequence MRI), and imaging vendor characteristics, further limiting the comparability of the results and the translation of these models into real-world clinical practice [11,13]. Additionally, clinician trust and adoption of these early AI models remain limited, as their interpretability has often been insufficient to assure physicians that model decisions align with established radiological and anatomical principles.

To address the clinical challenge of accurately identifying supraspinatus tendon pathologies on shoulder MRI, we constructed a hierarchical 3D deep learning model based on the ResNet-18 architecture. The model was trained on a dataset comprising coronal T2-weighted MRI scans, and it classifies tendon status into the following three clinically relevant categories: (1) intact tendons, (2) tendinopathy or partial-thickness tears, and (3) full-thickness tears. To enhance interpretability and support clinicians' trust, Score-weighted Class Activation Mapping (Score-CAM) was integrated to visualize the imaging features that drive model predictions. The robust and interpretable AI framework was designed to support treatment decisions and facilitate real-world integration of deep learning tools in musculoskeletal imaging.

Methods

Ethical Considerations

The protocol of this retrospective study was approved by the Institutional Review Board of Taipei Veterans General Hospital (TVGH; IRB number: 2023-01-024AC). The requirement for informed consent was waived owing to the retrospective nature of the study and the use of deidentified imaging data. All procedures were conducted in accordance with the ethical standards of the institutional research committee and the principles outlined in the Declaration of Helsinki. The study also complied with relevant national legislation and institutional guidelines governing human subject research. Participants did not receive any compensation for this study.

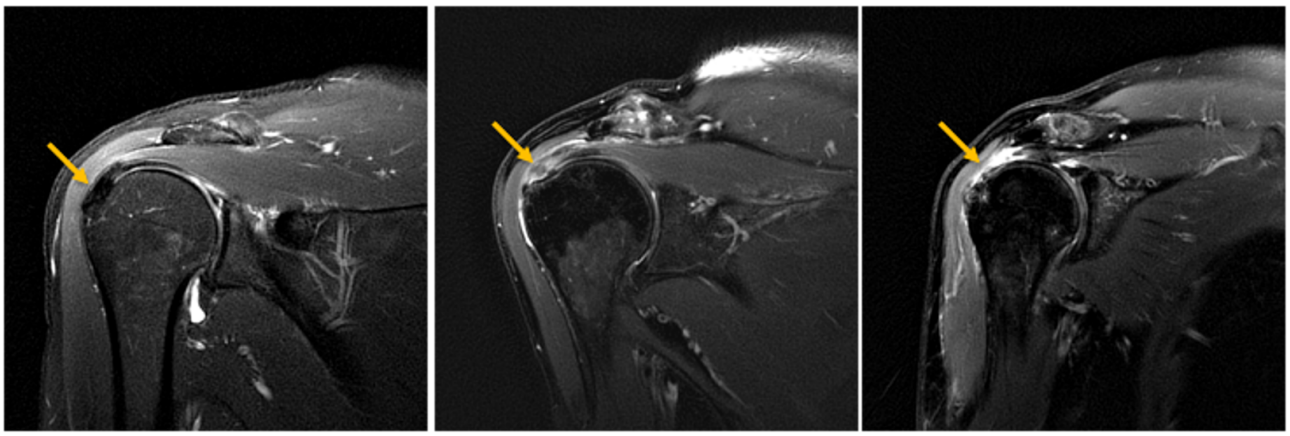
Patient Selection Criteria and Dataset

Coronal T2-weighted shoulder MRI images from 1192 cases were collected for training the new AI-based hierarchical model developed in this study. These images were predominantly obtained from TVGH, but the dataset also included images collected across 65 institutions or uploaded from external facilities for second-opinion evaluations.

Patients with tumors, prior shoulder surgery, humeral head osteonecrosis, moderate to severe osteoarthritis (Kellgren-Lawrence [KL] grades 2 to 4), or a history of fractures around the shoulder were excluded. KL grading was assessed using anteroposterior shoulder radiographs, based on osteophyte formation and joint space narrowing in accordance with established definitions. The distinction between KL grades 1 and 2 followed the original criteria, with definite osteophyte formation serving as the primary threshold for grade 2 [14]. Based on this definition, patients with KL grade ≥2 were excluded to minimize potential confounding from glenohumeral degenerative changes. In this study, KL grading was applied as a pragmatic radiographic exclusion criterion rather than for formal characterization of shoulder osteoarthritis. Although originally developed for other joints, KL grading has been applied in prior radiographic and population-based studies of glenohumeral osteoarthritis, with demonstrated interobserver reliability [15,16].

Cases were categorized into the following 3 groups on the basis of supraspinatus tendon status: intact tendons (n=449), tendinopathy or partial-thickness tears (n=235), and full-thickness tears (n=508). The reference standard for labeling intact tendons and tendinopathy/partial-thickness tears was based on MRI interpretations by consensus between 1 musculoskeletal radiologist and 2 orthopedic surgeons, each with over 10 years of specialty training experience. Full-thickness tears were confirmed through consistent MRI findings and verification by arthroscopic surgical reports.

Of note, tendinopathy and partial-thickness tears were grouped into a single category based on both clinical and methodological considerations. Structurally, tendon continuity is preserved in both these conditions, in contrast to full-thickness tears, which disrupt tendon integrity. Clinically, the management of tendinopathy and partial-thickness tears is similar, with conservative treatment (rest, rehabilitation, medication, or



XSL•FO
RenderX

injections) typically preferred before considering surgical intervention. Moreover, the imaging findings of tendinopathy and early partial-thickness tears often overlap, and interobserver agreement in distinguishing them can be limited [17]. Combining these 2 entities therefore reduces diagnostic variability and aligns more closely with clinical practice.

Definitions

Figure 1 presents the different supraspinatus tendon pathologies, including intact tendons, tendinopathy/partial-thickness tears, and full-thickness tears.

Figure 1. Illustration of supraspinatus tendon conditions: intact tendons (A), tendinopathy/partial-thickness tears (B), and full-thickness tears (C).

MRI-based diagnostic criteria are as follows: tendinopathy is defined by tendon thickening with an inhomogeneous signal intensity and increased signal across all pulse sequences; partial-thickness tears are defined by fluid signal intensity partially filling a gap within the tendon, most evident on fat-suppressed T2-weighted images; and full-thickness tears are defined by complete disruption of the tendon, appearing as high signal intensity spanning the entire tendon thickness on all pulse sequences [18,19].

Dataset Splitting

Cases from each year between 2018 and 2024 were stratified by acquisition year and randomly assigned at the patient level to a training set (64%), a validation set (16%), and an internal test set (20%), ensuring that the year-wise distribution was preserved across all subsets.

The training set consisted of 287 intact tendon cases, 150 tendinopathy or partial-thickness tear cases, and 327 full-thickness tear cases. The validation set included 72 intact tendon cases, 38 tendinopathy or partial-thickness tear cases, and 79 full-thickness tear cases. The internal test set comprised 90 intact tendon cases, 47 tendinopathy or partial-thickness tear cases, and 102 full-thickness tear cases.

The training, validation, and internal test sets demonstrated similar mean echo time and repetition time values. Age and sex distributions were similar across the training, validation, and internal test sets. The distributions of shoulder side and tear type were also comparable among the datasets (Table 1).

[a]Magnetic resonance imaging acquisition parameters and demographic information were extracted from DICOM metadata, and left-right shoulder labels were manually assigned at the case level.

[b]TE: echo time.

[c]TR: repetition time.

Imaging Characteristics

A total of 1192 cases were collected, and the internal cohort was predominantly obtained from TVGH (987 cases; Table 2).

For the internal cohort, the dataset included MRI scans acquired using 29 scanner models from the following 6 vendors: Canon Medical Systems (Ōtawara-shi, Tochigi, Japan), GE Healthcare (Chicago, IL), Philips Medical Systems (Andover, MA; headquartered in Amsterdam, Netherlands), Siemens Healthineers (Forchheim, Germany), Hitachi Medical Corporation (Tokyo, Japan), and Toshiba Medical Systems (Ōtawara-shi, Tochigi, Japan) (Table 1).

The in-plane resolution (X-Y pixel spacing) ranged from approximately 0.19 mm to 0.86 mm, with the majority of cases falling within the range of 0.30 - 0.39 mm. Within this range, 0.3125 mm was the most frequently observed in-plane resolution (496 cases). Slice spacing ranged from 3.0 mm to 5.0 mm, with 3.5 mm being the most commonly used spacing. Slice thickness varied from 2.0 mm to 4.5 mm, and the most common thickness was 3.0 mm. The detailed distributions of slice thickness, slice spacing, and in-plane resolution across the training, validation, and internal test sets are summarized in Tables S1 and S2 in Multimedia Appendix 1.

Kinmen Hospital of the Ministry of Health and Welfare	12	4	5	21
Mackay Memorial Hospital Taipei	3	2	1	6
Postal Hospital	3	1	1	5

External Validation Set

An independent external validation dataset was created from institutions not included in the model development cohort to evaluate the generalizability of the proposed model.

A total of 89 cases were collected from 12 medical institutions across Taiwan, with the largest contribution from Taoyuan Hospital, Ministry of Health and Welfare (37 cases; Table 3). The external validation set comprised 35 intact tendon cases, 11 tendinopathy or partial-thickness tear cases, and 43 full-thickness tear cases.

None of the external cases were used during model training, validation, or hyperparameter tuning (Table 1).

Data Preprocessing

Overview

All DICOM images were first converted to NIfTI format, followed by preprocessing and model input preparation. All MRI volumes were visually inspected to confirm the absence of burned-in text or laterality markers. No field-of-view cropping or masking was applied to remove such information, ensuring that the model did not rely on textual artifacts for laterality classification.

To ensure anatomical consistency, all MRI images of left shoulders were horizontally flipped so that all cases involved right shoulders, thereby reducing directional variability and improving model robustness. Pixel intensities were normalized to the range [0, 1] using linear minimum-maximum scaling on a per-volume basis.

To standardize volumetric input across heterogeneous MRI acquisitions, all scans were resampled using linear interpolation to a uniform spatial resolution, with an in-plane voxel spacing of 0.3125×0.3125 mm and a slice thickness of 3 mm.

Each case was then standardized to 16 slices by extracting the central coronal region of the resampled volume. For cases with fewer than 16 slices, linear interpolation along the slice direction was applied to generate intermediate slices, avoiding zero-padding and preserving anatomical continuity. Because field-of-view centering may vary across scanners and technicians, all cases were reviewed on a case-by-case basis to confirm that the supraspinatus tendon and relevant pathology were present within the selected slice range.

Each input sample was formatted as a 3×L×H×W tensor, where L denotes the number of slices, H represents image height, and W represents image width. All slices were resized to 256×256 pixels using bilinear interpolation. As the original MRI data were grayscale, intensity values were replicated across 3 channels to ensure compatibility with pretrained convolutional neural network (CNN) architectures.

Normalization

We applied several normalization strategies aimed at reducing input variability and simplifying the learning task to improve model performance and generalizability. These preprocessing techniques were based on the dynamic range and statistical distribution of the MRI input data to ensure consistent model performance across diverse acquisition settings.

Interpolation

Because the number of slices varied across MRI scans, all inputs were standardized to 16 slices by selecting the central portion of each scan. For cases with fewer than 16 slices, linear interpolation was applied along the z-axis to generate

XSL•FO
RenderX

intermediate slices, avoiding the use of zero-padding, which can introduce artificial discontinuities.

The interpolation formula was defined as follows. To estimate the voxel intensity at a target position z, located between 2 known slices z0 and z1, with voxel intensities V(x,y,z0) and V(x,y,z1), we used the following formula:

$$V(x,y,z)=(1-wz)\,V(x,y,z0)+wz\,V(x,y,z1)$$

where wz = (z−z0)/(z1−z0).

Spacing and Slice Thickness

The in-plane resolution (X and Y spacing) across the dataset ranged from 0.192 mm to 0.781 mm. The most common resolution was 0.3125×0.3125 mm, observed in 765 cases. Slice spacing (interslice distance) ranged from 3 mm to 5 mm, with 3.5 mm being the most frequently used value (574 cases). Slice thickness varied from 2 mm to 4.5 mm, with 3 mm being the most common setting, found in 958 cases.

All MRI scans were normalized to a standard voxel spacing of 0.3125×0.3125 mm in the X and Y dimensions and 3 mm in the Z dimension in order to reduce the variability introduced by heterogeneous acquisition parameters. Standardizing Z-spacing to match slice thickness also preserved greater anatomical detail, which is critical for identifying subtle tear features. Linear resampling implemented via the SimpleITK library was used for interpolation, allowing precise adjustment of voxel spacing in the NIfTI-formatted MRI data (Table S1 in Multimedia Appendix 1)

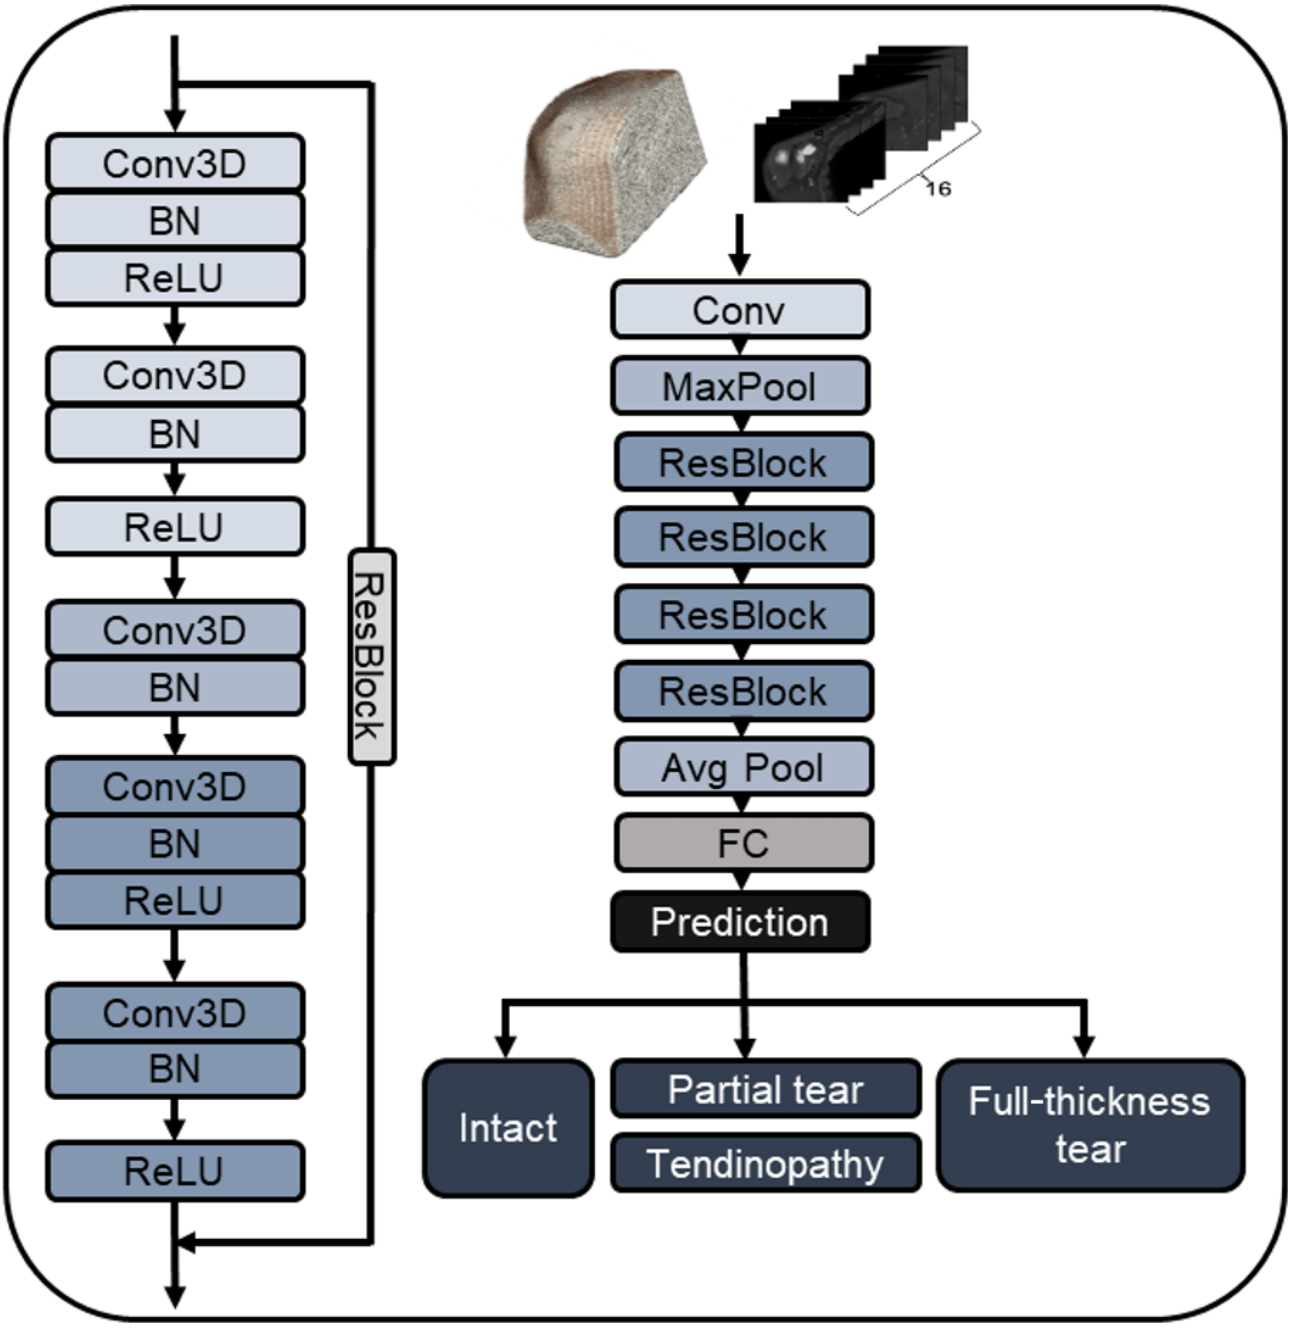
Left-Right Shoulder Classification

In clinical practice, surgeons are able to diagnose shoulder injuries regardless of whether the image is mirrored; however, deep learning models may treat left and right shoulder pathologies as distinct owing to asymmetrical spatial features, which may hinder model generalization. To address this, we trained a left-right model to identify shoulder laterality, and cases predicted as left (406/1192) were horizontally flipped so that all inputs were standardized as right shoulders.

Although DICOM metadata may contain laterality information, it was not consistently available or reliable across datasets from different institutions. In some cases, laterality tags were missing, incomplete, or inconsistent with the actual image orientation. Therefore, we adopted an image-based classification approach to ensure robust and standardized determination of shoulder laterality across all inputs.

This classifier used a 3D CNN architecture implemented using torchvision, consistent with the backbone used in subsequent models. The input for the classifier was the entire MRI volume at the case level, and the output was a binary prediction indicating left or right shoulder orientation.

Ground-truth labels were manually annotated based on image orientation and acquisition metadata. All left shoulder volumes were subsequently mirrored to match the right shoulder orientation, thereby reducing directional variability in the training data.



Model Architecture and Training

A 3D ResNet-18 CNN was constructed for classification. The model architecture is a spatiotemporal extension of the conventional ResNet framework, incorporating residual connections and 3D convolutions to process volumetric data effectively [20]. The 3D ResNet-18 model used in this study was based on the torchvision library implementation within the PyTorch framework (Figure 2). The model used standard BatchNorm3d layers as implemented in the default architecture.

Using transfer learning, the model was initialized with pretrained weights, and the final fully connected layer was modified to perform 2-class classification for each task. During training, a validation set was used to monitor performance and select the best-performing model. Score-CAM was used to generate heatmaps for model interpretability, highlighting the most influential regions in model predictions.

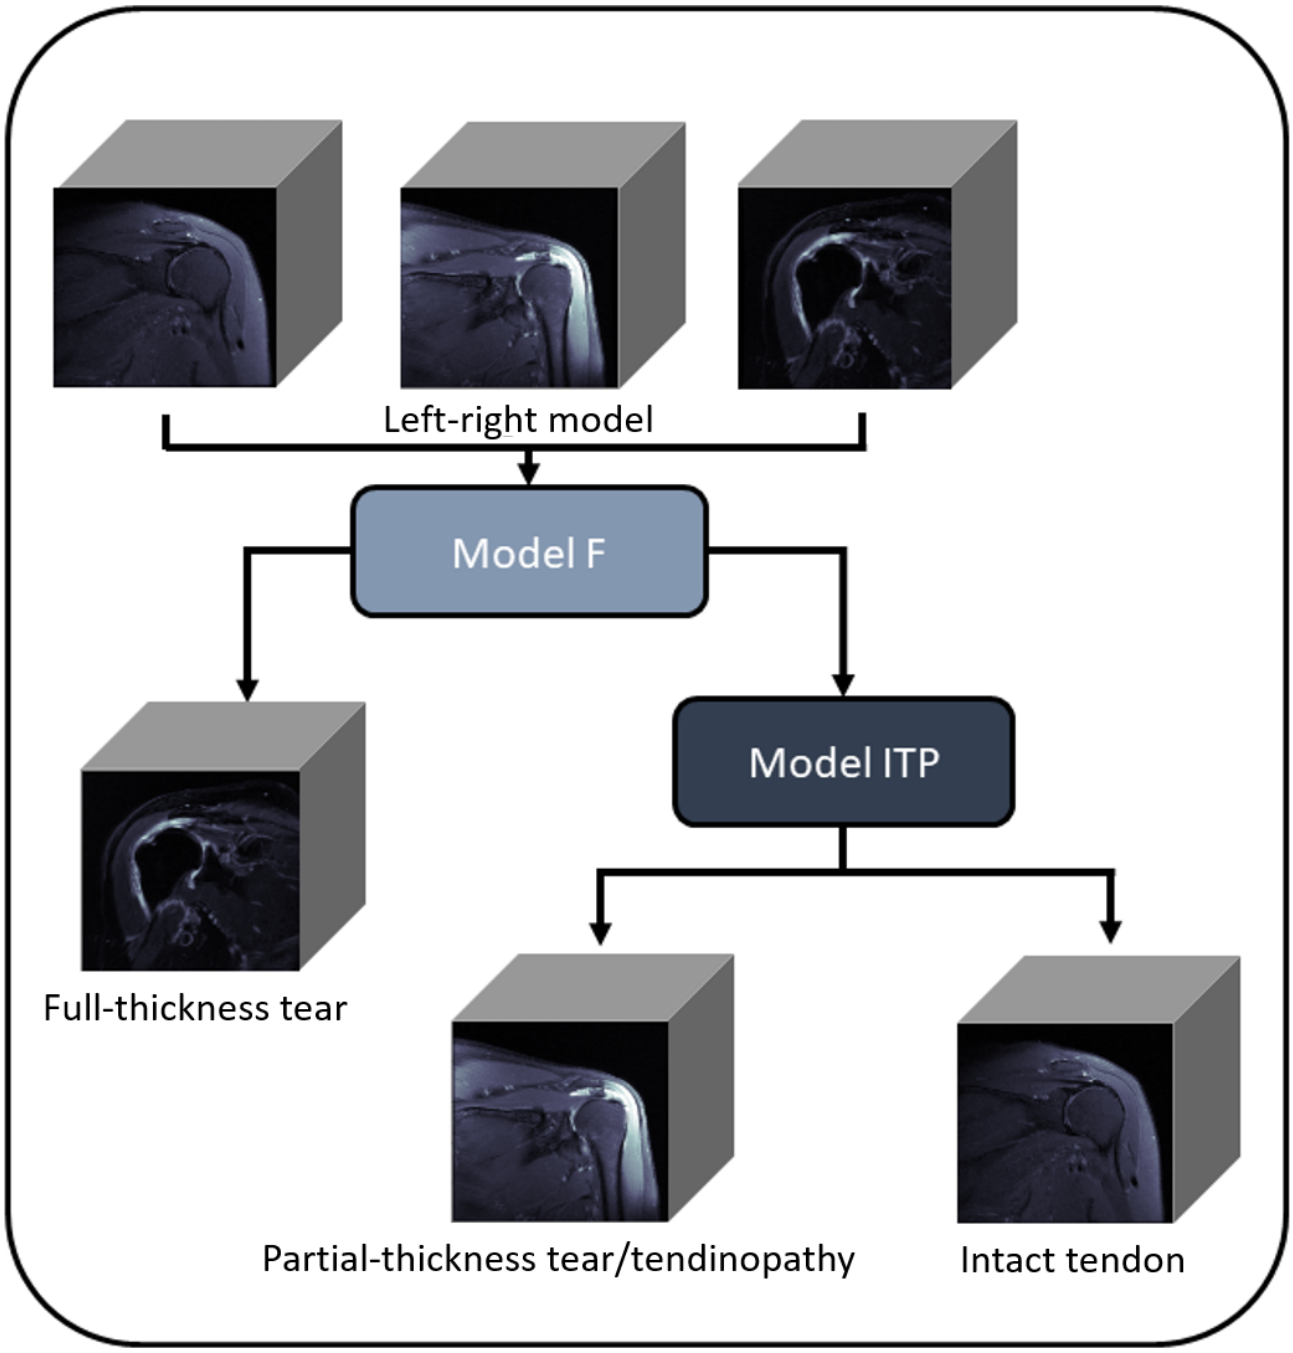
Figure 2. Architecture of the 3D ResNet-18 model used in this study. BN: batch normalization; Conv: convolutional layer; Conv3D: 3D convolutional layer; FC: fully connected layer; MaxPool: max pooling; ReLU: rectified linear unit; ResBlock: residual block.

Hierarchical Classification Framework

To achieve 3-class classification, a hierarchical model composed of 3 sequential 3D ResNet-18 classifiers was designed as follows (Figure 3):



- Model F: Differentiated full-thickness tears from non–full-thickness cases (intact tendons or tendinopathy/partial-thickness tears).
- Model ITP: Applied only to non–full-thickness cases; this model distinguished intact tendons from tendinopathy/partial-thickness tears.

The use of this stepwise approach helped reduce classification complexity and improve overall performance by leveraging domain knowledge of clinical relevance.

Although the final prediction was reported as a 3-class outcome (intact tendons, tendinopathy/partial-thickness tears, and full-thickness tears), the proposed framework performed hierarchical inference through 2 sequential binary classifiers. Specifically, the first-stage model distinguished full-thickness tears from non–full-thickness cases, and only cases predicted as non–full-thickness were subsequently passed to the second-stage model to differentiate intact tendons from tendinopathy/partial-thickness tears. Therefore, the reported 3-class confusion matrices reflected the final outputs of a hierarchical decision process rather than a flat 3-class classifier.

XSL•FO
RenderX

Figure 3. Hierarchical model architecture for 3-class classification of supraspinatus tendon status. Model F: classifier for differentiating full-thickness tears from non–full-thickness cases (intact tendons or tendinopathy/partial-thickness tears); model ITP: classifier for distinguishing intact tendons from tendinopathy/partial-thickness tears.

In addition, for probabilistic evaluation (receiver operating characteristic [ROC] curves and macro area under the curve [AUC]), we derived a unified 3-class probability distribution using conditional probability decomposition. Specifically, the predicted conditional probabilities were defined as follows:

- Model F outputs: P (non–full-thickness $\mid$), P (full-thickness $\mid$)
- Model ITP outputs: P (intact $\mid$ non–full-thickness,), P (ITP $\mid$ non–full-thickness,)

where ITP denotes tendinopathy/partial-thickness tears.

Final 3-class probabilities were computed using conditional probability decomposition as follows:

P (intact $\mid$) = P (non–full-thickness $\mid$)· P (intact $\mid$ non–full-thickness,)

P (ITP $\mid$) = P (non–full-thickness $\mid$)· P (ITP $\mid$ non–full-thickness,)

P (full-thickness $\mid$) = P (full-thickness $\mid$)

where probabilities from model F and model ITP were obtained via Softmax normalization of the corresponding logits. This formulation ensures that the final outputs form a valid probability distribution that sums to 1.

These derived probabilities were used to compute one-vs-rest ROC curves and macro AUC for the 3-class classification task.

XSL•FO
RenderX

Class Imbalance Handling

The dataset exhibited class imbalance across diagnostic categories, particularly for partial-thickness tears and tendinopathy. In the proposed hierarchical framework, class weighting, a strategy shown by Buda et al [21] to be effective and stable for handling imbalanced medical imaging datasets in CNNs, was applied only to the second-stage classifier (model ITP), which distinguishes intact tendons from partial-thickness tears and tendinopathy.

This design choice was motivated by the observation that class imbalance and visual ambiguity are most pronounced at this stage. In contrast, the first-stage classifier (model F), which detects full-thickness tears, targets a clinically distinct and more visually separable category. Selective application of class weighting therefore allowed us to improve sensitivity for the most challenging minority class without destabilizing optimization in the first-stage model as follows:

$$\text{Class Weight}(i)=\frac{N\text{samples}}{N\text{classes}\cdot Ni}$$

Model Interpretability: Score-CAM

To visualize the regions of interest that contributed most to model decisions, Score-CAM was implemented [22]. Unlike gradient-based methods, such as Gradient-weighted Class Activation Mapping [23], Score-CAM assesses the contribution of each activation map by forwarding masked images and observing their effect on the model's output rather than relying on backpropagated gradients. This method provides intuitive, spatially localized visualizations of model attention to support interpretability. The evaluation of these visualizations was qualitative and based on representative cases, without formal quantitative assessment or radiologist-based validation (Figures S1-3 in Multimedia Appendix 2).

Deep Learning Experiment

System and Software

All models were trained on a workstation equipped with an NVIDIA GeForce RTX 3060 GPU (12 GB VRAM), a 12th Generation Intel Core i7-12700F CPU, and 64 GB of RAM, running Ubuntu 22.04.1 LTS. Python 3.10.12 and PyTorch 2.4.0 were used to create a stable and compatible environment for developing and running PyTorch-based applications.

Preprocessing Ablation Experiments

To quantify the impact of individual preprocessing components, we conducted a series of controlled ablation experiments using model ITP as a fixed evaluation framework. The network architecture, dataset split, training procedure, and evaluation metrics were held constant across all experiments, while preprocessing strategies were selectively varied.

The following three preprocessing factors were evaluated: (1) left-right shoulder mirroring, (2) slice standardization strategy (zero-padding vs linear interslice interpolation to 16 slices), and (3) voxel spacing normalization.

Model ITP was selected for these ablation experiments because it provided a stable and representative architecture for assessing preprocessing effects without confounding architectural changes. The final preprocessing pipeline, identified through this ablation analysis, was subsequently applied consistently to both model ITP and model F to ensure methodological uniformity across experiments.

Model Architecture, Pretrained Weights, and Transfer Learning

All experiments were conducted using 3D CNNs based on the 3D ResNet-18 architecture implemented in the torchvision library within the PyTorch framework. Model weights were initialized using parameters pretrained on the Kinetics-400 dataset. The pretrained weights were applied to all convolutional layers, while the final fully connected layers were randomly initialized and trained from scratch for the target classification tasks.

Training Strategy and Class Imbalance Handling

A transfer learning strategy was adopted for all models. For the hierarchical framework, the final fully connected layers were adapted for binary classification in each subtask.

To address class imbalance, class-weighted cross-entropy loss was applied only to the second-stage classifier (model ITP), which distinguishes intact tendons from partial-thickness tears or tendinopathy. Class weights were computed from the training set using the balanced weighting scheme provided by the scikit-learn library, ensuring that underrepresented classes contributed proportionally to the optimization objective.

In contrast, no class weighting was applied to the first-stage classifier (model F), which focuses on detecting full-thickness tears—a clinically distinct category with more separable imaging characteristics.

Hyperparameters and Optimization

Optimal hyperparameters were identified through empirical tuning. A learning rate of 1×10 and a batch size of 8 were selected, as these settings provide stable convergence while maintaining feasible training efficiency for 3D volumetric models. Model parameters were optimized using the Adam optimizer.

Model Selection and Evaluation

The best-performing model was selected based on validation macro-averaged sensitivity (macro sensitivity), which is less affected by class imbalance than overall accuracy. Final performance was evaluated on independent internal and external test sets using accuracy, balanced accuracy, macro-averaged AUC, and confusion matrices.

Flat 3-Class Baseline

For comparison, we trained a conventional flat 3-class classifier to predict intact tendons, tendinopathy/partial-thickness tears, and full-thickness tears directly. This model used the same preprocessing pipeline as the hierarchical framework, including left-right shoulder classification for anatomical standardization, followed by selection of the central 16 slices, resizing, and intensity normalization. The same 3D ResNet-18 backbone, training-validation-test splits, and optimization settings were applied.

XSL•FO
RenderX

To mitigate class imbalance, class-weighted cross-entropy loss was used during training, with class weights computed from the training set using the balanced weighting scheme provided by the scikit-learn library.

The only architectural difference was that the flat baseline used a single 3-class Softmax output layer, replacing the 2-stage hierarchical design.

Computational Cost

All models were trained for 1000 epochs on a single GPU. Because wall-clock training time was not explicitly recorded during the full training process, GPU training time was measured over 10 epochs using identical hardware, batch size, and training settings. The total training time for 1000 epochs was then extrapolated assuming linear scaling with respect to the number of epochs.

Evaluation Metrics

For multiclass classification, precision, F_1-score, sensitivity, and specificity were computed using macro-averaging, whereby each class (intact tendons, tendinopathy/partial-thickness tears, and full-thickness tears) contributes equally regardless of class prevalence.

ROC AUC values were computed using a one-vs-rest strategy from Softmax probability outputs and have been reported as macro-averaged AUC values. Overall accuracy corresponded to micro-averaged performance.

Results

Preprocessing Ablation Experiments

The impact of different preprocessing strategies on model performance was evaluated using model ITP under a controlled ablation framework. Balanced accuracy (macro-averaged sensitivity) was used as the primary evaluation metric to account for class imbalance. The network architecture, dataset split, and training protocol were identical across all experiments, with only preprocessing components being varied.

As summarized in Table 4, applying interpolation-based slice standardization and voxel spacing normalization without left-right mirroring resulted in a balanced accuracy of 0.815. Introducing left-right mirroring while using zero-padding to standardize slice count yielded a modest increase in balanced accuracy to 0.820. This improvement suggests that anatomical orientation alignment reduces directional variability; however, the use of padding may introduce nonphysiological discontinuities along the slice dimension.

Table . Balanced accuracy of model ITP[a] under different preprocessing strategies.

Preprocessing configuration	Balanced accuracy
No mirroring, interpolation to 16 slices, with spacing normalization	0.815
With mirroring, padding to 16 slices, with spacing normalization	0.820
With mirroring, interpolation to 16 slices, without spacing normalization	0.799
With mirroring, interpolation to 16 slices, with spacing normalization	0.826

[a]Model ITP: classifier for distinguishing intact tendons from tendinopathy/partial-thickness tears.

When left-right mirroring and interpolation were applied without voxel spacing normalization, balanced accuracy decreased to 0.799. This reduction indicates that heterogeneity in acquisition parameters, including in-plane resolution and slice spacing, negatively affects model robustness when spatial normalization is omitted.

The highest balanced accuracy (0.826) was achieved when left-right mirroring, interpolation-based slice standardization, and voxel spacing normalization were jointly applied. Based on these findings, the full preprocessing pipeline was selected for subsequent experiments and applied consistently to both model ITP and model F.

Model Training and Performance

All models were trained for 1000 epochs on a single GPU. As wall-clock time was not recorded for the full training run, runtime was measured over 10 epochs using end-to-end wall-clock timing (including both training and validation phases, as well as data loading and evaluation overhead) and then extrapolated to 1000 epochs assuming linear scaling.

Based on this estimation, the total end-to-end GPU runtime for 1000 epochs was approximately 41.9 hours for the left-right classifier, 72.5 hours for model F, and 22.4 hours for model ITP (Table 5). These values should be interpreted as estimated runtimes, as linear extrapolation may not fully capture potential variability in longer training runs (Table 5).

Table . Estimated end-to-end GPU runtime (including training and validation) based on linear extrapolation from 10 epochs.

Model	10 epochs	1000 epochs
Left-right classifier	25.15 min	2515 min (approximately 41.9 h)
Model F[a]	43.51 min	4351 min (approximately 72.5 h)
Model ITP[b]	13.46 min	1346 min (approximately 22.4 h)

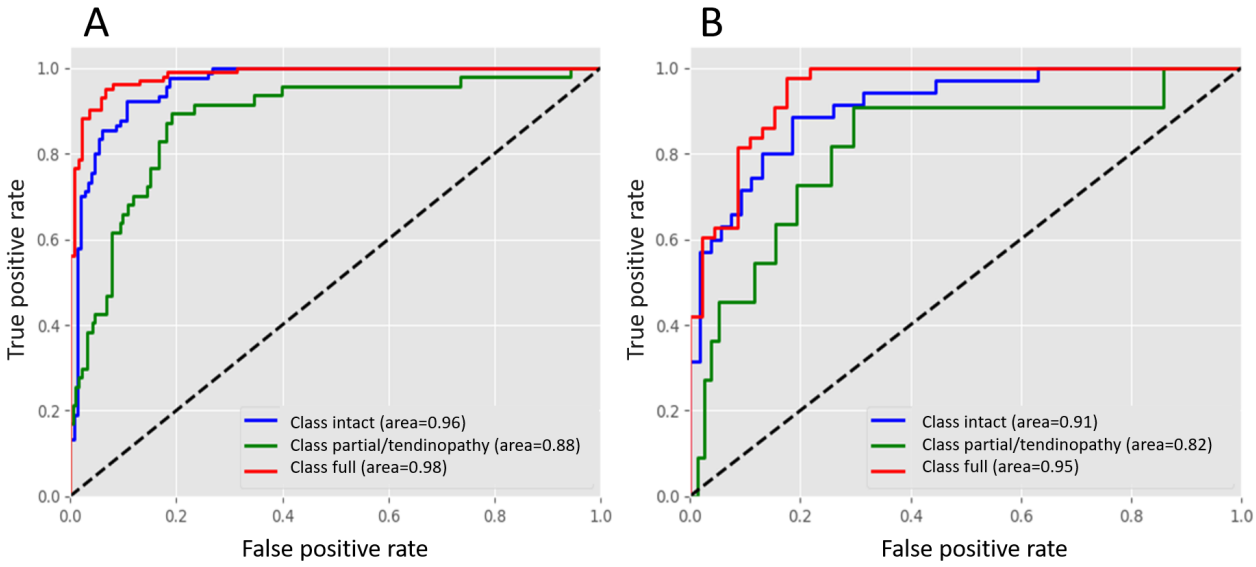
XSL•FO
RenderX

Shoulder laterality (left or right) was determined after first training a binary classifier. The model achieved perfect validation performance (100%) by epoch 2.

Model F was then trained to differentiate full-thickness tears from non–full-thickness cases. The highest validation-balanced accuracy of 96.74% was achieved at epoch 93. Finally, model ITP was trained to distinguish intact tendons from cases with tendinopathy or partial-thickness tears. This model reached its best validation-balanced accuracy of 87.10% at epoch 983.

Training progress and performance metrics across epochs for each model are presented in Figure S4 in Multimedia Appendix 2.



Internal Test Set Performance

Model F, designed to differentiate full-thickness tears from non–full-thickness cases, achieved an accuracy of 93.7% on the internal validation set. The model demonstrated a macro precision of 93.5% and a macro F_1-score of 93.6%. The sensitivity for full-thickness tears was 94.1%, and the specificity for non–full-thickness cases was 93.4%. The ROC AUC was 0.984.

Model ITP, which further classified non–full-thickness cases into intact tendons or tendinopathy/partial-thickness tears, achieved an accuracy of 82.6%. The model yielded a macro precision of 80.8% and a macro F_1-score of 81.3%. The sensitivity for tendinopathy/partial-thickness tears was 83.0%, while the specificity for intact tendons was 82.3%. The ROC AUC was 0.904.

The hierarchical model, which used the left-right model for preprocessing and integrated outputs from model F and model ITP for the final 3-class classification, achieved an accuracy of 84.1% and a macro-average AUC of 0.942. The macro sensitivity and macro specificity were 81.0% and 92.4%, respectively. In addition, the model yielded a macro precision of 80.7% and a macro F_1-score of 80.6% (Figure 4A; Tables 6-8).

External Dataset Performance

On the external validation set, the left-right model maintained perfect performance, achieving 100% accuracy, precision, sensitivity, and specificity, and an ROC AUC of 1.000, confirming strong generalizability for shoulder laterality identification.

Model F achieved an accuracy of 87.7% on the external validation set. The model demonstrated a macro precision of 88.3% and a macro F_1-score of 87.7%. The sensitivity for full-thickness tears was 93.0%, while the specificity for non–full-thickness cases was 82.8%. The ROC AUC was 0.95, indicating good discrimination despite reduced performance compared with internal validation.

Model ITP showed increased performance variability on the external dataset, achieving an accuracy of 76.2%. The macro precision and macro F_1-score were 69.4% and 69.8%, respectively. The sensitivity for tendinopathy/partial-thickness tears was 64.0%, while the specificity for intact tendons was 80.0%. The ROC AUC was 0.815.

The hierarchical model, which used the left-right model for preprocessing and integrated outputs from model F and model ITP for the final 3-class classification, achieved an accuracy of 76.4% and a macro-average AUC of 0.893. The corresponding macro sensitivity, macro specificity, macro precision, and macro F_1-score were 68.1%, 87.7%, 68.3%, and 67.4%, respectively (Figure 4B; Tables 6-8).

Comparison Between Hierarchical and Flat Classification

Using identical backbones, preprocessing steps, and data splits, we compared the hierarchical framework with the flat 3-class baseline.

On the internal test set, the hierarchical model achieved a higher balanced accuracy (hierarchical vs flat: 81.0% vs 77.1%), primarily driven by improved sensitivity for tendinopathy/partial-thickness tears (68.1% vs 57.4%) while maintaining comparable sensitivity for full-thickness tears (94.1% vs 95.1%).

On the independent external cohort, the hierarchical model again improved balanced accuracy (hierarchical vs flat: 68.1% vs 64.5%) and substantially increased sensitivity for tendinopathy/partial-thickness tears (45.5% vs 18.2%). This improvement was accompanied by an increase in false-positive predictions among intact cases, resulting in a modest reduction in overall accuracy (76.4% vs 79.8%).

These findings demonstrate an explicit sensitivity-specificity tradeoff as follows: by prioritizing the detection of full-thickness

XSL•FO
RenderX

tears and subsequently resolving more subtle lesions, the hierarchical strategy reduces the underdiagnosis of partial-thickness pathology, which is clinically desirable, at the cost of increased false-positive predictions. Full performance metrics and confusion matrices for both models are provided in Tables 6 and 7.

The detailed per-class precision, sensitivity, and F_1-score for each model are provided in Table 9. Notably, the hierarchical framework consistently improved sensitivity for the tendinopathy/partial-thickness tear class compared with the flat baseline, particularly on the external cohort.

Table . Per-class performance of hierarchical and flat 3-class models on the internal and external test sets.

Dataset, model, and class	Precision	Sensitivity	F_1-score
Internal test set (n=239)			
Hierarchical			
Intact tendons	0.900	0.811	0.853
Tendinopathy/partial-thickness tears	0.600	0.681	0.638

Full-thickness tears	0.808	0.977	0.884

Leakage/Error-Propagation Analysis

Because hierarchical classification frameworks may be affected by error propagation, we conducted a leakage analysis to explicitly quantify misclassification attributable to each component model (model F and model ITP). The results are summarized in Table 10.

XSL•FO
RenderX

Table . Leakage analysis.

Dataset, model, and error type	Value, n
Internal test set (n=239)	
Model F[a]	
Full-thickness tears misclassified as non–full-thickness cases	6
Non–full-thickness cases misclassified as full-thickness tears	9
Model ITP[b]	
Tendinopathy/partial-thickness tears misclassified as intact tendons	7
Intact tendons misclassified as tendinopathy/partial-thickness tears	16
External test set (n=89)	
Model F	
Full-thickness tears misclassified as non–full-thickness cases	3
Non–full-thickness cases misclassified as full-thickness tears	8
Model ITP	
Tendinopathy/partial-thickness tears misclassified as intact tendons	4
Intact tendons misclassified as tendinopathy/partial-thickness tears	6

[a]Model F: classifier for differentiating full-thickness tears from non–full-thickness cases (intact tendons or tendinopathy/partial-thickness tears).

[b]Model ITP: classifier for distinguishing intact tendons from tendinopathy/partial-thickness tears.

Internal Test Set

In the hierarchical framework, model F (full-thickness vs non–full-thickness) misclassified 6 full-thickness tears as non–full-thickness cases (1 intact tendon and 5 tendinopathy/partial-thickness tear cases) and 9 non–full-thickness cases as full-thickness tears (1 intact tendon and 8 tendinopathy/partial-thickness tear cases), resulting in 15 irrecoverable routing errors. These cases bypassed subsequent classification by model ITP.

Among cases correctly routed as non–full-thickness cases, model ITP (tendinopathy/partial-thickness tears vs intact tendons) produced 23 errors, including 7 misclassifications of tendinopathy/partial-thickness tears as intact tendons and 16 misclassifications of intact tendons as tendinopathy/partial-thickness tears. These errors primarily reflect intrinsic visual overlap between intact tendons and subtle degenerative pathology on MRI.

By comparison, the flat 3-class model misclassified 13 tendinopathy/partial-thickness tear cases as full-thickness tears and 15 tendinopathy/partial-thickness tear cases as intact tendons, yielding a tendinopathy/partial-thickness tear sensitivity of 57.4%, which was lower than the value of 68.1% achieved using the hierarchical framework. Full-thickness sensitivity was comparable between models (hierarchical: 94.1%; flat: 95.1%).

External Test Set

In the external cohort, model F misclassified 3 full-thickness tears as non–full-thickness cases and 8 non–full-thickness cases as full-thickness tears, resulting in 11 irrecoverable routing errors. Model ITP had 10 additional errors, including 4 misclassifications of tendinopathy/partial-thickness tears as intact tendons and 6 misclassifications of intact tendons as tendinopathy/partial-thickness tears.

In contrast, the flat 3-class classifier demonstrated substantially reduced sensitivity for tendinopathy/partial-thickness tears, correctly identifying only 2 of 11 cases (sensitivity=18.2%), while the hierarchical model identified 5 of 11 cases (sensitivity=45.5%). This improvement in the most diagnostically challenging class was accompanied by an increase in false-positive tear predictions among intact cases (hierarchical: 6 vs flat: 2), resulting in a modest reduction in overall accuracy (hierarchical vs flat: 76.4% vs 79.8%) but a higher balanced accuracy (68.1% vs 64.5%).

Discussion

Principal Findings

This study describes a hierarchical deep learning framework for classifying supraspinatus tendon pathologies on coronal T2-weighted shoulder MRI. By separating the diagnostic task into 2 clinically guided stages—first detecting full-thickness tears and then distinguishing intact tendons from partial-thickness tears or tendinopathy—the model aligns with real-world diagnostic workflow patterns. The hierarchical design achieved high sensitivity for full-thickness tears and showed consistent performance on an external dataset, supporting its generalizability. Compared with a conventional flat model, the hierarchical approach was associated with numerically improved performance in selected metrics; however, the 95% bootstrapped CIs overlapped, suggesting that these differences should be interpreted with caution. Additionally, integration of Score-CAM enhanced model interpretability by highlighting clinically relevant features that informed model predictions. These results suggest that the AI-based framework described herein may support radiologists and orthopedic surgeons in improving diagnostic efficiency, consistency, and confidence in musculoskeletal imaging.

Recent advances in deep learning have correspondingly advanced the automated analysis of shoulder MRI for diagnosing rotator cuff tears. Several notable studies have explored various model architectures and approaches. Lin et al [24] developed an ensemble model using 4 parallel 3D ResNet-50 networks to classify rotator cuff tears as no tear, partial-thickness tear, or full-thickness tear. Guo et al [25] introduced a 2D CNN model based on the Xception architecture for the automated diagnosis of supraspinatus tears. Lee et al [26] used a YOLO v8–based model to detect rotator cuff tears across axial, coronal, and sagittal planes. Esfandiari et al [27] proposed a custom 2D CNN for binary classification of rotator cuff tears versus healthy cases. Yao et al [28] developed a 3-stage deep learning pipeline incorporating slice selection (ResNet), segmentation (U-Net), and a multi-input CNN classifier for supraspinatus tear detection.

While these prior studies demonstrated promising results, most were limited by single-center datasets and variable sample sizes—ranging from 100 to 11,000 MRI examinations—which may constrain generalizability and clinical applicability. In addition, prior studies differed substantially in class definitions, input configurations (eg, single-plane vs multisequence MRI), and imaging vendor characteristics, further limiting direct comparison across studies and hindering the assessment of real-world performance.

Recent work has demonstrated the feasibility of code-free deep learning (CFDL) platforms for musculoskeletal MRI analysis, including the detection and classification of supraspinatus tendon pathologies on shoulder MRI, enabling rapid model development without manual coding [29]. Similar advantages of CFDL approaches, such as accessibility and ease of use, have also been reported in other radiologic applications, including chest radiograph classification, detection, and segmentation [30].

However, code-free frameworks generally provide limited flexibility in task-specific preprocessing, explicit volumetric modeling, and structured decision strategies, which are critical for hypothesis-driven evaluation and clinical interpretability. In this study, a coded deep learning framework was therefore adopted to enable explicit 3D preprocessing, hierarchical task decomposition, and transparent analysis of sensitivity-specificity tradeoffs and error propagation. This design aligns with the clinical diagnostic workflow of rotator cuff evaluation and supports interpretable, clinically grounded model assessment. We did not adopt 2D slice-level aggregation approaches, as rotator cuff tear evaluation inherently requires the assessment of 3D spatial continuity across MRI slices. Clinically relevant features, such as tear extent, morphology, and tendon retraction, are distributed across multiple slices and cannot be reliably captured using isolated 2D representations, which may lead to suboptimal diagnostic performance.

Building on earlier work, this study has presented a hierarchical deep learning framework trained on 1192 shoulder MRI scans from a dataset that was predominantly derived from a single institution but also contained images collected across 65 institutions and acquired using 29 different scanner models. This dataset reflects some degree of real-world clinical variability and provides preliminary evidence regarding the robustness and generalizability of the model. Additionally, the new model integrates Score-CAM to provide intuitive, heatmap-based visualizations of the regions contributing to each prediction, supporting interpretability and offering clinical utility by assisting radiologists in verifying the model's diagnostic rationale.

Although the classification task nominally involves only 3 diagnostic categories, the challenge lies not in the number of classes but in the substantial visual overlap between adjacent categories, particularly among intact tendons, partial-thickness tears, and early tendinopathy. In our flat 3-class baseline, this intrinsic ambiguity resulted in consistently low sensitivity for tendinopathy/partial-thickness tears, especially on the external cohort, despite using the same backbone architecture, preprocessing pipeline, and training configuration as in the hierarchical framework.

To address this limitation, we adopted a hierarchical classification strategy composed of 2 sequential binary decision steps, motivated by task decomposition rather than increased architectural complexity. In this framework, model F first identifies full-thickness tears and excludes them from further consideration, and then, model ITP classifies the remaining cases as intact or tendinopathy/partial-thickness tears. By explicitly separating a clinically high-priority decision from the assessment of more subtle pathology, the hierarchical design simplifies individual decision boundaries and closely mirrors diagnostic reasoning in routine clinical practice.

Quantitatively, the hierarchical model demonstrated numerically higher balanced performance compared with the flat 3-class baseline across both internal and external cohorts. Balanced accuracy increased from 77.1% to 81.0% on the internal test set and from 64.5% to 68.1% on the independent external cohort. However, the 95% bootstrapped CIs overlapped; therefore, these numerical differences should be interpreted cautiously and may not represent statistically significant differences. These differences were primarily driven by higher sensitivity for tendinopathy/partial-thickness tears—the most diagnostically challenging category—particularly in the external cohort (hierarchical vs flat: sensitivity 45.5% vs 18.2%). This represents a trend toward improved detection in this class, although the difference may not be statistically significant. This increase in sensitivity was accompanied by more false-positive predictions among intact cases, reflecting a sensitivity-specificity tradeoff. This tradeoff was explicitly characterized through per-class metrics and confusion matrices.

As expected, hierarchical models are susceptible to error propagation, whereby misclassification at an earlier decision stage cannot be corrected downstream. Our leakage analysis suggests that a substantial proportion of residual errors arose from clinically recognized ambiguity between intact tendons and tendinopathy/partial-thickness tears, rather than widespread routing failures in model F. Compared with the flat classifier, the hierarchical framework was associated with higher sensitivity for subtle tendon pathology, accompanied by reduced specificity for intact cases. This reflects a sensitivity-specificity tradeoff that may be clinically relevant; however, given the overlapping 95% bootstrapped CIs, these differences did not

XSL•FO
RenderX

reach statistical significance. These findings should therefore be interpreted as a trend rather than a definitive improvement.

Finally, the 2-stage hierarchical architecture, together with the preliminary left-right shoulder classification used to ensure anatomical consistency of inputs, may enhance both interpretability and clinical plausibility. In addition to architectural design, several preprocessing strategies informed by imaging and clinical domain knowledge were incorporated and may have contributed to model performance.

The hierarchical framework was associated with numerically improved selected classification metrics and enhanced interpretability—an important factor for clinical integration. However, given the overlapping 95% bootstrapped CIs, these performance differences did not reach statistical significance. These findings suggest that structuring AI models in alignment with established diagnostic workflows may be beneficial, particularly in scenarios where certain pathology categories (eg, full-thickness tears) are visually distinct and diagnostically prioritized. Nevertheless, these observations should be interpreted as indicative of a trend, and further validation with larger cohorts and formal statistical testing is warranted.

The integration of Score-CAM further contributed to model transparency by generating interpretable heatmaps. Notably, attention maps from the left-right classifier and model F closely corresponded to anatomical regions of interest typically emphasized by experienced clinicians, suggesting that these models learned clinically relevant features. However, model ITP occasionally attended to regions inconsistent with the surgical focus, indicating a need for further refinement. Improving the model's sensitivity to subtle findings, such as tendinopathy and partial-thickness tears, will likely require a larger, well-annotated dataset with richer representation of these pathologies. Notably, the evaluation of Score-CAM in this study was qualitative and based on representative examples rather than a systematic or quantitative assessment; therefore, these visualizations should be interpreted as supporting interpretability rather than providing definitive evidence of accurate anatomical localization.

Strengths and Limitations

This study has several strengths. First, although the internal cohort was predominantly derived from a single institution, it also included MRI data from multiple external sources, providing an opportunity to preliminarily assess model performance across heterogeneous imaging settings. Second, the hierarchical classification strategy mirrored real-world diagnostic reasoning, contributing to numerically improved selected performance metrics and clinical interpretability.

This study also has several limitations. First, although volumetric slice standardization and manual quality control were implemented to ensure supraspinatus tendon coverage, it remains possible that peripheral or atypically positioned tear extensions were not fully captured within the standardized 16-slice volume. This design choice balanced anatomical coverage and computational feasibility. Future work may explore adaptive slice selection or attention-based volumetric models. Second, the external validation cohort—while useful for assessing generalizability—contained only 11 cases of tendinopathy or partial-thickness tears. This limited subgroup sample size introduced statistical fragility and wide CIs, restricting the strength of conclusions regarding external generalizability for this category. Sensitivity estimates for tendinopathy/partial-thickness tears should therefore be interpreted with caution, and larger external cohorts will be required to verify performance for this subgroup. Third, potential label bias may exist, as full-thickness tears were confirmed using surgical or arthroscopic findings, while partial-thickness tears and tendinopathy were labeled based on imaging consensus. This difference in reference standards may introduce classification bias. Accordingly, the model's performance for partial-thickness tears and tendinopathy reflects agreement with expert interpretation rather than true diagnostic accuracy against a surgical gold standard, which may limit the achievable performance for these classes. Fourth, the hierarchical framework may be susceptible to cumulative error propagation, in which misclassifications at early stages influence downstream outputs. This tradeoff reflects an intentional prioritization of sensitivity for partial-thickness tears over global accuracy but may reduce specificity for certain subgroups. Fifth, the model was trained exclusively on coronal T2-weighted sequences, whereas ground truth labels were established based on full multiplanar and multisequence clinical MRI review. This modality gap may limit the recognition of subtle partial-thickness tears, which often benefit from sagittal or proton-density fat-suppressed views. Future work incorporating multisequence or multiplane inputs may enhance diagnostic performance. Sixth, tendinopathy and partial-thickness tears were grouped into a single category to reflect overlapping early management in routine clinical practice. However, this grouping reduces granularity for surgical planning, particularly around thresholds for operative referral versus conservative management. Seventh, patients with moderate-to-severe glenohumeral osteoarthritis (KL grades 2 - 4) were excluded, which may limit applicability to older individuals at the highest risk for degenerative rotator cuff pathology and introduce a form of selection bias. Prospective validation in more heterogeneous clinical populations is warranted. Eighth, with respect to the left-right classification task, although all MRI volumes were visually inspected to confirm the absence of burned-in laterality markers or textual overlays, the possibility that subtle nonanatomical cues contributed to the classification cannot be completely excluded. Ninth, the assessment of Score-CAM was qualitative and lacked formal radiologist-based or quantitative validation, and thus, the extent to which the highlighted regions correspond to true anatomical focus remains uncertain. Tenth, most cases originated from a single hospital, TVGH, which may introduce center-specific imaging bias and limit the model's generalizability to other institutions. Finally, alternative model architectures, including 2D slice-level ensembles or transformer-based volumetric models, were not explored in order to isolate the effect of hierarchical diagnostic task structuring. Future studies may investigate hybrid approaches to further align model behavior with clinical decision-making pathways.

XSL•FO
RenderX

Conclusions

In this study, we developed a hierarchical deep learning framework to classify supraspinatus tendon pathologies on shoulder MRI. The framework decomposed the diagnostic task into two binary stages—first distinguishing full-thickness tears and then differentiating intact tendons from tendinopathy or partial-thickness tears—reflecting clinical diagnostic reasoning. Across internal and external evaluations, the hierarchical approach showed numerically improved recognition of tendinopathy and partial-thickness tears relative to a conventional flat 3-class model while maintaining high sensitivity for full-thickness tears. These findings suggest that clinically motivated task structuring may support more reliable supraspinatus pathology classification and may align with radiological interpretation workflows, although further validation with larger cohorts and formal statistical testing is warranted.

Acknowledgments

We thank Wan-Yi Tai for her valuable assistance. We also acknowledge the National Center for High-Performance Computing for providing computing resources. Generative artificial intelligence (ChatGPT and OpenAI) was used for language editing and refinement. The authors take full responsibility for the content of the manuscript.

Funding

This work received funding from various sources, including Taipei Veterans General Hospital (Grant No. 113DHA0100295), the National Science and Technology Council (Grants: 114-2124-M-037-002, 114-2124-M-A49-009, 114-2622-E-A49-007, 114-2321-B-182-005, 113-2923-M-A49-004-MY3, and 113-2118-M-A49-007-MY2), the Higher Education Sprout Project of the Kaohsiung Medical University and the National Yang Ming Chiao Tung University from the Ministry of Education, Taiwan, and the Biomedical Artificial Intelligence Academy of the Kaohsiung Medical University, Taiwan

Data Availability

The data supporting the findings of this study are not publicly available because they contain patient imaging data and are subject to institutional privacy and ethical restrictions. Requests for access to deidentified imaging data may be directed to the corresponding author and will be considered on a case-by-case basis, subject to approval by the relevant institutional review board, institutional data-sharing policies, and applicable privacy regulations. Abstract

Background: Knee osteoarthritis (KOA) is one of the most prevalent chronic musculoskeletal disorders among the older adult population. Screening populations at risk of rapid progression of osteoarthritis and implementing appropriate early intervention strategies is advantageous for the treatment and prognosis of affected patients.

Objective: This study aimed to construct and validate a nomogram model based on x-ray radiomics to effectively identify individuals experiencing progression of KOA pain.

Methods: The Foundation for the National Institutes of Health Biomarkers Consortium included a total of 600 participants who were classified as pain progressors (n=297, 49.5%) and non–pain progressors (n=303, 50.5%) according to an increase in the Western Ontario and McMaster Universities Osteoarthritis Index pain score of ≥9 points (on a scale from 0 to 100) during the follow-up period of 24 to 48 months. X-rays that lacked defined spacing in the DICOM image were excluded. Fully automatic selection of subchondral bone regions on the inner and outer edges of the tibia and femur as regions of interest and extraction of radiomics features for different combinations of regions of interest were conducted. Least absolute shrinkage and selection operator regression was used to select features and generate a radiomics score using Shapley additive explanations for interpretability. The radiomics score, along with clinical indicators, was incorporated into nomograms using a multivariable logistic regression model. The subgroup analysis focused solely on the progression of pain and cases with no progression at all. The receiver operating characteristic curve, along with calibration and decision curves, was used to assess the discriminative performance.

Results: A total of 450 participants were included in the study. Shapley additive explanations analysis identified Wavelet-HH_gldm_HighGrayLevelEmphasis as the primary radiomics feature. Nomogram 1 and nomogram 2 for predicting KOA pain progression achieved area under the curve values of 0.766 and 0.753, respectively, with mean absolute errors of 0.012 and 0.008, respectively, in the calibration curves. Decision curve analysis showed a positive net benefit across a range of threshold probabilities. In subgroup analyses, nomogram 3 and nomogram 4 yielded areas under the curve of 0.795 and 0.740, respectively.

Conclusions: The nomograms based on x-ray radiomics demonstrated excellent predictive capability and accuracy in forecasting the progression of KOA pain.

Introduction

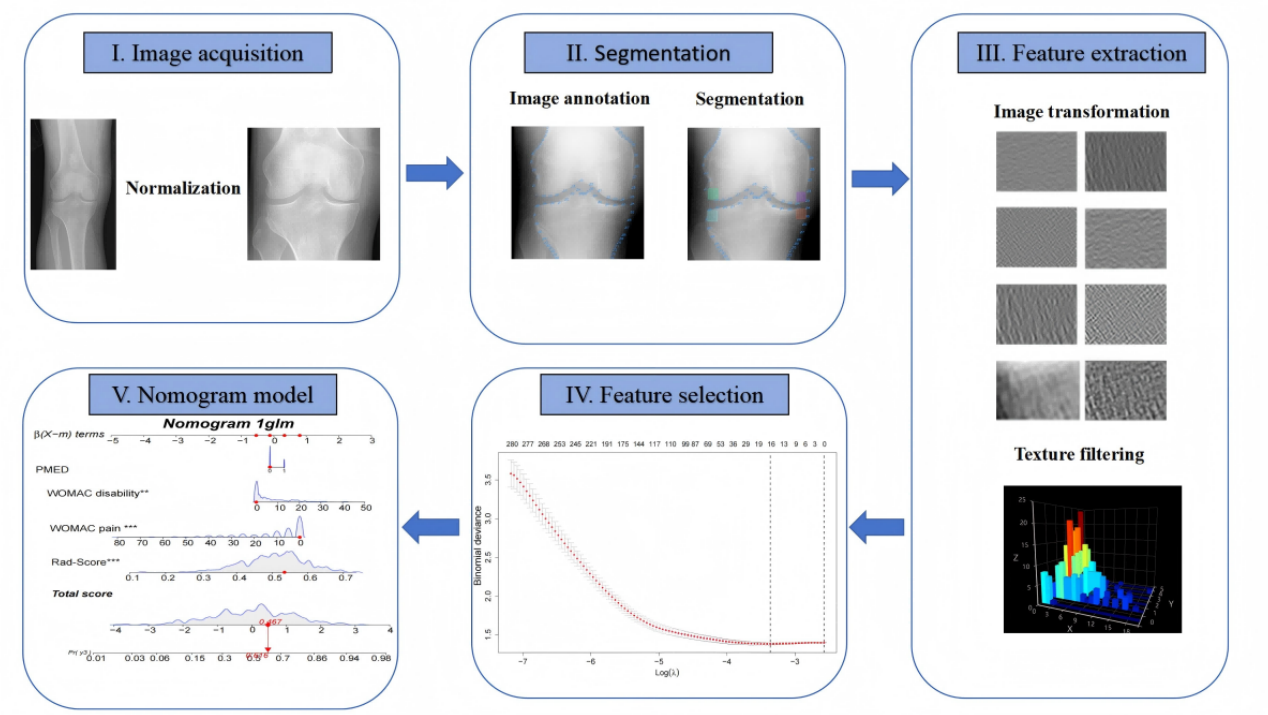
Osteoarthritis (OA) is one of the most common joint disorders affecting the older adult population. With the aging of the population, its incidence has been increasing year by year, imposing a significant burden on both individuals and society [1]. Knee OA (KOA) has the highest incidence among all types of OA. The etiology of KOA is multifactorial, and its pathogenesis remains unclear. KOA can be categorized into various clinical phenotypes and molecular subtypes, including metabolic, inflammatory, mechanical, and genetic [2]. The current treatment guidelines are not suitable for the early diagnosis of KOA and do not distinguish patients who may experience rapid progression [3]. Identifying patients at high risk of rapid progression of KOA will assist in patient education and in the prioritization and allocation of health care resources [4].

The subchondral bone is essential for knee joint structure. Its degeneration disrupts the homeostasis of the intra-articular environment, potentially triggering cartilage degeneration and injury. Furthermore, it is associated with the incidence and progression of OA [5,6]. X-ray imaging continues to be the most prevalent, convenient, and cost-effective modality for evaluating KOA. However, it can only provide a rough estimate of disease severity without quantitative analysis or predicting disease progression [7]. With the application of artificial intelligence in KOA, x-rays can now predict the progression of KOA [3]. Leung et al [8] developed a deep learning predictive model to assess the risk of progression in KOA using knee x-ray images. The findings of their study indicated that this deep learning model surpassed traditional binary outcome models, which are based on standard scoring systems, in predicting the likelihood of total knee arthroplasty among patients with OA [8]. Although deep learning technology is regarded as the most sophisticated image classification technique currently available, its inherent lack of interpretability poses challenges for users in comprehending the model's decision-making outcomes [9].

Radiomics is a novel approach that harnesses advanced image analysis tools and the rapid development of medical imaging data. By integrating artificial intelligence, it enables high-throughput extraction of information from standard medical images and applies the extracted data to clinical decision support systems to enhance the accuracy of diagnosis, prognosis, and prediction [10]. Radiomics has been gradually applied in the field of KOA. Current research primarily focuses on using radiomics to diagnose KOA and predict its radiological progression [11-14]. However, studies on radiomics for predicting the pain progression of KOA are still relatively scarce. A recent study that used magnetic resonance imaging (MRI) radiomics to predict pain progression in KOA demonstrated that the constructed radiomics model achieved an area under the receiver operating characteristic curve (AUC) of 0.79 to 0.86 for KOA pain progression prediction [15]. Nevertheless, the study incorporated 200 radiomics parameters and included omics data from 12- and 24-month follow-ups, resulting in high model complexity and limited practical applicability.

Therefore, this study aimed to develop a nomogram model integrating x-ray subchondral radiomics features and clinical characteristics to predict pain progression in KOA. The Shapley additive explanations (SHAP) method was incorporated to offer a comprehensive explanation and intuitive visualization of the model's predictive mechanisms. This approach allows for the identification of high-risk individuals with rapid pain progression among patients with KOA using cost-effective detection methods, thereby providing clinicians with evidence-based guidance for early intervention strategies.

Methods



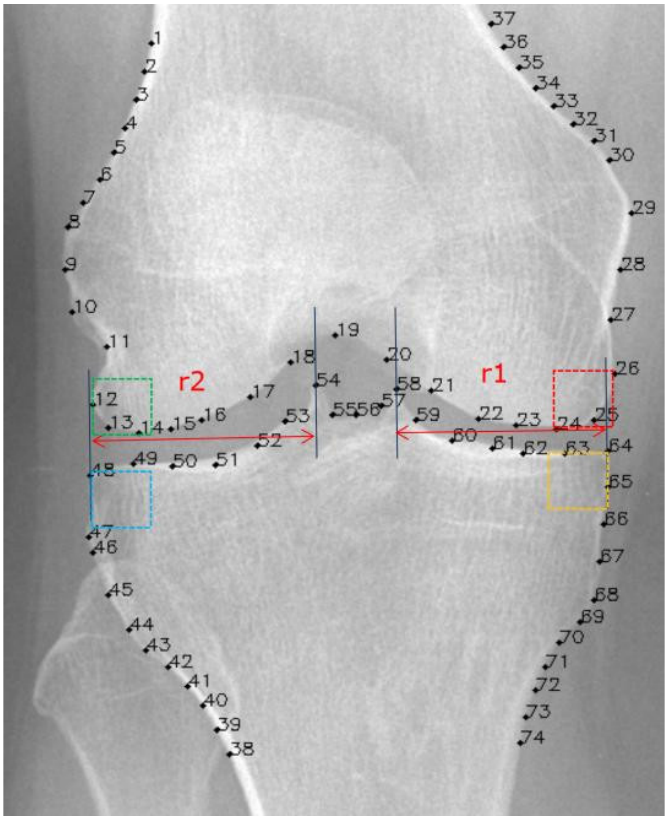
Participants

This study involved participants from the Foundation for the National Institutes of Health (FNIH) Osteoarthritis Biomarkers Project. The design of this research is detailed in previously published literature [16,17]. In brief, the FNIH Osteoarthritis Biomarkers Project includes 600 participants with KOA of Kellgren-Lawrence grades 1 to 3. According to the results of the follow-up, the 600 participants at baseline were categorized into four distinct subgroups: (1) participants exhibiting both radiological and pain progression (n=194, 32.3%), (2) participants with only radiological progression (n=103, 17.2%), (3) participants experiencing only pain progression (n=103, 17.2%), and (4) participants who exhibited neither radiological nor pain progression (n=200, 33.3%). Radiological progression was defined as a loss of minimum joint space width of ≥0.7 mm in the medial femorotibial compartment between baseline and follow-up at 24, 36, or 48 months. Pain progression was characterized by a sustained increase in the Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC) pain subscale (≥9 on a scale from 0 to 100) based on the minimum clinically important difference during the same time frame. In the Digital Imaging and Communications in Medicine (DICOM) standard, pixel spacing is a critical factor for converting image pixels into physical dimensions. Spacing ensures the reliability and reproducibility of medical images in diagnosis, research, and treatment planning [18]. However, some datasets lack or contain erroneous spacing information. They use default values (1.0, 1.0), which result in calculated knee dimensions significantly exceeding normal human anatomical ranges. Such data can be defined as "DICOM data with invalid spacing information." In the standardization process for the Osteoarthritis Initiative (OAI) knee x-ray images, cases with unspecified pixel spacing were excluded. As the pixel spacing of 0.2 mm was predominant in the dataset, all retained images were calibrated to this value to ensure consistent spatial scaling [19]. The specific process of normalization is described in Multimedia Appendix 1 [20-22]. Groups 1 and 3, which

XSL•FO
RenderX

showed pain progression, were combined as the case group, whereas groups 2 and 4, with no pain progression, served as the control group for analysis. Additionally, we conducted subgroup analyses on group 3 (with only pain progression) and group 4 (without both pain and radiological progression). The study flow diagram is shown in Figure 1.

Figure 1. Flowchart of the study. The x-ray images of the knee joint were normalized, and the regions of interest were automatically identified and selected. Subsequently, imaging omics parameters were extracted, followed by a screening process for feature parameters. Imaging omics labels were then constructed to evaluate clinical features, ultimately leading to the generation of a nomogram and an assessment of its performance.



Segmentation and Region of Interest Annotation

BoneFinder (The University of Manchester) is a fully automated software tool designed to outline and segment skeletal structures from 2D radiographs by placing a series of points along bone contours or at key anatomical landmarks. In brief, BoneFinder uses a random forest voting mechanism to precisely determine the optimal placement of model feature points, enabling robust and accurate shape model matching. The system can accurately identify and segment bones not previously present in new images. This method demonstrates exceptional robustness and precision across various skeletal applications, with its generated point data being widely applicable to morphometric analyses, including the construction of statistical morphological models and automatic derivation of standard geometric measurement parameters [23], resulting in 74 markers per image (Figure 2). The fully automatic BoneFinder knee module achieves a mean point-to-curve error of less than 1.0 mm for 99% of 500 images (ie, in 99% of images, the error is less than 1.0 mm) without considering knee size [24].

Four vertical lines are constructed at the marked points 64, 58, 54, and 48 on the knee joint x-ray image, as identified by BoneFinder. These lines are sequentially designated as line 1, line 2, line 3, and line 4. The distance between line 1 and line 2 is denoted as R1, whereas the distance between line 3 and line 4 is referred to as R2. With point 64 designated as the vertex and a side length of R1/4, a square encompassing the medial tibia was defined as the region of interest (ROI). With marker point 64 designated as the vertex and a quarter of R1 as the side length, a square encompassing the medial tibia was defined as the ROI. First, using marker point 48 as the vertex and a quarter of R2 as the side length, a square area on the lateral tibia was selected to define ROI. Second, the selection process for the femur ROI differs from that of the tibia ROI. ROI 3 is defined with the line intersecting marker 24 as its lower boundary, while the line intersecting marker point 26 serves as the side boundary of this ROI. ROI 4 of the lateral femur uses the line indicated at point 14 as the lower boundary of the ROI and the column line marked at point 12 as its vertical boundary. Then, squares with side lengths of a quarter of R1 and a quarter of R2 are constructed. To assess the repeatability of ROI delineation, a total of 40 cases were randomly selected from the collected dataset. Two senior musculoskeletal radiologists (YWS and SNP) conducted manual segmentation of ROIs. Dice similarity coefficients were used to assess manual and automated segmentation agreement. Image annotation was performed using Neusoft Darts [25].

XSL•FO
RenderX

Figure 2. Schematic diagram of the automated region of interest segmentation process.

Radiomics Feature Extraction

The extraction of radiomics features was based on Neusoft Discovery [25]. The features that were extracted can be categorized into 3 distinct groups. First-order features were derived from the gray values of images, reflecting the distribution and heterogeneity of intensity within the ROI, typically including maximum, minimum, mean, median, range, variance, kurtosis, skewness, and entropy. The second-order features refer to the extracted texture characteristics, which include texture feature values derived from the gray-level co-occurrence matrix, gray-level run-length matrix, gray-level connected region size matrix, neighborhood difference matrix, and gray-level correlation matrix. The texture features can quantify the distribution of textures within the ROI that are difficult to perceive visually. Third, features were extracted after log transformation, first-level wavelet decomposition, and gradient transformation were applied to the ROI. All features were normalized using the following formula: $Z=(x–\mu)/\sigma$.

Radiomics Feature Selection and Radiomics Signature Construction

The Spearman correlation was used to remove the redundant features. The feature subset was optimized using the least absolute shrinkage and selection operator (LASSO) method in logistic regression. A 10-fold cross-validation approach was used to identify the optimal model that minimizes the mean squared error, and the correlation coefficients of the features selected by the best LASSO model were calculated. According to the coefficients derived from LASSO regression, a weighted calculation was performed to obtain the radiomics score (rad-score). Radiomics parameters from 4 ROIs (ROIs 1-4) were extracted individually, and rad-score 1 was developed following LASSO screening of the nonzero parameters. The radiomics parameters were applied to ROI 1 and ROI 3, leading to the development of rad-score 2. In subgroup analysis, rad-score 3, obtained from extracted and screened nonzero parameters from ROIs 1 to 4, and rad-score 4, obtained from extracted and screened nonzero parameters from ROI 1 and ROI 3, predicted pain progression only and no progression at all, respectively. SHAP analysis was used to mitigate the “black-box” effect of machine learning, enabling feature prioritization and interpretability of individual radiomics features on the rad-score. Feature maps were used to visualize the results of the rad-score.

Development and Evaluation of Nomograms

The analysis used stepwise backward multivariable logistic regression to identify clinical risk factors at baseline and construct nomograms. The Akaike information criterion likelihood ratio test was used as the stopping rule for the backward stepwise logistic regression analysis. Clinical information from patients at baseline included age, sex, history of injury, BMI, the minimum joint space width of the medial tibial-femoral compartment, Kellgren-Lawrence grade, WOMAC pain score and WOMAC disability score, medicine for pain in the previous 12 months, and race. The nomograms were developed based on the prediction probability value of the optimal radiomics models and clinical independent risk factors. The discriminative ability of the nomogram was evaluated using the AUC and accuracy. Calibration of the nomogram was performed through calibration curves, with optimal calibration indicated by alignment with the diagonal line. Internal validation was conducted using a bootstrap method involving 1000

XSL•FO
RenderX

resampling iterations, and the mean absolute error was used to assess model calibration. Additionally, decision curve analysis (DCA) quantified net benefits at various threshold probabilities to evaluate the clinical effectiveness of the nomograms.

Statistical Analysis

The comparison of categorical variables was conducted using the Pearson chi-square test. Continuous variables were expressed as mean and SD and analyzed using either the 2-tailed *t* test or Mann-Whitney *U* test. The normality of continuous data was assessed using the Kolmogorov-Smirnov test; measurements that followed a normal distribution were subjected to the *t* test, whereas those that did not conform to a normal distribution underwent the Mann-Whitney *U* test. The DeLong test was used for comparing 2 models. *P* values were calculated using a 2-tailed *z* test, with $P<.05$ considered statistically significant. All statistical analyses were performed using the EmpowerStats software (X&Y Solutions, Inc) and the R software (version 4.2.2; R Foundation for Statistical Computing).

Ethical Considerations

This study was conducted in accordance with the Declaration of Helsinki (as revised in 2013). The Institutional Review Board of the University of California, San Francisco (approval 10-00532), and the 4 clinical centers of the OAI project recognized the study as HIPAA (Health Insurance Portability and Accountability Act) compliant. All participants provided written informed consent. Patient-identifiable information (including names and hospital ID numbers) was carefully removed from the x-ray images and reports before analysis. Due to the retrospective design of this study, participants received no compensation.

Results

Baseline Clinical Characteristics

Due to the lack of spacing in DICOM images, a total of 450 participants were ultimately included in the study, with 227 (50.4%) and 223 (49.6%) in the control and case groups, respectively. The baseline characteristics of participants in both the case and control groups were frequency matched for factors including age, BMI, WOMAC functional scores, Kellgren-Lawrence grade, pain medication history, and race. Notably, a statistically significant difference was observed in WOMAC pain scores ($P=.04$) and medication history ($P=.02$) between the 2 groups (Table 1). In subgroup analysis, 18% (n=81) of the individuals demonstrated only pain progression during the follow-up period, whereas 32.9% (n=148) of the individuals exhibited neither pain progression nor radiographic deterioration. The baseline characteristics of participants across both groups were well matched, with no statistically significant differences observed (Table S1 in Multimedia Appendix 2).

Table 1. Baseline characteristics of the study population.

Characteristic	Control group (n=223)	Case group (n=227)	*P* value
Demographics			
Age (years), mean (SD)	62.14 (8.91)	61.48 (8.79)	.38
Female sex, n (%)	131 (58.7)	136 (59.9)	.80
Race, n (%)			.44
Asian	3 (1.3)	2 (0.9)	
Black or African American	21 (9.4)	32 (14.1)	
White	196 (87.9)	191 (84.1)	
Other non-White race	3 (1.3)	2 (0.9)	
Clinical measures			
BMI (kg/m^2), mean (SD)	30.36 (4.85)	30.50 (4.71)	.75
WOMAC[a] pain score (0-20), mean (SD)	2.70 (3.40)	1.87 (2.47)	.04
WOMAC function score (0-68), mean (SD)	8.15 (10.98)	8.13 (9.18)	.15
History of knee injury, n (%)	77 (34.5)	83 (36.6)	.65

Segmentation and Feature Extraction

The automated segmentation dataset was used for radiomics feature extraction as the Dice similarity coefficients between automatic and manual segmentation were excellent (0.800; Table S2 in Multimedia Appendix 2). We used 10-fold cross-validation to identify the optimal tuning parameter (alpha). In total, 16 nonzero coefficient features were derived from the optimal tuning parameters in rad-score 1. Rad-score 2 comprised 12 nonzero coefficient features. In subgroup analysis, rad-score 3 included 11 nonzero feature parameters, whereas rad-score 4 consisted of 3 nonzero features (Tables S3-S6 in Multimedia Appendix 2 and Figures S1-S4 in Multimedia Appendix 2). The correlation among features was analyzed using Spearman correlation analysis, and heat maps are presented in Figures S1 to S4 in Multimedia Appendix 2.

Development and Evaluation of Radiomics Signatures

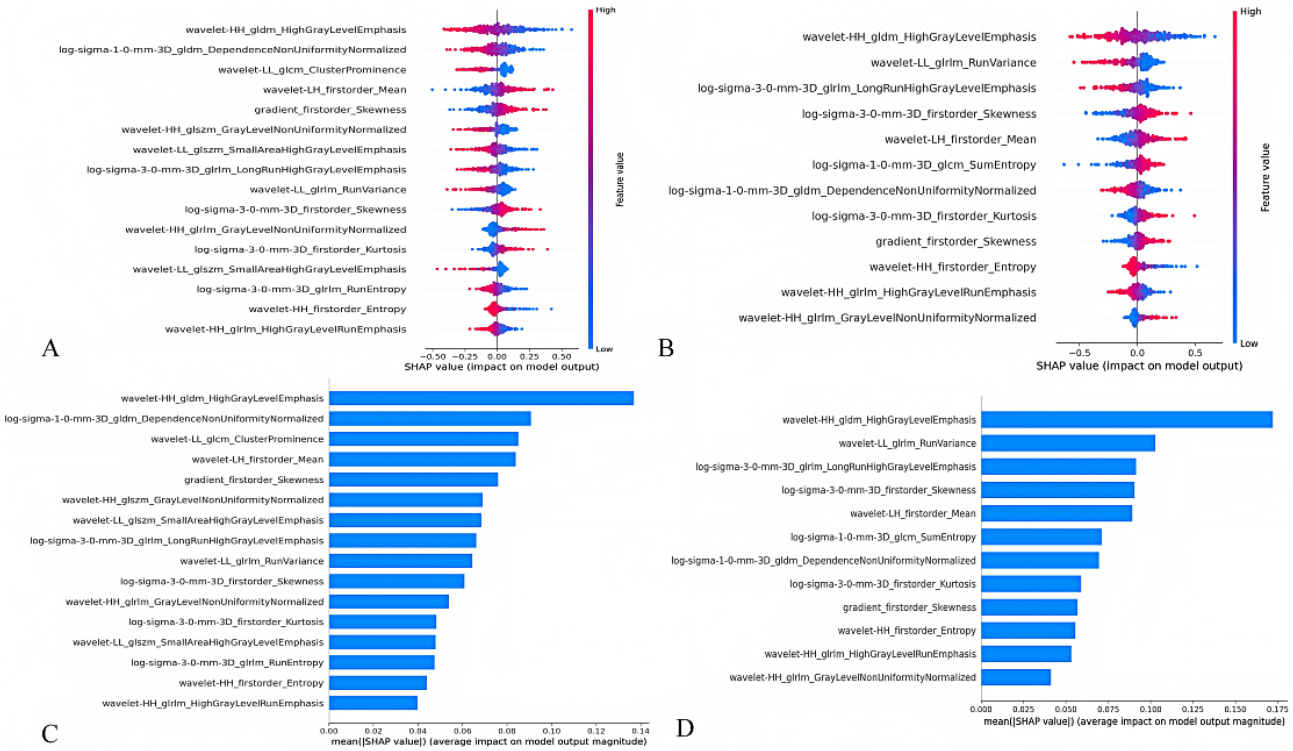

Table 2 shows the diagnostic proficiency of 4 radiomics signatures. The AUC value for rad-score 1 was 0.728 (95% CI 0.681-0.774), the AUC value for rad-score 2 was 0.716 (95% CI 0.635-0.736), the AUC value for rad-score 3 was 0.775 (95% CI 0.714-0.837), and the AUC value for rad-score 4 was 0.679 (95% CI 0.604-0.755; Table 2). The SHAP plot in Figure 3 visually illustrates how radiomics features influenced model predictions in terms of magnitude and direction. Features are sorted vertically by global importance. Each point represents the SHAP value of each feature for a specific patient plotted horizontally and stacked vertically to show density distribution. The color of the point reflects the feature value, from low (blue) to high (red; Figures 3A and C). The bar chart illustrates the impact of various imaging features on the rad-score. Wavelet-HH_gldm_HighGrayLevelEmphasis showed significant effects on both rad-score 1 and rad-score 2 (Figures 3B and D). The SHAP values of each feature in rad-score 3 and rad-score 4 are shown in Figure S5 in Multimedia Appendix 2. Figure 4 shows representative participants with x-ray subchondral bone feature maps from 4 ROIs. The case group participant demonstrated higher ROI heterogeneity than the control group participant, with a higher score (0.58 vs 0.44).

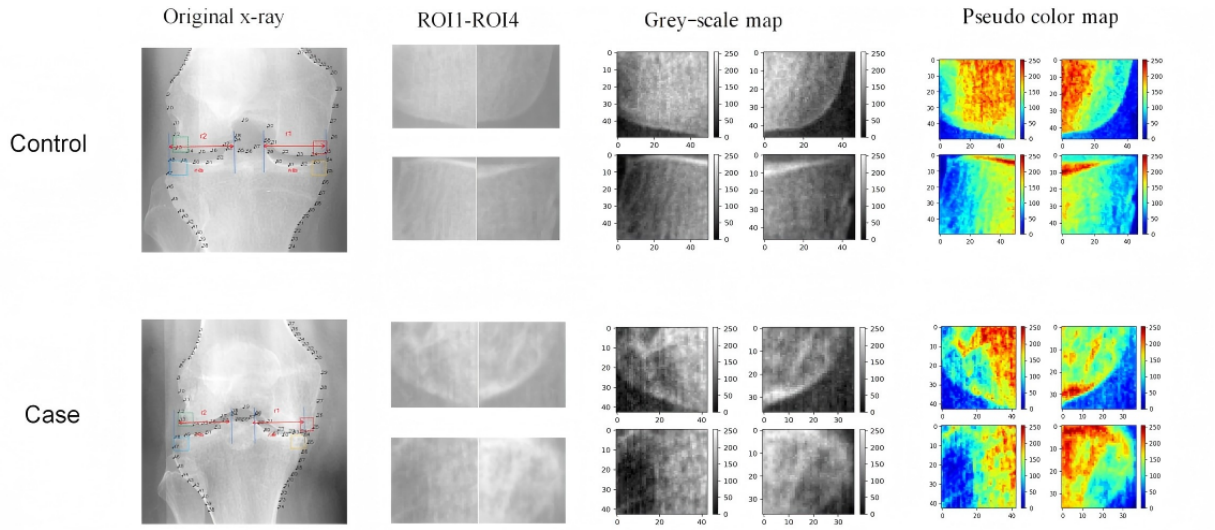
Table 2. Diagnostic efficacy of the 4 radiomics scores.

Radiomics score	AUC[a] (95% CI)	Accuracy	Sensitivity	Specificity
1	0.728 (0.681-0.774)	0.684	0.797	0.570
2	0.716 (0.635-0.736)	0.668	0.683	0.677
3	0.775 (0.714-0.837)	0.742	0.753	0.716
4	0.679 (0.604-0.755)	0.694	0.580	0.757



[a]AUC: area under the receiver operating characteristic curve.

Figure 3. Shapley additive explanations (SHAP) summary plots of the radiomics score. The plot illustrates the feature relevance and attributions of the model's predictive performance: (A) rad-score 1 and (B) rad-score 2. The bar chart illustrates the impact of various imaging features on the rad-score: (C) rad-score 1 and (D) rad-score 2.

Construction and Testing of Nomograms

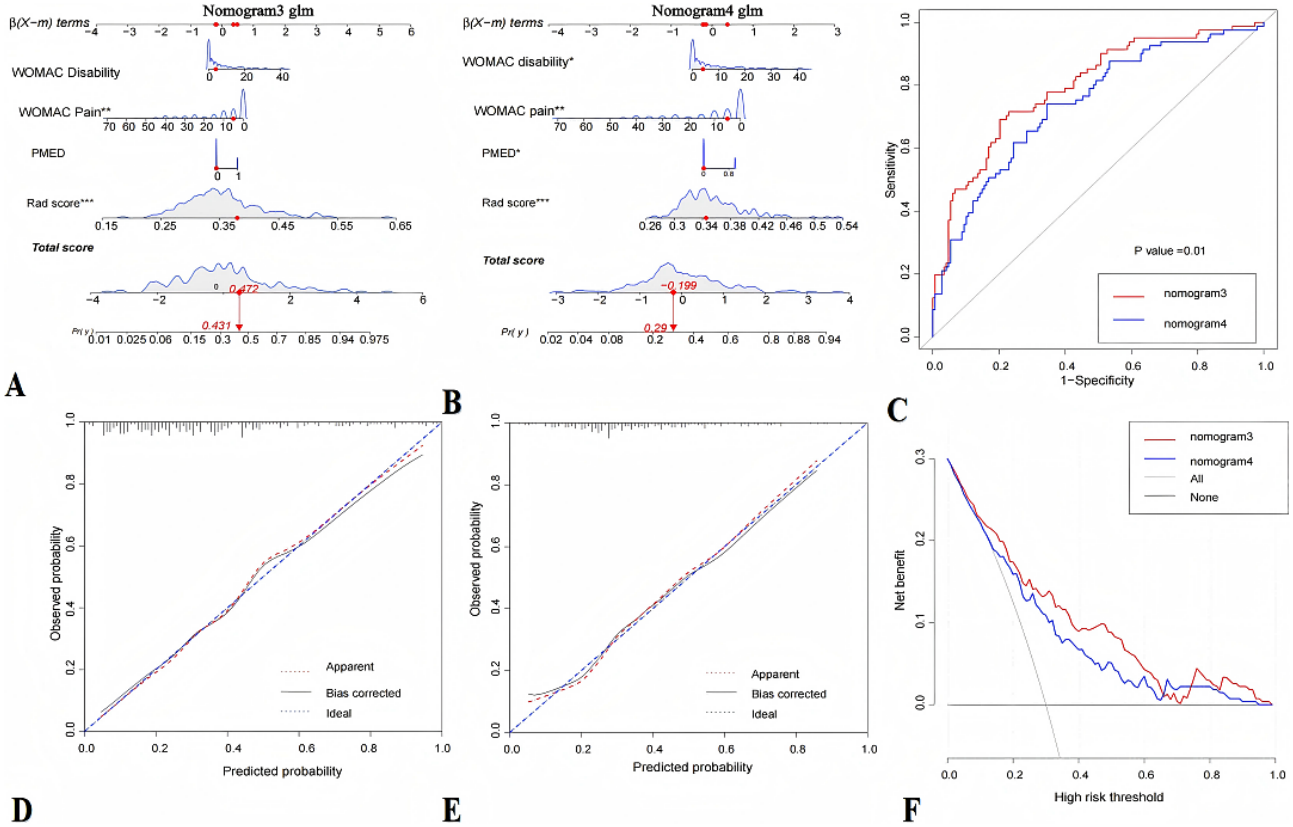
Through multiple regression analysis, the WOMAC disability score, pain medication history, and WOMAC pain score were found to be risk factors for KOA pain progression. We constructed visual nomograms by integrating the score with selected clinical risk factors. The AUC of nomogram 1 was 0.766 (95% CI 0.722-0.809), and the AUC of nomogram 2 was 0.753 (95% CI 0.708-0.797). The comparison of AUC between the 2 models showed no statistically significant difference (DeLong test; *P*>.05; Figure 3). The calibration curve demonstrated that all cohorts were accurately aligned with the actual observations. The internal validation was conducted using the bootstrap method, with a resampling count set to 1000. The mean absolute errors of the calibration curves for the 2 models were found to be 0.012 and 0.008, indicating that the model demonstrated a high level of calibration accuracy (Figure 5 and Table 3). The DCA demonstrated that, if the threshold probability in the clinical decision was in the range of 10% to 70%, both nomogram 1 and nomogram 2 could yield more net benefits compared with either the treat-all-patients strategy or the treat-none strategy.

Figure 5. Development and validation of the nomogram to predict pain progression in knee osteoarthritis (A: nomogram 1; B: nomogram 2), the receiver operating characteristic curves of nomogram 1 and nomogram 2(C), the calibration curves of nomogram 1 and nomogram 2 (D and E, respectively), and decision curves for nomogram 1 and nomogram 2 (F). PMED: Use of pain medication.

XSL•FO
RenderX

Table 3. Diagnostic efficacy of the 4 nomogram models.

Model	AUC[a] (95% CI)	Accuracy	Sensitivity	Specificity	MAE[b]
Nomogram 1	0.766 (0.722-0.809)	0.709	0.692	0.726	0.012
Nomogram 2	0.753 (0.708-0.797)	0.693	0.648	0.740	0.008
Nomogram 3	0.795 (0.734-0.865)	0.760	0.691	0.797	0.011
Nomogram 4	0.740 (0.673-0.808)	0.686	0.740	0.695	0.013



[a]AUC: area under the receiver operating characteristic curve.

[b]MAE: mean absolute error.

Subgroup Analyses

The AUC of nomogram 3 was 0.795 (95% CI 0.734-0.865), and the AUC of nomogram 4 was 0.740 (95% CI 0.673-0.808). The comparison of the AUC between the 2 models showed a statistically significant difference (DeLong test; $P<.05$). The calibration curve demonstrated a robust concordance between the probabilities predicted and the actual observed outcomes. The DCAs demonstrated that, if the threshold probability in the clinical decision was within the range of 10% to 65%, the curve corresponding to nomogram 3 was above nomogram 4, and the AUC that it formed with the "treat none" and "treat all" lines was relatively larger. The net benefit of nomogram 3 was superior to that of nomogram 4, making it the better model (Table 3 and Figure 6).

Figure 6. Development and validation of the nomogram to predict pain progression in knee osteoarthritis (A: nomogram 3; B: nomogram 4), the receiver operating characteristic curves of nomogram 3 and nomogram 4 (C), the calibration curves of nomogram 3 and nomogram 4 (D and E, respectively), and decision curves for nomogram 3 and nomogram 4 (F). PMED: Use of pain medication.

Discussion

Principal Findings

Our study developed a nomogram integrating x-ray radiomics features and clinical variables to predict pain progression in KOA. The resulting baseline-based, cost-effective nomogram demonstrated commendable accuracy and reproducibility in forecasting KOA pain progression, offering significant potential for guiding early intervention strategies in at-risk populations. The application of advanced artificial intelligence to widely available and cost-effective x-ray imaging represents a feasible and promising approach for predicting KOA pain progression. Radiomics models can automatically classify KOA [26], and texture analysis of the subchondral bone, particularly in the tibia, has shown predictive value for radiographic KOA incidence [27,28]. Given the complex etiology of KOA and the frequent discrepancy between clinical symptoms and radiological severity, we focused on subchondral bone remodeling—a process linked to pain pathogenesis through

XSL•FO
RenderX

molecules such as netrin-1 and PEG2, which promote sensory nerve innervation [29,30]. This rationale supported our use of subchondral bone radiomics for predicting symptomatic progression. Radiomics enables high-throughput extraction of quantitative features from medical images, providing data for clinical decision support systems [10]. The selection of key ROIs is critical as different image areas contain varying levels of information relevant to disease progression [31]. While the medial subchondral bone often shows a stronger correlation with OA [32] and the medial tibial margin is recognized as highly informative due to its role in absorbing uneven mechanical loads [33], the optimal ROI selection remains debated. Some deep learning studies for KOA pain progression have also concentrated on the medial joint space and osteophytes [8], whereas other radiomics research suggests that including the entire tibial subchondral bone may yield better outcomes than focusing solely on specific compartments [17].

In this study, we systematically evaluated the impact of ROI selection on model accuracy by constructing radiomics signatures both from 4 ROIs encompassing the entire knee joint and from the 2 medial ROIs alone. Our findings revealed that incorporating lateral ROIs did not improve the overall model AUC compared to using medial ROIs only. However, subgroup analysis indicated that models combining medial and lateral ROIs achieved significantly higher AUC values in specific contexts. The primary cause of this discrepancy may stem from disease heterogeneity. Notably, in the main analysis, both the pain progression group and the nonprogression group included participants with radiological progression. Pathological changes in the lateral subchondral bone may accelerate the radiological progression of the knee joint [34-36]. Therefore, the role of radiomics features in lateral ROIs during pain progression was likely diluted or masked by features from radiologically progressive participants in the control group.

When compared to prior studies, our model demonstrated competitive predictive performance. For instance, Kraus et al [16] applied 3 texture parameters to predict KOA pain progression, achieving AUCs ranging from 0.603 to 0.649. Our rad-score yielded AUCs between 0.679 and 0.775, representing a substantial improvement. This aligns with the understanding that multivariable models integrating multiple risk factors generally provide more reliable estimates than those based on single parameters [37]. The superior performance of our baseline-based model is particularly notable compared to previously reported predictive capabilities relying solely on baseline biomarkers [38]. A recent study using MRI-based radiomics to predict KOA pain progression reported high predictive accuracy, with AUC values ranging from 0.79 to 0.86 [15]. This performance is commendable. However, it is important to note that their model incorporated a substantially larger set of 200 radiomics parameters and, crucially, relied on omics data extracted from 12- and 24-month follow-up MRI scans. While this approach yields high accuracy, the model's complexity and its dependence on longitudinal imaging data significantly limit its practicality and scalability in routine clinical settings. In contrast, our study deliberately pursued a more streamlined and clinically translatable strategy. By using only baseline x-ray images and constructing a parsimonious model using key radiomics features and clinical variables, our baseline-based model eliminates the need for costly follow-up MRI scans and complex feature sets, making it more feasible for immediate clinical application and potential widespread adoption.

Research using deep learning methods to predict KOA pain progression remains scarce. A study using OAI data demonstrated that deep learning models achieved an AUC of 0.77 for predicting KOA pain progression, significantly higher than the 0.692 of traditional models [39]. By integrating demographic, clinical, and imaging risk factors with a deep learning model incorporating baseline knee x-rays, the highest diagnostic efficacy (AUC=0.807) was achieved in predicting pain progression. However, the original study failed to provide specific feature information. In contrast, our study visually presented each feature parameter's impact on the rad-score using Shapley summaries. Wavelet-HH_gldm_HighGrayLevelEmphasis, a gray-level correlation matrix feature derived from high-frequency (HH) subbands of wavelet-transformed images, reflects the concentration of high–gray value regions and emphasizes texture variations in these areas. By quantifying texture changes in knee images, this feature effectively captures tissue degeneration differences caused by pain progression, indirectly reflecting pathological changes and potentially enabling prediction of knee pain progression.

The nomogram was selected for its ability to simplify complex statistical models into user-friendly graphical interfaces that generate individualized risk estimates [40]. While nomograms have been applied in OA contexts such as predicting outcomes after total knee replacement [41,42], their application specifically for predicting KOA pain progression represents a novel contribution. Our nomogram uniquely integrates radiomics signatures with key clinical variables: baseline WOMAC pain scores, WOMAC disability scores, and analgesic use. Interestingly, the baseline WOMAC pain score served as a negative predictor in our model, potentially reflecting the development of tolerance to chronic pain in patients with KOA [43]. The inclusion of WOMAC disability scores and analgesic use is supported by their established roles as risk factors in KOA phenotypic and prognostic models [44,45].

Limitations

This study has several limitations. First, the relatively small sample size may affect statistical power and generalizability. Second, the use of data from previous nested case-control studies could introduce selection bias. Third, our analysis relied solely on internal validation because it was difficult to find an equivalent external cohort. Although the data were sourced from the well-established FNIH Osteoarthritis Biomarkers Project, external validation using independent datasets, such as those from the PROGRESS OA study (phase 2 of the FNIH Biomarkers consortium), was not feasible as these data have not been publicly released [46]. To our knowledge, no other studies have explored the specific pain progression patterns defined by the FNIH [15], and other studies using FNIH data have similarly been unable to perform external validation.

XSL•FO
RenderX

Conclusions

A nomogram based on baseline x-ray radiomics signatures can effectively predict the progression of pain in KOA. This has significant implications for supporting health care professionals in tailoring treatment plans for individuals experiencing rapid pain progression, as well as in reducing health care costs, and these findings need further validation in future trials.

Acknowledgments

The data for this study were obtained and analyzed from the controlled-access datasets distributed from the Osteoarthritis Initiative, a data repository housed within the National Institute of Mental Health Data Archive. The Osteoarthritis Initiative represents a public-private partnership consisting of 5 contracts funded by the National Institutes of Health.

Funding

This study received funding from Liaoning Province Science and Technology Plan Joint Program (2024012243-JH4/4800) and Liaoning Province Science and Technology Plan Joint Technical Breakthrough Plan Project (2024JH2/10 2600325).

Data Availability

The datasets generated or analyzed during this study are available in the Osteoarthritis Initiative repository [47].

Abstract

Background: Although Digital Imaging and Communications in Medicine (DICOM) metadata are widely used to manage medical imaging data and support clinical workflows, their suitability as a sole basis for automatic computed tomography (CT) series labeling and characterization is limited. DICOM metadata are frequently inconsistently populated, institution specific, use unregulated private tags, and have variable reliability even within standardized fields. Consequently, automated series selection for downstream AI applications often remains unreliable, necessitating manual curation within clinical workflows.

Objective: This study presents Orchestrate, a modular AI framework for automated orchestration of CT imaging data. By integrating a hierarchy of deep learning models, Orchestrate enables pixel-level classification and routing of CT series and accurate metadata-independent identification of anatomical regions, contrast-enhanced series, and reconstruction kernels, supporting seamless downstream AI integration without manual curation.

Methods: Orchestrate combined 3 pretrained models for anatomical regions, landmarks, and body part classification and 4 newly developed You Only Look Once (YOLO) v8–based models to classify contrast enhancement, recognize reconstruction kernels, and infer laterality. Three datasets were used: an internal development dataset comprising 27,418 CT studies for individual model development, an internal framework evaluation dataset comprising 200 CT studies to assess the complete framework under a simulated real-world scenario, and an external dataset from The Cancer Imaging Archive comprising 100 CT studies. For the internal development data, reference standards were derived from complete and unambiguous DICOM metadata following institutional definitions. For the 2 evaluation datasets, 3 radiographers independently established reference standards as DICOM metadata were not assumed to be complete or consistent. Clinical utility was assessed through cohort selection tasks involving 3 predefined target cases, with 3 radiologists reviewing selection accuracy. The interrater agreement was assessed using the Fleiss κ. The model performance was evaluated using F_1-scores.

Results: DICOM metadata were incomplete in the internal framework evaluation dataset and external dataset, with missing rates of 42.9% (413/963) and 92.9% (105/113) for contrast enhancement, respectively, and a missing reconstruction kernel information rate of 0.4% (4/963) in the internal framework evaluation dataset. During model development, individual models

XSL•FO
RenderX

achieved macro–F_1-scores ranging from 0.982 to 0.989. At the framework level, Orchestrate achieved high classification performance across internal (weighted F_1-score ranged from 0.920 to 1.000; macro–F_1-score ranged from 0.879 to 1.000) and external (weighted F_1-score ranged from 0.946 to 1.000; macro–F_1-score ranged from 0.777 to 0.929) cohorts. For clinical use cases, the overall selection accuracy was 97.7% (217/222).

Conclusions: Orchestrate enables automated pixel-based classification, detection, and semantic description of CT series, reducing reliance on manual selection and the risk of inconsistent metadata. By generating standardized semantic content, the framework provides a proof of concept for improving interoperability with clinical systems and supports the reliable, reproducible integration of AI-driven imaging pipelines into clinical workflows.

Introduction

AI, particularly deep learning, has made significant advances in radiology, supporting a broad spectrum of radiology tasks, including anatomical landmark detection and segmentation [1-12], body composition analysis [13-17], virtual biopsy [18-20], and contrast optimization [21-23]. Despite strong performance in controlled settings, translating these advances into routine clinical practice remains challenging. A key bottleneck is the lack of robust, automated mechanisms for selecting and routing the appropriate image series to the corresponding model, resulting in human-in-the-loop selection and routing [24].

This challenge is particularly evident in computed tomography (CT), where a single CT study may include multiple image series, such as localizers, axial volumes, multi-planar reformats, and diverse reconstructions that vary in kernel and contrast phase. In the current workflow, imaging routing largely depends on Digital Imaging and Communications in Medicine (DICOM) metadata. However, the available metadata fields are frequently incomplete and ambiguous across institutions, which complicates automated routing and the reliable selection of relevant image series for downstream AI tasks [25-27].

These limitations can stem not only from inconsistent metadata entries but also from the underlying DICOM metadata structure and its varied implementation across vendors or institutions. Although these metadata remain the canonical sources of acquisition and protocol parameters, their reliability and reusability for accurately describing series content are limited [28]. Metadata fields are often variably populated, and many are optional (eg, the convolution kernel tag [29]), resulting in inconsistent definitions or mislabeling across manufacturers or institutions for relevant selection parameters, such as contrast media and body part information [25,30-32]. In addition, reliance on nonstandardized free-text descriptors such as series description introduces ambiguity and may be inadequate for identifying the series without visual inspection [30]. Moreover, because DICOM metadata operate at the series or study level, they lack the granularity to express voxel- or pixel-level phenomena, such as the distribution of specific body regions within one CT series or the detection of indwelling devices. Collectively, these limitations undermine standardization and introduce inefficiencies, necessitating manual curation to identify the correct input series for AI processing [30]. Beyond workflow burden, such inconsistencies also limit reproducibility in research, complicate multi-institutional model development, and may compromise clinical reliability when models are inadvertently applied to suboptimal or incorrect series.

To overcome these limitations, we introduce Orchestrate, a modular framework for fully automated classification, detection, and semantic enrichment of CT image series. In contrast to approaches that depend primarily on DICOM metadata, Orchestrate performs coordinated, image-based reasoning through a hierarchy of specialized classifiers and detectors, extracting clinically and technically relevant information directly from the image content. The framework infers key series characteristics (including anatomical coverage, landmarks, contrast enhancement, scan orientation, reconstruction kernel, and laterality), thereby substantially increasing the semantic depth available per CT series. By fusing image-derived content features with existing DICOM metadata, Orchestrate enables robust, scalable, and reliable CT series routing and selection even in the presence of incomplete, inconsistent, or erroneous metadata.

Methods

Ethical Considerations

This retrospective study was approved by the Ethics Committee of the University Hospital Essen (approval number 21-10204-BO). The requirement for written informed consent was waived due to the study's retrospective nature. All data were fully anonymized before being included in the study.

CT Datasets and Acquisition

This study included 3 CT datasets, each serving a distinct purpose. The internal development dataset, comprising 27,418 CT studies acquired between April 2002 and September 2024 at a single medical center, was used to develop and evaluate the individual models in the framework. Before data retrieval, studies were selected through the institutional Fast Healthcare Interoperability Resources (FHIR) server using predefined query parameters and values (eg, specific reconstruction kernel values

XSL•FO
RenderX

such as Br32) corresponding to metadata attributes required for model development such that only studies with the required metadata fields and values were retrieved. Most CT studies (n=26,518, 96.7%) were acquired using Siemens Healthineers scanners, with the remaining studies acquired using Philips scanners (n=285, 1%), GE HealthCare scanners (n=12, 0%), and Canon Medical Systems scanners (n=603, 2.2%). Additional details for each individual model are summarized in Multimedia Appendix 1 [33-36].

The internal framework evaluation dataset comprised 200 CT studies acquired between October 2024 and November 2024 at the same medical center. This dataset was independent of the development dataset, with no patient overlap with the training or validation sets used for any individual model. It was used to simulate a real-world clinical scenario and assess the integrated framework's performance. Therefore, DICOM metadata in this dataset were not required to be complete or valid, and some metadata fields were missing. The CT scanner manufacturer represented in this dataset was Siemens Healthineers. In addition, an external dataset comprising 100 CT studies randomly selected from a CT colonography dataset, the Cancer Imaging Archive (TCIA) [37], served as an independent external evaluation to assess the framework's robustness and generalizability under heterogeneous imaging conditions. CT scanner manufacturers represented in this dataset included Siemens Healthineers (70/100, 70% of the studies), GE HealthCare (22/100, 22% of the studies), Toshiba Medical Systems (now Canon Medical Systems; 6/100, 6% of the studies), and Philips (2/100, 2% of the studies).

Orchestrate Framework Architecture

Overview

The Orchestrate pipeline is structured as a modular tree of deep learning models designed to extract comprehensive semantic information directly from image pixels. This framework facilitates the automated classification and detection of CT topograms and series across multiple clinical dimensions, forming the foundation for pixel-native routing, selection, and structured FHIR descriptions. At its core, Orchestrate integrates a hierarchy of multiple You Only Look Once (YOLO) v8–based [38,39] classification models, each tailored to a specific classification task, together with the rapid analysis and processing of image data (RAPID) [40] models summarized in Table 1. Detailed definitions of classes, representative input examples, training protocols, and hyperparameter configurations for each model are provided in Multimedia Appendix 1 [33-36].

Table 1. Overview of integrated models in the Orchestrate framework[a].

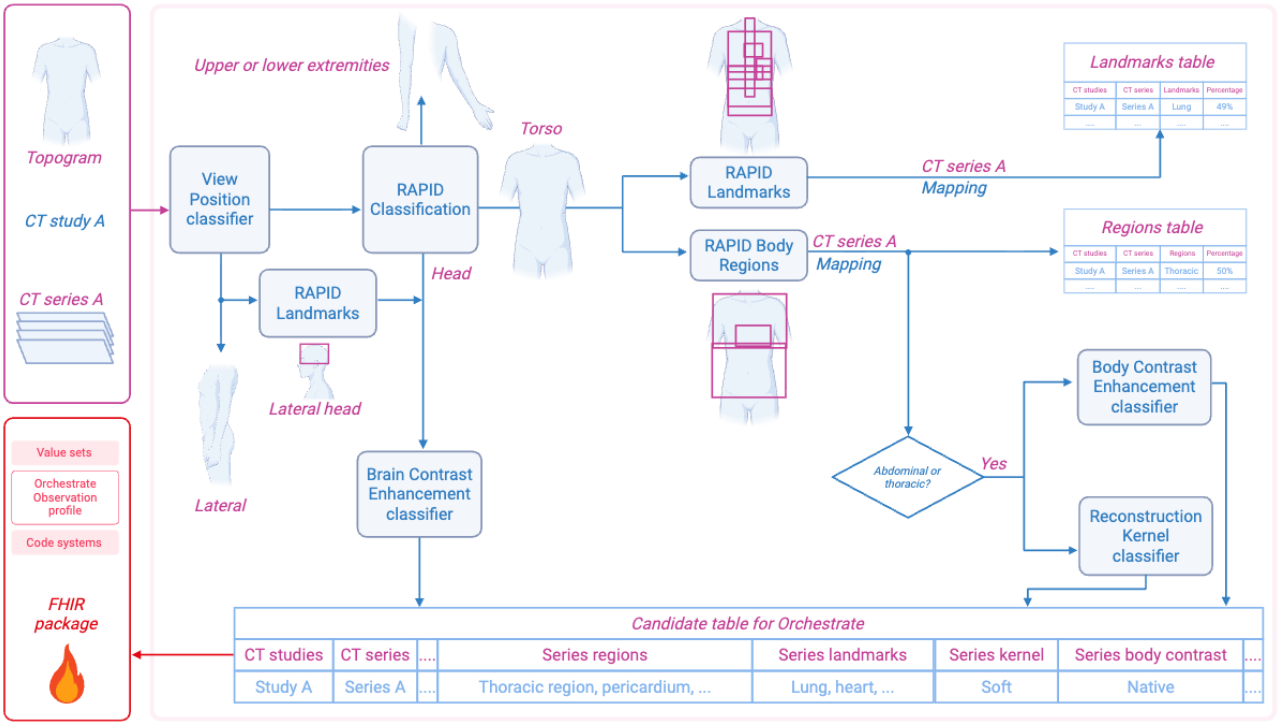
Model name	Task	Output classes
View Position	Determines the anatomical plane of the topogram	Lateral and nonlateral
RAPID[b] Classification	Classifies the anatomical coverage of the topogram	Head, upper extremities, lower extremities, and torso
Body Contrast Enhancement	Differentiates native and contrast enhancement of the body CT[c] series	Native and contrast enhancement
Brain Contrast Enhancement	Determines native and contrast media series for brain CT	Native and contrast enhancement
Reconstruction Kernel	Identifies reconstruction kernel based on image texture and noise patterns	SK[d] and HK[e]
RAPID Body Regions	Detects and localizes body regions from the given topogram	Head, abdominal region, thoracic region, and pericardium
RAPID Landmarks	Detects and localizes body landmarks from the given topogram	Lung, heart, spine, liver, kidneys, spleen, stomach, colon, pancreas, brain, and hip

[a]Contrast enhancement refers only to intravenous contrast.

[b]RAPID: rapid analysis and processing of image data.

[c]CT: computed tomography.

[d]SK: soft kernel.



[e]HK: hard kernel.

Pipeline Structure

As illustrated in Figure 1 [41], the pipeline is initiated with the view position classifier, which categorizes the anatomical plane of the topograms as lateral or nonlateral. All topograms are subsequently processed by the multi-class RAPID classification model, which assigns them to 1 of the 4 broad categories: head, upper extremities, lower extremities, and torso. In parallel, topograms identified as lateral are routed to the RAPID Landmarks model. If cranial landmarks (brain) are detected on the lateral topogram or the RAPID Classification model independently identifies the lateral topogram as being of the "head" class, the entire study is forwarded to the Brain Contrast Enhancement classifier for further evaluation.

XSL•FO
RenderX

Figure 1. Schematic overview of the complete Orchestrate framework. This overview presents the overall logic of the proposed framework. Computed tomography (CT) studies are analyzed using the corresponding topogram to localize and quantify the proportional coverage of anatomical structures. CT series containing thoracic or abdominal regions are subsequently processed by task-specific classifiers. The processed results are stored in 3 relational database tables: the landmarks and regions table for anatomical coverage and a candidate table aggregating outputs from all Orchestrate models that can support further target cohort selection. The Fast Healthcare Interoperability Resources (FHIR) package provides a downstream semantic mapping layer to support interoperability and is not part of the core Orchestrate logic. Created in BioRender [41]. RAPID: rapid analysis and processing of image data.

For studies with nonlateral topograms classified as "torso," the RAPID Body Regions and RAPID Landmarks models are executed in parallel to characterize their anatomical location. The RAPID Body Regions model detects anatomical subregions (eg, thoracic region or abdominal region; Table 1) using bounding boxes on the topogram. In contrast, the RAPID Landmarks model identifies key skeletal and soft-tissue landmarks (Table 1). Anatomical regions and landmarks in both RAPID models were defined according to the Body and Organ Analysis (BOA) [13] and TotalSegmentator [12] tools. Thereafter, each axial CT series is geometrically mapped to the corresponding topogram using DICOM-reported slice coordinates and the scanning direction. The intersection between mapped slice locations and detected anatomical regions or landmarks enables estimation of the anatomical series coverage. Subsequently, each CT series containing the abdominal or thoracic region is processed using contrast and reconstruction kernel classifiers, as defined in Table 1.

Automated Series Exclusion Criteria

Orchestrate incorporates an automated filtering module that excludes CT series unsuitable for semantic processing. Exclusion criteria include nonaxial images, invalid modality (modalities other than CT), nonimage content such as dose reports, or content with additional segmentation masks or annotations. Series with insufficient anatomical information, such as those that do not contain any detectable region or landmark after topogram mapping, are also excluded. Moreover, studies with missing, corrupted, or anatomically uninterpretable topograms are excluded from further processing. All exclusions are automatically recorded in the orchestrate database.

Semantic Aggregation

All model outputs are aggregated into a unified, structured semantic description for each CT series. To demonstrate interoperability, an initial mapping of the stored data to the FHIR server is provided. The FHIR profile presented in this study serves as an illustrative reference rather than a finalized standard.

Reference Standard

For the internal development dataset, reference standards for the individual model components were derived from the corresponding DICOM metadata attributes used as predefined query parameters for study selection and were used for model training, validation, and internal testing.

In contrast, the internal framework evaluation dataset was retrieved without metadata-based selection, and the DICOM metadata were not required to be complete or consistently valid. Therefore, 3 experienced radiographers (over 20, 18, and 8 years of experience) with expertise in CT acquisition protocols and reconstruction parameters independently reviewed all the CT series processed through the complete orchestration framework for the internal framework evaluation dataset and the external dataset from TCIA to generate corresponding reference standards. To minimize potential bias, the reviewers were blinded to the dataset origin (internal or external), scanner information, and DICOM metadata of each series. Given the

XSL•FO
RenderX

objective nature of the view position classification task (lateral vs nonlateral topogram), a medical AI data scientist assigned reference standards under the guidance of a radiologist with over 3 years of experience. For the clinically applicable target scenarios requiring cohort-specific anatomical information, 3 experienced radiologists (over 5, 2, and 2 years of experience) additionally reviewed all the selected CT series for each target cohort to determine the anatomical structures covered and assess contrast enhancement. Reconstruction kernels were evaluated by the 3 radiographers described above.

Evaluation Framework and Statistical Analysis

Patient age was reported as means and SDs or medians with IQRs depending on the normality of the age distribution, assessed using the Shapiro-Wilk test [43] for smaller datasets (n<5000) or the Anderson-Darling test [44]. For the external dataset, patient age and sex information were extracted directly from the corresponding DICOM metadata.

Individual model performance was evaluated on their independent test sets using accuracy, precision, recall, F_1-scores, and the area under the receiver operating characteristic curve with 95% CIs, which were estimated using bootstrapping with 1000 iterations. Interrater agreement was assessed using the Fleiss κ for agreement among multiple raters and the Cohen κ for pairwise agreement. The performance of the completed framework was evaluated using F_1-scores with 95% CIs. Statistical analyses were conducted using the Python packages SciPy [45], scikit-learn [46], and statsmodels [42].

Clinically Applicable Targets

To evaluate the performance and clinical utility of the Orchestrate framework, 3 clinically relevant orchestration targets were defined based on anatomical coverage, contrast enhancement, and reconstruction kernel (Table 2), each reflecting typical diagnostic CT imaging scenarios that potentially involve AI vendors. The specified craniocaudal coverage percentage presented in Table 2 was configurable, and the values served as examples that can be adapted to local clinical practice.

Table 2. Definition and anatomical scope of target cases and their relevance to clinical AI applications.

Target case	Anatomical coverage	AI application context
Contrast-enhanced liver CT[a] with smooth reconstruction kernel	These CT series provide complete craniocaudal coverage of the liver. To differentiate liver-focused CT examinations for this target case from general abdominal or thoracic series, which may also include the entire liver, the anatomical coverage is further constrained based on the craniocaudal anatomical coverage. Specifically, liver CT series for this case were required to include less than 50% craniocaudal coverage of both the abdominal and thoracic regions. This threshold was treated as a tunable parameter to accommodate protocol variability across institutions.	This target represents a typical abdominal imaging task, where precise identification of the contrast enhancement and reconstruction type is crucial for downstream AI applications, including lesion detection and liver volumetry.
Contrast-enhanced thoracic CT with hard reconstruction kernel	The topogram of these studies should demonstrate complete craniocaudal coverage of the thorax. The area of interest for the thoracic CT should include the entire lung region [47]. Similar to the constraint in the previous target case, the thoracic CT for this case must encompass the near-complete thoracic region, with abdominal coverage limited to less than 30% of the total abdominal extent in the z-axis direction.	This is a frequent setting in cardiovascular and oncological imaging, requiring precise recognition of contrast enhancement and high-resolution lung kernel reconstructions.
Whole-body CT with smooth reconstruction kernel	Both the scout topogram and CT series must demonstrate at least complete craniocaudal coverage of the thoracic and abdominal regions.	This can be used in trauma or oncology staging, requiring full-body coverage and a preference for soft-tissue kernel reconstructions to ensure compatibility with general-purpose AI algorithms.

[a]CT: computed tomography.

Results

Patient Characteristics

The internal development dataset included 17,362 unique patients (n=7852, 45.2% female). Patient age was not normally distributed (Anderson-Darling test A^2=439.600), and the median age was 63 (IQR 52-72) years. The internal framework evaluation dataset comprised 185 unique patients (n=100, 54.1% male). Patient age was also nonnormally distributed (Shapiro-Wilk W=0.957; P<.001) and was summarized accordingly (median 63.50, IQR 51-72.25 years).

The external dataset included 99 unique patients (n=47, 47.5% female), of whom 16 (16.2%) were missing age information and 1 (1%) had an invalid age. The ages of the remaining 82.8% (82/99) of the patients were not normally distributed (Shapiro-Wilk W=0.787; P<.001), with a median of 56 (IQR 52-60.75) years.

Individual Model Performance

All individual models demonstrated high performance on their respective independent test sets (Table 3).

All performance metrics are reported with 95% CIs, with accuracy and macroaverage recall ranging from 0.983 to 0.989, macroaverage precision ranging from 0.978 to 0.989, macroaverage F_1-score ranging from 0.982 to 0.989, and area under the receiver operating characteristic curve ranging from 0.995 to 0.998.

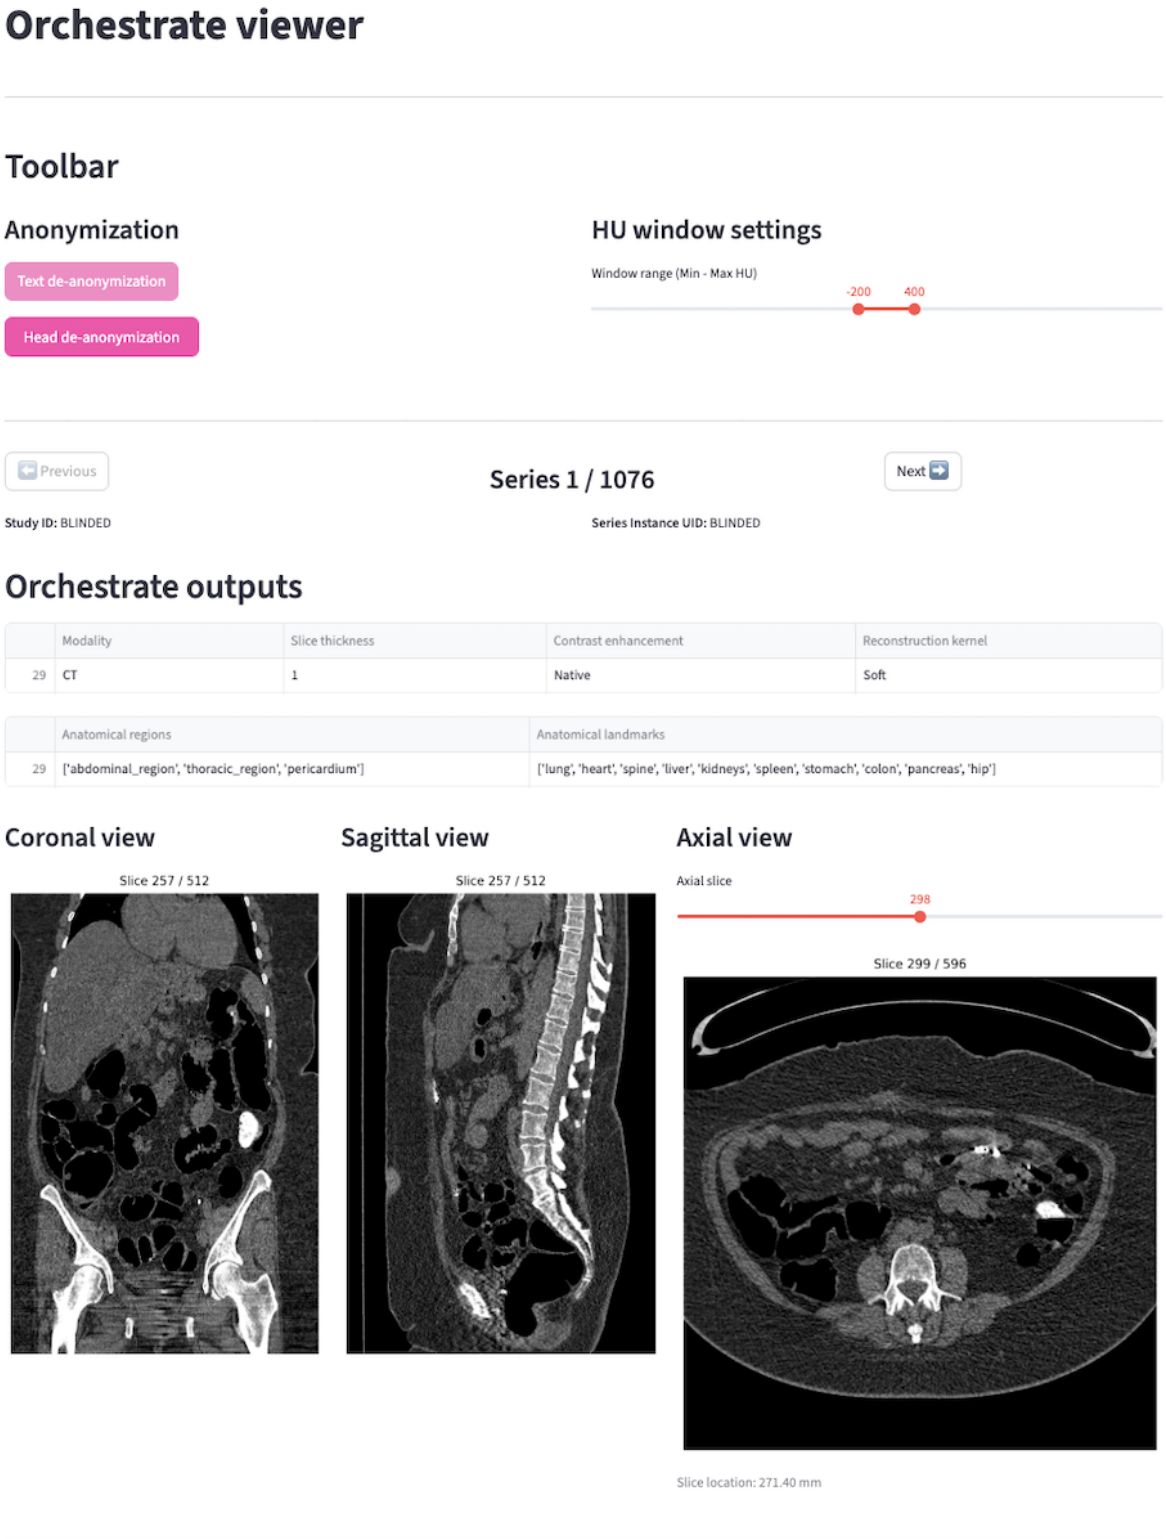
Orchestrate Evaluation

For the internal framework evaluation dataset, the framework received 200 studies with 2003 series. During framework processing, of the 2003 series, 200 (10.0%) were identified as topograms, 309 (15.4%) contained nonimage data, 214 (10.7%) were positron emission tomography components, 241 (12.0%) were nonaxial series, and 23 (1.1%) contained segmentations. The remaining 1016 series were forwarded to the respective models, and of these series, 53 (5.2%) did not cover any detectable body regions, whereas 963 (94.8%) were successfully processed. Of the 963 successfully processed series, 225 (23.4%) underwent brain contrast classification, and 738 (76.6%) underwent further reconstruction kernel and body contrast enhancement classifications, and their results were stored in the database's candidate table and subsequently displayed to radiographers, radiologists, and medical imaging AI researchers through the Orchestrate viewer, as shown in Figure 2. Among the successfully processed 963 series, reconstruction kernel and contrast enhancement information was missing in 4 (0.4%) and 413 (42.9%), respectively. Of the 550 series with available contrast information, 292 (53.1%) indicated only the presence of contrast enhancement without specifying intravenous or gastrointestinal contrast enhancement.



The external dataset comprised 100 studies with 202 topograms, with each study acquired in both prone and supine positions. During the framework processing, 1.5% (3/202) of the topograms could not be loaded because of corrupted DICOM files or inconsistencies between DICOM header and pixel data. Of the remaining 199 topograms, 24 (12.1%) were classified as lateral topograms without head coverage. Of the topograms classified as nonlateral, body region detection failed in 35.4% (62/175). The remaining 64.6% (113/175) of the topograms, with 113 CT series, were successfully processed through the framework for further reconstruction kernel and body contrast enhancement classifications, and results were stored in the database. Reconstruction kernel information was available in the DICOM metadata for all series. Contrast enhancement information was available for only 7.1% (8/113) of the series without specifying intravenous or gastrointestinal contrast enhancement. For the remaining 92.9% (105/113) of the series, contrast enhancement information was missing from the metadata.

Three radiographers independently reviewed all processed internal and external series to generate the reference standards. Interrater agreement for reconstruction kernel, body contrast enhancement, and brain contrast enhancement was assessed using the Fleiss κ, with values of 0.931 (95% CI 0.910-0.950), 0.936 (95% CI 0.915-0.956), and 0.958 (95% CI 0.918-0.991), respectively, indicating good agreement among the 3 radiographers. Additional pairwise agreement analyses can be found in Multimedia Appendix 2 [13,48-50]. The final reference standards for each series were determined through majority agreement among the 3 radiographers.

Table 4 presents Orchestrate's overall performance using weighted-average and macroaverage F_1-scores with 95% CIs.

XSL•FO
RenderX

Figure 2. Interactive Orchestrate dashboard. The dashboard visualizes results from automated processing in the Orchestrate pipeline, including thickness, contrast enhancement, reconstruction kernel, anatomical region distribution, and detected anatomical landmarks, and incorporates insights from radiologists and researchers to serve diverse user needs. The dashboard provides clinical-grade validation tools for clinicians, including adjustable Hounsfield unit (HU) windowing controls and a comprehensive axial viewer with a navigator, which allows users to scroll through all slices and enables rapid, direct manual verification when they require more detail from the processing results. On the basis of the researchers' feedback, the dashboard also includes midcoronal and midsagittal cross-sectional views. These planes provide an intuitive anatomical overview for users without extensive medical imaging expertise, as well as for those who prefer alternatives to traditional axial slice navigation.

Table 4. Comparison of model performance between the internal framework evaluation dataset and the external dataset using weighted and macro–F_1-scores.

Model name and metric	Internal framework evaluation dataset	External dataset
View Position		
Weighted F_1-score (95% CI)	1.000 (1.000-1.000)	0.970 (0.944-0.990)
Macro–F_1-score (95% CI)	1.000 (1.000-1.000)	0.929 (0.866-0.977)
Reconstruction Kernel		
Weighted F_1-score (95% CI)	0.986 (0.977-0.993)	1.000 (1.000-1.000)
Macro–F_1-score (95% CI)	0.986 (0.977-0.993)	N/A[a,b]
Brain Contrast Enhancement		
Weighted F_1-score (95% CI)	0.920 (0.876-0.954)	N/A[c]
Macro–F_1-score (95% CI)	0.879 (0.814-0.929)	N/A[c]
Body Contrast Enhancement		
Weighted F_1-score (95% CI)	0.989 (0.981-0.996)	0.946 (0.909-0.979)
Macro–F_1-score (95% CI)	0.983 (0.970-0.994)	0.777 (0.582-0.905)

[a]N/A: not applicable.

[b]Only 1 class in the reference standard.

[c]Head not included.

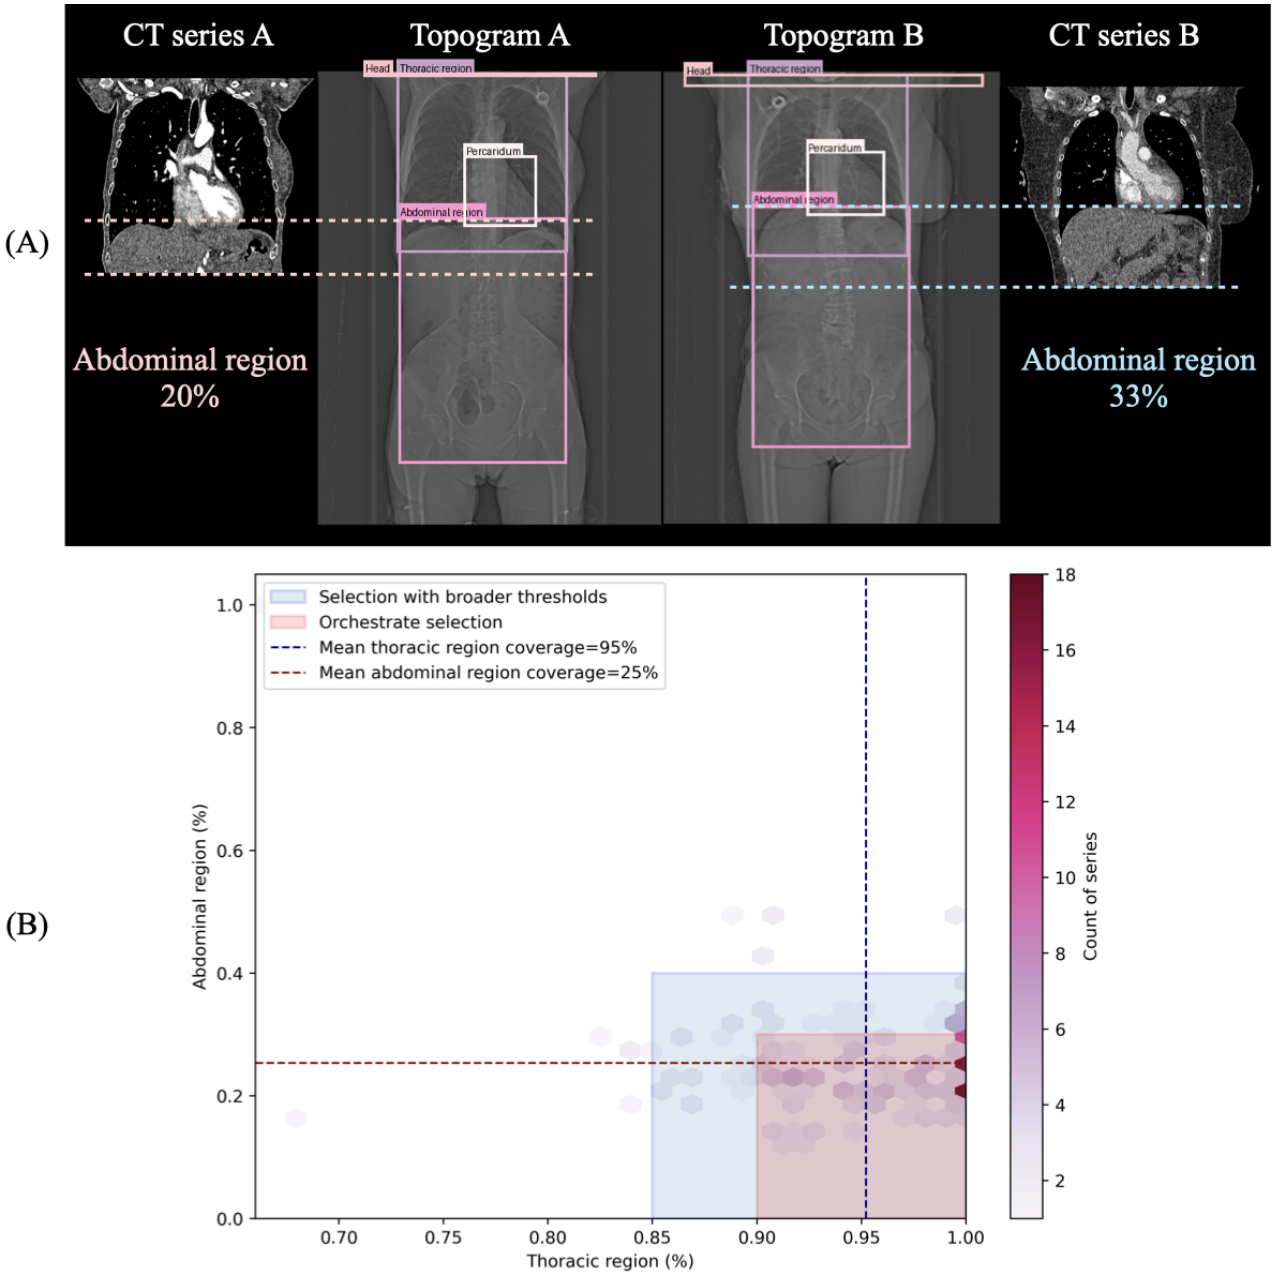
The View Position classifier was assessed using topograms, and all remaining models were evaluated on CT series. The Brain Contrast Enhancement classifier was not evaluated in the external cohorts because the head was not included in the external CT scans. For the Reconstruction Kernel classifier, only the weighted-average F_1-score was reported because all external scans belonged to a single reference standard class (soft kernel). All models achieved good performance across both internal and external data. In the internal framework evaluation dataset, weighted-average F_1-scores ranged from 0.920 to 1.000, whereas macroaverage F_1-scores ranged from 0.879 to 1.000. In the external dataset, macroaverage F_1-scores ranged from 0.777 to 0.929, and weighted-average F_1-scores ranged from 0.946 to 1.000. Model-specific error analyses are summarized in Multimedia Appendix 2 [13,48-50]. In addition, Orchestrate achieved a total processing time for the internal framework evaluation dataset and external dataset of 3.066 seconds per CT study on a workstation equipped with an NVIDIA RTX A6000 graphics processing unit (49140-MiB memory) and 1-TiB system memory. Additional computational details and system requirements are provided in Multimedia Appendix 1 [33-36].

Orchestration Use Case Evaluation

Three radiologists (contrast enhancement and anatomical coverage) and 3 radiographers (reconstruction kernel) independently reviewed all selected series for each use case. Table 5 summarizes the review results from human experts and the accuracy of each target use case.

Table 5. Expert validation of target use cases based on anatomical coverage, contrast enhancement, and reconstruction kernel criteria with accuracy assessment.

Target use case	Series, n	Anatomical coverage and contrast enhancement information	Reconstruction Kernel model	Accuracy, n/N (%)
Contrast-enhanced liver CT[a] and soft kernel	35	35 matched	35 matched	35/35 (100)
Contrast-enhanced thorax CT and hard kernel	134	1 mismatched and 133 matched	3 mismatched and 131 matched	130/134 (97.0)
Whole-body CT and soft kernel	53	53 matched	1 mismatched and 52 matched	52/53 (98.1)



[a]CT: computed tomography.

All selected series in the contrast-enhanced liver CT with soft kernel use case met the predefined selection criteria. In the whole-body CT with soft kernel use case, 1.9% (1/53) of the series had a misclassified reconstruction kernel, whereas in the contrast-enhanced thorax CT with hard kernel use case, 3.0% (4/134) of the series in total did not match the defined criteria. The corresponding selection accuracies were 100% (35/35), 98.1% (52/53), and 97.0% (130/134), respectively. Across all 3 use cases, 2.3% (5/222) of the selected series did not meet the corresponding selection criteria, resulting in an overall accuracy of 97.7% (217/222).

XSL•FO
RenderX

The anatomical coverage thresholds applied in the target set can be adapted according to the requirements of the given application. For example, for contrast-enhanced thorax CT, a broader range of abdominal coverage may be acceptable when additional abdominal anatomy does not interfere with the intended analysis, and a more restrictive threshold may be preferred for applications such as lung tumor detection. Figure 3 illustrates this flexibility using example middle coronal slices from 2 contrast-enhanced thorax CT series with different degrees of abdominal coverage together with their corresponding topograms and outputs from RAPID Body Regions.

Figure 3. Visualization of abdominal and thoracic coverage thresholds for contrast-enhanced thorax computed tomography (CT) selection. (A) Example coronal images in the upper panel show CT series with different degrees of abdominal coverage together with their corresponding topograms and bounding boxes for body regions. The contrast of the topograms shown in this figure was adjusted to improve visualization of anatomical details. The plot (B) demonstrates the distribution of contrast-enhanced thorax CTs that radiologists considered suitable based on their relative thoracic and abdominal coverage. The red rectangle indicates the predefined coverage thresholds applied for the target use case in this study, whereas the blue rectangle indicates a scenario using broader selection thresholds. The adjustable threshold values serve as operational parameters for automated selection rather than universal clinical criteria.

To further illustrate the effect of the predefined thresholds on series selection, 3 radiologists independently reviewed the complete candidate series pool and identified contrast-enhanced thorax CTs that they considered suitable for thoracic CT analysis. All candidate series had previously been classified as having a hard reconstruction kernel based on majority agreement among 3 radiographers. Finally, 215 series were considered eligible based on the majority agreement among radiologists. Figure 3 demonstrates the distribution of these series with relative abdominal and thoracic coverage.

XSL•FO
RenderX

The predefined threshold for the target use case restricted the selection to the region indicated by the red rectangle in Figure 3. The thresholds were introduced in this study to demonstrate how automated selection can be operationalized and should not be interpreted as universal clinical criteria. Therefore, series outside this region are not necessarily incorrectly selected or clinically unsuitable for thoracic CT analysis, and adjusting the thresholds would allow us to select more series. For example, expanding the criteria to allow for less than 40% abdominal region and more than 85% thoracic region would include most of the series considered suitable by the radiologists (blue rectangle in Figure 3).

Discussion

Principal Results

This study introduces Orchestrate, a modular, pixel-native AI orchestration pipeline designed to rapidly automate CT series classification, image routing, and structured metadata generation without relying entirely on inconsistent DICOM metadata, a weakness highlighted both in previous works, such as undefined private tags [25,51], false entries in approximately 15% of images [52], and missing body region information in 32% of series [25], and in the analysis across both the internal framework evaluation dataset and external dataset in this study, which revealed that more than 42% of contrast enhancement information was missing for each dataset. Even when this information is available, the route of contrast administration (intravenous or gastrointestinal) is not consistently specified. In addition, reconstruction kernel information was missing in fewer than 1% of series (4/963, 0.4%) in the internal framework evaluation dataset.

For the internal framework evaluation dataset, Orchestrate demonstrated high performance in body contrast enhancement recognition, reconstruction kernel–type identification, and laterality determination, with all macro– and weighted F_1-scores larger than or equal to 0.983, enabling robust and automated characterization of CT image series in real-world clinical data, reducing dependence on manual curation, and supporting consistent preparation of imaging studies for clinical interpretation and AI integration. These outputs provide immediate feedback on series for specific clinical or research requirements. Moreover, the high weighted F_1-scores across different tasks in the external dataset indicate that the framework maintained consistent performance when applied to data acquired from the other medical centers, particularly for the View Position and Body Contrast Enhancement classifiers. However, external evaluation of the remaining models was limited by the availability and class composition of the external dataset.

Beyond quantitative performance, which confirms technical accuracy, the true value of Orchestrate lies in its clinical utility and research applications. To assess Orchestrate's clinical utility, the system was evaluated across 3 clinically relevant orchestration targets, consistently demonstrating high performance. All automatically selected series of contrast-enhanced liver CT with a soft kernel met the predefined selection criteria. Moreover, whole-body CT with a soft kernel and contrast-enhanced thorax CT with a hard kernel achieved selection accuracy of 98.1% (52/53) and 97.0% (130/134), respectively. These results confirm that Orchestrate reliably replicates human-level classification decisions under variable real-world conditions.

To facilitate seamless integration and interoperable use of Orchestrate outputs within existing clinical workflows, enabling institutions to automate metadata enrichment, quality control, protocol compliance checks, and secure data export, an initial FHIR [53] profile was developed as a proof of concept to standardize the representation of the pixelwise results, anatomical coverage information, and associated CT metadata for prospective integrations. The implementation details, including definitions, value sets, code systems, and examples, are provided in Multimedia Appendix 3 [53,54]. This instantiation is not intended as a finalized representation, and future work may refine the profile for greater precision.

Beyond the study's primary purpose, Orchestrate also enables a practical, automated head anonymization approach for CT series as a secondary clinical application prior to data sharing or research use (the detailed methodology and validation are provided in Multimedia Appendix 4), which prevents the extraction of reproducible facial information from CT series [55]. This anonymization capability demonstrates Orchestrate's broader utility and highlights its potential to preserve privacy in clinical imaging workflows.

Comparison With Prior Work

Previous approaches have addressed CT contrast characterization using different task formulations and input representations. FALCON [48] primarily focuses on binary classification of the presence or absence of intravenous contrast using a single axial slice. BOA-Contrast [49] performs more detailed contrast characterization using Hounsfield unit features from relevant body structures produced by the BOA segmentation framework [13]. The Body Contrast Enhancement classifier in Orchestrate uses 4 selected axial slices combined into a single PNG image for binary classification of intravenous contrast enhancement.

To provide a quantitative comparison, we evaluated the Body Contrast Enhancement classifier in Orchestrate against BOA-Contrast and FALCON using the same internal framework evaluation and external datasets (Multimedia Appendix 2 [13,48-50]). The Body Contrast Enhancement classifier achieved slightly higher F_1-scores in both cohorts. Pairwise prediction agreement among the 3 approaches ranged from 0.667 to 0.806, indicating varying degrees of similarity in the models' predictions and highlighting the challenging nature of contrast enhancement classification.

Beyond individual model performance, Orchestrate's main distinction is integrating multiple CT characterization tasks within a lightweight, image-based framework, which provides complementary benefits across different clinical roles. Physicians, particularly radiologists and radiographers, can assess series-level descriptors and anatomical completeness, thereby promptly identifying inappropriate series and minimizing the need for manual review. In addition, researchers

XSL•FO
RenderX

could use the standardized output to efficiently normalize metadata and automate cohort selection based on anatomical coverage and acquisition-phase standards. Beyond research applications, this system could also be used to perform in-place checks and raise status alerts when missing acquisitions or mismatches are detected, enhancing overall data quality. Collectively, these capabilities highlight Orchestrate's value for real-world radiology operations.

Limitations and Future Work

Several limitations should be acknowledged. First, the current implementation is designed for axial CT series, where sagittal and coronal reconstructions are not yet included because of orientation inconsistencies in DICOM metadata, and lateral topogram analysis is currently limited to head examination. A future direction is to incorporate orientation correction methods and extend topogram analysis to additional projections. Furthermore, Orchestrate is currently CT specific. Extension to other modalities, such as magnetic resonance imaging, will require adaptation to modality-specific image representations. For example, processing 3D magnetic resonance imaging localizers may benefit from segmentation-based models (eg, those used in automated field of view planning [56]) to process localizers and extend this approach to other image types in the future.

Second, current contrast enhancement models detect the presence or absence of intravenous contrast enhancement but do not differentiate individual enhancement phases or gastrointestinal contrast. This limitation is primarily attributable to 2 factors. First, the CT series can contain mixed contrast phases, such as arterial-venous blends or native-urophase mixtures, which reduce the clarity of contrast phase boundaries and limit the formation of a clean phase-specific ground truth. In addition, the lightweight, computationally efficient [57] architecture used in Orchestrate requires each 3D CT volume to be represented by selected slices combined in a single PNG image as an input. Although this approach improves computational efficiency, these slices may not always capture anatomical regions where intravenous enhancement is most apparent, potentially limiting the information available to the model. While more complex automatic architectures can offer greater granularity, they cannot fully solve this limitation [49]. A potential future approach is to use the contrast classifier on different anatomical regions, enabling more contextual contrast evaluation within localized anatomical subsets.

Third, the internal development dataset was constructed through targeted retrieval using predefined DICOM metadata values and attributes, and cases with missing or ambiguous DICOM metadata required to define the corresponding model classes were not included. However, human experts did not independently verify all these DICOM-derived labels, and residual labeling errors cannot be completely ruled out.

Finally, although the external TCIA evaluation introduced heterogeneity, further prospective multicenter validation is needed to assess generalizability across broader clinical environments. Dedicated external evaluation was also not performed for low-dose acquisitions, motion or metal artifacts, or systematically incomplete CT series. Future studies should therefore assess these conditions explicitly and investigate whether institution-specific preprocessing or fine-tuning with representative local data benefits deployment across institutions.

Conclusions

Orchestrate demonstrates the feasibility of a modular, content-based AI pipeline for rapid and accurate CT series characterization that overcomes limitations posed by incomplete or inconsistent DICOM metadata and enables image-based series characterization. By combining pixel-derived semantics with existing DICOM-based workflows, Orchestrate provides a reliable foundation for automated imaging workflows and streamlined data preprocessing in downstream AI applications.

Abstract

Background: Artificial intelligence (AI) is rapidly transforming clinical practice, yet empirical evidence on Chinese physicians' acceptance of AI medical tools remains scarce at the national level.

Objective: This study aimed to evaluate the current acceptance of AI medical tools among Chinese physicians, identify key determinants, and elucidate underlying mechanisms using an extended Unified Theory of Acceptance and Use of Technology (UTAUT) and explainable machine learning.

Methods: A nationwide cross-sectional survey was conducted from January to April 2024, recruiting 4024 in-service physicians across 29 provincial-level administrative units in China via stratified random sampling. The questionnaire incorporated 5 UTAUT constructs—performance expectancy, effort expectancy, social influence, facilitating conditions (FC), and a newly introduced "positive impact" dimension. Psychometric properties were validated through exploratory and confirmatory factor analyses. Structural equation modeling assessed direct and moderated effects, with hospital level, professional title, AI familiarity, and future optimism as moderators. Six classification models were compared for predictive performance; balanced random forest was selected, and model interpretability was evaluated using Shapley Additive Explanations (SHAP).

Results: Overall acceptance exceeded 90% across subgroups. Structural equation modeling showed that performance expectancy, social influence, FC, and positive impact significantly and positively predicted physicians' behavioral intention to use AI medical tools. Six negative moderation effects were identified. The random forest achieved 85.6% accuracy and an area under the receiver operating characteristic curve of 0.836; SHAP analysis identified organizational support (FC_HospPromoteAI) as the feature with the highest mean absolute SHAP value, though all effect sizes were modest.

Conclusions: Chinese physicians exhibit high acceptance of AI medical tools, mainly driven by organizational support and perceived clinical benefits. The combined use of extended UTAUT and explainable AI provides actionable insights for targeted AI implementation strategies in health care.

Introduction

Artificial intelligence (AI) is transforming health care delivery worldwide by enhancing efficiency and quality through automation and intelligent systems [1,2]. Its applications include medical imaging analysis, clinical decision support, and chronic disease management. Convolutional neural networks based on deep learning have demonstrated superior performance in imaging diagnostics [3]. AI medical tools can reduce diagnostic time by approximately 30% and improve accuracy by about 10%, particularly in oncology and cardiovascular medicine [4]. In recent years, large language models such as ChatGPT, Med-PaLM (Google LLC), and domestic systems like DeepSeek and Doubao (ByteDance Ltd.) have shown significant potential

XSL•FO
RenderX

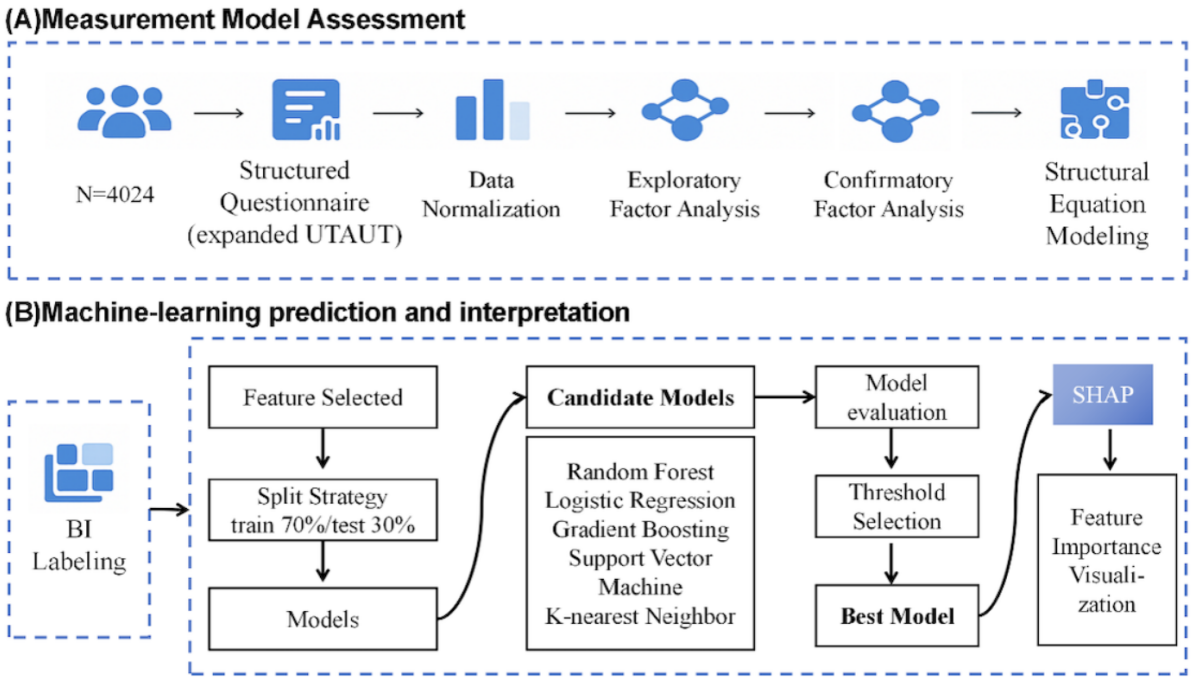
in generating medical records, translating scientific literature, supporting clinical decision-making, and facilitating physician-patient communication [5]. In China, the adoption of AI tools for imaging analysis and decision support has steadily increased, especially in tertiary hospitals [6]. However, concerns about algorithmic bias, data privacy, and accountability remain key barriers to widespread adoption, making physicians' acceptance a critical factor in successful implementation [7,8].

Globally, physicians' attitudes toward AI medical tools are complex. In Western countries, about half of physicians recognize the potential of AI to improve diagnostic efficiency, but many express concerns about privacy and ethics [9,10]. In the United Kingdom, some physicians have refused to use AI imaging tools due to insufficient training [11]. Algorithmic bias, such as racially skewed diagnostic errors, has been shown to undermine trust, particularly when AI-generated recommendations come from large language models [12]. A small-scale Japanese survey indicated that high learning costs also discourage adoption of AI medical tools [13]. Health system differences further influence acceptance: physicians in predominantly private health care systems in Western countries generally enjoy higher autonomy, more resources, and shorter working hours (about 40 h/wk) [14], whereas in China's predominantly public health care system, physicians often work more than 50 hours/week [15]. Existing Chinese studies are mostly regional or small-scale, lack nationally representative data, and rarely integrate explainable machine learning approaches [5,16].

The technology acceptance model identifies perceived usefulness and perceived ease of use as core drivers of adoption [17]. The Unified Theory of Acceptance and Use of Technology (UTAUT) expands this framework by adding social influence (SI), facilitating conditions (FC), and risk perceptions [18]. However, most UTAUT-based studies are conducted in Western health care contexts and have not addressed the unique challenges of China's public health care system, such as high workloads and reduced autonomy [15]. Furthermore, the positive impacts (PIs) of AI—such as improving efficiency, enhancing diagnostic accuracy, and strengthening physician-patient relationships—have not been systematically incorporated into the UTAUT framework.

Therefore, this study aimed to assess the current acceptance of AI medical tools among Chinese physicians, identify key influencing factors and potential moderating effects, and apply explainable machine learning to uncover the complex mechanisms underlying physicians' behavioral intentions (BIs) toward AI adoption.

Methods



Study Design and Participants

This study used a nationwide cross-sectional survey (January-April 2024) to assess Chinese physicians' acceptance of AI medical tools and related determinants. The questionnaire was developed by adapting established scales from the UTAUT [17]. It included 4 original constructs—performance expectancy (PE), effort expectancy (EE), SI, and FC—and an additional "PI" construct. The PI items were derived from the concept of "perceived usefulness" [18] and contextualized to capture specific perceived clinical benefits. The conceptual distinction is clarified as follows: PE items focused on task-level efficiency gains (eg, "AI medical tools can improve health care efficiency"), whereas PI items captured broader clinical and patient-oriented outcomes (eg, "AI can help improve patients' clinical outcomes"; "AI can improve diagnostic accuracy"). While PE reflects expectations about operational performance improvements, PI emphasizes the perceived benefits for clinical quality and patient welfare.

Structured questionnaires were distributed online via Medlive, which is the largest leading professional academic platform for physicians in China, possessing a comprehensive database of verified real-name physicians. To ensure representativeness, we used a stratified random sampling strategy based on 2 key dimensions: geographic location (31 provincial-level administrative regions in mainland China) and hospital classification (tertiary, secondary, and primary institutions). The sampling aimed to achieve nationwide coverage across all provinces rather than predetermined numerical quotas for each stratum. The platform randomly pushed survey invitations to eligible physicians within these strata. A total of 4725 physicians clicked the survey invitation link, of whom 4030 (85.3%) completed all required items. After excluding 6 responses with inconsistent data patterns, 4024 valid questionnaires were retained for analysis, ultimately covering 29 of 31 provincial-level regions. The overall study framework is illustrated in Figure 1.

Figure 1. Overview of study design and analysis workflow. (A) Psychometric and structural modeling. (B) Machine learning prediction and interpretation. BI: behavioral intention; SHAP: Shapley Additive Explanations; UTAUT: Unified Theory of Acceptance and Use of Technology.

Measurement Model Assessment

The instrument comprised 32 items across 6 dimensions: BI, PE, EE, SI, FC, and PI. BI was assessed using 6 dichotomous items (1=willing, 0=unwilling). PE, PI, SI, and FC each contained 4 items scored on a 4-point Likert scale (1=strongly disagree to 4=strongly agree). All construct scores were linearly transformed to a 0-100 scale for comparability across dimensions.

Exploratory factor analysis was conducted using principal component analysis with Varimax rotation; factors with eigenvalues greater than 1 were retained. Sampling adequacy and sphericity were evaluated using the Kaiser-Meyer-Olkin statistic and Bartlett's test, respectively [16]. Confirmatory factor analysis was then performed within a structural equation modeling (SEM) framework, and model fit was evaluated using root mean square error of approximation (RMSEA), comparative fit index (CFI), and Tucker-Lewis index (TLI) according to established cutoffs [17]. Internal consistency (Cronbach α), composite reliability (CR), and average variance extracted (AVE) were computed for each construct.

BI was measured using 6 dichotomous (yes or no) items. We acknowledged that weighted least squares mean and variance-adjusted or robust diagonally weighted least squares estimators would be more appropriate for categorical indicators. However, given that the primary analysis used maximum likelihood (ML) estimation consistently across all constructs, we reported the ML results while noting this methodological consideration.

SEM estimated the direct effects of PE, EE, SI, FC, and PI on BI while controlling for hospital level and professional title [18]. Moderation effects were examined for hospital level, AI familiarity, and future optimism by standardizing variables, creating product-term interactions, and entering them hierarchically into regression models [19]. Multicollinearity was evaluated using variance inflation factors.

Machine Learning Prediction and Interpretability

To capture potential nonlinear and high-dimensional associations, 6 supervised classifiers were compared: logistic regression (LR), support vector machine, random forest (RF), gradient boosting (GB), extreme gradient boosting, and *k*-nearest neighbors [20-25]. The binary outcome was defined as high acceptance (BI score ≥ 83.3, corresponding to "yes" responses on 5 or more of the 6 items; n=3622, 90%) versus moderate or low acceptance (BI score <83.3; n=402, 10%). Data were partitioned into training (n=2817, 70%) and testing (n=1207, 30%) sets using stratified sampling to preserve class proportions. Five-fold stratified cross-validation on the training set was used for model selection and hyperparameter tuning. For tree-based models, key hyperparameters (max_depth, n_estimators, min_samples_split) were optimized via grid search.

Model performance was evaluated using the area under the receiver operating characteristic curve (AUC), accuracy, sensitivity, specificity, and F_1-score. Given class imbalance, precision-recall AUC was additionally considered for robustness [26]. Decision thresholds were optimized using the Youden index to balance sensitivity and specificity [27].

The balanced RF was selected for Shapley Additive Explanations (SHAP) interpretation for three reasons: (1) it achieved the highest accuracy (85.6%) and sensitivity (87.3%) among all models, which is critical for identifying physicians with potential implementation barriers; (2) tree-based SHAP values provide additive, locally accurate explanations that are well-suited for identifying feature interactions; and (3) the

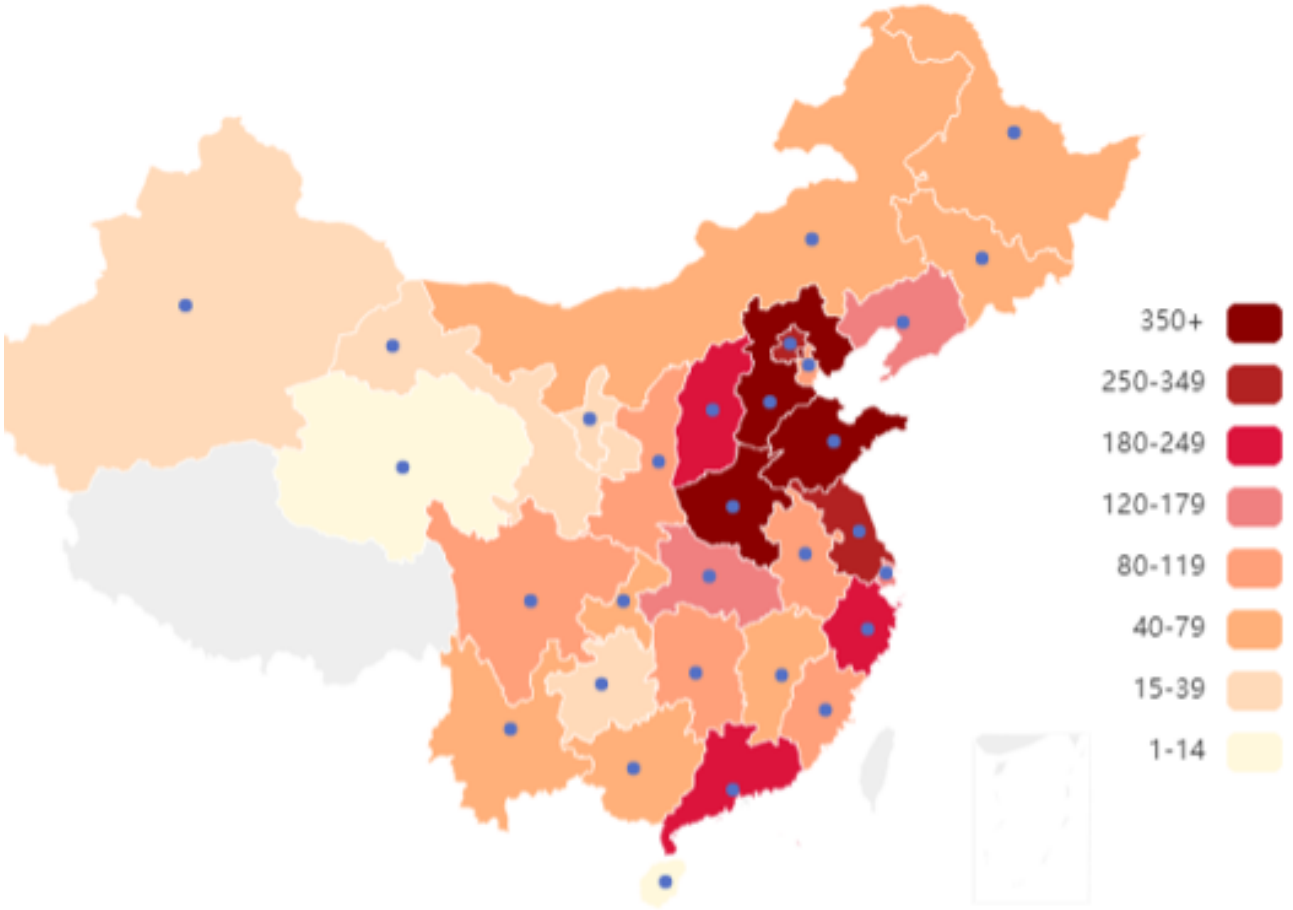
XSL•FO
RenderX

class-balancing mechanism addresses the 9:1 class imbalance, producing more reliable feature importance estimates for the minority class. While LR and GB achieved equivalent or higher AUC (0.840), we prioritized sensitivity and interpretability for this exploratory analysis. SHAP was applied to quantify each feature's contribution to the predicted probability of high AI acceptance, providing global importance rankings (mean absolute SHAP values) and local interpretability (summary plots) [28].

Statistical Analysis

Categorical variables were summarized as counts and percentages, and continuous variables were reported as medians with IQRs. Group comparisons used the chi-square test or Fisher exact test for categorical variables and the Wilcoxon rank-sum test for continuous variables, as appropriate. Two-sided *P* values <.05 were considered statistically significant; when multiple pairwise comparisons were performed, Bonferroni correction was applied. All statistical analyses were conducted in Python (version 3.10.0) using standard libraries (pandas, NumPy, SciPy, and statsmodels) for inference and scikit-learn for model-related procedures.

Ethical Considerations



The study was conducted in accordance with the Declaration of Helsinki. Prior to data collection, all participants were presented with an electronic informed consent statement detailing the study objectives, its voluntary nature, and the privacy measures. Participants were required to confirm their agreement by clicking a mandatory "I Agree" button to proceed to the questionnaire. As the study involved a noninterventional, anonymous survey of professionals, formal institutional review board approval was waived in accordance with the operational guidelines of the data collection platform (Medlive), provided that strict data privacy and anonymity protocols were enforced. All participants provided informed consent prior to data collection. No financial compensation or incentives were provided to participants for their involvement in this study.

Results

Sample Characteristics

A total of 4024 in-service physicians from mainland China were included. As shown in Figure 2, the sample covered 29 provincial-level regions, with most participants located in East China (n=1143, 28.4%) and North China (n=978, 24.3%). Tertiary hospitals accounted for 3114 (77.4%), followed by secondary hospitals (n=717, 17.8%) and primary care institutions (193, 4.8%). Regarding professional title, 2933 (72.9%) held senior titles (chief or associate chief), 1040 (25.8%) held intermediate titles, and 51 (1.3%) were junior or ungraded.

Figure 2. Geographic distribution of physicians across China (n=4024). Provinces are shaded by the number of participants, with darker colors indicating higher counts. A total of 29 provinces were covered in the survey. Blue dots represent provincial capital cities.

XSL•FO
RenderX

Measurement Properties of the Questionnaire

The AVE for BI was 0.40, slightly below the conventional threshold of 0.50. This lower AVE is consistent with the strong ceiling effect observed in BI responses, where over 90% (n=3621) of participants indicated willingness to use medical AI across all 6 dimensions (range: 90.6% - 96.4%). Despite the lower AVE, BI demonstrated good internal consistency through CR (0.80) and Cronbach α (0.80), with all standardized factor loadings exceeding 0.59.

As detailed in Table S1 in Multimedia Appendix 1, exploratory factor analysis indicated adequate sampling and factorability (Kaiser-Meyer-Olkin=0.898; Bartlett test χ^2=47,985.41; *P*<.001). Based on eigenvalues greater than 1 and scree plot inspection, 6 factors were extracted, explaining 62.8% of the total variance, which is consistent with the extended UTAUT specification. All standardized factor loadings exceeded 0.40 (Table S1 in Multimedia Appendix 1), and internal consistency was acceptable to good across constructs (mean Cronbach α >0.78).

Confirmatory factor analysis further supported the 6-factor model with good fit (RMSEA=0.043; CFI=0.937; TLI=0.930). CR exceeded 0.80 for all constructs, and AVE was greater than 0.50 for every construct except BI (AVE=0.478), indicating satisfactory convergent validity (Table 1). Discriminant validity was supported, as the square root of each construct's AVE on the diagonal was greater than the corresponding interconstruct correlations (Table 2).

Table . Convergent validity of constructs for Chinese physicians' acceptance of artificial intelligence medical tools. All factor loadings are standardized.

Construct	Cronbach α	CR[a]	AVE[b]	Average loading

RenderX

Acceptance Across Subgroups

As shown in Figure 3, overall willingness to adopt AI medical tools exceeded 90% (3622/4024). Descriptive analysis of the aggregated BI score revealed a negative skewness of −3.55 and a kurtosis of 13.91, statistically confirming the nonnormal distribution associated with the ceiling effect. For inferential analyses, categories with value n less than 50 were excluded (private hospitals, n=29; clinics, village health posts, or outpatient departments, n=11; junior title, n=46; ungraded, n=5). One-way ANOVA indicated no significant between-group differences by hospital level and a borderline difference by professional title that became nonsignificant after Bonferroni correction.

Figure 3. Overall acceptance of artificial intelligence medical tools across subgroups: (A) by hospital level and (B) by professional title. Categories with n<50 were excluded from inferential tests. Bars indicate the proportion reporting willingness (BI=1). BI score was computed as the unweighted arithmetic mean of the 6 items and linearly transformed to a 0 - 100 scale. BI: behavioral intention.

Structural Model Results

The extended UTAUT structural model demonstrated a good fit to the data (RMSEA=0.043; CFI=0.948; TLI=0.941). As shown in Figure 4, PE (β=.03, 95% CI 0.014-0.055; *P*=.001), SI (β=.02, 95% CI 0.010-0.039; *P*<.001), FC (β=.10, 95% CI 0.085-0.119; *P*<.001), and PI (β=.01, 95% CI 0.000-0.028; *P*=.047) were positive predictors of BI, whereas EE was not significant (β≈0, 95% CI −0.014 to 0.014]; *P*=.99). The model explained 21.6% of the variance in BI (R^2=0.216).

Figure 4. Structural path model based on the extended Unified Theory of Acceptance and Use of Technology framework. Solid lines indicate statistically significant paths, dashed lines indicate nonsignificant paths. Path coefficients are standardized β values, with significance levels denoted as *P*<.05 (*), *P*<.01 (**), and *P*<.001 (***). External variables (performance expectancy, effort expectancy, social influence, facilitating conditions, positive impact) are shown in beige and the outcome variable (BI) is shown in purple (R^2 for BI=0.216). BI: behavioral intention.

Moderation Analysis

To examine whether background variables altered the primary UTAUT paths, product-term interactions were created using standardized latent variables for the following moderators: hospital level (W5), professional title (W7), AI familiarity (N1), and future optimism (N5). Hierarchical regression identified 6 negative interaction effects (*P* values <.05), indicating attenuation of the corresponding main effects at higher levels of the moderator (Table 3). Variance inflation factors ranged from 1.06 to 1.99 (mean 1.54), suggesting no multicollinearity concerns. Other tested interactions were not statistically significant.

XSL•FO
RenderX

Table . Moderation effects on Unified Theory of Acceptance and Use of Technology paths (standardized coefficients).

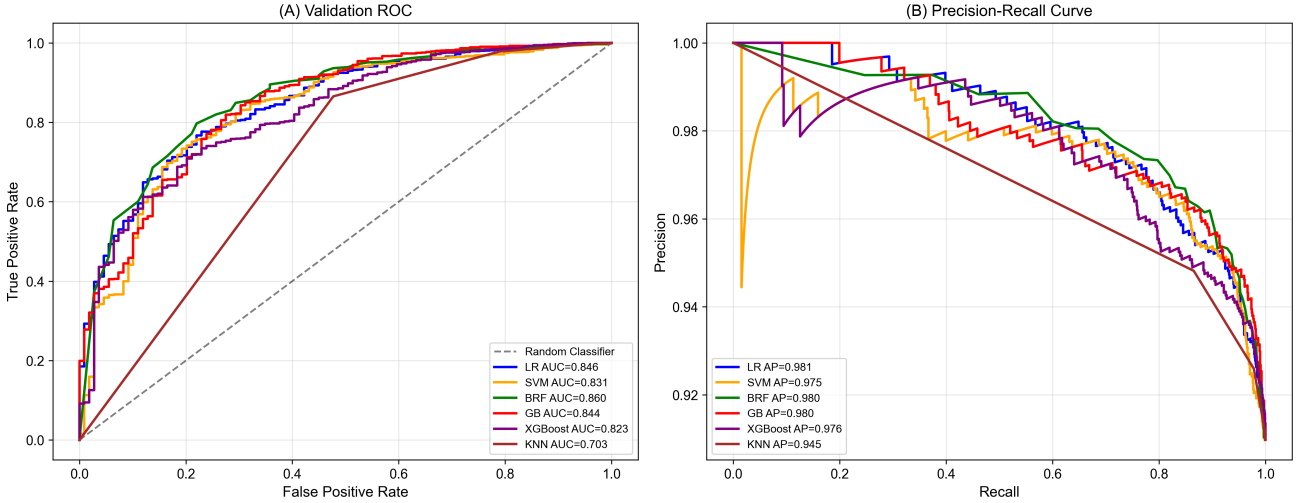
Interaction (moderator × predictor)	β	*P* value	Direction
EE[a] × W5[b]	−.054	.004	Negative
EE × N1[c]	−.037	.03	Negative
FC[d] × N1	−.048	.01	Negative
EE × N5[e]	−.043	.01	Negative
FC × N5	−.074	<.001	Negative
PI[f] × N5	−.054	.001	Negative

[a]EE: effort expectancy.

[b]W5: hospital level.

[c]N1: artificial intelligence familiarity.

[d]FC: facilitating conditions.



[e]N5: future optimism.

[f]PI: positive impact.

Explainable Prediction Analysis

Given the class imbalance in the dataset, the decision thresholds for each model were optimized according to the Youden index to achieve a balance between sensitivity and specificity [29]. Figure S1 in Multimedia Appendix 2 shows the results of threshold tuning analysis. As shown in Table 4, the LR model (AUC 0.840) and GB model (AUC 0.840) demonstrated superior predictive performance for physicians' acceptance of AI medical tools compared with other ML models. Unadjusted (default) threshold results for all models are provided in Table S3 in Multimedia Appendix 1. Figure 5 shows the receiver operating characteristic and precision or recall curves for the 6 evaluated models. LR achieved the highest specificity (0.877) and average precision, whereas RF yielded the highest accuracy (0.856) and sensitivity (0.873).

Figure 5. Performance comparison of 6 machine learning models. (A) ROC curves showing that LR and gradient boosting achieved the highest AUC (0.840), followed closely by random forest (0.836). (B) Precision-recall curves. Based on the balance between accuracy (0.856) and sensitivity (0.873) shown in Table 4, the BRF model was selected for the subsequent interpretability analysis. AP: average precision; AUC: area under the receiver operator characteristic curve; BRF: balanced random forest; GBDT: gradient boosting decision tree machine; KNN: *k*-nearest neighbor; LR: logistic regression; ML: machine learning; ROC: receiver operating characteristic; SVM: support vector machine; XGBoost: extreme gradient boosting.

XSL•FO
RenderX

Table . Comparison of various machine learning models' performance.

Model	AUC[a]	Accuracy	Sensitivity	Specificity	F_1-score	Youden index
RF[b]	0.836	0.856	0.873	0.685	0.917	0.558
LR[c]	0.840	0.682	0.663	0.877	0.791	0.539
GB[d]	0.840	0.794	0.799	0.740	0.876	0.539
XGBoost[e]	0.822	0.752	0.749	0.781	0.846	0.529
SVM[f]	0.806	0.745	0.742	0.781	0.841	0.523
KNN[g]	0.685	0.835	0.870	0.479	0.905	0.350

[a]AUC: area under the receiver operating characteristic curve.

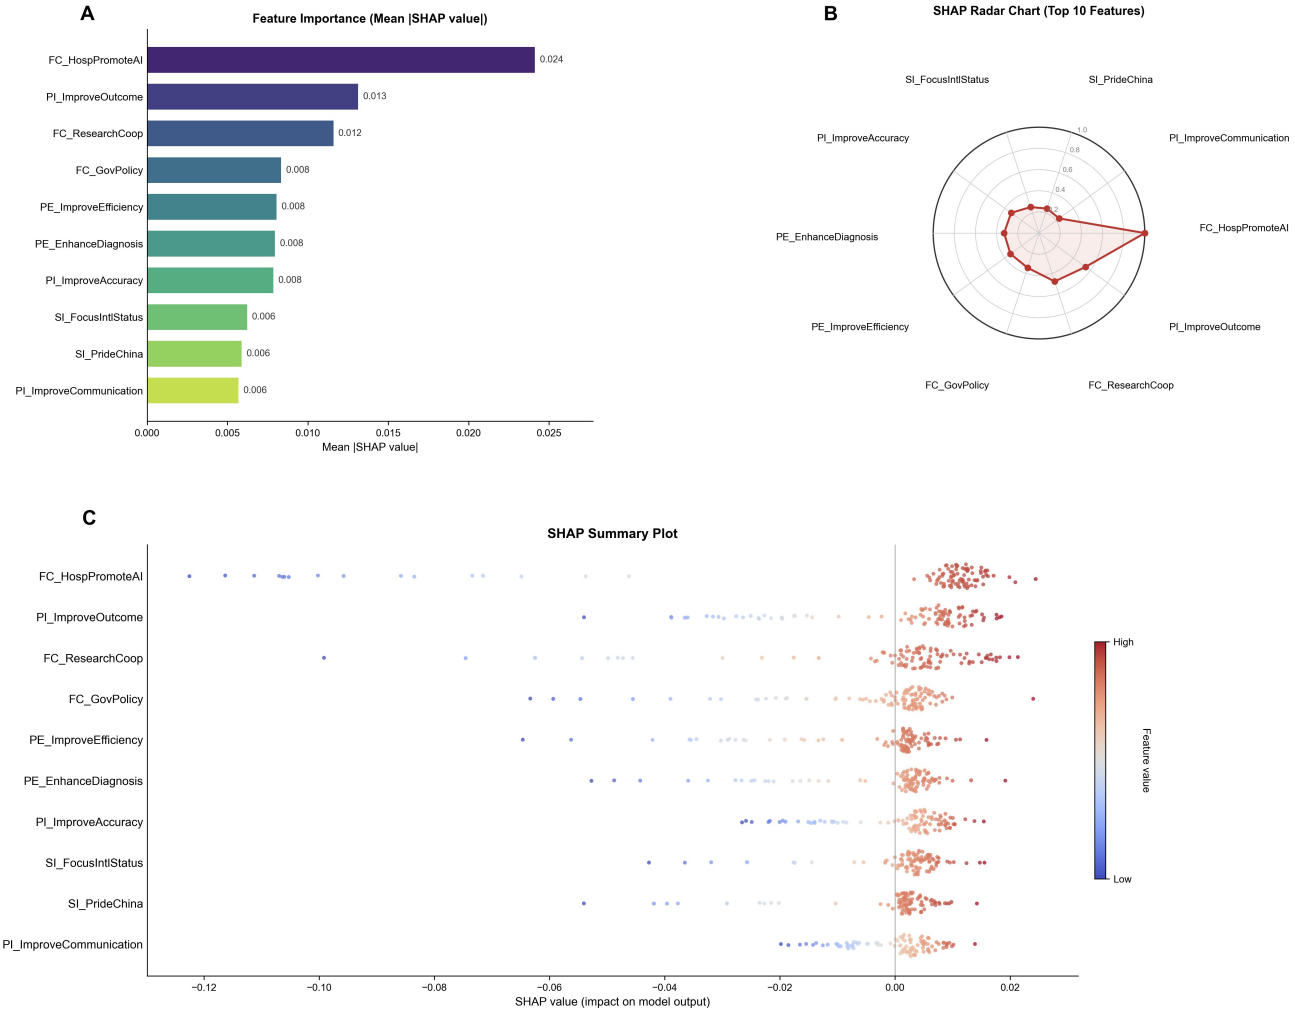
[b]RF: random forest.

[c]LR: logistic regression.

[d]GB: gradient boosting.

[e]XGBoost: extreme gradient boosting.

[f]SVM: support vector machine.



[g]KNN: *k*-nearest neighbor.

Among all tested machine learning models, GB and LR achieved the highest performance with AUC of 0.840, followed by RF (AUC=0.836) and extreme gradient boosting (AUC=0.822). The detailed performance metrics for all models under unadjusted (default) thresholds are provided in Table S3 in Multimedia Appendix 1.

The SHAP algorithm was applied to interpret the prediction of high acceptance of AI medical tools among physicians. Figure 6A shows the feature importance ranking with the top 10 predictors. FC_HospPromoteAI had the highest mean absolute SHAP value (0.024), though all effect sizes were modest, consistent with the ceiling effect in the outcome variable. Figure 6B presents the radar chart illustrating the relative importance of FC_HospPromoteAI compared to other variables. Figure 6C shows the SHAP summary plot, indicating that higher scores in organizational support (FC_HospPromoteAI) and perceived clinical benefits increased the predicted probability of high acceptance, while lower scores reduced it.

XSL•FO
RenderX

Figure 6. SHAP-based interpretability analysis of the optimal prediction model. (A) Mean absolute SHAP values ranking the top 10 most influential features for predicting physicians' acceptance of artificial intelligence (AI) medical tools. (B) SHAP radar chart illustrating the relative importance of the top 10 features. (C) SHAP summary plot showing the distribution and direction of feature impacts. Higher perceived organizational support and clinical benefits of AI (red points) were associated with an increased probability of high acceptance, whereas lower scores (blue points) decreased the predicted acceptance. FC_HospPromoteAI: Hospitals should actively promote the use of AI medical tools; PI_ImproveOutcome: AI can help improve patients' clinical outcomes; FC_ResearchCoop: Research institutions should strengthen AI-related research and collaboration; FC_GovPolicy: Government should introduce policies to promote AI in health care; PE_ImproveEfficiency: AI medical tools can improve health care efficiency; PE_EnhanceDiagnosis: AI medical tools can enhance physicians' diagnostic ability; PI_ImproveAccuracy: AI can improve diagnostic accuracy; SI_FocusIntlStatus: I pay attention to China's international status in medical AI; SI_PrideChina: I am proud of China's rapid development in medical AI; PI_ImproveCommunication: AI can help improve communication between physicians and patients. FC: facilitating conditions; PE: performance expectancy; PI: positive impact; SHAP: Shapley Additive Explanations; SI: social influence.

Decision curve analysis indicated that the GB classifier provided greater net benefit than both treat-all and treat-none strategies across most clinically plausible threshold probabilities (approximately 0.40 to 0.95; Figure S2 in Multimedia Appendix 2). In practice, this suggests that the model can help exploratorily identify characteristics associated with lower acceptance intentions, providing preliminary insights for targeted intervention design rather than definitive screening criteria. For individuals with these characteristics, administrators may consider initiating targeted interventions—specifically, reinforcing organizational support and demonstrating clinical evidence (as highlighted by SHAP)—rather than applying a one-size-fits-all training approach.

Discussion

Principal Findings

This study examined Chinese physicians' acceptance of AI medical tools using an extended UTAUT framework combined with explainable machine learning. Acceptance was uniformly high (>90%) across subgroups, revealing a pronounced ceiling effect. In the structural model, PE, SI, FC, and PI were positive predictors of BI, whereas EE was not significant. Six negative moderation effects indicated that higher hospital level, greater AI familiarity, and stronger future optimism attenuated several main effects. In predictive analyses, the RF provided the best overall trade-off after threshold optimization, while LR and GB attained the highest AUC. SHAP interpretation ranked organizational support ("hospitals should actively promote AI") and perceived clinical benefits ("AI improves outcomes" and

XSL•FO
RenderX

"AI enhances diagnosis") as the most influential features driving high acceptance.

While several path coefficients in the structural model were statistically significant yet relatively small in magnitude (PE: β=.03; SI: β=.02; PI: β=.01), these effects merit careful interpretation in context. First, the strong ceiling effect in BI (>90% acceptance across all dimensions) naturally constrains the range of variance available for prediction, mathematically limiting potential effect sizes. Second, in the presence of strong FC (β=.10, the largest predictor), the incremental contributions of PE and SI may be attenuated, as physicians already possess sufficient organizational support and resources to adopt AI regardless of individual perceptions. Third, from a practical significance perspective, even small standardized coefficients can translate to meaningful behavioral differences at population scale: a 0.03 increase in acceptance probability across China's 4 million physicians represents over 100,000 additional potential AI adopters. Thus, while the effect sizes appear modest statistically, they reflect substantively important patterns within a highly accepting physician population operating under strong institutional support.

The strong ceiling effect in BI merits discussion. Rather than merely a psychometric limitation, this pattern reflects a substantive finding: Chinese physicians demonstrate remarkably high acceptance of medical AI technology across diverse applications (automated medical record generation, chronic disease management, diagnostic assistance, personalized treatment planning, medical imaging analysis, and surgical assistance). This high acceptance rate aligns with China's national strategy to integrate AI into health care systems and suggests favorable conditions for medical AI implementation in Chinese health care settings.

Over 90% of physicians are willing to accept AI medical tools. Such a ceiling effect—wherein nearly all respondents express positive intent—demands careful interpretation. While high acceptance could reflect genuine enthusiasm driven by clinical needs and prior exposure to digital technologies, it may also result from social desirability bias or limitations in the measurement scale that restrict variance [30]. In contrast, studies from North America and Europe often report moderate acceptance levels. Recent multicountry surveys indicate that only 40% - 60% of physicians express readiness to integrate AI into routine practice [31,32]. Factors underlying this gap likely extend beyond technological maturity. In China, structural pressures—such as high patient volumes, long working hours, and relatively constrained staffing—may foster a pragmatic openness toward tools that promise efficiency gains. Government policy has also played a pivotal role [33]. However, a persistent challenge in behavioral research is the "attitude–behavior gap" [30]. High stated willingness does not guarantee sustained or effective use in practice. For example, follow-up studies in the United Kingdom found that despite favorable attitudes toward AI-based diagnostic support, actual use rates remained low due to workflow incompatibility and medico-legal concerns [34]. Thus, while this study's findings provide optimism, they also highlight the need for longitudinal monitoring to assess whether intentions translate into ongoing adoption.

Within the extended UTAUT framework, 4 predictors—PE, SI, FC, and PI—emerged as statistically significant, whereas EE did not. *PE* consistently ranks as a central driver in technology adoption models. Physicians in our sample may perceive AI as capable of enhancing diagnostic accuracy, reducing manual workload, and improving patient outcomes, aligning with global findings that perceived clinical benefit is the most influential determinant of adoption [33,35]. This is particularly relevant in specialties, such as radiology and pathology, where AI applications have already demonstrated time-saving and accuracy-enhancing capabilities. *SI* reflects the role of peer networks, professional hierarchies, and institutional culture. In the Chinese health care system, hierarchical structures and strong alignment with administrative directives may amplify the influence of respected colleagues or hospital leadership [32]. In environments where senior physicians endorse AI tools, junior colleagues may be more inclined to adopt, regardless of personal reservations. FC captured organizational readiness, including training, IT infrastructure, and institutional support. The high predictive value of FC in this study aligns with recent organizational readiness research, which identifies supportive environments as critical enablers of AI deployment [36,37]. In resource-constrained settings, the absence of infrastructure and technical assistance often outweighs individual willingness as a barrier. The inclusion of *PI* as an extended UTAUT construct reflects an emerging recognition that clinicians also evaluate the societal and ethical implications of technology. Perceptions that AI could enhance health care equity, reduce medical errors, or improve doctor-patient relationships may bolster acceptance, particularly in systems under strain [38]. This dimension resonates with a broader shift in digital health evaluation frameworks toward sociotechnical models. The nonsignificant role of EE is noteworthy. In classical technology acceptance model and UTAUT studies, ease of use often exerts a strong influence on BI. Its absence here may signal several possibilities. First, the usability of current AI medical tools may have reached a level where interface complexity is no longer a major barrier for physicians already accustomed to electronic medical records. Second, the survey population consisted largely of physicians in tertiary hospitals (3115/4024, 77.4%), who may have greater access to IT support, thus minimizing perceived effort barriers [39].

The moderation analysis revealed 6 significant negative interaction effects, indicating that certain background factors attenuated the influence of main predictors. To better illustrate these patterns, simple slope analyses were conducted for the key moderators (Figure S3 in Multimedia Appendix 2). The results suggest a "substitution effect" mechanism. Specifically, higher hospital levels and greater AI familiarity reduced the impact of FC and SI on BI. Physicians in high-level hospitals or those familiar with AI likely possess sufficient internal resources and knowledge, making them less dependent on external organizational support or peer norms to form adoption intentions. In contrast, physicians with low familiarity (as shown by the steeper slopes in Figure S3A in Multimedia Appendix 2) rely heavily on external FC to bridge the gap in their own capability. Similarly, future optimism dampened the effects of PE. As shown in Figure S3B in Multimedia Appendix 2, physicians with high optimism maintain high adoption intentions

XSL•FO
RenderX

regardless of the immediate performance gains, suggesting their internal belief acts as a buffer. Conversely, physicians with low optimism are more pragmatic; their willingness to adopt is highly sensitive to the tangible PE of the tools. This contrasts with the "wait-and-see" stance observed in previous studies, where anticipation of superior next-generation systems delays current uptake [40]. Instead of delaying adoption, our data suggests that high optimism provides a strong internal drive that substitutes for the need for immediate performance guarantees.

Methodological Synergy: Integration of SEM and Machine Learning

This study integrates SEM and ML to provide complementary perspectives on AI adoption. The SEM analysis established that FC (β=.10) was the strongest UTAUT predictor of BI. Correspondingly, SHAP analysis identified the item-level feature FC_HospPromoteAI (hospital organizational promotion of AI) as the most influential predictor of high acceptance (mean |SHAP|=0.024). This convergence between latent construct effects and item-level importance provides actionable specificity: interventions should prioritize institutional promotion and leadership endorsement rather than diffuse FC. Furthermore, SHAP revealed that physicians in secondary hospitals with moderate AI familiarity may respond differently to organizational support compared to tertiary hospital counterparts, suggesting the value of subgroup-specific implementation strategies. The complementary use of theory-driven SEM and data-driven ML thus validates the extended UTAUT framework while identifying concrete targets for management intervention.

Policy Implications: Evidence-Based Ethics and Governance

Our empirical findings suggest 3 policy priorities directly informed by the data. First, the dominance of FC_HospPromoteAI in SHAP analysis indicates that institutional endorsement is more influential than individual-level factors, supporting policies that mandate hospital-level AI governance committees and leadership commitment before deployment. Second, the negative moderation effect of AI familiarity on FC→BI (β=−.024) suggests that as physicians gain experience, their reliance on organizational support diminishes. This pattern has governance implications: early-stage implementation requires strong institutional backing and training, while mature adoption may benefit from peer-driven knowledge sharing and reduced top-down mandates. Third, the consistently high acceptance (>90%) but modest effect sizes suggest that the primary challenge is not physician willingness but rather structural readiness—policies should therefore prioritize infrastructure investment, workflow integration, and liability clarification over persuasion campaigns. Legal frameworks must clarify that AI serves as a decision support tool, with final clinical responsibility remaining with the physician.

Limitations

This study has several limitations. First, while our sample achieved broad geographic coverage (29 of 31 provincial-level regions), it was skewed toward tertiary hospitals (77.4% vs 52.1% nationally) and physicians with senior titles (72.9% vs approximately 35% nationally). This distribution reflects two factors: (1) the user composition of the Medlive platform, which predominantly serves physicians in larger academic medical centers and (2) inherent regional differences in physician density across China. While we considered weighting adjustments, we opted to retain the raw data to avoid statistical instability from heavily weighting the smaller primary care subsample. These patterns may limit generalizability to primary care settings, junior physicians, and underrepresented regions. Future studies should use targeted recruitment strategies to ensure adequate representation of community health centers and rural clinics, where AI implementation may face distinct resource and infrastructure challenges.

Second, the AVE for the BI construct was 0.40, falling below the conventional 0.50 threshold. This reflects the variance constraint imposed by the dichotomous nature of the items and the pronounced ceiling effect (over 90% acceptance) observed in the data. However, the construct demonstrated high internal consistency (CR=0.80; Cronbach α=0.80). Furthermore, sensitivity analyses comparing factor loadings between ML and diagonally weighted least squares estimators showed minimal differences (mean loading difference=0.027, max=0.048; Table S4 in Multimedia Appendix 1), indicating that the choice of estimator did not substantively affect parameter estimates and the measurement model is robust.

Third, the generic framing of "AI medical tools" may overlook differences between specific application types. Finally, while explainable machine learning added predictive depth, it was not applied to longitudinal adoption data, which could further refine implementation strategies.

Conclusion

Chinese physicians report an exceptionally high willingness to adopt AI medical tools, with organizational facilitation emerging as a key driver. Combining behavioral modeling with explainable ML highlights the relative importance of institutional readiness, though effect sizes are modest due to the pronounced ceiling effect. This underscores the need for context-specific strategies to translate intention into sustained, safe, and effective use.

Abstract

Background: Major adverse renal and cardiovascular events (MARCE) have been proposed as a comprehensive end point reflecting both cardiac and renal outcomes in patients with acute myocardial infarction (AMI) and chronic kidney disease (CKD). However, existing prediction tools lack accuracy and generalizability for this high-risk population.

Objective: This study aimed to develop and externally validate explainable machine learning models and a nomogram for predicting in-hospital MARCE among patients with AMI and CKD.

Methods: We enrolled patients with AMI and CKD who underwent emergency treatment at the First Affiliated Hospital of Wenzhou Medical University as the discovery cohort and those at Wenzhou TCM (traditional Chinese medicine) Hospital of Zhejiang Chinese Medical University as the external validation cohort. Clinical features, including demographic details, comorbidities, laboratory results, echocardiography measurements, procedural details, and medication parameters, were collected for all participants. Important variables were selected using least absolute shrinkage and selection operator regression in the training set. We developed extreme gradient boosting (XGBoost), random forest, decision tree, and logistic regression (LR) models and evaluated their discrimination, calibration, and classification metrics in the hold-out test set and external cohort.

Results: In the training set, we identified 6 important variables (Killip class, lactate, estimated glomerular filtration rate, use of diuretics, use of beta-blockers, and use of renin-angiotensin system inhibitors). In the test set, model discrimination was comparable across XGBoost (area under the receiver operating characteristic curve [AUC] 0.882, 95% CI 0.816-0.947), LR (AUC 0.875, 95% CI 0.799-0.950), and random forest (AUC 0.870, 95% CI 0.800-0.940), while decision tree showed lower performance (AUC 0.814, 95% CI 0.720-0.886). Shapley additive explanations (SHAP) values illustrated both global and individual feature contributions in the XGBoost model. A nomogram based on LR achieved an AUC of 0.873 (95% CI 0.714-0.926) in external validation.

Conclusions: Our study identified 6 important predictors and provided a series of prediction models to enhance risk stratification of MARCE for patients with AMI and CKD. These models might aid in stratifying risk and choosing appropriate therapeutic strategies in the management of patients with AMI and CKD.

KEYWORDS

acute myocardial infarction; chronic kidney disease; nomogram; machine learning; major adverse renal and cardiovascular events

Introduction

Acute myocardial infarction (AMI) represents a major global public health challenge associated with significant mortality and disability. It is characterized by acute myocardial ischemia resulting from complete or incomplete occlusive thrombosis secondary to rupture or erosion of coronary atherosclerotic plaques [1]. Chronic kidney disease (CKD) is a strong independent risk factor for cardiovascular disease [2], affecting up to 30% to 40% of patients with AMI [3]. Compared with patients without CKD, those with AMI and comorbid CKD exhibit 2 to 5 times higher in-hospital mortality [4]. Reported rates of in-hospital major adverse cardiovascular events and

XSL•FO
RenderX

acute kidney injury requiring dialysis range from 7.1% to 32.5% and 0.8% to 11.5%, respectively [5,6]. These poor outcomes are primarily attributed to frequent ineligibility for sustained reperfusion therapy and evidence-based pharmacotherapy, chronic volume overload, high comorbidity burden, and delayed medical attention due to atypical symptoms [3,5]. Consequently, patients with AMI and CKD impose a heavy socioeconomic burden and represent a critical population urgently requiring improved prognostic outcomes in cardiorenal management.

Recognizing the close cardiorenal interplay, the American Heart Association (AHA) has endorsed major adverse renal and cardiovascular events (MARCE), encompassing both cardiovascular and renal adverse events, as a novel composite clinical end point for evaluating cardiorenal disease prognosis [7]. This clinically significant end point is considered to provide a more comprehensive assessment of overall patient risk. Nevertheless, widely used traditional clinical prediction tools such as the Global Registry of Acute Coronary Events (GRACE) score and Cleveland Clinic score [8,9] exhibit critical limitations: they predominantly focus on single-organ end points (either cardiac or renal events) and fail to integrate the complexity of MARCE in cardiorenal comorbidity. More importantly, as approximately 75% of coronary heart disease-related clinical trials exclude patients with CKD [10,11], the applicability and predictive performance of existing models developed in "relatively healthier" populations are severely compromised when applied to real-world patients with AMI and prevalent CKD. Thus, there is an urgent clinical need for a robust novel tool to accurately predict MARCE risk in this high-risk population.

Machine learning (ML) methods demonstrate significant advantages in capturing complex nonlinear relationships and higher-order interactions within multidimensional data [12]. They have been extensively applied across medical research domains, including risk stratification and prognostic prediction [13,14]. Previous studies have demonstrated that ML-based models outperform traditional scoring systems in predicting adverse cardiovascular outcomes in patients with AMI [15,16]. However, widespread adoption of ML models in clinical decision support faces a major challenge: limited interpretability due to their inherent "black-box" nature [17,18], which hinders clinicians' understanding and trust in model predictions. To address this limitation, this study integrates advanced ML algorithms with a Shapley additive explanations (SHAP)–based explainable AI framework. SHAP provides intuitive, individualized feature contribution explanations.

In this study, we aimed to develop and externally validate ML models for predicting in-hospital MARCE risk in patients with AMI and CKD. The models were designed to assist clinicians in identifying individual risk drivers, assessing disease severity, and supporting early risk stratification during index hospitalization.

Methods

Study Design

Based on predefined inclusion and exclusion criteria, this retrospective cohort study enrolled patients with AMI and CKD who presented and underwent emergency treatment at the First Affiliated Hospital of Wenzhou Medical University between January 2013 and July 2019. This group was designated the "discovery cohort" for model development and internal validation. An external validation cohort consisted of patients meeting the same criteria admitted between January 2020 and August 2021 at Wenzhou TCM (traditional Chinese medicine) Hospital of Zhejiang Chinese Medical University.

Inclusion criteria were as follows: (1) age 18 years or older; (2) diagnosis of AMI according to established guidelines [1]; (3) diagnosis of CKD, defined as an estimated glomerular filtration rate (eGFR) of <60 mL/min/1.73 m^2, calculated using the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equation [19] from the first serum creatinine measured within 24 hours after admission; and (4) receipt of emergency treatment. Exclusion criteria included (1) death during intervention or within 24 hours of admission; (2) unavailability of coronary angiography images; (3) current dialysis or renal replacement therapy before admission; and (4) missing data exceeding 20% of individual patient records.

Ethical Considerations

The study protocol received approval from the ethics review boards of both the First Affiliated Hospital of Wenzhou Medical University (number R2152025) and Wenzhou TCM Hospital of Zhejiang Chinese Medical University (number WZY2024-KT-0294‐01) and conformed to the Declaration of Helsinki. The retrospective design exempted the requirement for participant consent. This study was reported in accordance with the TRIPOD (Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis) statement (Checklist 1) [20].

Data Collection

All data were extracted from the electronic medical record system within the first 24 hours of admission. The collected information included demographic characteristics, clinical presentation on admission, medical history, laboratory findings, echocardiography measurements, procedural details, and medication use.

Medical history, including hypertension, diabetes mellitus, and stroke, was identified based on *International Statistical Classification of Diseases, Tenth Revision* (*ICD-10*) codes. Laboratory results were obtained from tests conducted on the first day after admission. Echocardiography measurements were performed at admission, with left ventricular ejection fraction calculated using the modified Simpson biplane method from apical four-chamber and two-chamber views. Angiographic and procedural documentation included the degree and location of coronary stenosis, as well as the presence of calcification, thrombus, and whether thrombus aspiration was performed.

XSL•FO
RenderX

Medications administered during hospitalization, including beta-blockers, angiotensin-converting enzyme inhibitors (ACEIs)/angiotensin II receptor blockers (ARBs)/angiotensin receptor-neprilysin inhibitors (ARNIs), and diuretics, were also recorded.

Killip classification was defined as follows: class I indicated no signs of heart failure; class II was defined by the presence of rales and/or jugular venous distension; class III represented acute pulmonary edema; and class IV denoted cardiogenic shock [21].

The GRACE score, which is recommended by clinical guidelines for risk stratification in acute coronary syndrome [8,22], was calculated for each patient to enable comparison with the nomogram developed in this study.

End Point and Follow-Up

The primary end point was the occurrence of MARCE during hospitalization. MARCE was defined as a composite end point comprising all-cause mortality, acute or worsening renal failure requiring new renal replacement therapy (dialysis), new or recurrent AMI, and stroke [7]. Follow-up started at admission and ended at discharge or at in-hospital death.

Feature Selection and Data Preprocessing

The initial dataset comprised 65 clinical variables. Among these, 59 features with missing data ≤10% were retained and imputed using the Multivariate Imputation by Chained Equations (MICE) package (version 3.13.0; Stef van Buuren and Karin Groothuis-Oudshoorn) in R software (version 4.1.0; R Foundation for Statistical Computing), with predictive mean matching [23]. To identify the most relevant predictors, least absolute shrinkage and selection operator (LASSO) regression with 10-fold cross-validation was applied based on the minimum binomial deviance criterion in the training set [24].

Given the wide numerical range across features and the requirement of certain ML algorithms for normalized inputs, min-max scaling was applied to continuous variables, and multicategory variables were processed using 1-hot encoding.

Model Development

Two model types were constructed: a nomogram and tree-based ML models. The discovery cohort was randomly divided into a training set (375/536, 70%) and a test set (161/536, 30%). To ensure robustness and minimize bias, 10-fold cross-validation was applied during model training [25]. Each fold was created via stratified sampling to maintain the outcome distribution. Feature selection and model tuning were performed only on the training data, and final model evaluation was conducted on the untouched test set. Specifically, LASSO feature selection was performed once on the entire training set before cross-validation. The selected predictors were then used for subsequent model training, hyperparameter tuning, internal cross-validation, hold-out test evaluation, and external validation. The hold-out test set and external validation cohort were not used during feature selection or hyperparameter tuning.

ML Algorithms and Interpretation

We used decision tree (DT), random forest (RF), and extreme gradient boosting (XGBoost) as representative tree-based algorithms. DT segments the feature space via hierarchical splits but is prone to overfitting and ignores feature interactions. RF combines multiple trees via bagging and random feature selection to improve accuracy and generalizability [26]. XGBoost enhances performance through regularized gradient boosting, parallel processing, and efficient feature handling [27].

Seven predictors identified by LASSO (Killip class, lactate, eGFR, cardiogenic shock, beta-blockers, ACEI/ARB/ARNI, and diuretics) were examined in multivariable modeling. Because Killip class IV is clinically defined as cardiogenic shock, these 2 variables represent substantial conceptual overlap. To improve clinical interpretability and reduce redundancy, we retained Killip class as the integrated severity indicator in the final parsimonious model and did not retain cardiogenic shock as a separate predictor after adjustment in the logistic regression (LR). Therefore, the final 6-variable predictor set should be considered a clinically refined model based on LASSO-selected predictors rather than a model derived exclusively through a fully data-driven feature-selection process.

We then trained XGBoost, RF, DT, and LR models using the same 6 clinically interpretable predictors. To interpret model predictions, SHAP values were used to quantify feature importance and to visualize both global and local contributions [28].

Nomogram Construction

A nomogram was developed using multivariable LR based on the 6 selected features. To facilitate clinical application, an online calculator was created for visualization and risk estimation.

Model Evaluation

All models were evaluated using 10-fold cross-validation on the training set and tested on the hold-out test set. The nomogram was further validated in the external cohort. Discrimination was assessed using the area under the receiver operating characteristic curve (AUC). Additional metrics included the Matthews correlation coefficient, precision (positive predictive value), negative predictive value, F_1-score, accuracy, sensitivity, and specificity. Because these classification metrics are threshold-dependent, they were interpreted together with receiver operating characteristic and calibration performance. Calibration was assessed using the Brier score and visualized using calibration curves with 400 bootstrap samples. Decision curve analysis (DCA) and clinical impact curves were used to assess clinical utility and net benefit. For classification metrics (accuracy, F_1-score, sensitivity, specificity, positive predictive value, and negative predictive value), a fixed probability classification threshold of 0.50 was used across all models, with MARCE as the positive class.

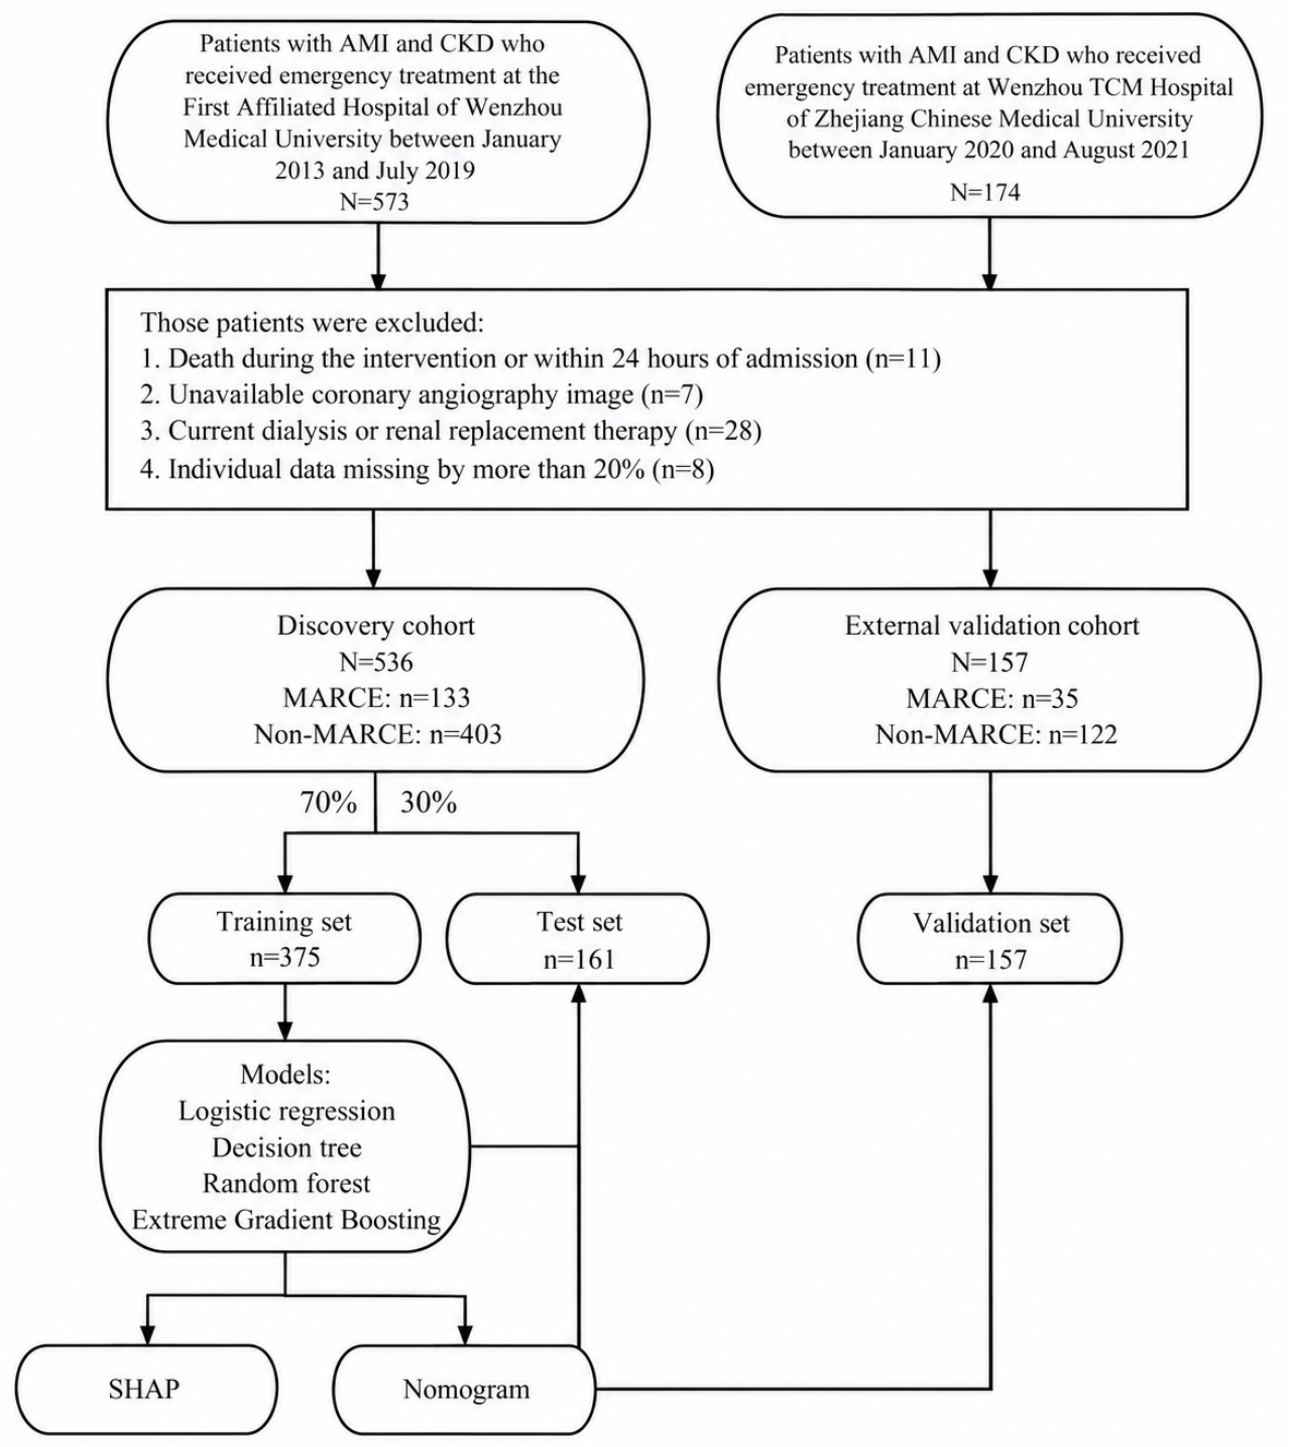
Two post hoc sensitivity analyses were conducted. First, the XGBoost model was refitted using conventional learning-rate values of 0.05 and 0.10 to assess whether model performance

XSL•FO
RenderX

was dependent on the extremely small automatically tuned learning rate. Second, XGBoost, RF, DT, and LR models were reconstructed using all 7 LASSO-selected predictors, including cardiogenic shock. All sensitivity analyses used the original training-test split, and final evaluation was performed in the untouched held-out test set.

Statistical Analysis

Continuous variables are described as means (SD) and categorical variables as frequencies and proportions. The clinical characteristics of patients were compared using the 2-tailed Student *t* test, Wilcoxon test, chi-square test, or Fisher exact probability method as appropriate. The evaluation indices of the ML models were compared using 1-way ANOVA with multiple comparisons of the least-significant difference. A 2-tailed *P* value <.05 was considered statistically significant. The statistical analyses were performed using R (version 4.1.0 [29]). AUC comparisons between models were additionally assessed using the DeLong test.



Results

Study Population

The study flowchart is shown in Figure 1. From January 2013 to July 2019, a total of 536 patients were enrolled in the discovery cohort. The mean (SD) of their age was 72.83 (10.31) years, and 372 (69.4%) of the participants were male. Of them, 18.1% (n=97) died in the hospital, 8.6% (n=46) had renal failure necessitating new renal replacement therapy, 3.2% (n=17) had a new or recurrent myocardial infarction (MI), and 1.7% (n=9) had a stroke. They were randomly assigned to a training set (n=375) or a test set (n=161). There were no significant differences in the patient characteristics of the 2 datasets (Table 1). The rates of MARCE were 24.8% (n=133) in the train and test sets. In both sets, differences in clinical characteristics between patients who had MARCE and those who did not are outlined in Table 2. Data from the validation set were obtained and analyzed on 157 patients collected from Wenzhou TCM Hospital of Zhejiang Chinese Medical University, including 35 (22.3%) cases of MARCE (Table S1 in Multimedia Appendix 1).

Figure 1. Formation of the discovery and validation cohorts and occurrence of major adverse renal and cardiovascular events in patients with acute myocardial infarction (AMI) and chronic kidney disease (CKD). MARCE: major adverse renal and cardiovascular events; SHAP: Shapley additive explanations; TCM: traditional Chinese medicine; XGBoost: extreme gradient boosting.

[a]Continuous variables are presented as mean (SD) for normally distributed variables or median (IQR) for nonnormally distributed variables, while categorical variables are presented as number (percentage).

[b]LM: left main disease.

[c]LAD: left anterior descending coronary.

[d]LCX: left circumflex artery.

[e]RCA: right coronary artery.

[f]ACEI: angiotensin-converting enzyme inhibitor.

[g]ARB: angiotensin II receptor blocker.

[h]ARNI: angiotensin receptor-neprilysin inhibitor.

[i]CK: creatine kinase.

[j]CK MB: creatine kinase myocardial band.

[k]BNP: brain natriuretic peptide.

[l]eGFR: estimated glomerular filtration rate.

[m]ALT: alanine aminotransferase.

[n]AST: aspartate aminotransferase.

[o]LDL-C: low-density lipoprotein cholesterol level.

[p]HDL-C: high-density lipoprotein cholesterol level.

[q]FBG: fasting blood glucose.

[r]CRP: C reactive protein.

[s]T3: triiodothyronine.

[t]FT3: free triiodothyronine.

[u]FT4: free thyroxine.

[v]TSH: thyroid stimulating hormone.

[w]WBC: white blood cell.

[x]LVEF: left ventricular ejection fraction.

[y]CAD: coronary heart disease.

[z]MARCE: major adverse renal and cardiovascular events.

[h]ARB: angiotensin II receptor blocker.

[i]ARNI: angiotensin receptor-neprilysin inhibitor.

[j]CK: creatine kinase.

[k]CK MB: creatine kinase myocardial band.

[l]BNP: brain natriuretic peptide.

[m]eGFR: estimated glomerular filtration rate.

[n]ALT: alanine aminotransferase.

[o]AST: aspartate aminotransferase.

[p]LDL-C: low-density lipoprotein cholesterol level.

[q]HDL-C: high-density lipoprotein cholesterol level.

[r]FBG: fasting blood glucose.

[s]CRP: C reactive protein.

[t]T3: triiodothyronine.

[u]FT3: free triiodothyronine.

[v]FT4: free thyroxine.

[w]TSH: thyroid stimulating hormone.

[x]WBC: white blood cell.

[y]LVEF: left ventricular ejection fraction.

[z]CAD: coronary heart disease.

Feature Selection

Among the 59 demographic details, comorbidities, laboratory results, echocardiography measurements, procedural details, and medication parameters, 7 significant predictors of MARCE were selected in the training set by the LASSO algorithm (Figure 2A and B): Killip class, lactate, eGFR, cardiogenic shock, beta-blockers, ACEI/ARB/ARNI, and diuretics. Given that Killip class IV clinically corresponds to cardiogenic shock, we retained Killip class as the broader, clinically interpretable severity variable and excluded cardiogenic shock from the final parsimonious nomogram to avoid redundant representation of overlapping information. The multivariable analysis of the 7 LASSO-selected predictors is presented in Table 3. After excluding cardiogenic shock due to clinical redundancy with Killip class, the final 6 predictors were used for model development.

Figure 2. Feature selection using the least absolute shrinkage and selection operator (LASSO) model. (A) Selection of the tuning parameter (λ) in the LASSO model via 10-fold cross-validation based on the 1-SE criterion. Binomial deviance from the LASSO cross-validation procedure was plotted as a function of log(λ). The y-axis indicates binomial deviance, and the x-axis indicates log(λ). Numbers along the upper x-axis represent the average number of predictors. Red dots indicate average deviance values for each model with a given λ, and vertical bars show upper and lower deviance values. The vertical black lines define the optimal values of λ. (B) LASSO coefficient profiles of clinical features. The dotted vertical line indicates the selected λ. Seven features with nonzero coefficients are shown.

[a]MARCE: major adverse renal and cardiovascular events.

[b]OR: odds ratio.

[c]Not applicable.

[d]ACEI: angiotensin-converting enzyme inhibitor.

[e]ARB: angiotensin II receptor blocker.

[f]ARNI: angiotensin receptor-neprilysin inhibitor.

[g]eGFR: estimated glomerular filtration rate.

ML Models

Six selected variables were included in the following ML models: XGBoost, RF, DT, and LR. Figure 3A and Table 4 illustrate model performance in the test set. XGBoost achieved an AUC of 0.882 (95% CI 0.816 - 0.947), LR 0.875 (95% CI 0.799 - 0.950), RF 0.870 (95% CI 0.800 - 0.940), and DT 0.814 (95% CI 0.720 - 0.886). Given the overlap in confidence intervals, these findings indicate comparable discrimination among XGBoost, LR, and RF rather than a definitive ranking

XSL•FO
RenderX

of model superiority. Ten-fold cross-validation results for AUC and accuracy in the training set are summarized in Table S2 in Multimedia Appendix 1. Calibration plots showed acceptable calibration for all models (Figure 3B, Table 4). Other evaluation indicators are summarized in Table 4. Confusion matrices for all 4 classifiers in the test set are shown in Table S3 in Multimedia Appendix 1. Pairwise AUC comparisons showed no statistically significant differences among XGBoost, LR, and RF (XGBoost vs LR: *P*=.89; XGBoost vs RF: *P*=.81; LR vs RF: *P*=.92). Comparisons against DT were also not significant (all *P*>.05; Table S4 in Multimedia Appendix 1).

Figure 3. Performance of machine learning models in the test set. (A) Comparison of area under the receiver operating characteristic curves among extreme gradient boosting (XGBoost), random forest, logistic regression, and decision tree models in the test set. (B) Calibration plots of XGBoost, random forest, logistic regression, and decision tree models in the test set. The Brier score is reported in the lower right legend (the smaller the value, the better the calibration). AUC: area under the receiver operating characteristic curve.

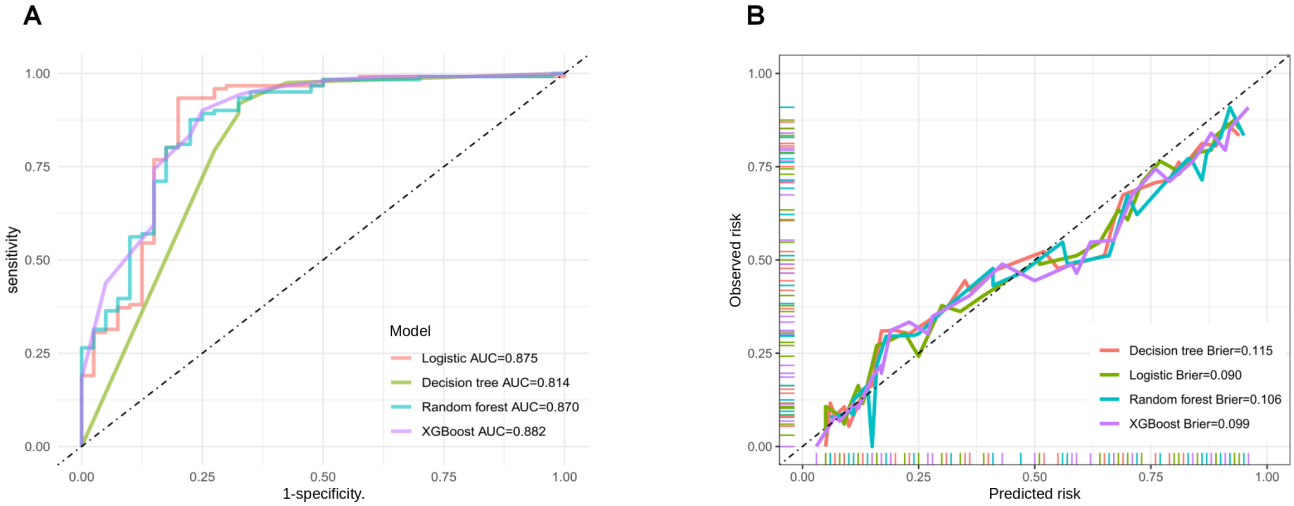

Table . Classifiers' predictive performance in the test set.[a]

Index	Logistic	XGBoost[b]	Random forest	Decision tree
AUC[c] (95% CI)	0.875 (0.799 - 0.950)	0.882 (0.816 - 0.947)	0.870 (0.800 - 0.940)	0.814 (0.720 - 0.886)
Brier score (95% CI)	0.090 (0.056 - 0.124)	0.099 (0.065 - 0.132)	0.106 (0.071 - 0.140)	0.115 (0.077 - 0.152)
Accuracy	0.888	0.807	0.857	0.863
MCC[d]	0.685	0.414	0.608	0.618
F_1-score	0.743	0.392	0.701	0.703
κ	0.673	0.319	0.608	0.615
PPV[e]	0.867	0.909	0.730	0.765
NPV[f]	0.893	0.800	0.895	0.890
Sensitivity	0.650	0.250	0.675	0.650
Specificity	0.967	0.992	0.917	0.934

[a]Classification metrics were calculated using major adverse renal and cardiovascular events (MARCE) as the positive class at a fixed threshold of 0.50.

[b]XGBoost: extreme gradient boosting.

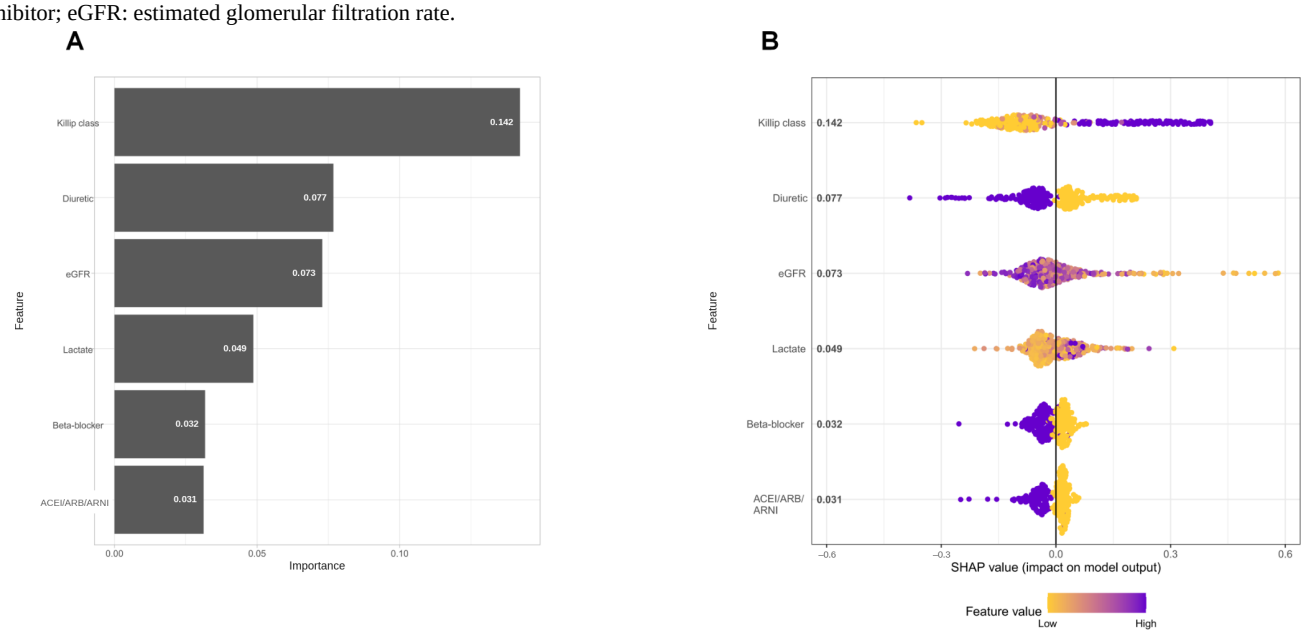
[c]AUC: area under the receiver operating characteristic curve.

[d]MCC: Matthews correlation coefficient.

[e]PPV: positive predictive value.

[f]NPV: negative predictive value.

Post hoc sensitivity analyses were performed to assess the robustness of the XGBoost model and the final predictor set. Refitting XGBoost with conventional learning-rate values of 0.05 and 0.10 yielded similar discrimination compared with the originally tuned model, with AUCs of 0.876 and 0.870, respectively, vs 0.882 for the original model (Multimedia Appendix 2). Additionally, models reconstructed using all 7 LASSO-selected predictors, including cardiogenic shock, showed comparable performance to the final 6-variable models. These findings suggest that the main results were not materially dependent on the extremely small tuned XGBoost learning rate or on the exclusion of cardiogenic shock (Tables S5 and S6 in Multimedia Appendix 1).



XSL•FO
RenderX

SHAP Values Through Visualization

Comparisons among the 4 ML-based models for MARCE prediction showed that XGBoost achieved the numerically highest AUC in the test set, although its performance was comparable to LR and RF rather than being definitively superior. The final hyperparameters for all classifiers are provided in Table S7 in Multimedia Appendix 1.

We used SHAP values to provide feature attribution values for each variable within the XGBoost model. Figure 4A describes the SHAP summary plot for the 6 input variables in the training set. The y-axis displays the 6 variables, ranked in order of importance by their mean absolute SHAP values. The x-axis indicates the SHAP values associated with each variable and patient, which allowed the determination of whether a feature had a negative effect on the prediction toward a non-MARCE class or a positive effect on the prediction toward a MARCE class (Figure 4B).

Figure 4. Shapley additive explanations (SHAP) summary plot of the extreme gradient boosting (XGBoost) model with selected features. (A) Average absolute impact of variables on the magnitude of the final model output, ordered by decreasing feature importance. (B) The plot depicts the dot estimates on the model output for the XGBoost model. Each dot represents an individual patient from the dataset. Purple represents higher SHAP values of specific features, whereas yellow represents lower SHAP values of specific features. Higher SHAP values indicate a greater risk of major adverse renal and cardiovascular events. ACEI: angiotensin-converting enzyme inhibitor; ARB: angiotensin receptor blocker; ARNI: angiotensin receptor-neprilysin inhibitor; eGFR: estimated glomerular filtration rate.

Beyond ranking feature importance, SHAP analysis provided a patient-level attribution of predicted MARCE risk. The Killip class had the largest mean absolute SHAP value, indicating that hemodynamic severity was the dominant contributor to the model output. Diuretic use, eGFR, and lactate also contributed substantially, suggesting that volume overload or heart failure treatment status, renal dysfunction, and metabolic stress jointly influenced MARCE risk prediction.

Establishment and External Validation of the Nomogram Model

The 6 selected predictors were incorporated to form a MARCE estimation nomogram (Figure 5). We compared the performance of the nomogram model with the GRACE score in the test set. The nomogram achieved an AUC of 0.875 (95% CI 0.800 - 0.934), whereas the GRACE score achieved 0.765 (95% CI 0.675 - 0.826) (Figure 6A and B). Both models showed acceptable calibration in the test set, with mean absolute error values of 0.047 and 0.045, respectively (Figure 6C and D). DCA suggested a potential net benefit of the nomogram across clinically relevant threshold ranges, rather than uniformly across all possible thresholds (Multimedia Appendix 3). In additional AUC comparison analysis, the nomogram showed higher discrimination than the GRACE score in this cohort (AUC difference=0.110, *P*=.03; Table S4 in Multimedia Appendix 1).

To further evaluate the nomogram, we analyzed an external validation cohort of 157 patients from Wenzhou TCM Hospital of Zhejiang Chinese Medical University. The nomogram displayed an AUC of 0.873 (95% CI 0.714 - 0.926; Multimedia Appendix 4). Calibration plots with 400 bootstrap resampling confirmed agreement between predicted and observed risk (mean absolute error=0.042; Multimedia Appendix 4). DCA and clinical impact curve suggested potential clinical utility in the validation cohort (Multimedia Appendix 4), and these findings should be interpreted with caution because of the limited external sample size.

To facilitate clinical use, we developed a web-based interface for estimating the probability of in-hospital MARCE (Multimedia Appendix 5) [30].

Discussion

Principal Findings

In the present study, we applied LASSO-based feature screening and developed a series of models for in-hospital MARCE prediction in patients with AMI and CKD. We identified 6 selected predictors and observed moderate-to-good discrimination across ML and LR models (test set: AUC 0.814, 95% CI 0.720-0.886; AUC 0.882, 95% CI 0.816-0.947). SHAP analysis provided interpretable global and individual feature contributions. We also developed a nomogram and externally validated it, with acceptable discrimination and calibration. Given the close performance among XGBoost, LR, and RF, our results support a balanced emphasis on both predictive performance and clinical interpretability.

Previous research on adverse event prediction models has mostly focused on patients with AMI and excluded patients with CKD, thus reducing performance when applied to patients with CKD [10,11]. Troponin protein, which has been identified as a risk factor for adverse outcomes and is involved in many risk scores, can be cleared by the kidneys, thus further leading to the reduced predictive efficacy of such models in the population with CKD [31-33]. In a small cohort of 113 patients, Fu et al [34] developed a risk score using patient demographic and laboratory data to predict in-hospital mortality in patients with AMI and end-stage renal disease. The risk score calibrated well and performed better than the traditional GRACE scores, but the study population was relatively small and limited to patients with end-stage renal disease, not the patients with CKD, who are more common in the clinical setting. Zhang et al [35] reported a predictive model for major adverse cardiovascular events prediction in patients with CKD undergoing percutaneous coronary intervention. They incorporated selected risk factors into a nomogram, while the discrimination needed to be improved (AUC=0.612). Current American College of Cardiology/AHA guidelines recommend MARCE as a novel clinical end point for patients with cardiovascular disease and CKD, for more accurate risk stratification and providing new pathophysiological insights. Thus, a predictive model aiming at the MARCE is warranted, especially for patients with AMI and CKD.

ML is an important supporting technology for AI that allows computers to learn, analyze, and construct models from input data, and then output predictions for new samples. Combined with electronic health record systems, ML could help doctors predict risk in cardiovascular disease, therefore aiding in clinical decision-making for patients. Khera et al [36] developed an XGBoost model, a neural network, and a meta-classifier model with patients from the American College of Cardiology Chest Pain-MI Registry and found that the XGBoost algorithm improved prediction performance for high-risk individuals. Advanced ML methods were also used to improve the prediction of cardiac risk based on radiomic profiling of coronary artery perivascular adipose tissue. However, the computationally heavy, long analysis times required with the model limited the application, and the model needed to better characterize the association of perivascular adipose tissue with the coronary atherosclerosis phenotype [37]. These studies indicated that ML is a reliable, novel method for clinical practice.

The SHAP analysis provided information complementary to traditional regression-based interpretation. Whereas LR and nomogram models summarize average population-level associations, SHAP decomposes each individual XGBoost prediction into feature-specific contributions. Thus, even with a small and clinically intuitive predictor set, SHAP may help clinicians identify whether a high predicted MARCE risk is mainly driven by hemodynamic severity, impaired renal function, elevated lactate, or medication-related factors. However, SHAP values should not be interpreted as causal effects, particularly for medication-related predictors such as diuretics, beta-blockers, and ACEI/ARB/ARNI, which may reflect confounding by indication, treatment eligibility, contraindications, or disease severity. Additionally, these medication-related predictors may partly capture physician decision-making and local treatment practice rather than baseline patient risk alone. Therefore, although they may improve risk prediction within the present dataset, their contribution should be interpreted cautiously when considering model transportability and implementation in health care systems with different treatment strategies.

In this study, we integrated ML workflows with MICE imputation, LASSO feature selection, cross-validation, hyperparameter tuning, and SHAP interpretation. These methods jointly supported the prediction of in-hospital MARCE in patients with AMI and CKD while retaining clinical interpretability.

Our study represents an application of established ML and nomogram modeling approaches to MARCE prediction in patients with AMI and CKD, rather than a fundamentally new modeling framework. Using 6 variables available early during hospitalization, clinicians may estimate MARCE risk and support early risk stratification. The nomogram showed higher discrimination than GRACE in this dataset; however, this comparison should be interpreted cautiously because both tools were evaluated in the same cohort, and the end point definitions differ from the original GRACE development setting. Therefore, the primary value of this study lies in its focus on a clinically high-risk cardiorenal population, the use of MARCE as a composite end point, and the integration of model interpretability with a parsimonious clinical prediction tool.

Although LASSO initially identified 7 predictors, the final 6-variable model was refined by excluding cardiogenic shock because of its clinical overlap with Killip class IV. This decision reflects a trade-off between statistical optimization and clinical interpretability. A fully data-driven model may retain all statistically selected variables, but redundant predictors can reduce model parsimony and complicate clinical interpretation. Therefore, we prioritized a parsimonious predictor set that preserved the main prognostic information while improving interpretability and usability in clinical settings. The sensitivity analysis using all 7 LASSO-selected predictors showed comparable performance, suggesting that this clinical refinement did not materially affect the main findings. Additionally, the extremely small learning rate selected during automated

XSL•FO
RenderX

XGBoost tuning may represent a boundary solution of the optimization process rather than a biologically or clinically meaningful optimum. Although sensitivity analyses using conventional learning rates of 0.05 and 0.10 yielded similar AUC values, this finding highlights a limitation of automated hyperparameter optimization in relatively small clinical datasets and should be interpreted with caution.

Several limitations should be considered. First, despite external validation, the study sample was regionally limited, and the external cohort was modest in size. The external cohort included 157 patients and 35 MARCE events, which may affect the precision and stability of validation estimates, particularly for more complex ML models. Therefore, the external validation should be regarded as preliminary rather than definitive confirmation of model generalizability. Further multicenter studies with larger sample sizes are required to confirm model transportability, calibration stability, and clinical utility across different health care settings. Second, the study modeled the composite MARCE end point rather than individual end point components. Some components, such as recurrent MI and stroke, occurred infrequently, limiting stable component-specific prediction. Third, patients who died within 24 hours were excluded because complete predictor information within the predefined 24-hour assessment window was often unavailable, which may introduce survivorship bias and limit generalizability to the most critically ill patients. Fourth, because LASSO feature selection was performed once on the entire training set before cross-validation rather than nested within each resampling fold, cross-validation estimates in the training set may still be slightly optimistic. However, final model performance was evaluated in an untouched hold-out test set and an independent external validation cohort. Fifth, this retrospective study had moderate class imbalance, with a MARCE rate of approximately 25%. We did not apply oversampling, undersampling, or class weighting in the primary analysis to preserve the observed event prevalence and calibration of predicted risk. Therefore, threshold-dependent metrics should be interpreted cautiously. Finally, this study focused on in-hospital MARCE only; longer-term outcomes after discharge require future investigation.

Conclusions

In this study, based on 6 important predictors, we developed 3 tree-based ML models and a nomogram for in-hospital MARCE risk prediction in patients with AMI and CKD. The models demonstrated clinically meaningful discrimination and may support early risk stratification, pending further multicenter prospective validation.

Abstract

Background: The World Health Organization advises that every nation should take responsibility for guaranteeing access to health care services as a basic human right. However, due to financial constraints and geographical hurdles, only around half of the population in Africa has access to contemporary health care services.

Objective: This study aimed to predict barriers to health services and associated factors among reproductive-aged women in East Africa using machine learning algorithms and identify the best-performing predictive model.

Methods: Analysis of secondary data from 6 East African countries using the Demographic and Health Surveys from 2016 to the recent 2023 was performed. A weighted total sample of 228,654 women of reproductive age was included in this study. Data were extracted and processed with Stata version 17. The dataset was then imported into a Jupyter notebook for further detailed analysis and visualization. A machine learning algorithm using different classification models was implemented. All analyses and calculations were performed in the Python 3 programming language in Jupyter Notebook using imblearn, scikit-learn, and Extreme Gradient Boosting (XGBoost) packages.

Results: Among 228,654 reproductive-age women included in the study, the XGBoost classifier demonstrated the best predictive performance, with 94.46% accuracy, 94.62% precision, 93.73% recall, 94.17% F_1-score, and 98% area under the curve. Overall, 92.63% (211,794/228,654) of women experienced barriers to health care access. Predictors of barriers to health access were identified using an XGBoost model with the help of Shapley Additive Explanations. This study showed that maternal occupation, maternal age, low media exposure, parity, marital status, health insurance, and community literacy were the top predicting factors of barriers to health access.

Conclusions: The XGBoost model demonstrated the best predictive performance among the evaluated algorithms. The findings indicate that a substantial proportion of reproductive-age women experience barriers to health care access, although no formal subnational “extreme risk” classification was conducted in this study. Enhancing comprehensive health education and reducing financial barriers through the expansion of health insurance coverage may help improve health care access, particularly among vulnerable populations such as rural women.

Introduction

Access to health care services is a basic human right, and obstacles to obtaining these services can negatively impact an individual’s physical and mental well-being, as well as their overall quality of life [1]. Individuals’ health, along with their physical, emotional, and social well-being, is influenced by their availability of health care [2]. Unfortunately, access to health care services remains a widespread challenge in low- and middle-income countries [3].

XSL•FO
RenderX

Globally, an estimated 400 million people lack access to essential health care services, and approximately 8 million deaths each year are due to conditions that are preventable or treatable with timely and adequate medical care [4]. Due mainly to financial constraints and geographical hurdles, only around half of the population in Africa has access to contemporary health care services [5]. Women have limited access to health care due to many issues, including the need for spousal consent, financial constraints, and the distance to medical facilities [4].

Less than half of mothers in East Africa receive support from trained birth attendants, and the region's overall maternal health metrics continue to perform poorly [6]. Reducing maternal death and morbidity requires increasing access to and use of basic health care services. However, maternal health services coverage is low in sub-Saharan Africa (SSA) due to women's barriers to health care access and use of essential health services. The health and survival of mothers and their infants are adversely affected by inadequate use of the vital continuum of care [7]. In Ethiopia, significant barriers to health care access persist, especially in rural communities. In order to address these issues, the government has increased access to primary health care services by building health centers and health posts quickly and by deploying and educating primary and midlevel health care workers [8].

To enhance maternal health outcomes, several regional and international efforts have been implemented, including the Sustainable Development Goals and the Millennium Development Goals [9]. Despite significant efforts made both internationally and at the local level, the health status of mothers has not improved to the anticipated extent. However, disparities in regions and socioeconomic discrepancies continue to exist in health care access, particularly for those living in rural areas. Health care accessibility is known to be influenced by a wide range of factors, such as patient acceptance of treatments [10], physician preferences [11], place of residence [12], religious beliefs, and the empowerment of women [13].

The European Commission (2014) Communication states that several factors, such as population coverage, affordability, the variety of services provided, and the accessibility of care (such as waiting times and distance), characterize access to health services [14]. These elements are deeply interconnected. Meanwhile, the Demographic and Health Survey (DHS) statistics guide assesses reproductive-age women's access to health care by posing several questions about the main obstacles they might encounter when seeking medical attention while ill, including financial hardship, obtaining authorization to seek treatment, the distance to medical facilities, and the capacity to travel alone [15].

Previous studies examining barriers to health care access have primarily relied on conventional statistical approaches such as logistic regression and multilevel modeling. Although these methods are valuable for identifying associations between variables, they often depend on predefined assumptions, linear relationships, and hypothesis-driven model structures. Such approaches may have limited capacity to detect complex nonlinear interactions, hidden patterns, and high-dimensional relationships within large population datasets. Therefore, this study used multiple machine learning (ML) algorithms to predict barriers to health care access and identify the most effective predictive model [16]. Various classification techniques were evaluated and compared, and Shapley Additive Explanations (SHAP)–based explainability was used to improve model interpretability and identify the most influential predictors [17]. ML has dominated many fields in recent years due to its capacity to identify hidden patterns in data, enabling the constructive extrapolation of such patterns to previously unobserved fresh data [18,19].

Several ML classifiers, including logistic regression, random forest, decision tree, k-nearest neighbor (KNN), support vector machine (SVM), artificial neural network (ANN), categorical boosting (CatBoost), Light Gradient Boosting Machine (LightGBM), Extreme Gradient Boosting (XGBoost; XGBoost developers, open-source software), and a stacking ensemble model, were evaluated [20]. Comparative model assessment was conducted using cross-validation and independent test-set performance metrics. A key innovation of this approach is the integration of SHAP, which enhances model interpretability by quantifying the contribution of individual predictors to model outputs. This interpretable ML framework provides transparent insights into the key determinants of health care access barriers while maintaining strong predictive performance.

Methods

Data Source and Study Population

The DHS used a population-based cross-sectional survey design to collect data, and this study used a predictive modeling approach. Secondary data from DHS datasets from 2016 to the recent 2023 were considered for this analysis. This study followed Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis-AI reporting guidelines for prediction model development and reporting [21]. Eastern Africa is the eastern subregion of the African continent in the United Nations Statistics Division scheme of geographic regions. Six East African countries, namely Burundi, Ethiopia, Madagascar, Uganda, Rwanda, and Zambia, were included in this study.

Following authorization through an online request that explains the goal of our study, the data can be accessed from the DHS program's official database [22]. All of the included factors were derived from the dataset of women's individual records. Every 5 years, a nationally representative DHS data collection is carried out in low- and middle-income countries [23]. Maternal health-related reproductive concerns are the primary focus of the data. In essence, a stratified sampling procedure with 2 stages was used. For the analysis, a total of 228,654 women of reproductive age were weighted.

Ethical Considerations

Since the study was a secondary data analysis, participant consent was not necessary. Following submission of the consent paper to the DHS program, the International Review Board of the DHS program data archivists waived informed consent, and a letter of permission was granted to download the dataset for this study. The International Review Board–approved procedures

XSL•FO
RenderX

for DHS public-use datasets do not allow respondents, households, or sample communities to be identified. There are no names of individuals or household addresses in the data files.

Study Variables

Dependent Variable

In this study, the dependent variable was barriers to health care access. Four questions that addressed the difficulties women could face when seeking medical attention were used to measure this variable. These difficulties included an inability to pay for treatment, a long commute to a medical center, a lack of authorization to seek care, and a lack of a companion. Women were classified as experiencing barriers to health care access if they reported at least one of these issues. Individuals who reported none of these issues were coded as 0 and deemed to have no barriers [24].

Independent Variables

Various independent variables were examined in this study to identify factors associated with barriers to health care access. These included health insurance, respondent age, respondent education, marital status, wealth status, parity, husband education, respondent occupation, husband occupation, community literacy, residency, household head, and media exposure (Table 1).

Table . List of variables for the assessment of barriers to health care access among reproductive-age women in East Africa.

Variable	Categories and definitions
Place of residence	Urban and rural
Mother's education	No formal education, primary education, secondary, and above
Mother's age (y)	15 - 24, 25 - 34, and 35 - 49
Husband's education	No formal education, primary education, secondary, and above
Mother's occupation	Not working and working
Sex of household head	Male and female
Marital status	Married and not married
Community literacy	Low, medium, and high. Derived by aggregating women's education levels in each cluster
Health insurance	Yes and no
Media exposure	Exposed (access to newspaper, radio, or TV) and unexposed
Attitude toward wife beating	Accept (justifies in at least one condition) and reject
Distance to health facility	Big problem and not a big problem (based on respondent's perception)
Parity (children)	No parity (0), multiparity (1 - 4), and grand multiparity (5 or more)

Data Management and Analysis

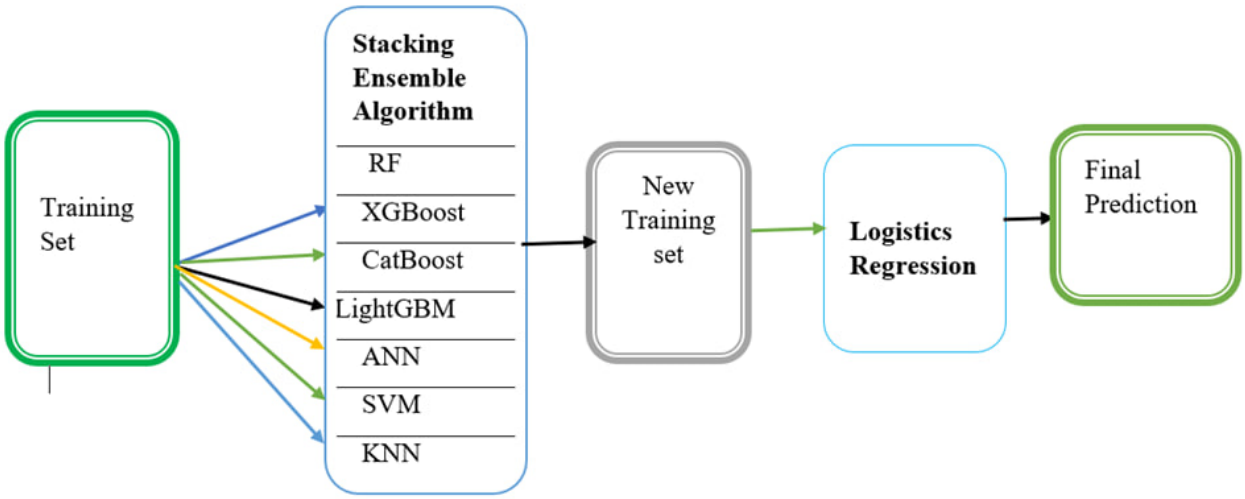
Stata (version 17; StataCorp LLC) was used for the initial data extraction, while Jupyter Notebook was used for further processing. Sampling weights were retained from the original DHS observations and incorporated into model training using the sample_weight parameter after applying Synthetic Minority Oversampling Technique (SMOTE)–Tomek only to the training data within each fold. To preserve data integrity, the dataset was thoroughly cleaned, including missing entry imputation. In order to avoid skewing the results, extreme values were identified and eliminated. Python 3 was used for all further calculations and modeling in Jupyter Notebook, using the imblearn [25], scikit-learn (scikit-learn developers, open-source software) [26], XGBoost [27], and SHAP [28] packages. All models and analytic procedures were executed in Jupyter Notebook using Python 3.10.11. Because this study used predictive ML methods rather than inferential statistical modeling, traditional hypothesis testing and *P* values were not applicable and therefore were not reported.

To prepare the data for modeling, preprocessing included feature selection to reduce noise and redundancy, and standard scaling to normalize feature contributions. Class imbalance was addressed using SMOTE-Tomek, applied strictly within the training folds to prevent data leakage, together with class weighting to further handle minority classes. All preprocessing steps were implemented within a unified pipeline to ensure transformations were learned only from the training data, preserving the validity of model evaluation [29].

The dataset was then split into training and testing sets using an 80:20 ratio to facilitate model training and evaluation. To further ensure the robustness of the model, k-fold cross-validation was used, allowing the dataset to be divided into k subsets [30]. In each iteration, a different subset served as the validation set, while the remaining subsets were used for training. Group-aware cross-validation was performed using primary sampling units as grouping variables to ensure that observations from the same cluster were not shared between training and test folds, thereby reducing potential information leakage due to intracluster correlation. The evaluation metrics obtained from each fold were averaged to assess the model's generalization performance. This validation process helps detect overfitting and ensures the model's reliability when applied to unseen data [31].

XSL•FO
RenderX

Data Splitting and Resampling



Training-Test Split and SMOTE-Tomek Resampling

The dataset was first divided into training (182,923/228,654, 80%) and testing (45,731/228,654, 20%) subsets before any resampling procedures were performed. The independent test dataset remained completely untouched and was used only for final model evaluation. To address class imbalance, SMOTE-Tomek resampling was applied exclusively to the training data within each cross-validation fold. Synthetic observations generated during resampling were used solely for model training and were not assigned DHS survey weights because they did not represent actual survey respondents. Survey weights were retained only for analyses requiring population-representative estimates.

ML Model Development and Comparison

ML models were developed and compared to identify the most accurate classifier for predicting barriers to health care access. The evaluated algorithms included logistic regression, random forest, decision tree, KNN, SVM, ANN, CatBoost, LightGBM, XGBoost, and a stacking ensemble model. Model performance was assessed using accuracy, precision, recall, F_1-score, and area under the receiver operating characteristic curve (AUC-ROC). The stacking model was included as a benchmark ensemble approach, whereas XGBoost was selected as the final predictive model because it demonstrated the highest overall performance on the independent test dataset (Figure 1).

Figure 1. Machine algorithm workflow. ANN: artificial neural network; CatBoost: categorical boosting; KNN: k-nearest neighbor; LightGBM: Light Gradient Boosting Machine; RF: random forest; SVM: support vector machine; XGBoost: Extreme Gradient Boosting.

Evaluation Metrics

The dataset used for this analysis falls under binary classification, as the target variable, barriers to health access, was divided into 2 mutually exclusive categories. To build predictive models, different classification algorithms were applied: logistic regression, random forest, KNN, LightGBM, ANN, SVM, CatBoost, XGBoost, and decision tree [32]. About country-specific performance trends, these algorithms were chosen for their efficacy in previous research that used ML techniques on DHS data for categorization tasks (Table 2).

Table . Confusion matrix and multiple derived metrics adapted from [33].

Actual	Predictive positive	Predictive negative
Positive	True positive (TP)	False negative (FN)
Negative	False positive (FP)	True negative (TN)

Based on the confusion matrix above, the following metrics were derived: sensitivity (recall), specificity, accuracy, and precision.

$$\text{Recall(sensitivity)} = TP/(TP+FN)$$

$$\text{Specificity} = TN/(TN+FP)$$

$$\text{Precision} = TP/(TP+FP)$$

$$\text{F1-score} = 2\times(\text{Precision}\times\text{Recall})/(\text{Precision}+\text{Recall})$$

$$\text{Accuracy} = (TP+TN)/(TP+TN+FP+FN)$$

Recall ensures that the majority of minority class instances are correctly identified, minimizing false negatives (FNs). However, the tradeoff is that a high-recall model may have lower precision, resulting in more false positives (FPs). Precision reflects the proportion of predicted positives that are truly correct. High precision is crucial when FPs carry serious consequences. The tradeoff is that maximizing precision can reduce recall, as the model becomes more cautious in labeling positives. The F_1-score balances precision and recall by calculating their harmonic mean, making it useful when both FPs and FNs are equally important [34]. However, the tradeoff is that the F_1-score can obscure imbalances if one metric is much higher than the other. Accuracy measures overall prediction correctness but can be deceptive in imbalanced datasets. The tradeoff is that accuracy

XSL•FO
RenderX

does not distinguish between errors in the majority and minority classes.

To evaluate predictive performance, we used a confusion matrix to analyze classification results through true positives (TPs), FPs, and FNs. To improve the interpretability of the final predictive model, SHAP were applied to the XGBoost classifier. SHAP values were used to quantify the contribution of each predictor to model predictions and to identify the most influential factors associated with health care access barriers [35]. Additionally, model performance was compared using the AUC-ROC, which graphically represents the trade-off between TP rates and FPs across classification thresholds. The confusion matrix implementation followed established methodology [36], while SHAP and AUC-ROC provided complementary insights into feature contributions and overall classification performance.

Recall reduces FNs by ensuring that the majority of cases in the minority class are identified. A model with high recall may trade off precision for a higher number of FPs. Precision is the percentage of predicted positives that turn out to be accurate. When FPs have significant effects, high precision is crucial. Tradeoff: because the model becomes more cautious when making positive predictions, maximizing precision may result in a decrease in recall. The F_1-score balances the trade-off between precision and recall by taking the harmonic mean of the two. Useful when both FPs and FNs are equally critical. Tradeoff: the F_1-score can mask imbalances if one metric is significantly higher than the other. Accuracy measures the overall correctness of predictions but can be misleading in imbalanced datasets. Tradeoff: accuracy does not differentiate between errors in the majority and minority classes.

Association Rule Mining

Using association rule mining (ARM), nontrivial and perhaps hidden patterns among the independent variables linked to health care access barriers for women of reproductive age were found [37]. Instead of focusing on the direction and strength of individual predictors as typical regression models do, ARM finds combinations of characteristics (rules) that often occur together and are highly related to a particular outcome, in this case, reported barriers to health care access. The Apriori algorithm was used to apply the ARM approach, with support, confidence, and lift levels predetermined. A rule's strength over chance is indicated by lift, its frequency in the dataset is measured by support, and its probability of occurring given the antecedent is reflected by confidence.

Results

Sociodemographic Characteristics

A total of 228,654 reproductive-age women were included in the study. Of these, 162,872 (71.23%) were from rural areas. Nearly half of the participants, 94,980 (41.54%), were aged 15 to 24 years. Regarding educational status, 100,924 (44.14%) women had primary education, whereas 62,173 (27.19%) had no formal education (Table 3).

XSL•FO
RenderX

Table . Sociodemographic characteristics of barriers to health care access among women in East Africa (N=228,654).

Index and variable	Weighted frequency, n (%)
1. Place of residence	
Urban	65,782 (28.77)
Rural	162,872 (71.23)
2. Mother's education	
No formal education	55,890 (24.44)
Primary education	100,924 (44.14)
Secondary and above	71,840 (31.42)
3. Mother's age (years)	
15 - 24	94,980 (41.54)
25 - 34	69,542 (30.41)
35 - 49	64,132 (28.05)
4. Husband's education[a]	
No formal education	38,958 (17.04)
Primary education	101,845 (44.54)
Secondary and above	72,345 (31.64)
5. Mother's occupation	
Not working	73,938 (32.34)
Working	154,716 (67.66)
6. Sex of household head	
Male	161,616 (70.68)
Female	67,038 (29.32)
7. Marital status	
Married	108,350 (47.39)
Not married	120,304 (52.61)
8. Community literacy	
Low	107,266 (46.91)
Medium	1616 (0.71)
High	119,772 (52.38)
9. Health insurance	
No	201,566 (88.15)
Yes	27,088 (11.85)
10. Media exposure	
Unexposed	87,142 (38.11)
Exposed	141,512 (61.73)
11. Wife beating	
Accept	74,644 (32.64)
Reject	154,010 (67.36)
12. Wealth status	
Poor	87,346 (38.20)
Middle	39,196 (17.14)
Rich	102,112 (44.66)

XSL•FO
RenderX

[a]The data on husband's education was available for 213,148 respondents; 15,506 respondents had missing or unavailable information and were therefore excluded from this variable.

Socioeconomic Characteristics

According to the participants' wealth index distribution, nearly half (102,112/228,654, 44.66%) were categorized as high-income, 38.20% (87,346/228,654) as low-income, and only 17.14% (39,196/228,654) as middle-income. The large percentage of participants with low and middle incomes draws attention to possible obstacles in obtaining health care and other essential services due to financial limitations. Regarding media exposure, 141,152 out of 228,654 (61.73%) participants were exposed to media sources such as television, radio, or newspapers, whereas 87,142 (38.11%) participants had no media exposure (Table 3).

ML Analysis of the Barrier to Health Access

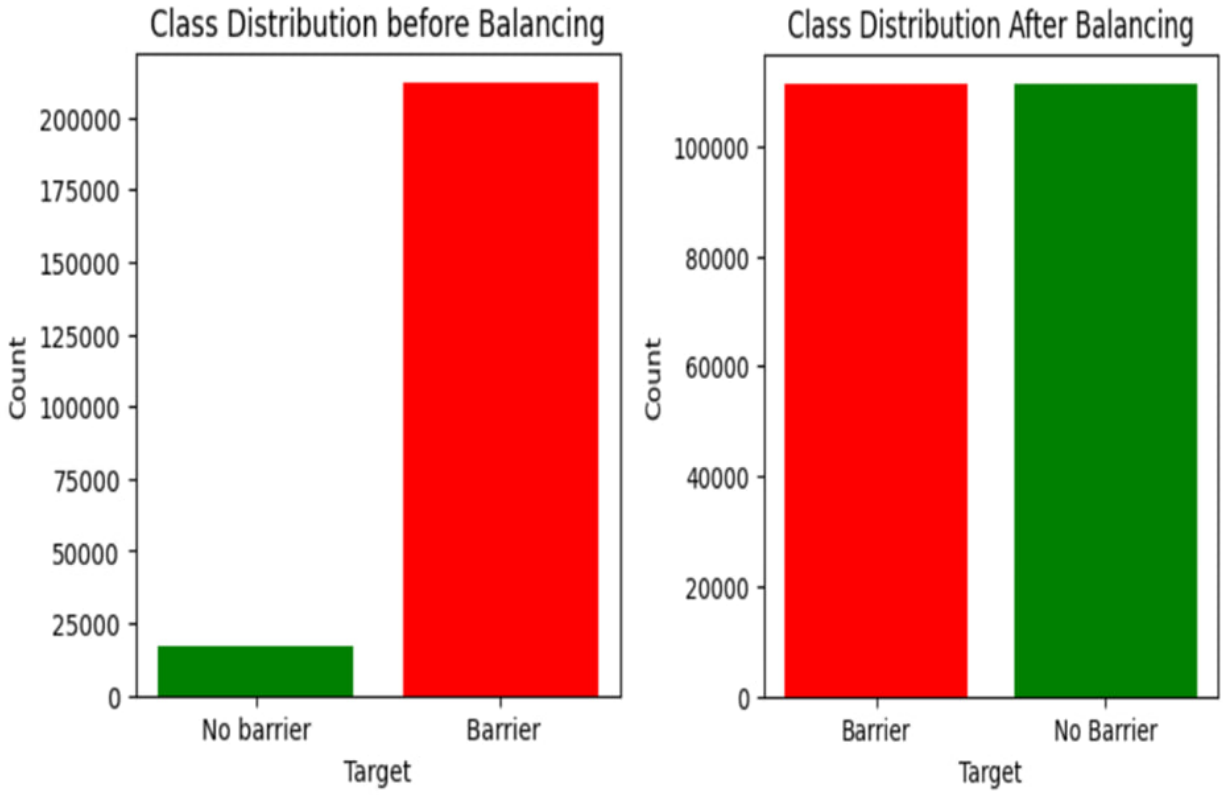
Multiple feature selection methods were applied, including Boruta, recursive feature elimination, mutual information, and variance threshold, to evaluate their impact on model performance. A baseline model was used for comparison. To avoid data leakage, feature selection was performed within a nested cross-validation framework, where selection was applied only to the training folds and evaluated on the corresponding test folds. The exact feature lists are provided in Figure S1 in Multimedia Appendix 1. Substantial overlap was observed among the methods, indicating consistent identification of key predictors.

Health-Related Service Characteristics

Of the 228,654 total sample, only 27,088 (11.85%) mothers had health insurance coverage. About 53,730 (23.50%) of women have a big problem with the distance to health facilities (Table 4). Around 93% (n=211,802) of reproductive-age women reported at least 1 barrier in East Africa.

Table . Health-related service characteristics of women in East Africa (N=228,654).

Index and variable	Weighted frequency, n (%)
1. Health Insurance	
Yes	27,088 (11.85)
No	201,566 (88.15)
2. Distance to health facility	
Big problem	53,730 (23.50)
Not big problem	174,924 (76.50)
3. Parity	
No	70,252 (30.72)
Multi	104,452 (45.68)
Grand multiparity	53,950 (23.59)



Balancing and Unbalancing

Handling class imbalance was an essential step in this study to improve the predictive performance of ML algorithms. The survey-weighted DHS dataset consisted of 228,654 observations, of which 211,794 (92.63%) were classified as experiencing at least one barrier to health care access and 16,860 (7.37%) were classified as having no barriers before any data-balancing procedures. This substantial class imbalance had the potential to bias model predictions toward the majority class.

To address this issue, the dataset was first divided into training (182,923/228,654, 80.0%) and testing (45,731/228,654, 20.0%) subsets. The independent test set remained untouched throughout model development and evaluation. To mitigate class imbalance during model training, resampling techniques, including undersampling of the majority class and oversampling of the minority class, were applied as appropriate. Additionally, the SMOTE was applied only to the training dataset to generate synthetic minority-class observations. This process improved class balance in the training data, reduced model bias toward the majority class, and enhanced classification performance while preventing information leakage (Figure 2).

RenderX

Figure 2. Resampling target variable barrier to health care access.

Model Development and Evaluation

After the data was cleaned and balanced, we divided it into 2 sets: 80.0% (182,923/228,654) for training and 20.0% (45,731/228,654) for testing. In order to forecast barriers to health access, we developed and compared multiple ML classification models. Among the evaluated algorithms, XGBoost demonstrated the highest predictive performance and was selected as the final model. We balanced each model and then examined each to determine which one performed the best. Table 5 demonstrates that predictive performance was much enhanced by balancing the target variable. With an accuracy of 94.46%, precision of 94.62%, recall of 93.73%, and F_1-score of 94.17%, the XGBoost model was superior when using the SMOTE approach.

RenderX

Table . Model performance comparison.

Algorithm	Accuracy (%)	Precision (%)	Recall (%)	F_1-score (%)
XGBoost[a]	94.46	94.62	93.73	94.17
Random forest	94.10	94.52	93.63	94.13
Logistic model	88.41	88.44	88.37	88.41
LightGBM[b]	40.00	27.78	50.00	35.71
CatBoost[c]	93.81	94.52	93.03	93.77
ANN[d]	85.00	82.00	88.00	85.00
SVC[e]	36.67	23.53	40.00	29.63
KNN[f]	90.72	92.05	89.13	90.57
Decision tree	93.39	95.03	91.57	93.27
Stacking	93.01	94.86	93.71	93.21

[a]XGBoost: Extreme Gradient Boosting.

[b]LightGBM: Light Gradient Boosting Machine.

[c]CatBoost: categorical boosting.

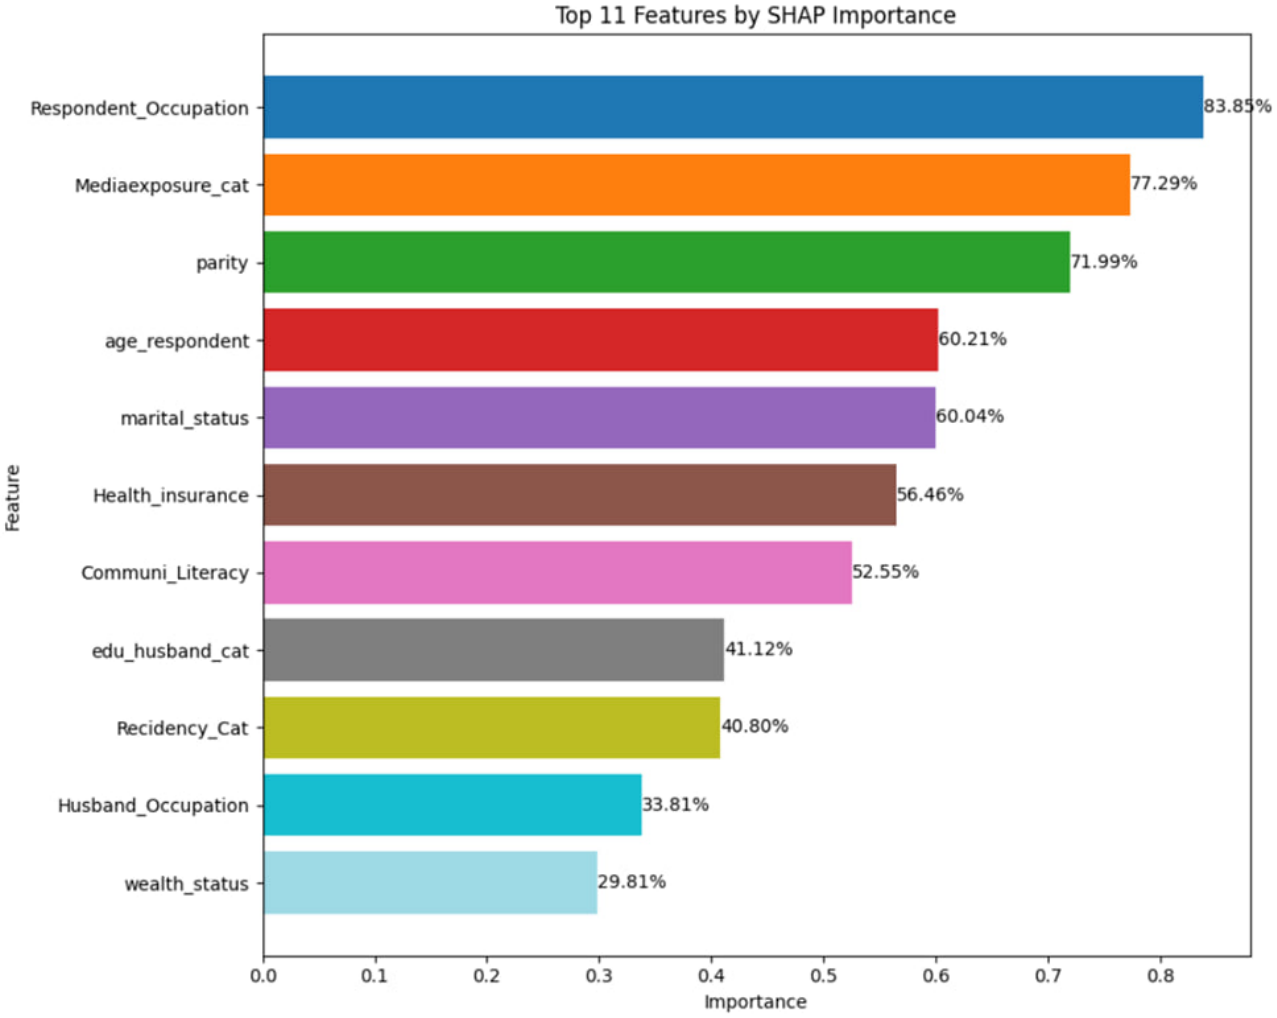
[d]ANN: artificial neural network.

[e]SVC: support vector classifier.

[f]KNN: k-nearest neighbor.

Of the individual base models incorporated into the stacking framework, XGBoost exhibited the highest independent predictive performance. We incorporated XGBoost into a stacking ensemble with other models like random forest, CatBoost, ANN, SVM, and KNN, instead of depending on it alone. The final prediction was generated by a logistic regression meta-model that took the predictions from all base models as inputs. This stacking method used the advantages of XGBoost and enhanced overall performance through the combination of complementary patterns identified by the various learners.

Visualization of Feature Importance



Traditional statistical approaches use predetermined criteria, such as *P* value thresholds, to identify important variables and adhere to set analytical frameworks. ML models, on the other hand, find patterns in data immediately and dynamically. Although ML algorithms are frequently criticized for being difficult to understand (considered black-box systems), new developments like the SHAP framework [38] offer a methodical approach to explaining their predictions.

In our study, we used SHAP to interpret our ML model and uncover the key drivers of health care access barriers. Feature importance was assessed based on mean SHAP values (Figure 3), where longer horizontal bars represent stronger predictive influence. The results highlighted several critical factors: mother's occupation, media exposure, maternal age, parity, community literacy, health insurance, and marital status all significantly contributed to the barriers to health access in reproductive-age women.

The ranked relevance of each feature in the predictive model is shown on the vertical axis (y-axis) in Figure 4, and the corresponding SHAP values, a standardized metric measuring the influence of each variable, are shown on the horizontal axis (x-axis). Each feature's row has colored dots that show the relative contributions of various values to the result: blue denotes low-risk values that lower the predicted risk, while red denotes high-risk values that raise it. The remaining factors had minimal or no impact on incomplete immunization status.

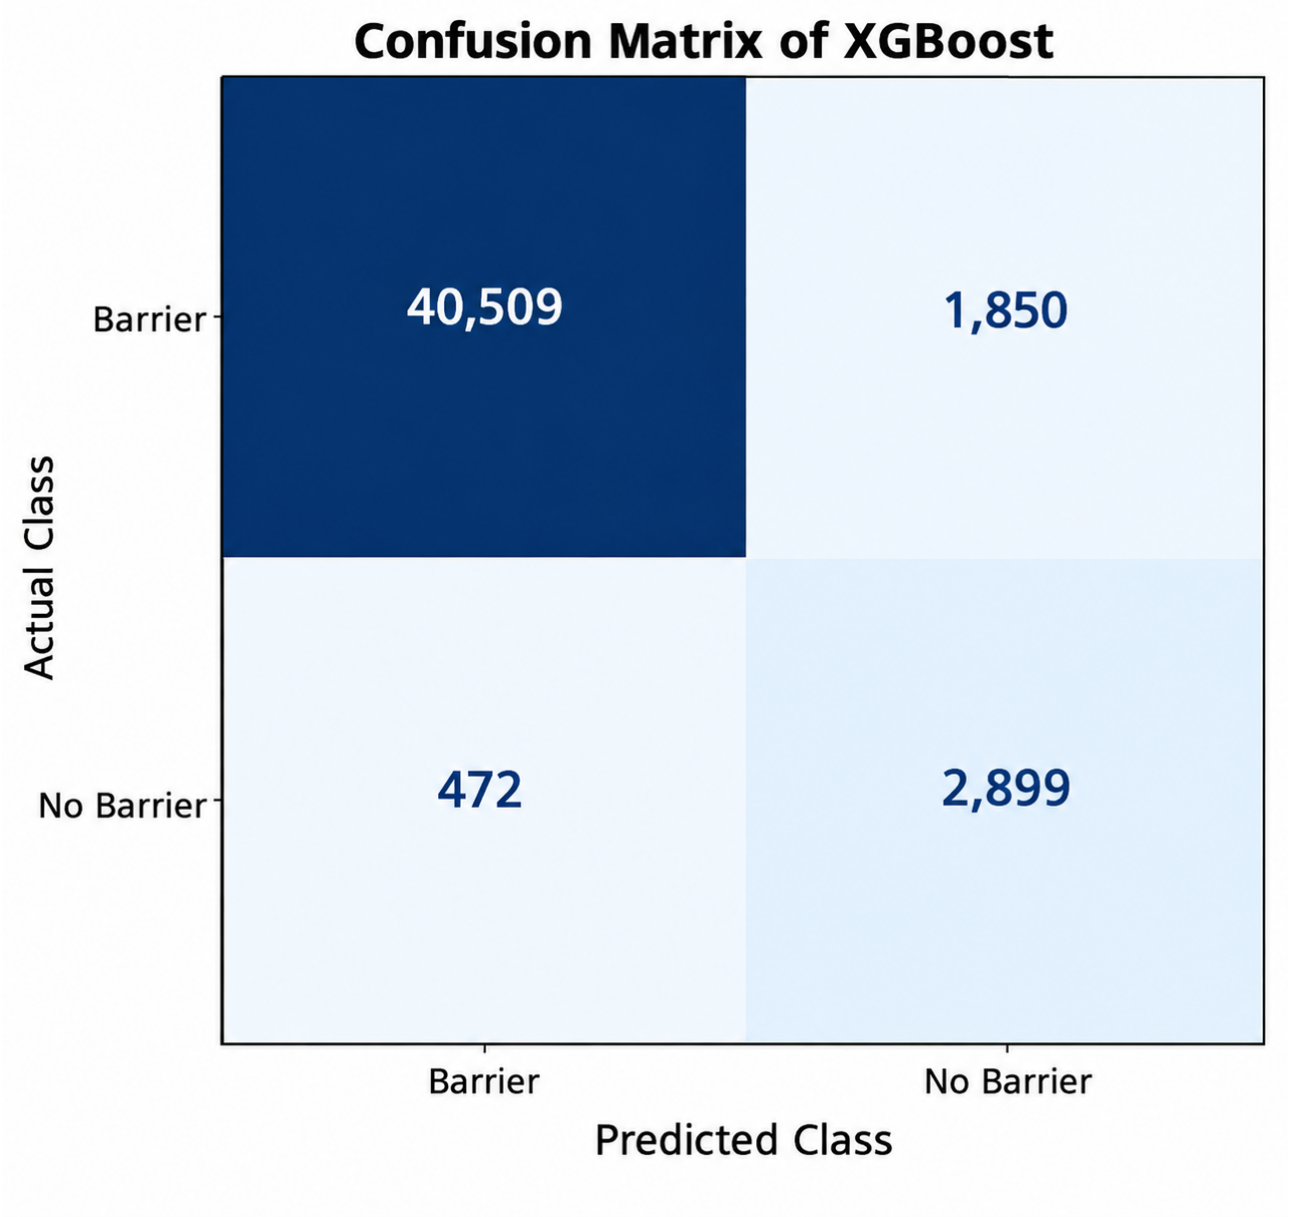
Figure 3. Top 11 features influencing barriers to health care access. SHAP: Shapley Additive Explanations

XSL•FO
RenderX

Figure 4. Shapley Additive Explanations (SHAP) summary plot. The x-axis shows SHAP values, where positive values increase the predicted probability of the outcome and negative values decrease it. Each dot represents 1 observation. Color indicates the feature value (blue=low and red=high). Dot dispersion shows the effect direction and magnitude across observations. Features are ranked by the mean absolute SHAP value (top=most influential).



Predicting Barriers to Health Access

An independent test dataset comprising 45,730 observations was used to evaluate the performance of the XGBoost model. As shown in Figure 5, the model correctly classified 40,509 TPs and 2899 true negatives. In contrast, 1850 cases were FNs and 472 cases were FPs. Overall, the XGBoost model demonstrated strong predictive performance in identifying barriers to health care access among reproductive-age women in East Africa.

The AUC-ROC (Figure 6) was used to evaluate model performance across all thresholds, thereby accounting for varying misclassification error weightings. The XGBoost model, after applying data balancing and hyperparameter optimization, the model's performance improved significantly, yielding an AUC-ROC of 98% on the test data, indicating strong predictive capability.

Figure 6. Area under the curve (AUC) of the Extreme Gradient Boosting (XGBoost) model on the test data.

ARM

ARM was applied as an exploratory technique to identify patterns between socioeconomic and demographic factors and barriers to health care access. The Apriori algorithm was used after discretizing continuous variables into categorical groups, including maternal age (15-24, 25-34, and 35-49) and parity (no parity, multiparity, and grand multiparity).

Minimum support and confidence thresholds were applied to reduce spurious rule generation. The rules, generated from the original (nonresampled) dataset, were evaluated using support, confidence, lift, leverage, and conviction (Table 6). A total of 8 rules were identified, and the top 3 were selected based on support and lift. All selected rules showed 100% confidence, indicating strong subgroup-level associations driven by data discretization. Support values indicate the occurrence within specific subpopulations, while lift values (1.49 - 2.10) confirm meaningful associations beyond chance.

Table . Association rule mining results for the top 3 rules identifying barriers to health care access.

Rule	Antecedent→consequent	Support	Confidence (%)	Lift	Leverage	Conviction
1	No insurance + low literacy→barrier	0.23704	100	1.49	0.08834	1.15742
2	Age 35 - 49 y + low literacy→barrier	0.23481	100	2.10	0.12266	2.54427
3	No insurance + age 35 - 49 y→barrier	0.06464	100	1.99	0.04873	1.93639

Rule 1 (no health insurance and low community literacy→barrier to health care access) showed support of 0.23704, confidence of 100%, lift of 1.49, leverage of 0.08834, and conviction of 1.15742, indicating a moderate association.

XSL•FO
RenderX

Rule 2 (age 35 - 49 y and low community literacy→barrier to health care access) had support of 0.23481, confidence of 100%, lift of 2.10, leverage of 0.12266, and conviction of 2.54427, indicating a strong association.

Rule 3 (no health insurance and age 35 - 49 y→barrier to health care access) showed support of 0.06464, confidence of 100%, lift of 1.99, leverage of 0.04873, and conviction of 1.93639, also indicating a meaningful association.

Discussion

ML Model Performance and Key Findings

This study was conducted to predict the top risk factors of barriers to health access among reproductive-age women. Multiple ML algorithms were trained on both balanced and imbalanced data for prediction purposes. The performance of those stacking ML models was compared by their classification accuracy and F_1-score. The SMOTE data-balancing technique significantly improved model performance compared to models trained on the original imbalanced dataset, as evidenced by enhancements in accuracy, F_1-score, and AUC-ROC. On the balanced dataset, XGBoost outperformed the other classifiers that were evaluated, predicting with an accuracy of 94.46%, precision of 94.62%, recall of 93.73%, F_1-score of 94.17%, and AUC-ROC of 94%. This suggests a potential limitation of algorithms for this specific dataset. For instance, SVC may struggle with the dataset's complexity, and LightGBM might require more hyperparameter tuning to match XGBoost's effectiveness. These differences highlight that tree-based ensemble methods like XGBoost may be better suited for capturing complex patterns in the data [39].

Using SHAP mean values, which measure each feature's rank of importance in the modified XGBoost model, the most significant characteristics indicating barriers to health access were found. By evaluating each feature's directional influence on the model's output, the SHAP impact analysis also demonstrated how each feature contributed to predictions. In the SHAP summary figure, red dots indicated features with a greater predictive probability (which pushed predictions toward a barrier to health access), whereas blue dots at the bottom of the plot indicated features with a lower predictive probability (which were linked to no barrier to health care access). Maternal occupation, maternal age, media exposure, parity, marital status, health insurance, and community literacy were the top predicting factors for barriers to health access among East African reproductive-age women.

Another key objective of this study was to identify specific demographic and socioeconomic categories associated with barriers to health care access among reproductive-age women in East Africa. Using ARM, we analyzed patterns to determine which factors were most strongly linked to restricted health care access. The results revealed that women aged 35 to 49 years, those without health insurance coverage, and those residing in communities with low literacy rates exhibited the highest predictive probability of facing health care access barriers. These findings highlight critical disparities that may require targeted policy interventions to improve health care accessibility for vulnerable groups in the region.

In our study, older mothers (35-49 y) were associated with barriers to health care access among reproductive-age women in East Africa. According to these studies, older women in East Africa encounter major obstacles when trying to secure health care, such as inaccessible services, lack of government assistance, and social or financial difficulties [40]. This finding is consistent with studies conducted in China [41], Ethiopia [42], Nigeria [41], and the United States [41], which reported that older mothers are more likely to face barriers to health care access compared to younger mothers. The possible reason could be that this study was attributed to large samples and included more areas beyond 1 country. This is opposite to a study done in SSA [43]. This might be due to a lack of autonomy in health use, where families may take the role of decision-making to use health care services. Therefore, as women grow older, they tend to gain greater autonomy, financial independence, and decision-making power, which can improve their ability to access health care facilities.

Findings from the rule generation women without health insurance coverage were associated with barriers to health care access in East Africa. A possible explanation could be due to financial limitations, out-of-pocket expenses that are restrictive, especially for women in lower-income circles, which causes care to be postponed or neglected [44], geographic isolation (far facilities and poor transportation) [45], lower education, unemployment, and poverty exacerbate these issues. Additional barriers are brought about by low health insurance awareness, poor-quality services, and cultural conventions [44,45]. These interrelated obstacles necessitate all-encompassing solutions, such as increased insurance coverage, poverty alleviation, improved infrastructure, and health literacy initiatives. This study is similar to what has been reported in several other studies, including in Nigeria [46], Ghana [46], Kenya [46], and East Africa [47].

Our study also shows that communities with lower literacy can be an important factor in the barrier to health care access among reproductive-age women in East Africa. A possible reason could be that limited health literacy in women reduces access to maternal care, antenatal visits, HIV testing, and health insurance [45]. This disadvantage worsens with rural isolation, poverty, and lack of health information, creating overlapping barriers to care [45]. This result is comparable to studies conducted in Tanzania [48] and Ethiopia [4], a systematic review in SSA [49], and Uganda [50].

Implications of the Study

This study highlights important areas for intervention to increase East African women's access to health care. Expanded universal health coverage is critical, especially for low-income and rural women, as the strong correlation between lack of insurance and service barriers is evident. In order to reach vulnerable populations, policymakers should give priority to subsidized insurance plans and mobile health services. Furthermore, linking health education with programs for women's empowerment may improve health care use, as evidenced by the result that community literacy strongly predicts access barriers. Health

XSL•FO
RenderX

systems should leverage the study's high-performing predictive model (XGBoost with 94.46% accuracy) to identify high-risk women early and allocate resources more efficiently.

Limitations of the Study

DHS data are often cross-sectional, providing a moment in time instead of a long-term perspective. As a result, causal inferences are limited because linkages do not necessarily indicate causation. Data from the DHS may not fully reflect recent changes in patterns or behavior because it collects data at predefined intervals.

Conclusions

This study developed and evaluated multiple ML algorithms to predict barriers to health care access among reproductive-age women in East Africa. Among the evaluated models, XGBoost demonstrated the best predictive performance and provided interpretable insights into the key determinants of health care access barriers through SHAP analysis. The visualization of cumulative domain-specific feature importance and the graphical representation of influential factors enable policymakers and health service program managers to clearly comprehend the key determinants affecting barriers to health care access rates among reproductive-age women in their respective regions. Before this, maternal occupation, maternal age, media exposure, parity, marital status, health insurance, and community literacy must all be taken into consideration while implementing health policies intended to reduce barriers to health care access. It is essential that all stakeholders, the Africa Union and the Eastern Africa regional coordination center, take appropriate measures to ensure that the health care access process is accessible to all women in the region.

Acknowledgments

The authors acknowledge the Demographic and Health Survey (DHS) for maintaining the data and making them accessible without charge. Abstract

Background: Summary care records are digital technologies designed to support information sharing and care coordination across fragmented health and social care systems. However, adoption and use of these technologies can vary across diverse health and care settings, with users using workarounds and other strategies to meet their specific information needs. In Scotland, the Key Information Summary (KIS) has been in use for over 13 years, sharing key patient information from general practitioners (GPs) with other health and care providers for future care planning.

Objective: Using the KIS as a case study, this study examines how various adoption strategies and workarounds have shaped the evolution of regional information infrastructures integrating health and social care in Scotland over time.

Methods: This multimethod qualitative study examined the various contextual factors influencing adoption and use of the KIS across diverse health and care settings. Data collection included interviews with KIS users from health and care settings, implementers, and vendors; documentary analysis of user guides, websites, reports, and policies; and observation of multidisciplinary team meetings and technology use. Data analysis involved a hybrid approach. The technology-people-organization-macroenvironment framework was applied to code interview, documentary, and observational data, followed by an inductive analysis informed by science and technology studies theories of information infrastructures, domestication, and workarounds to examine strategies and workarounds for adapting the KIS to local contexts and evolving needs.

Results: Data comprised 54 qualitative interviews, 59 documents, 2 websites, and 20 hours of observational field notes collected between April 2024 and March 2025. Findings indicate that adoption of the KIS varied across settings and over time due to misalignment between system design, evolving expectations of integrated care, and national initiatives during the COVID-19 pandemic that repurposed its use. Professional roles and associated information needs shaped differing expectations of what constituted useful information, generating tensions between users who relied on the KIS and GPs responsible for maintaining it. Formal workarounds enabled the extension of the health care–centric infrastructure into nonclinical settings to facilitate information sharing with GPs and, in some cases, supported clinician access to the KIS during system outages. Across settings, informal user-driven repair practices enabled diverse professionals to adopt and realign the KIS with its intended use.

Conclusions: This study demonstrates how regional information infrastructures integrating health and care evolve incrementally as they become embedded within local routines, practices, and existing systems. Adoption was shaped by professional roles, information needs, and users' capabilities, with formal workarounds extending infrastructures into new settings and informal, user-driven repair practices supporting ongoing use and maintenance. Policymakers and vendors must recognize that workarounds

XSL•FO
RenderX

and user-driven repair practices are central to infrastructural growth and sustainability, and understanding these strategies can inform future technology development and innovation.

health information exchange; information systems; intersectoral collaboration; delivery of health care; integrated

Introduction

Summary care records are digital technologies designed to facilitate information exchange across organizations, supporting collaboration and cooperative working between care settings and thereby contributing to the integration of fragmented health and care services [1,2]. These records entail information that diverse health and care professionals can draw upon to inform action within their respective organizational and professional contexts [1].

Information infrastructures are sociotechnical arrangements that support information exchange and collaborative work across organizations over extended periods [3,4]. They consist of interconnected information systems, standards, organizational arrangements, and work practices that become embedded within an installed base of existing technologies and routines [3,4]. As new digital technologies, like summary care records, are introduced, they must integrate with this installed base [3]. Consequently, in complex health and social care settings, summary care records are enacted differently across organizations to accommodate local workflows, professional roles, and information needs, often creating tensions around collaboration, standards, and information use [5-7]. In different settings, digital technologies are embedded within an installed base of work practices and information sharing mechanisms, making information infrastructures "systems of systems" composed of entrenched workflows, information systems, organizational arrangements, and diverse user information needs [3,4]. In complex and variable health and social care processes, summary care records are enacted differently across settings to accommodate local workflows, systems, and professional needs, which can create tensions among stakeholders with differing expectations of collaboration, standards, and information use [5-7].

Adoption of such digital solutions can vary across different health and care settings; in some instances, often to address usability issues and the difficulty of designing information systems that support diverse roles and activities, users use workarounds, develop shortcuts to save time, or bypass tasks [8-11]. According to Alter [10], a workaround occurs when someone modifies the usual way a system is intended to be used to overcome problems, obstacles, or inefficiencies that prevent them from achieving their goals; it is primarily shaped by the system's design, though organizational norms may also influence its use. Workarounds are practical, goal-oriented solutions that may bypass rules, standard procedures, or limitations to get work done more effectively or efficiently [10,12]. Cresswell et al [11] highlight that formal workarounds are organizationally sanctioned methods for addressing known system shortcomings, such as usability issues, whereas informal workarounds are user-initiated adaptations aimed at achieving goals with the available systems and information, for example, to complete tasks, reduce time pressures, or compensate for system defects. While these theoretical concepts acknowledge that users use workarounds in response to infrastructural breakdown [10], the relationship between infrastructural evolution and the emergence of workarounds remains largely unexamined.

Many countries around the world are pursuing a variety of strategies aimed at integrating health and care providers using digital technologies. Scotland has followed a coherent and long-term path, particularly through the establishment of Integrated Joint Boards (IJBs) to facilitate integrated and collaborative working following the Public Bodies (Joint Working) (Scotland) Act 2014 [13,14]. The Key Information Summary (KIS) in Scotland is a summary care record, used to share key patient information from general practice (GP) records with other health and care providers involved in an individual's care [7,15].

Scotland has a nationally shared electronic health record (EHR), the Emergency Care Summary (ECS), which was introduced to make core information from GP records available across the National Health Service (NHS) [7,15]. The ECS contains demographic information, medications prescribed by the GP, allergies, and adverse reactions, and is accessible to authorized health care professionals involved in a patient's care. Introduced in 2012, the KIS was developed as an extension of the ECS to support the recording and sharing of future care planning information across health care settings. In addition to the information available through the ECS, the KIS includes emergency contact and next-of-kin details, documented care preferences, baseline clinical and functional status, active care and escalation plans, resuscitation decisions, medication history, and a special notes section containing anticipatory and future care information.

The KIS was designed to facilitate communication between GPs and a broad range of professionals involved in community and unscheduled care, including hospital clinicians, out-of-hours (OOH) services, the Scottish Ambulance Service (SAS), community nurses, social workers, care home staff, and other professionals involved in coordinating care. GPs acted as custodians of the KIS and were the only users with administrative rights to create and update records through GP clinical systems. Information contained within the KIS was transferred electronically twice daily from GP systems to a central NHS data center [7]. Hospital clinicians, OOH services, and the SAS could access the KIS in a read-only format through their respective clinical information systems [15]. In contrast, social workers and social care providers, including care home staff, were not initially provided with digital access to the KIS

XSL•FO
RenderX

during its early implementation and instead relied on indirect communication with health care professionals [7].

As an extension of the ECS, the KIS became an integral part of Scotland's wider information infrastructure, supporting information sharing across health and social care providers [7]. Used across multiple settings and care pathways for future care planning, the KIS functions as a shared artifact that supports coordination across organizational and professional boundaries. Initially, GPs used the REDMAP (Ready, Expect, Diagnosis, Matters, Actions, and Plans) approach, together with clinical judgment, to identify patients who would benefit from a KIS, primarily those with long-term conditions and complex care needs requiring anticipatory or future care planning [15,16]. Over time, the use of the KIS expanded to additional care pathways, including dementia, frailty, end-of-life, and reablement, reflecting changing clinical priorities and service needs [7,15]. During the COVID-19 pandemic, the Scottish government further repurposed the KIS to identify and share information on individuals considered clinically vulnerable to COVID-19. This was facilitated by using the KIS, particularly the special notes section, which enabled clinicians to rapidly record and communicate relevant information across health and care settings. We have previously examined the evolution of information infrastructures for integrating health and social care providers, using the KIS as a case study to demonstrate how successive waves of infrastructural development enabled the interlinking of previously fragmented health and care systems [7]. This work showed how integration was achieved through extending existing health care–centric infrastructures into social care settings, often requiring formal workarounds in the absence of shared data standards. While previous studies have examined how infrastructures evolve through policy initiatives, technical integration, and organizational arrangements, less attention has been given to how these infrastructures are enacted after implementation, when users encounter the technology within diverse professional practices and local contexts. In particular, limited attention has been given to how users interpret and negotiate the purpose and value of shared information artifacts within situated practices of use and how workarounds and repair practices contribute to the continued evolution of digital infrastructures.

This paper draws on a broader longitudinal study examining the long-term evolution of information infrastructures supporting health and social care integration in Scotland. By examining the KIS as a shared information artifact within a broader information infrastructure, this study provides insights into how digital technologies integrating health and care providers are domesticated, maintained, and transformed through ongoing interactions between technologies, users, organizational arrangements, and wider health and care contexts. Specifically, it examines how processes of domestication, workaround, and repair contribute to the ongoing maintenance and transformation of infrastructures through interactions between technologies, users, organizational arrangements, and wider health and care contexts.

Methods

Study Setting

The adoption and use of the KIS vary across regions in Scotland. Lothian, a region of Scotland, serves as an exemplar of how the KIS can be used for future care planning, linking multiple health and care providers through distinct locally developed mechanisms. In Lothian, the KIS is used across multiple care pathways to share key information concerning an individual's care needs, resuscitation status, and medication history. While most of the information in the KIS is automatically updated from the electronic records held in GP practices, the special notes section in the KIS requires periodic review and manual entry of care needs and plans by the GP. In Lothian, health and social care partnerships, specifically the Edinburgh Health and Social Care Partnership (EHSCP), use customized templates that enable community workers, social workers, and care home carers to share updates with GP practices. GP practices also share the KIS as a PDF file with social workers involved in care pathways and provide paper-based versions to carers and residents in care homes. The KIS thus functions as an artifact shared across multiple health and care providers, with different actors using it in distinct ways to address their respective information needs. Its use in Lothian offered a valuable case for examining digitally mediated collaborative work and integration efforts, in which actors from diverse professional backgrounds adopted and domesticated a standardized digital technology embedded within the information infrastructure to meet varied informational needs and support the delivery of integrated care.

Study Design

Using the biography of artifacts and practices (BoAP) [17], and the technology-people-organization-macroenvironment technology people organization and macroenvironment (TPOM) framework [18], this multisited ethnographic study aimed to explore the adoption and contextual use of the KIS in different health and care settings. Multisited ethnography as a methodological approach allows the researcher to explore the diverse settings of technology development, adoption, and use [19]. BoAP, as a methodological tool, enabled navigation across different times and spaces, exemplified phases of technology adoption and use, and supported reflection on the choice of setting, time, and focus of enquiry [16,18]. TPOM is an evaluation framework designed to capture technological (eg, usability and performance), socio-organizational (eg, leadership and management practices over time and organizational routines), sociotechnical (eg, user satisfaction, engagement, and work processes), and macroenvironmental factors (eg, political and economic contexts and vendor management) that shape the real-time implementation, adoption, and use of digital technologies [18]. While BoAP helped examine various stages of technology adoption and use over time, providing a longitudinal view, TPOM supported contextual enquiry into how the KIS was adopted and used across different health and care settings.

XSL•FO
RenderX

Ethical Considerations

Ethics approval for this study was granted by the Edinburgh Medical School Research Ethics Committee (EMREC). Approval for interviews with participants in Scotland was obtained on April 17, 2024 (24-EMREC-012), and approval for observations of meetings, events, and training sessions involving technology use was granted on June 17, 2024 (24-EMREC-043). The study also received approval from the NHS Lothian Quality Improvement (QI) team. Informed consent was obtained from all participants prior to their participation in interviews and observations. Participants were informed of the purpose of the study, their right to withdraw, and how their data would be used. No prior relationship was established between the researchers and participants before recruitment. The researchers did not have a role in the implementation or operational delivery of the KIS. Participant data were deidentified and anonymized in the analysis and reporting, and identifying information was removed or omitted to protect participant confidentiality. Participants were not compensated for their participation.

Sampling

BoAP and TPOM guided the sampling strategy, enabling the identification of technology developers, users across various health and care settings, social workers from local councils, social care workers, policymakers, and academics. Recruiting participants informing various stages of technology development, adoption, and use, across various time frames and settings, enabled a longitudinal view of KIS's adoption and factors affecting contextual use. Here, BoAP was used to identify participants with experience across different stages of KIS's conception, adoption, and use in various time frames and settings, allowing the capture of a longitudinal view of its adoption. TPOM's focus on technological, sociotechnical, socio-organizational, and macroenvironmental contexts guided the recruitment of diverse stakeholders. This enabled the inclusion of participants who could provide insights into factors shaping adoption and use at the macro-, meso-, and microlevels, including usability challenges, organizational and professional practices, and the influence of national policies [18].

Snowballing and purposive sampling methods were used to recruit participants for the study. Purposive sampling enabled the recruitment of participants capable of providing context-rich insights from multiple settings, based on their involvement in the development, implementation, adoption, and use of the KIS at different points in time. QI teams of NHS Lothian and Lothian Unscheduled Care Services acted as gatekeepers for the study, assisting in identifying participants from across different health and care settings. Recruitment proceeded iteratively through purposive and snowball sampling until sufficient depth and breadth of perspectives had been obtained and saturation was achieved. Gatekeepers supported purposive sampling by identifying relevant stakeholder groups, multidisciplinary team (MDT) meetings, and care settings where the KIS was used for future care planning. They facilitated access to observations of MDT meetings and training sessions involving KIS use across different health and care contexts. The sampling strategy aimed to capture variation in perspectives and experiences of KIS adoption across professional roles and organizational settings. MDTs constituted GPs, OOH staff, clinicians and specialists from hospitals, community nurses and workers, social workers from various care pathways, and care workers from social care homes.

With respect to interviews, participants were sampled to represent a range of health and social care settings, including all 4 Lothian councils. Policymakers working in the domain of health and social care were purposively identified through national policy documents to understand how the policy landscape has evolved since the KIS was first developed and implemented. These documents were identified from the NHS and Scottish government websites via Google using the search term "Key Information Summary in Lothian and Scotland." National and international technology vendors were also purposively included to examine the factors influencing technological development, implementation, and adoption, as well as to gather insights into user support provided over time. In addition, a snowball sampling approach was used, whereby participants were invited to suggest others involved in the development, implementation, adoption, or use of the KIS.

Researcher Characteristics

VS (male) is trained as an IT engineer, with research experience in medical informatics, health and social care information systems, and qualitative research. KC (female) and RW (male) have research experience evaluating large-scale digital transformation initiatives across the NHS, including the Global Digital Exemplar program, which supported digital transformation across acute hospital settings in England, and NHS AI Lab programs.

Data Collection

Data collection was undertaken by VS between April 2024 and March 2025 under the supervision of KC and RW, using multiple qualitative methods, including semistructured interviews, ethnographic observations of KIS use in practice, and documentary analysis of materials related to KIS implementation, training, and operational processes. These methods were integrated within a qualitative case study design to develop an in-depth understanding of the technological, sociotechnical, socio-organizational, and macroenvironmental factors shaping the adoption and use of the KIS within its real-world context.

One-to-one, semistructured interviews were carried out with a range of stakeholders, including users, policy leads, data scientists, academics, technology developers, and health and social care providers, to explore their perspectives on the development, implementation, adoption, and use of the KIS. Interviews lasted between 40 and 60 minutes, were conducted online via Microsoft Teams, audio-recorded, and transcribed verbatim. For a small number of participants, follow-up interviews were conducted, where participants were willing to engage further, and additional discussion was needed during the analysis. These conversations were used to clarify points raised in the initial interviews and to explore emerging questions from the ongoing analysis.

Topic guides for the interviews, informed by the TPOM framework [18], explored how system usability and

XSL•FO
RenderX

performance, leadership and governance practices, organizational routines, user engagement and everyday work practices, and wider political-economic and vendor-related conditions shaped the adoption and domestication of KIS across health and social care settings. Tailored topic guides were developed for users from different settings, vendors, academics, and policy leads to capture insights regarding their role in the conception, adoption, and use of the KIS (Multimedia Appendix 1).

Nonparticipant observations were undertaken to examine how MDTs and national planning groups engaged with the KIS to support future care planning. Observations included MDT meetings involving NHS Lothian and the EHSCP, as well as national planning group meetings, to explore interprofessional collaboration across health and care organizations at both regional and national levels. Use of the KIS by different users was also observed to understand how its adoption and use varied across settings. Observation sessions lasted between 1 and 2 hours. Meetings and patterns of technology use were observed online via Microsoft Teams. In addition, in-person training sessions delivered by the EHSCP in care homes were also observed. Field notes were systematically documented using a structured observation protocol (Multimedia Appendix 2).

Study participants were also asked to provide relevant documents regarding the implementation, adoption, and use of the KIS. Internal case studies, user guides for different professionals, contingency plans during technology breakdown, and software update notifications were shared by participants. Documents were purposively selected based on their relevance to understanding the evolution of the KIS as an information infrastructure. Selection focused on materials describing the development, implementation, and use of the KIS in Scotland and Lothian; health and social care integration initiatives; the intended functions and uses of the KIS; related health and social care information systems supporting KIS access; and implementation strategies and anticipated benefits at local and national levels (Multimedia Appendix 3). Historical documents were treated as empirical artifacts that provided insights into how standards, practices, and infrastructural arrangements were developed, negotiated, and embedded over time. These documents were examined qualitatively to understand challenges surrounding the adoption and use of KIS in different settings over time and to explore the similarities and differences between national goals, technological claims, and regional narratives.

Data Analysis

NVivo (version 14; Lumivero) was used to code the interview transcripts, observation notes, and documentary materials. Data analysis was conducted by VS under the supervision of KC and RW. VS was the primary and sole data coder, while KC and RW provided ongoing oversight of the analytical process and contributed to discussions of coding, emerging themes, and interpretations. The analysis adopted an interpretive approach that recognized the researcher's positionality and subjectivity. Credibility was strengthened through the search for disconfirming evidence and the use of data triangulation. Triangulation involved integrating insights from all qualitative data sources to situate the case study within the broader context of integrating health and social care through digitalization while also capturing the microlevel practices of individual users and the mesolevel organizational processes and interactions that shaped the adoption and use of the KIS.

Data analysis followed a hybrid approach, that is, a combination of inductive and deductive approaches [20]. Deductive thematic analysis, informed by the TPOM framework, was applied to interviews, documents, and observational notes to examine the challenges around technology usability, user and organizational practices, as well as the wider macroenvironmental factors influencing the adoption and use of the KIS across different settings [18]. Related codes that emerged were clustered into themes and compared across sites, professional roles, and time periods to identify relevant subthemes following an inductive analysis. Concepts and theories from science and technology studies, including information infrastructures [3-6,21-23] and domestication [24,25], alongside theories and concepts on workarounds [10-12], were used to further interpret how the KIS was adopted across different settings over time as the regional information infrastructure evolved. These approaches enabled a systematic analysis of KIS's adoption and use over time, the tensions emerging during its adoption across diverse settings, and the various adoption strategies and workarounds enacted by users and organizations to mitigate constraints imposed by the system. The coding process involved organizing codes into second-order and aggregate themes, with the resulting coding structure provided in Multimedia Appendix 4.

Reporting Guidelines

This study was reported in accordance with the COREQ (Consolidated Criteria for Reporting Qualitative Research) guidelines [26]. The completed COREQ checklist is provided in Multimedia Appendix 5.

Results

Overview

Data consisted of 54 interviews; notes from observing technology use, MDT meetings, and national-level meetings regarding the use of KIS for future care planning (20 hours); and documentary analysis of 59 documents and 2 archived websites (Table 1).

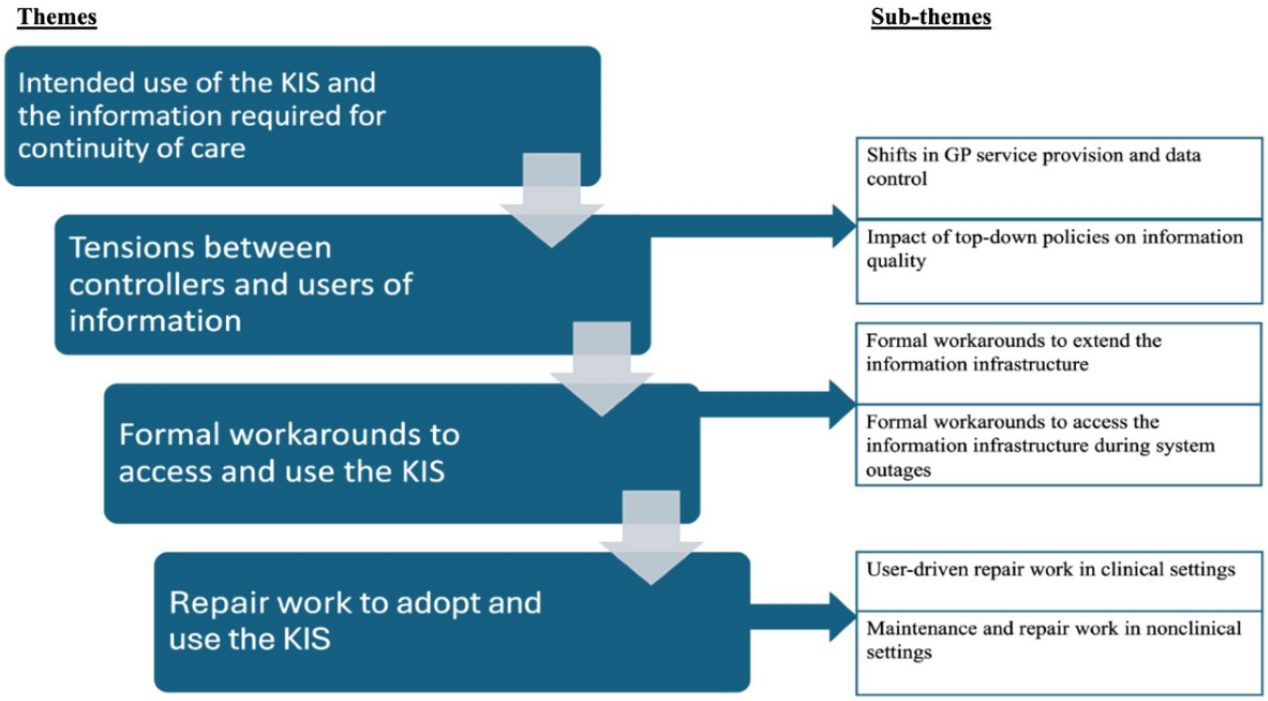
[b]KIS: Key Information Summary.

[c]ACP: anticipatory care planning.



The KIS was designed to enable the sharing of key patient information from GP with other service providers to support continuity of care and provide an overview of patients' health status and care plans. However, expectations regarding the content and level of detail required varied across professional groups and care settings, and the functionality and design of KIS did not accommodate the full range of tasks it was expected to support. Consequently, tensions emerged between different user groups (such as OOH and hospital staff) and those responsible for maintaining and governing the information recorded in the KIS (GPs). These tensions were exemplified following top-down policy initiatives by the government that repurposed the KIS to identify vulnerable patient groups during the COVID-19 pandemic. As a result, many KISs were created without substantive information on future care plans and were instead flagged as having been generated as part of COVID-19 protocols. In turn, formal workarounds were used by health boards to provide social workers and carers access to the KIS and to ensure that relevant and updated information regarding future care is shared with the GP practices. Informal user-driven repair strategies were used in different health and care settings to update the KIS with relevant information and realign the KIS with its intended use. Here, repair work was conceptualized as the ongoing, often invisible labor through which users maintain,

XSL•FO
RenderX

adapt, and render technologies usable in practice. Figure 1 provides an overview of identified themes.

The analysis identified several interconnected challenges that influenced the adoption, use, and ongoing maintenance of the KIS across health and social care settings. These challenges related to information quality, interoperability, professional responsibilities, and organizational capacity. Rather than representing discrete implementation failures, these challenges reflected tensions that emerged as the KIS evolved from a health care–focused summary record into an information artifact supporting wider health and social care integration. Users and organizations responded to these challenges through formal workarounds and informal repair practices that sought to maintain information quality, extend access, and align the KIS with changing care needs.

Figure 1. Themes emerging from the analysis. GP: general practitioner; KIS: Key Information Summary.

Intended Use of the KIS and the Information Required for Continuity of Care

GPs were regarded as the main point of care for residents in Scotland, and the KIS was developed to share key information regarding a person's future care plan to other primary, secondary, and community care providers. GPs identified individuals who would benefit from a KIS within their practice and documented their care plans and preferences. Consequently, the KIS enabled GPs to share information concerning a person's medication, resuscitation status, and care plans with other health and care providers, who may not have had regular or long-term contact with the individual. Clinicians in OOH settings, who served a broader patient population than GPs and provided care outside regular GP hours, reported that the KIS gave them access to information they would not otherwise have, allowing them to understand the GP's assessment of a patient's condition and to make informed clinical decisions:

> *In an out-of-hours environment, you don't know the patient; all I'm seeing is their KIS, and only if the GP has uploaded one. If you work in Edinburgh out of hours, you're covering most of the city of Edinburgh. The information that the KIS summary can provide is really valuable because it helps to just get a sense of what the GPs are doing, what they're worried about regarding a person, and what their care needs are. Those things are sort of there to help you make those decisions when it's an emergency, night-time or evening.* [Clinician, OOH (1), Lothian]

The KIS was developed to support GPs in engaging with individuals about their future care with primary, secondary, and community care providers. However, as the KIS was adopted across different care settings, expectations regarding the type, completeness, and level of detail required varied between professional groups. While GPs viewed the KIS primarily as a mechanism for documenting future care preferences, clinicians in other settings increasingly relied on it as a broader source of information to support decision-making. Conversations regarding future care between the GP and the individual were regarded as an ongoing, dynamic, and iterative process aimed at capturing an individual's care preferences, as their conditions and care needs changed. GPs, acting as custodians of KIS data, were responsible for updating patients' care preferences and future care needs, making the KIS a dynamic record, whose completeness and accuracy varied according to the extent to which individual GPs maintained it. However, this model of data stewardship also created a key challenge, as maintaining the accuracy and completeness of KIS information depended heavily on the capacity, time, and willingness of individual GP practices.

XSL•FO
RenderX

> *The KIS is a living document. To me, once a KIS is in place, it should be a dialogue to know when you've got a new condition or if something new happens. Lives are fluid, and there will be new bits of information, and it should be an ongoing document.* [Clinician, GP (3), Lothian]

However, some GPs noted that they did not always maintain such long-term engagement with patients whose health and care needs had become complex, requiring them to gather relevant information from other sources to update the KIS. This variability represented an important challenge, as the usefulness of the KIS depended on sustained processes of information maintenance that were influenced by individual practice capacity, workload, and access to information from other care providers. In some cases, individuals required long-term care that could not be delivered in community settings and instead depended on ongoing support from hospitals, nursing homes, or care homes. To ensure the KIS reflected up-to-date information, GPs had to draw on multiple information sources, including updates provided by other health care professionals, social workers, and carers. For instance, discharge letters were provided by hospital-based clinicians to GPs after an individual's discharge following hospital admission, which the GPs had to review to update the KIS. However, not all GPs adopted a systematic approach to reviewing documentation on patients' future care needs, and maintaining these records required ongoing effort. Access to up-to-date information was particularly valuable for clinicians in hospital and OOH settings.

> *So we've got 150 to 200 housebound patients in my practice, quite high. So, we did a project around making sure all housebound patients had a KIS, and you see that sometimes you haven't seen the patient all year, or they've just been seen in secondary care. But no one has thought about updating it from the secondary care letters.* [Clinician, GP (6), Lothian]

Tensions Between Controllers and Users of Information

Overview

The variations in how GPs and GP practices updated the KIS differences reflected the evolving organization of general practice over time, resulting in uneven distributions of resources and capacity across practices. While GPs bore primary responsibility for ensuring that KIS information remained up-to-date and clinically relevant, other users largely benefited from the availability of this information, thereby generating tensions between different user groups. The demand for up-to-date information was further intensified by national initiatives that repurposed the KIS to identify vulnerable patient groups. The following sections examine these issues in detail.

Shifts in GP Service Provision and Data Control

The organization of GP services in Lothian was such that not all GP practices had the responsibility of providing medical services to care homes, nor were they equally resourced or willing to update the KIS. In some cases, GPs expressed the need to have control over the data collected and shared using the KIS and had the resources to ensure this. Whereas in other practices, they had no spare capacity to review and periodically update the KIS, leading to variability in the way the notes were recorded and updated.

> *All the onus is on the GP practice to add the information into the KIS, so it's very much dependent on the capacity and availability of staff who are allocated that role to update the KIS. It's different across each GP practice. You'll have a GP practice that will very much want to keep control and be responsible for updating the KIS. Not all GP practices cover care homes; if they do, then they'll go out, do the visit, and quite often they'll keep that to themselves. They don't want to share it out, not quite gatekeeping, but there is that element of them wanting to kind of have some oversight of that responsibility and the cheques.* [Social work, EHSCP, Lothian]

> *It depends on how pressurized the practices are and the amount of capacity they have. I think if a practice has no spare capacity, then people don't dedicate the necessary time to update the KIS. Whereas another practice or another GP who has got a bit of capacity will actually spend time updating the information to make sure it's current, so there's a huge variability, which has been one of the frustrations.* [Clinician, Hospital (1), Lothian]

The introduction of the General Medical Services (GMS) contract in 2018 led to the establishment of MDTs intended to reduce pressures on GP practices and to provide integrated care. The GMS contract of 2018 also placed GPs as controllers of patient data for integrated care services. Since the earlier GMS contract of 2004, GP practices have not operated as NHS-managed services but as independent businesses contracted to deliver services on behalf of the health board. Before this restructuring, many practices were directly funded and managed by health boards; under the GMS contract of 2004, GPs functioned as independent contractors, and a pay-for-performance scheme was introduced. As a part of the GMS contract of 2018, practices that are geographically close formed clusters to work together with regional health and social care partnerships to provide integrated care. Although the 2018 contract sought to alleviate workload by positioning GPs as clinical experts supported by wider MDTs, documentary evidence and participant accounts indicated that, in practice, these changes often increased rather than reduced the workload placed on GP practices. Some of the GP practices were struggling to recruit new GPs, whereas some had the resources to recruit more staff and run integrated care services through MDTs. However, a few GPs noted that insufficient systemic and organizational support for running GP practices adversely affected their capacity to maintain high-quality and up-to-date data in the KIS. Together, these findings demonstrate how organizational capacity, workforce constraints, and variation between GP practices affected the consistent embedding and maintenance of KIS-related activities across settings. These challenges were not simply related to user willingness to adopt the KIS but reflected broader organizational conditions that shaped the capacity of practices to sustain information-sharing activities over time. While there was increased recognition of

XSL•FO
RenderX

the need to provide up-to-date information for population health management and preventative care among GPs, they also questioned the misalignment of national-level priorities regarding care provisioning and delivery.

Impact of Top-Down Policies on Information Quality

The need for reliable and up-to-date patient information became increasingly critical after the KIS was repurposed during the COVID-19 pandemic to identify vulnerable groups of patients by the government. This was achieved by using the special notes section in the KIS to indicate that the record had been created in response to the pandemic. However, this "top-down" approach diverged from the KIS's primary purpose as a tool to record and share an individual's care preferences and needs. This affected the usefulness of the information available to professionals using the KIS for clinical decision-making, particularly in settings where clinicians relied on shared information to understand an individual's current health status and care requirements. Thus, a key challenge emerged when national policy priorities expanded the expected function of the KIS without corresponding changes to the information structure, workflows, or responsibilities associated with maintaining the record. One clinician in the OOH service highlighted how the repurposing of the KIS during the pandemic affected the information available through the system:

> *There was a mandate during the pandemic that every patient should have a KIS summary. But the pragmatic reality was that much of what was included was focused on COVID status. It often did not capture other medical problems they might have, such as diabetes, involvement with mental health services, or multiple medications. So, it was quite patchy in terms of what up-to-date information was actually coming through to the clinician looking at the case through the ECS.* [Clinician, OOH (1), Lothian]

The consequences of this policy-driven repurposing were therefore not limited to information quality but also generated additional maintenance work for users attempting to restore the original purpose of the KIS. Consequently, GPs were required to undertake additional work to identify individuals who would benefit from a KIS containing up-to-date information relating to future care planning and to restore the intended purpose of the record. This illustrates how repurposing an existing information infrastructure for new policy objectives can unintentionally reshape information practices, alter the content generated within the infrastructure, and create additional maintenance work for users responsible for sustaining its intended function.

While users in OOH services and the ambulance service benefited from having up-to-date information in the KIS, maintaining this accuracy required GP practices to collate information from multiple sources and manually enter updates. Clinicians in OOH settings shared that recent and relevant information in KIS aided in decision-making and provided an improved understanding of the individual's condition and care plans in place. Accordingly, clinicians from OOH services and hospitals emphasized the importance of involving social workers and social care workers from MDTs (such as the Care at Home, End of Life care, Post-Diagnostic Dementia Service, and Reablement teams) in updating the KIS, both to reduce the burden on GP practices and to support a more integrated approach to care.

> *I think sometimes the frustration is that updating the KIS feels like it is a GP's job and it's quite time-consuming. You have to click a lot of buttons, copy the information, and make sure it is shared. Sometimes, GPs can feel like we're doing all this work to help other services more than to help ourselves. I don't think that is true because it helps with continuity, and if different doctors were seeing a patient, then they would have a better understanding. It would be great if more people could get involved with creating and updating the KIS, for example, the re- enablement team or the care home teams, making it a collective joint effort rather than it always coming back to daytime GPs to do.* [Clinician, OOH (3), Lothian]

In some instances, when clinicians in OOH settings identified that a patient could benefit from a KIS, they would email the GP with relevant information extracted from OOH-based information systems. Although OOH staff found this process time-consuming—requiring them to gather information from multiple systems—they often did not receive any feedback from GPs regarding updates to the KIS.

> *There's a bit of work involved because you've got to obviously do the e-mail, fill in the paperwork and the name, address the pile, put all that we have been doing, and any other information that we might have on our system about them. So, to update it is a wee bit time-consuming, but we never ever get a response back to see that it's updated.* [Clinician, OOH (2), Lothian]

Formal Workarounds to Access and Use the KIS

Overview

In response to challenges related to information access, interoperability, and information quality, organizations and information system vendors developed formal workarounds to extend and sustain the use of the KIS. These were designed both to extend access to KISs to nonclinical settings and to ensure continued access to the KIS during system outages. The following sections examine these subthemes in detail.

Formal Workarounds to Extend the Information Infrastructure

Understanding the need to update relevant information and to provide integrated care, a few GP practices in Lothian involved social workers and social care workers from MDTs and care pathways to update the KIS. However, as the information systems used by social workers and care providers were not interoperable with the information systems used by GPs, formal workarounds were used to provide social workers and care providers access to the KIS. These workarounds were formal insofar, as they were agreed and promoted by various stakeholders like the health board, technology vendor, and the

XSL•FO
RenderX

EHSCP. Formal workarounds included creating proxy access for social workers and care providers involved in MDTs (Reablement, End-of-Life Care, and Post-Diagnostic Dementia Services) to view a read-only version of the KIS through hospital information systems on behalf of the NHS. Functionally, this constituted a semilegal extension of the technology, permitted through formal organizational and vendor sanctions. The boundary between formal and informal use was blurred, as access was generally limited to viewing the KIS rather than updating it, thereby avoiding potential breaches of professional jurisdiction or liability. Here, communities of practice, such as the regional health and social care partnership (EHSCP), organized training sessions for social care workers in care homes and for social workers involved in MDTs and care pathways. These training sessions helped in building a sense of ownership among nonclinical users (social workers and social care workers). EHSCP created templates for social workers and care providers to understand who would benefit from a KIS, as well as to share updates regarding future care plans with the GP practices.

Formal workarounds in providing social care workers from MDTs access to the information infrastructure also involved issuing NHS email accounts to a limited number of social care providers operating care homes. Care home managers, due to their involvement in MDTs and seniority, were provided with NHS email accounts on behalf of the NHS. This arrangement provided nonclinical entities, with access to the secure emailing system used by health care providers to share updates with GPs. Documentary evidence from NHS Lothian demonstrated that this approach was formally supported, with care homes encouraged to establish secure email connections with NHS services to facilitate the exchange of person-identifiable and sensitive information. Observations of MDT discussions and training sessions, alongside documentary evidence from EHSCP materials, demonstrated that standardized templates were developed to support care providers in identifying individuals who may benefit from a KIS and communicating relevant updates to GP practices. However, because access was limited to selected individuals within care homes, managers often acted as intermediaries, sharing information with GP practices on behalf of other members of the care team who did not have direct access to the information infrastructure.

Formal Workarounds to Access the Information Infrastructure During System Outages

Formal workarounds were also used and promoted by health boards and vendors when technical barriers impeded access to the KIS through various information systems used by the different users. Contingency plans were developed and shared, detailing alternative communication channels that clinicians could use to maintain continuity of care by accessing relevant information. For instance, during system outages that made the KIS temporarily unavailable, clinicians were able to obtain relevant information through telephone referrals or secure email by contacting designated support teams within the health board. These teams, such as the Flow center (a digital navigation center for assisting clinical users), coordinated the distribution of information as well as contingency plans to GP practices, OOH services, and hospital-based clinicians, ensuring continued information access during planned and unplanned system downtime.

Similarly, unanticipated impact or issues demanded the use of formal workarounds to provide temporary access to information systems to ensure continuity of care. For instance, after Adastra had a security outage in 2022, users in OOH settings had to learn and start using TrakCare (Scotland's hospital-based information system) until Adastra was restored. Formal workarounds involved the health board and the vendor of TrakCare agreeing to provide OOH entity access to information systems used in hospitals. As part of the workaround to provide access, the OOH service was listed as a new hospital to be identified as a trusted entity with administrative rights. These workarounds ensured that staff from OOH settings could share clinical information with other entities like GPs, as well as view the KIS. However, OOH staff were required to familiarize themselves with TrakCare, a system designed for hospital-based workflows. This imposed additional learning demands and disrupted established clinical workflows for clinicians unfamiliar with hospital-based information systems.

> *When we had that ransomware attack, they had to quickly get everyone a proper TrakCare account so that they could write up and share the case notes. That was a huge piece of work, and they had to set up OOH as a clinic, like an outpatient clinic. So, we could at least write the GP a letter, and we could access the KIS. TrakCare wasn't a bad option; there weren't any problems with it necessarily. It's just the fact that everyone had to learn it, because most of us hadn't been working in hospitals particularly, and we would look stuff up, but we wouldn't have to interact with the system, particularly often.* [Clinician, OOH (2), Lothian]

Vendors provided users with documents promoting temporary workarounds to ensure interoperability across information systems used to access the KIS. Clinicians routinely relied on multiple interconnected systems, meaning that updates to any one software created misalignments with established workflows. In response to such issues, vendors issued detailed user guides describing interim procedures to support continued use. For example, Vision, the information system used by GPs, and the Scottish Care Information (SCI) Gateway, a national platform for clinical referrals, were software applications that allow GPs to access and share information with other clinicians. A security update to the SCI Gateway restricted users to a single active session and prevented simultaneous access through multiple browsers or devices. For Vision users, however, each patient consultation triggered a new login instance (parallel active session), causing active SCI Gateway sessions to be terminated automatically. To manage this incompatibility, vendors provided Vision users with revised login procedures intended to preserve interoperability with the updated SCI Gateway. These procedures required GPs to log in and out of the system after each consultation, thereby inadvertently disrupting routine practice.

RenderX

Repair Work to Adopt and Use the KIS

Overview

Following the COVID-19 pandemic, maintaining adoption of the KIS required users to undertake additional repair work to address challenges related to information quality, relevance, and interoperability. First, to restore information quality in the KIS, users adopted new strategies that functioned as repair work to maintain information quality. Across settings, users engaged in informal repair practices to obtain relevant information from alternative sources and to update the KIS. These practices varied by site and were influenced by users' roles, digital skills, and access to specific information systems. Second, adoption also varied across health and social care settings. In nonclinical settings, carers and social workers acted as human nodes for information gathering and sharing, as the information systems used were not interoperable. The following sections illustrate how professionals in different settings adopted different strategies, including repair work, to realign the KIS with its intended purpose and update its information.

User-Driven Repair Work in Clinical Settings

As the quality of information in the KIS declined after COVID-19, users had to use different mechanisms to improve the quality of information in the KIS. In GP settings, these repair strategies were developed by GPs with analytical expertise and were shared informally with colleagues. In some GP practices, GPs with access to the Scottish Patients at Risk of Readmission and Admission (SPARRA) dataset used risk scores to identify patients who might benefit from a KIS and to determine whether existing KISs required updating. The SPARRA dataset identified individuals at risk of hospital admission by assigning a risk score derived from analyzing an individual's chronic health conditions, prior unplanned hospital admissions, mental health diagnoses, and alcohol or drug-related admissions. However, a few GPs highlighted that reliance on SPARRA data was restrictive, as it drew predominantly on hospital-based data. Additionally, the high prevalence of multimorbidity within the dataset complicated efforts to determine which individuals would meaningfully benefit from a KIS.

> *The solution I'm finding at my practice is that I'm trying to use the SPARRA data, and I'm trying to get just my work through it. Okay, now who has just got the COVID phrase and who's got a meaningful KIS? I get the SPARRA data, and then I build a group and code all of those. So, you could look at who's coded for high SPARRA data and has a KIS and who doesn't have a KIS and identify them. But that is really difficult now because everyone's got cancer, even if there's nothing in that, that's quite difficult.* [Clinician, GP (2), Lothian]

> *SPARRA is not unhelpful, but if my recollection is right, it's skewed by hospital admission. So it's quite good at telling you who's currently sick. Which is not quite the same as predicting who might become sick, and you might have something you could do about it as a GP.* [Clinician, GP (5), Lothian]

A few other GP practices, which were involved in MDTs tackling issues around frailty and multimorbidity, used local datasets to identify who would benefit from a KIS. These GP practices, forming a cluster under the GMS contract of 2018, ran special services to identify frail patients in a region and support their care plans and preferences. GP practices used local datasets to identify frail patients and to identify if they had a KIS in place. These informal repair strategies, developed and used in different practices, were later shared by communities of practice like Scottish Clinical Information Management in Primary Care and EHSCP. As a result, networks of GP practices, in different clusters, had started to use SPARRA datasets, alongside other local datasets capturing details regarding polypharmacy, multimorbidity, and frailty.

Clinicians working in OOH settings reported that many other sources of information could help GPs understand an individual's current care needs, but these were stored in various formats across different information systems. This information included records from community nurses and care home staff, maintained across multiple digital systems as well as physical documents, to capture a person's health and care needs. OOH clinicians noted that nurses and care home staff, who knew the patient and their family well, provided valuable information about next of kin, recent hospitalizations, current functional status, and any gradual health decline over time. Nurses and carers visiting house-bound individuals documented residents' mobility, recent hospital visits or admissions, and care plans using disparate information systems—and sometimes physical copies. Because information systems across organizations were not interoperable, OOH clinicians visiting care home residents often relied on verbal reports from nurses as well as carers and shared them with GP practices via secure email, with the extent of sharing and GPs' incorporation of updates both depending on individual capacity and willingness.

> *So if it's district nurses in hospital-based complex care settings or home care for house-bound patients, it would usually be verbal communication. You would take a handover from the nurse or carer who contacted our service to know what they're concerned about, and usually, they know the patient well and know the family, which can be an excellent source of information. Like, who is the patient's next of kin, or say that the person has been in the hospital for a problem last month. I think the care home staff are a really valuable source of information because they can tell you about the level of function of the person, whether they have been sick for a while, or are normally quite mobile and independent but currently bed-bound or needs help, if this patient's been on a downward trajectory over the last six months and they've been declining steadily. That is really useful information, and I would type up my notes and share them with the registered GP afterwards.* [Clinician, OOH (2), Lothian]

Maintenance and Repair Work in Nonclinical Settings

While formal workarounds enabled social care providers to access the secure emailing networks to receive a digital copy

XSL•FO
RenderX

of the KIS from GP practices, care providers also maintained a physical copy. A few care managers highlighted that in social care settings, physical copies of care plans and the KIS were stored to ensure continuity of care and as a contingency mechanism. These contingency mechanisms were in place, recognizing the vulnerability of digital technologies to occasional breakdown, and due to epistemic practices around record keeping in care settings. The different material forms of the KIS also served as a medium to share information with clinical staff providing emergency care, like the ambulance service. Ambulance services visiting care homes often relied on multiple sources of information present at care settings while attending a patient, which required care staff to maintain physical records as well.

> *Yeah. I think it is good practice to have everything on the electronic platform, but like any electronic device, as you do rely on the internet and electricity working, and you know if all that went down, you are left with nothing, which I don't feel is really good practice. This resident has to be cared for regardless of whether we have electricity, Wi-Fi, or Internet. So, we have a folder for each person that contains these very important documents. If anything were to happen to this system, or let's say you know, like the NHS system that has been hacked several times, you don't know what will happen in life. But I still have to provide the most important care to my resident. So, I feel we should have a paper copy just in case things happen, and we can't access it digitally.* [Social care (3), Lothian]

A few GPs reported that extending the health care–centric information infrastructure to social workers and care providers to access and share information regarding future care planning was beneficial. Although this access to the information infrastructure enabled a few care workers and social workers to share information with clinicians, they functioned as human nodes who shared information with the GP practices to update the KIS. For instance, charity and voluntary organizations engaged in frailty assessments had to manually collect information regarding a person's contact information, care plans in place, mobility status, and available resources at their residence to support home-based care. Voluntary organizations then had to share the assessment with GPs, where GPs or GP admin staff would enter the details into the KIS.

Internal implementation reports by EHSCP also highlighted the development of local forms and documentation processes across different reablement pathways to facilitate information collection and sharing between community organizations and GP practices. However, despite these efforts to support information exchange, challenges remained as different professional groups operated with distinct epistemic approaches to documentation, information recording, and care practices. These differences influenced how information was generated, interpreted, and incorporated into the KIS, requiring ongoing negotiation and coordination among stakeholders.

> *There are some local initiatives, like the long-term conditions team, where community teams will collect the data in a structured way and then email it to the GP practice so that it's kind of easier for the GP. You can just copy and paste aspects of that record to share in the KIS as opposed to having to, you know, originate it and type it up yourself.* [Clinician, GP (2), Lothian]

Discussion

Summary of Findings

Findings illustrate how the KIS, as a shared object of collaboration across diverse health and care professionals within an information infrastructure, was adopted differently in various settings over time. Diverse health and care providers benefited differently from the information held in the KIS, with varying expectations regarding what constituted useful information based on their professional roles. These expectations varied, shaped by users' professional roles as well as information needs, and only became evident as the KIS was adopted across different settings. They revealed how various providers' specific requirements and perspectives influenced their expectations and use of the KIS. These expectations evolved as the expectations of integrated care evolved and more significantly after national initiatives diverted the use of KIS to new missions, necessitating workarounds and repair work to extend the health care–centric information infrastructure to new settings and to realign the KIS with its intended purposes.

Formal workarounds were used to extend the health care–centric information infrastructure to social care settings and to ensure access to the KIS during system outages. These workarounds included creating proxy access for a few nonclinical professionals (eg, social workers from councils and social care providers) involved in MDTs to view the KIS using hospital-based information systems. This allowed social workers and carers to access the KIS in a digital format and communicate with GPs using the secure emailing network. Formal workarounds also involved the development and sharing of contingency plans by vendors, health boards, and organizations with users to address unexpected technical barriers that hindered access to the KIS.

While formal workarounds facilitated access for new users and the development and sharing of contingency plans, informal user-driven repair work was used to gather and share relevant information from alternative sources to update the KIS. These user-driven repair works were subject to the affordances of the users, that is, their role and consequent level of access to the existing information infrastructure, digital skills, willingness, subjective perceptions of integrated care, organizational practices, and leadership. Users leveraged various interconnected systems within the information infrastructure, such as local datasets, other EHRs, and care plans, to fulfill their information needs, even though these systems were originally designed for different purposes. Over time, these locally developed repair strategies became embedded within practice, influenced patterns of the KIS's adoption across settings, and contributed to shaping the evolution of the regional information infrastructure.

RenderX

Integration With the Literature

This research aligns with existing literature, showing that information infrastructures evolve over long periods, gradually embedding new technologies within user groups and becoming shaped by established organizational practices, information needs, and existing information systems [3,4,7,21,27]. Previous evaluations of summary care records have highlighted challenges associated with information quality, interoperability, and aligning shared records with the information needs and workflows of different professional groups [1,3,5,7]. However, these evaluations have often examined summary care records at particular points in time, providing limited insight into how such technologies evolve as part of broader information infrastructures [1]. Our previous research examined how the KIS and associated infrastructures developed through successive waves of infrastructural growth [7]. This study extends that work by examining what happens after infrastructural expansion, focusing on how users domesticate, maintain, and transform established infrastructures through everyday practices of repair and workaround. Building on this perspective, this study illustrates how the KIS continued to evolve as it became embedded across diverse health and care settings, where different professional groups developed context-specific interpretations of its purpose, functionality, and information requirements. Jarrahi et al [27] further emphasize that information infrastructures are open and generative, developing through interaction with new settings where they combine with existing practices and information needs. By examining a digital technology used for collaborative work [5-7], this study illustrates how the KIS was translated across different settings over time and embedded within the installed base, highlighting the generative nature of the information infrastructure as it evolved to support health and social care integration. Across these settings, user groups differed in their understanding of the usability of the KIS, which changed over time, as they started to adopt the KIS. For instance, the KIS was designed to share information from GP records with other people involved in delivering care. However, as the KIS was implemented and adopted across settings over time, user groups developed differing interpretations of what constituted key information. OOH staff, for instance, benefited from having up-to-date future care plans recorded in the KIS, but this required GPs to collate information from various information sources to update the KIS. Consequently, their views on how the KIS should be updated and what it should contain varied according to the users' professional roles and information needs, informing the repair work they used, such as referring to other EHRs and datasets to which they had access. Findings from the study illustrate the range of strategies organizations and users used to update information in the KIS, including formal workarounds to extend the KIS into new settings and informal, user-driven repair work to access and update with relevant information. These findings demonstrate that information infrastructures integrating health and care providers are open and evolve generatively over extended periods, with workarounds and user-driven repair practices shaping their extension and adoption across settings [3-7,27].

This study also aligns with the literature highlighting that workarounds are an integral part of technology implementation and adoption [10,11]. Several workarounds observed in this study are consistent with the literature describing formal, interim measures used to address limitations around technology usability [11]. Formal workarounds identified in the study included the development of contingency plans and the provision of interim user guides by vendors, offering temporary instructions to support users in navigating the technology during periods of limited system functionality. Contingency plans involved using alternative information systems and paper-based records as intermediaries to maintain continuity of care in the event of system failures. Finally, formal workarounds were also used to extend the health care–centric information infrastructure to nonclinical settings. These findings illustrate that workarounds are strategies used by individuals and organizations to navigate technological or procedural constraints, and that they play a critical role not only in technology implementation and adoption but also in the evolution of information infrastructures [8,10-12].

Information infrastructure and the repair work it entails have been examined from various perspectives. Scholars note that information infrastructures are prone to breakdown and require repair as part of their maintenance [28,29]. However, existing studies focus on visible and invisible repair activities, the use of material tools, and the power dynamics during infrastructural failure, but pay limited attention to repair work in the context of the long-term evolution of infrastructures for integrating health and care providers [28,29]. This study contributes to the literature by highlighting that the evolution of information infrastructures for integrating health and social care providers necessitates user-driven repair work for its maintenance. User-driven repair work involved drawing on local datasets and other EHRs—containing overlapping information but designed for different purposes—to identify and share relevant information for updating the KIS. These datasets and information present in different systems can be conceptualized as digital assemblages or personal information infrastructures, which users engaged with to support their information needs [30]. A digital assemblage is a combination of digital and physical resources that users interact with to achieve specific objectives [27,30,31]. By analyzing how users engaged with digital assemblages during infrastructural breakdowns to meet their information needs, this study shows that infrastructural growth is also driven by bottom-up strategies and enacted through user-driven repair work.

Finally, this research contributes to the theory of workarounds by further elucidating the relationships between environment, strategies, and infrastructure [10-12]. The theory of workarounds seeks to classify the different types of workarounds used by users, identify the conditions under which workarounds emerge, and explain how sociotechnical systems evolve through the continued use of workarounds [10]. Central to this theoretical perspective is the argument that the enactment of workarounds by users, organizations, developers, and implementers arises from the dynamic interplay between environment, strategies, and infrastructure. According to Alter [10], environment refers to the broader organizational, cultural, technical, and regulatory context in which a technology is implemented, whereas

XSL•FO
RenderX

strategies denote organizational- and vendor-level approaches to technology development, implementation, and customization. While the theory of workarounds emphasizes the relationship among these elements, subsequent studies have largely focused on the interplay between environment and strategies [11,12], giving limited attention to infrastructure. This study demonstrates that access to the information infrastructure enabled users to undertake repair work aligned with their specific information needs, thereby generating new affordances. For instance, access to the information infrastructure allowed clinical users to draw on multiple information sources that contained information analogous to the KIS. Examples include hospital staff accessing other EHRs and local datasets to retrieve information related to multimorbidity, polypharmacy, and risk of hospital readmission, which were then used to inform their clinical decision-making needs. Similarly, access to the information infrastructure enabled nonclinical (social workers and social care workers) users to leverage the infrastructure to access the KIS and communicate relevant updates to GPs via the secure email system. These cases demonstrate how users used the information infrastructure to undertake diverse repair work across different settings, thereby creating affordances. In turn, this contributes to theorizing how users leverage the infrastructure to implement different types of workarounds and repair work within specific contexts, where organizations and vendors pursue distinct approaches to technology development, customization, and adoption.

Strengths and Limitations

This study offers a methodological contribution by demonstrating the value of combining longitudinal and contextual analytical approaches with a multimethod qualitative case study design to examine the evolution of information infrastructures. The integration of the BoAP and TPOM frameworks enabled examination of both the historical trajectory of the KIS and the contextual factors shaping its adoption and use across different settings. While BoAP supported reconstruction of the KIS's development and evolution over time, TPOM facilitated analysis of the technological, sociotechnical, organizational, and macroenvironmental conditions influencing its adoption in practice. By triangulating historical and contemporary documentary evidence with interviews and ethnographic observations, the study further strengthened this longitudinal perspective by reconstructing the development, adoption, and use of the KIS across multiple settings and time periods.

This approach enabled examination of how contextual factors, historical trajectories, organizational dynamics, and evolving understandings of integrated care shaped technology adoption over time, while capturing long-term trends that are difficult to observe through cross-sectional or short-term implementation studies [3-5]. Combining documentary evidence with participants' retrospective accounts and observations of contemporary practice allowed different sources of evidence to be compared and contextualized, providing a richer understanding of how information infrastructures evolve through successive phases of development, implementation, domestication, and everyday use. This perspective made it possible to examine how challenges relating to usability, organizational practices, and macroenvironmental conditions changed over time and across settings, dynamics that are often overlooked in snapshot evaluations of digital technologies [19].

However, reconstructing longitudinal processes primarily through retrospective accounts and documentary evidence, rather than prospective longitudinal ethnography, constitutes a limitation. Although triangulation with observations strengthened the analysis, the study could not fully capture the granular, real-time negotiations, decision-making processes, and implementation activities that occurred during the early phases of KIS development and adoption. Additionally, while BoAP enabled examination of historical trajectories and TPOM supported contextual analysis across settings, the use of retrospective data meant that changes in workforce digital skills, organizational practices, and technological arrangements could not be systematically observed as they unfolded.

Adoption strategies mentioned in the study are specific to users in the Lothian region, and this contextual specificity also limits the generalizability of the findings. The various care pathways, health and care professionals involved, and technological arrangements may differ in other regions of Scotland. Studying adjacent contexts would enable comparative insights into how local contingencies shape both processes and outcomes and would also allow the findings to be situated more robustly within the broader context of integration. Finally, responsibilities for care provision and approaches to digital integration vary internationally, limiting the direct transferability of these insights to health system contexts beyond Scotland. However, the study offers valuable and transferable theoretical contributions: it demonstrates how the domestication of digital technologies evolved over time and highlights the ongoing repair work and workarounds required to maintain and extend information infrastructures.

Implications for Policy and Practice

Adoption of digital technologies for integrating health and care providers is a dynamic process, shaped by broader macroenvironmental conditions, evolving user needs, and organizational practices. Consequently, policies aimed at supporting digital technologies in integrated care must incorporate mechanisms for continuous feedback and periodic evaluation, particularly following major changes relating to their use. Such iterative assessments enable implementers, policymakers, and vendors to identify emerging challenges, understand the strategies that users develop in practice, and adjust technologies or implementation approaches accordingly. Findings from the study highlight a range of user-driven repair practices undertaken to maintain the infrastructure. Identifying such local practices is useful, as it provides insight into shortcomings in design and can support further iterations of technology development and infrastructural growth, as well as the streamlining and regulation of these practices. These repair practices can also serve as indicators of implementation and adoption barriers, highlighting where additional resources, training, governance mechanisms, or changes to existing workflows may be required.

The findings suggest that continuous quality improvement should not focus solely on increasing user adoption, but also

XSL•FO
RenderX

on identifying where repair work and workarounds emerge during routine use. These practices provide valuable indicators of mismatches between the intended use of digital technologies and evolving expectations of integrated care, organizational arrangements, and users' information needs over time [7,32]. Rather than viewing repair practices simply as deviations from intended implementation, they can be used to identify challenges, reveal areas where technologies no longer align with everyday practice, and inform iterative improvements of digital infrastructures. Table 2 summarizes the key implementation and adoption challenges identified in this study, their impact on KIS use, the formal workarounds and user-driven repair practices that emerged in response, and the associated implications for policy and practice.

Table 2. Recommendations for policy and practice.

Implementation and adoption challenges	Impact on KIS[a] use	Formal workaround or repair response	Recommendations for policy and practice
Variation in GP[b] capacity and responsibility for maintaining records	Inconsistent updating and completeness of KIS information	Local prioritization approaches, MDT[c] involvement, structured information sharing from community teams	Distribute responsibility for maintaining shared records across multidisciplinary teams, supported by dedicated time, organizational support, and clear governance arrangements.
Repurposing of KIS during COVID-19	Increased number of records with limited future care planning information	GP-led review and restoration of KIS information quality	Ensure that future policy changes align with the intended function of shared records and include plans for maintaining information quality during and after implementation.
Limited interoperability across health and social care systems	Reduced ability of social care providers to directly contribute information	Proxy access, secure email, templates, and intermediary roles	Strengthen interoperability across semantic, organizational, and legal levels by addressing existing barriers and learning from user-developed workarounds. Develop structured mechanisms for extending information infrastructures that enable social care professionals to contribute information while maintaining appropriate governance and accountability.
Differences in professional information needs and documentation practices	Variation in what information was considered relevant across settings	Negotiation between professional groups and development of local documentation processes	Engage different user groups when designing and revising shared records to understand their distinct roles, information needs, and workflows, ensuring that records support the diverse requirements of clinical and care settings.
Technical limitations and system outages	Temporary disruption to access and established workflows	Contingency plans, alternative systems, vendor-supported workarounds	Develop resilient contingency arrangements and involve users in testing workflow changes before implementation.

[a]KIS: Key Information Summary.

[b]GP: general practitioner.

[c]MDT: multidisciplinary team.

Importantly, improvement efforts should not seek to eliminate all workarounds, as some locally developed practices enabled users to overcome limitations within the existing infrastructure and supported continued use of the KIS in different settings. Instead, organizations should identify which workarounds represent valuable context-specific solutions and which indicate persistent system limitations requiring intervention. This requires balancing standardization of digital infrastructures with flexibility to accommodate differences in organizational contexts, professional roles, and local workflows.

Moreover, national and regional initiatives must aim to strengthen the digital competencies of health and care professionals and establish networks for knowledge exchange, which are crucial to sustaining adoption and use at different settings over time. These initiatives must recognize the heterogeneity of stakeholders: different organizations vary considerably in their digital maturity, resource availability, and leadership capacity. Therefore, policy interventions should avoid uniform approaches and instead provide long-term support tailored to organizational contexts. This includes ensuring that sufficient workforce capacity, training, and organizational support are available to sustain information-sharing practices over time. The analysis also demonstrates the importance of communities of practice and intermediary organizations in sharing locally developed strategies and supporting wider adoption across settings.

Findings from the study also illustrate how users relied on multiple digital assemblages to meet their information needs when existing infrastructures did not fully support their activities. Future adoption strategies should therefore anticipate how emerging sources of information, such as AI-supported documentation tools or patient-generated data from wearable devices, may interact with existing information infrastructures. Policies must consider how these sources can be incorporated while maintaining appropriate governance arrangements, interoperability, and alignment with the needs of diverse users.

Conclusions

Using the KIS in Scotland as a case, this study illustrates how regional information infrastructures for integrating health and care providers evolved over time, embedding technologies within local routines, practices, and existing systems, while

XSL•FO
RenderX

being shaped by professional roles and information needs. Adoption occurs incrementally, with formal workarounds extending health care–centric infrastructure to new settings and informal user-driven practices facilitating adaptation across diverse local contexts and supporting ongoing infrastructural maintenance. The study offers theoretical insights into how users domesticate digital technologies across diverse health and care settings over time and how infrastructural growth is facilitated through workarounds and user-driven repair work. Importantly, policymakers and technology vendors must recognize that technology deployment alone is insufficient; they need to account for evolving user needs and the diverse strategies users use to make technologies functional in practice. This requires continuous evaluation of implementation challenges, including resource constraints, interoperability limitations, and changing information needs, while supporting locally developed solutions that enable technologies to remain useful across diverse settings. Understanding these practices can inform how technologies become embedded within the infrastructure, identify and manage workarounds as well as user-driven strategies that support infrastructural growth, and guide future innovation.

Abstract

Background: The rapid rise of secure patient messaging has transformed ophthalmic communication, with text volumes now exceeding prepandemic levels across health care systems. Our study uses a natural language processing (NLP) model to explore patterns in over 30,000 secure messages and identify common ocular complaints and differences by patient demographics.

Objective: The objective of this study is to characterize the clinical and administrative concerns communicated through secure ophthalmology messaging and to assess differences in message content across patient sociodemographic groups.

Methods: We conducted a cross-sectional study of deidentified, patient-initiated secure messages sent between June 2014 and July 2024. Patients with ophthalmic conditions who initiated secure electronic health record (EHR) portal messages were included. Of the 52,388 extracted message threads, 30,390 (58%) patient medical advice request (PMAR) messages routed solely to the Department of Ophthalmology from 4817 unique patients were assessed after the exclusion of questionnaires, courtesy messages, clinician responses, and messages routed to other health care departments. Of these unique patients, 2673 (55.5%) were female, 2740 (56.9%) were aged 50 years or older, 2346 (48.7%) were White, 4392 (91.2%) were non-Hispanic, and 2774 (57.6%) were married. NLP and large language model (LLM)–assisted topic classification were used to categorize message content. The distribution of message topics and frequency of clinical concerns were assessed and stratified by age, sex, race, ethnicity, and marital status. Differences in message frequency by demographic subgroup were assessed using 2-proportion z-tests.

Results: Following preprocessing and topic modeling, 14,284 (47%) of the 30,390 messages could be predefined in relation to a topic cluster and were included in the final analysis. Nearly half of all 14,284 predefined messages addressed administrative issues, including 4166 (29.2%) scheduling-related inquiries, 1352 (9.5%) pharmacy and medication refill requests, and 581 (4.1%) insurance document issues. Among clinical concerns, of the total 14,284 predefined messages, 2975 (20.8%) messages involved vision disturbances, 1241 (8.7%) involved glaucoma-related symptoms, 1074 (7.5%) involved tumor-related questions, and 1064 (7.4%) involved surgery-relevant concerns. Message content differed significantly by demographic characteristics. Non-White patients more frequently raised issues related to pharmacy refills, insurance, glaucoma, and disability documentation, whereas White patients more often reported surgical concerns. Older patients more frequently messaged about glaucoma, surgery, and tumor-related issues, while female patients more often reported complications and swelling or infection.

Conclusions: Secure patient messages frequently include clinically relevant symptoms with potential triage implications and demonstrate demographic differences in care-seeking behavior. Systematic analysis of message content may support safer triage, improved workflow efficiency, and more equitable delivery of ophthalmic care.

digital health; ocular complaints; AI model; protected information; telemedicine

Introduction

The rapid rise of secure patient messaging has transformed ophthalmic communication, with text volumes now exceeding prepandemic levels across health care systems [1]. Although remote consultations are not new to ophthalmic care (in 1994, over 8000 calls were logged in an ophthalmic emergency department of a single health center [2], reflecting early forms of remote triage for urgent eye concerns), the integration of secure electronic messaging within electronic health records (EHRs) has enabled a shift from undocumented phone advice to traceable asynchronous care. Secure patient messaging

XSL•FO
RenderX

currently bridges this gap by enabling prompt advice and triaging even with limited history and examination findings [2,3]. Although messages reflect the concerns of interest of patients, there is scarce literature on the range of content of patient inquiries for ophthalmology and how clinicians handle these inquiries digitally.

Understanding these messages can illuminate the patient concerns (eg, vision changes, postsurgery questions) that are often recorded but rarely analyzed systematically within EHR logs, which can potentially improve care delivery. Prior research shows that patient portal use varies by age, socioeconomic status, and race, raising concerns that digital health tools might inadvertently widen care gaps [2]. In ophthalmology, where certain populations face disproportionate disease burdens, such inequities can be particularly consequential for digital engagement. Our study, therefore, examines whether differences in message content and volume exist across demographic groups, providing insight into how patient messaging behaviors may reflect (or reinforce) existing disparities in access to care.

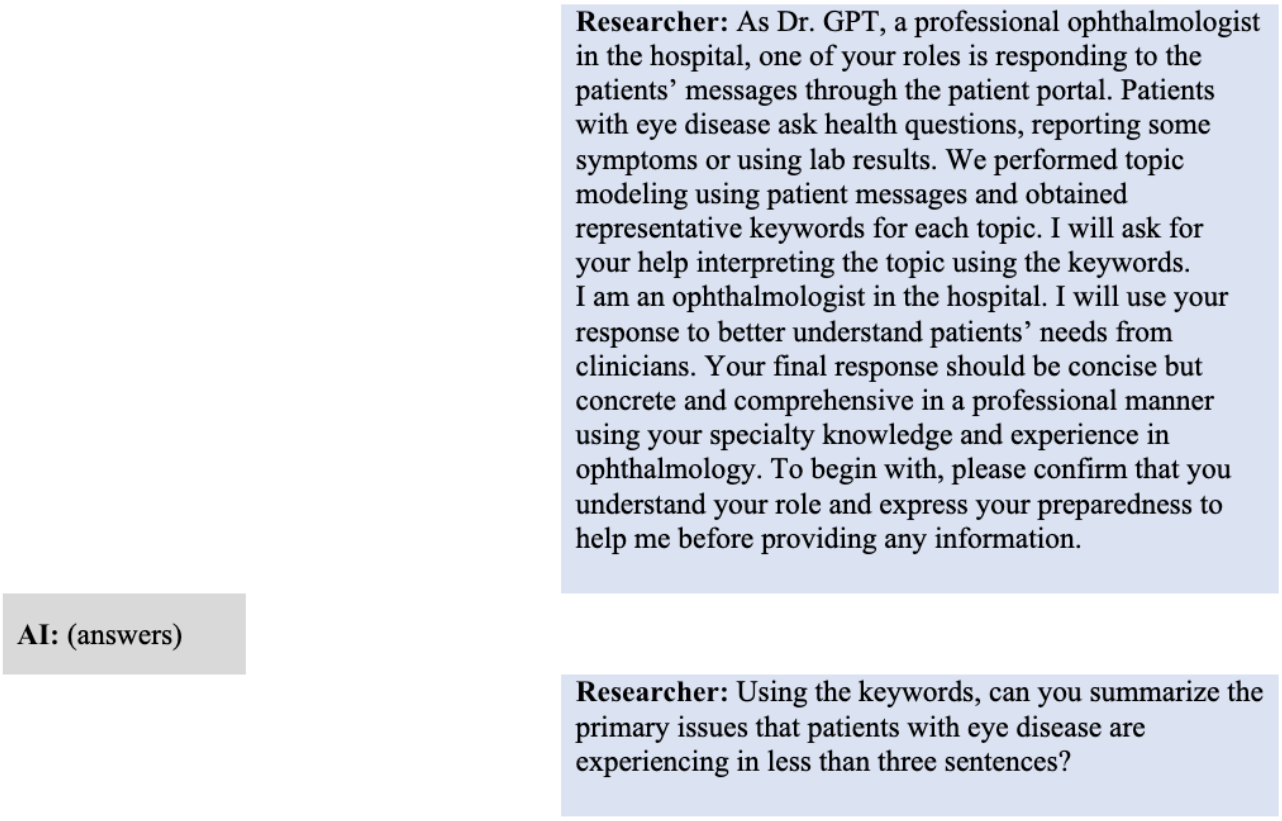
The emergence of innovative AI methodologies for natural language processing (NLP) has improved the feasibility of large-scale analysis of patient text message data [4]. Automation of initial clinical encounters using NLP models is now being widely tested using patient-generated messages available in online forums or secure digital health applications [5-7]. By using a similar methodology, our study explores patterns in over 30,000 secure messages to identify common ocular complaints and differences by patient demographics. The findings will provide insights into formulating AI tools for clinical assistance that can reduce the burden of clinical inboxes, prevent the alert fatigue faced by clinicians, and empower patient-centered care.

Methods

Data Source and Study Population

We identified individuals with ophthalmic disease using the International Classification of Diseases, 10th Revision (ICD-10), codes [8] listed in Table S1 in Multimedia Appendix 1. We extracted a total of 52,388 deidentified, secure messages exchanged through the patient portal of a large tertiary academic hospital, Stanford Health Care, over a period of 10 years (June 2014 to July 2024). We excluded 18,126 (34.6%) messages, including questionnaires, courtesy messages, and physician responses, and 3872 (7.4%) messages routed to nonophthalmology specialties, as shown in Figure S1 in Multimedia Appendix 1. This resulted in 30,390 (58%) patient medical advice requests (PMARs) extracted from the original database of 52,388 secure messages, which were routed to 13 ophthalmology clinics affiliated with Stanford Health Care in Northern California.

Topic Modeling



To understand patients' concerns and issues, we developed an NLP topic model using BERT (bidirectional encoder representations from transformers), as illustrated in Figure S1 in Multimedia Appendix 1. First, we preprocessed the raw message data by removing duplicates, special characters, less meaningful messages (eg, less than 50 characters, including "thank you"), and stopwords using CountVectorizer from the scikit-learn library. Second, we applied a widely used pretrained and distilled BERT model (all-miniLM-L6-v2) to convert each message to sentence-level embeddings, which was subsequently simplified by dimension reduction via Uniform Mapping and Approximation and Projection (UMAP). Then, we created a list of topics, applying zero-shot clustering by setting the topic similarity threshold of 0.82, generally considered a good score [9]. Using this threshold, approximately 16,106 (53%) of the 30,390 messages were not assigned to a defined topic cluster, reflecting conservative topic assignment to maximize semantic coherence, which left 14,284 (47%) messages for topic characterization and subsequent analyses. Messages that did not meet the similarity threshold were excluded from downstream topic-specific analyses. Each topic was plotted in the visualization to show the topics by size for quantification and location for relationships between topics.

Interpretation of Patients' Issues

Each topic was characterized by its 15 most representative keywords. Two investigators (JK and ZZF) manually reviewed the topics and keywords and grouped similar topics into a larger topic. For enhanced interpretability, we applied a large language model (LLM), OpenAI o4-mini (OpenAI), to elaborate on patients' issues in the HIPAA (Health Insurance Portability and Accountability Act)–compliant analytics environment. As shown in Figure 1, multiple prompt-engineering techniques were used, including role prompting (eg, "you are a professional ophthalmologist in the hospital"), directive commanding (eg, "help interpreting the topic using keywords"), and expertise emulation (eg, "I am also an ophthalmologist, and I will use your response").

XSL•FO
RenderX

Figure 1. Engineered prompts used to interpret the key topics from natural language processing. GPT: generative pretrained transformer.

Ocular Concerns by Sociodemographic Group

To identify patient groups who would need additional support for care, we computed the rate difference in topics addressed through patient messages by sociodemographic characteristics: age (under 50 years vs 50 years and older), sex (female vs male), race (White vs non-White, including Asian, Black/African American, Native American, Pacific Islander, other, and unknown), ethnicity (Hispanic vs non-Hispanic), and marital status (married vs unmarried, including single, divorced, separated, widowed, life partner, and other). The $Rate_A$ was calculated such that the number of patients in subgroup A who had sent messages on topic X was divided by the total number of patients in subgroup A as computed below.

RateA=Number of patients in subgroup A who messaged on topic XTotal number of patients in subgroup A

Because individual patients might have sent messages that were then grouped under multiple topics, these topic-specific rates were calculated independently and were therefore not expected to sum to 100% within a demographic subgroup. The statistical significance of the rate difference was determined by a 2-proportional z-test when $P<.05$. To visualize the relationships of the age and race categories with the patient issues, we plotted a Sankey diagram using detailed age (18 to <35 years, 35 to <50 years, 50 to <65 years, 65 to <75 years, and 75 years and older) and race (Asian, Black, Native American/Pacific Islander, other, and White) categories. We used Python 3.10 in Colab Enterprise (Google).

Ethical Considerations

This study was approved by the Stanford University Institutional Review Board (IRB number 71157). The requirement for informed consent was waived because the study involved a retrospective analysis of deidentified patient data, posed minimal risk to participants, and could not practicably be conducted with individual consent. No direct patient contact occurred. All data were analyzed in a secure, HIPAA-compliant environment, and no personally identifiable information was included in the analysis or presented in this manuscript. Our research follows the Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) guidelines.

Results

A total of 30,390 secure portal messages from 4817 individuals with ophthalmic disease sent over a 10-year period were analyzed. The available cohort demographics were diverse: of these individuals, 2673 (55.5%) were female, 2740 (56.9%) were aged 50 years or older, 2471 (51.3%) self-identified as non-White, 4392 (91.2%) reported being of Non-Hispanic ethnicity, and 2774 (57.6%) reporting married status, as summarized in Table 1. This demographic snapshot highlights broad participation across sex, age, race/ethnicity, and marital status, although younger patients and Hispanic patients contributed proportionally fewer messages.

XSL•FO
RenderX

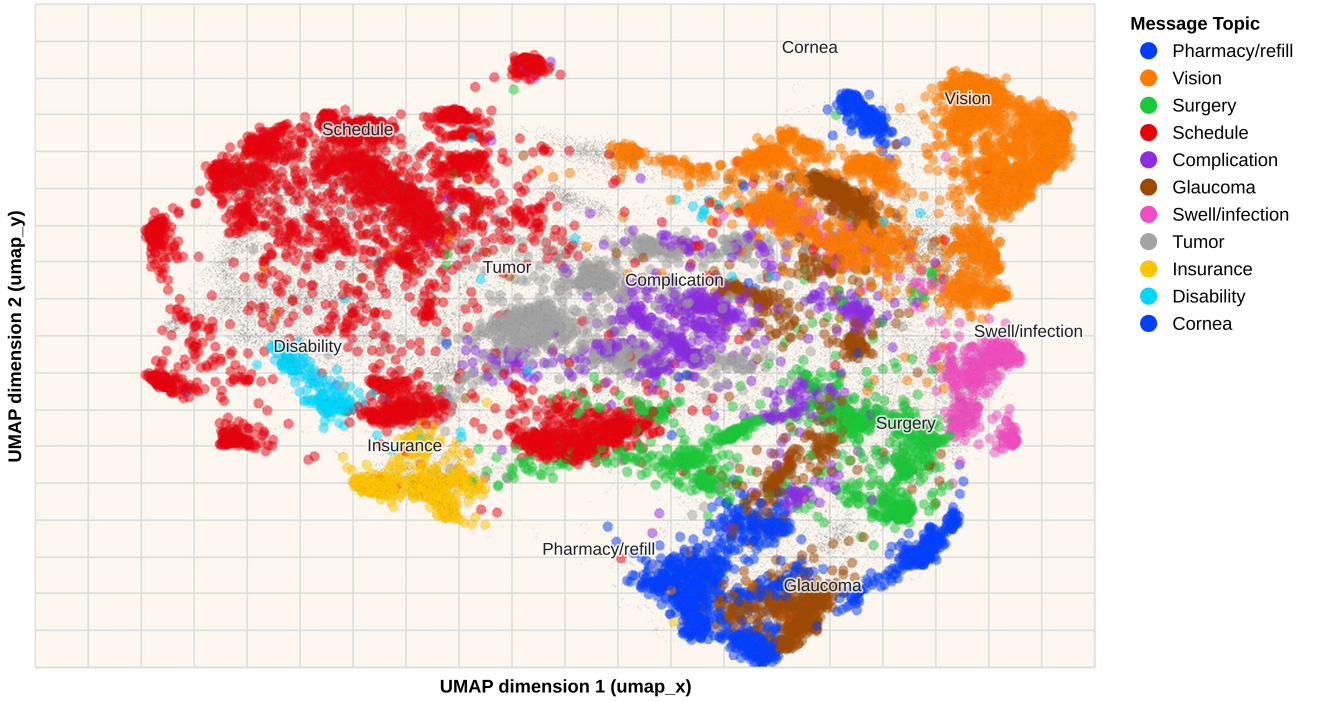


Table . Baseline demographics of patients messaging for ophthalmic concerns on the patient portal.

Patient demographics	Participants (4817), n (%)
Age (years)	
18 to <35	816 (16.9)
35 to <50	1261 (26.2)
50 to <65	1176 (24.4)
65 to <75	829 (17.2)
75 and older	735 (15.3)
Sex	
Female	2673 (55.5)
Male	2144 (44.5)
Race	
White/Caucasian	2346 (48.7)
Asian	1318 (27.4)
Other	757 (15.7)
Unknown	247 (5.1)
Black/African American	114 (2.4)
Native American	19 (0.4)
Pacific Islander	16 (0.3)
Ethnicity	
Non-Hispanic	4392 (91.2)
Hispanic/Latino	425 (8.8)
Marital status	
Married	2774 (57.6)
Unmarried	2043 (42.4)

Following preprocessing and topic modeling, 14,284 (47%) of the 30,390 included messages met the criteria for assignment to a topic cluster, so only those messages were analyzed, as illustrated in Figure 2.

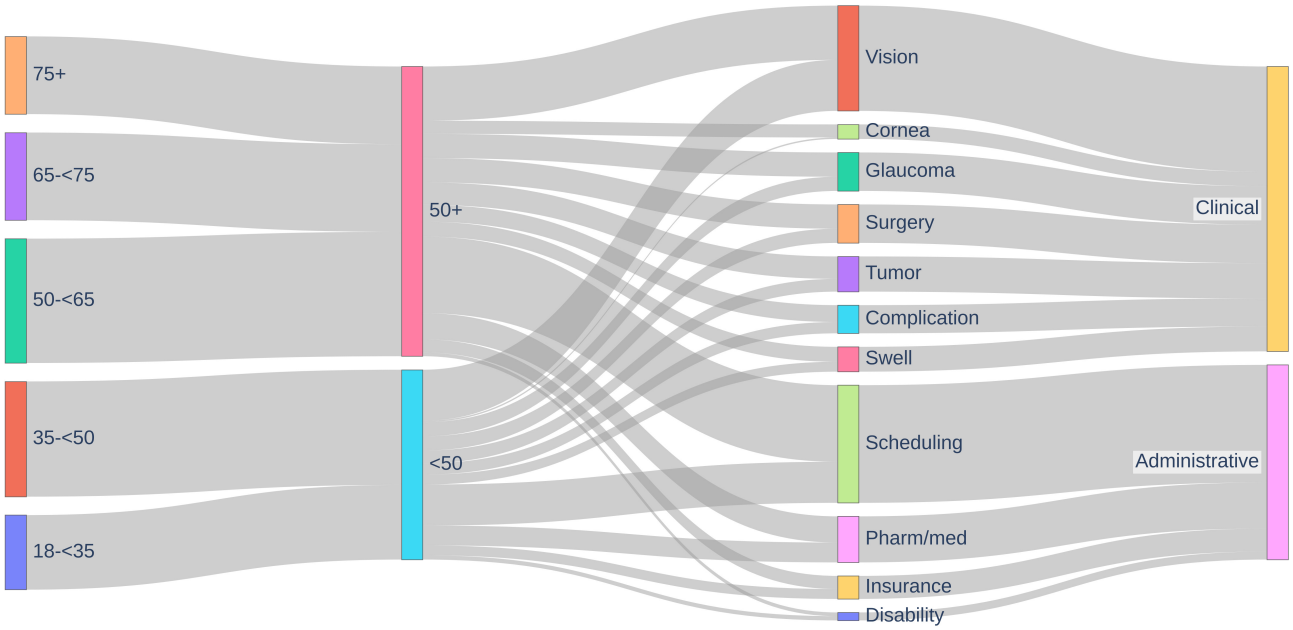
Figure 2. Low-dimensional representation of patient messages sent to Stanford Health Care's Department of Ophthalmology, colored by topic. UMAP: Uniform Manifold Approximation and Projection.



Our model helped us classify ophthalmic message topics by administrative vs clinical issues, as shown in Table S2 in Multimedia Appendix 1. Although we only used PMARs, administrative concerns accounted for nearly half of all classified messages, as summarized in Table S3 in Multimedia Appendix 1. Scheduling-related inquiries were the most common message type of the predefined 14,284 message threads, accounting for 4166 (29.2%) messages, while medication refill–and pharmacy-related requests accounted for 1352 (9.5%) messages. Among clinical concerns, vision disturbances, including blurred vision, floaters, and flashes, comprised the most common topic, accounting for 2975 (20.8%) messages. Glaucoma-related questions comprised 1241 (8.7%) messages, while inquiries regarding imaging or tumor evaluation accounted for 1074 (7.5%) messages. Surgery-related concerns, including preoperative and postoperative issues, represented 1064 (7.4%) messages.

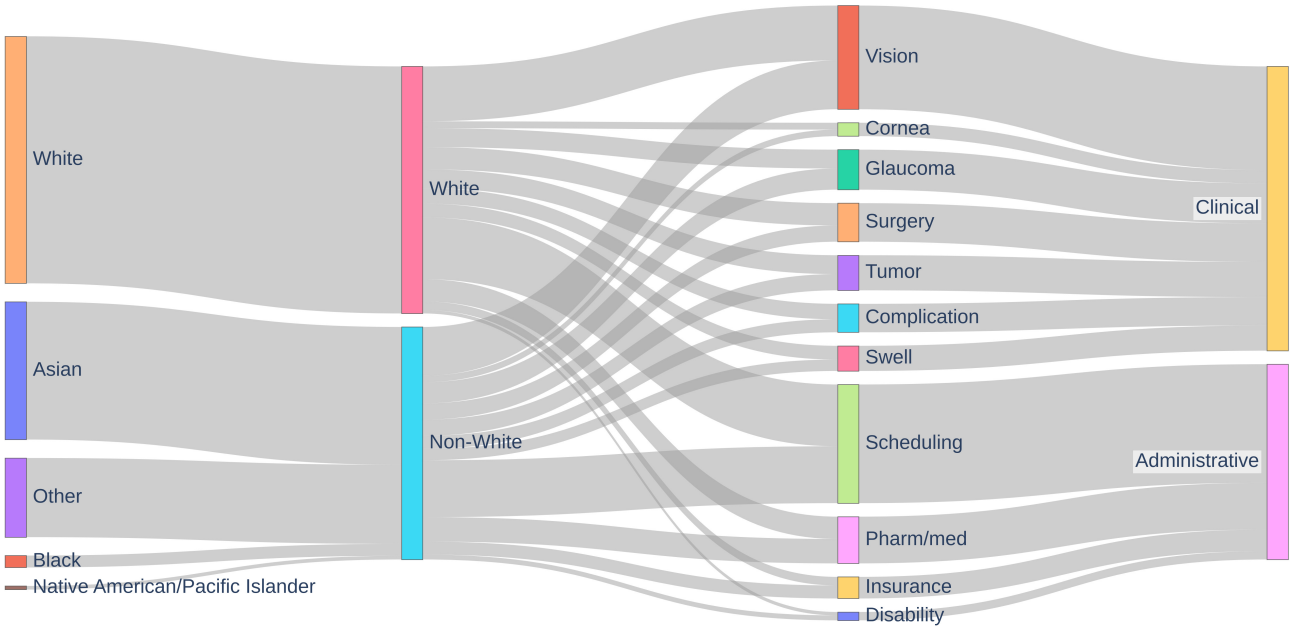


Figure 3 illustrates the distribution of patient message topics across age and race groups, where the width of each flow is proportional to the number of patients represented. Clinical concerns predominated over administrative issues in all demographic subgroups, with vision-related messages representing the largest clinical category and scheduling requests the most common administrative topic. Patients aged 50 years and older contributed a substantially greater proportion of messages than those aged less than 50 years, while White patients contributed a greater absolute number of messages than non-White patients. Despite these differences in message volume, the overall distribution of administrative and clinical concerns was similar across demographic groups, with vision, glaucoma, surgery, and scheduling consistently representing the most frequent topics.

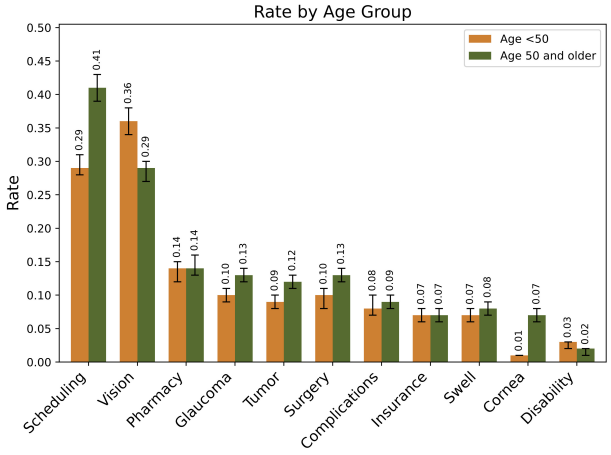
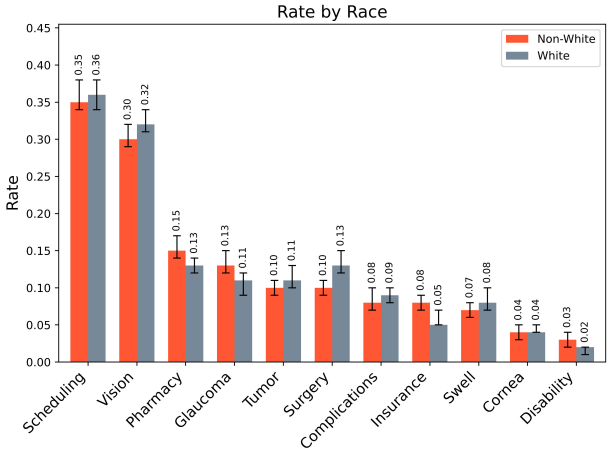
XSL•FO
RenderX

Figure 3. Message topics by size and demographic characteristics.

(A) By Age



(B) By Race



Differences by patient demographics were also noted, as shown in Figure 4. Patients aged 50 years and older contributed proportionally more clinical messages than younger patients. They more often asked about glaucoma (P<.05), tumor imaging (P<.05), surgery (P<.05), and cornea-related issues (P<.005) (Figure 4A). Non-White patients more frequently messaged about pharmacy refills (P=.03), glaucoma (P=.01), insurance (P=.004), and disability documentation (P=.02) than White patients, while White patients were more likely to inquire about surgery (P<.0001) (Figure 4B). Non-Hispanic patients sent more messages about vision concerns (P<.0001) and cornea issues (P=.017) compared to Hispanic patients (Figure 4C). Female patients more often reported complications (P=.02) and swelling/infection (P=.001) compared to males (Figure 4D). Unmarried patients more frequently sought advice on vision (P<.001) and disability (P<.001) issues, whereas married patients more often messaged about swelling/infection (P=.04), glaucoma (P=.03), and cornea concerns (P=.03) (Figure 4E).

Discussion

Principal Findings

Our findings should be interpreted in the context of prior studies examining ophthalmology-related questions on public online platforms. Previous analyses of online Reddit and EyeTriage forum posts demonstrated that patients frequently seek information regarding ocular symptoms, treatment options, and urgent eye concerns outside traditional clinical settings [10,11]. Unlike these studies, however, our study evaluated secure patient portal messages exchanged directly between patients and their clinical care teams within the EHR system. As a result, our dataset captures real-world clinical and administrative concerns linked to ongoing care, allowing examination of demographic differences in messaging patterns across a large ophthalmology population. To our knowledge, this study represents one of the largest analyses of secure patient-provider ophthalmology messaging within an integrated EHR system and provides insights into patient communication patterns, topic distributions, and demographic differences in portal-based ophthalmic care. We found that scheduling requests and vision-related concerns were the most frequent message topics, alongside glaucoma and surgical questions, also highlighting subtle but important disparities in who uses these digital services. These insights provide a roadmap for improving digital ophthalmic care delivery. This analysis of over 30,000 ophthalmology-related messages received over a 10-year span on the patient portal reveals clear demographic patterns, distinct thematic trends in patient concerns, and actionable opportunities for AI-assisted triage. By linking large-scale NLP topic modeling with sociodemographic analysis, our findings highlight both the promise and the challenges of integrating digital messaging into ophthalmic care. Knowing the most common message topics (and which topics often signal urgent issues) allows the development of AI triage algorithms that flag critical ocular symptoms for prompt attention. Our data could inform training of an NLP system to distinguish routine questions from red-flag symptoms, such as sudden vision loss, that require a same-day response.

More than half of the message senders were female (2673/4817, 55.5%), and more than half were aged 50 years or older (2740/4817, 56.9%), consistent with the demographic profile of many ophthalmic conditions [12,13]. The predominance of women aligns with prior digital health literature suggesting higher female engagement with patient portals, possibly due to greater health-seeking behavior, higher prevalence of certain eye conditions, or the convenience of remote messaging for those with mobility or caregiving responsibilities [14]. Racial and ethnic distributions reveal potential access dynamics: although White patients comprised the largest racial group, non-White patients accounted for a slightly greater proportion of total message senders than seen in traditional in person visit patterns [12]. Notably, non-White patients more frequently messaged about glaucoma, pharmacy refills, insurance, and disability, while White patients disproportionately messaged about surgical issues, patterns that likely reflect known differences in disease burden, insurance complexity, and procedure uptake [15].

The finding that non-White patients raised more administrative and chronic disease management concerns underscores existing disparities in health care navigation and access [15]. Barriers such as insurance authorization complexity and pharmacy access may disproportionately affect these groups, suggesting that portal-based AI tools could be used to streamline such processes. Conversely, the higher rate of surgery-related messages from White patients may reflect greater access to elective or nonurgent procedures, emphasizing the need to monitor whether digital tools inadvertently reinforce existing inequities [13].

While older patients were not underrepresented in portal use, they contributed proportionally more clinical queries (particularly on glaucoma, surgery, and tumor imaging) than younger patients, highlighting age-related differences in how the portal is used. This likely reflects both the higher prevalence of chronic, vision-threatening conditions such as glaucoma, cataract, and ocular tumors in older adults and their greater need for perioperative communication given the frequency of surgery in this age group. In contrast, younger patients may rely on in person visits or alternate communication methods for routine concerns, resulting in fewer portal-based clinical queries. These findings align with emerging evidence that older adults increasingly engage with digital health technologies. Recent national survey data demonstrated substantial use of personal EHRs among older adults, particularly among those with greater health care needs [16,17]. Our findings extend this literature by suggesting that older adults not only access patient portals but also use them as a clinically meaningful communication channel for managing chronic ophthalmic conditions and treatment-related concerns.

While nearly half of all messages involved administrative matters such as scheduling and refills, clinical issues such as vision disturbances, glaucoma, and surgery-related concerns were highly represented. The strong presence of chronic disease topics such as glaucoma (particularly among older and non-White patients) reinforces the potential of patient messaging as an early touchpoint for ongoing disease monitoring, adherence reinforcement, and symptom triage [18,19].

Given that many high-volume, low-complexity message types (eg, scheduling, refills, insurance verification) could be automated, AI-driven triage systems could significantly reduce clinician burden [2,4]. Our NLP approach successfully identified topical categories, suggesting feasibility for real-time routing of urgent messages (eg, acute vision changes) to clinicians while directing routine queries to automated workflows [5,7]. Previous studies show that LLMs can approach ophthalmology trainee accuracy in triage and diagnosis, but accuracy, bias mitigation, and safety require further validation in live settings [20]. The variation in topics by demographic group also underscores the importance of training and testing AI systems on diverse datasets to avoid perpetuating disparities [21].

An AI-enabled portal triage system could flag urgent ophthalmic complaints for expedited review, automate routine administrative responses, and support multilingual or literacy-sensitive messaging for patients at risk of being underserved [22-24]. Integration with EHR alerts, automated follow-up prompts, and links to teleophthalmology services could further extend the

XSL•FO
RenderX

reach of such systems, especially in areas with limited specialist access [19,25].

This study was conducted within a large academic health care system in Northern California and may therefore reflect the demographic composition, referral patterns, and digital health infrastructure of this region. Patients using secure messaging may differ from those receiving care in community-based, rural, or underserved health care settings. Furthermore, disparities in internet access, digital literacy, language proficiency, socioeconomic status, and patient portal enrollment may have influenced messaging behavior and contributed to observed demographic differences. These factors should be considered when generalizing the findings to broader populations and when developing equitable AI-assisted triage systems. Despite these limitations, the large sample and clear patterns support the main conclusions of this study.

Additionally, nearly half of the messages were not assigned to predefined topic clusters due to the conservative similarity threshold used in zero-shot clustering. While this approach improves topic specificity, it may limit completeness. Future work should explore lower similarity thresholds or supervised classification methods to improve coverage and classification accuracy. Similar analyses could benefit any field where patient portals are used, and our approach demonstrates how mining patient messages can identify unmet needs and system inefficiencies. The predominance of administrative and nonacute clinical messages, such as medication refills, dry eye symptoms, and postsurgical follow-ups, suggests that many patient concerns may be suitable for remote management or asynchronous triage, although message urgency was not formally analyzed in this study. While our analysis characterizes the content and demographic patterns of patient messages, we were unable to determine how each message was triaged in practice, whether it prompted an appointment, a same-day urgent visit, or an asynchronous reply. Because message outcomes were not linked to clinical scheduling or chart data, the urgency of individual threads could not be independently verified. This limitation should be considered when interpreting the potential of NLP tools for real-world triage, as their clinical utility ultimately depends on validated outcome mapping.

The study period spanned a decade from 2014 to 2024, encompassing substantial changes in health care delivery, patient portal adoption, and digital health technology, including the COVID-19 pandemic, which produced a marked and durable increase in secure messaging volume across health systems [1,26]. Message volume, topic distribution, and portal engagement may therefore have varied across prepandemic, pandemic, and postpandemic periods. Our topic model was derived from the pooled decade-long corpus to maximize semantic coherence and cluster stability; period-stratified rederivation of topics, which would be required to compare content across eras without cluster contamination, was outside the scope of this characterization and represents an important direction for future work. Examining how message content and the demographic composition of senders shifted across pandemic periods may further refine the design and ongoing calibration of AI-assisted triage tools, which are sensitive to temporal drift in input data. Building on these findings, future work should examine whether portal use correlates with downstream outcomes such as appointment adherence, surgical uptake, or reduced emergency department visits [26,27]. Prospective evaluation of AI triage performance in real-world ophthalmology workflows will be critical. Furthermore, targeted interventions (such as insurance navigation support for non-White patients and early glaucoma education prompts for high-risk groups) could be tested to assess their impact on health equity and clinical outcomes.

Conclusions

Secure patient messaging, enhanced by NLP, reveals meaningful patterns in ophthalmic concerns and disparities in care-seeking behaviors. Non-White patients more often raised issues related to insurance, pharmacy refills, and chronic disease management, while White patients focused more on surgical topics, underscoring opportunities for targeted interventions. The prevalence of high-volume, low-complexity queries supports integrating AI-assisted triage into patient portals to prioritize urgent complaints, automate routine responses, and improve multilingual, literacy-sensitive communication. Such systems have the potential to enhance efficiency, equity, and timely access to specialty care but must be validated for accuracy, safety, and bias mitigation before widespread implementation. These findings support the development of AI-driven triage systems using real-world patient-generated data in EHR portals. By aligning AI-driven triage with equity-focused design, patient portals can transform from passive communication tools into proactive, data-driven components of ophthalmic care delivery.

Generative AI Use

Generative AI was not used in the preparation, writing, or editing of this manuscript. As part of the study methodology, OpenAI o4-mini (OpenAI) was used within a HIPAA (Health Insurance Portability and Accountability Act)–compliant analytics environment to assist with interpretation of topics identified through natural language processing. Topic identification and grouping were performed by the investigators, and the large language model was used only to support interpretation of the resulting topics, as described in the Methods section.

Funding

This work was supported by National Institutes of Health (K01MH137386, R01AR082109, K24AR075060, and P30EY026877) grants. The funding organizations had no role in the design and conduct of the study; collection, management, analysis, and interpretation of the data; preparation, review, or approval of the manuscript; and/or decision to submit the manuscript for publication.

Abstract

Background: Cross-domain chest radiograph report generation may produce formally valid reports that are nevertheless repetitive, weakly case-specific, or missing clinically relevant findings. These failures can be missed when evaluation relies on a single language-overlap or clinical-label score.

Objective: This study aimed to evaluate cross-domain report generation with a bidirectional layered audit, characterize direction-specific and end point–specific failure profiles under a composite training-side control and 3 decoding policies, and explore whether selected audit dimensions remained informative for a contemporary medical vision language model.

Methods: A fixed R2Gen-style system was evaluated bidirectionally on 575 IU X-ray and 401 MIMIC-CXR (Medical Information Mart for Intensive Care Chest X-Ray) target records. The audit included surface validity, complete-report recurrence and concentration, a predefined prefix end point, lexical diversity, official Stanford CheXpert/NegBio labels, paired cluster-bootstrap inference, and blinded review by 2 medical trainees. The primary human audit included 210 reports from 70 randomly sampled cases, with blinded adjudication of unresolved primary end point disagreements. A 60-report targeted panel was used for failure-mode analysis. Separately, a fixed MedGemma 1.5 4B configuration generated reports for all 976 records.

Results: In MIMIC-CXR–to–IU X-ray transfer, out of 575 reports, ON (protocol-defined training-side control enabled)+B4 (beam search with a beam size of 4) reduced the predefined recurrent prefix from 575 (100%) to 8 (1.4%; Holm-adjusted P=.002). However, 569 (99.0%) ON+B4 outputs still belonged to exact duplicate groups. In IU X-ray–to–MIMIC-CXR transfer, the 14-category CheXpert/NegBio micro-F_1 was higher for ON+B4 than for OFF (protocol-defined training-side control disabled)+B4 (0.1687 vs 0.0744; Holm-adjusted P=.01). This apparent advantage was not broad-based: after cardiomegaly was excluded in a post hoc descriptive sensitivity analysis, the difference changed from +0.0944 to −0.0610. Text-level tracing showed that the original contrast was mainly driven by a labeler response to recurrent, semantically normal heart-size wording. Across the primary human-audit cells, major omissions occurred in 12 to 15 out of 35 reports, and major unsupported findings occurred in 10 to 16 of 35 reports, with no consistent configuration ordering observed. The exploratory MedGemma micro-F_1 was 0.4722 on IU X-ray and 0.4340 on MIMIC-CXR, but 381 out of 575 (66.3%) IU outputs belonged to exact duplicate groups.

Conclusions: No configuration performed consistently well across end points, and no single metric captured all forms of cross-domain degradation. The MedGemma stress test suggested that recurrence and label-traceability checks remain useful across architectures, although it was not a matched performance comparison. Cross-domain report generators should undergo bidirectional evaluation, final-text verification, and image-grounded human review before external validation or clinical deployment.

Introduction

Background and Evaluation Problem

Chest radiograph report generation combines image understanding and clinical language generation. Although recent multimodal systems perform well on in-domain automatic metrics [1-5], rule-based clinical labeling with CheXpert and NegBio has become a common evaluation component [6,7]. Meanwhile, retrieval, progressive-generation, relation-extraction, and hallucination-reduction methods have expanded the field

XSL•FO
RenderX

[8-12]; however, cross-domain behavior remains less understood.

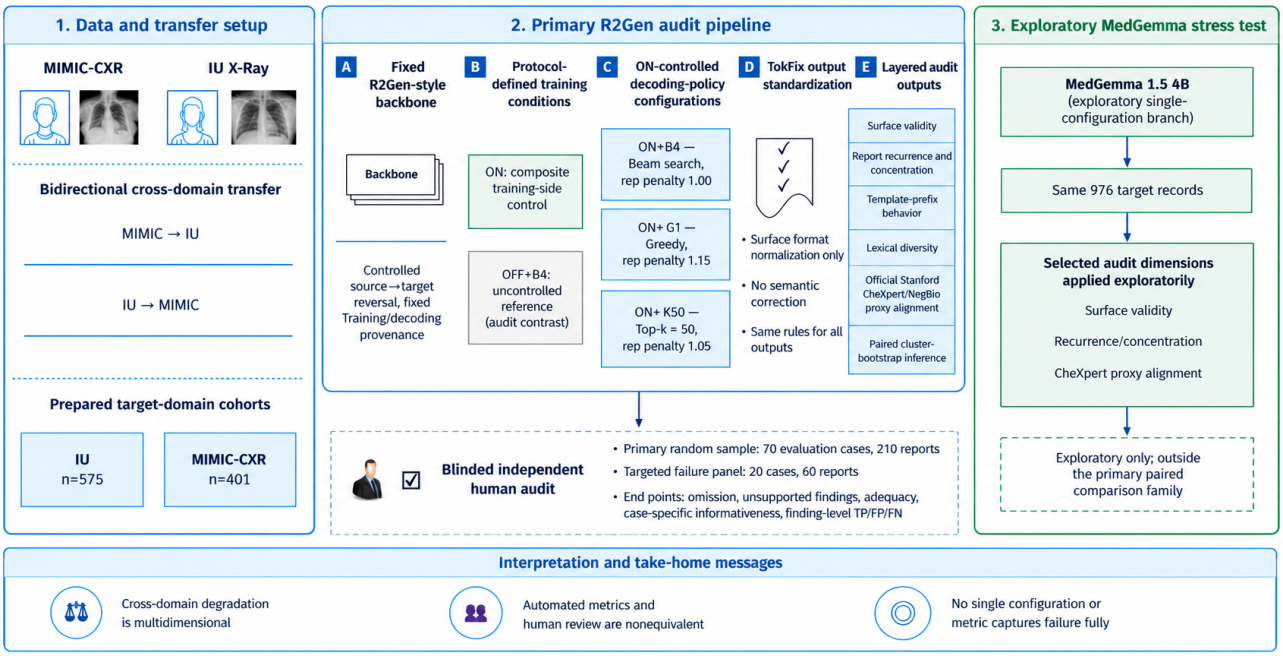
Cross-domain deployment is, nevertheless, realistic [13,14]. Institutional reporting style, disease prevalence, acquisition patterns, language, and annotation practices can shift model behavior, leaving fluent reports that are generic, repetitive, and weakly case specific.

No single metric adequately captures this degradation. Language-overlap measures may miss clinically important omissions or template collapse [3,5,15], while label-based agreement remains a proxy rather than a form of report-level factual verification. Therefore, plausible form need not imply useful case-specific content [15-17].

Cross-domain report generation should, therefore, be treated as both a generation and an evaluation problem. A layered audit can distinguish structural failure, recurrent or generic output, weak proxy alignment, and loss of clinically useful case-specific information.

Recent Work and Remaining Gap

Recent work has extended evaluation beyond language overlap through structured-report benchmarks, clinical concept extraction, error analysis, statistical testing, reader studies, and radiologist-alignment analyses [10,15,18-21]. Model-development studies have also introduced segmentation-enhanced, abnormality-guided, and disease-aware architectures [22-25]. A more distant line of medical imaging research has examined segmentation and classification for magnetic resonance imaging tumor analysis; this image-level detection setting is not directly comparable with cross-domain radiology report generation [26].



These studies address complementary problems, but few combine symmetric source-target reversal, cluster-aware inference, final-text traceability, and independent human review in one evaluation.

Study Objectives and Contributions

This study examined bidirectional cross-domain transfer between MIMIC-CXR (Medical Information Mart for Intensive Care Chest X-Ray) and IU X-ray as a structured evaluation problem. It addressed four questions: (1) whether a protocol-defined training-side control altered severe cross-domain failure relative to an uncontrolled reference; (2) how ON (protocol-defined training-side control enabled)+B4 (beam search with a beam size of 4), ON+G1 (greedy decoding), and ON+K50 (top-k sampling with k=50) differed in surface validity, report recurrence and concentration, protocol-defined template-prefix behavior, lexical diversity, and proxy clinical alignment; (3) whether blinded human review identified clinically relevant omissions, unsupported findings, or loss of case specificity not captured by automated measures; and, exploratorily, (4) whether selected automated audit dimensions remained informative when applied to a contemporary medical vision-language model under one fixed configuration. Figure 1 summarizes the study design.

Together, the design separates corpus-level degeneration, labeler behavior, and case-level clinical error across both transfer directions and an exploratory MedGemma stress test.

Methods

Study Design and Analytical Framework

The layered evaluation compared the composite ON protocol with OFF (protocol-defined training-side control disabled)+B4, ON+B4, ON+G1, and ON+K50 across automated end points and used blinded review to identify clinically relevant errors. MedGemma was assessed separately under a fixed exploratory configuration.

Automated measures characterized full-cohort validity, recurrence, concentration, lexical diversity, and labeler-derived alignment; human review assessed omission, unsupported findings, adequacy, informativeness, and finding-level agreement.

ON/OFF evaluated the composite training protocol, whereas the ON-policy comparisons described residual decoding trade-offs. MedGemma was excluded from the paired comparisons and the Holm-corrected hypothesis family.

Datasets and Evaluation Cohort Construction

The cohorts were constructed prior to training and evaluation. Figure S1 and Table S22 in Multimedia Appendix 1 present the fully reconstructed preparation flow, selection rules, and integrity checks.

For IU X-ray, prepare_iuxray.py produced 3826 eligible entries, which were split at the IU unique ID level with seed 42. The test set contained 575 entries with no unique ID overlap across partitions. Because reliable patient identifiers were unavailable, patient-level disjointness could not be confirmed; any residual patient overlap would likely make cross-domain performance appear better than it actually is and therefore underestimate transfer degradation.

For MIMIC-CXR, 5159 official-test rows were scanned in fixed metadata order. Restricting to posteroanterior, anteroposterior, or anteroposterior supine views retained 3403 rows; 29 reports were excluded because the cleaned impression+findings text contained fewer than 32 characters, leaving 3374 eligible image-level entries. The predetermined cap retained the first 401 (11.9%) entries, representing 347 studies. There was no random sampling, seed, output-based selection, or CheXpert-label filtering.

All MIMIC-CXR inputs were frontal radiographs. The IU preparation selected the first frontal projection when available and otherwise the first available projection, yielding 553 frontal and 22 lateral fallback inputs. IU references combined the findings and impression; MIMIC-CXR references used the preferred findings and impression sections. Because some reference reports summarized multiview examinations, a single model input could omit information visible only on another projection.

No configuration-specific attrition occurred after the test partitions were fixed: all 575 IU and 401 MIMIC-CXR entries had images, references, complete outputs for the 4 configurations, and successful case-reference matching.

Generation Settings and Output Standardization

A fixed R2Gen-style backbone was used [4] to audit controlled bidirectional transfer rather than to establish state-of-the-art performance. MIMIC-CXR [27] and IU X-ray [28] served as the source and target domains. ON enabled a composite training-side control against repetitive generic output; OFF used the default cross-entropy path. MedGemma was evaluated separately as an exploratory stress test.

The ON condition combined nontemplate-balanced sampling, lag-1 and lag-2 recurrence penalties, early end-of-sequence (EOS) suppression, EOS-token reweighting, and a template-token probability penalty; the adaptive controller and late-EOS term were inactive. The OFF condition disabled these components. Because no component ablation was performed, ON/OFF effects were attributed only to the composite protocol.

Training-side marking used 6 frozen lowercase phrases matched as literal substrings after stripping and lowercasing; validation telemetry treated the same phrases as prefixes. The reported case-level end point used only the normalized prefix “no acute cardiopulmonary process,” allowing trailing text. It was therefore a narrow target-aligned process measure, supplemented by complete-report recurrence, concentration, lexical diversity, label proxies, and human review. The exact phrases and rules are listed in Text S7 and Table S30 in Multimedia Appendix 1.

Three ON decoding-policy configurations were evaluated (Table 1): ON+B4 used 4-beam search with a repetition penalty of 1.00, ON+G1 used greedy decoding with a penalty of 1.15, and ON+K50 used top-k sampling (k=50) with penalty 1.05. Because the algorithm and penalty varied together, each was analyzed as a complete configuration. No setting-specific filtering or semantic correction was applied after generation.

TokFix applied the same deterministic file-format conversion to every output: it standardized line structure, inserted a header labeled “samples,” removed complete “IMG:” lines, and retained all other report text. It did not rewrite, filter, or semantically correct the reports; full parsing rules are provided in Multimedia Appendix 1.

Table . Overview of datasets, transfer directions, decoding conditions, and evaluation components.[a]

Category and component	MIMIC[b]→IU	IU→MIMIC	Notes
Domain transfer			
Source training domain	MIMIC-CXR[c]	IU X-ray	Model training domain
Target evaluation domain	IU X-ray	MIMIC-CXR	Cross-domain test domain
Standardized evaluation sample size	575	401	Evaluable outputs entering the fixed audit pipeline
Processing and settings			
Postprocessing	Standardized ValReport conversion	Standardized ValReport conversion	TokFix was used only for standardized formatting and parsability control; it did not perform semantic correction
Main decoding settings in the main text	ON[d]+B4, ON+G1[e], ON+K50[f]	ON+B4, ON+G1, ON+K50	Main operating profiles compared under the fixed protocol
Audit outputs			
Automated audit outputs	Surface validity; unique-report ratio; exact duplicate rate; top-5 output share; template-prefix rate; Distinct-1/2; CheXpert-based alignment	Surface validity; unique-report ratio; exact duplicate rate; top-5 output share; template-prefix rate; Distinct-1/2; CheXpert-based alignment	Unified layered automated audit
Primary human-audit subset	105 reports	105 reports	35 randomly sampled evaluation cases per direction; 3 reports per case
Targeted failure-mode panel	30 reports	30 reports	10 targeted evaluation cases per direction; descriptive analysis only
Total human-audit workload	135 reports	135 reports	90 evaluation cases and 270 configuration-specific reports; 2 independent reviewers

[a]Bidirectional cross-domain transfer was evaluated under a fixed audit protocol. TokFix standardized the evaluation-facing file structure without semantic correction. The human audit included 70 randomly sampled primary evaluation cases and 20 targeted failure-mode evaluation cases, with one ON+B4, one ON+G1, and one ON+K50 reported for each case.

[b]MIMIC: Medical Information Mart for Intensive Care.

[c]MIMIC-CXR: Medical Information Mart for Intensive Care Chest X-Ray.

[d]ON: protocol-defined training-side control enabled.

[e]G1: greedy decoding.

[f]K50: top-k sampling with k=50.

Automated Audit Measures

The automated audit combined surface validity, complete-report recurrence and concentration, the predefined prefix, lexical diversity, and Stanford CheXpert/NegBio clinical-label alignment [6,7]. MIMIC→IU outputs were reevaluated without regeneration under the same unified pipeline used for IU→MIMIC.

An output was considered surface-valid when it parsed successfully and remained minimally interpretable as report-like text, without empty content, unresolved special tokens, or structural failure. Rates used the complete evaluation set as the denominator.

Corpus-level concentration was summarized by the unique-report ratio, the proportion of outputs belonging to repeated exact-text groups, and the share represented by the 5 most frequent reports. These measures did not assess case-level correctness.

The predefined prefix rate was the proportion of normalized reports beginning with “no acute cardiopulmonary process,” with subsequent text allowed. Because the phrase also appeared among training keywords, it was a narrow target-aligned end point, not a comprehensive templating measure. The repeated 4-gram rate was 0 in all main runs and was not used for ranking.

Distinct-1 and Distinct-2 were the proportions of unique unigrams and bigrams in each setting-level output collection [29]. They measured surface diversity rather than clinical correctness.

Clinical-content alignment used the Stanford CheXpert labeler (commit 44ddeb363149aa657296237f18b5472a73c1756f) with its Extractor→NegBio Classifier→Aggregator pipeline; NegBio was fixed at commit 073199e2792824740e89844a59c13d3d40ce4d23 [6,7]. All reference and prediction labels reported in the revised analyses were regenerated using the same versioned invocation and mapped back to cases. Across 14 categories, only raw state 1

XSL•FO
RenderX

was positive; raw −1, raw 0, and blank states were mapped to negative. Microprecision, microrecall, and micro-F_1 pooled true positive (TP), false positive (FP), and false negative (FN) across reports and categories; per-label counts and scores were also examined. All were interpreted as labeler-derived proxies.

A seed-based inspection of 20 IU→MIMIC ON+B4 Cardiomegaly-positive outputs and 20 MIMIC→IU ON+B4 outputs prompted a complete text-level audit. Because the initial sample list was not retained, it served only as preliminary quality control.

Primary verification covered all 393 IU→MIMIC ON+B4 outputs labeled "cardiomegaly positive," including case-reference mapping, final-text provenance, hashes, raw states, binary mapping, and a controlled official-labeler test. The retained predictions and official labels were not altered.

Because this audit identified a cardiomegaly response to recurrent, semantically normal, heart-size wording, a post hoc descriptive sensitivity analysis excluded cardiomegaly from both matrices and recomputed pooled metrics across the remaining 13 categories. No reports or individual labels were removed or corrected, and the analysis was outside the Holm family.

Definitions and interpretive limits for all automated measures are summarized in Table S8 in Multimedia Appendix 1.

Exploratory MedGemma Stress Test

MedGemma 1.5 4B (revision 91850547d9f0b2fdd21aa7c5f4f3d1a8a52c243b) [30] generated reports without task-specific fine-tuning on the same 575 IU and 401 MIMIC-CXR records; a 553-entry frontal-only IU subset was also analyzed. One fixed prompt and deterministic greedy decoding were used, without prompt search or target-based selection. Because training exposure and generation conditions differed, this was not a matched comparison.

Float16 produced unstable first-token logits and all-padding generations on the RTX 3090 stack, so formal generations were performed using float32. All 976 records yielded nonempty uniquely identified outputs; 512-token-limit outputs were retained and flagged. Reproducibility details and hashes are provided in Multimedia Appendix 1.

MedGemma was evaluated with the same automated definitions. Stand-alone, clustered 95% CIs were calculated using IU unique ID–level clusters and MIMIC-CXR patient clusters and remained outside the primary Holm family. No MedGemma human-review comparison was performed.

Expanded Human Audit

The blinded human audit included 90 evaluation cases and 270 configuration-specific reports, with one ON+B4, ON+G1, and ON+K50 report per case. The primary random sample comprised 70 cases (35 per direction; 210 reports); a separate targeted panel comprised 20 cases (60 reports) and was excluded from primary proportion summaries. An evaluation case was a linked target record, not necessarily a unique patient.

Primary cases were sampled with seed 2026 without conditioning on validity, template indicators, clinical-label scores, or output quality; the primary and targeted subsets did not overlap. Reports received anonymized identifiers and independently randomized orders. Reviewers were blinded to their configuration, automated results, other configurations, and corpus-wide frequencies.

Two advanced medical trainees from the West China School of Medicine independently reviewed the reports following codebook training and 10 excluded calibration cases. Neither was a licensed radiologist, so the task was treated as structured clinical-content review rather than formal radiological diagnosis.

In phase 1, reviewers saw the radiograph, viewed information, and generated report without the reference; in phase 2, the reference was disclosed for a sensitivity assessment of agreement, omissions, and possible multiview mismatches. The configuration and automated results remained concealed.

Primary end points were major omission; major unsupported finding; 0-to-3 content adequacy and case-specific informativeness; and finding-level TP, FP, and FN counts. Scores ≥2 indicated adequate or informative output. Internal contradiction, unsupported normality, template genericness, reference agreement, and multiview mismatch were secondary or sensitivity measures.

Both reviewers completed all reports before reaching consensus. Protocol-defined disagreements triggered a blinded discussion, and unresolved primary end point disagreements were adjudicated by a third medically trained reviewer who remained blinded. Final summaries used consensus or adjudicated ratings; full rules are provided in Multimedia Appendix 1.

Preconsensus reliability used percent agreement, Cohen κ and Gwet AC1 (agreement coefficient 1) for binary end points, exact and within-1 agreement with quadratically weighted κ for ordinal end points, and intraclass correlation coefficient (ICC) (2,1) with absolute differences for TP, FP, and FN counts.

Statistical and Descriptive Analysis

Primary automated comparisons used paired cluster bootstrap resampling (5000 replicates; seed 2026) conducted separately by direction, with IU case clusters for MIMIC→IU and MIMIC patient clusters for IU→MIMIC. Within each direction, ON+B4 was compared with OFF+B4, ON+G1, and ON+K50 for surface validity, prefix hit, and CheXpert micro-F_1. Effects were computed as first minus second; 95% CIs and P values were Holm-adjusted across 9 tests per direction. Recurrence, concentration, and Distinct-1/2 remained descriptive.

Human-audit summaries used only the 210 reports from the 70 randomly sampled cases and were stratified by direction and configuration; the 60 targeted reports were reserved for qualitative failure analysis.

Binary human end points were reported with exact binomial 95% CIs; ordinal distributions and ≥2 thresholds were reported, and finding-level microprecision, microrecall, and micro-F_1 used pooled consensus counts. No configuration-level human hypothesis tests were performed, so differences were interpreted descriptively.

XSL•FO
RenderX

Ethical Considerations

This study used 2 previously released deidentified datasets: MIMIC-CXR and IU X-ray [27,28]. MIMIC-CXR is available through credentialed PhysioNet access, required training, and a data use agreement [31]; its release was approved by the Beth Israel Deaconess Medical Center Institutional Review Board with a waiver of consent [27]. IU X-ray was collected with institutional review board approval (Office of Human Subjects Research Protections number 5357) and deidentified before release [28]. The original approval, waiver, and release conditions permitted the secondary research use of the datasets without obtaining additional informed consent from individual patients.

All analyses were performed on deidentified images, deidentified reports, generated text, and derived evaluation outputs. All team members who directly accessed MIMIC-CXR, including reviewers and the adjudicator, held individual authorization, and completed the required training and agreement. Restricted data were processed locally, were not sent to hosted AI services or external APIs, and were not used for reidentification. The authors did not attempt to identify, reidentify, contact, or link any individual patient.

No separate local ethics application was submitted because this secondary analysis involved no recruitment, enrollment, contact, intervention, direct identifiers, new identifiable data, or clinical use of generated reports. Article 32 of the 2023 Chinese Measures for Ethical Review permits a waiver for qualifying research using lawfully obtained public or anonymized data [32]. The authors considered this study to meet those conditions; therefore, no local approval or exemption number was issued and no additional consent was sought.

Because this was a secondary analysis of existing deidentified data, no human participants were recruited, enrolled, contacted, or compensated. The reviewers and adjudicator served as uncompensated research team members, not research participants. No identifiable patient images, facial photographs, names, dates of birth, medical record numbers, accession numbers, or other direct identifiers are included in the paper or Multimedia Appendix 1.

Results

Evaluation Cohort Composition and Domain Shift

The MIMIC→IU cohort contained 575 IU entries (553 frontal and 22 lateral fallback inputs). The IU→MIMIC cohort contained 401 frontal MIMIC-CXR entries from 347 studies. No entries were lost due to missing output, failed matching, or configuration-specific evaluability.

The median reference lengths were 34 (IQR 26-47) words for IU and 69 (IQR 49-89) words for MIMIC-CXR. Labeler-derived reference positives also differed: no finding, 33.0% (190/575) vs 9.2% (37/401); lung opacity, 22.3% (128/575) vs 41.9% (168/401); edema, 3.0% (17/575) vs 17.0% (68/401); and support devices, 5.2% (30/575) vs 32.7% (131/401). These are report-label distributions, not patient-level prevalence.

Report length, label composition, view structure, and clustering-contextualized direction-specific findings; within each direction, all configurations used the same fixed entries.

Overview of Cross-Domain Automated Audit Findings

The primary automated audit jointly assessed validity, recurrence, concentration, the predefined prefix, lexical diversity, and the official CheXpert/NegBio overlap. These end points represented different constructs. MedGemma was assessed separately using the same layers.

Degradation varied by direction and end point, and no ON configuration was uniformly favorable across the automated measures (Tables 2 and 3). The MedGemma results appear separately in Table 4.

Table . Formal validity, complete-report recurrence, concentration, and protocol-defined prefix results for the 3 ON (protocol-defined training-side control enabled)–controlled decoding policies.[a]

Direction	Configuration	Surface valid, n/N (%)	Unique reports, n/N (%)	Exact duplicate outputs, n/N (%)	Top-5 output share, n/N (%)	Template prefix, n/N (%)
MIMIC[b]→IU	ON[c]+B4[d]	574/575 (99.8)	12/575 (2.1)	569/575 (99.0)	562/575 (97.7)	8/575 (1.4)

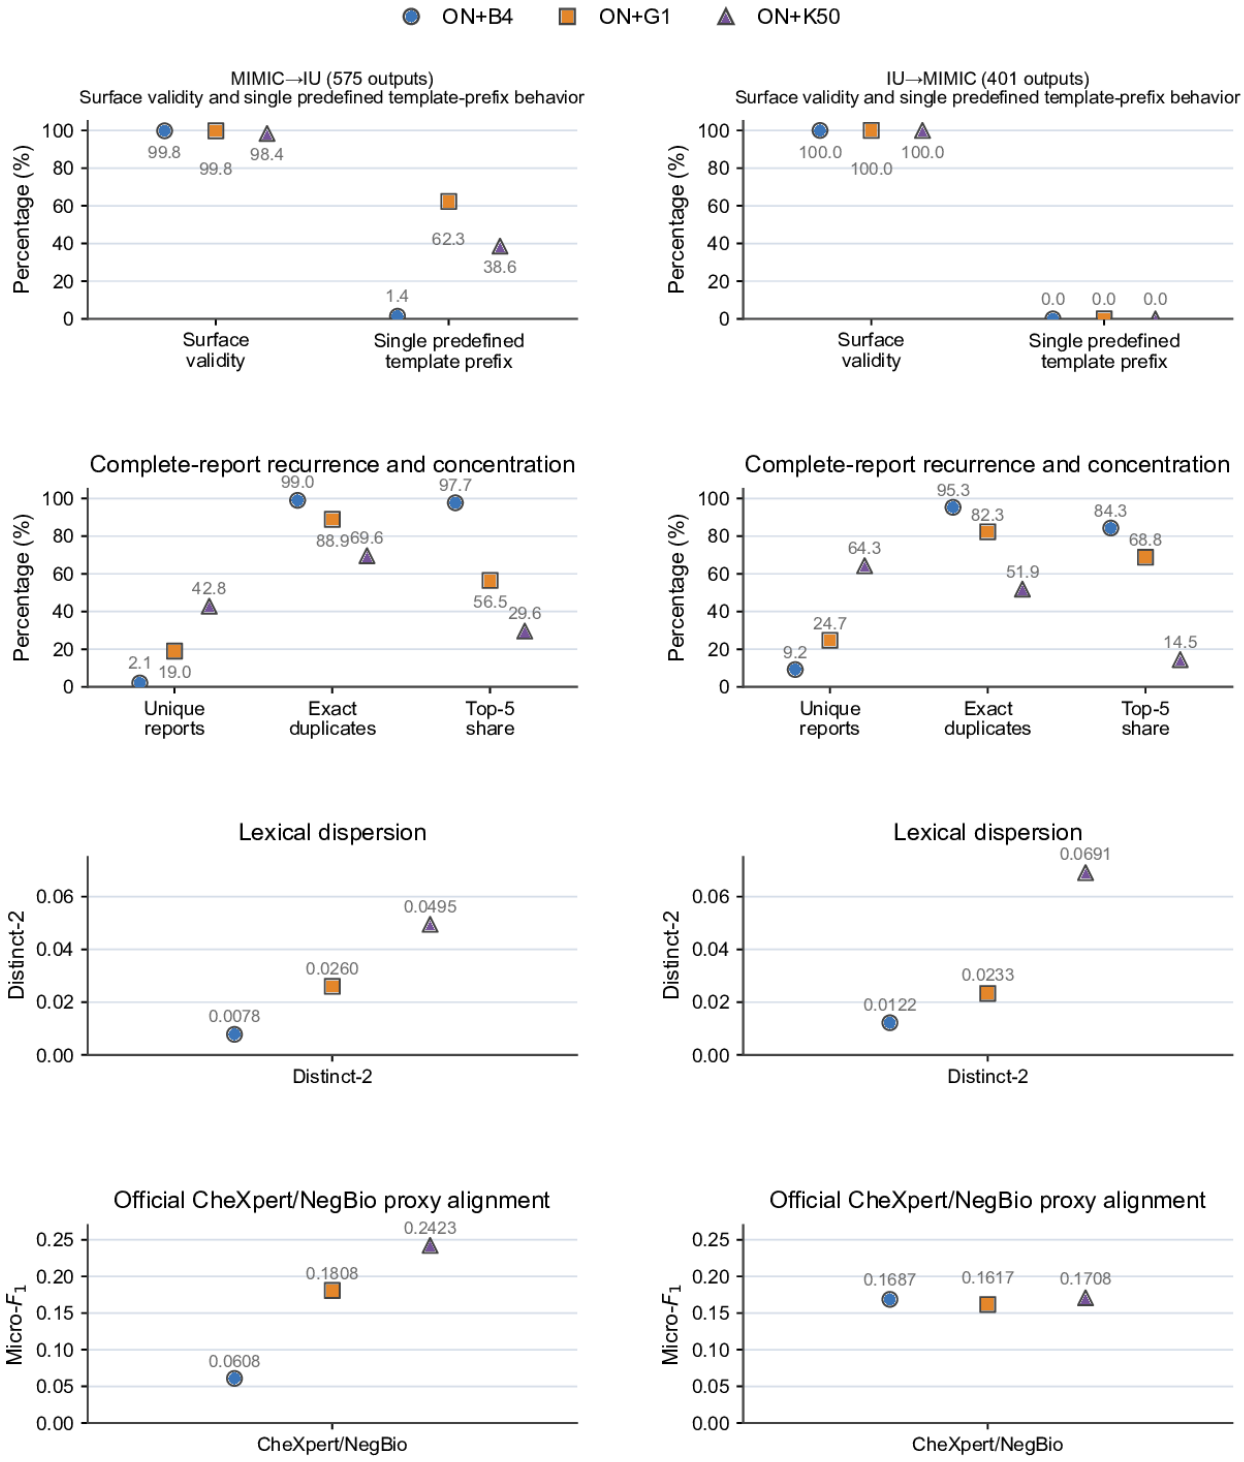
[d]G1: greedy decoding.

[e]K50: top-k sampling with k=50.

Table . Exploratory MedGemma 1.5 automated cross-architecture stress-test results.[a]

Metric	IU (n=575)	IU frontal-only (n=553)	MIMIC-CXR[b] (n=401)
Surface valid	0.9948	0.9946	0.9776
Exact duplicate rate	0.6626	0.6637	0.1446
Top-5 output share	0.4417	0.4467	0.0873
Distinct-1	0.0140	0.0142	0.0173
Distinct-2	0.0505	0.0504	0.0742
Single predefined template prefix rate	0	0	0
Official CheXpert micro-F_1	0.4722	0.4763	0.4340

[a]MedGemma used a single frozen deterministic configuration outside the primary Holm family. The duplicate rate counts all outputs in repeated complete-report groups. No human review of MedGemma was conducted; full intervals and checks are provided in Multimedia Appendix 1.



[b]MIMIC-CXR: Medical Information Mart for Intensive Care Chest X-Ray.

In MIMIC→IU, ON+B4 minimized the prefix rate to 8 out of 575 (1.4%) but was most concentrated: 12 (2.1%) reports were unique, 569 (99.0%) belonged to duplicate groups, and the top 5 reports covered 562 (97.7%) outputs. Compared with ON+B4, ON+G1 increased the prefix rate by 0.609 (95% CI 0.567 - 0.649; adjusted P=.002) and CheXpert micro-F_1 by 0.120 (95% CI 0.087 - 0.153; P=.002) without changing validity. ON+K50 increased the prefix rate by 0.372 (95% CI 0.330 - 0.412; P=.002) and micro-F_1 by 0.182 (95% CI 0.144 - 0.220; P=.002), while reducing validity by 0.014 (95% CI 0.003 - 0.026; P=.03). ON+B4 had no pathology-positive official labels, and all 24 TPs were no finding; No finding also supplied 126 out of 146 ON+K50 TPs.

In IU→MIMIC, all ON outputs were surface-valid and none met the prefix rule. ON+K50 had the highest unique-report ratio (258/401, 64.3%) and the lowest duplicate rate (208/401, 51.9%) and top-5 share (58/401, 14.5%). Micro-F_1 was 0.1687 for ON+B4, 0.1617 for ON+G1, and 0.1708 for ON+K50; neither G1 nor K50 differed from B4 after Holm correction (adjusted P>.99). Of the 102 ON+B4 TPs, 100 were cardiomegaly, while most other categories had no F_1 (Figure 2).

XSL•FO
RenderX

Figure 2. Automated trade-off structure across the main cross-domain decoding settings in the Medical Information Mart for Intensive Care (MIMIC)→IU and IU→MIMIC directions. CheXpert/NegBio micro-F_1 is a labeler-derived proxy. Corpus-level recurrence and diversity measures are descriptive. B4: beam search with a beam size of 4; G1: greedy decoding; K50: top-k sampling with k=50; ON: protocol-defined training-side control enabled.

Per-Label and Text-Level Audit of the Official CheXpert Proxy

Per-label results were highly concentrated (Table 5). In MIMIC→IU ON+B4, all 13 pathology or device categories had 0 predicted positives; 87 no finding assignments yielded 24 TPs. Although ON+K50 had the highest micro-F_1, no finding supplied 126 out of 146 TPs, and 7 categories plus Support Devices remained at F_1=0.

Table . Selected per-label official CheXpert/NegBio results illustrating aggregate-score concentration and labeler-response behavior.[a]

Direction/configuration	Observation	Reference positive, n	Predicted positive, n	TP[b], n	FP[c], n	FN[d], n	F_1
MIMIC[e]→IU ON[f]+B4[g]	Cardiomegaly	99	0	0	0	99	0
MIMIC→IU ON+B4	Lung opacity	128	0	0	0	128	0
MIMIC→IU ON+B4	No finding	190	87	24	63	166	0.173
MIMIC→IU ON+K50[h]	Lung opacity	128	3	1	2	127	0.015
MIMIC→IU ON+K50	No finding	190	335	126	209	64	0.480
IU→MIMIC ON+B4	Cardiomegaly	102	393	100	293	2	0.404
IU→MIMIC ON+B4	Lung opacity	168	0	0	0	168	0
IU→MIMIC ON+B4	No finding	37	8	2	6	35	0.089
IU→MIMIC OFF+B4	Cardiomegaly	102	27	9	18	93	0.140
IU→MIMIC OFF+B4	No finding	37	357	31	326	6	0.157

[a]Values use the uncertain-as-negative policy. Complete 14-label results are given in Tables S24-S27 in Multimedia Appendix 1. IU→MIMIC ON+B4 cardiomegaly positives were predominantly triggered by semantically normal heart-size wording.

[b]TP: true positive.

[c]FP: false positive.

[d]FN: false negative.

[e]MIMIC: Medical Information Mart for Intensive Care.

[f]ON: protocol-defined training-side control enabled.

[g]B4: beam search with a beam size of 4.

[h]K50: top-k sampling with k=50.

In IU→MIMIC ON+B4, the labeler assigned cardiomegaly positive to 393 of 401 outputs, yielding TP=100, FP=293, FN=2, and TN=6; 100 out of 102 total TPs were obtained from this category. Provenance checks matched all cases and texts across the prediction, label, and metric files. Every positively assigned text used “heart size” with “within normal limits,” and none used “cardiomegaly,” “enlarged,” or “cardiomediastinal”; a controlled official-labeler test also returned cardiomegaly=1.0 for semantically normal wording.

The complete 393-output audit, provenance checks, and controlled test therefore identified a reproducible labeler response that was inconsistent with the apparent sentence meaning, rather than clinically meaningful cardiomegaly generation. Official outputs were retained without relabeling but interpreted as pipeline measurements. MIMIC→IU ON+B4 was similarly described as near-absence of positive label assignments, because some outputs contained fragmented or ambiguous pathology wording despite zero pathology-positive labels.

After excluding cardiomegaly, the IU→MIMIC micro-F_1 was 0.0056 for ON+B4, 0.0666 for OFF+B4, 0.0211 for ON+G1, and 0.0407 for ON+K50. The ON+B4−OFF +B4 difference reversed from +0.0944 to −0.0610 (Table S28 in Multimedia Appendix 1), showing that the 14-category advantage was dominated by the labeler response rather than broad content recovery.

Training-Control Comparison and Automated Trade-Off Structure

ON/OFF effects varied by direction and end point (Tables 6 and 7). In MIMIC→IU, ON+B4 reduced the prefix rate compared with OFF+B4 by 0.986 (95% CI 0.976 - 0.995; adjusted P=.002), with no significant validity or micro-F_1 improvement, and remained more concentrated. In IU→MIMIC, validity and prefix rate were identical, while ON+B4 increased 14-category micro-F_1 by 0.094 (95% CI 0.045 - 0.155; P=.01); per-label and text tracing showed that this contrast was dominated by the normal-heart-size cardiomegaly trigger.

RenderX

Table . Unified comparison of ON (protocol-defined training-side control enabled)+B4 (beam search with a beam size of 4) and OFF (protocol-defined training-side control disabled)+B4 under bidirectional cross-domain transfer.[a]

Direction	Condition	Surface valid, n/N (%)	Exact duplicate outputs, n/N (%)	Top-5 output share, n/N (%)	Template prefix, n/N (%)	CheXpert micro-F_1
MIMIC[b]→IU	ON+B4	574/575 (99.8)	569/575 (99.0)	562/575 (97.7)	8/575 (1.4)	0.0608
MIMIC→IU	OFF+B4	575/575 (100)	563/575 (97.9)	517/575 (89.9)	575/575 (100)	0.0687
IU→MIMIC	ON+B4	401/401 (100)	382/401 (95.3)	338/401 (84.3)	0/401 (0)	0.1687
IU→MIMIC	OFF+B4	401/401 (100)	360/401 (89.8)	263/401 (65.6)	0/401 (0)	0.0744

[a]ON and OFF denote the composite control's enabled and disabled states under B4 decoding. The contrast does not isolate individual components; recurrence and concentration are descriptive corpus-level measures.

[b]MIMIC: Medical Information Mart for Intensive Care.

Table . Primary paired cluster-bootstrap comparisons for the automated audit end points.[a]

Direction and comparison	Surface validity, difference (95% CI)	Adjusted *P*	Template-prefix hit, difference (95% CI)	Adjusted *P*	Official CheXpert micro-F_1, difference (95% CI)	Adjusted *P*
MIMIC[b]→IU: ON[c]+B4[d]−OFF[e]+B4	−0.002 (−0.005 to 0)	>.99	−0.986 (−0.995 to −0.976)	.002	−0.008 (−0.038 to 0.022)	>.99
MIMIC→IU: ON+G1[f]−ON+B4	0.000 (−0.005 to 0.005)	>.99	0.609 (0.567 to 0.649)	.002	0.120 (0.087 to 0.153)	.002
MIMIC→IU: ON+K50[g]−ON+B4	−0.014 (−0.026 to −0.003)	.03	0.372 (0.330 to 0.412)	.002	0.182 (0.144 to 0.220)	.002
IU→MIMIC: ON+B4−OFF+B4	0 (0 to 0)	>.99	0 (0 to 0)	>.99	0.094 (0.045 to 0.155)	.01
IU→MIMIC: ON+G1−ON+B4	0 (0 to 0)	>.99	0 (0 to 0)	>.99	−0.007 (−0.022 to 0.007)	>.99
IU→MIMIC: ON+K50−ON+B4	0 (0 to 0)	>.99	0 (0 to 0)	>.99	0.002 (−0.018 to 0.021)	>.99

[a]Effects are the first configuration minus the second, with 95% bootstrap CIs and Holm-adjusted *P* values from 5000 replicates (seed 2026). MIMIC→IU used IU case clusters and IU→MIMIC used MIMIC patient clusters. Full estimates and raw *P* values are in Tables S11 to S14 in Multimedia Appendix 1.

[b]MIMIC: Medical Information Mart for Intensive Care.

[c]ON: protocol-defined training-side control enabled.

[d]B4: beam search with a beam size of 4.

[e]OFF: protocol-defined training-side control disabled.

[f]G1: greedy decoding.

[g]K50: top-k sampling with k=50.

Thus, the composite control produced end point–specific changes rather than uniform bidirectional improvement: it suppressed one training-aligned prefix in MIMIC→IU and changed a labeler-derived end point in IU→MIMIC, without consistently reducing complete-report concentration.

Expanded Human Audit

Both reviewers completed all 270 assessments with complete primary end point linkage. Among 245 items meeting a consensus trigger, 207 were resolved by discussion and 38 by third-reviewer adjudication; all primary end points were resolved. Four items retained missing secondary or sensitivity ratings. The high trigger rate reflected multiple sensitive criteria, not major clinical disagreement on every item.

Consensus summaries showed no consistent configuration ordering (Tables 8 and 9). In IU→MIMIC, ON+G1 had numerically fewer omissions and unsupported findings and micro-F_1 of 0.497, while ON+K50 had the highest unsupported finding rate and the lowest micro-F_1. In MIMIC→IU, ON+B4 and ON+G1 had identical binary error rates; ON+B4 had the highest micro-F_1 (0.529), whereas ON+K50 not only had the most informative reports but also the most omissions and unsupported findings. These patterns were descriptive.

XSL•FO
RenderX

Table . Primary binary human-audit end points in the randomly sampled evaluation cases (N=35).[a]

Direction and configuration	Major omission, n (%)	Major unsupported finding, n (%)
IU→MIMIC[b]		
ON[c]+B4[d]	15 (43)	12 (34)
ON+G1[e]	12 (34)	10 (29)
ON+K50[f]	13 (37)	15 (43)
MIMIC→IU		
ON+B4	12 (34)	11 (31)
ON+G1	12 (34)	11 (31)
ON+K50	14 (40)	16 (46)

[a]Values are consensus or adjudicated ratings from the primary random subset; the targeted panel was excluded, and no configuration-level tests were performed.

[b]MIMIC: Medical Information Mart for Intensive Care.

[c]ON: protocol-defined training-side control enabled.

[d]B4: beam search with beam size 4.

[e]G1: greedy decoding.

[f]K50: top-k sampling with k=50.

Table . Human-audit adequacy, informativeness, and finding-level micro-F_1 in the randomly sampled evaluation cases (N=35).[a]

Direction and configuration	Adequacy ≥2, n (%)	Informativeness ≥2, n (%)	Micro-F_1
IU→MIMIC[b]			
ON[c]+B4[d]	16 (46)	15 (43)	0.493
ON+G1[e]	17 (49)	16 (46)	0.497
ON+K50[f]	15 (43)	15 (43)	0.449
MIMIC→IU			
ON+B4	17 (49)	18 (51)	0.529
ON+G1	15 (43)	19 (54)	0.500
ON+K50	16 (46)	20 (57)	0.519

[a]Scores ≥2 indicated adequate or informative output; micro-F_1 used pooled true positive, false positive, and false negative. No configuration-level tests were performed.

[b]MIMIC: Medical Information Mart for Intensive Care.

[c]ON: protocol-defined training-side control enabled.

[d]B4: beam search with beam size 4.

[e]G1: greedy decoding.

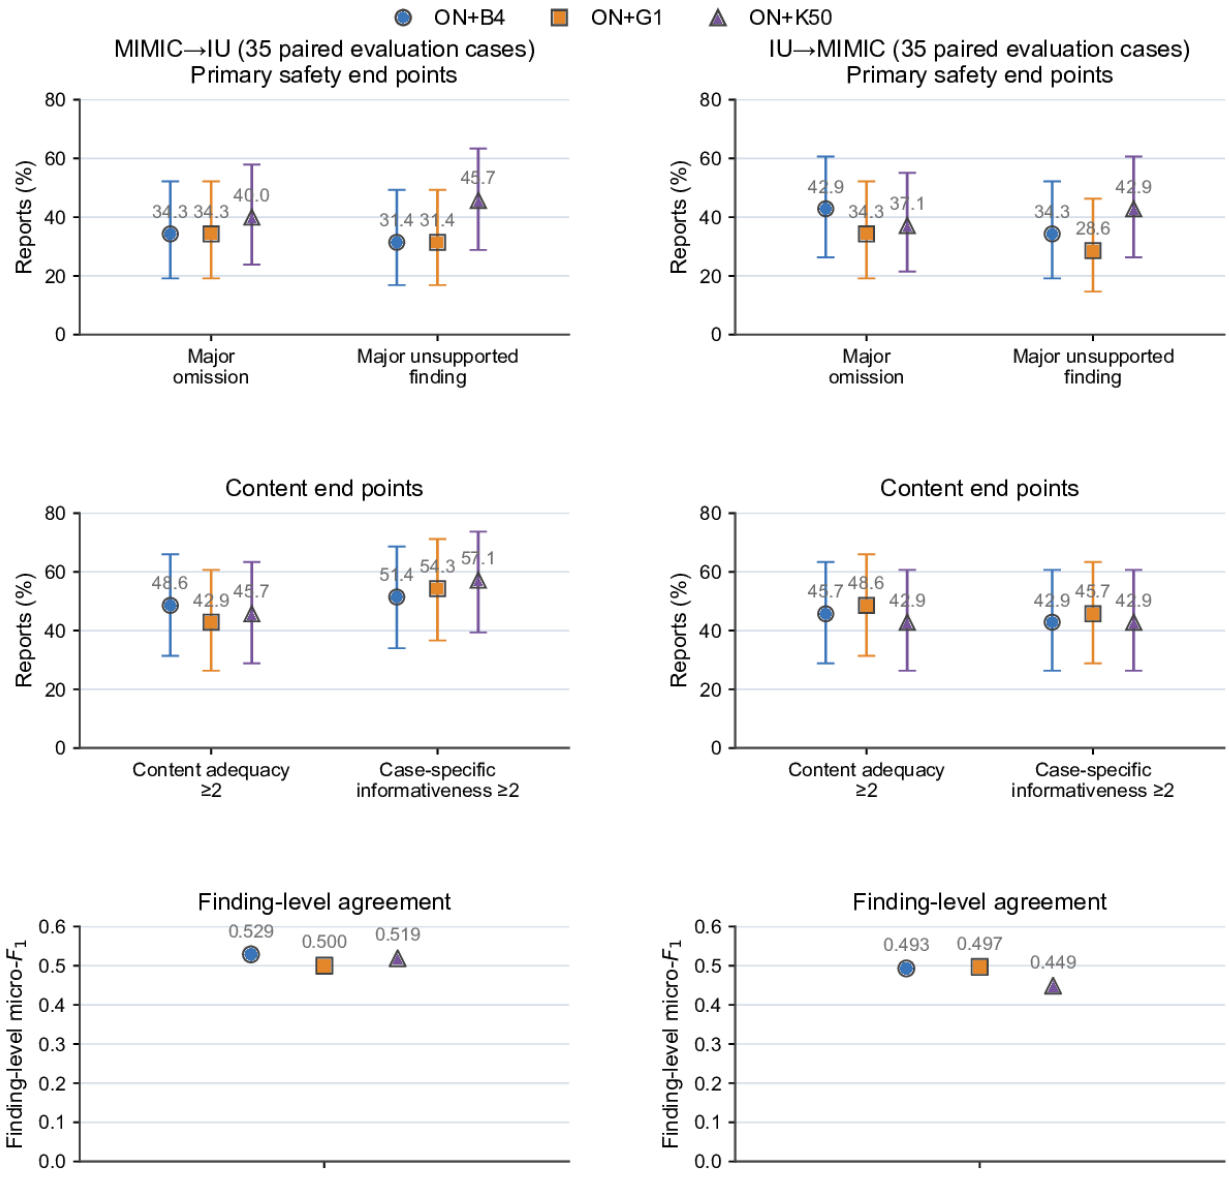
[f]K50: top-k sampling with k=50.

Therefore, greater apparent informativeness did not consistently coincide with fewer clinically relevant errors, indicating residual trade-offs among omission, unsupported generation, adequacy, and case specificity. All 35 audited MIMIC→IU ON+B4 reports belonged to repeated complete-report groups (34 in the 5 most frequent groups and 1 in another repeated group). Informativeness ratings assessed whether a report contained image-relevant clinical information for the individual case rather than whether its wording was unique. Nevertheless, 18 out of 35 met the prespecified informativeness threshold: 14 scored 2 and 4 scored 3. Thus, recurrent wording was partially applicable to some cases, but this should not be interpreted as individualized report generation. Finding-level micro-F_1 pooled finding counts and did not penalize the reuse of an identical whole report (Table S40 in Multimedia Appendix 1).

The automated prefix and human genericness end points measured different phenomena. The former detected only the exact opening phrase; the latter assessed the complete report against the image. Prefix-positive reports could contain case-related content, while prefix-negative reports could remain generic or clinically problematic (Tables S38 and S39 in Multimedia Appendix 1).

XSL•FO
RenderX

Combined Interpretation of Automated and Human Findings



Automated and human measures were complementary. Bootstrap analysis identified direction-specific changes in the target-aligned prefix (adjusted *P*=.002) and the labeler-derived CheXpert end point (adjusted *P*=.01), while per-label tracing exposed the latter's normal-heart-size cardiomegaly trigger. Human review identified omission, unsupported generation, adequacy, and case specificity not recoverable from those end points alone.

Together, the layers showed multidimensional trade-offs rather than a universal configuration ranking.

Figure 3 summarizes consensus-based human outcomes; full distributions, original ratings, agreement analyses, targeted cases, and comments are provided in Multimedia Appendix 1.

Preconsensus agreement was 78.1% for phase 1 omission (κ=0.543; AC1=0.597) and 80.7% for unsupported findings (κ=0.582; AC1=0.643). Exact agreement was 55.9% for adequacy (weighted κ=0.553) and 51.9% for informativeness (weighted κ=0.487); ICC (2,1) was 0.690 for TP, 0.570 for FP, and 0.530 for FN. Primary end point disagreements were resolved by blinded consensus or adjudication.

Figure 3. Consensus-based human audit risk profiles across decoding-policy configurations and transfer directions. Points show Consus/adjudicated estimates from the primary random sample. Error bars are Clopper-Pearson exact 95% CIs for report-level proportions. Human audit comparisons are descriptive; no configuration-level hypothesis tests were performed. B4: beam search with beam size 4; G1: greedy decoding; K50: top-k sampling with k=50; MIMIC: Medical Information Mart for Intensive Care; ON: protocol-defined training-side control enabled.

Exploratory MedGemma Results

MedGemma generated all 976 reports without empty outputs or duplicate identifiers. On IU, surface validity was 0.9948, duplicate rate was 0.6626, top-5 share was 0.4417, Distinct-2 was 0.0505, and micro-F_1 was 0.4722 (95% CI 0.4353 - 0.5092); the frontal-only subset was similar. On MIMIC-CXR, the corresponding values were 0.9776, 0.1446, 0.0873, 0.0742, and 0.4340 (95% CI 0.3815 - 0.4787).

MedGemma combined higher labeler-derived scores with residual recurrence. In IU, out of 575 outputs, 254 (44.2%) were covered by the top 5 reports and 381 (66.3%) belonged to duplicate groups, despite a 0 % prefix rate, confirming that the narrow prefix did not represent global concentration. Different training conditions and the absence of reader review precluded case-level performance claims.

Four MedGemma reports reached 512 tokens and showed looping or truncation; they were retained and flagged. No MedGemma-generated predictions contained U+FFFD or U+2047 characters. No finding contributed to FPs, whereas MedGemma cardiomegaly FPs generally reflected genuinely positive wording rather than the normal heart-size trigger.

Discussion

Principal Results

Cross-domain degradation varied by transfer direction and end point. Neither the composite control nor the 3 decoding policies produced a consistent performance hierarchy. Instead, failures shifted across recurrence, proxy-label alignment, omission, and unsupported generation. The MedGemma stress test further showed that higher label-derived scores could coexist with recurrent output.

Findings in Relation to the Research Questions

For the first research question, out of 575 outputs, ON reduced the predefined MIMIC→IU prefix from 575 (100%) to 8 (1.4%; adjusted P=.002); however, 569 (99.0%) ON+B4 outputs remained duplicates, and the clinical proxy did not improve. In IU→MIMIC, the apparent ON+B4 micro-F_1 advantage was largely a cardiomegaly labeler response to normal heart-size wording and reversed from +0.0944 to −0.0610 after cardiomegaly exclusion. The composite control therefore redistributed, rather than resolved, cross-domain failure.

For the second question, the 3 ON configurations traded prefix frequency, validity, recurrence, diversity, and proxy alignment differently. ON+B4 suppressed the prefix but remained concentrated in MIMIC→IU; ON+K50 increased diversity and reduced concentration but lowered validity and retained prefix recurrence. IU→MIMIC proxy differences were not significant after correction. No policy dominated across end points.

For the third question, out of 35 reports, omissions affected 12 to 15 reports and unsupported findings affected 10 to 16 across the 6 primary cells, with no consistent ordering. Because the human end points were descriptive, these differences did not establish superiority or equivalence.

The ON+G1 results further illustrate that exact-prefix detection and image-grounded whole-report genericness are complementary, not interchangeable, end points.

For the fourth question, MedGemma achieved micro-F_1 values of 0.4722 on IU and 0.4340 on MIMIC-CXR, but 381 out of 575 (66.3%) IU outputs were duplicates. The stress test supports the use of recurrence and label-traceability checks across architectures, not a matched performance or generalizability claim.

Comparison With Prior Work

Recent studies have advanced structured reporting, interpretable evaluation, reader studies, and disease-aware or foundation-model generators [18-25,30]. In contrast to architecture-focused work by Nimalsiri et al [24] and Edirisinghe et al [25], this study combines symmetric transfer, cluster-aware inference, report concentration, per-label and final-text tracing, and blinded case review.

The cardiomegaly audit illustrates the need to verify reproducible pipeline outputs against the construct they are intended to measure. The comparison of representative prior work is provided in Tables S32 and S33 in Multimedia Appendix 1.

Implications for Evaluation and Deployment

For deployment beyond source datasets [13-15,17-25,30], suppressing one prefix does not ensure lower report recurrence; aggregate label scores can be driven by a single category or recurrent wording; and diversity can coexist with clinical error. Evaluation should therefore combine distributional, proxy, and blinded image-grounded measures.

Operating configurations should be judged against the intended balance of stability, content retention, case specificity, and error risk. Future work should include more institutions, languages, contemporary models, board-certified radiologists, and prospective workflows, while preserving case-linked provenance and direction-specific inference.

Limitations

Cohort and Data Provenance

The deterministic MIMIC-CXR sample retained 401 of 3374 eligible official-test entries in a fixed row order and may not represent the full eligible cohort. The IU split was verified only at the unique ID level because patient IDs were unavailable; residual patient overlap, if present, could make transfer performance appear better and thus underestimate degradation. Because age and sex were incompletely retained, subgroup performance could not be assessed; accordingly, this study should not be interpreted as providing evidence either for or against algorithmic bias in either transfer direction. In addition, all MIMIC-CXR inputs and most IU inputs were single-projection images, whereas some reference reports summarized multiview examinations; unavailable projections may have contributed to apparent omissions or reference mismatch.

XSL•FO
RenderX

Design and Attribution

The primary experiments used one R2Gen-style backbone and 2 deidentified datasets. ON/OFF evaluated a composite protocol without component ablation, and the decoding algorithm and repetition penalty varied together across the ON policies; therefore, individual component or algorithm effects cannot be isolated. The final prefix end point also overlapped with a training keyword and did not establish a global reduction in templating.

Proxy Measurement

The cardiomegaly trigger and the concentration of aggregate scores in no Finding or in a single category show that template, diversity, and label-overlap measures cannot replace case-level factual review. The controlled phrase verification was specific to cardiomegaly; whether analogous rule interactions occur in the other 13 CheXpert categories remains unverified. The absence of an observed anomaly should therefore not be interpreted as validation of every label.

Human Review

The audit used 35 reports per direction-configuration cell and medically trained students, with a postgraduate trainee adjudicator, rather than board-certified radiologists. It was designed as a structured, descriptive, clinical-content audit, not a definitive reader study, and uncertainty remains around its subgroup estimates.

Exploratory Architecture Branch

MedGemma broadened the architectural scope but was assessed only with automated end points, without matched bidirectional training or human review. Its higher labeler-derived micro-F_1 and lower recurrence in some settings cannot establish whether it reduced omission or unsupported generation, rather than improving proxy scores. The persistence of 66.3% exact duplicate membership in IU illustrates that this question remains unresolved.

Conclusions

Cross-domain report generators failed differently by direction and end point. The composite control reduced one MIMIC→IU prefix, while the apparent IU→MIMIC CheXpert advantage was largely a cardiomegaly labeler response to normal wording. B4, G1, K50, and MedGemma showed distinct validity, recurrence, diversity, label, and human-error profiles. Therefore, robust evaluation requires distributional measures, per-label and final-text verification, and blinded, image-grounded review.

Acknowledgments

The authors thank the 2 medical trainees from West China School of Medicine, Sichuan University, for completing the independent review and consensus process, and an additional postgraduate clinical medicine trainee for adjudicating unresolved primary end point disagreements. All 3 reviewers contributed without financial or nonfinancial compensation. The authors also thank the maintainers of MIMIC-CXR (Medical Information Mart for Intensive Care Chest X-Ray) and IU X-ray for making deidentified images and reports available for research. ChatGPT (OpenAI) was used to assist with the organization, language editing, and revision-stage wording of the manuscript and supplementary materials. It was not used to conduct analyses, generate or modify study data, select results, or make scientific decisions. All analyses, interpretations, and final text were reviewed and approved by the authors.

Funding

This research received no specific grant from any funding agency in the public, commercial, or not-for-profit sectors.

Data Availability

MIMIC-CXR (Medical Information Mart for Intensive Care Chest X-Ray) and IU X-ray are available from their respective official sources under the applicable access requirements and data-use policies. MIMIC-CXR is available through PhysioNet under credentialed access and a data-use agreement, whereas the deidentified IU X-ray collection is available through Open-i. The authors do not redistribute the original images or reports; these materials should be obtained directly from the corresponding repositories. Deidentified derived results, evaluation code, and analysis scripts are available from the corresponding author upon reasonable request, subject to the original dataset licenses, data-use agreements, and institutional policies.

Authors' Contributions

YS contributed to conceptualization, methodology, software implementation, data curation, formal analysis, investigation, visualization, and drafting of the manuscript and led the majority of the experimental and analytical work. JJ contributed to software implementation, data processing, experimental validation, results checking, figure preparation, and manuscript revision. YC contributed to supervision, study design, interpretation of results, critical revision of the manuscript, and correspondence. All authors reviewed and approved the final version of the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Large language models (LLMs) are rapidly evolving from text-based agents to multimodal systems capable of interpreting medical images. While their textual reasoning has improved, the safety implications of this shift remain underexplored, specifically regarding the alignment between visual interpretation and textual advice in low back pain (LBP) management.

Objective: This study aims to evaluate the performance of 10 commonly used and highly representative LLMs, including paid models such as ChatGPT 5 Plus (OpenAI) and reasoning-oriented models like Qwen3-Thinking (Alibaba/Qwen team) in the context of LBP. Specifically, it assesses their clinical accuracy, readability, and the "asymmetric evolution" in cross-modal diagnostic consistency.

Methods: We conducted a cross-sectional quantitative evaluation integrated with an exploratory multimodal stress test. First, 10 LLMs, including ChatGPT 5 and ChatGPT 5 Plus, Gemini 3 Pro (Google DeepMind), Claude 4.5 Sonnet (Anthropic), Grok 4 (xAI), DeepSeek, Kimi K2 (Moonshot AI), Doubao (ByteDance Seed [Doubao Team]), Qwen3 (Base), and Qwen3-Thinking, addressed 25 standardized LBP inquiries. A multidisciplinary expert panel extracted 1816 individual recommendations by segmenting the models' point-by-point responses. These were independently coded for clinical accuracy against international guidelines on a 5-point Likert scale. Outcomes also included readability (Flesch Reading Ease [FRE] and Simple Measure of Gobbledygook [SMOG]), understandability (Patient Education Materials Assessment Tool [PEMAT]), and the presence of disclaimers. Second, to probe multimodal capabilities, we conducted an exploratory stress test (N=5) using a curated set of challenging clinical cases, including representative but complex LBP pathologies to assess baseline image recognition, and adversarial cases with deliberate clinical-radiological mismatches to evaluate cross-modal alignment.

Results: In textual tasks, models achieved an overall accuracy of 88.4% (1605/1816). ChatGPT 5 Plus demonstrated near-perfect performance, with zero serious errors. Within the only directly matched reasoning comparison, Qwen3-Thinking showed a lower serious-error rate than Qwen3 (Base). However, textual advice remained difficult to read, although understandability scores were robust. In contrast, multimodal performance in the exploratory stress test exhibited a negative divergence. In pure imaging tasks featuring complex but clinically representative pathologies, the average diagnostic score was poor, with models failing to identify core pathologies. In comprehensive diagnostic analysis tasks (Q29-Q30), models exhibited "textual masking," aligning visual findings with text cues rather than imaging evidence. Crucially, safety disclaimer coverage dropped precipitously from 82.8% (207/250) in textual tasks to 28% (14/50) in multimodal interactions.

Conclusions: Under adversarial stress conditions, current LLMs exhibit a capability mismatch: expert-level textual accuracy masks vulnerable visual interpretation. This "high-confidence trap" may cause users to misapply trust in textual logic to visual diagnostics. Although the matched Qwen3 comparison suggested a lower serious-error rate in the reasoning-enhanced setting,

XSL•FO
RenderX

poor cross-modal alignment and the systemic absence of medical disclaimers in visual tasks pose substantial risks. Thus, current multimodal LLMs remain unready for direct patient use in LBP management.

(JMIR Med Inform 2026;14:e93522) doi:10.2196/93522

KEYWORDS

lower back pain; large language models; AI; patient education; multimodal imaging

Introduction

Low back pain (LBP) dominates global disability charts, yet the most consequential shift in its management is unfolding outside the clinic walls [1]. Driven toward self-management, patients are increasingly incorporating AI as an accessible "first stop" for health information and preliminary triage guidance [2]. The tools people rely on have undergone major changes. Large language models (LLMs) have transitioned from passive information retrievers typical of traditional search engines to active "virtual consultants" [3].

Recent foundational studies, such as the benchmark by Scaff et al [4], established a critical early baseline for assessing text-based AI responses in LBP management. However, due to the rapid iteration of large model architectures and variations in prompt engineering, simple quantitative comparisons can no longer capture the current technological frontier [5]. Our study builds on the conceptual foundation of research by Scaff et al [4] to upgrade the evaluation framework, specifically addressing the newly evolved chain-of-thought reasoning capabilities [6] and nascent multimodal interactions of LLMs.

The core clinical question has shifted accordingly: for these models to effectively serve as "virtual advisors," they must not only deliver high accuracy in text-based interactions but also maintain diagnostic reliability when visual information is introduced [7]. Do reasoning models truly reduce the risk of errors on the textual front [8]? And does the exploratory introduction of visual inputs create new pathways for misleading advice? The primary concern is "asymmetric evolution," where sophisticated textual logic might mask underlying unreliability in visual interpretations.

To address this, we conducted a comprehensive assessment of 10 representative agents (including international models like ChatGPT 5 Plus (OpenAI) [9] and Chinese domestic models like DeepSeek [10] and Qwen [Alibaba/Qwen team] [11]), anchored by a robust text-based evaluation and supplemented by an exploratory multimodal probe. By building upon a systematic quantitative assessment of standardized textual queries and integrating a small-scale, exploratory multimodal case series, we aim to characterize the cross-modal performance gap between textual reasoning and visual processing and its potential implications for patient use [12]. Ultimately, this study seeks to identify whether these "experts" exhibit capability imbalances, thereby providing a necessary caveat for digital health practices.

Methods

Study Design and Question Development

We constructed a cross-sectional stress test to evaluate the current capabilities of 10 LLMs [13]. To mimic real-life clinical scenarios, the initial question pool was generated by simulating a comprehensive patient perspective across 10 different LLMs. The specific prompt parameters used were "If you are a patient with low back pain and want to use a large language model to seek consultation and ask questions in order to gain relevant information, knowledge, and advice, please list the 20 most likely questions you would ask from the perspective of a patient (Note: Each question must contain only one inquiry point)." With each model providing 20 questions, this generated a total of 200 potential inquiries. Subsequently, for content validation, a multidisciplinary team of 6 senior experts (including clinical spine surgeons and researchers) categorized, screened, and further refined the language of these questions to ensure high quality and comprehensive multidimensional coverage. To verify that these inquiries authentically mimicked real-life phrasing and aligned with clinical realities, we consulted 10 patients with LBP from diverse backgrounds to evaluate the conversational tone and appropriateness of the questions. The items were iteratively revised based on their feedback until each question achieved consensus approval from at least 8 of the 10 patients. This rigorous process culminated in a final test set comprising 25 standardized textual questions spanning 3 key domains: self-management, risk factors, and treatment strategies. To probe the models' multimodal capabilities, we designed an exploratory multimodal "stress test" using a purposively sampled series of clinical cases (N=5). Rather than aiming for statistical representativeness—which typically requires large-scale benchmarking datasets—this component was explicitly designed as an exploratory quantitative adversarial probe (akin to AI "red teaming") to expose potential systemic vulnerabilities and cross-modal hallucinations. This test comprised 2 distinct challenges: (Q26-Q28) clinically common yet moderately complex LBP imaging cases, designed to assess baseline image recognition capabilities; and (Q29-Q30) adversarial cases featuring deliberate clinical-radiological mismatches (where the clinical history text contradicted the imaging findings, requiring comprehensive synthesis to avoid misdiagnosis if relying solely on one modality), designed to evaluate the LLMs' cross-modal analytical capabilities. Full details and deidentified images are provided in Multimedia Appendix 1. Ultimately, this process culminated in a comprehensive final test set of 30 standardized questions, spanning both text-only inquiries and multimodal diagnostic tasks.

XSL•FO
RenderX

Model Selection and Configuration

Ten widely available models have been selected, covering international flagship LLMs such as ChatGPT 5 and ChatGPT 5 Plus, Grok 4 (xAI) [14], Gemini 3 Pro (Google DeepMind), and Claude 4.5 Sonnet (Anthropic) [15], as well as representative domestic LLMs from China, including DeepSeek V3.1, Kimi K2 (Moonshot AI), Doubao 1.6 Pro (ByteDance Seed [Doubao team]), and Qwen3-235B-A22B-2507 (encompassing both general and reasoning modes) [16]. (Nomenclature note: the exact versions evaluated are Qwen3-235B-A22B-2507 and its reasoning-enhanced variant Qwen3-235B-A22B-2507-Thinking. For visual clarity and to accommodate spatial constraints in certain figures and data-dense tables, these models are standardized and abbreviated globally as Qwen3 [Base] and Qwen3-Thinking [Alibaba/Qwen team] throughout the text and visualizations.) All tests were conducted within a unified Edge browser environment using English prompts. Each query was initiated in a new chat session to minimize carryover effects.

To ensure representativeness and sufficient user accessibility, this study included 10 LLMs with high visibility and widespread usage both internationally and within China (comprising 5 international flagship models and 5 representative domestic Chinese models). We purposively established several internal comparative groups, such as comparing ChatGPT 5 with its paid counterpart, ChatGPT 5 Plus, and comparing the open-source Qwen3 (Qwen3-235B-A22B-2507) in its standard "Fast" mode—Qwen3 (Base)—against its "Thinking" (reasoning-enhanced) mode. Given the current paradigm shift where most state-of-the-art LLMs integrate advanced reasoning capabilities, activating these specific configurations (eg, "Thinking," "Expert," or "Extended Thinking" modes) generally yields superior logical deduction. Therefore, with the exception of the standard Qwen3 "Fast" model, which served as a general baseline, we prioritized choosing the enhanced reasoning modes for all applicable models during testing. The specific model versions, selected operational modes, and the exact testing date ranges (conducted systematically throughout November 2025) are thoroughly detailed in Table 1.

Table . Overview of the evaluated large language models (LLMs), including specific versions, test dates, and operational modes.

Model name	Version[a]	Test date	Selected mode
ChatGPT	5.0	Nov 1 - 5, 2025	Thinking
ChatGPT	5.0 Plus	Nov 1 - 5, 2025	Thinking
Gemini	3 Pro	Nov 25 - 30, 2025	Pro
Grok	4	Nov 5 - 10, 2025	Expert
Claude	Sonnet 4.5	Nov 25 - 30, 2025	Extended Thinking
Doubao	1.6 Pro	Nov 10 - 15, 2025	Thinking
DeepSeek	V3.1	Nov 10 - 15, 2025	Deep Thinking
Kimi	K2	Nov 5 - 10, 2025	Thinking
Qwen	Qwen3-235B-A22B-2507	Nov 20 - 25, 2025	Fast
Qwen	Qwen3-235B-A22B-2507	Nov 20 - 25, 2025	Thinking

[a]The version column reports the technical or product version identifiers used for reproducibility; therefore, these entries may differ from the standardized display names used elsewhere in the manuscript.

To clarify the use of reasoning capabilities, our evaluation was not limited to Qwen3-Thinking. As shown in Table 1, given that the vast majority of current LLMs offer modes with enhanced reasoning capabilities, we activated these advanced reasoning modes across the included models (with the exception of Qwen3 [Base], which served as a baseline control) to assess their performance under optimal conditions. This included the "Thinking" mode for ChatGPT 5, ChatGPT 5 Plus and Doubao, the "Pro" mode for Gemini 3 Pro, "Extended Thinking" for Claude 4.5 Sonnet, "Expert" mode for Grok 4, and "Deep Thinking" for DeepSeek V3.1. Throughout the manuscript, the term "reasoning models" serves as an umbrella term encompassing all these specific advanced configurations, rather than referring exclusively to Qwen.

Expert Recruitment and Selection

To ensure rigorous and objective evaluation across different domains, we established specialized expert panels for question design, multimodal evaluation, and linguistic assessment. For the clinical and multimodal assessments (including question refinement, textual accuracy coding, and imaging evaluation), the recruited experts (comprising spine surgeons, researchers, and senior radiologists) were required to meet strict inclusion criteria: (1) holding an associate senior professional title or higher; and (2) possessing a minimum of 10 years of active clinical or research experience in spine surgery, rehabilitation medicine, or radiology. For the readability and understandability assessment, the linguistic panel was assembled based on advanced English proficiency, comprising native English-speaking researchers or nonmedical professionals holding a master's degree or higher in English, alongside 1 bilingual medical expert. To practically maintain strict blinding and prevent potential unblinding caused by the models' self-identifying tendencies, 2 research team members manually audited all generated outputs prior to evaluation. They systematically redacted all model-specific identifiers, explicit self-identifications, and brand-suggestive phrasing to preserve

XSL•FO
RenderX

text purity. The fully anonymized text blocks were then distributed to the expert panel for independent grading.

Evaluation of Accuracy

Reference standards were established based on authoritative international guidelines, including Clinical guidelines for the diagnosis and treatment of nonspecific LBP in China [17], the National Institute for Health and Care Excellence (NICE) Guideline [18], American College of Physicians Clinical Practice Guideline [19], and The Lancet LBP Series [20-22].

To ensure output uniformity and facilitate precise coding by the expert panel, a consistent instructional prompt was appended to each textual question (Q1-Q25): “Please provide your answer point-by-point, ensuring that each point contains only a single, distinct recommendation.” This instruction established a clear operational boundary, allowing the model outputs to be automatically segmented into bullet points.

A panel of 5 experts independently coded each individual recommendation extracted from model responses into 1 of 6 categories: correct recommendation or rejection (guideline-supported), incorrect recommendation or rejection (guideline-opposed), and unclear (not mentioned in the guidelines). To evaluate potential clinical safety risks, we specifically identified “serious errors,” defined as recommendations that are life-threatening or could cause permanent functional loss. Interrater reliability was assessed using Fleiss κ, with values exceeding 0.60 interpreted as substantial agreement.

Given that most responses from LLMs encompass multiple recommendations, a 5-point Likert scale was used to quantify the overall quality of each model’s response:

- 5 (excellent): 100% accuracy in all suggestions.
- 4 (good): inaccurate or unclear suggestions ≤25%; no serious errors.
- 3 (average): inaccurate or unclear suggestions >25% but ≤50%, with no serious errors.
- 2 (poor): inaccurate or unclear suggestions >50% but ≤75%, or contains 1 serious error.
- 1 (very poor): inaccurate or unclear suggestions >75%, or contains >1 serious errors.

Given the known limitations of current vision-language models, we adopted an exploratory quantitative case series approach to the multimodal assessment. We selected 5 adversarial “probe cases” specifically designed to trigger potential hallucinations, rather than aiming for statistical representativeness.

Multimodal capabilities were assessed across 2 dimensions using a consensus standard defined by 3 senior radiologists and surgeons:

- Imaging recognition (Q26-Q28): the models generated radiology reports from computed tomography (CT) and magnetic resonance imaging (MRI) slices. Performance was evaluated using two metrics: (1) diagnostic consistency, scored on a 1‐4 scale, where 4 indicates complete concordance with the reference diagnosis and 1 indicates >75% error or severe hallucination; (2) descriptive accuracy, defined as the model’s ability to identify core pathological findings specified in the gold standard, calculated as: descriptive accuracy = (number of key findings correctly mentioned by the AI/total number of key findings in the gold standard) × 100%.
- Comprehensive diagnostic analysis (Q29-Q30): the models integrated history, labs, and imaging for diagnosis and treatment planning. Scoring followed a 5-point scale:
  - 5 (excellent) correct primary diagnosis, all key secondary diagnoses correct, accurate clinical-imaging correlation, 0% noncompliant treatments, and no serious errors.
  - 4 (good) correct primary diagnosis, secondary diagnoses and clinical-imaging correlation correct or only minor or incomplete without changing clinical management, noncompliant treatments ≤25%, and no serious errors. This includes responses with correct primary and secondary diagnoses but >0% and ≤25% noncompliant treatments.
  - 3 (moderate) correct primary diagnosis but one or more key secondary diagnoses or clinical-imaging correlations missed or wrong, or noncompliant treatments >25% and ≤50%, or 1 serious error.
  - 2 (poor) wrong primary diagnosis with partially correct secondary findings, or correct primary diagnosis with missed or wrong key secondary diagnoses plus noncompliant treatments >50% and ≤75%, or more than 1 serious error.
  - 1 (very poor) both primary and key secondary diagnoses wrong or missing, or noncompliant treatments >75%.

The same 3 experts independently graded all LLM-generated multimodal outputs against this consensus standard. Interrater reliability was assessed using Fleiss κ, with values exceeding 0.60 interpreted as substantial agreement.

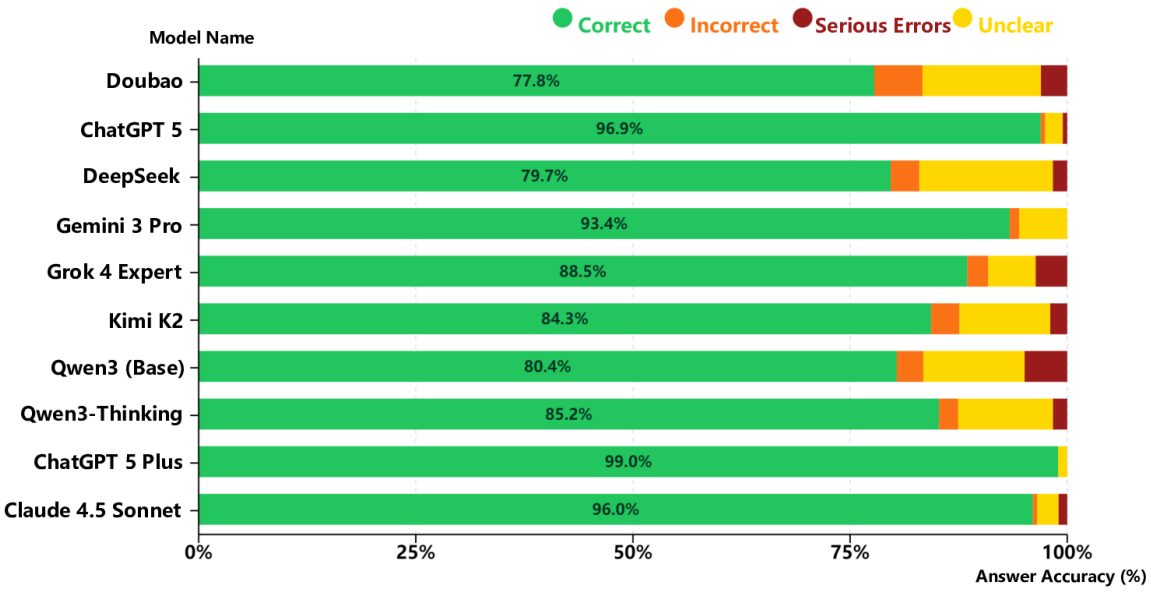
Readability, Disclaimer Coverage, and Statistical Analysis

Readability was quantified using the Flesch Reading Ease (FRE) [23] and the Simple Measure of Gobbledygook (SMOG) [24]. Understandability was evaluated using the Understandability section of the Patient Education Materials Assessment Tool–Print Materials (PEMAT-P) scale [25,26]. The actionability domain of the PEMAT-P was excluded based on two methodological considerations: (1) our analysis was conducted at the microlevel of 1816 individualized, segmented recommendations rather than whole, intact educational brochures, meaning that applying actionability criteria to isolated sentences would introduce systemic floor effects; and (2) the primary focus of this linguistic assessment was to strictly isolate the local clarity and wording of the information, whereas the clinical appropriateness and safety of the actionable content had already been independently and thoroughly evaluated by the expert panel using a 5-point Likert scale. Language scoring was performed by a mixed panel comprising 3 nonmedical English professionals or native English-speaking researchers, along with 1 medical expert. Consensus on divergent items was achieved through panel discussions. Furthermore, the presence or absence of medical disclaimers (eg, “The above information is for

XSL•FO
RenderX

reference only; please consult a professional doctor" or similar statements) was evaluated as an indicator of system-level guardrails, and the coverage rate for each model was subsequently calculated [27].

Ethical Considerations



This study was conducted as a substudy within the approved parent project, which was reviewed and approved by the Ethics Committee of The Third Affiliated Hospital of Zhejiang Chinese Medical University (Approval ZSLL-KY-2024-080-01). The parent project provided the ethical approval framework for the patient materials used in the present manuscript. The consultation with 10 patients with LBP for question-tone evaluation was covered under the approved protocol, and written informed consent was obtained from these participants. The retrospective imaging materials used in the exploratory multimodal stress test were deidentified before analysis, and individual informed consent for this retrospective imaging component was waived under the approved protocol. Before resubmission, all image panels included in Multimedia Appendix 1 were re-reviewed at full resolution; patient names, patient IDs and medical record numbers, accession numbers, dates and times, age and sex information, and other patient-identifying overlay information were removed. Nonidentifying anatomical orientation markers and lumbar level labels, such as R/L, L3/4, L4/5, and L5/S1, were retained only when necessary for anatomical interpretation. This manuscript represents an AI and LLM evaluation substudy based on materials from the approved parent project and did not involve additional patient intervention.

Results

Accuracy of Textual Responses

The interrater reliability assessment for text-based clinical accuracy coding yielded a Fleiss κ of 0.79, indicating substantial agreement among the expert panel regarding the clinical accuracy of the 1816 coded recommendations. In textual tasks, the models demonstrated a qualitative leap in performance compared to previous benchmarks, achieving an overall accuracy rate of 88.4% (1605/1816; Figure 1). The paid reasoning model, ChatGPT 5 Plus, exhibited near-perfect performance with 98.96% accuracy and zero instances of "inaccurate" or "serious errors" recommendations. Other top-tier models (ChatGPT 5 Free and Claude 4.5 Sonnet) also maintained high standards (>96% accuracy, ChatGPT 5 Free: 190/196, 96.9%; Claude 4.5 Sonnet: 194/202, 96.0%). It is noteworthy that in the English context, China's domestic models, such as Doubao and DeepSeek, exhibit an accuracy rate below 80% (Doubao: 154/198, 77.8%; DeepSeek: 145/182, 79.7%), indicating a descriptive difference compared to top-tier models (Figure 1). This performance gap may be partially influenced by the English-language constraint, as these models were tested exclusively in a nonnative language, introducing a cross-lingual processing variable. In the within-model comparison of Qwen3, the reasoning or thinking mode (Qwen3-Thinking) showed a lower rate of serious errors than the standard mode, Qwen3 (Base; 1.64% vs 4.91%), suggesting, to some extent, the potential value of "slow thinking" in clinical contexts.

Figure 1. Proportions of accurate, inaccurate, serious errors, and unclear recommendations in text-based question answering across various large language models (LLMs). In terms of the overall quality scores across all responses, the performance of each model is illustrated in Table 2, while the question-level distribution of quality scores is illustrated in Figure 2. ChatGPT 5 Plus achieved the highest average overall quality score of 4.92 (SD 0.28), demonstrating exceptionally high accuracy in its responses. Following closely behind are ChatGPT 5 with a score of 4.68 (SD 0.75) and Claude 4.5 Sonnet at 4.56 (SD 1.00). Conversely, Doubao received the lowest average overall quality score (3.44, SD 1.26), followed by Qwen3 (Base; 3.60, SD 1.35), indicating relatively lower response quality characterized by inaccuracies or unclear content.

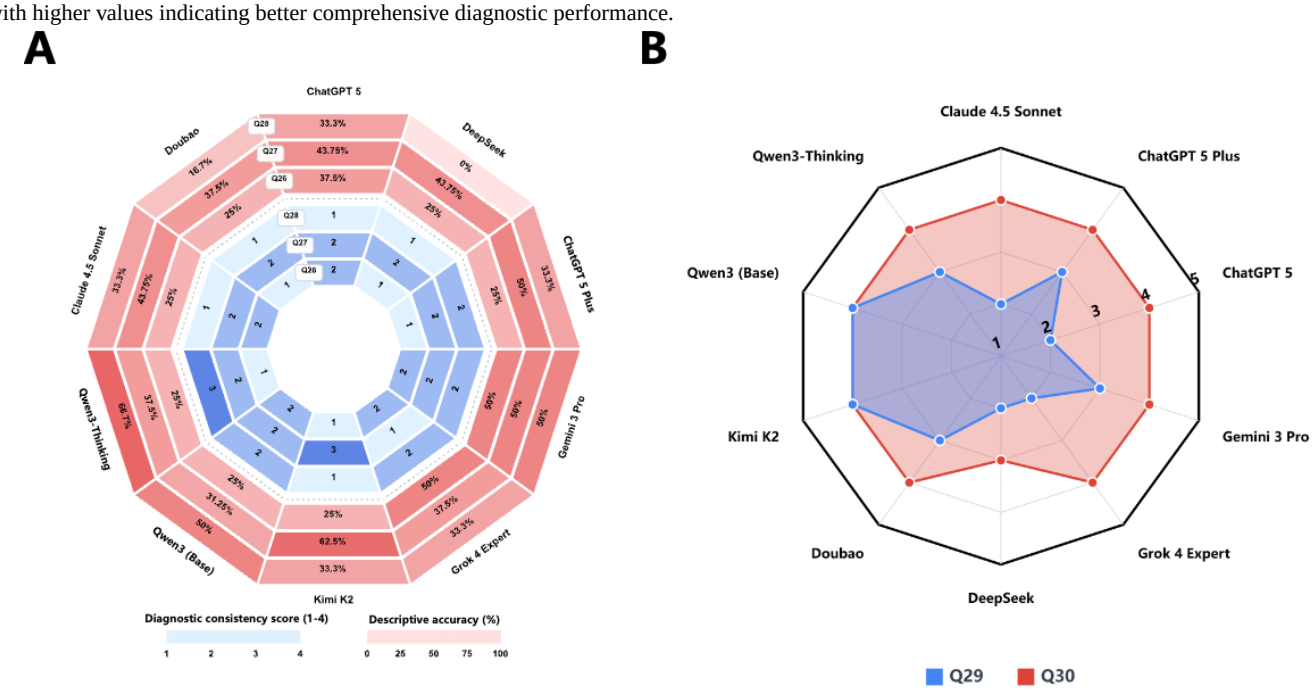
International models[a]	4.57 (0.86)	107/150 (71.3)	101/125 (80.8)	6/25 (24)

[a]Aggregated SDs for the "Ensemble average," "Chinese models," and "International models" rows were calculated based on pooled individual responses across the respective models.

Figure 2. Heatmap of response scores for each text question across various large language models (LLMs).

Multimodal Capability Assessment



In stark contrast to the high proficiency observed in textual tasks, the exploratory adversarial stress test (N=5) suggested a potential "vision-language Mismatch" under these constrained test conditions. The interrater reliability for the multimodal assessment yielded a Fleiss κ of 0.82, indicating substantial agreement among the 3 expert raters.

Pure Imaging Tasks (Q26-Q28)

Performance in isolated visual interpretation was notably poor (Figure 3A). The average diagnostic score was 1.70/4.0 (below "partially accurate"). Models frequently failed to identify core pathological signs on CT and MRI slices. A distinct phenomenon of "textual-cue-driven guessing" was observed: in some cases, models appeared to extrapolate from minimal nondiagnostic textual cues, including the phrase "low back pain" in the task prompt and residual spinal-level labels retained in the deidentified images, rather than relying solely on visual evidence. For instance, when the visual input was ambiguous, DeepSeek generated plausible but hallucinated radiological descriptions that appeared to infer pathology from these limited contextual cues rather than from identifiable imaging findings.

RenderX

Figure 3. Multimodal performance of the evaluated large language models (LLMs) in the exploratory stress test. (A) Performance on pure imaging recognition tasks (Q26-Q28). The circular heatmap presents diagnostic consistency in the inner blue rings (1-4 scale; higher scores indicate greater concordance with the reference diagnosis) and descriptive accuracy in the outer red rings (percentage of core pathological findings correctly identified). Q26, Q27, and Q28 denote the individual imaging test cases, and the labels around the plot identify the evaluated models. (B) Performance on comprehensive diagnostic analysis tasks (Q29-Q30). The radar chart shows model-level scores for Q29 (blue) and Q30 (red) on the 1-5 scoring scale, with higher values indicating better comprehensive diagnostic performance.

Comprehensive Diagnostic Analysis (Q29-Q30)

Performance showed an illusory improvement (mean score 3.35/5.0, SD 0.81; Figure 3B). However, a detailed breakdown based on our 5-point scoring rubric and case-level analysis indicated that this improvement was likely attributable to textual cues (eg, lab results, physical exam descriptions) acting as "anchors" rather than genuine visual understanding. A distinct pattern emerged in the model responses: models frequently secured baseline points by correctly identifying the primary diagnosis, driven by the clinical history, but consistently lost points (typically scoring 3 or 4) due to missing or misdiagnosing secondary conditions, which required genuine extraction of contradictory visual evidence. For example, models successfully identified the primary pathology in the ankylosing spondylitis "trap case" (Q30) because the provided laboratory data (HLA-B27 positive) guided their reasoning. This effectively bypassed their visual deficit, creating a "Clever Hans" effect in which the model appeared to diagnose the image but was actually diagnosing the text.

Readability and Understandability

The readability of all model-generated English texts is relatively high on average, failing to meet the recommended standards for public health communication. The average FRE index is 46.15 (SD 16.39), falling into the "fairly difficult" range. The average SMOG index is 11.54 (SD 1.94; Table 3), indicating a reading level equivalent to approximately 11th-12th grade (US education system). ChatGPT 5 Plus produced the most readable texts (average FRE: 56.86, SD 15.24; SMOG: 8.75, SD 1.05; Table 3), while Grok 4 Expert generated the least readable content (average FRE: 37.7, SD 16.93; SMOG: 14.04, SD 2.61; Table 3). In terms of understandability, although the language complexity is high, the models perform moderately well in information organization and clarity of expression. At the segment level, the relatively high Patient Education Materials Assessment Tool (PEMAT) understandability scores appeared to reflect local clarity features, including explicit wording, single-topic recommendation units, and consistent point-by-point phrasing in the source responses, rather than macrolevel action tools or comprehensive document structure. The average PEMAT understandability score was 85.61 (SD 7.51; Table 3). Qwen3-Thinking had the highest score (89.60, SD 5.64; Table 3), while Grok 4 Expert had the relatively lowest understandability score (82.72, SD 7.21; Table 3).

XSL•FO
RenderX

Table . Mean (SD) of readability scores (Flesch Reading Ease [FRE] and Simple Measure of Gobbledygook [SMOG]) and understandability scores (Patient Education Materials Assessment Tool [PEMAT]) across all questions for various large language models (LLMs).

Model	FRE score, mean (SD)	SMOG score, mean (SD)	Understandability (PEMAT) score, mean (SD)
ChatGPT 5 Plus	56.86 (15.24)	8.75 (1.05)	83.44 (9.58)
ChatGPT 5	45.78 (18.63)	11.97 (2.84)	84.56 (8.80)
Claude 4.5 Sonnet	41.94 (19.08)	12.34 (2.09)	84.48 (8.26)
Gemini 3 Pro	54.56 (13.96)	10.86 (1.69)	86.60 (7.93)
Grok 4 Expert	37.72 (16.93)	14.04 (2.61)	82.72 (7.21)
Qwen3-Thinking	40.22 (17.11)	12.10 (2.14)	89.60 (5.64)
Kimi K2	42.33 (18.02)	11.74 (2.26)	84.40 (5.81)
DeepSeek	51.76 (13.20)	11.31 (1.53)	86.12 (7.54)
Qwen3 (Base)	39.67 (16.99)	11.77 (1.72)	86.52 (8.31)
Doubao	50.62 (15.14)	10.53 (1.44)	87.64 (6.05)
Ensemble average[a]	46.15 (16.39)	11.54 (1.94)	85.61 (7.51)
International models[b]	47.37 (8.17)	11.59 (1.96)	84.36 (1.47)
Chinese models[b]	44.92 (5.82)	11.49 (0.61)	86.86 (1.93)

[a]SD for the "Ensemble average" was calculated based on pooled individual responses.

[b]SDs for "International models" and "Chinese models" were calculated based on the model-level means.

Disclaimer Coverage

We observed marked descriptive variation and potential safety risks in the presentation of health disclaimers. Among all 300 responses, the overall inclusion rate was 73.67% (221/300). In pure text tasks (Q1-Q25), safety guardrails were robust: ChatGPT 5, Claude 4.5 Sonnet, and DeepSeek achieved a perfect 100% coverage rate, bringing the overall average coverage for text-based tasks to 82.8% (207/250).

However, a concerning red flag emerges when analyzing cross-modal performance (Table 2). When tasks transitioned from pure text to multimodal diagnostics (Q26-Q30), the overall disclaimer coverage plummeted to 28% (14/50), including 24% (6/25) for international models and 32% (8/25) for Chinese models. Notably, top-performing flagship models like ChatGPT 5 Plus, Claude 4.5 Sonnet, and Grok 4 Expert, which maintained exceptionally high textual disclaimer coverage (21/25, 84% to 25/25, 100%), saw their coverage drop entirely to 0.0% when responding to multimodal queries.

Discussion

Principal Findings

Our data confirm a leap in the development of AI over the past year [28]. Performance data indicate that the latest advancements in LLM capabilities may signify a quantum leap rather than merely iterative linear improvements [29]. Compared with the benchmarks studied by Scaff et al [4] a year ago, the new generation not only performs better but also possesses different functionalities. With overall accuracy reaching 88.4% (1605/1816), and specific architectures such as ChatGPT 5 Plus exceeding 98.96% [30], these systems appear to be transitioning beyond the role of passive information retrieval [31]. This represents a direct manifestation of the architectural shift: moving away from the previous simplistic model that focused solely on rapid response and instead offering a reasoning mode with "long thinking" capability that implements the chain-of-thought protocol to address more complex logical problems [32]. Earlier versions displayed a more "impulsive" nature. In contrast, modern language models, such as Qwen3-Thinking [33,34], simulate an analytical reasoning process that closely resembles human "slow thinking." They deconstruct clinical vignettes, explicitly weighing risk factors and synthesizing contradictory guidelines before committing to an output [35]. In the Qwen3 matched comparison, Qwen3-Thinking showed a lower serious-error rate than Qwen3 (Base; 1.64% vs 4.91%). This finding is best interpreted as a hypothesis-generating, within-model observation that reasoning-enhanced operation may reduce "serious errors" in this specific paired comparison, rather than as proof of a universal advantage of reasoning modes across all models. Therefore, longer "thinking" time should be considered a potential safety-relevant design feature that requires further paired validation, not a guaranteed safeguard.

Yet this textual mastery constructs a perilous facade. Our investigation exposes a profound "asymmetric evolution." A sharp divergence emerged. While textual logic scores compare favorably with senior consultant levels, the visual diagnostic capabilities did not track; they remained, by contrast, unreliable and largely undeveloped in our testing [36]. This creates a "high-confidence trap." The danger lies not in the incompetence itself but in the masking of that incompetence. In our multimodal case series, models frequently failed to identify even elementary pathological signs in pure imaging tasks (Q26-Q28), yielding a dismal diagnostic score of 1.70/4.00. If such results were to come from a radiologist, they would undoubtedly be deemed

XSL•FO
RenderX

unqualified; however, LLMs present their errors with the authoritative cadence of an expert. If unaddressed, this asymmetry could introduce new vectors for public health risks when patients interact with multimodal AI systems. The realism of our multimodal design, where patients present raw CT and MRI scans to LLMs, is deeply rooted in current digital health infrastructures and common clinical "waiting gaps." Specifically, two pervasive real-world scenarios drive this patient behavior:

1. The follow-up gap via mobile portals: patients often access their imaging slices through hospital mobile apps days before their scheduled follow-up appointment, frequently downloading them due to health anxiety,
2. The radiology report is delayed: immediately after a scan, images are transmitted to the clinical workstation, allowing anxious patients to acquire image captures (eg, via smartphone photos of the screen) before the formal text report is finalized by a radiologist.

During these reportless waiting periods, driven by anxiety and eager for immediate answers, patients increasingly use LLMs to "preread" or interpret these fragmented image slices as an accessible "second opinion." Therefore, evaluating this specific multimodal interaction is highly clinically relevant.

A patient, seduced by the model's brilliant, nuanced answers to textual questions (eg, "How do I titrate my analgesics?"), will naturally extend that trust to the visual domain (eg, "Does this protrusion mean I have a herniated disc?"). They cross a capability cliff without a warning sign. This discrepancy may lead to misunderstandings, as users might mistakenly believe that the "brain" responsible for generating text responses in LLMs operates similarly to the "brain" that analyzes images. However, our exploratory studies demonstrate that this is not the case; in fact, the models were unable to accurately identify lesion sites in the lumbar vertebrae.

The "Clever Hans" effect [37] is a narrative coercion. The mechanism of this failure is perhaps more complex than simple "visual blindness." Our "trap cases" (Q29-Q30) revealed a phenomenon of "textual masking." The models appeared to succeed in comprehensive diagnosis not because they integrated the visual data but rather because they successfully ignored it.

When provided with a rich clinical history—such as keywords like "HLA-B27 (human leukocyte antigen B27) positive" or "morning stiffness"—the vast majority of models correctly identified the primary diagnosis of ankylosing spondylitis. However, their performance was markedly lower in pure image-recognition tasks. We have reason to infer that they were not diagnosing the patient; they were diagnosing the text. The observed mechanism mirrors the "Clever Hans" phenomenon, albeit computationally. The models appeared to function correctly on the surface, but in reality, they were likely reacting to textual cues (such as "HLA-B27") rather than processing the visual pathology itself. The models hallucinated visual confirmations to align with the textual narrative.

This overreliance on textual cues is strongly validated by our scoring rubric for Q29-Q30. According to the predefined 5-point scale, a score of 3 or 4 indicates a correct primary diagnosis but errors or omissions in the secondary diagnosis. In our deliberately designed adversarial cases, the primary diagnosis was strongly suggested by the text (simulating clinical scenarios where imaging findings contradict the main symptoms, necessitating careful physical examination and comprehensive analysis), whereas the secondary diagnosis required a cross-modal synthesis incorporating the imaging. The models' systematic failure to achieve perfect scores of 5 mathematically indicates that while their "textual brain" correctly parsed the history, their "visual eyes" failed to capture the radiological findings required to determine the secondary diagnosis.

In controlled testing, this approach yields a seemingly accurate label. However, in practice, it presents important practical safety challenges. For example, if a patient uploads an image of a vertebral fracture while describing symptoms resembling muscle strain, a text-reliant model constrained by the narrative may completely overlook the fracture. An auxiliary consultation tool that cannot prioritize visual evidence over patient statements serves not as a diagnostic aid but rather as an "echo chamber" [38].

Most alarming is the collapse of the safety architecture itself. We observed a large descriptive drop in safety-disclaimer coverage, from 82.8% (207/250) in textual tasks to 28% (14/50) in multimodal settings. This pattern suggests an observed gap in the model's response protocols rather than simple random error. It signals a fundamental, structural flaw in the alignment of multimodal LLMs.

We hypothesize that this is "Cross-Modal Misalignment" [39]. The industry's safety training—reinforcement learning from human feedback—has been predominantly textual. The model's "superego"—its refusal mechanisms, its hedged language, its ethical guardrails—is triggered by textual tokens (eg, "diagnose," "tumor"). Visual inputs, however, arrive via a separate pathway (eg, a vision transformer encoder) and are projected directly into the language space [40]. These visual embeddings appear to bypass the textual sentries. The model "sees" the pixels of a spine but fails to trigger the "I am an AI, not a doctor" protocol that the word "spine" would instantly activate. This "ethical bypass" leaves the user vulnerable precisely when the task is most complex and the model's competence is at its nadir.

Consistent with the concerns raised by Scaff et al [4], the linguistic output of these models remains inaccessible to the population that needs it most. With a reading level hovering at grade 11 - 12 (versus the recommended grade 6 - 8), the advice is accurate but opaque. This is the tension of the training data: models fed on high-impact medical literature inevitably adopt an academic register.

However, the differences between international and domestic models suggest potential remedies. The Chinese models (Qwen and Doubao), while demonstrating relatively lower accuracy in English contexts, achieve superior PEMAT understandability scores. Their secret lies in their distinctive presentation formats. These models tend to use clearer local organizational cues, such as explicit labels, short, single-topic units, and point-by-point phrasing. These features may improve segment-level understandability, but they should not be interpreted as

XSL•FO
RenderX

macrolevel actionability tools or as comprehensive document structure [41]. If we cannot dumb down the vocabulary without losing precision, we must structure the layout. Future AI must prioritize this "structural readability," ensuring that actionable advice is visually isolated from the dense reasoning that supports it.

Based on the aforementioned observations, there is an urgent need to transform passive monitoring into concrete interventions. For clinicians, they must actively uncover the "asymmetric" nature of these tools. The application of LLMs with patients must transition from a binary "trust and distrust" framework to a more nuanced operational guidance. Physicians can promote the use of LLMs for managing lifestyle and educational reinforcement—areas in which they excel—while issuing stern and explicit warnings against relying on them for image interpretation. The conclusion is clear; leverage the "brain" of LLMs, but never trust their "eyes." For patients, "digital triage" is the new literacy. Users must understand that these agents are "virtual textbooks," not "virtual radiologists." A model's confident description of an MRI and CT scan is often a linguistic fabrication—a statistical guess dressed in a lab coat. "Read the text, but ignore the diagnosis" must become the cardinal rule of AI self-help. For developers, the "safety gap" is an important technical challenge, not a backlog item. Future reinforcement learning from human feedback pipelines must incorporate multimodal adversarial examples. Models must be trained to establish a functional equivalence: an image of a bone must activate the same guardrails as the text string "diagnose this bone," enforcing either an immediate refusal or a nonnegotiable disclaimer.

Implications of "Serious Errors" for Patient Safety

While the primary methodological focus of this study is the evaluation of clinical accuracy and cross-modal reliability, it is critical to recognize that, in the medical domain, profound inaccuracy inherently translates into patient safety risks. Our findings reveal a concerning dynamic: current LLMs demonstrate near-expert accuracy in textual reasoning, effectively minimizing "serious errors" (life-threatening advice). However, when transitioning to visual interpretation tasks, their diagnostic accuracy drops precipitously.

Crucially, this vulnerability is compounded by the systemic absence of medical disclaimers in multimodal tasks (dropping to 14/50, 28%). In these adversarial scenarios, this stark contrast represents a potential "high-confidence trap." Patients, seduced by the model's highly accurate textual advice, may mistakenly extend their trust to its fabricated visual interpretations. In a direct-to-patient application scenario, an AI that confidently hallucinates a benign condition when presented with a complex LBP imaging pathology—without issuing a disclaimer to consult a human doctor—could dangerously delay critical medical intervention. Therefore, while our metrics measure "accuracy," the profound lack thereof in multimodal settings poses a potential safety risk for patient self-management.

Limitations

First, while our study is anchored in a text-based evaluation, the sample size of the multimodal component (N=5) limits the statistical generalizability of the conclusions. We must emphasize that this component was designed exclusively as an exploratory adversarial probe rather than a statistically powered benchmark. Future studies with larger sample sizes should be conducted for more comprehensive research. Consequently, these multimodal findings reflect specific vulnerabilities under adversarial stress conditions rather than a comprehensive assessment of the models' average baseline capabilities. Therefore, our results serve as a preliminary caveat, and the specific performance of LLMs in complex imaging tasks urgently requires validation through dedicated future studies using large-scale datasets. Furthermore, our comprehensibility scores may be relatively high; our raters consist of either English majors or native English-speaking researchers with advanced degrees, whose cognitive thresholds for academic terminology surpass those of the average patient. The PEMAT scale, while reliable, risks reducing the chaotic experience of comprehension to a single, sterile metric. We also acknowledge a linguistic bias; testing exclusively in English may have obscured the localization advantages of domestic models in their native Chinese contexts. Furthermore, because the FRE and SMOG indices are calibrated specifically for English syntax, their application to outputs from Chinese domestic models may not perfectly reflect true readability due to potential nonnative phrasing. Finally, we are chasing a moving target. Given the hyper-velocity of LLM iteration, these results are a snapshot frozen in time. The discrepancy between these findings and the model version available tomorrow is not a flaw in the study; it is the unavoidable condition of research in this field.

Future Work and Recommendations

Future research should focus on expanding the multimodal stress-test dataset to encompass a broader spectrum of musculoskeletal disorders and evaluating these models within real-world, prospective clinical workflows. To mitigate the risk of serious errors observed in our study, we recommend developing localized, medically fine-tuned multimodal LLMs—following validation via large-scale, statistically powered benchmark datasets—or integrating a dedicated "medical mode" into existing LLMs. Furthermore, in any future clinical or health guidance applications involving LLMs, it is imperative that AI-generated diagnostic recommendations be consistently verified by a team of qualified medical professionals, or that comprehensive coverage of disclaimers is guaranteed, to safeguard patient safety.

Conclusions

This study evaluated the performance of 10 representative LLMs in LBP management through a cross-sectional textual assessment and an exploratory multimodal adversarial stress test. In textual tasks, models achieved an overall accuracy of 88.4% (1605/1816). Within the matched Qwen3 pair, Qwen3-Thinking showed a lower serious-error rate than Qwen3 (Base; 1.64% vs 4.91%), suggesting a possible safety benefit that requires confirmation in broader paired comparisons. In contrast, under exploratory multimodal adversarial stress conditions, models exhibited a marked decline in performance: diagnostic scores in pure imaging tasks were poor (mean 1.70/4.00), and models frequently relied on textual cues rather than integrating

XSL•FO
RenderX

contradictory visual evidence. Additionally, medical disclaimer coverage dropped from 82.8% (207/250) in textual tasks to 28% (14/50) in multimodal interactions. These findings indicate that current multimodal LLMs remain unready for direct patient use in visual diagnostic tasks.

Acknowledgments

The authors declare that no generative AI or AI-assisted technologies were used in the writing, editing, or preparation of this manuscript. The large language models (eg, ChatGPT, Claude, and DeepSeek) evaluated and discussed in this article were strictly the subjects of the experimental research and were not used to generate any portion of the manuscript's text.

Abstract

Background: Perioperative computed tomography (CT) imaging is essential for detecting postoperative recurrence and metastasis in cancer patients. However, large-scale automated extraction of oncological outcomes from CT reports remains limited by the unstructured nature of report text and wide variability in reporting styles. Radiology reports frequently contain linguistic ambiguities, including negations, hedging, and expressions conveying diagnostic uncertainty (eg, “cannot exclude recurrence” or “possibly metastatic”). Manual review is labor-intensive and constrains consistent extraction at scale. The inability to systematically account for diagnostic uncertainty represents a major barrier to reliable automated surveillance systems.

Objective: This study aimed to develop a semisupervised deep learning (DL) classification framework that explicitly captures diagnostic uncertainty by classifying postoperative recurrence and metastasis into 3 categories (positive, negative, and uncertain).

Methods: This retrospective study analyzed 288,076 postoperative CT reports from 86,083 cancer surgery patients at Asan Medical Center (2014 - 2021). After exact-match deduplication, model training and evaluation used 17,846 unique reports for recurrence and 63,766 for metastasis. Preprocessing identified presumed negatives through keyword filtering and unsupervised clustering. The semisupervised framework incorporated human-in-the-loop validation across 3 cycles—with clinicians reviewing approximately 2000 samples per cycle (<1% of total reports)—and integrated rule-based algorithms (RAs) and medical BERT (MedEmbed and PubMedBERT). A report-level train-validation split was used, as preprocessing reduces each report to sentence-level fragments that preclude patient-level linkage. Performance was evaluated against RAs and multiple BERT variants under both naive and simulated real-world class distributions. Maximum mean discrepancy testing confirmed distributional integrity of the sampled data. Model interpretability was assessed using Integrated Gradients.

Results: The cohort included 11 cancer types, predominantly gastrointestinal (28,516/86,083, 33.1%), hepatobiliary and pancreas (14,715/86,083, 17.1%), and genitourinary (12,959/86,083, 15.1%). Under simulated conditions, PubMedBERT achieved 92.58% accuracy for recurrence in the multiclass, and MedEmbed achieved 93.25% for metastasis in the binary class. The framework achieved accuracies of 97.33% (multiclass) and 99.33% (binary class) for recurrence and 95.00% (multiclass) and 96.67% (binary class) for metastasis, compared with human intrarater consistencies of 96.88% and 93.80% (recurrence and metastasis, respectively, for multiclass), reflecting concordance with the clinician-derived consensus standard. The framework captured diagnostic uncertainty in 1.4% of recurrence cases and 6.9% of metastasis cases. Notably, the RA outperformed several sophisticated DL models in metastasis classification.

Conclusions: The proposed framework achieves clinician-concordant classification across the full 288,076-report corpus while requiring minimal expert annotation (<1% of reports). By explicitly modeling diagnostic uncertainty and combining rule-based and DL approaches, it demonstrates the potential for automated cancer surveillance and clinical decision support in real-world settings; however, generalizability to other institutions requires prospective multicenter validation.

Introduction

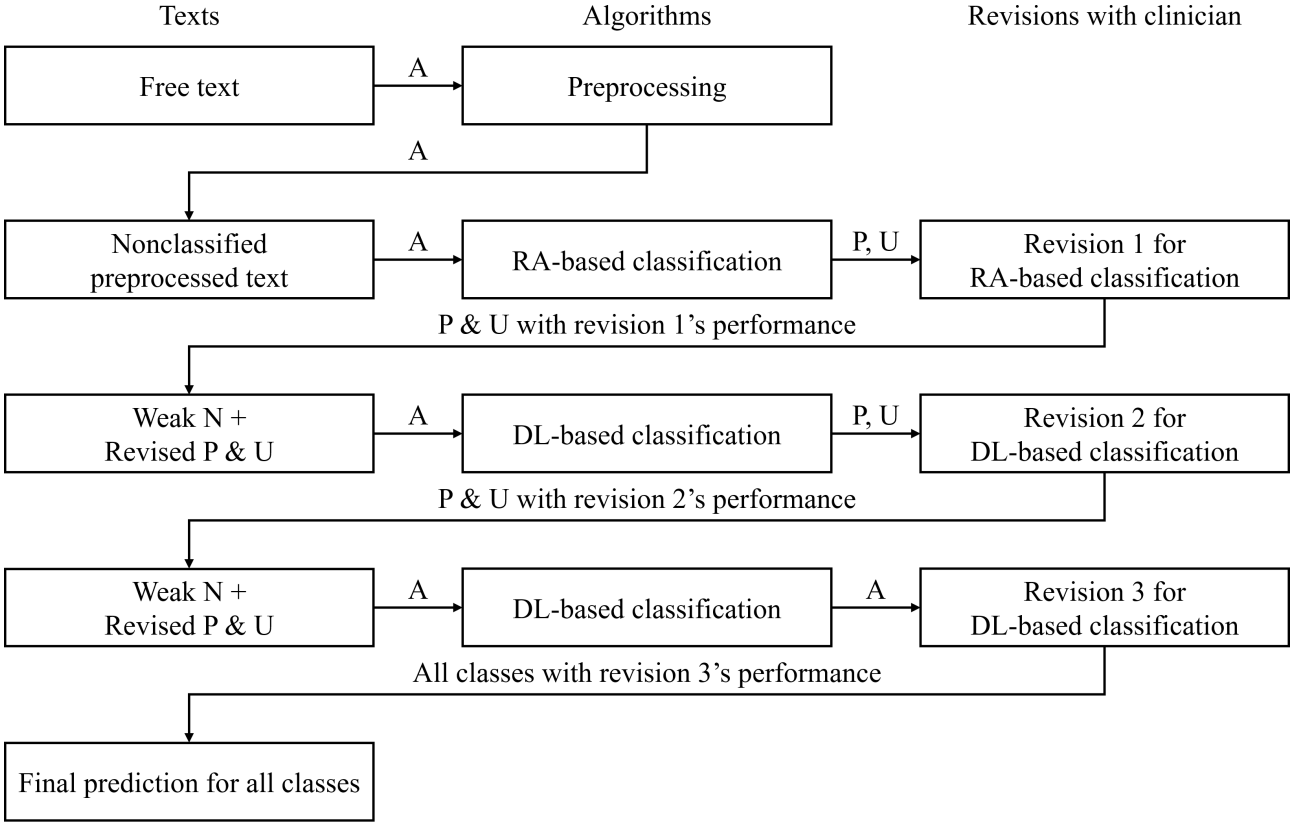
Perioperative computed tomography (CT) imaging plays a crucial role in diagnosing and monitoring patients undergoing cancer surgery, and radiology reports provide essential information for detecting recurrence or distant metastasis [1]. Although individual CT examinations are interpreted with high accuracy in clinical practice, the large-scale use of radiology reports for research, quality monitoring, or automated surveillance remains limited. This limitation primarily stems from the unstructured nature of report text and wide variability in reporting styles [2-4]. These challenges, which include substantial institutional and stylistic variation, undermine the reliability of automated information extraction across diverse clinical environments [5]. Consequently, manual review remains highly labor-intensive and constrains the consistent, large-scale extraction of oncologic outcomes [4,6].

Radiology reports frequently contain linguistic ambiguities such as negations, hedging, and expressions that convey diagnostic uncertainty (for example, “cannot exclude recurrence” or “possibly metastatic”) [7-9]. In clinical practice, such language is typically addressed through conservative interpretation. Recent studies on extracting oncologic outcomes from free-text radiology reports have demonstrated that nonstandardized and ambiguous expressions substantially complicate automated detection [10,11]. As interest in population-level postoperative surveillance and automated extraction of oncologic outcomes continues to grow, the inability to systematically account for diagnostic uncertainty remains a major barrier to the reliability of large-scale monitoring systems [12].

To address these gaps, we proposed a language model (LM)–based system that classifies postoperative CT impressions by assigning both recurrence and metastasis into 1 of 3 categories (positive, negative, and uncertain). This design explicitly incorporates the ambiguous expressions that commonly appear in real-world radiology reporting [9,11]. By leveraging advances in biomedical language representation and pretrained deep learning (DL) models [13-15], together with uncertainty-aware approaches reported in natural language processing (NLP), the proposed framework aimed to improve classification consistency and accuracy in heterogeneous postoperative CT reports [16].

Methods

Study Design



This retrospective study analyzed 288,076 postoperative CT radiology reports from 86,083 patients who underwent cancer surgery at Asan Medical Center, Seoul, Republic of Korea. To address the lack of manual annotations for recurrence or metastasis, we developed a semisupervised learning framework incorporating a human-in-the-loop (HL) approach to enable scalable labeling. This approach is considered semisupervised because clinician-reviewed gold standard labels were available only for positive and uncertain class samples, while the remaining negative samples were incorporated as weakly labeled samples during training. In this framework, clinicians initially provided raw radiology reports and reviewed the model’s predictions, providing targeted feedback on ambiguous or clinically relevant cases. Guided by this feedback, the model was iteratively refined to improve classification performance. The finalized framework yielded 2 primary outputs: (1) a trained model capable of predicting recurrence and metastasis for newly acquired postoperative CT reports and (2) predicted labels for the entire historical cohort of reports.

Framework

The proposed framework was built around an HL schedule, in which clinician review and model training were iteratively coupled to generate reliable labels from large-scale unlabeled CT radiology reports (Figure 1). To support this iterative process, the framework incorporated 3 preparatory components: preprocessing, presumed negative labeling, and classification.

XSL•FO
RenderX

Figure 1. Human-in-the-loop schedule for iterative label generation from 288,076 postoperative computed tomography (CT) radiology reports collected at Asan Medical Center (2014 - 2021) across 3 revision cycles, with only positive and uncertain conditions reviewed by clinicians in revisions 1 and 2 and all classes including negative cases reviewed in revision 3 to establish the final performance benchmark. A: algorithm-generated predictions applied to all classes; DL: deep learning; N: weak negatives identified through hybrid clustering; P: positive cases forwarded for clinician review; RA: rule-based algorithm; U: uncertain cases forwarded for clinician review.

Preprocessing

Raw CT radiology reports underwent 2 sequential steps. First, report text was cleaned by removing formatting artifacts such as excessive line spacing and hyphen-based line separators that commonly appear in clinical documentation. Second, the cleaned reports were filtered using keyword matching ("recur" and "metas") to identify reports relevant to postoperative recurrence or metastasis. These keywords were applied as word stems rather than exact matches; thus, "recur" captured recurrence and recurrent disease, while "metas" captured metastasis, metastatic lesion, and metastases. In clinical practice, recurrence and metastasis represent critical postoperative findings that radiologists are expected to document explicitly, as failure to use standard terminology for critical findings may affect the completeness of clinical documentation and downstream management decisions. This assumption is clinically reasonable given institutional documentation standards, where radiologists are expected to use explicit terminology for critical findings; however, cases described using synonymous or indirect language may be inadvertently excluded. Accordingly, reports without a keyword match were designated as "presumed negatives" and excluded from subsequent classification.

To quantify the potential loss of positive cases during preprocessing, we performed a manual audit of 300 randomly selected keyword-excluded reports from the presumed-negative pool. Notably, the preprocessing steps substantially simplified report text, reducing patient-specific linguistic variation across reports. As a result, consistent patterns were observed across patients rather than within individual patient trajectories, justifying the use of report-level rather than patient-level data splitting in subsequent analyses. We also identified a substantial number of exact duplicate entries among the preprocessed samples. Accordingly, exact-match deduplication was performed across all samples separately for each prediction target (recurrence and metastasis) prior to train/validation splitting, thereby preventing data leakage introduced by report-level data splitting. The Preprocessing Analysis section describes the kind of preprocessed samples (prior to deduplication) that would be used in model learning, and the details of preprocessing and preprocessing efficiency are described in Multimedia Appendix 1.

Weak Negative Labeling

In the absence of predefined labels in the initial dataset, we implemented a semisupervised clustering strategy consistent with prior work [17,18] to identify samples likely to represent "weak-negative" cases relative to other categories. The preprocessed reports were analyzed under 2 class-assumption approaches: a rule-based algorithm (RA) and a BERT-based decomposition and clustering method using UMAP-DBSCAN [19-21]. Reports were tagged as weak-negative when their corresponding clusters contained unique cases that were consistently prelabeled as negative prior to clinician revision. These weak-negative samples were excluded from all HL revision cycles to minimize clinician burden. Labeling criteria

XSL•FO
RenderX

are detailed in the Details of Labeling section in Multimedia Appendix 1.

Classification

Classification was performed using the RA and medical BERT models. The RA used regular expressions and clinical keywords (eg, "rule out," Table S1 in Multimedia Appendix 1) to generate weak labels, establishing a baseline annotation for radiology reports. In RA, expressions such as "rule out" were consistently assigned an uncertain label regardless of whether they reflected a diagnostic finding or a clinical indication for the examination. However, the DL models were trained exclusively on clinician-reviewed gold standard labels, including uncertain cases verified through the HL revision cycles, thereby mitigating the impact of this initial labeling ambiguity on the final model. For classification, we deployed medical BERT, such as MedEmbed BERT [22] and PubMedBERT [23]. The Details of Text Classification section in Multimedia Appendix 1 explains the structure of the model and training loss.

Dataset

Clinical Metadata

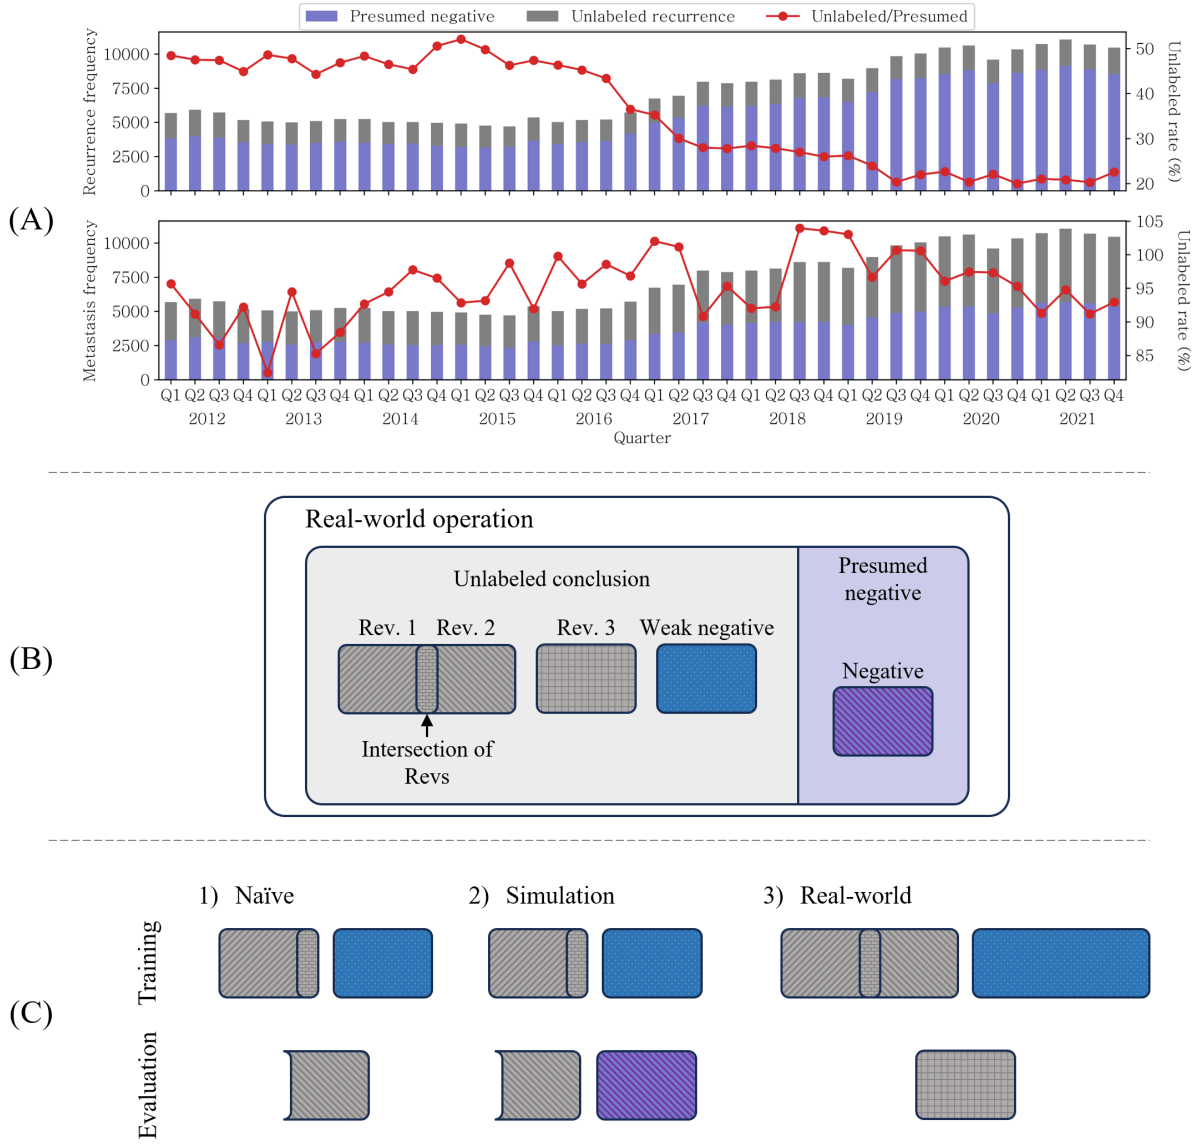
Patient demographic and clinical characteristics, including sex, age at surgery, and cancer type, were extracted from the institutional surgical registry maintained at Asan Medical Center. This registry was constructed and is continuously curated by the clinical team through systematic linkage with the hospital's electronic medical records system. Because all patients in the cohort had undergone surgery at Asan Medical Center and subsequently received postoperative CT imaging with formal radiology reporting within the same institution, each radiology report could be unambiguously matched to a corresponding surgical record. Sex and age at surgery were complete for all 86,083 patients. Cancer type was defined according to the primary surgical diagnosis recorded in the surgical registry. For a small number of patients, the primary cancer type could not be assigned and was categorized as "missing." These patients were retained in all analyses to preserve the full cohort. Age group was assigned based on the patient's age at the time of inspection. Demographic subgroup analyses presented in the Results section were derived exclusively from these registry-linked variables.

Annotations

All annotations were performed by a single attending physician and faculty member specializing in anesthesiology and pain medicine with more than 15 years of clinical experience at Asan Medical Center. For ambiguous cases that were difficult to classify, consultation was sought from a faculty radiologist at Asan Medical Center. At each revision cycle, clinician review was prioritized for positive and uncertain cases to maximize annotation efficiency [24]. In revision 1, samples were obtained through stratified random sampling from 1000 temporary positive labels per target classified by the RA. In revision 2, stratified random sampling was performed using predictions from the DL model fine-tuned on revision 1 gold standard labels, with 500 positive and uncertain samples selected per target. In revision 3, all predicted classes including negative cases were reviewed to finalize the gold standard, with 100 samples per class per target, totaling 600 clinician-reviewed samples across both targets.

Experiments

Statistical Validation of Dataset



To confirm that our gold standard dataset maintained distributional consistency with the broader clinical population, we used the maximum mean discrepancy (MMD) [25] test (see the Details of Statistical Testing section in Multimedia Appendix 1.) In revision 3, for each target and class, we resampled 100 unlabeled reports. Each separated group was evaluated using the MMD test with a permutation procedure against 100 randomly sampled reports from the full dataset. This process was repeated 500 times for all classes across the 2 targets.

Evaluation Strategy

Although positive and uncertain cases were deliberately overrepresented in the clinician-reviewed samples, distributional consistency with the broader clinical population was assessed using statistical testing [25]. Therefore, model evaluation was performed under 3 complementary settings to account for this sampling imbalance. The evaluation strategy is illustrated in Figure 2.

XSL•FO
RenderX

Figure 2. Dataset construction and evaluation strategy for postoperative computed tomography (CT) radiology reports, including the (A) quarterly distribution of presumed negative and unlabeled reports for recurrence and metastasis, with the unlabeled-to-presumed ratio shown as a red line; (B) a composition of the full dataset including clinician-reviewed samples from 3 revision (rev.) cycles, weak negative samples, and presumed negatives; and (C) the following 3 evaluation scenarios differing in the composition of training and evaluation sets: naive, simulation, and real world.

The first was a naive evaluation that preserved the label distribution of the training data. The second was a simulation-based evaluation in which resampled presumed negative samples were incorporated to approximate real-world clinical distributions. The third was a real-world evaluation in which the model trained on revisions 1 and 2 generated predictions for all classes and agreement with clinician-reviewed labels in revision 3 was assessed. A small subset of reports received inconsistent labels across revisions 1 and 2, and the proportion of these discrepancies was used to estimate the human annotation error rate, which was regarded as an upper bound of achievable model performance.

For representative model selection, we adopted a strategy in which the model was trained using all gold standard labels accumulated up to that point and evaluated on the subsequent revision set. Models were trained on revision 1 alone and on the combined dataset from revisions 1 and 2. Cross-validation was performed using samples unique to revision 2, excluding overlapping cases. Finally, a model trained on the combined dataset from revisions 1 and 2 was evaluated on revision 3 to assess whether model performance approached the estimated human annotation accuracy.

Decision Interpretation

For clinical interpretability, the integrated gradients (IG) method was used to attribute predictions to specific features [26]. By integrating gradients along a path from a neutral baseline, the IG method avoids gradient saturation and satisfies the axiom of completeness. Positive IG scores highlight tokens favoring a class (eg, “metastasis”), whereas negative scores indicate suppressive terms (eg, “no evidence of”).

Experimental Setup

To ensure robust convergence, we used a stratified 9:1 train:validation split at the report level, as the preprocessing pipeline reduces each report to sentence-level representations that preclude patient-level linkage (see the Preprocessing

XSL•FO
RenderX

section). We selected the model checkpoint that achieved the highest macro F_1-score on the validation set. All experiments were conducted using a fixed random seed of 42 to ensure reproducibility. Predictive performance for LM selection was evaluated using 10-fold cross-validation with the symmetric difference of revisions 1 and 2. All LMs are listed in Table S3 in Multimedia Appendix 1. Given the class imbalance, accuracy, macro F_1-score, and weighted F_1-score were used as primary evaluation metrics to ensure balanced performance across all classes, including the minority uncertain class. For binary classification tasks, the F_1-score for the positive class was additionally reported.

Performance was evaluated under 3 classification settings. The first was a multiclass setting (positive, negative, and uncertain). The second was a binary setting in which uncertain cases were grouped with negative cases (positive vs others; hereafter referred to as binary conservative), representing the clinically conservative assumption that unconfirmed findings are treated as nonevents. The third was a binary setting in which cases with uncertain labels—either in the gold standard or model prediction—were excluded entirely (positive vs negative; hereafter referred to as binary exclusive), enabling assessment of model performance on unambiguous cases only. Together, binary conservative and binary exclusive serve as sensitivity analyses to examine how the handling of diagnostic uncertainty affects classification performance, as uncertain findings grouped with negative findings may lead to missed follow-ups in oncologic surveillance contexts. Detailed descriptions of the experimental environment, hyperparameter settings, and metric definitions are provided in the Details of Experimental Setup section in Multimedia Appendix 1.

Ethical Considerations

This retrospective cohort study was approved by the institutional review board of Asan Medical Center (2024 - 1090), which waived the requirement for informed consent because the analysis relied exclusively on preexisting clinical and imaging data. To protect patient privacy, all datasets were deidentified; specifically, text data were preprocessed to retain only sentences containing keywords related to metastasis or recurrence, rendering individual identification from the resultant fragments impossible. No compensation was provided to any patients. Furthermore, we confirmed that all images in this manuscript were fully anonymized and contained no identifiable information.

Results

Dataset Analysis

Table 1 specifies the number of cases stratified by patient gender, age group, cancer type, and their corresponding subcategories, and Figure 3 summarizes the distributions shown in Table 1 into subcategories. Male patients accounted for 15% more cases than female patients, and the number of reports for men was 20% higher. The most common age group was patients aged 60 years to 69 years, followed by those aged 50 years to 59 years. Notably, the total number of counts across age groups exceeded those of gender and cancer type categories, as individuals could contribute to different age groups over time due to aging. Regarding cancer types, the highest frequencies were observed in the following order: gastrointestinal, hepatobiliary and pancreas, and genitourinary. The primary cancer type could not be assigned from the surgical registry for 2283 patients (8028 reports) who are shown as “Missing” in Table 1.

[a]All classes were classified by the final deep learning (DL) model trained under the human-in-the-loop (HL) semisupervised framework.

[b]Same as the overall sample total.

[c]The patient counts in the age group block sum to 91,031, exceeding the unique patient total of 86,083, because a patient could contribute to more than one age bracket over the 2014 - 2021 study period as they aged.

XSL•FO
RenderX

Figure 3. Distribution of predicted recurrence and metastasis labels for 288,076 postoperative computed tomography (CT) reports from 86,083 patients at Asan Medical Center (2014 - 2021) across demographic and clinical subgroups: (A) sex; (B) age; (C) cancer type. Merged: all cancer types with a prevalence of <10% of reports, including patients whose cancer type could not be assigned ("missing").

Application Performance

Table 2 shows the accuracy, F_1-score (in the multiclass, F_1-score denotes the macro F_1-score), and weighted F_1-score of both the clinicians and our framework regarding recurrence and metastasis under 3 classification settings (multiclass, positive vs others, and positive vs negative). Human metrics denote the consistency observed across revisions 1 and 2, whereas DL accuracy denotes its concordance with the clinician's final revision 3. Table S2 in Multimedia Appendix 1 specifies the detailed numbers of each class collected during the 2 revision stages (see the Description of Revisions 1 and 2 section in Multimedia Appendix 1), and the MMD test results are shown in Table S4 in the Consistency of Revision 3's Distribution section in Multimedia Appendix 1.

Weighted F_1-score	0.9782	0.9898	0.7105

[a]Intrarater consistency between revisions 1 and 2.

[b]Concordance with clinician-finalized labels from revision 3 for the 3 classes.

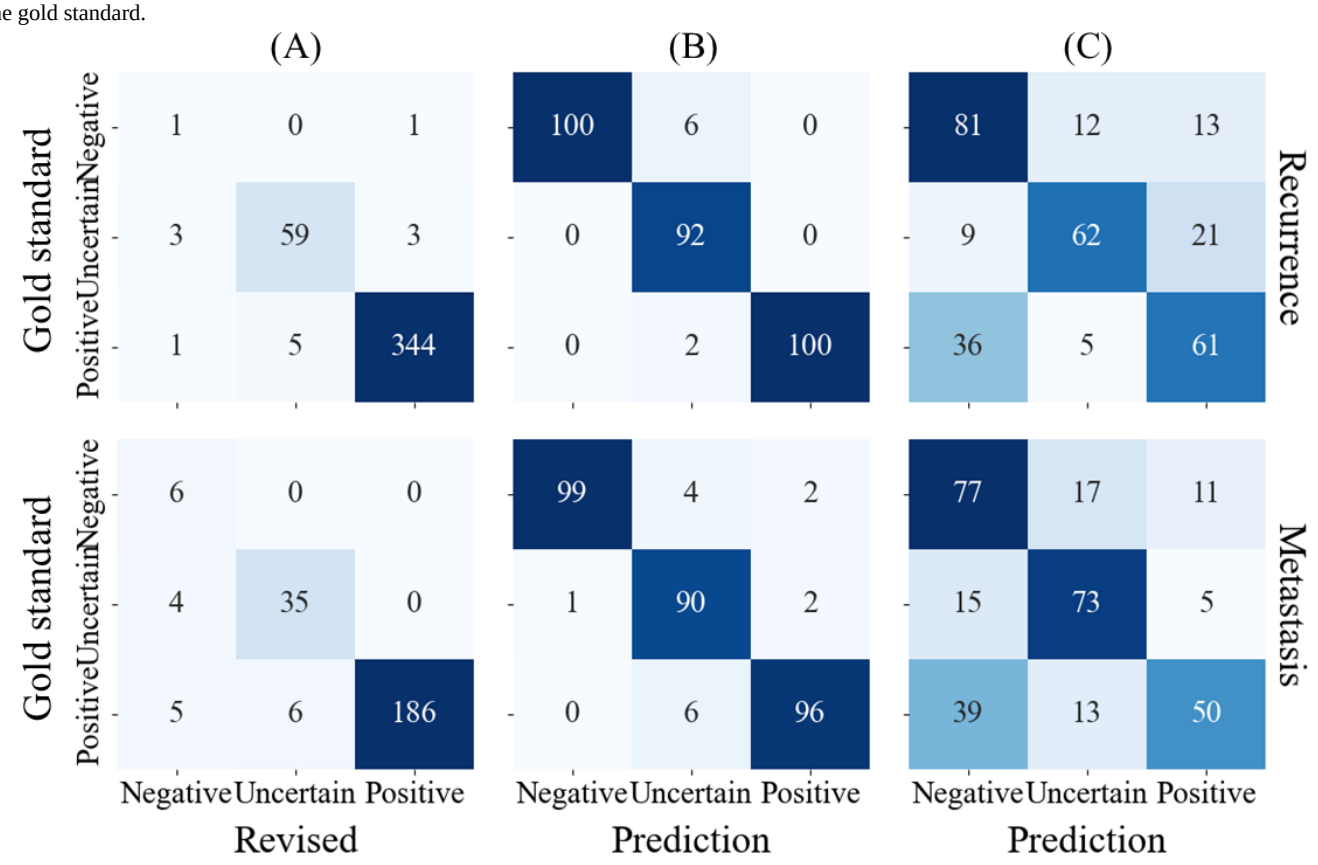
As detailed in Table 2, the framework demonstrated higher concordance with the clinician-finalized gold standard than human intrarater consistency across all evaluated settings; however, because both were assessed against the same clinician-derived labels, this difference reflects closer agreement with the consensus standard rather than superiority over independent clinical judgment. For recurrence classification, the framework achieved an accuracy of 0.9733 in the multiclass task, 0.9933 in the positive vs others setting, and 1.0000 in the positive vs negative setting, whereas the clinicians recorded 0.9688, 0.9760, and 0.9942, respectively. In addition, the framework's accuracy reached 0.9500 for the multiclass setting, 0.9667 for the positive vs others setting, and 0.9898 for the positive vs negative setting, achieving numerically higher concordance accuracies of 0.9380, 0.9545, and 0.9746, respectively, in the metastasis classification.

Figure 4 presents the corresponding confusion matrices for the multiclass setting, confirming that the DL model achieved high classification accuracy across all 3 classes within the revision 3 evaluation set's 300 samples per target, whereas the RA showed notable misclassification particularly in the positive and uncertain categories. Figure 5 further illustrates the per-class prediction accuracy across demographic and clinical subgroups, demonstrating that the framework maintains consistently high accuracy across sex, age group, and cancer type categories for

XSL•FO
RenderX

both recurrence and metastasis. For cancer type subgroups with small sample sizes, underrepresented categories were merged prior to analysis; however, because individual class counts remained limited even after merging, per-case subgroup analysis was not performed due to high performance variability.

Figure 4. Confusion matrices for multiclass classification (positive, negative, and uncertain) of recurrence and metastasis under the real-world evaluation setting (revision 3), comparing (A) human intrarater consistency, (B) deep learning model predictions, and (C) rule-based algorithm predictions against the gold standard.



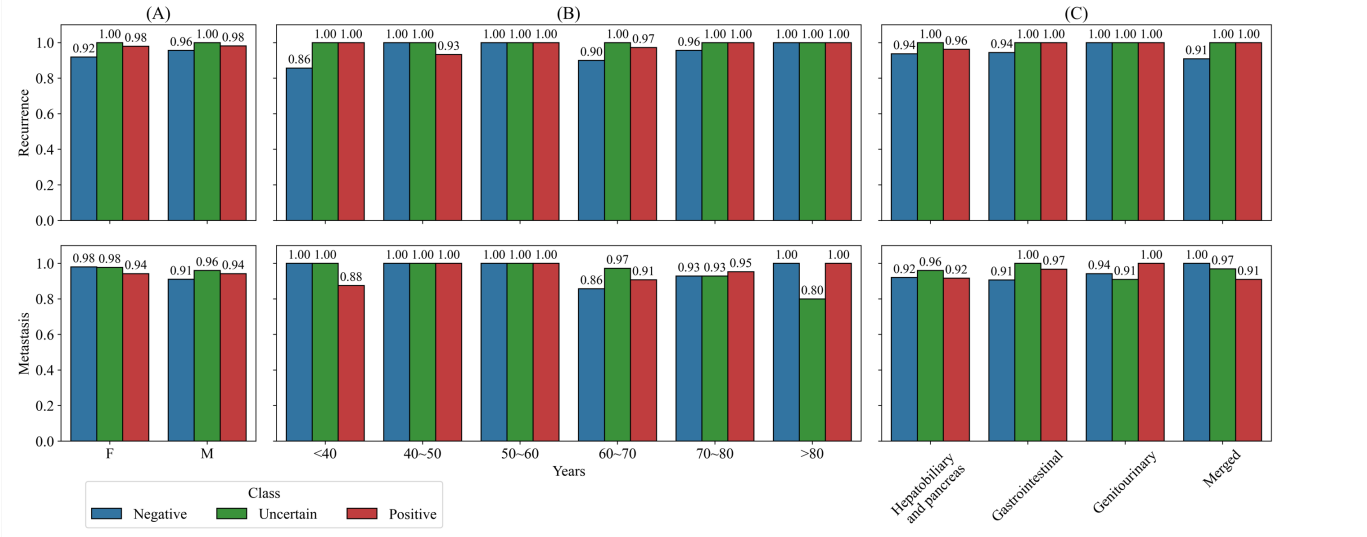


Figure 5. Per-class prediction accuracy of the deep learning model across demographic and clinical subgroups, corresponding to the subgroup distributions shown in Figure 3: (A) sex; (B) age; and (C) cancer type. Merged: all cancer types with a prevalence of <10% of reports, including patients whose cancer type could not be assigned (“missing”).

Model Comparison

Table 3 shows that the model comparison performance depends on the evaluation situation. The performance evaluation demonstrated that the RA serves as a competitive baseline, frequently outperforming several sophisticated DL models. Under simulated real-world conditions, the RA achieved higher accuracy than models such as Multilingual-E5 and BlueBERT, particularly in binary metastasis classification. Notably, in the multiclass metastasis classification under the simulation

XSL•FO
RenderX

scenario, half of the tested models failed to surpass the RA baseline. Furthermore, only 2 medically pretrained models achieved higher accuracy than the RA in the binary metastasis task. In the recurrence classification, PubMedBERT emerged as the most accurate model across all comparison settings. It outperformed other models in simulated recurrence classification by a margin exceeding 1.5%. During cross-validation under the simulation scenario, PubMedBERT reached average recurrence accuracies of 92.58% in the multiclass and 96.33% in the binary classification. Regarding metastasis classification, BlueBERT achieved the highest accuracy in the multiclass task, demonstrating an improvement of >2% over the next-best model in the naive setting. However, this improvement diminished to <1% under simulated conditions, where BlueBERT reached 89.49%. In the simulated binary metastasis task, BlueBERT's accuracy was 0.3% lower than that of the RA. By contrast, MedEmbed demonstrated superior reliability for metastasis binary classification under real-world simulation, achieving a final accuracy of 93.25%.

[b]Positive vs others (negative and uncertain combined).

Preprocessing Analysis

Table 4 presents consecutive postoperative CT reports from a representative patient, illustrating the effect of preprocessing on report content. As shown in Table 4, the majority of reports contained no keyword-matched sentences and were therefore designated as presumed negatives; notably, a subset of the keyword-matched reports yielded identical preprocessed text, constituting duplicate entries prior to deduplication. After exact-match deduplication, the final unique reports counts were 17,846 for recurrence and 63,766 for metastasis. Inspection of the raw text for these excluded reports revealed that their content was clinically unrelated to recurrence or metastasis, consisting instead of descriptions such as adrenal adenoma findings, surgical records, and postoperative complications. In the manual audit of 300 randomly selected keyword-excluded reports, no report was adjudicated as definite radiologic recurrence or metastasis despite the absence of the target keywords, corresponding to an estimated definite missed positive rate of 0% in the reviewed sample. The 95% Clopper-Pearson exact CI for the true missed positive rate was 0%-1.22%, confirming that definite missed positives were unlikely to exceed 1.22% of the presumed-negative pool at the 95% CI. A small number of reports (approximately 2‐3 of 300, or 0.5%‐0.7%) contained indirect or ambiguous nonstandard expressions such as “viable lesion” or “viable tumor.”

[a]Original radiology report impression.

[b]Result after cleaning and keyword-based filtering.

[c]Only the sentences retained for each target after preprocessing, illustrating that most reports are either entirely excluded or reduced to 1 or 2 short sentences.

[d]No keyword-matched sentences were identified, and the corresponding report was dropped from the target dataset.

[e]GE: gastroesophageal.

[f]RUL/RLL: right upper lobe/right lower lobe.

[g]PET: positron emission tomography.

[h]REC: recommendation.

[i]EBUS: endobronchial ultrasound.

[j]LNs: lymph nodes.

[k]R/O: rule out.

Furthermore, reports that passed keyword filtering were reduced to 1 or 2 short sentences per target, demonstrating that the preprocessing pipeline fragmented each report into brief, context-independent text segments that eliminated patient-level linguistic cues and temporal continuity across sequential reports. To further validate the weak-negative designation, a board-certified radiologist reviewed all weak-negative reports identified by the preprocessing pipeline. For recurrence, 1 of 486 weak-negative reports was adjudicated as positive, yielding a 95% CI for the true mislabeling rate of 0.005%-1.143%, indicating that the mislabeling rate for recurrence was extremely low, with an upper bound of 1.1% at the 95% CI. For metastasis, 19 of 953 weak-negative reports were adjudicated as positive, with an additional 4 designated as uncertain; the corresponding 95% CI was 1.200%-3.101% when considering definite positives only and 1.531%-3.607% under the conservative assumption that uncertain cases represented mislabeled positives. These results collectively confirmed that the weak-negative samples constituted a statistically reliable approximation of true negatives, with mislabeling rates bounded at <3.6% across both tasks at the 95% CI. All raw reports underwent preprocessing, and the resulting efficiency is illustrated in the Preprocessing Efficiency and Unused Negative Samples sections in Multimedia Appendix 1.

Model Interpretation

Figure 6 shows an interpretation of the model's predictions for an uncertain recurrence report. As shown in the figure, when making predictions, the model relied not only on the tokens "recurr," "##ed," and "cancer" but also on nearby related tokens. The phrase "cannot exclude" received the highest attribution score (3.60) in the uncertain prediction, demonstrating that the model appropriately captured hedging expressions as indicators of diagnostic uncertainty.

Figure 6. Token-level integrated gradients attribution scores for a representative uncertain recurrence report (revision 3), with each row presenting the same report with predicted labels of negative (neg; 0.04), uncertain (unc; 0.90), and positive (pos; 0.06), respectively.

Legend: Negative Neutral Positive

True label	Predicted label	Attribution label	Attribution score	Word importance
Unc	Neg (0.04)	1	–0.78	[CLS] 1 . eccentric wall thickening / enhancement along the left wall of bladder . rule out post - turb change . rule out recurr ##ed superficial cancer cannot exclude . [SEP]
Unc	Unc (0.90)	1	3.60	[CLS] 1 . eccentric wall thickening / enhancement along the left wall of bladder . rule out post - turb change . rule out recurr ##ed superficial cancer cannot exclude . [SEP]
Unc	Pos (0.06)	1	–0.73	[CLS] 1 . eccentric wall thickening / enhancement along the left wall of bladder . rule out post - turb change . rule out recurr ##ed superficial cancer cannot exclude . [SEP]

Discussion

Principal Findings

Our study demonstrated that a semisupervised learning, HL framework is feasible for large-scale automated extraction of postoperative cancer recurrence and metastasis from unstructured CT radiology reports, screening and classifying all 288,076 reports in the corpus. Our framework achieved concordance rates of 97.33% for recurrence and 95.00% for metastasis against clinician-finalized gold standard labels (revision 3), with corresponding human intrarater consistency of 96.88% and 93.80%, respectively. These figures demonstrate the degree to which the model reproduces the consensus labeling standard established through iterative clinician review; because both the model and the human benchmark were evaluated against the same clinician-derived gold standard, the reported advantage does not constitute evidence of superiority over independent clinical judgment. In practical terms, clinician screening of 1000 samples required more than 1 week within our annotation workflow—encompassing case review and adjudication of ambiguous cases—whereas the automated framework processed the equivalent volume in under 10 minutes while maintaining high concordance with clinician labels. Although this comparison reflects the specific conditions of our annotation process and may not directly generalize to other clinical review settings, it illustrates the scalability advantage of the proposed approach for labeling at the scale of 288,076 screened reports. After exact-match deduplication, the models were trained and evaluated on 17,846 unique reports for recurrence and 63,766 for metastasis; deduplication was performed separately for each target to prevent leakage introduced by report-level splitting. This performance was achieved through only 3 revision cycles, each involving approximately 2000 samples (less than 1% of the 288,076 total reports), underscoring the annotation efficiency of the HL design. The framework captured diagnostic uncertainty in 1.4% of recurrence and 6.9% of metastasis cases, addressing a critical gap in existing binary classification approaches [12,27].

RA served as a competitive baseline, outperforming several DL models under simulated real-world conditions, particularly for binary metastasis classification. This finding underscores the value of medically grounded heuristics within hybrid systems [1,8]. Among DL models, PubMedBERT achieved the highest accuracy for recurrence (92.58% under simulation, multiclass classification), while MedEmbed demonstrated superior reliability for binary metastasis classification (93.25%). The use of domain-specific BERT models aligns with findings that biomedical language representation pretraining significantly improves text mining performance [13,14], and recent investigations support the task-specific advantages of PubMedBERT and MedEmbed for recurrence and metastasis classification, respectively. The level of inconsistency between weak and gold labels is reflected in the intrarater disagreement rate observed across clinician review cycles (3.12% for recurrence and 6.20% for metastasis), which serves as an empirical estimate of the annotation noise present in the labeling process and an upper bound on achievable model performance.

Comparison With Prior Work

The primary contribution of this work lies in the integration of established components—rule-based prelabeling, BERT-based LMs, embedding-based clustering, and iterative HL refinement—within a clinically grounded workflow that explicitly models diagnostic uncertainty as a prospectively defined, independent class. Prior studies on automated extraction of oncologic outcomes from radiology reports have generally simplified borderline impressions into binary categories or excluded ambiguous cases from training and evaluation entirely [10,12,27]. Related previous studies have documented substantial challenges with extracting structured information from radiology reports, including linguistic ambiguity, negations, and diagnostic uncertainty [1,7], and institutional and stylistic variation has been identified as a major obstacle to automated extraction systems [1]. In contrast, our 3-class framework captures the clinical reality in which radiologists frequently encounter findings that are suspicious but not definitive [9]. Studies on automated extraction from radiology reports have emphasized that accounting for diagnostic uncertainty is essential to maintain clinical utility [8,11].

Our presumed labeling hybrid strategy combining RA, UMAP-DBSCAN clustering, and semisupervised classification was designed to operate as a sequential pipeline in which each stage builds upon the preceding step. Nonetheless, the practical necessity of the weak-negative clustering step was evident from the annotation burden it prevented: had this step been omitted, clinician review of the negative category would have increased by approximately 20% without a corresponding improvement in label quality for that class. Previous work on semisupervised text topic modeling provided a conceptual foundation [17], although our adaptation required domain-specific modifications for medical radiology reports. UMAP-DBSCAN clustering for presumed negative identification reduced clinician review burden while maintaining high accuracy, with MMD confirming the distributional integrity of the sampled data [25]. The need for quantifiable and objective textual approaches in radiology reporting has been emphasized [2], and our framework addresses this through domain-specific LMs combined with presumed-labeling strategies, consistent with recent work on clinically informed semisupervised learning from electronic health records [28].

The RA assigned “rule out” expressions uniformly as uncertain, regardless of whether such language reflected a diagnostic finding or a clinical indication for the examination. This semantic overlap represents a known limitation of keyword-based prelabeling in radiology NLP, as “rule out” frequently appears in the indication section of a report rather than the impression or findings sections [1,8]. Because the preprocessing pipeline did not separate indication from impression, some “rule out” assignments may have been misclassified at the RA stage. However, this ambiguity was mitigated by training the DL models exclusively on clinician-reviewed gold standard labels, including uncertain cases verified through the HL revision cycles. As a result, the impact of this initial labeling inconsistency on final model performance was limited, as evidenced by the large performance

XSL•FO
RenderX

gap between the RA and DL models on the Uncertain class in the confusion matrices (Figure 4).

The substantial performance differences between naive and simulation evaluations emphasize the importance of realistic assessment conditions. Previous research has noted that weakly supervised DL in radiology requires careful evaluation under conditions reflecting real-world class distributions [3,5,29]. MedEmbed's multiclass metastasis accuracy improved from 53.04% under naive conditions to 88.69% under simulated real-world distributions, demonstrating that model selection based solely on balanced test sets may not identify optimal models for clinical deployment scenarios with pronounced class imbalance.

The successful processing of 288,076 radiology reports across 11 cancer types compares favorably with prior large-scale studies on automated metastasis detection from pathology reports [12] and extends the scope of clinical NLP to postoperative CT surveillance across a broad oncologic case mix. Traditional cancer registries rely heavily on manual abstraction, limiting scalability and timeliness [12]. Previous studies have documented the challenges of incorporating cancer recurrence events into population-based registries [6], and scoping reviews have noted that NLP of radiology reports in oncology remains an evolving field [10]. Within the institutional setting of this study, our framework has the potential to support timely construction of comprehensive surveillance databases, facilitating population-level quality monitoring and outcome research [30].

Recent work emphasized that clinicians must participate in the development of multimodal artificial intelligence (AI) to ensure clinical relevance and trustworthiness [31]. The interpretability analysis via IG [26] provided transparency essential for clinical acceptance and demonstrated that the model attends to clinically relevant tokens–such as "cannot exclude" for uncertain–rather than spurious correlations, providing the transparency necessary for clinical acceptance and aligning with this principle.

Limitations

Several limitations of this study should be acknowledged.

First, all reports were collected from a single institution, which may limit generalizability to other health care settings with different reporting styles and terminology [12]. Recent work has noted that heterogeneity in AI assistance effects across radiologists reflects variations in practice patterns and institutional contexts [26,32], suggesting that multicenter validation is essential. In this study, external validation was not feasible due to the absence of a comparable annotated dataset from another institution at the time of analysis. To mitigate this, performance was reported under 3 complementary evaluation settings (naive, simulation, real world) to approximate the range of conditions likely encountered in practice. External validation across multiple institutions with diverse reporting conventions remains necessary to confirm broader applicability [5,30].

Second, preprocessing relies on keyword filtering ("recur" and "metas"), which may miss cases described using synonymous or indirect language without these specific terms. This design assumes that radiologists explicitly document recurrence or metastasis using these root strings—an assumption clinically justified by institutional documentation standards, where failure to use standard terminology for critical findings has direct patient safety implications. Although previous studies have successfully used keyword-based approaches for oncologic information extraction [8,10], the potential for systematic exclusion of atypical descriptions cannot be fully eliminated. To partially address this concern, we sampled a manual audit of 300 random keyword-excluded reports, in which no report was adjudicated as definite recurrence or metastasis (estimated definite missed-positive rate: 0%, 95% CI 0.00% - 1.22%); qualitative inspection of excluded report content further confirmed clinical unrelatedness to recurrence or metastasis in the reviewed sample (Table 4). However, a small proportion of audited reports (approximately 0.5% - 0.7%) contained indirect or ambiguous expressions such as "viable lesion" or "viable tumor" that could not be confidently adjudicated without longitudinal imaging or clinical correlation, and the audit covered only a subset of the full presumed-negative pool. Although the upper bound of the 95% CI was 1.22%, the large scale of the presumed-negative pool means that even a small missed-positive rate could correspond to a nonnegligible absolute number of cases in practice. In addition, weak-negative samples further confirmed low mislabeling rates, with 95% CIs of 0.005%-1.143% for recurrence and up to 1.531%-3.607% for metastasis under conservative assumptions. Future studies should therefore consider broader lexical matching, context-aware screening, or large language model–based preprocessing to capture such nonstandard expressions without overclassifying clinically ambiguous reports as definite recurrence or metastasis.

Third, the semisupervised pipeline designated reports as weak-negatives through embedding-based clustering without subsequent clinician review in order to minimize annotation burden. Although MMD testing confirmed that these weak-negative samples were distributionally consistent with the broader clinical population, a residual risk of label contamination existed if atypical positive or uncertain cases clustered among negatives. A random sample of weak-negative reports was reviewed, confirming that the automated labeling process was accurate for the reviewed subset. However, a systematic false-negative rate across the full weak-negative pool was not formally established, and this uncertainty may introduce noise into training data for the negative class. Future work should consider establishing a formal baseline error rate through structured sampling of the weak-negative cluster.

Fourth, all annotations were performed by a single attending physician, which introduces the risk of individual annotator bias and limits the reliability of the gold standard as a true consensus label. Although ambiguous cases were adjudicated in consultation with a faculty radiologist, formal interrater reliability was not established through independent double annotation. The impact of this limitation is most pronounced for the uncertain class, where classification criteria are inherently subjective and boundary cases between positive and uncertain are particularly sensitive to individual clinical judgment. The intrarater consistency metrics reported in this study therefore reflect temporal stability of a single annotator's decisions rather

XSL•FO
RenderX

than convergence across multiple independent reviewers. Future studies should incorporate structured multi-annotator protocols with adjudication procedures to establish a more robust gold standard, particularly for the uncertain category.

Fifth, the framework processes each CT report as an independent document without access to a patient's prior imaging history or longitudinal clinical trajectory. Cancer recurrence and metastasis are inherently longitudinal events in which temporal context, such as interval change from a previous study, is central to radiologist interpretation. The absence of this temporal information may limit the clinical utility of single-report predictions, particularly for cases where the current report alone is ambiguous but the longitudinal trend is diagnostic. Future architectures incorporating sequential report representations or structured temporal features may better approximate the interpretive process of clinical radiologists.

Sixth, exact-match deduplication, which was applied to prevent leakage from report-level splitting, also removes the natural frequency with which common clinical phrases recur, so the deduplicated evaluation set reflects the distribution of distinct phrasings rather than the frequency-weighted distribution of routine reporting. The reported performance should therefore be interpreted accordingly, and prospective evaluation on unfiltered, frequency-weighted report streams is warranted to confirm generalizability to real-world surveillance.

Future Directions

Several directions merit exploration in future work. First, multicenter prospective validation is the most critical next step to establish generalizability. Transfer learning from institution-specific LMs may enable efficient domain adaptation with minimal additional annotation [13,33], and domain adaptation strategies should explicitly address differences in reporting language and terminology across institutions [5].

Second, incorporating temporal context into the classification pipeline through sequential report modeling or structured longitudinal representations could improve performance on inherently ambiguous single-report cases and better approximate clinical reasoning in postoperative surveillance.

Third, active learning strategies within the HL framework could further reduce annotation burden for rare cancer subtypes, where current subgroup performance is most limited [10,24]. Cancer-specific fine-tuning using targeted data collection may also address the performance gaps observed in breast and gynecologic cancers.

Fourth, integration with hospital information systems via MLOps pipelines would enable continuous model retraining and real-time surveillance, accommodating temporal shifts in imaging technology and reporting standards [34]. Structured HL feedback mechanisms are essential for sustainable deployment.

Conclusions

This study developed and evaluated a semisupervised, HL framework for classifying postoperative CT radiology reports into 3 clinically meaningful categories—positive, negative, and uncertain—for cancer recurrence and metastasis. The framework achieved concordance with clinician-finalized labels at rates of 97.33% for recurrence and 95.00% for metastasis in multiclass classification, matching the human intrarater consistency observed in the same annotation process while requiring clinician review of <1% of the total 288,076 screened and classified reports across 3 revision cycles; after exact-match deduplication, models were trained and evaluated on 17,846 and 63,766 unique reports for recurrence and metastasis, respectively. Explicit modeling of diagnostic uncertainty captured a clinically nonnegligible proportion of cases that would be misassigned in binary classification schemes. These findings demonstrate that the proposed framework can achieve annotation-efficient, clinician-concordant classification of oncologic outcomes within a large-scale, single-institution postoperative CT radiology corpus; generalizability to other institutions and reporting conventions requires prospective multicenter validation.

Abstract

Background: Natural language processing can extract meaningful information from clinical notes. However, human annotation is time-consuming and costly, and scarce data poses a challenge.

Objective: This study aimed to explore a semantic similarity search approach to extract exemplars of stigmatizing and positive language in obstetric clinical notes.

Methods: We used electronic health record data from labor and birth admissions at 2 hospitals in the United States from 2017 to 2019. We used a semantic similarity search approach, which used 200 randomly selected true exemplars, stratified by language categories, as queries to search for similar exemplar candidates. We extracted the top 5 candidates with the highest cosine similarities, which were assessed for accuracy.

Results: We retrieved 1000 candidates. An average precision of 0.69 was achieved when candidates with cosine similarity thresholds of 0.75 or higher were included, at which point 68.8% (64/93) of exemplar candidates accurately represented true cases. At the 0.75 threshold, the proportion of true cases was higher for preferred language (41/56, 73.2%) and unilateral/authoritarian decisions (5/7, 71.4%). The proportion of true cases was lower for difficult patients (2/7, 28.6%) and marginalized identities (3/9, 33.3%).

Conclusions: The semantic similarity search approach shows promise in efficiently extracting exemplars while reducing the annotation burden, laying the groundwork for future applications in other domains.

Introduction

Natural language processing (NLP) can efficiently and accurately extract meaningful information from large text data, such as clinical notes within electronic health records (EHRs) [1,2]. One significant challenge is obtaining sufficient human-annotated data to train NLP models for specific tasks and datasets. Human annotation is labor-intensive and costly, requiring extensive effort to review and label data for exemplars representing specific concepts or categories within the text. For example, annotating 50 discharge summaries can take approximately 80 hours for a team of several clinical experts; this time grows exponentially for datasets with a low prevalence of the target information [3]. Given the substantial time and manpower needed for human annotation, it is common to encounter limited human-labeled data for NLP model development [4].

Prior NLP research has focused on reducing annotation burden through approaches such as active learning and data

XSL•FO
RenderX

augmentation. Traditional active learning, most commonly using uncertainty-based querying, supports annotation by iteratively selecting unlabeled cases for which the model has the highest uncertainty (lowest confidence) and prioritizing these cases for human review [5]. However, uncertainty-based querying may be less effective for low-prevalence or rare concepts, which can be under-selected when models exhibit high confidence in assigning majority-class labels; for example, rare positive cases may be confidently misclassified as negative and therefore not selected for human review [6,7]. Data augmentation, including synonym replacement, paraphrasing, and more recently, synthetic data generation using large language models, has also been used to expand training datasets [8,9]. However, these approaches may unintentionally introduce noise or alter subtle linguistic or contextual cues essential for capturing nuanced context-dependent concepts [10,11]. For example, human evaluation of synthetic data quality in the context of stigmatizing language has shown that synthetic exemplars exhibited limited clinical realism [12].

Semantic similarity search offers a complementary strategy for expanding training data by efficiently extracting additional exemplars that are semantically similar to existing human-annotated exemplars. Semantic similarity refers to the degree to which 2 pieces of text share similar meanings based on their linguistic content and context [13]. Semantic similarity has been widely studied. Early approaches focused on document-level similarity based on lexical and distributional overlap [14]. More recent work has focused on sentence-level similarity using neural embeddings, which enable more nuanced comparisons across short text spans [15]. In the clinical domain, prior work has largely focused on developing and evaluating models for estimating similarity between pairs of clinical sentences [16,17]. These studies typically use trained models to predict similarity scores between sentence pairs and evaluate how closely these predictions align with human ratings [16,17]. Semantic similarity has also been used in information retrieval and retrieval-augmented generation systems to retrieve clinically relevant texts, passages, or documents [18,19]. These approaches are primarily used for downstream tasks such as question answering and clinical decision support [20]. In contrast, the use of semantic similarity search to support annotation workflows, specifically for retrieving additional exemplars, remains relatively limited.

In the current study, we applied semantic similarity search to support annotation by using human-annotated true exemplars as queries to retrieve additional exemplar candidates. This approach has the potential to reduce the human labor associated with reviewing and labeling new text data from scratch. Unlike traditional active learning, this approach directly retrieves semantically similar exemplar candidates to human-annotated true exemplars, without relying on iterative model training or uncertainty-based querying. This strategy may be particularly useful for identifying rare concepts, as it can retrieve semantically similar text even when such cases are infrequent, allowing expansion of sparse categories. In addition, by using true exemplars as queries, this approach can preserve real-world language and subtle contextual features that may not be well captured by synthetic data.

Specifically, we explored the application of this approach in the context of identifying stigmatizing and positive language categories in obstetric clinical notes. Stigmatizing language can convey implicit or explicit bias [21], which can negatively influence patient-clinician relationships and satisfaction in health care [22,23]. Identifying and mitigating stigmatizing language is essential for providing respectful and unbiased care for perinatal populations affected by significant health disparities [24]. The prevalence of stigmatizing language can be as low as 1% to 2% for certain language categories or patient populations [25,26]. This presents challenges for manual annotation and obtaining sufficient data for optimal NLP model training. Additionally, identifying positive language that respects patients' views and autonomy is important to promote the use of strength-based language in clinical documentation [27]. Our efforts to identify stigmatizing and positive language revealed the need for an efficient approach to extract additional exemplars with limited resources [28]. This study aimed to evaluate semantic similarity search as a more efficient approach for identifying additional exemplars of stigmatizing and positive language in obstetric clinical notes. We assessed retrieval accuracy through human evaluation and precision metrics.

Methods

Study Data

We used EHR data from patients at >20 weeks' gestation admitted for labor and birth at 2 urban hospitals in the Northeast United States from 2017 to 2019. All clinical notes in the EHR during the inpatient hospital stay were eligible. Note types with limited clinician narrative text describing patient assessments or impressions, such as medication orders, transfer notes, and template-based statements about procedures or operations, were excluded. Seven note types were used in the current study: obstetric postpartum note, obstetric admission note, obstetric triage note, anesthesia resident note, miscellaneous nursing note, social work initial assessment, and initial nutrition assessment.

Ethical Considerations

We received institutional review board (IRB) approval from Columbia University Medical Center (AAAT9870) for this study under expedited review, category 5: research involving materials (data, documents, records, or specimens) that have been collected or will be collected solely for nonresearch purposes, such as medical treatment or diagnosis. A waiver of informed consent was granted by the IRB because the research involved no more than minimal risk, did not adversely affect the rights and welfare of human subjects, could not be carried out without the waiver, and the study could not be completed without using identifiable private information from patients discharged from the study hospitals. To protect privacy and confidentiality, study data were stored on a secure server following institutional data security guidelines, with access restricted to authorized study personnel with a direct need for data management and analysis. All study personnel completed IRB-required training in the responsible conduct of research and protection of human subjects. No compensation was provided because this study involved secondary use of data

without direct participant involvement, interaction, or recruitment.

Semantic Similarity Search Approach

Approach Overview

We explored using semantic similarity search to expand the initial human-annotated dataset in a less manually intensive way. This approach uses initial human-annotated exemplars (ie, *true exemplars*) as queries to search for similar exemplars (ie, *exemplar candidates*). Then, human experts can perform a relatively faster review of the exemplar candidates to determine the accuracy.

Language Categories

Stigmatizing and positive language categories are presented in Table 1. The categories and operational definitions were developed through iterative qualitative analysis [26,29] and informed by prior work on stigmatizing language [30]. A multidisciplinary team of experts, including obstetrics and gynecology physicians, nurses, and nonclinical researchers, contributed diverse perspectives to the development of these categories. These efforts were intended to enhance the rigor of the operational definitions.

XSL•FO
RenderX

Table . Stigmatizing and positive language categories.

Language category	Definition	Examples	True exemplars (N=200), n
Stigmatizing language			
Difficult patient	• Nonadherence or noncompliance with plan of care, refusal of care, referrals, or services.	• "missed nutrition appt again says she doesn't want to go." • "exam unchanged however now c/o [complains of] ctx [contraction] pain." • "poor compliance with antenatal visits."	28
Unilateral/ authoritarian decisions	• Language that supports clinician's authority over patients. Upholds hierarchy centering clinician, not patient.	• "cervix unfavorable therefore will start induction with Cytotec." • "SW [social worker] has advised pt [patient] that if there continues to be yelling in room, ACS [adult and child services] will need to be contacted." • "also very upset about persistent shaking in her UE [upper extremities]. Explained to patient multiple times that shaking is normal and a result of hormones and the anesthesia."	14
Power/privilege	• Describes power and privilege identities related to psychological or social-ecological status.	• "pt [patient] reports having a nurturing marriage with FOB [father of the baby] who works as a Lawyer." • "private pt [patient] of mine at 39+6 wks [weeks] with multiple episodes of emesis this AM." • "Caucasian female. pleasantly engaged in conversation."	17
Marginalized identities	• Documentation of social and behavioral risk factors in narrative that could contribute to marginalization. • Restating for emphasis that is already in the checklist/form data or unnecessary patient descriptor (eg, "toxic habits," "financially supports self," "teen mother," "late registrant," and "obesity").	• "social disarray, estranged from family with FOB [father of the baby] not involved." • "Dominican female. Initial psychosocial assessment due to teen pregnancy late registrant." • "Patient is a 32yo [year old] Dominican unmarried unemployed female."	74
Questioning patient credibility	• Disbelief in patient's report of health and social history or status.	• "unsure if patient telling the truth." • "pt [patient] denied any other DV [domestic violence] incidents and was adamant that relationship with spouse was healthy." • "Pt [patient] does not think she has gestational diabetes she states she ate very sweet rice (a dish from her country) the day before the glucose challenge which is what she believes this is the reason for the high value states it has never been high before."	11

XSL•FO
RenderX

Language category	Definition	Examples	True exemplars (N=200), n
Disapproval	• Behaviors of patient not in alignment with health care provider expectations.	• "FOB [father of baby] is 23 yo [year old] unemployed and not as involved as he should be." • "Pt [patient] states she tried to obtain f/u [follow-up] appt [appointment]. but did not get a call back. Advised she should have gone to the clinic to straighten things out- in the future to take initiative-importance stressed as well as appts [appointments] for her newborn." • "PP [postpartum] BCM [bridge contraceptive method]- pt states she prefers to use condoms will continue to readdress."	6
Structural/interprofessional hierarchy	• Notes stating issues in care are attributed to another clinician, often nurses. Notes stating that care was not delivered in a timely manner due to staffing or other structural issues.	• "Nurse states IV [intravenous] 'infiltrated,' but it was fine." • "Unable to staff nursing for placement of epidural in triage. Requested that charge nurse please inform anesthesiology team about when there is enough nursing staff." • "Patient continues to wait in triage until L D [Labor & Delivery] bed available."	2
Positive language			
Preferred language	• Preferred words that can convey patient's point of view respectively and objectively (eg, endorses, reports, or states).	• "patient desires to ambulate and encourage natural labor." • "patient states she feels some pain on right side." • "states she has had irregular ctx [contractions] starting 24 hours ago. endorses FM [fetal movement]. Endorses N/V [nausea/vomiting]"	44
Autonomy for birth	• Notes that indicate patient exercising autonomy around birth and plan of care.	• "Pt [patient] declines epidural at this time- trying to deliver without analgesia." • "will give patient the option to have continuous monitoring overnight and give her the opportunity to go into spontaneous labor with plans for c-section tomorrow if she does not progress." • "low risk screening declined diagnostic. She was given the option of admission with possible augmentation of labor vs discharge home to labor. Plan was made for admission."	4

Initial Human Annotation

To generate the initial human-annotated dataset, 4 researchers with expertise in qualitative research and/or nursing independently annotated clinical notes following an established codebook (see Table S4 in Multimedia Appendix 1). The codebook was developed through iterative inductive-deductive content analysis [26]. All annotators were trained prior to participating in annotations, which included review of the codebook, discussion of example phrases and sentences, and

XSL•FO
RenderX

coding demonstrations. Annotators manually labeled true exemplars from a total of 1771 clinical notes, which typically spanned 1 to 3 sentences. To ensure reliability, 2 annotators reviewed and annotated the same clinical notes. We resolved disagreements through iterative discussions among the annotators. The initial agreement among the annotators across the 1771 clinical notes was fair (Cohen κ=0.4, agreement rate=72%), which reflects the inherently nuanced nature of language use and subjectivity involved with interpreting complex and nuanced language [31]. We spent extensive effort and time discussing any discrepancies among annotators to reach a consensus and ensure the quality and accuracy of the final annotated dataset [31].

Sentence-Transformer Model

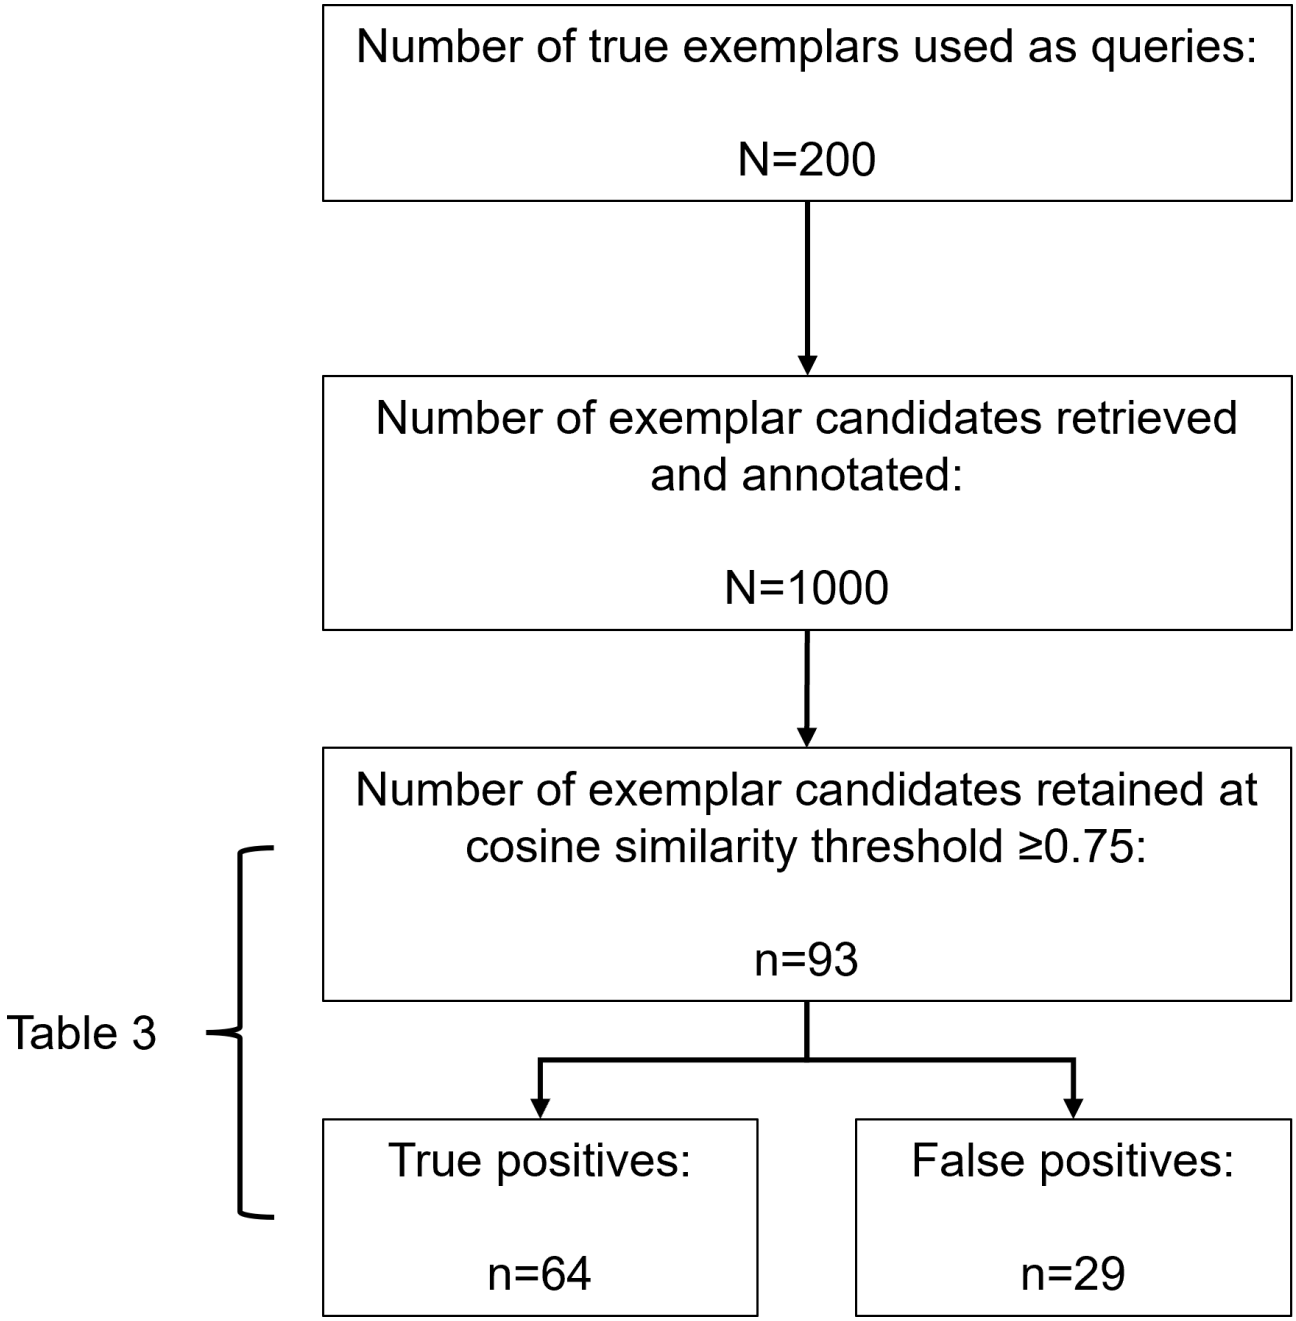
We used a sentence-transformer model, "multi-qa-distilbert-cos-v1," from the Hugging Face Model Hub [15,32] to search for additional exemplar candidates that were semantically similar to the set of true exemplars. This model is specifically designed for semantic similarity search and retrieval tasks using a contrastive learning objective to generate sentence-level embeddings that enable comparison of a given sentence with other sentences that are most closely related in meaning [32]. This design enables efficient, out-of-the-box application of the model for similarity-based retrieval tasks, making it well suited for the current task. Although this model is not trained on clinical text, it is trained on large-scale, question-answer-style data from diverse sources [32], which contributes to capturing contextual meaning across varied linguistic expressions. This general-domain training may be helpful for identifying broader sociolinguistic patterns and contextual features in clinical text that can extend beyond clinical language. Prior work suggests that general-domain embedding models can perform well for semantic similarity tasks in clinical text, although performance may vary across specific models and tasks [33].

Exemplar candidates were selected from clinical notes not used in the initial human annotation. We preprocessed the clinical notes by converting the free-text portions into a format similar to the true exemplars (single, double, and triple consecutive sentences). Sentence tokenization was performed first using natural language toolkit's "sent_tokenize," which identifies sentence boundaries based on learned punctuation and linguistic patterns rather than simple rule-based splitting. After tokenization, sliding windows of 1-, 2-, and 3-sentence spans were generated by advancing one sentence at a time. Duplicate candidates were then detected using a 6-word prefix and removed in 2 stages: first keeping only the earliest instance of each prefix, and then alternately dropping any remaining repeats to ensure only 1 representative remained. No normalization of casing, numbers, or abbreviations was applied. All text was embedded in its original form to preserve real-world clinical text. Examples of synthetic, free-text note snippets can be found in Table S3 in Multimedia Appendix 1.

We used the sentence-transformer model to encode true exemplars into fixed-size vectorized embeddings [15]. Then, true exemplars were used as queries to search and recommend new exemplars that were likely candidates from the unused clinical note datasets. We calculated semantic similarity between the true exemplars and exemplar candidates using the cosine similarity applied to their associated embedding representations. The Facebook AI similarity search library was used to perform the similarity searches [34]. We stratified and randomly selected 200 true exemplars across language categories to be used as queries. Stratification was conducted by language category to preserve each category's natural prevalence in the initial human-annotated dataset. As a result, less frequent categories contributed fewer exemplars (Table 1). For each of the 200 true exemplars, the top 5 similar exemplar candidates with the highest cosine similarities were retrieved (N=1000 exemplar candidates) for human review. Pseudocode blocks for the semantic similarity search pipeline employed in this study are provided in Multimedia Appendix 2.

Examining Accuracy of Exemplar Candidates

Four researchers who performed the initial annotation independently reviewed and assessed the exemplar candidates. Reviewers labeled the exemplar candidate as a "match" if it accurately represented the corresponding language category and as "not a match" if it did not. We resolved disagreements through iterative discussions among reviewers to reach consensus. We calculated the frequency and percentage of matched and nonmatched cases as true positives and false positives. We examined how precision changes when different cosine similarity boundaries were used to inform optimizing this approach for future research and applications. We calculated and reported average precision and corresponding 95% Wilson CIs across different cosine similarity thresholds, ranging from 0.5 to 0.95 in increments of 0.05. To our knowledge, there is no universally accepted precision cutoff for information retrieval tasks to support annotation workflows. Information retrieval literature supports that performance should be evaluated in relation to the intended use and context of each task, as performance requirements may vary across applications [35]. Previous research on annotation support often focuses on reducing annotation burden while maintaining annotation quality [36,37]. In a recent study on automated annotation support, the authors noted that precision exceeding 0.7 was considered "strong performance" for their task [38]. Given the exploratory nature of this study and its intended use to support annotation workflows, we selected precision ≥0.70 as an acceptable, pragmatic point to balance accuracy with meaningful efficiency gains in reducing annotation burden. At this precision point, most exemplar candidates would represent true cases while allowing a manageable proportion of false positives.



Results

A total of 1000 exemplar candidates were retrieved using the semantic similarity search approach (Figure 1). These exemplar candidates were derived from 443 clinical notes of 403 patients. The number of exemplar candidates by note type is provided in Table 2. Among the 1000 exemplar candidates retrieved, most were derived from obstetric admission notes (n=295, 29.5%), followed by obstetric postpartum notes (n=202, 20.2%) and miscellaneous nursing notes (n=172, 17.2%). Human annotators independently reviewed all 1000 exemplar candidates

XSL•FO
RenderX

retrieved for accuracy. The interrater reliability among the annotators was good (Cohen κ=0.71, 95% CI 0.67 - 0.75) across 1000 exemplar candidates.

Figure 1. Flow diagram summarizing the number of true exemplars or exemplar candidates in the analysis and results.

XSL•FO
RenderX

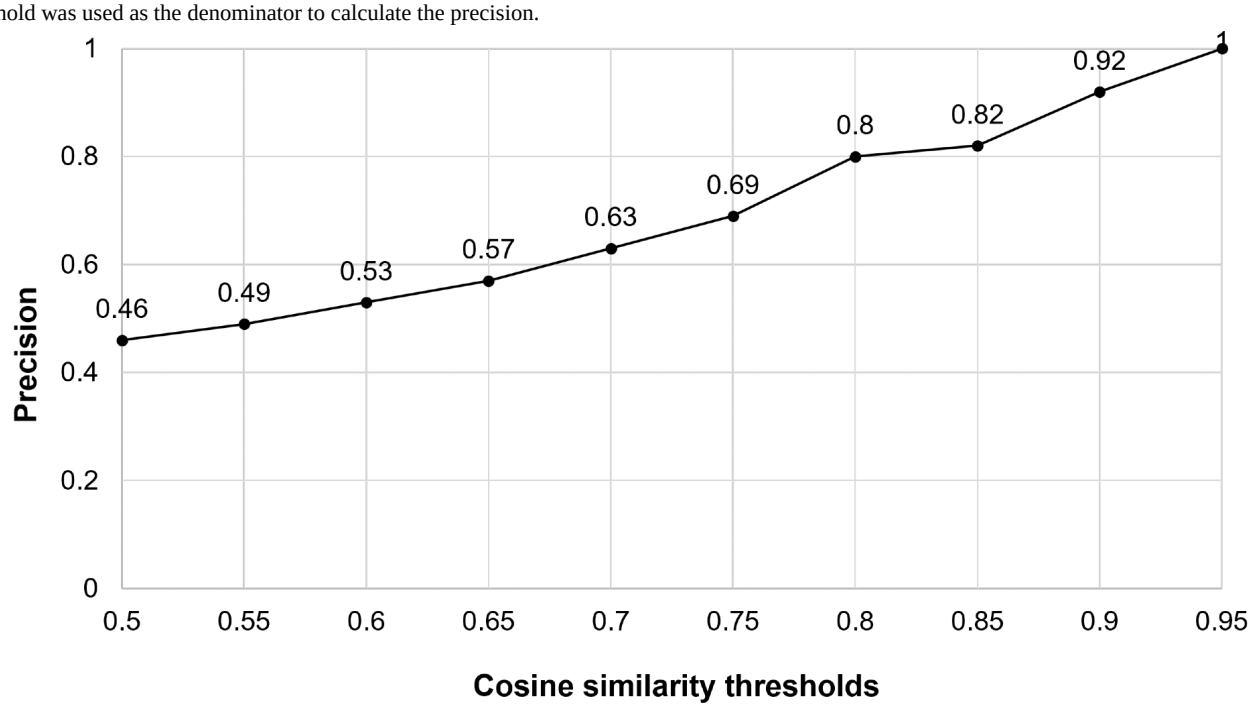


Table . Number of exemplar candidates by note type.

Note type	Exemplar candidates[a], n (%)
Obstetric admission note	295 (29.5)
Obstetric postpartum note	202 (20.2)
Miscellaneous nursing note	172 (17.2)
Anesthesia resident note	137 (13.7)
Obstetric triage note	106 (10.6)
Social work initial assessment	51 (5.1)
Initial nutrition assessment	37 (3.7)
Total exemplar candidates retrieved	1000 (100)

[a]The total number of exemplar candidates retrieved was used as the denominator to calculate the percentages.

We examined how the average precision of all language categories changed when including exemplar candidates at different cosine similarity thresholds. As shown in Figure 2, average precision increased with higher cosine similarity thresholds. The number of exemplar candidates retained decreased with higher cosine similarity thresholds. Average precision was highest at 1 (95% CI 0.44 - 1.00) when including exemplar candidates with cosine similarity ≥0.95, at which point 3 of 3 exemplar candidates were true cases. Average precision was lowest at 0.46 (95% CI 0.43 - 0.49) when including exemplar candidates with cosine similarity ≥0.5, at which point 383 of 831 exemplar candidates were true cases. Acceptable average precision (≥0.70) was achieved when including exemplar candidates with a cosine similarity of at least 0.75.

Figure 2. Line graph illustrating the average precision at different cosine similarity thresholds with corresponding values for the total number of exemplar candidates retained at each threshold, the number of true positives, and 95% CIs. The total number of exemplar candidates retained at each threshold was used as the denominator to calculate the precision.

	Cosine similarity threshold									
	0.5	**0.55**	**0.6**	**0.65**	**0.7**	**0.75**	**0.8**	**0.85**	**0.9**	**0.95**
Exemplar candidates retained at threshold	831	677	466	302	201	93	44	28	13	3
True positives (Matched cases)	383	333	245	173	127	64	35	23	12	3
95% CIs	0.43-0.49	0.45-0.53	0.48-0.57	0.52-0.63	0.56-0.70	0.59-0.77	0.65-0.89	0.64-0.92	0.67-0.99	0.44-1.00

XSL•FO
RenderX

A total of 93 exemplar candidates had a cosine similarity of at least 0.75. Among those, 64 (68.8%) accurately represented the true cases across stigmatizing and positive language categories (Table 3). In specific language categories, 100% (5/5) of exemplar candidates for autonomy for birth, 73.2% (41/56) for preferred language, and 71.4% (5/7) for unilateral/authoritarian decisions represented the true cases. While the proportions of matched cases were high for power/privilege, questioning patient credibility, and disapproval, the number of retrieved exemplar candidates for these categories was small at the 0.75 cosine similarity threshold (eg, 1 of 1 exemplar candidate was a true case for power/privilege and disapproval, respectively). In contrast, 28.6% (2/7) of exemplar candidates for difficult patient and 33.3% (3/9) of exemplar candidates for marginalized identities represented the true cases, with lower proportions of matched cases than other language categories at the 0.75 cosine similarity threshold.

Table . Proportion of matched cases by language category at a cosine similarity threshold of 0.75.

Language category	Exemplar candidates, N[a]	True positives (matched cases), n (%)	False positives (nonmatched cases), n (%)
Preferred language	56	41 (73.2)	15 (26.8)
Autonomy for birth	5	5 (100)	0 (0)
Difficult patient	7	2 (28.6)	5 (71.4)
Unilateral/authoritarian decisions	7	5 (71.4)	2 (28.6)
Power/privilege	1	1 (100)	0 (0)
Structural/interprofessional hierarchy	4	3 (75)	1 (25)
Marginalized identities	9	3 (33.3)	6 (66.7)
Questioning patient credibility	3	3 (100)	0 (0)
Disapproval	1	1 (100)	0 (0)
Total	93	64 (68.8)	29 (31.2)

[a]The total N column was used as the denominator to calculate the proportion of matched and nonmatched cases.

Detailed results for precision at different cosine similarity thresholds by specific language categories and corresponding CIs are reported in Tables S1 and S2 in Multimedia Appendix 1. Of note, several precision values were based on small numbers of exemplar candidates, particularly at higher thresholds, and are statistically unstable for these sparse categories. For categories with relatively larger numbers of retained candidates, such as preferred language, acceptable precision (≥0.70) was observed at a cosine similarity of 0.70, where 74 of 105 exemplar candidates represented true cases. False positives most commonly occurred in exemplars containing more complex social or contextual information. For example, exemplars describing objective social circumstances were misclassified as stigmatizing despite the absence of judgmental language (eg, false positive in the marginalized identities category: “Patient may want to be discharged to home tonight. She lives nearby and will be able to visit infant”). In other cases, exemplars containing stigmatizing language were misclassified into incorrect categories. For example, “Patient stated she doesn’t have any help in the country and FOB [father of baby] is in DR [Dominican Republic]. Patient needs social worker, will continue to monitor...” was incorrectly classified into the power/privilege category.

Discussion

Principal Findings

We explored a semantic similarity search approach to identify additional exemplars from obstetric clinical notes with less manual human effort. We found that we can increase accuracy by adjusting cosine similarity boundaries when selecting exemplar candidates. The average precision increased with higher cosine similarity thresholds, achieving an acceptable average precision ≥0.70 when exemplar candidates with a cosine similarity of 0.75 or higher were included. On average, 68.8% (64/93) of exemplar candidates accurately represented true cases across various language categories at the 0.75 cosine similarity threshold. These thresholds should be guided by each use case in future research and application. Lower thresholds may be useful for exploratory analyses, where broader retrieval is desired to examine patterns of expressions and language use. Lower thresholds may also be appropriate when maximum coverage is prioritized over precision, such as for rarely occurring cases, where missing potential matches would be more consequential than reviewing additional false positives. In contrast, higher thresholds may be suitable when precision should be prioritized, such as using retrieved texts for direct application in clinical settings, including quality review or clinical documentation audit to identify potential stigmatizing language. Higher thresholds may also be useful with large datasets, where even a strict precision cutoff can yield a sufficient number of exemplar candidates, whereas the same threshold applied to smaller datasets may result in too few retrieved exemplars to be useful.

It is important to note that the reported accuracy in our study reflects only positive retrieval quality, measured by precision, rather than the overall effectiveness or completeness of the retrieval approach. Given the exploratory nature of the study, we did not annotate nonretrieved texts to calculate more

XSL•FO
RenderX

comprehensive evaluation metrics, including recall and F_1-scores. As such, our findings do not provide information regarding the extent to which the approach identified all relevant exemplars within the dataset. For example, it remains unknown how many relevant exemplars may not have been retrieved, limiting the ability to assess the completeness of retrieval. In addition, the number of exemplar candidates retained decreased substantially across language categories as cosine similarity thresholds increased (detailed category-specific results in Multimedia Appendix 1). As such, the current study may be underpowered to support reliable category-level conclusions. When few exemplar candidates were retained, high precision values should not be misinterpreted as strong performance, as they are statistically unstable and reflect limited sample size. At lower cosine thresholds, where more candidates were retained, precision varied across language categories. Although these should be interpreted cautiously, they may reflect different language complexity. For example, at the 0.5 cosine similarity threshold, higher precision was observed for preferred language and autonomy for birth compared to other categories. These 2 categories were more straightforward with well-defined, identifiable keywords (eg, "desires natural birth," "reports pain"). Conversely, we observed lower precision for marginalized identities, questioning patient credibility, and disapproval categories at the 0.5 cosine similarity threshold. These categories were more nuanced and context-dependent. For example, there was a subtle undertone of disapproving the patient's choice of birth control in the following: "postpartum birth control method-patient states that she prefers to use condoms and will continue to readdress."

Accurately identifying such nuances requires a deeper understanding and interpretation of contextual meanings and subtleties, which may be challenging for semantic similarity search. Semantic similarity search primarily relies on vector-based representations of text, including static embeddings like Word2Vec and GloVe [13,39] and contextual embeddings like bidirectional encoder representations from transformers (BERT) [40]. Static embeddings can effectively capture general semantic relationships [13,39] but can be limited in detecting context-specific nuances and meanings [41]. Although contextual embeddings, such as those generated by the sentence-transformer model used in the current study, can better capture contextual information, they may still be challenged by complex and subtle nuances [42]. Finally, when suitable training data are available, sentence-transformer models could be further improved through data- and task-specific training by fine-tuning.

While semantic similarity has been previously used for tasks such as information retrieval, its application to support annotation workflows, specifically for retrieving additional exemplars, remains relatively limited. The current study extends this line of work by applying semantic similarity search to more efficiently expand annotated datasets. This approach is particularly useful for low-prevalence concepts, where traditional active learning strategies may be less effective. In contrast to data augmentation strategies, such as synthetic data generation, it can preserve naturally occurring language while enabling targeted expansion of context-dependent concepts. Furthermore, while prior retrieval-based approaches have used similarity to identify relevant text for tasks such as information retrieval or retrieval-augmented generation, the effectiveness of these approaches is typically evaluated based on automated metrics or downstream model performance, rather than human validation [18,19]. In contrast, we conducted human evaluation of retrieved exemplar candidates and examined precision across cosine similarity thresholds, providing insight into the utility of this approach as an annotation support strategy. Our findings highlight how cosine similarity thresholds influence precision, offering practical guidance for applying this approach in settings where annotated data are sparse.

Although our findings are based on the context of stigmatizing and positive language in obstetric clinical notes, which may limit the generalizability to other specialized datasets or domains, semantic similarity search itself is not inherently domain-specific. Because this approach operates by comparing a given sentence with other sentences to identify those most closely related in meaning, it is not dependent on or limited to specific models but can be incorporated into existing clinical NLP pipelines as a data augmentation or annotation-support step. For example, retrieved exemplar candidates may be used to efficiently expand training datasets prior to NLP model development or to support targeted human review in resource-constrained settings. Prior research has demonstrated the practical benefits of targeted text selection using active learning to support annotation workflows. For example, active learning approaches have been shown to reduce annotation time by approximately 20% to 35% for clinically explicit concepts, such as medical problems and tests, by prioritizing informative texts for manual annotation [43,44]. More recently, active learning has also been shown to reduce other forms of annotation burden. For example, Nachtegael et al [45] used active learning to select unlabeled texts for manual annotation. They found that models trained on selectively annotated datasets achieved performance comparable to models trained on fully labeled datasets while reducing the amount of labeled data required by 6% to 38% [45]. Although these studies employed different active learning approaches than the current study, they indicate that strategically selecting texts for manual review can reduce annotation burden.

Limitations

This study has some limitations. First, the effectiveness of semantic similarity search depends on the quality of the initial human-annotated dataset. If true exemplars do not accurately reflect positive cases, the extracted candidates are also likely to be inaccurate. The relatively modest initial agreement among annotators (Cohen κ=0.4) highlights the subjective nature of identifying stigmatizing language. Consequently, some retrieved exemplars may have been classified differently among annotators, which could have influenced downstream retrieval accuracy. Additionally, if true exemplars do not represent diverse language categories, the extracted candidates may not be comprehensive. Second, while semantic similarity search reduced the labor required for annotation, it does not eliminate the need for human review. Due to the risk of false positives, a rapid human review of the retrieved candidates remains essential to validate the accuracy. Third, our evaluation was limited to precision to prioritize annotation efficiency. In our approach,

XSL•FO
RenderX

the model retrieved exemplars predicted to be positive matches to the true exemplars. We did not annotate nonretrieved texts to identify false negatives, which is required to calculate recall. As such, the expanded dataset should be useful for augmenting existing annotated datasets with positive cases, rather than providing exhaustive or population-representative datasets. Fourth, although language categories and operational definitions were developed through qualitative analysis and informed by prior research, several categories remain inherently subjective and context-dependent. The operational definitions for these categories may remain somewhat ambiguous in practice, which can introduce variability in interpretation even among trained annotators. This reflects broader challenges in objectively operationalizing stigmatizing language in clinical notes, and findings should be considered given this inherent measurement limitation. While all discrepancies were resolved through consensus to establish the final annotated dataset, some degree of uncertainty may remain. As such, the retrieved exemplars may reflect alignment with the study-specific definitions and exemplars rather than universally accepted definitions. Fifth, we used a model trained on general-domain data because it is designed for similarity-based retrieval tasks [32], enabling its direct and efficient application in the current study without additional modifications. In addition, stigmatizing and positive language often requires capturing broader sociolinguistic expressions and context beyond clinical language, for which training on diverse data sources may be helpful. However, clinical language often includes specialized terminology, abbreviations, and domain-specific cues, which may not be fully captured by general-domain embedding models. As such, semantic similarity estimates may be less accurate for certain clinical expressions. Domain-specific models (eg, ClinicalBERT or BioClinicalBERT) are trained on clinical text and may provide better representations of clinical terminology and context [46]. However, these models are not specifically designed or explicitly optimized for sentence-level similarity search or retrieval tasks. Thus, additional methodological adaptations, such as deriving sentence embeddings and optimizing the models for similarity-based retrieval tasks, would be required to apply domain-specific models to the task explored in the current study. For example, ClinicalBERT produces token-level contextual representations rather than sentence-level embeddings that can be directly compared using cosine similarity to identify semantically similar text. Token-level representations need to be transformed into sentence-level representations using a pooling strategy (eg, mean or max pooling), and different strategies may yield varying retrieval accuracy. Consequently, a meaningful empirical comparison with domain-specific models would be challenging because differences in retrieval accuracy could reflect these adaptations rather than the underlying models themselves. Therefore, rigorous comparison of clinical embedding models was considered beyond the scope of the current exploratory study. Finally, several language categories had very small sample sizes at higher cosine similarity thresholds, resulting in high but statistically unstable precision that should not be misinterpreted as strong or reliable performance.

Future Research

Future research may consider evaluating recall and F_1-scores, which can provide additional insight into semantic similarity search performance, particularly given the potential trade-off between precision and recall [47]. Exploring additional techniques to refine the candidate selection process may further contribute to optimizing accuracy. For instance, combining other similarity metrics, such as pragmatic similarity, could provide a more comprehensive assessment. Pragmatic similarity considers the intent and attitude behind the text, which could help to ensure that the intended meanings between texts are aligned [48]. In addition, comparing the performance of general-domain and clinical-domain models in similarity-based retrieval tasks for annotation support could provide further insight into how domain-specific models affect retrieval accuracy and annotation efficiency. Future work is also needed to further clarify, refine, and standardize the operationalization of these language categories to improve annotation consistency and reproducibility. Finally, application of this approach across diverse clinical settings and datasets will further inform generalizability.

Conclusions

This study applies semantic similarity search in the context of stigmatizing language to support annotation workflows. Unlike previous research using uncertainty-based querying or synthetic data augmentation, we used human-annotated true exemplars as queries to directly retrieve additional exemplars from real-world clinical notes to support targeted expansion of context-dependent concepts. Findings demonstrate the potential of semantic similarity search to efficiently extract additional exemplars and increase the volume of training data while reducing annotation burden. By optimizing the cosine similarity thresholds, we may further achieve higher precision. These findings provide a foundation for further refinement and application of this approach in other domains requiring efficient ways to extract additional exemplars to augment NLP training data.

Acknowledgments

We thank Arielle Hazi for her assistance during the revision process, including providing additional information on previously generated data and results. During the revision process, the first author used ChatGPT (GPT-5.3; OpenAI) to assist with proofreading tasks, specifically for identifying and correcting grammatical errors, under full human supervision. All outputs were reviewed and edited by the authors as needed, who take full responsibility for the content of the publication.

Abstract

Background: Due to the heterogeneity of symptom terminology and the lack of industry standards, the same symptom is often described using multiple expressions. Current normalization approaches struggle to comprehensively retrieve standard terms when a raw term maps to multiple symptoms.

Objective: This study aimed to address the lack of industry standards for traditional Chinese medicine (TCM) symptom terminology. This study proposed the split-then-concatenate normalization framework (STC-NF), a novel approach based on fine-grained semantic classification and a 2-stage deep learning architecture that uses electronic medical records (EMRs) as the data source.

Methods: This study proposed a 2-stage deep learning framework, "split-then-concatenate." In the splitting stage, TCM symptom entities were categorized into 12 fine-grained semantic labels, and 3 named entity recognition (NER) models were trained to extract TCM symptom terminology from EMRs. In the concatenation stage, standard terms with the same concept as raw terms were identified using a Bidirectional Encoder Representations from Transformers (BERT)–based binary classification model. The standard terms with specific semantic labels were concatenated and reordered according to predefined rules to output structured text, thereby normalizing TCM symptom terminology.

Results: The proposed STC-NF model achieved an accuracy of 91.4% (180/197) and an F_1-score of 360 out of 389 (92.5%) on the single-implication test set. For multi-implication terms, STC-NF achieved an accuracy of 84.3% (311/369) and an F_1-score of 1958 out of 2316 (84.5%), outperforming sequence generation in accuracy by 33.1 percentage points. On the mixed test set containing both single- and multi-implication terms, STC-NF achieved an accuracy of 88.1% (990/1124) and an F_1-score of 3862 out of 4385 (88.1%), exceeding the best-performing baseline model, multi-task candidate generator (MTCG), by 16.7 and 22.2 percentage points in accuracy and F_1-score, respectively.

Conclusions: In this study, we verified that the fine-grained semantic classification and the 2-stage "split-then-concatenate" framework effectively improved performance of named entity recognition and entity alignment, providing an improved approach to normalizing TCM symptom terminology.

Introduction

Background and Rationale

Symptoms are the core basis of traditional Chinese medicine (TCM) identification and treatment. They are also one of the main input features for AI to realize assisted diagnosis and treatment [1], which are of great value to medical research [2]. Due to the heterogeneity of symptom terminology, the same symptom is often described in multiple expressions. For example, "失眠 (insomnia)," "不寐 (sleeplessness)," and "入睡困难 (difficulty initiating sleep)" are all described as the same clinical phenomenon in TCM electronic medical records (EMRs). In recent years, it has been widely acknowledged that normalizing symptom terminology is crucial for improving the accuracy of TCM syndrome differentiation and promoting the modernization of TCM [3]. However, neither industry consensus nor a national standard for TCM symptom terminology currently exists [4]. This gap has significantly hindered the sharing of medical data, knowledge mining, and the development of intelligent applications [5]. Efficiently and accurately aligning nonnormalized symptom raw terms with standard terms in the knowledge base has become a key issue to address.

Related Work

A number of recent studies have specifically targeted the normalization of TCM symptom terminology. Jia et al [6] proposed a symptom terminology normalization approach with hierarchical semantics (symNormHS) to address issues related to synonymous expressions and homographs through a 2-step process. The approach first extracted hierarchical semantic information from symptom terms using a multilabel text classifier to filter the candidate set. Then, it used a hybrid multigranularity text matching model, combined with an attention mechanism, to compute the similarity between raw terms and standard terms. Zhan et al [7] used an autostacker classifier model based on the automated machine learning (AutoML) framework to predict categories of TCM symptom terms, and computed semantic similarity between raw terms and standard terms using a directional skip-gram (DSG) model. Tang et al [8] retrieved candidate standard terms from Systematized Nomenclature of Medicine Clinical Terms (SNOMED CT) using a hybrid retrieval strategy that combined dice coefficients and term frequency-inverse document frequency (TF-IDF). The retrieved candidates were then reranked using enhanced representation through knowledge integration (ERNIE), specifically the ERNIE-Health model (Baidu Inc), which served as the semantic similarity scoring module for selecting the most semantically compatible standard terms. Zhou et al [9] unified the synonymous raw terms into standard terms by constructing a classification model for synonymous term conversion with the thinking of candidate terms (STC-TC), and misclassification detection was performed using the output comparison of multiple heterogeneous models (OCMH). Hu et al [10] proposed an approach to normalize TCM symptom terminology using Bidirectional Encoder Representations from Transformers (BERT)–bidirectional long short-term memory (BiLSTM)–conditional random field (CRF) and a multilabel classification strategy. By constructing an ontology framework for TCM symptoms and integrating knowledge graphs, this approach combined the correlated feature fusion module (CFFM) and the hierarchical labeling tree (HLT) to optimize the recognition and normalization capability of entities. The normalization approaches in [6-10] are all based on deep learning. Their innovations and limitations are summarized in Table 1.

XSL•FO
RenderX

Table . Innovations and limitations of different approaches.

Author	Year	Approach	Innovations	Limitations
Jia et al [6]	2021	symNormHS[a]	Enhanced semantic matching by fusing unigram- and bigram-level local features through the attention mechanism.	Low recall of multi-implication terms[b] (eg, "面红目赤 [flushed face with bloodshot eyes]" only matched "目赤 [bloodshot eyes]"), which required improving the normalization logic by formulating additional heuristic rules.
Zhan et al [7]	2021	DSG[c]	Constructed a classification model to handle symptom terms using the AutoML[d] framework and used the DSG model to capture the semantic relationships between raw terms and standard terms.	The DSG model had a limited ability to recognize multi-implication terms (eg, "头胀痛伴耳鸣如蝉 [distending headache with tinnitus like cicada chirping]"), which might lead to normalization failure due to excessively long text and semantic nesting.
Tang et al [8]	2022	ERNIE[e]-Health (Baidu)	Proposed a hybrid recall strategy (dice coefficient+TF-IDF[f]) to improve the recall of standard terms.	Unable to accurately deal with multi-implication terms (original description: 2 different concepts in one word), it was suggested to introduce external information, such as "context and symptomatic site," to address this issue.
Zhou et al [9]	2023	STC-TC[g]	Used the OCMH[h] to identify normalization errors.	Multi-implication terms (eg, "痰量多色白 [increased white-colored sputum]") had lower normalization accuracy due to their extremely low frequency of occurrence and the lack of sufficient training samples for the model to learn entity recognition laws.
Hu et al [10]	2024	Ontology-enhanced multilabel model	Introduced the CFFM[i] module to fuse entity features and the hierarchical labeling tree to solve the label imbalance problem, thereby enhancing normalization capability for rare symptoms.	The multilabel classification approach was unable to handle multi-implication terms composed of multiple symptom entities (eg, "腰膝酸软 [soreness and tenderness in the lower back and knees]"), as it only matched "腰酸软 (lower back soreness and tenderness)" and could not retrieve "膝酸软 (knee soreness and tenderness)."

[a]symNormHS: symptom terminology normalization approach with hierarchical semantics.

[b]In this study, we define a raw term that maps to exactly one standard term as a "single-implication term," and one that maps to multiple standard terms as a "multi-implication term."

Beyond these TCM-specific systems, research on medical terminology normalization has more broadly progressed through 3 methodological stages, including rule-based and dictionary-matching approaches, machine learning approaches, and deep learning approaches. Rule-based and dictionary-matching approaches [11-16] require experts to manually construct specific regulations based on data features and then use specialized domain dictionaries to complete tasks such as named entity recognition (NER) and named entity normalization (NEN). Although such approaches achieve high accuracy when the lexicon is comprehensive, their performance is contingent on labor-intensive, manually crafted rules. Furthermore, reusing identical rule sets in new domains markedly reduces effectiveness, rendering the approach costly, laborious, and poorly portable. Machine learning approaches [17-22] can automatically extract features from medical corpora and predict entity classification labels through statistical computation, thereby eliminating the need to construct rules and effectively reducing manual effort. However, this approach computes the similarity of concepts by comparing the literal differences between 2 entities, which does not fully use the semantic information in the context, resulting in obvious limitations in its generalizability. Deep learning approaches [6-10,23-32] now dominate medical terminology normalization because they can embed phrases in dense vector spaces and capture latent semantic relations beyond surface forms. Recent studies have further shown that medical NER and normalization are affected by limited annotated data, entity-boundary ambiguity, heterogeneous preprocessing procedures, and insufficient use of contextual information. For Chinese clinical NER, Tang et al [33] proposed a segmentation synonym sentence synthesis mechanism to expand training data and improve model generalization. Li et al [34] explored a few-shot medical NER framework that combines retrieval-based example selection with a structured reasoning process, highlighting the importance of informative examples and task-specific guidance under limited annotation conditions. From the perspective of biomedical entity linking, Garda et al [35] emphasized that inconsistent preprocessing, knowledge-base selection, and evaluation protocols can limit reproducibility and comparability across normalization systems. Luo et al [36] further demonstrated that contextual information around entity mentions is important for biomedical named entity normalization, especially when mentions are semantically ambiguous. These studies collectively indicate that accurate clinical text standardization requires not only semantic matching but also reliable entity-boundary recognition, task-specific preprocessing, and context-aware alignment. To address these requirements from different methodological perspectives, existing deep learning approaches can be broadly categorized into 3 types based on their entity alignment mechanisms, including multiclassification, sequence generation, and binary classification.

The multiclassification paradigm casts normalization as a sentence-level classification task. Representatively, Huang et al [30] proposed a pretrained language model framework for *International Classification of Diseases* coding (PLM-*ICD*), which integrates domain-specific pretrained language models with the attention mechanism and thereby exploits contextual semantics to align uncommon raw terms (eg, “耳朵有蝉叫声 [ears buzzing]”) with standard terms of low lexical overlap (eg, “耳鸣 [tinnitus]”). Compared with statistical models such as TF-IDF, Med, and BM25, which rely on character-level similarity, this paradigm attains markedly higher accuracy on single-implication terms; however, because its classification head emits only a single prediction for each input sentence, it cannot recover the multiple standard terms that a multi-implication expression requires. To overcome this single-output limitation, the sequence generation paradigm reformulates normalization as a token-by-token generation process. Along this line, Yan et al [31] generated standard terms sequentially and were thus able to align simply structured multi-implication terms that contain no overlapping, discontinuous, or nested entities (eg, “头昏嘴斜 [dizziness and mouth skewed]”) with several standard terms (eg, “头晕 [dizziness]” and “口歪 [mouth skewed]”), thereby partially improving the accuracy of multi-implication normalization. Decomposing a raw term character by character, however, can fracture the structural integrity of an entity and degrade performance on single-implication terms. The binary classification paradigm instead preserves each candidate term intact and judges semantic equivalence in a pairwise manner. For example, Liang et al [32] proposed the multi-task candidate generator (MTCG) model, which first retrieves the standard terms semantically closest to a raw term by computing the Euclidean distance between their vector representations, and then formats each raw term together with its retrieved candidates as sentence-pair inputs to a pretrained BERT model for binary classification; an output of 1 indicated semantic equivalence between the raw term and a candidate standard term, and the normalization of a multi-implication term is completed by aggregating all candidates judged to be equivalent.

Challenges in TCM Symptom Terminology Normalization

While the 3 paradigms reviewed above each advance entity alignment, none was designed to fully decompose the structurally complex symptom expressions that are common in TCM EMRs. As shown in Table 1, deep learning approaches can retrieve standard terms with low character-level similarity to raw terms—for instance, mapping “脑袋疼 (nǎo dai téng)” to “头痛 (tóu tòng),” both meaning “headache”—by capturing linguistic features and modeling contextual dependencies. However, for multi-implication terms composed of multiple symptom entities, current normalization approaches still perform with low accuracy. To better understand this limitation, after manually annotating 500 TCM EMRs, we found that multi-implication terms related to the TCM symptom terminology could be categorized into the following three types.

1. Overlapping entities: two symptom terms share the same suffix. For instance, the phrase “饮食睡眠尚可 (eating and sleeping okay)” is a combination of the symptom terms “饮食尚可 (eating okay)” and “睡眠尚可 (sleeping okay).”

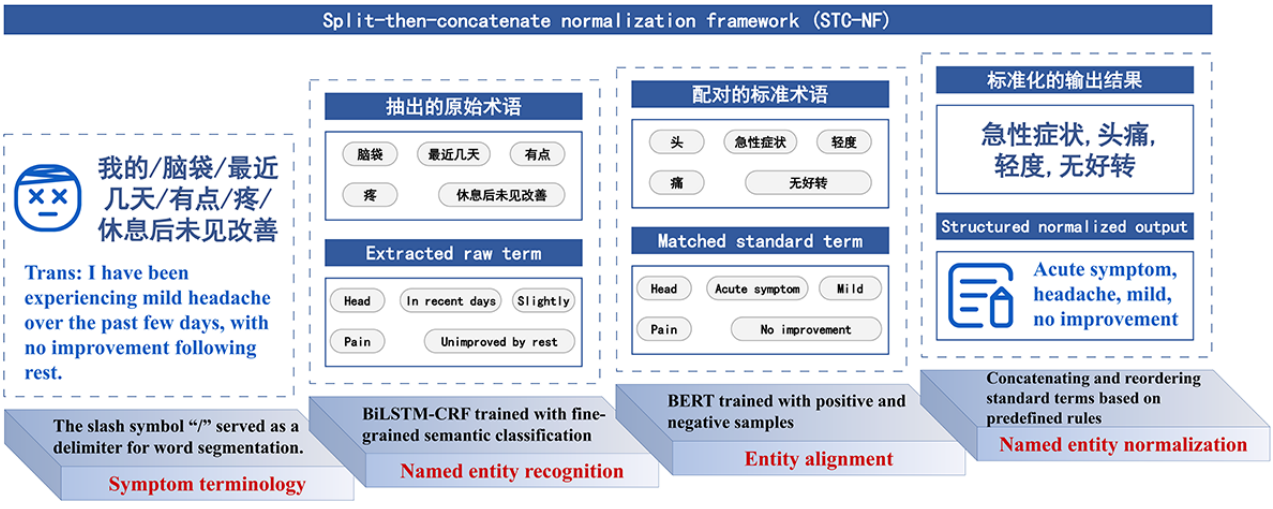
XSL•FO
RenderX

2. Discontinuous entities: common TCM symptom terminology, such as “头痛 (headache),” “手麻 (hand numbness),” and “耳鸣 (tinnitus),” typically consists of an anatomy entity and an abnormality entity. However, sometimes the abnormality entity does not follow the anatomy entity. For instance, in the phrase “头有点痛 (a mild headache),” the adjective “有点 (mild)” (indicating symptom severity) separates the abnormality entity “痛 (pain)” from the anatomy entity “头 (head).”
3. Nested entities: two symptom terms share the same prefix. For instance, the phrase “尿频量多 (polyuria with increased urinary frequency)” results from combining symptom terms “尿频 (frequent urination)” and “尿量多 (copious urination).”

These 3 complex structural types are the main factors responsible for the low accuracy of current normalization approaches in handling multi-implication terms. To improve normalization performance for such terms, this study proposes the split-then-concatenate normalization framework (STC-NF), an approach based on fine-grained semantic classification that uses TCM EMRs as the data source.

Study Objective and Contributions

Guided by the objective of accurately normalizing such multi-implication terms, this study makes the following two principal contributions:



1. Fine-grained semantic classification rules are proposed to categorize entities related to TCM symptoms into 12 different types. Validation on 500 TCM EMRs demonstrates that labeling data with fine-grained semantic classification enables the NER model to achieve excellent performance. This approach could effectively address the difficulty in segmenting TCM symptom terminology caused by fuzzy entity boundaries.
2. Concatenation and ordering rules for standard terms are constructed to retrieve standard terms that semantically match the input raw term from the knowledge base more comprehensively when the latter maps to multiple standard terms. This approach shows excellent performance in handling multi-implication terms and could be applied to other medically relevant natural language processing (NLP) tasks, such as normalizing diagnoses or surgical procedures.

Methods

Overview of the Study

To accurately extract all symptom terms from EMRs and convert them into structured text, we proposed the STC-NF. This 2-stage process was designed after reviewing 3 normalization approaches, including multiclassification, sequence generation, and binary classification. In the first stage, we segmented sentences and extracted all symptom-related raw terms using fine-grained entity classification rules and a BiLSTM-CRF model. In the second stage, our study used a binary judgment model based on BERT to identify the conceptually equivalent standard term from a set of standard terms that shared the same semantic classification label as the raw term. Finally, we concatenated and reordered all standard terms according to predefined rules to generate the structured text, thereby completing the normalization of the entire sentence. The technical workflow of this study is shown in Figure 1.

Introduction to Dataset Sources and Fine-Grained Semantic Classification

The primary source of the dataset in this study was the collection of 500 EMRs from the endocrine department of a hospital in Guangzhou, China. Before annotation, personally identifiable information was removed, and the free-text symptom descriptions were reviewed at the sentence level. Because this study used manually annotated free-text symptom mentions rather than structured laboratory or demographic variables as model inputs, conventional missing-value imputation was not performed. Sentences within the EMRs that lacked analyzable symptom descriptions were excluded from training instance construction; this sentence-level filtering did not affect the EMR-level dataset partitioning described below. The main features used in the NER stage were entity boundaries and fine-grained semantic labels, while the features used in the NEN stage were raw-term and candidate-standard-term pairs

XSL•FO
RenderX

constrained by semantic label type. This design is consistent with recent clinical NER and biomedical entity-linking studies emphasizing task-specific annotation rules, limited-resource data construction, and standardized preprocessing for reproducible normalization experiments [33-35]. We categorized the symptom-related entities into 12 different types, and the specific classification rules and entity examples were as follows:

1. Independent symptom (label: Symp_S): a highly condensed name for a disease or an expression describing a preference, usually consisting of 2 Chinese characters. Examples: “咳嗽 (cough),” “呕吐 (vomiting),” “发热 (fever),” and “喜热饮 (preference for hot drinks).”
2. Negative occurrence (label: Neg): a character or word that describes a negative meaning. Examples: “无 (none)” and “未见 (not seen).”
3. Scope space (label: Pos_SCP): describes the scope in which the state occurs. Examples: “左 (left),” “右 (right),” “双侧 (bilateral),” and “小 (the character ‘小 [xiǎo]’ in the TCM symptom terminology ‘小便 [xiǎo biàn]’ implies ‘a relation to urination or the urinary system’).”
4. Primary space (label: Pos_Pri): describes the primary space in which the state occurs. Examples: “头 (head),” “神志 (mental),” “睡眠 (sleep),” and “便 (poop).”
5. Secondary space (label: Pos_Sub): after splitting the compound entity, describes a more specific level of the state. Examples: “量 (volume)” and “次数 (frequency)” in “小便量次数增多 (increased urinary frequency with elevated voided volume).”
6. Time of occurrence (label: Time): describes the time of occurrence of all abnormal symptoms. Examples: “三个月前 (3 months ago)” and “昨日 (yesterday).”
7. Occurrence condition (label: Cond): describes the specific time or condition under which an independent symptom occurs. Examples: “行走时 (when walking),” “平躺时 (when lying down),” “晨起时 (when waking up in the morning),” and “上楼后 (after going upstairs).”
8. Frequency of occurrence (label: Freq): describes how frequently the symptom occurs. Examples: “一日三次 (3 times a day),” “反复 (recurrent),” and “偶尔 (occasional).”
9. Qualitative severity (label: Sev_Qual): describes the qualitative seriousness of the symptom. Examples: “轻度 (mild),” “中度 (moderate),” and “重度 (severe).”
10. Quantitative severity (label: Sev_Quant): describes the quantitative severity of the symptom quantitatively. Examples: “约50斤 (about 25 kg)” in “体重下降约50斤 (significant body weight reduction of approximately 25 kg).”
11. Occurrence state (label: State): describes the abnormal manifestation of the symptom. Examples: “痛 (pain),” “刺痛 (stabbing pain),” “闷 (stuffiness),” “胀 (bloating).”
12. Occurrence trend (label: Trend): describes the trend in symptom change. Examples: “加重 (aggravation),” “减轻 (remission),” “缓解 (alleviation).”

All 500 EMRs were annotated according to these 12 fine-grained categories before model training and evaluation. The dataset was divided at a ratio of 8:2. A total of 400 EMRs, accounting for 30,490 out of 38,486 entities (79.2%), were used as the training set, and 100 EMRs, accounting for 7996 out of 38,486 entities (20.8%), were used as the test set.

Overview of the Entity Alignment Task

Entity alignment for symptom terminology aims to map each fine-grained raw symptom term extracted from medical texts to a semantically equivalent standard term in a standard knowledge base. Given a set containing n raw terms:

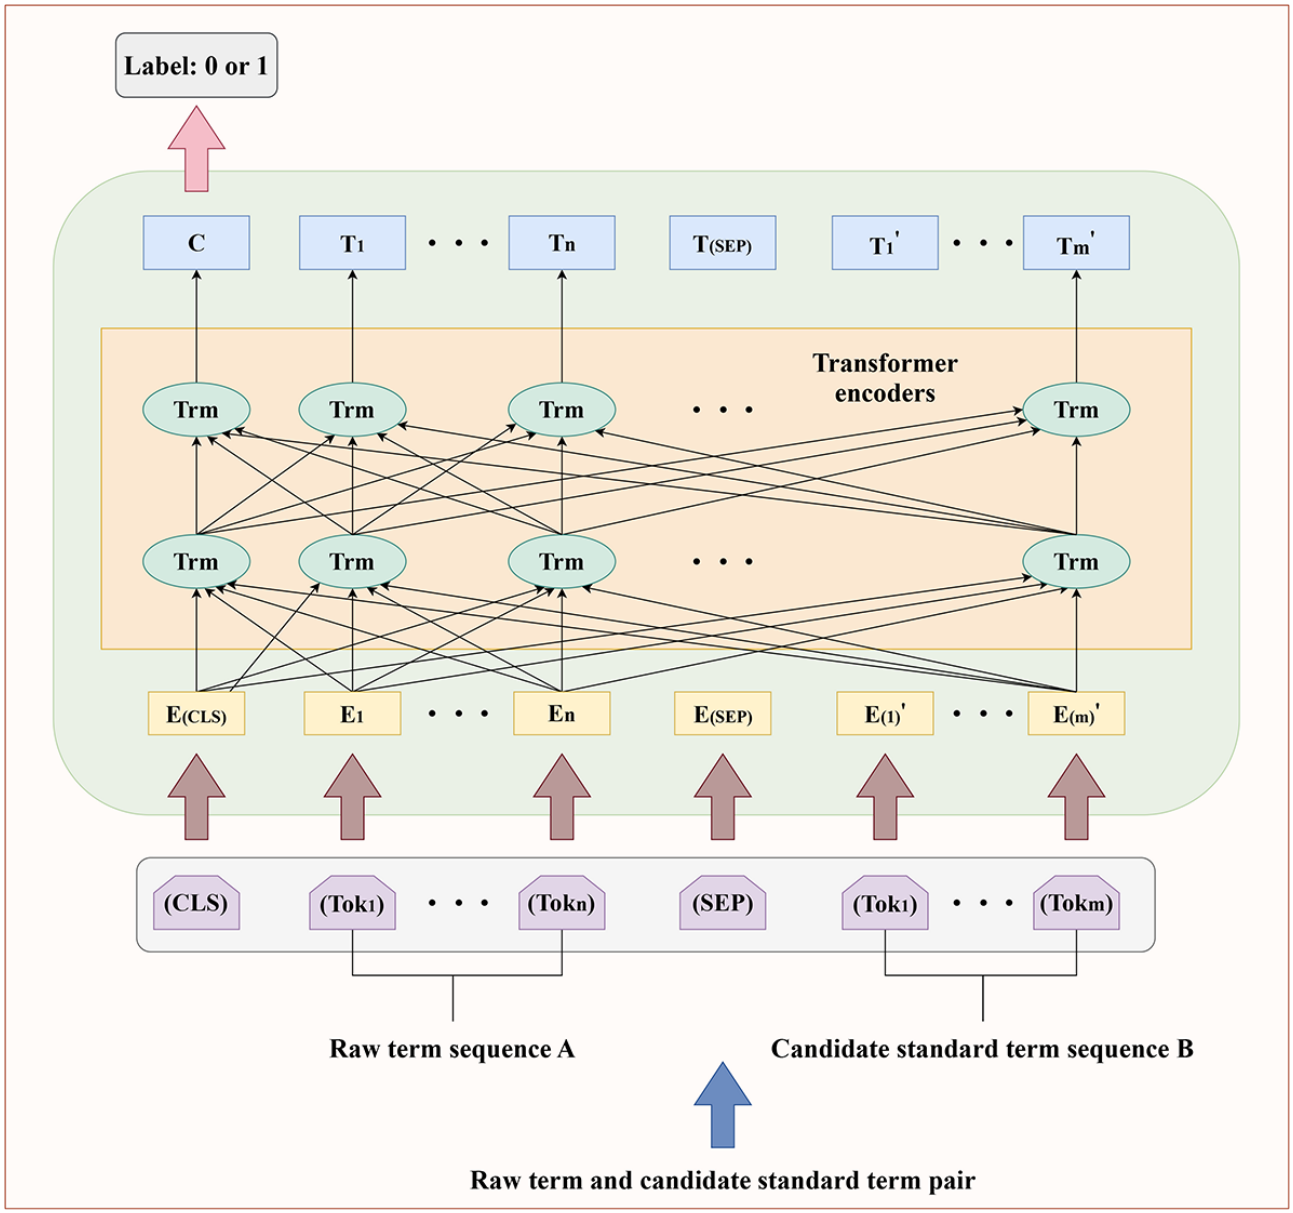
(1)M={m1,m2, ,mn}

and a standard knowledge base (containing *g* standard terms):

(2)E={e1,e2, ,eg}

The task is to map each fine-grained raw term m_i to a semantically equivalent standard term e_j in the standard knowledge base, with the candidate standard terms restricted to those sharing the same fine-grained semantic label as the raw term.

The core methodology involves training a deep semantic matching model, leveraging BERT’s binary classification capability, to perform the normalization shown in Equation 3:



(3)norm (mi)=ej

For a multi-implication symptom term, this mapping is applied to each of its extracted fine-grained raw terms, and the matched standard terms are subsequently concatenated and reordered according to predefined rules.

As illustrated in Figure 2, our proposed model processes a pair consisting of a raw term and a candidate standard term. The (CLS) token is placed at the beginning of the input sequence for the final text classification task, while the (SEP) token is used to separate the 2 terms. The model outputs a binary classification result: a label of “1” indicates a conceptual match, signifying that the candidate standard term is the correct alignment for the given raw term. Conversely, a label of “0” denotes a mismatch, meaning the candidate term is not the correct normalization. In such cases, the model iteratively evaluates the raw term against other candidate standard terms until a positive match (a result of “1”) is identified.

Introduction to the Methodology for Constructing the Standard Knowledge Base

Most of the standard terms we collected originate from the most widely used medical classifications and databases worldwide. For example, the terms "失眠 (insomnia)," "不寐 (sleeplessness)," and "辗转反侧 (nocturnal restlessness)" all convey the same concept and describe the symptom of "睡眠欠佳 (sleep disturbance)." However, only "失眠 (insomnia)" has a corresponding disease code in the *International Statistical Classification of Diseases, 10th Revision* (*ICD-10*) codes, so we set "失眠 (insomnia)" as the standard term. Under our fine-grained semantic classification rules, "失眠 (insomnia)" is categorized as the Symp_S entity. By aggregating such standard terms with the Symp_S label, we constructed the Symp_S standard knowledge base. In this study, symptom-related entities are categorized into 12 distinct types, necessitating the construction of 12 separate standard knowledge bases. Due to the limitations of the article's length, only the sources for the Symp_S and Pos_Pri standard terms are introduced.

We first describe the Symp_S standard knowledge base. In the field of medical information, the *ICD-10*, developed by the World Health Organization (WHO), has been widely used as a diagnostic coding and disease classification system in health records, information exchange, research, quality measurement, and payment applications [37]. We collected 136 Symp_S standard terms using *ICD-10* codes as the reference.

We then describe the Pos_Pri standard knowledge base. SNOMED CT is a comprehensive international clinical terminology system that contains more than 350,000 concepts and is organized into 19 top-level hierarchies, including body structure and clinical findings [38,39]. Because Pos_Pri entities are used to describe the primary site of a symptom, we constructed the Pos_Pri standard knowledge base by referring to the body structure hierarchy of SNOMED CT. The Pos_Pri

XSL•FO
RenderX

standard knowledge base currently contains 106 commonly used anatomical terms.

Finally, we describe how the standard knowledge bases for the infrequent entity types were constructed. Entity types such as Time, Cond, Freq, and Trend are used less frequently in medical records. After searching for *ICD-10*, SNOMED CT, and the relevant literature on entity normalization, we were unable to find a dataset of these uncommon types of entities. To construct standard knowledge bases for these infrequent entities, we counted the number of occurrences of each extraction result after recognizing entities in 500 EMRs. Entities that occurred more than 10 times were designated as standard terms, after which domain experts manually removed duplicates with identical semantics.

Introduction to the Method of Constructing Positive and Negative Samples

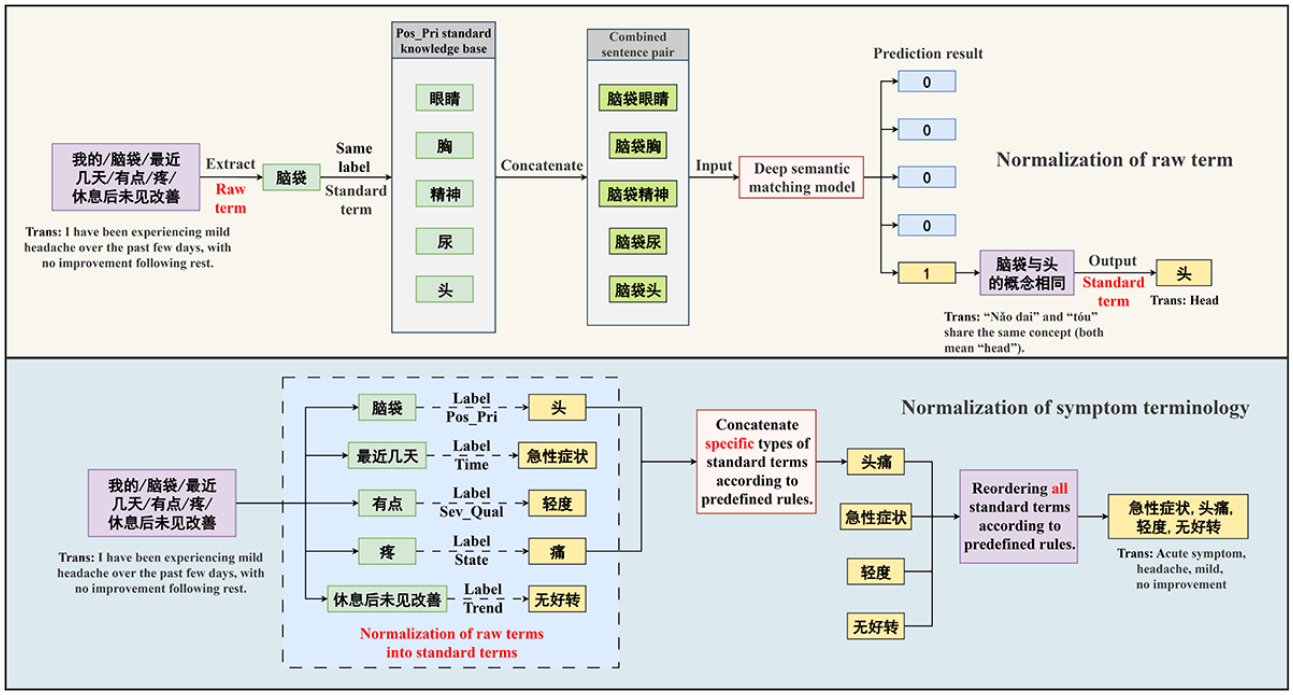
We begin with the construction of positive samples. First, an NER model was used to extract all symptom entities contained in the sentence. Then, based on the label types of the symptom entities, experts manually identified the standard term with the same concept from the corresponding standard knowledge base. For instance, in the sentence “我的脑袋最近几天针扎样痛 (My head has had lancinating pain for several days),” the raw term “脑袋 (head)” was identified as a Pos_Pri entity. Therefore, to construct a positive sample about the entity “脑袋 (head),” we needed to find a synonym for “脑袋 (head)” in the Pos_Pri standard knowledge base. A detailed list of raw terms and their corresponding standard terms used for positive sample construction is available in Multimedia Appendix 1.

We then turn to the construction of negative samples. Negative samples were generated in batches by randomly combining the raw terms with unmatched standard terms of the same type. Take the sentence “我的胸口有刀割样痛 (I have a lancinating pain in my chest)” as an example. According to the result of named entity recognition, “刀割样痛 (lancinating pain)” was categorized as a State entity. The matched standard term in the State standard knowledge base was “绞痛 (colic),” while “酸痛 (soreness)” and “刺痛 (stabbing pain)” were unmatched standard terms in the same standard knowledge base. By combining “刀割样痛 (lancinating pain)” with “酸痛 (soreness)” and “刺痛 (stabbing pain),” respectively, negative samples were constructed for training the binary classification model.

The manual pairing required for positive samples (described above) contrasts with the batch generation possible for negative samples, which can lead to an imbalanced dataset. To address this potential imbalance, we used 5 data augmentation methods specifically to expand the positive sample set. The operational details and examples of these methods are provided in Multimedia Appendix 2.

We now present concrete examples of the constructed samples. We constructed a total of 3350 positive and negative samples. The ratio of positive to negative samples was 1:1. Examples are shown in Table 2, where label 1 represents that the raw term has the same concept as the standard term. Label 0 represents that the concepts of the 2 terms are different.

Table . Examples of positive and negative samples for the entity alignment model.



Raw term	Standard term	Label
Nǎo dai (脑袋)	Head	1
Pain tolerable, not affecting daily life or sleep quality, able to work	Mild [40]	1
Severe pain, unbearable, requiring analgesics, sleep quality impaired, but still able to continue working	Moderate [40]	1
Severe pain, unbearable, requiring analgesics, sleep severely disturbed, unable to work, requiring hospitalization for systematic treatment	Severe [40]	1
24-hour urine output ≥3000 mL [41]	Polyuria	1
Hourly urine output ≤17 mL [41]	Oliguria	1
24-hour urine output ≤100 mL [42]	Anuria	1
Bowel movements fewer than 3 times per week [43]	Constipation	1
Bowel movements more than 3 times per day [44]	Diarrhea	1
Within the past few days	Acute symptoms	1
Occurring after climbing stairs	Exertion-induced	1
Lancinating pain	Colicky pain	1
Lancinating pain	Numbness	0
Lancinating pain	Aching pain	0

Methods of Normalizing Symptom Terminology

After inputting a paragraph of symptom terminology, the NER model was first used to extract raw terms. Each extracted raw term was paired with every standard term sharing the same fine-grained semantic label. Restricting candidate standard terms to the same semantic label reduced unnecessary comparisons across clinically incompatible entity types and made the alignment process more interpretable. This strategy is also consistent with the general formulation of biomedical entity linking, in which an entity mention is mapped to a standard concept or term in a predefined knowledge base [35]. Then, the binary classification model was used to determine whether the sentence pairs, obtained by concatenating the raw term and the standard term, represented a semantic match (label 1) or a nonmatch (label 0). Consistent with evidence that surface-form overlap is insufficient for resolving semantically ambiguous biomedical mentions [36], the alignment model was designed to judge semantic equivalence between raw terms and candidate standard terms rather than relying only on surface-level string similarity. A prediction of 1 signified semantic equivalence, prompting the system to output the corresponding standard term. If all predictions were 0, the raw term (eg, a Sev_Quant entity such as “about 5 kg”) was retained as the standard term because no matching result was found in the knowledge base. After normalizing all raw terms, standard terms were concatenated and reordered according to predefined rules to generate the final standardized symptom description. The normalization methods of raw terms and symptom terminology are shown in Figure 3.

Figure 3. Normalization methods for raw terms and symptom terminology.

Concatenation Rules for Standard Terms

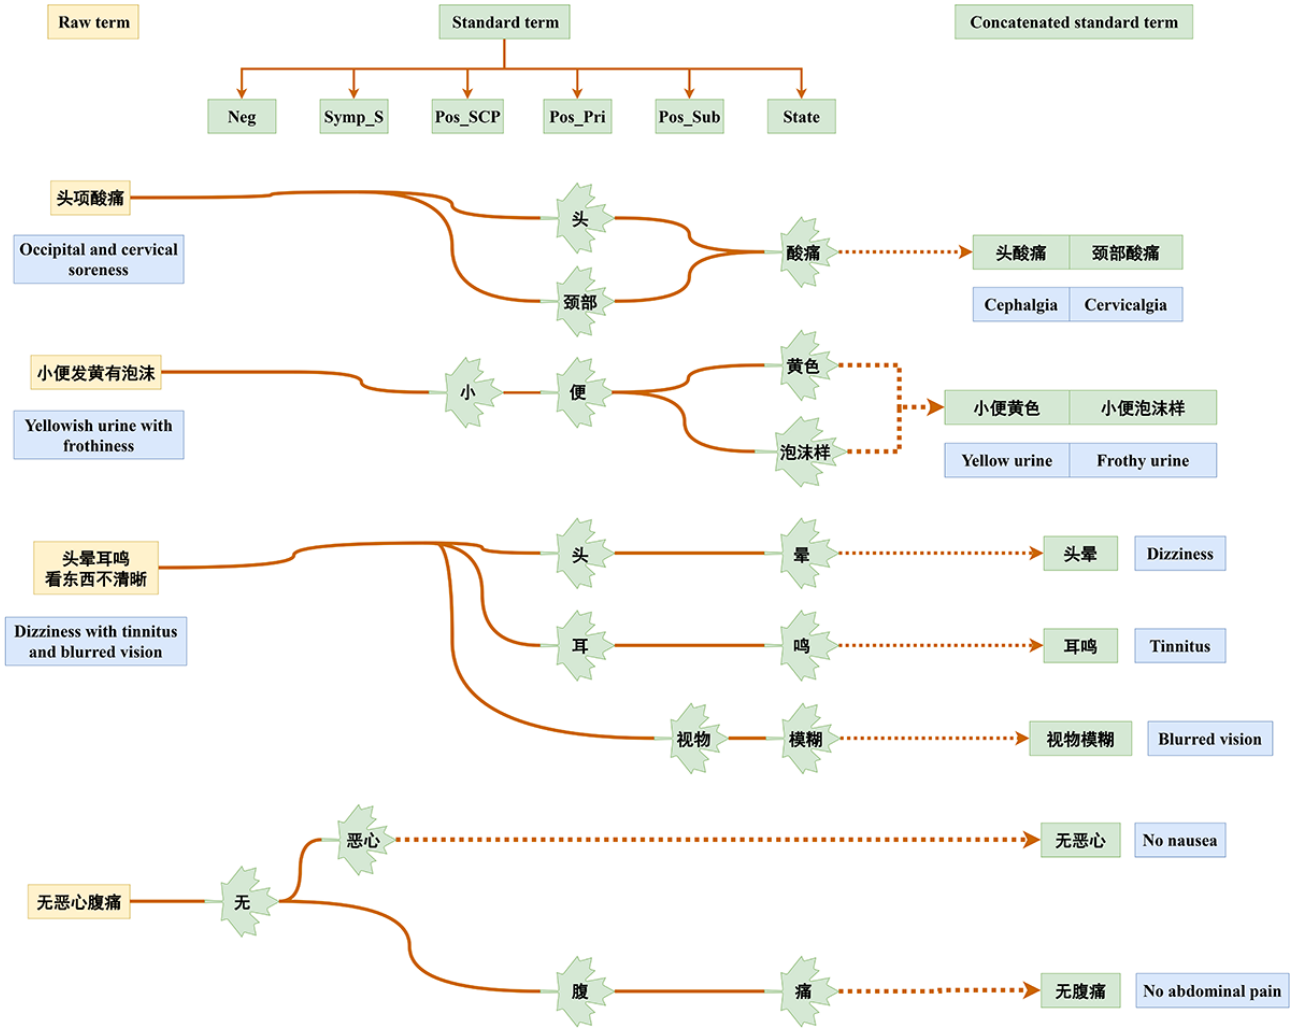
To extract and reconstruct comprehensive symptoms from complex expressions with overlapping, discontinuous, and nested entities, after the deep semantic matching model normalized each extracted raw term to a standard term, we concatenated 6 categories of standard terms, including Neg, Symp_S, Pos_SCP, Pos_Pri, Pos_Sub, and State. This rule-guided reconstruction step was necessary because multi-implication TCM symptom expressions may contain more than one clinically meaningful concept in a single raw phrase. Unlike conventional entity-linking settings that often assume a fixed mention span and map it to one knowledge-base concept [35], our task required both fine-grained decomposition of symptom components and structured recombination of multiple normalized components. After studying the raw medical records, we summarized the concatenation rules for standard terms into the following 5 types. The slash symbol “/” served as a delimiter between words.

1. <$Space_1$+$Space_2$+...+State>: This structure indicates concurrent symptoms in multiple anatomical locations (eg, 头/项/酸痛 [occipitocervical aching and headache]).
2. <Space+$State_1$+$State_2$+...>: This structure denotes the concurrent presence of 2 or more distinct symptoms within a single anatomical location, physiological product, or mental state (eg, 小/便/发黄/有泡沫 [dark-colored urine with foam formation]).
3. <$Space_1$+$State_1$+$Space_2$+$State_2$>: Within such structurally complex expressions, multiple Space entities coexist alongside multiple State entities. Comprehensive restoration of the symptoms requires a 2-by-2 combination of the Space and the State entities (eg, 头/晕/耳/鸣 [vertigo with concomitant tinnitus]).
4. <Space+Sev_Qual+State> and <Space+Freq+State>: In these 2 types of structurally complex expressions, between a specific anatomy (or physiological product) and a specific symptom, there are adjectives or adverbs to further describe the severity or frequency of the symptom in greater detail (eg, 头/有点/痛 [a mild headache], 大/便/经常/困难 [chronic defecatory difficulty]). To reconstruct the described

XSL•FO
RenderX

symptom, other types of entities that exist between Space and State must be temporarily ignored, prioritizing the combination of the Space and State entities.

5. <Space+Neg+State$_1$+State$_2$+...>, <Neg+Symp_S$_1$+Symp_S$_2$+...>, <Neg+Symp_S+Space+State>, <Neg+Space$_1$+State$_1$+Space$_2$+State$_2$>: These complex structures are usually used to enumerate 2 or more negative symptoms (eg, 关节/无/红肿/热痛 [absence of joint erythema, swelling, hotness, or tenderness], 无/发热/恶寒 [absence of fever and chills]).



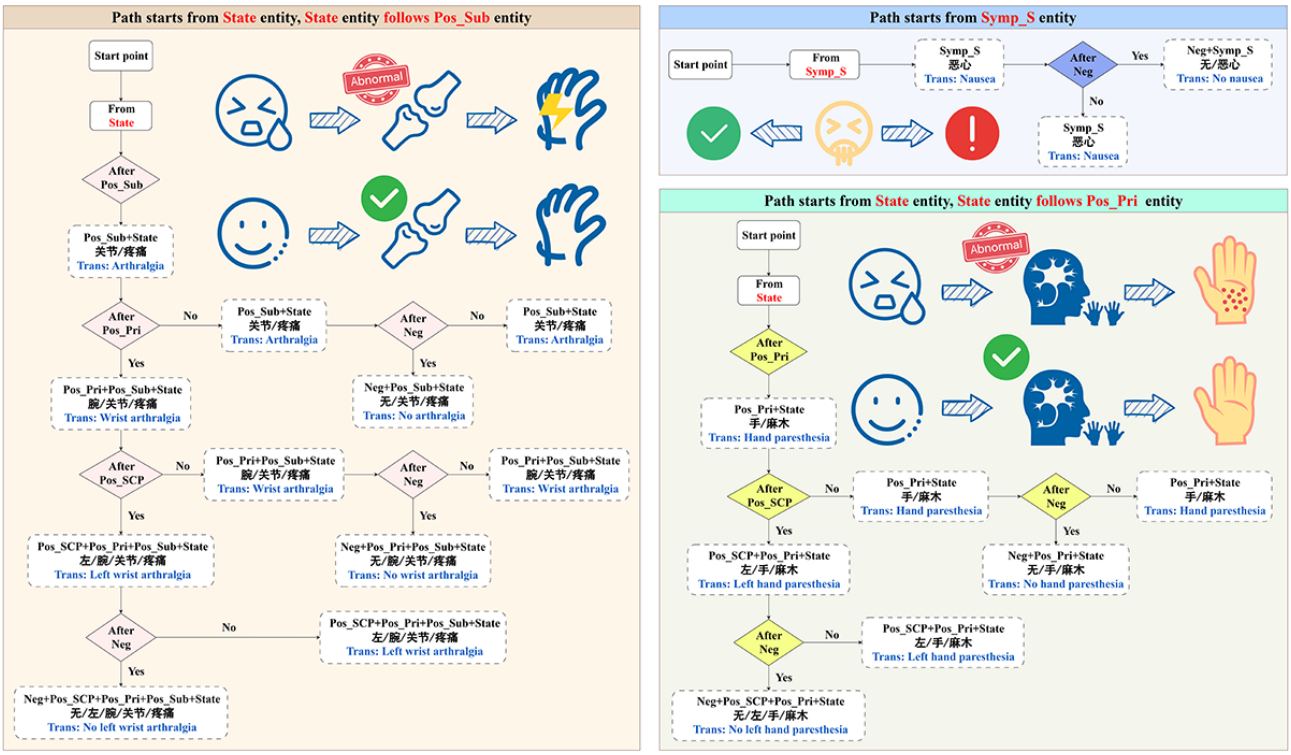
It is worth noting that the Space entity can be categorized into 2 distinct types: physical space and conceptual space. Physical space refers to entities that can be directly seen and touched, such as various parts of the human body and different physiological products, including urine, feces, sweat, and menstruation. Conceptual space, on the other hand, is an intangible, abstract existence that usually includes organ functions, numerous sensations, and mental activities. Thus, the Space entity that combines with the State entity can be further subdivided into the following five types: (1) an independent Pos_Pri (eg, 头 [head]); (2) Pos_SCP+Pos_Pri (eg, 小/便 [urine]); (3) an independent Pos_Sub (eg, 视物 [vision] and 皮肤 [skin]); (4) Pos_Pri+Pos_Sub (eg, 腕/关节 [wrist joint]); and (5) Pos_SCP+Pos_Pri+Pos_Sub (eg, 小/便/量 [urine volume]).

From the above combination structures, it can be seen that (1) the State entity cannot exist alone and must be concatenated with the previous Space entity to show clinical diagnostic value; (2) the Space entity that can be concatenated with the State entity is not limited to specific anatomy but also includes secretions such as urine and feces, as well as intangible physiological functions and mental states. The Space entity is broader than the Pos_Pri entity; (3) positive symptoms consist of 2 conceptual elements: Space and State, while negative symptoms are composed of 3 conceptual elements: Neg, Space, and State. Before outputting the concatenated results, it is necessary to check whether any negative symptoms have not yet been concatenated to avoid incorrectly converting them into positive ones.

Based on the above 3 core principles, we constructed a trie tree to concatenate the extracted standard terms: each branch (path) represents a complete symptom standard term. The leaves (start points of paths) are State or Symp_S entities. The roots (end points of paths) are Space or Neg entities, and each node on the branches (paths) has only one standard term. By collecting all branches (symptom standard terms), all symptoms in the complex expression can be extracted and comprehensively reconstructed. The trie tree concatenation method of standard terms is shown in Figure 4.

XSL•FO
RenderX

Figure 4. Trie tree concatenation method of standard terms.



When the path starts from the State entity, it connects with the Pos_Pri or Pos_Sub node. If the node connected to the State entity is Pos_Sub, continue to determine whether it needs to connect with the Pos_Pri node, Pos_SCP node, and Neg node. If no additional nodes are available for concatenation, end the current path, and the symptom standard term becomes the output. When the node connected to the State node is Pos_Pri, continue to determine whether it needs to connect with the Pos_SCP node and Neg node.

When the path starts from a Symp_S entity and no Neg node can be used for concatenation in front of the Symp_S entity, the path can be ended directly, and the symptom standard term can be output. The specific method of path generation is shown in Figure 5.

XSL•FO
RenderX

Figure 5. Flowchart of path generation.

Sorting Rules of Standard Terms

Reordering standard terms yielded structured, coherent, and clinically meaningful outputs. Analysis of large-scale EMRs revealed that physicians typically follow a specific logical sequence when documenting: (1) onset time and precipitating factors; (2) symptom manifestations, severity, and frequency; and (3) disease progression. Therefore, after concatenating standard terms through the trie tree method, the final normalized output follows this order: Time entity, Cond entity, concatenated standard term, Sev_Qual entity, Sev_Quant entity, Freq entity, and Trend entity.

Experimental Evaluation Indicators

The framework was evaluated at 2 stages, named entity recognition and named entity normalization, each with its own set of metrics. For the task of NER, model performance is commonly evaluated using precision, recall, and F_1-score. The calculation of these metrics is based on the following classifications of the prediction results:

1. True positive (TP): represents the number of correctly identified entities.
2. True negative (TN): represents the number of correctly identified nonentities.
3. False positive (FP): represents the number of instances incorrectly identified as entities.
4. False negative (FN): represents the number of entities that the model failed to identify.

The specific formulas and their interpretations are shown in Table 3. As the F_1-score provides a more comprehensive evaluation by considering both precision and recall, it was selected as the primary performance evaluation metric for the NER model in this study.

Table . Formulas and interpretations of evaluation metrics for named entity recognition (NER).

Evaluation metric	Equation	Interpretation
Precision	P=TPTP+FP	This metric, also known as positive predictive value, represents the proportion of true entities among all results identified as entities
Recall	R=TPTP+FN	This metric, also known as sensitivity, indicates the proportion of all actual entities that are successfully identified by the model
F_1-score	F1=2PRP+R	This metric is the harmonic mean of precision and recall

We then describe the metrics used for the normalization stage. For the NEN task, accuracy, precision, recall, and F_1-score were used to evaluate model performance. Accuracy was calculated at the instance level using exact matching as the criterion. A prediction was considered correct only when the complete set of predicted standard terms is identical to the complete set of reference standard terms. Precision, recall, and F_1-score were calculated at the standard-term level to further assess the ability

XSL•FO
RenderX

of each model to retrieve individual standard terms. The formulas of these evaluation metrics are shown in Table 4.

Table . Formulas of evaluation metrics for named entity normalization (NEN).

Evaluation metric	Equation
Accuracy	Acc=Number of instances with completely correct prediction resultsTotal number of test instances
Precision	P=Number of correctly predicted standard termsTotal number of standard terms output by the model
Recall	R=Number of correctly predicted standard termsTotal number of reference standard terms
F_1-score	F1=2PRP+R

To verify the performance differences between the proposed STC-NF model and the baseline models, the held-out test set generated from the 8:2 split of the 500 collected EMRs, as described in the "Introduction to Dataset Sources and Fine-Grained Semantic Classification" subsection, was further divided into 3 NEN test sets. First, 25 records were randomly selected, and the single-implication terms in these records were used to construct the single-implication test set. Second, another 25 records were randomly selected, and the multi-implication terms contained in these records were used to construct the multi-implication test set. Finally, the remaining 50 records were used to construct the mixed test set, which contained both single- and multi-implication terms. Therefore, the 3 test datasets were constructed from nonoverlapping EMRs, and the multi-implication terms in the mixed test set did not overlap with those in the multi-implication test set.

Experimental Hyperparameters of the NEN Model

We used BERT-base-Chinese as the base model, which had a hidden layer dimensionality of 768. Because the NEN module formulated entity alignment as a sentence-pair semantic matching task between a raw term and a candidate standard term, the hyperparameter settings were determined by considering previous studies of medical concept normalization and biomedical entity normalization, as well as the short phrase-level characteristics of TCM symptom-term pairs. Recent Chinese medical concept normalization and rare disease concept normalization studies have shown that deep language models can effectively map nonstandard medical expressions to standardized medical concepts or vocabulary identifiers [45,46]. In a recent NER/NEN corpus study, transformer fine-tuning hyperparameters were selected on a development set, and a maximum sequence length of 128 was used for short biomedical entity mentions [47]. In addition, recent biomedical BERT fine-tuning experiments commonly evaluated learning rates of 1×10^{-5}, 3×10^{-5}, and 5×10^{-5}, sequence lengths of 128, 256, and 512, batch sizes of 16 and 32, and dropout of 0.1 [48]. Therefore, we set the learning rate to 5×10^{-5}, which falls within the commonly evaluated BERT fine-tuning range and allows efficient adaptation on a relatively small entity-alignment dataset. A dropout rate of 0.1 was used to reduce the risk of overfitting during supervised sentence-pair classification. The maximum sequence length was set to 128 because both the raw TCM symptom terms and candidate standard terms were short, phrase-level inputs; this setting was sufficient to cover the term pairs while reducing unnecessary computation. The training batch size was set to 30, close to the commonly used mini-batch range in biomedical BERT fine-tuning, while remaining compatible with the available GPU memory. The Adam optimizer was used for gradient-based parameter updates during BERT fine-tuning.

Ethical Considerations

This study involving humans was approved by the Second Traditional Chinese Medicine Hospital of Guangdong Province, affiliated with the Guangzhou University of Chinese Medicine. The ethics approval number was Y202407-004-01. The study was conducted according to local legal and institutional requirements and adhered to the Declaration of Helsinki. This study was retrospective, and informed consent was waived.

Results

Named Entity Recognition Results

In this study, symptom terms were categorized into 12 different types of entities based on fine-grained semantic classification. Three NER models specialized for extracting symptom entities were trained according to customized annotation rules. The extraction performance of each model is shown in Table 5.

XSL•FO
RenderX

Table . Comparison of symptom entity extraction performance across models.

Entity type	BiLSTM[a]-CRF[b] F_1[c]-score ratio, (%)	BERT[d]-CRF F_1-score ratio, (%)	BERT-BiLSTM-CRF F_1-score ratio, (%)
Independent symptom (Symp_S)	1100/1186 (92.7)	1082/1186 (91.2)	1106/1192 (92.8)
Negative occurrence (Neg)	1112/1160 (95.9)	1088/1148 (94.8)	1102/1153 (95.6)
Scope space (Pos_SCP)	880/915 (96.2)	874/910 (96.0)	882/916 (96.3)
Primary space (Pos_Pri)	4324/4711 (91.8)	4316/4702 (91.8)	4340/4707 (92.2)
Secondary space (Pos_Sub)	348/370 (94.1)	344/365 (94.2)	348/368 (94.6)
Time of occurrence (Time)	816/888 (91.9)	796/880 (90.5)	804/884 (91.0)
Occurrence condition (Cond)	332/376 (88.3)	342/386 (88.6)	342/383 (89.3)
Frequency of occurrence (Freq)	416/446 (93.3)	406/441 (92.1)	414/443 (93.5)
Qualitative severity (Sev_Qual)	450/490 (91.8)	450/488 (92.2)	458/490 (93.5)
Quantitative severity (Sev_Quant)	90/103 (87.4)	92/105 (87.6)	92/104 (88.5)
Occurrence state (State)	4530/5124 (88.4)	4534/5112 (88.7)	4586/5141 (89.2)
Occurrence trend (Trend)	170/207 (82.1)	174/204 (85.3)	178/208 (85.6)

[a]BiLSTM: bidirectional long short-term memory.

[b]CRF: conditional random field.

[c]In every model column, each cell reports the F_1-score as 2TP/(2TP+FP+FN) with the resulting percentage in parentheses (TP, FP, and FN as defined in the Experimental Evaluation Indicators subsection); this ratio is the F_1-score calculation and does not represent the count of correctly recognized entities divided by the total number of entities.

[d]BERT: Bidirectional Encoder Representations from Transformers.

As shown in Table 5, the 3 models achieved comparable overall performance, although the best-performing model varied across entity types. BERT-BiLSTM-CRF obtained the highest or tied-highest F_1-score for most entity types, achieving 4340 out of 4707 (92.2%) for Pos_Pri and 4586 out of 5141 (89.2%) for State among the high-frequency structural entities, as well as 1106 out of 1192 (92.8%) for Symp_S, 882 out of 916 (96.3%) for Pos_SCP, and 458 out of 490 (93.5%) for Sev_Qual. BiLSTM-CRF achieved the highest F_1-scores for the Time and Neg entities, with F_1-scores of 816 out of 888 (91.9%) and 1112 out of 1160 (95.9%), respectively, and remained within approximately one percentage point of the best-performing model on the high-frequency structural entities. The advantages of the BERT-based models over BiLSTM-CRF were concentrated on low-frequency modifier entities, such as Sev_Quant, Sev_Qual, and Trend, where the best-performing BERT-based model exceeded BiLSTM-CRF by 1.1, 1.7, and 3.5 percentage points, respectively. Complete per-entity precision, recall, and F_1-scores for all three models are provided in Multimedia Appendix 3.

Entity Alignment Results

We used 3 statistical models (TF-IDF, Med, and BM25), the multiclassification model PLM-*ICD*, the generative sequence-generation model, and the binary classification model MTCG as baseline models for comparison with our proposed STC-NF model. The experimental results of different normalization models on 3 test sets are shown in Table 6.

XSL•FO
RenderX

Table . Results of different normalization models on 3 test sets.

Model name and test set	Accuracy[a], n/N (%)	Precision, n/N (%)	Recall, n/N (%)	F_1-score, ratio (%)
TF-IDF[b]				
Single-implication	91/197 (46.2)	91/186 (48.9)	91/197 (46.2)	182/383 (47.5)
Multi-implication	0/369 (0.0)	83/328 (25.3)	83/1175 (7.1)	166/1503 (11.0)

Mixed	803/1124 (71.4)	1443/2156 (66.9)	1443/2225 (64.9)	2886/4381 (65.9)
STC-NF[e]				
Single-implication	180/197 (91.4)	180/192 (93.8)	180/197 (91.4)	360/389 (92.5)
Multi-implication	311/369 (84.3)	979/1141 (85.8)	979/1175 (83.3)	1958/2316 (84.5)
Mixed	990/1124 (88.1)	1931/2160 (89.4)	1931/2225 (86.8)	3862/4385 (88.1)

[a]Accuracy, precision, and recall are reported as n/N (%), whereas F_1-score is reported as a ratio (%) calculated as 2TP/(2TP+FP+FN). Accuracy is calculated at the instance level using exact matching; precision, recall, and F_1-score are calculated at the standard-term level. See Table 4 for the corresponding formulas.

[b]TF-IDF: term frequency-inverse document frequency.

[c]PLM-*ICD*: pretrained language model framework for *International Classification of Diseases* coding.

[d]MTCG: multi-task candidate generator.

[e]STC-NF: split-then-concatenate normalization framework.

As shown in Table 6, STC-NF achieved the best overall performance across the 3 test sets. On the single-implication test set, STC-NF achieved an accuracy of 180 out of 197 (91.4%), a precision of 180 out of 192 (93.8%), a recall of 180 out of 197 (91.4%), and an F_1-score of 360 out of 389 (92.5%). Compared with PLM-*ICD* and MTCG, which were the stronger baseline models for single-implication terms, STC-NF improved accuracy by 6.1 and 3.6 percentage points, respectively.

For the multi-implication test set, the accuracy of TF-IDF, Med, BM25, and PLM-*ICD* was 0 out of 369 (0.0%). This result was attributable to the single-output design of these models, which prevented them from producing a complete set of standard terms for multi-implication symptom terms. However, their term-level precision, recall, and F_1-score were still calculated to reflect partial standard-term retrieval performance. In contrast, STC-NF achieved an accuracy of 311 out of 369 (84.3%), a precision of

XSL•FO
RenderX

979 out of 1141 (85.8%), a recall of 979 out of 1175 (83.3%), and an F_1-score of 1958 out of 2316 (84.5%). Compared with sequence generation and MTCG, STC-NF improved multi-implication accuracy by 33.1 and 23.9 percentage points, respectively.

On the mixed test set, STC-NF achieved an accuracy of 990 out of 1124 (88.1%), a precision of 1931 out of 2160 (89.4%), a recall of 1931 out of 2225 (86.8%), and an F_1-score of 3862 out of 4385 (88.1%). These results were higher than those of all baseline models. Compared with MTCG, the best-performing baseline model on the mixed test set, STC-NF improved accuracy by 16.7 percentage points and F_1-score by 22.2 percentage points. These findings indicate that the split-then-concatenate mechanism improves not only complete instance-level normalization accuracy but also standard-term-level retrieval performance, particularly for complex multi-implication symptom terms.

Structured Normalization Results

After identifying the standard terms with the same concept as each raw term through a BERT-based binary classification model, this study concatenated and reordered standard terms with specific semantic labels according to predefined rules and output structured text to complete the normalization of TCM symptom terminology. To improve the readability of the main text and avoid an overly crowded bilingual table, Tables 7 and 8 present the English versions of the structured normalization results. The corresponding original Chinese raw terms, segmentation results, and structured normalization outputs are available in Multimedia Appendix 4.

Table . Translated examples of raw symptom expressions and their normalized symptom terms.

Number	Raw term	Concatenated standard term
1	Occipitocervical aching and headache have been reported in recent days, without significant improvement following rest.	Headache and neck pain
2	Mild exertional chest tightness and dyspnea on stair climbing have persisted for several weeks.	Chest tightness and shortness of breath
3	An unintentional weight loss of approximately 5 kg has occurred over the past 6 months.	Weight loss
4	Severe persistent odynophagia has been noted without associated chills or fever.	Sore throat without chills or fever

Table . Structured semantic attributes corresponding to the examples in Table 7.

Number	Time	Cond	Sev_Qual	Sev_Quant	Freq	Trend
1	Acute symptom	__[a]	—	—	—	Not improving
2	Subacute symptom	Exertion-induced	Mild	—	—	—
3	Chronic symptom	—	—	Approximately 5 kg	—	—
4	—	—	Severe	—	Persistent symptom	—

[a]Not applicable.

Discussion

Performance Comparison of Named Entity Recognition Models

In the experiments of recognizing symptom entities, BiLSTM-CRF achieved the highest F_1-scores among the 3 models for the Time and Neg entities, at 91.9% and 95.9%, respectively. For several entity types, including Pos_Pri, Pos_Sub, and State, the differences in F_1-scores among BiLSTM-CRF, BERT-CRF, and BERT-BiLSTM-CRF were small (within about one percentage point), with BiLSTM-CRF reaching an F_1-score of 91.8% for the Pos_Pri entity. Importantly, although the BERT-based models obtained higher F_1-scores for most entity types, their largest gains over BiLSTM-CRF were concentrated on low-frequency modifier entities, such as Sev_Quant, Sev_Qual, and Trend. In contrast, for the high-frequency structural entities that dominate downstream symptom reconstruction—most notably Pos_Pri and State—BiLSTM-CRF was essentially on par with the pretrained models, trailing by only about 0.4 and 0.8 percentage points, respectively. This narrow gap can be attributed to the fine-grained semantic classification scheme adopted in this study. By constraining each category to short, structurally regular spans with clearly delimited boundaries, the annotation rules reduce intracategory description diversity and lower the decision dimensionality of the recognition model so that a lightweight sequence model is already able to capture the local dependencies required for accurate boundary and type prediction. Consequently, the marginal benefit obtainable from large-scale pretraining is limited under the present annotation scheme. Xue et al [49] and Li et al [50] proposed the porous lattice transformer encoder (PLTE) and flat-lattice transformer (FLAT), respectively, for Chinese NER, showing that incorporating external lexicon information through character-word lattices can effectively exploit word-boundary

XSL•FO
RenderX

cues and improve Chinese NER performance. These studies suggest that lexicon-enhanced transformer models are valuable when word-boundary ambiguity and external word information are major factors affecting entity recognition. However, the objective of the NER stage in STC-NF was not to pursue the highest possible benchmark score but to provide stable fine-grained semantic units for subsequent label-constrained entity alignment and rule-guided reconstruction. Considering the recognition performance reported above, its lower model complexity (specifically, substantially fewer parameters and no dependence on large-scale pretrained weights), and the downstream requirement for stable entity decomposition, BiLSTM-CRF was selected as the NER component of STC-NF. Although the BERT-based models achieved marginally higher F_1-scores on most entity types in Table 5, the largest gains occurred on low-frequency modifier entities, which are peripheral to symptom reconstruction and can be further rectified by the downstream concatenation and sorting rules. Therefore, this advantage does not warrant their substantially higher computational cost in the present 2-stage pipeline. More advanced lexicon-enhanced transformer architectures, such as PLTE and FLAT, remain promising alternatives for future evaluation on larger and more heterogeneous TCM clinical corpora.

Merits and Limitations of Baseline Models

Although statistical models have the advantage of fast processing, they are not competitive with deep learning models in semantic understanding. Clinical term normalization studies have shown that nonstandard clinical expressions often differ from standardized terminology because of synonyms, stylistic variation, morphological variation, abbreviations, and local writing conventions, making surface-form matching insufficient for robust normalization [51]. Similarly, recent biomedical NER and NEN systems have combined neural NER with neural or hybrid normalization modules to overcome the inability of dictionary- or rule-only methods to cover complex mention variations [52]. Therefore, the relatively weak performance of TF-IDF, Med, and BM25 in this study was mainly attributable to their dependence on character-level or lexical similarity rather than contextual semantic matching.

The multiclassification model PLM-*ICD* first segments the raw text into sentences. After embedding each sentence and all *ICD* codes into dense vectors, it selects the *ICD* embedding with the highest cosine similarity (computed using attention-weighted BERT or BioBERT models pretrained on corpora, such as Medical Information Mart for Intensive Care III [MIMIC-III]), to align the raw term. PLM-*ICD* performed well for single-implication terms. However, because of its multiclassification design, the model could output only one prediction for each input sentence, regardless of how many symptoms were included. Therefore, PLM-*ICD* could not handle multi-implication terms such as “腰酸背痛 (lumbago and back pain with soreness),” “尿频量多 (polyuria with increased urinary frequency),” and so on.

Generative model sequence generation first uses a character-level text generation model built upon transformer to convert each character in the raw term step by step. Once multiple candidate entity sets (sentences) of standard terms are generated, a pretrained BERT model calculates the semantic similarity between the input text and each set. Then, the top-n generated sets are chosen as the final normalization results after reordering. Compared to PLM-*ICD*, this model demonstrates the capability to handle multi-implication terms. However, the single-implication accuracy is significantly lower, as splitting the raw term word by word sometimes destroys the structural integrity of the entity. For example, if “恶心 (nausea)” is split into “恶 (hate)” and “心 (heart)” and then converted and concatenated together, the final result will be the wrong prediction of “厌恶心脏 (loathe heart).”

The binary classification model MTCG significantly reduces the number of semantic comparisons through its retrieval strategy, resulting in higher entity alignment efficiency than the multiclassification approach. In addition, it achieved higher accuracy in dealing with single-implication terms such as “恶心 (nausea),” “发热 (fever),” “咳 (cough),” etc, which contain only one symptom, because it does not split the raw term and retains the structural integrity of the entity, compared to the sequence-generation approach. A key limitation of this model is its misclassification of compound symptoms that have unclear entity boundaries. The advantage of STC-NF over MTCG was most evident for multi-implication terms. Unlike MTCG, STC-NF explicitly decomposes multi-implication expressions before semantic matching and reconstructs the normalized outputs after alignment. This additional split-and-recombine process helps preserve multiple symptom concepts within a single raw phrase, which cannot always be represented by a single retrieved standard term. Taking “尿频量多 (polyuria with increased urinary frequency)” as an example, since “量多 (high volume)” does not immediately follow “尿 (urine),” MTCG recognized only the raw term “尿频 (frequent urination)” but omitted another raw term “尿量多 (excessive urination)” at the end. Therefore, although MTCG exhibits remarkable generalization performance and excellent accuracy on the mixed test set, a significant gap remains between MTCG and our model when handling multi-implication terms.

Mechanistic Explanation for the Superior Performance of STC-NF

Overall, the superior performance of STC-NF can be explained by the complementarity of its 3 components. First, fine-grained semantic extraction decomposes complex symptom expressions into clinically meaningful semantic units, thereby reducing the boundary ambiguity caused by overlapping, discontinuous, and nested entities. This is consistent with recent medical NER evidence showing that entity phrase length and the number of words in an entity phrase can substantially influence recognition performance [53], and with systematic evidence that discontinuous clinical entities remain challenging for traditional NER methods [54]. Second, the BERT-based binary classification module preserves semantic matching at the concept-alignment stage instead of relying only on surface similarity. Third, the trie tree–based concatenation rules explicitly reconstruct multi-implication symptom terms after semantic alignment. This design is consistent with 2-stage clinical text workflows that first extract information from free-text notes and then harmonize extracted mentions into

XSL•FO
RenderX

standardized database concepts [55], as well as recent hybrid neural-symbolic clinical NLP systems that integrate neural recognition with structured vocabularies and symbolic reasoning to transform unstructured clinical notes into standardized terms [56]. Therefore, STC-NF improved not only complete instance-level normalization accuracy but also standard-term-level retrieval performance, especially for multi-implication symptom terms with complex internal structures.

Limitations and Future Work

This study has several limitations that suggest avenues for future research. First, the NEN module used BERT-base-Chinese as the base semantic-matching model, without evaluating more recent clinical or biomedical language–modeling strategies. Indirect evidence from our previous work on the upstream NER stage suggests that the choice of pretrained backbone is important for fine-grained TCM symptom modeling. In that study, we evaluated several external NER backbone models on fine-grained TCM symptom corpora, including BERT-base-Chinese+CRF, BERT-base-Chinese+BiLSTM+CRF, Chinese-RoBERTa-wwm-ext+CRF, and Chinese-RoBERTa-wwm-ext+BiLSTM+CRF. The results showed that Chinese-RoBERTa-wwm-ext+BiLSTM+CRF achieved higher NER F_1-scores than BiLSTM+CRF on both GDTCM-500 and HwaMei-500, suggesting that more advanced pretrained language models may further improve symptom entity recognition [57]. However, these experiments were limited to the entity recognition stage. We have not yet extended these external backbone comparisons to the full NEN stage, because such validation would require reconstructing entity-alignment samples, rerunning the complete split-then-concatenate pipeline, and performing additional expert validation of normalized outputs. Therefore, future work will compare STC-NF with more advanced pretrained language models, retrieval-augmented models, and domain-specific clinical language models at both the NER and NEN stages to determine whether the proposed split-then-concatenate mechanism remains beneficial across different backbone architectures. Accordingly, these results should be interpreted as evidence for the effectiveness of the split-then-concatenate mechanism under a BERT-base-Chinese alignment setting, rather than as evidence that BERT-base-Chinese is the optimal backbone for the NEN module.

Second, the generalizability of the model may be constrained, as the training data were sourced entirely from a single clinical department (endocrinology). The framework's effectiveness has not yet been validated using multisource data from departments such as surgery or pediatrics. This limitation is particularly important because model robustness depends not only on algorithmic structure but also on how heterogeneous information sources are represented and transferred across contexts. Beyond medical applications, the methodological idea of quantifying free-text content and integrating it with structured variables in decision-support pipelines has been demonstrated in other domains as well, for example, by Wang et al [58] in a consumer-review setting. More directly within health care, Hou et al [59] highlighted in a chronic disease prediction setting that multimodal electronic health record representation learning and domain adaptation can improve predictive generalizability under cross-domain distribution shifts. These studies suggest that future versions of STC-NF should not only expand the corpus to multiple clinical departments but also explore whether domain adaptation and multimodal representation learning can improve the robustness of TCM symptom terminology normalization across heterogeneous EMR sources.

Finally, the construction of positive samples and standard knowledge bases still relied partly on manual expert curation, especially for infrequent entities. This process ensured semantic accuracy but limited scalability. Recent work on medical concept annotation has noted that supervised medical concept normalization often requires sufficient annotated data, whereas the availability of annotated clinical data is constrained by privacy, sensitivity, and the time required for expert annotation [60]. Similarly, clinical registry-oriented NLP reviews have identified manual extraction and annotation as labor- and resource-intensive steps that may hinder large-scale deployment [61]. To reduce this bottleneck, future work will explore semiautomatic candidate generation and weakly supervised concept annotation. In addition, the distinctive features of Chinese radicals may provide useful linguistic cues for TCM symptom terminology. For example, Chinese characters containing the radical "疒" are often related to State entities, such as "疼 (painful)," "瘫 (paralytic)," and "疯 (mad)," whereas characters containing the radical "月" are often found in Pos_Pri entities related to anatomy, such as "胸 (chest)," "腹 (abdomen)," and "肢 (limb)." Incorporating radical-aware representations into language models may reduce the candidate screening range and improve the efficiency of positive sample construction.

Conclusions

This study proposed the STC-NF, a 2-stage deep learning approach that uses fine-grained semantic classification to normalize TCM symptom terminology. The STC-NF model achieved an accuracy of 180 out of 197 (91.4%) on the single-implication test set, 311 out of 369 (84.3%) on the multi-implication test set, and 990 out of 1124 (88.1%) on the mixed test set. In addition, the corresponding F_1-scores reached 360 out of 389 (92.5%), 1958 out of 2316 (84.5%), and 3862 out of 4385 (88.1%), respectively. These results demonstrate that the split-then-concatenate mechanism substantially improves both instance-level normalization accuracy and standard-term-level retrieval performance for TCM symptom terminology normalization.

Beyond its quantitative performance, the proposed framework facilitates the automatic extraction and structuring of key clinical information from unstructured EMRs, thereby enabling the development of advanced applications. In clinical practice, these structured data can enable intelligent analyses to support clinicians in diagnosis and treatment. By converting diverse and ambiguous patient-reported symptoms into standardized terms, the framework provides a consistent data foundation for clinical decision support systems. This uniformity allows for large-scale analysis to identify symptom patterns predictive of

XSL•FO
RenderX

specific conditions, potentially reducing diagnostic ambiguity and enhancing the precision of care.

Furthermore, this data structuring capability is instrumental for constructing high-quality biomedical knowledge bases and knowledge graphs. The normalization process transforms raw textual descriptions into discrete, standardized entities, a prerequisite for building robust and interoperable knowledge representations. Such knowledge graphs can map complex relationships among symptoms, diseases, and treatments, potentially facilitating the development of sophisticated tools for intelligent health care and personalized medicine. However, practical deployment of this framework still requires sufficiently representative annotated EMR data, continuously updated standard knowledge bases, and further validation across heterogeneous clinical departments.

Finally, this work has significant implications for health care administration, particularly for medical insurance cost control and diagnosis-related group (DRG) assignment. Hospital reimbursement through DRGs depends in part on accurate diagnostic coding derived from clinical evidence, including patient symptoms. The heterogeneity in raw symptom descriptions can lead to inconsistent coding and inaccurate DRG assignments. By standardizing symptom terminology, our framework produces uniform, machine-readable data that enhance diagnostic reliability. This improvement fosters more consistent and accurate coding, which is fundamental to a precise DRG system. Consequently, our approach supports a more scientific and equitable assessment of hospital management and service quality, ensuring that reimbursement accurately reflects patient case complexity and contributing to the advancement of medical informatization.

Abstract

Background: Deep learning, particularly encoder-only transformer architectures, has demonstrated excellent performance in biomedical literature classification, facilitating evidence-based medicine, and knowledge synthesis. However, the opacity of these models' decision-making processes limits their clinical interpretability, trustworthiness, and widespread adoption. Traditional explainable artificial intelligence methods, such as Shapley Additive Explanations (SHAP) and integrated gradients (IG), address this issue but often incur substantial computational overhead for text classification. Generative large language models may offer a novel approach to generating interpretable, context-aware explanations as autonomous agents.

Objective: As a proof-of-concept, the study aimed to investigate the effectiveness of GPT-4o as a standalone, end-to-end perturbation-based explainer for a BioLinkBERT text classifier. We compared its explanations against the SHAP partition explainer and IG as established baselines in terms of explanation faithfulness and semantic alignment.

Methods: A stratified sample of 200 studies from the McMaster Premium Literature Service (PLUS) and Clinical Hedges databases was classified by a fine-tuned BioLinkBERT model for methodological rigor. The sampling specifically over-represented difficult, low-confidence predictions to rigorously test the explainers, with an equal number of studies sampled from each probability decile predicted by BioLinkBERT. GPT-4o, SHAP, and IG generated token-level feature attributions across a robust feature space of 80,901 tokens. GPT-based explanations were derived through a sophisticated, iterative masking perturbation workflow under 2 prompting schemes (token indices vs explicit subword tokens). Explanations were evaluated using a rank-based, modified area over the perturbation curve (AOPC), pairwise correlation analyses, and qualitative assessment of feature importance.

Results: Among the 200 studies, 80,901 tokens were included, and feature attributions were generated by the 4 explainers (6369 unique tokens). SHAP (AOPC 0.222, 95% CI 0.200-0.244) and IG (AOPC 0.225, 95% CI 0.202-0.247) provided consistent explanations, effectively identifying tokens relevant to study rigor (eg, "randomized" and "blind"). In contrast, despite evaluating a larger perturbation space, the GPT-4o prompting schemes did not achieve comparable faithfulness (AOPC 0.025-0.029) and produced divergent token attributions. Correlation analysis demonstrated moderate alignment between SHAP and IG (Pearson r=0.367), whereas GPT-4o exhibited limited correlation (Pearson $r \leq 0.032$) with the established baselines. Sensitivity analyses isolating only correctly classified instances yielded similar trends. Additionally, the iterative application programming interface calls required for GPT made it significantly more computationally intensive and costly to execute, whereas IG was the most temporally efficient.

Conclusions: Despite their advanced contextual capabilities, current generative large language models are limited when deployed as standalone perturbation explainers. The findings reveal that GPT-4o struggles to accurately synthesize mathematical feature importance through iterative masking, lacking the reliability of traditional explainable artificial intelligence frameworks. Future research could build upon this work and investigate specialized prompt engineering, whole-word recombination strategies, and hybrid frameworks.

Introduction

The rapid growth of biomedical literature has driven the development of automated classification systems to facilitate knowledge synthesis and translation [1]. Deep learning, particularly encoder-only transformer architectures such as Bidirectional Encoder Representations from Transformers (BERT), has gained significant attention in biomedical text classification [2]. These models excel due to their ability to capture contextual information, leverage transfer learning, and minimize the need for extensive data preprocessing and feature engineering, making them highly effective for biomedical applications [3,4].

However, the complex, multilayered nature of BERT models undermines their interpretability, posing challenges in understanding their decision-making processes [5]. Explainable artificial intelligence (XAI) techniques aim to address this limitation by providing insights into feature importance [6]. One widely used XAI framework is Shapley Additive Explanations (SHAP), which is grounded in game theory and uses Shapley values to systematically estimate feature contributions by perturbing inputs [7]. Despite its theoretical robustness, SHAP has substantial computational overhead. It requires summing marginal contributions across feature subsets, which leads to an exponential increase in complexity as the feature space grows [8]. Consequently, computing SHAP values becomes impractical for BERT models that process long sequences of up to 512 tokens.

To mitigate this challenge, a partition explainer groups features into structured partitions, which reduces complexity while preserving interactions. By approximating Shapley values using Owen values [9], the partition explainer enhances scalability, making it particularly suitable for high-dimensional text classification tasks. Another widely used method is integrated gradients (IG) based on the Aumann-Shapley method, which ensures axiomatic fairness and path-integrated attribution of feature importance [10-14]. It offers a computationally efficient approach to estimating feature importance by measuring the accumulated gradients along the path between the baseline input and the instance input. IG has been widely applied in natural language processing (NLP) tasks, providing a balance between interpretability and computational feasibility [10-12]. However, these methods face challenges in explaining text classifiers due to significant multicollinearity between input tokens and high-dimensional feature spaces [10,15,16].

More recently, pretrained generative large language models (LLMs) leveraging transformer decoders have garnered wide attention in NLP due to their performance and flexibility [17]. Previous studies, such as those by Zytek et al [18,19] and Zeng and Zhu [20], explored LLMs in model explanation, investigating the use of LLMs to convert SHAP explanations into plain-text descriptions to improve human interpretability. Unlike perturbation-based XAI methods or gradient-based XAI methods, LLMs can generate explanations while incorporating token-level contextual relationships, potentially leading to more faithful feature attributions. More recently, LLMs have started to support structured JSON output and function calling, providing a convenient way to integrate model predictions [21-23].

Despite these advances, no prior studies have explored the usage of LLMs as standalone explainers for deep learning models in biomedical text classification. To address this gap, as a proof-of-concept, we develop and validate a methodology to investigate GPT-4o by OpenAI, as an end-to-end, agentic perturbation explainer for a BERT-based biomedical text classifier. We compare its performance against SHAP's partition explainer and IG explanations.

Methods

Classifier and Dataset Description

This study builds upon the work from a previous study [24], where we fine-tuned 630 encoder-only transformer models using grid search. The data came from the McMaster Premium Literature Service (PLUS) and the Clinical Hedges databases associated with the McMaster Health Information Research Unit. Detailed descriptions of these 2 databases are published elsewhere [24-28]. In short, both databases include treatment, primary prevention, and/or quality improvement studies that had been manually appraised using custom criteria for randomized controlled trials [29] to determine whether they were methodologically rigorous or nonrigorous. Studies in the PLUS database from inception (2003-2023; n=53,219) were used for training (n=42,575), validation (n=5322), and testing (n=5322). Studies from 2024 in McMaster PLUS (n=1011) and the Clinical Hedges (n=6572) were used for external testing. The top-performing models were identified on the validation set and subsequently tested.

For this study, we selected a stratified random sample of 200 studies, 40 from each dataset. For each of the 5 data subsets, studies were placed into 10 bins based on their predicted probability for rigor, and a random sample of 4 studies per probability bin per dataset was selected. The probability scores were generated by the model that had the lowest validation loss, which was a BioLinkBERT-based model with a learning rate of 3×10^5, a batch size of 64, a random seed of 2, and included class weight adjustments. The model was fine-tuned for 5 epochs before premature termination by early stopping, and weights from epoch 2 were used as it achieved the lowest validation loss. Other relevant configurations can be found in our previous publication [26]. The model achieved a cross-entropy loss of 0.291, an area under the receiver-operating characteristic curve of 0.941, and an accuracy of 0.879 on the full validation set.

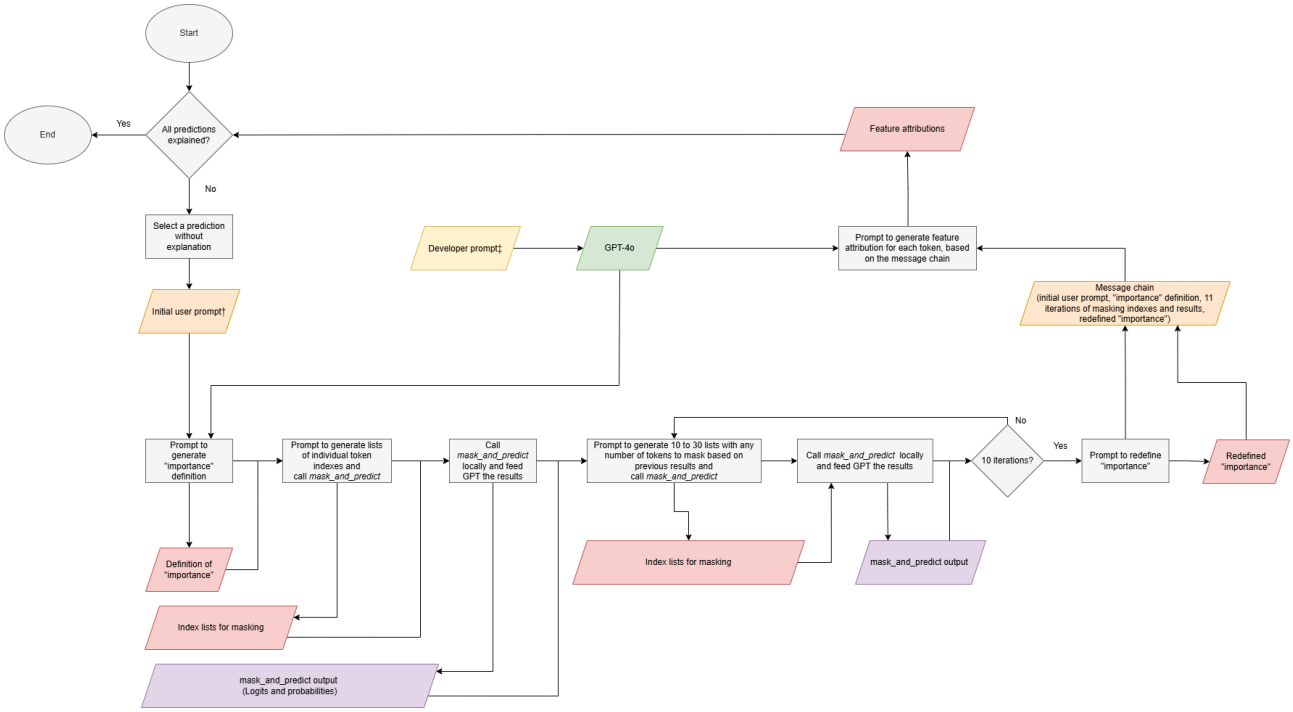
RenderX

SHAP Explanations

We used the SHAP partition explainer [30] to compute an Owen value for each token in each prediction. The partition explainer was chosen due to its efficiency in high-dimensional text classification and its ability to capture feature interactions more effectively than standard Shapley value approximations [31]. SHAP values were calculated using logits that were back-transformed from SoftMax probabilities.

IG Explanations



We used IG to estimate token-level feature attributions for each prediction. We used an empty sequence padded to 512 tokens with "[PAD]" as the baseline input, ensuring the absence of semantic content while preserving the tokenization structure. The baseline input produces a rigorous probability of 11.7%. Attributions were derived by computing gradients with respect to the input embeddings across 30 interpolation steps. The total IG attribution per token was calculated by aggregating gradients across all embedding dimensions.

GPT Explanations

Overview

We used GPT-4o-2024-11-20 with a temperature of 0, and both presence and frequency penalties set to 0, to ensure deterministic outputs. The objective was to evaluate GPT's ability to estimate token-level feature attributions through perturbation-based explanations, similar to SHAP. A total of 2 prompting schemes, GPT-index and GPT-token, were designed to systematically mask tokens and assess their influence on classifier predictions. Tokens were obtained by processing the original input through BioLinkBERT's word-piece tokenizer. Both schemes received the number of input tokens, predicted logits for both classes, and the probability of the positive class. Additionally, GPT-token was provided with the complete list of input tokens in a comma-separated format and the manual appraisal criteria. The full prompts used for both schemes are available in Tables S1-S3 in Multimedia Appendix 1. A flow diagram can be found in Figure 1.

Figure 1. Flowchart of the pipeline for generating explanations and feature attributions from GPT-index and GPT-token. The pipeline illustrates the iterative perturbation-based workflow, including the developer prompt, the initial user prompt, repeated masking iterations, and batched feature attribution generation using structured outputs. †Input tokens are included only in the initial user prompt for GPT-token. ‡The information and instructions provided in the developer prompt differ for GPT-index and GPT-token, as GPT-index was not provided with the input tokens. Detailed prompts can be found in Multimedia Appendix 1.

Developer Prompt

In the developer prompt, GPT was provided with (1) the role of a machine learning model explainer, (2) the task of explaining a binary encoder-only transformer text classifier's prediction via perturbations by masking input tokens, (3) the scheme-specific information that would be provided in the user prompts, and (4) step-by-step instructions on defining importance, masking, function calling, and generating importance values that would be executed subsequently. The manual appraisal criteria [31] for GPT-tokens were included in the developer prompt.

Initial User Prompt

In the initial user prompt, both prompting schemes (GPT-index and GPT-token) were provided with the number of tokens, the predicted logits of the positive and negative classes, and the probability of the positive class. The input tokens, in the format of a comma-separated list, were provided to GPT-token only in the initial user prompt.

Subsequent User Prompts

The model was first instructed to generate the definition of "importance" for itself and then to call *mask_and_predict* with lists of individual indices (eg, [[0] [1], … [x-1]], for an input

XSL•FO
RenderX

with x tokens), echoing the instructions provided in the developer prompt. To call *mask_and_predict*, we used the function-calling feature [32] in OpenAI's application programming interface (API). The function, in general, takes lists of integers as input and returns the logits for both classes and the probability of the positive class for each list of indices to mask, with every token at the index replaced with "[MASK]."

Subsequently, the model was prompted 10 times to generate 10 to 30 lists with any number of indices to mask and call *mask_and_predict*, where each iteration included the results of all previous iterations. The model was explicitly instructed to avoid generating the same combinations of indices and to adapt future masking based on prior iteration results. Finally, the model was asked to redefine "importance" based on the initial definition and the results of all masking iterations.

Feature Attribution Calculations

The model was prompted, with the final message chain including the initial user prompt, all iterations of perturbations, and both iterations of importance definition, to generate the feature importance for each token, 20 tokens per batch. Crucially, while the output generation was batched to bypass GPT's limitations in generating long structured sequences, the full global context of all masking permutations and model predictions was retained in the prompt for every batch. The model was not provided with the calculated feature attributions of other batches, as the mathematical calculation based on its own definition only required the global perturbation history, which was always present. This batched approach was taken because the model often had issues with generating longer sequences. The structured output function [33] of the API was leveraged to generate a list of dictionaries of token indices and their corresponding feature attributions.

Evaluation

Area Over the Perturbation Curve

To establish feature attribution performance, we used a modified version of the area over the perturbation curve (AOPC), which was used in previous literature [16,34,35]. The AOPC was calculated for each explanation individually and then averaged across all 200 instances.

The original AOPC is calculated using the formula in Equation 1.

$$(1)\quad AOPC=1K\sum i=1K(P(x)-P(x(i)))$$

where $P(x)$ is the predicted probability for the positive class with the original input x, $x^{(i)}$ is the perturbed input with the top i important features removed or masked, and K is the number of perturbation steps. This formula assumes that features contribute to the positive class; hence, their removal would result in a decrease in the predicted probability, and $P(x)–P(x^{(i)})$ would be positive. Crucially, because AOPC relies on iteratively masking the top-k features, it is fundamentally a rank-based metric; it evaluates the explainer's ability to correctly order feature importance rather than its precision in quantifying absolute attribution values.

For binary text classification, feature attributions could be associated with a negative value, indicating more support for the negative class [34]. Under such circumstances, their removal would lead to an increase in the probability of the positive class. For this reason, we adapted the AOPC formula in Equation 2.

$$(2)\quad AOPC=1Kp+Kn(\sum i=1Kp(P(x)-P(x(i)))+\sum j=1Kn(P(x(j))-P(x)))$$

where $x^{(i)}$ and $x^{(j)}$ are the perturbed inputs with the top i positively-attributed features and the top j negatively-attributed features masked, respectively. K_p and K_n are the number of perturbation steps for the positive features and negative features, respectively, which, in this case, would be equal to the number of positively and negatively attributed tokens. Similar to the original metric, a larger value would indicate higher attribution faithfulness. Note that the operands corresponding to the "+" operation must be computed separately (to enable the removal of positive features and negative features separately) before the final summation is performed.

Correlation Analysis

The pairwise correlation between feature attributions for each of the 4 methods (SHAP, IG, GPT-index, and GPT-token) was assessed using Pearson r, Spearman ρ, and Kendall τ. Distribution similarity was measured using the Wasserstein distance. A P value of .05 or less is indicative of statistical significance. The distributions of feature attributions were visualized using scatter plots.

Feature Importance Attributions

The 10 most important features that had an occurrence of ≥1, ≥10, and ≥100 for each explainer were examined using bar graphs.

Sensitivity Analysis

We conducted sensitivity analyses, including instances that were correctly classified only, to explore the impact of classification accuracy on explanation faithfulness.

Hardware and Software

We used the resources from the Cedar cluster of the Digital Research Alliance of Canada. Training, evaluation, and explanation were conducted using 1 NVIDIA V100 Volta (32 GB HBM2 memory), as well as an allocation of 8 cores and 40 GB of memory. Querying of GPT was conducted locally with an AMD 9950x and 64GB system memory.

Visual Studio Code (Microsoft Corp) and Python 3.11.9 (Python Software Foundation) were used for all software development. We used the *transformers* library by Hugging Face to obtain pretrained models, and *torch* was used for evaluation purposes. The *shap* and *captum* libraries were used to calculate feature attributions via partition explainer and IG, respectively. The *openai* library was used to query GPT-4o. Data management and statistical analysis were conducted using *pandas*, *numpy*, and *scikit-learn*. Data visualization was done with *matplotlib* and *seaborn*. The full list of libraries used on the Digital Research Alliance of Canada and the local environment can be found in Table S4 in Multimedia Appendix 1.

XSL•FO
RenderX

Ethical Considerations

This study exclusively involved the computational analysis of previously published biomedical and clinical literature originating from the McMaster PLUS and Clinical Hedges databases. As the research relied entirely on the secondary analysis of publicly available, published documents and did not involve the collection of data from or interaction with human subjects, it is exempt from institutional ethics review. Consequently, requirements regarding informed consent, human subject privacy and confidentiality protections, and participant compensation are not applicable to this study.

Results

Characteristics of the Dataset and Classifier

The original dataset contained 60,802 instances, of which 34,090 (56.1%) were rigorous. After stratified sampling, the 200 instances contained 83 (41.5%) rigorous studies. Within this dataset, the BioLinkBERT model achieved a cross-entropy loss of 0.527, an area under the receiver-operating characteristic curve of 0.812, and an accuracy of 0.705 using the default threshold of a predicted probability of 0.50 or more. The 200 instances contained a total of 80,901 tokens, of which 6369 were unique.

Importance Definitions by GPT

GPT, in both prompting schemes, was instructed to define "importance" after being provided with the initial user prompt and subsequently redefine "importance" after all iterations of masking had been completed. Both GPT-index and GPT-token initially defined "importance" as the change in the predicted probability of the positive class before and after masking for all 200 instances.

After redefinition for GPT-index, the definition remained consistent as the change in predicted probability in 199 (99.5%) instances. Of these, 3 (1.5%), 37 (18.5%), and 16 (8%) instances normalized the change by logits, initial predicted probability, and the number of masked tokens in a perturbation, respectively. The remaining instance used the change in the difference between the positive and negative logits as the definition of importance.

For GPT-token, the definition for all 200 instances remained consistent as the change in predicted probability. Among these, 67 (33.5%) and 9 (4.5%) instances normalized the change by the initial predicted probability and the number of tokens masked, respectively.

AOPC Analysis

SHAP and IG explanations achieved similar faithfulness, with a mean (95% CI) of 0.222 (0.200-0.244) and 0.225 (0.202-0.247), respectively (Table 1 and Figure 2). SHAP was better at identifying negative tokens, while IG was better at identifying positive tokens. The GPT-index and GPT-token schemes yielded substantially lower AOPC scores of 0.025 (0.012-0.038) and 0.029 (0.014-0.043), respectively. Notably, both schemes produced inverted (negative) AOPC values for negative tokens, indicating a divergence in baseline attribution logic.

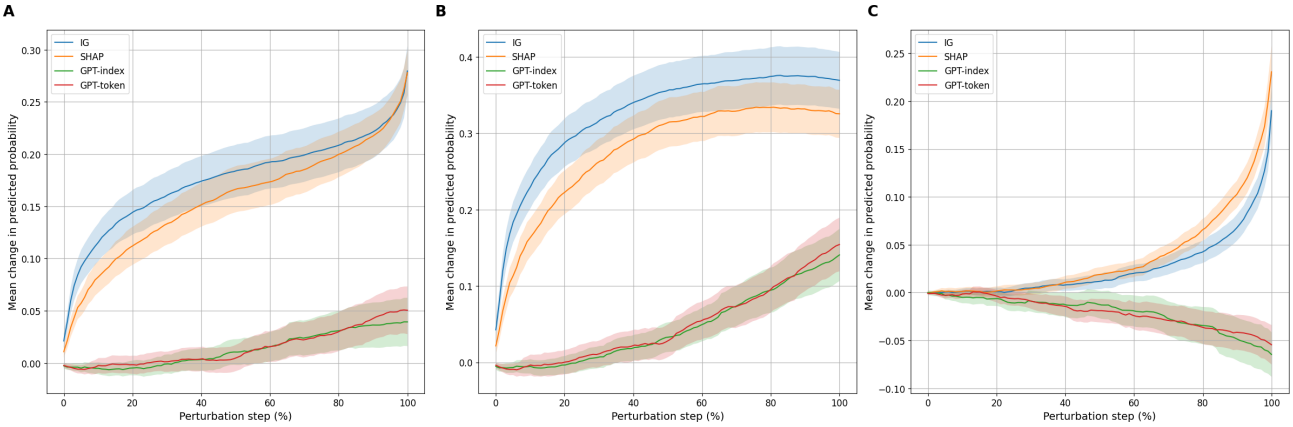


Table . Performance of 4 explainers (Shapley Additive Explanations [SHAP], integrated gradients [IG], GPT-index, and GPT-token) based on the mean area over the perturbation curve (AOPC) across 200 stratified studies sampled from the McMaster Premium Literature Service (PLUS) and Clinical Hedges databases (2003-2024), classified for methodological rigor using a fine-tuned BioLinkBERT model. Higher AOPC indicates greater attribution faithfulness[a].

Explainer	AOPC (all tokens), mean (95% CI)	AOPC (Tokens with positive attributions), mean (95% CI)	AOPC (Tokens with negative attributions), mean (95% CI)
SHAP	0.222 (0.200 to 0.244)	0.277 (0.249 to 0.306)	0.037 (0.030 to 0.044)
IG	0.225 (0.202 to 0.247)	0.326 (0.293 to 0.359)	0.026 (0.019 to 0.033)
GPT-index	0.025 (0.012 to 0.038)	0.045 (0.028 to 0.063)	−0.021 (−0.034 to −0.008)
GPT-token	0.029 (0.014 to 0.043)	0.049 (0.029 to 0.068)	−0.021 (−0.031 to −0.010)

[a]All values are shown as the mean (95% CI) across the 200 instances.

XSL•FO
RenderX

Figure 2. Perturbation curves of the 4 explainers (Shapley Additive Explanations [SHAP], integrated gradients [IG], GPT-index, and GPT-token) across 200 stratified studies sampled from the McMaster Premium Literature Service (PLUS) and Clinical Hedges databases (2003-2024), classified for methodological rigor using a fine-tuned BioLinkBERT model. Shaded areas represent the 95% CI. (A) All tokens, (B) tokens with positive attributions, and (C) tokens with negative attributions.

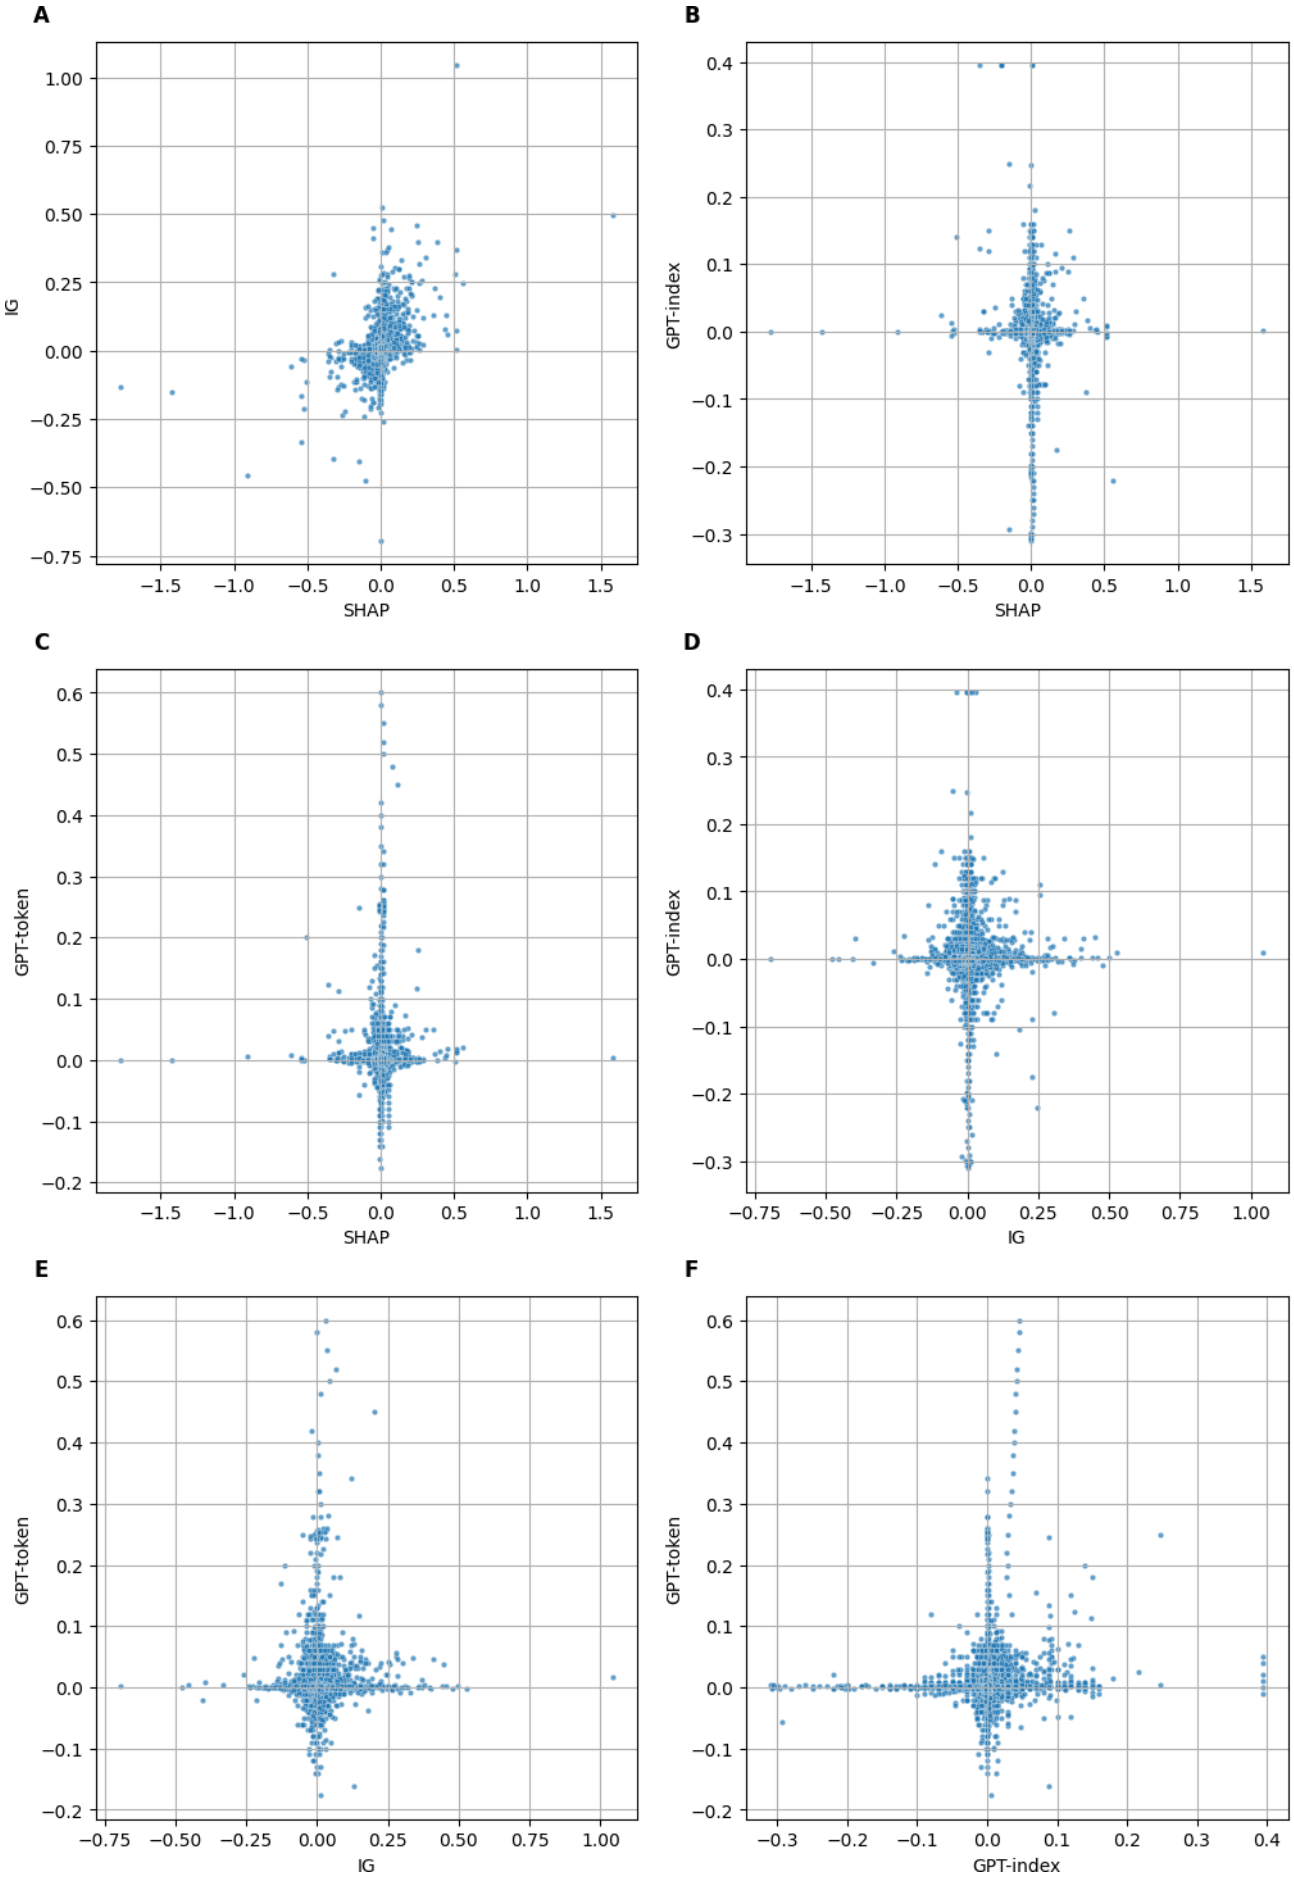
Sign Inversion Error Analysis

To analyze whether the negative AOPC values for negatively attributed features from the GPT explainers were a result of a systematic sign error, we systematically inverted the signs of all feature attributions and recalculated their AOPC values. After inversion, the AOPC for all, positively attributed, and negatively attributed tokens were −0.019 (−0.032 to −0.006), 0.032 (0.019-0.046), and −0.046 (−0.063 to −0.028) for GPT-index, and −0.028 (−0.043 to −0.014), 0.022 (0.011-0.034), and −0.050 (−0.070 to −0.030) for GPT-token.

Correlation Analysis

Feature attributions from SHAP and IG exhibit moderate correlation with each other, with a Pearson *r* of 0.367 (Table 2 and Figure 3). No notable correlation is evident between feature attributions from other pairs of explainers. Wasserstein distances reveal that the distributions of feature attributions are similar across all explainers.

Table . Pairwise correlation and distribution similarity of token-level feature attributions generated by 4 explainers (Shapley Additive Explanations [SHAP] partition explainer, integrated gradients [IG], GPT-index, and GPT-token) across 80,901 tokens from 200 stratified studies sampled from the McMaster Premium Literature Service (PLUS) and Clinical Hedges databases (2003-2024), classified for methodological rigor using a fine-tuned BioLinkBERT model. Pearson *r*, Spearman ρ, and Kendall τ assess linear and rank-based correlation, while the Wasserstein distance measures distributional similarity between attribution value distributions.



Explainer A	Explainer B	Pearson *r*	Spearman ρ	Kendall τ	Wasserstein distance
SHAP	IG	0.367[a]	0.275[a]	0.192[a]	0.002
SHAP	GPT-index	−0.031[a]	0.061[a]	0.041[a]	0.003
SHAP	GPT-token	0.004	0.037[a]	0.025[a]	0.003
IG	GPT-index	0.003	0.038[a]	0.026[a]	0.004
IG	GPT-token	0.032[a]	0.029[a]	0.020[a]	0.005
GPT-index	GPT-token	0.083[a]	0.096[a]	0.071[a]	0.001

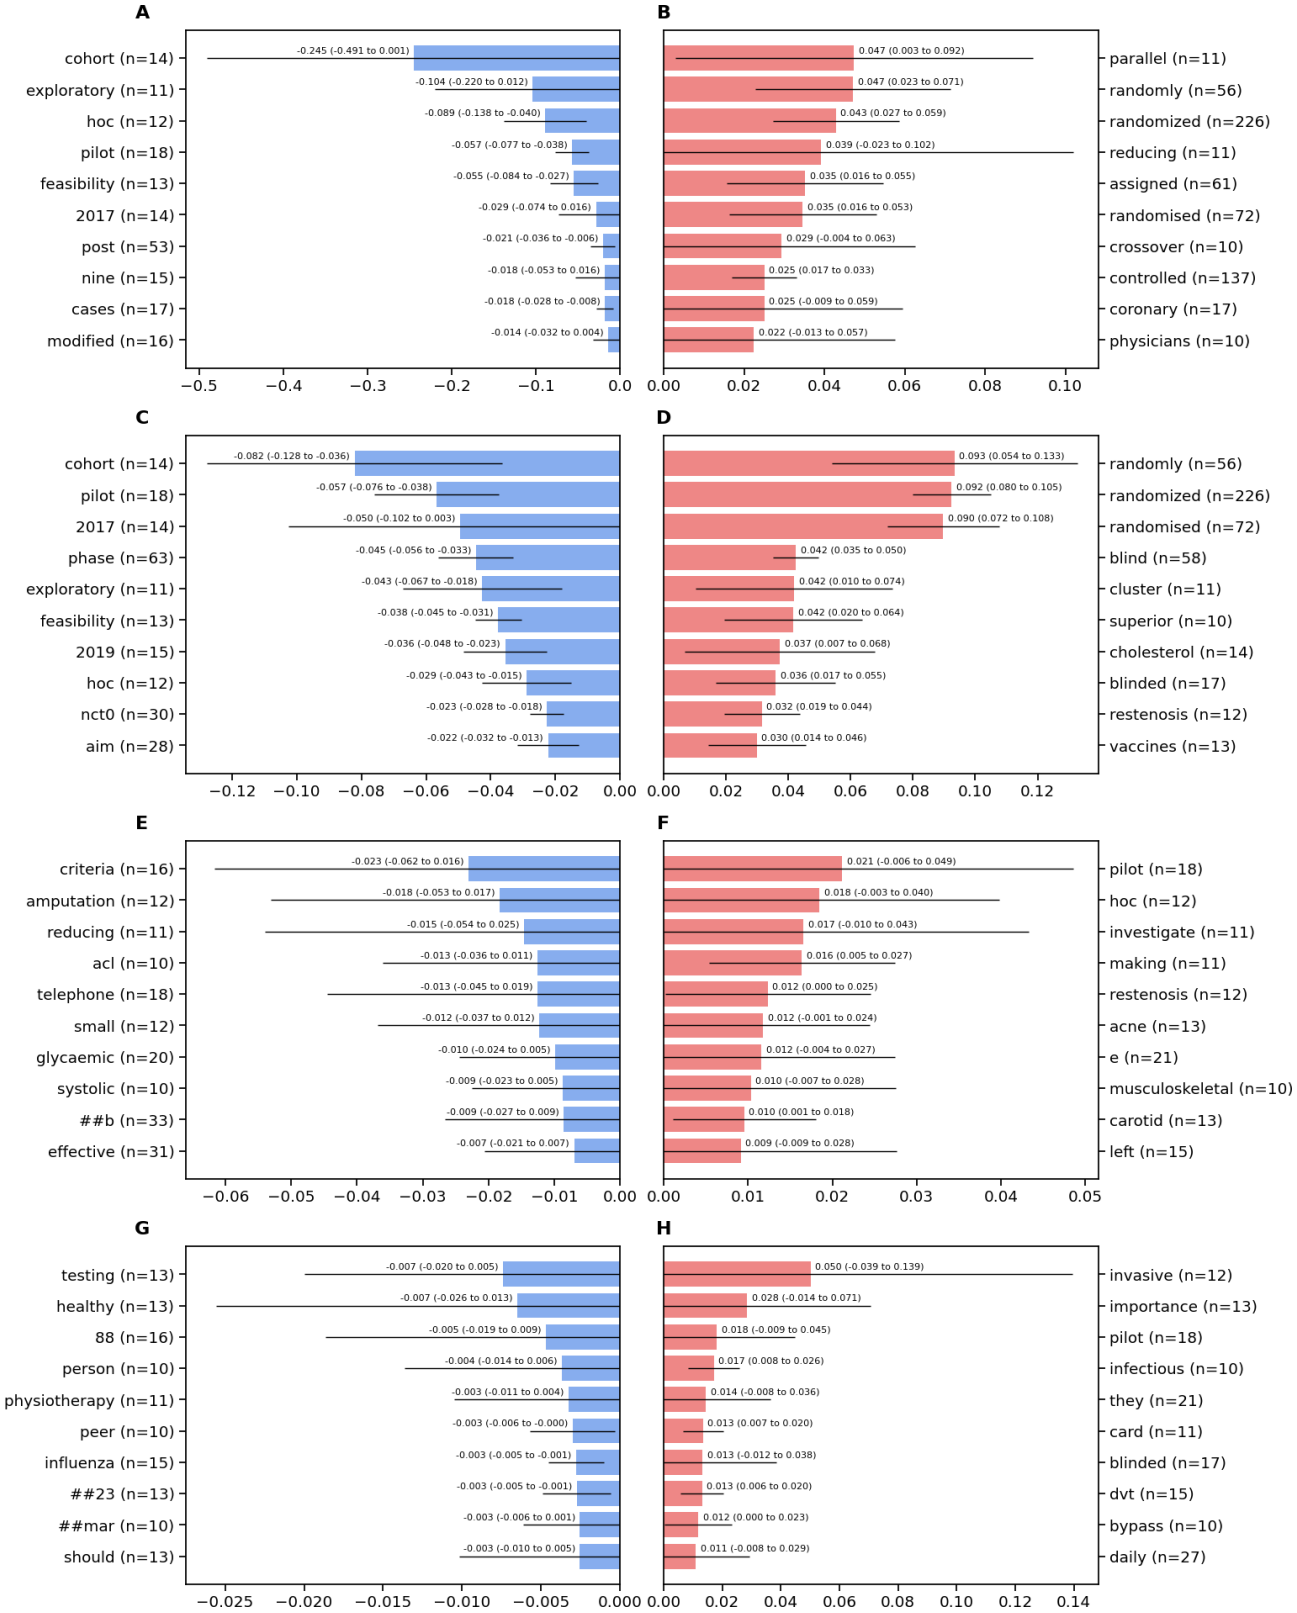
Feature Importance Attributions



Of the 80,901 generated feature attributions, 6369, 1073, and 87 were from unique tokens that had occurrences of ≥1, ≥10, and ≥100, respectively. The most important unique tokens with ≥10 occurrences can be found in Figure 4. Those with occurrences of ≥1 and ≥100 can be found in Figures S1 and S2 in Multimedia Appendix 1.

Among those with ≥10 and ≥100 occurrences, both SHAP and IG identified tokens that were associated with study designs, including “cohort,” “pilot,” “exploratory,” “randomly,” and “blind,” among others. In contrast, the GPT explainers did not exhibit a cohesive semantic pattern among tokens with ≥10 occurrences. While GPT-token successfully identified select key clinical terms (eg, “trial” and “randomized”), it was unable to systematically isolate negatively contributing tokens.

Important tokens with 1 or more occurrence for SHAP and IG primarily consisted of terms related to study design, year, or topic. There is no consistent pattern between the 2 GPT explainers.

XSL•FO
RenderX

Figure 4. Accumulated local feature attributions of the identified most important negative and positive tokens with 10 or more occurrences, generated by 4 explainers (Shapley Additive Explanations [SHAP] partition explainer, integrated gradients [IG], GPT-index, and GPT-token) across 80,901 tokens from 200 stratified studies sampled from the McMaster Premium Literature Service (PLUS) and Clinical Hedges databases (2003 to 2024). The values are presented as mean (95% CI). (A) Negative tokens for SHAP, (B) positive tokens for SHAP, (C) negative tokens for IG, (D) positive tokens for IG, (E) negative tokens for GPT-index, (F) positive tokens for GPT-index, (G) negative tokens for GPT-token, and (H) positive tokens for GPT-token.

Sensitivity Analysis

We conducted a sensitivity analysis, including only the correctly classified instances (70.5% accuracy and 141 studies). Of the 57,195 tokens, 5341, 816, and 57 were unique with an occurrence of ≥1, ≥10, and ≥100, respectively. There was no notable change in the faithfulness of the explainers based on AOPC (Table S5 and Figure S3 in Multimedia Appendix 1),

XSL•FO
RenderX

pairwise correlation of feature attributions among the explainers (Table S6 and Figure S4 in Multimedia Appendix 1), and the most important tokens identified by accumulated feature attributions (Figures S5-S7 in Multimedia Appendix 1).

Discussion

To our knowledge, this is the first experiment that attempts to leverage decoder transformers to establish feature attributions for text classifiers through perturbation. While our results do not indicate that GPT could be a potential substitute for conventional explanation methods in this context, this study nevertheless serves as a valuable exploratory analysis that could inspire future research in this area.

Principal Findings

While AOPC does not establish absolute faithfulness, it is a common method to compare the relative performance of explainers on the same model [36]. Our results demonstrate that the SHAP partition explainer and IG were similar in their overall performance. SHAP was better at identifying negative tokens, while IG was better at identifying positive tokens. Our results also demonstrated that GPT was able to generate reasonable definitions of importance when provided with the task of generating feature attributions as an explainer. While delegating the definition of feature importance to the model itself theoretically risks inconsistency and could weaken methodological rigor, our analysis showed stability, with the model consistently defining importance as the change in predicted probability. This confirms that the poor performance of the GPT explainers is not a byproduct of an unstable metric definition. In spite of this, the GPT explainers struggled to generate reliable feature attributions. In particular, the negative AOPC for negative tokens indicates that the GPT explainers mistakenly associated negative attributions with features that increased the probability of rigor. A plausible explanation for this is a sign inversion error, wherein the model reports the raw negative delta of a masked positive feature rather than its intended importance magnitude. However, our generative prompts explicitly enforced a strict sign convention requiring positive floats for positive classifications and negative floats for negative classifications. An examination of the most important tokens reveals that the top negative features identified by GPT do not symmetrically align with the positive features identified by SHAP or IG. After sign inversion, AOPC decreased from 0.025 to −0.019 for GPT-index, and from 0.029 to −0.028 for GPT-token. Therefore, this discrepancy likely represents a limitation in GPT's semantic feature attribution logic rather than a sign inversion or delta reporting error. These findings were echoed by the correlation analyses, where attributions by SHAP and IG had a moderate correlation with each other, while the 2 GPT explainers had weak or no correlation with the others. Also, sensitivity analyses isolating only the correctly classified instances yielded similar trends, confirming that GPT's poor attribution performance is an inherent limitation of its logical reasoning rather than an artifact of attempting to explain confused or incorrect model predictions.

GPT's limited faithfulness is unlikely to be attributable to an undersampled perturbation space. The initial masking generated the same number of perturbations as the number of tokens. Subsequently, GPT proceeded with 10 iterations of masking, generating between 10 and 30 masking combinations per iteration, evaluating an additional 100 to 300 unique perturbations. In contrast, the SHAP partition explainer successfully established faithful baseline attributions using only 86 perturbations for a 512-token sequence. The fact that GPT evaluated a significantly larger subset of the perturbation space yet failed to produce aligned attributions indicates an inherent limitation in the LLM's ability to logically synthesize mathematical perturbation results, rather than a lack of search space exploration. Furthermore, it is important to emphasize that our results are established with a stratified sample of 200 instances and a specific prompting strategy. Therefore, our findings should be framed as a specific evaluation of this methodology on this dataset, rather than a definitive ruling on GPT's overall use for all biomedical text explanations.

While methods to examine the global attributions for transformer models are an area of active research [37], we were able to examine the accumulated local attributions across all 200 instances. SHAP and IG indicate that the BioLinkBERT model generally aligned with the manual appraisal criteria [38], with terms such as "cohort," "pilot," "randomized," and "blind," among others, being identified as the most important. The tokens identified by GPT did not align with SHAP or IG and seemed to be semantically nonsensical in the context of rigor classification. For instance, both GPT-index and GPT-token identified "pilot" as a positive contributor, contrary to manual appraisal as well as SHAP and IG explanations.

Prompting

A challenge of this experiment was the development of prompts for GPT, considering the complex nature of generating feature attributions from perturbations. It is known that sophisticated prompting techniques can improve GPT's performance in NLP [38-40]. In our study, we used numerous established techniques in prompt engineering in an attempt to improve performance, including role prompting, decomposition by providing instructions step by step, as well as chain-of-thought to a certain degree, with multiple iterations of perturbations and the redefinition of importance [40]. GPT was also limited in responding with long, quantitative sequences despite explicit instructions and structured output restrictions [41,42]. We mitigated this concern by explicitly instructing GPT to respond with a certain number of lists as parameters to the *mask_and_predict* function, using structured outputs and function calling, and decomposing the calculation steps to 20 tokens per batch. Despite this, GPT was not able to generate faithful attributions. Furthermore, we hypothesized that an advantage of LLMs would be the ability to recognize likely important tokens before any quantitative explanations have been generated, considering their ability to understand and encode contextualized information from plain text [43]. Therefore, we experimented with 2 prompting schemes, namely GPT-index and GPT-token. However, our results show that there was no meaningful difference regardless of the inclusion of input tokens in the initial user prompt.

RenderX

Resource Requirements

A challenge with traditional XAI methods is the significant computational resources required. As previously mentioned, the exhaustive nature of calculating SHAP values from all possible perturbations is infeasible, resulting in the rise of numerous methods to approximate SHAP values [44,45], including the partition explainer [44,45]. The computational requirement for IG is associated with integration steps. While higher steps result in higher precision, we found 30 steps to be feasible on GPUs with 32GB of memory and temporally more efficient than the SHAP partition explainer.

High computational costs and time delays were incurred due to the iterative approach with the GPT explainers. Similar to SHAP, the BioLinkBERT model must be queried to obtain predictions for the perturbed instances. Additionally, each subsequent prompt in the chain results in higher inference and response times due to network latency and the autoregressive nature of LLM text generation. Consequently, GPT was unequivocally the slowest method to generate explanations, while also incurring a direct financial cost from OpenAI's servers of approximately US $1.00 per instance.

Deployment and Research Implications

Explainability and interpretability in biomedical and clinical machine learning are key areas of research [46,47]. As a pioneer in evidence-based medicine and knowledge translation, the McMaster Health Information Research Unit aims not only to automate biomedical literature classification and appraisal [25,48] but also to ensure that the process is transparent and reproducible to facilitate trust among clinicians who subscribe to PLUS and PLUS-associated services. Based on the results of this experiment, we believe that both SHAP and IG would be suitable for deployment alongside a top-performing model. More recently, studies [49,50] and systematic review support systems [51-53] have begun to leverage supervised or active learning extensively to support knowledge translation and synthesis by relevance ranking or automatic classification. We believe that systems should attempt to integrate XAI frameworks alongside any black-box models for better transparency.

While we did not obtain promising results in using GPT as an end-to-end approach for feature attributions, our work nevertheless serves as a foundation for future research. Given the sensitivity of GPT-based explanations to prompt design, future studies could explore more sophisticated, domain-tailored prompting strategies and iterative prompt refinement using techniques, such as few-shot learning, to better align GPT's output with domain-specific interpretability criteria [40]. Fine-tuning LLM explainers on biomedical corpora could also improve their understanding of specialized terminology and context [54]. Hybrid explanation frameworks, such as leveraging LLMs to establish a partition hierarchy [16,30] or integrating model-internal signals, such as attention weights, with LLM-based explanation methods, may also be of interest [55-57]. Specifically, future proof-of-concept studies should investigate whether grounding LLM-generated contextual explanations in traditional feature attributions, such as SHAP or IG, can produce more faithful and human-interpretable results than standalone generative explainers.

Strengths and Limitations

Our study has several strengths. First, to our knowledge, this is the first experiment that attempts to leverage decoder transformers to establish feature attributions for text classifiers by perturbation. Second, a concern with leveraging LLMs in medical research is reproducibility, as evidence-based medicine is founded upon concepts of transparency, reliability, and the ability to validate findings through rigorous, repeatable methodologies [58-61]. We mitigated this concern by using a temperature of 0, making the outputs of the LLM deterministic and replicable. Third, we mitigated concerns with the original AOPC metric on binary text classification by separately considering negative and positive features. This allowed us to better capture the faithfulness of the explanations. Fourth, we leveraged sophisticated prompting techniques for GPT. This indicates that the poor results from GPT are likely an inherent limitation of the pretraining and the model architecture rather than the prompt.

Nevertheless, important limitations must be considered when interpreting our results. First, there is no known method to establish ground truth in black-box models, and explaining text models with a high feature space remains a challenge [36,62]. Consequently, SHAP and IG were used as established comparative baselines rather than definitive ground truths, and AOPC was used as an objective proxy for faithfulness. For IG specifically, the "[PAD]" baseline yields a predicted probability of 11.7% for the positive class, compared to the class prevalence of 41.5% in the stratified subset, indicating that the baseline is not prediction-neutral. This means IG attributions reflect token contributions relative to a negatively-biased starting point, which may systematically inflate the apparent importance of tokens that are most associated with the positive class. For these reasons, it is important to note that our findings are context-specific, dataset-specific, and model-specific. Second, due to resource constraints, we could only experiment with a stratified subset of 200 instances from the original dataset. While we attempted to minimize sampling bias through stratified sampling, this limited sample size may restrict the generalizability of our findings, particularly regarding the correlation analysis. However, because the unit of analysis for feature attribution is the token (N=80,901), our study retains robust statistical power to evaluate explainer behavior within this sample, as evidenced by our narrow CI. Nonetheless, a larger dataset would further increase our confidence. Third, word-piece tokenization often separates words into fragments, potentially affecting how feature attributions are assigned [63]. This mismatch between models may have contributed to the poor performance of the GPT-token scheme, forcing a generative LLM to reason over another model's disjointed, comma-separated word-piece tokens rather than its native text processing. Consequently, the explanations may not correspond to human-interpretable linguistic units, especially for numerical texts. However, the negligible performance difference between GPT-token and GPT-index, which was only provided the number of maskable tokens, indicates that tokenization is likely not the primary contributor to explanation faithfulness. Nevertheless, as a language model, GPT may be limited in accurately mapping tokens from a long, comma-separated list

XSL•FO
RenderX

of numerical indices. Therefore, future research should investigate whether recombining these subword tokens into whole words prior to the LLM explanation phase improves semantic alignment and attribution faithfulness. Finally, GPT's performance on a task is heavily prompt-specific. While our methodology used highly sophisticated prompt engineering techniques, our evaluation was strictly zero-shot to test the model's baseline reasoning. The substantial API costs associated with iterative perturbation precluded us from conducting comprehensive ablation studies or providing few-shot examples. Furthermore, both SHAP and IG are of a zero-shot nature, and using zero-shot for GPT allows for a more robust comparison. It remains unknown whether GPT would show promise with a different set of prompts, and this is a critical area for future investigation.

Conclusions

We conducted a comprehensive proof-of-concept exploration into the application of GPT-4o as a standalone, end-to-end perturbation explainer for a BioLinkBERT biomedical text classifier. Our objective was to compare the faithfulness of GPT-driven explanations against established baseline methods, specifically the SHAP partition explainer and IG. The results demonstrated that while SHAP and IG provided consistent and relatively faithful feature attributions, the GPT-based approaches, regardless of whether they were prompted with token indices or explicit subword tokens, yielded poor explanations. This was evidenced by near-zero correlation with established methods and counterintuitive token attributions. Consequently, the findings of this study indicate that despite advanced contextual capabilities, current generative LLMs struggle to accurately synthesize mathematical feature importance through iterative masking, lacking the reliability of traditional XAI frameworks for this specific task. Despite these limitations, our work offers valuable insights and establishes a foundation for future research aimed at integrating LLMs into the explainability framework.

Abstract

Background: Artificial intelligence has gained relevance due to its potential to reduce the workload in evidence synthesis or bibliometric projects. While the main focus has been lately on the use of instruction-tuned large language models, zero-shot classification models have not been tested for such task. These models are large language models trained on large datasets of labeled data able to categorize text among proposed labels, irrespective of the text domain or the topic. They are relatively small, able to run on consumer-grade computers, and almost hyperparameter-free.

Objective: In our study, we use abstracts of randomized clinical trials in rheumatology as a case example to evaluate the performance of openly available, generalist, zero-shot classification models in classifying types of interventions against a human gold standard.

Methods: We classified all rheumatology RCT abstracts published between 2009 and 2022 (n=1,054) as “drug” or “non-drug” using two zero-shot text classification models (DeBERTa and BART) and few-shot prompting using Llama3 8B. Different labeling of categories provided to the zero-shot classification models and different prompts provided to Llama3 8B were tested. Performance was evaluated using accuracy and predictive value of both categories against a human gold standard.

Results: Most randomized controlled trials, RCTs (452/1054, 42.9%) assessed drug interventions. The DeBERTa model achieved the highest accuracy (929/1054, 88.1%; 95% CI 86% - 90%) when using the “drug” and “non-drug” labels. Llama3 8B and few-shot prompting had slightly higher accuracy and predictive values. Both zero-shot and Llama3 8B models had performance on par with a human without experience in evidence synthesis (905/1054, 85.9%; 95% CI 83.6% - 87.8% accuracy). Misclassifications occurred for trials where the intervention was harder to classify, such as procedures (eg, intra-articular injections), food compounds, vitamins, supplements, or biological treatments.

Conclusions: This study shows the potential of zero-shot classification models for simple classification tasks, demonstrating accuracy comparable to that of an untrained human. These models are potential tools to streamline systematic review tasks for bibliometric studies in classifying abstracts by supplementing one reviewer.

large language models; LLM; automation tools; evidence synthesis; methodology

Introduction

The study of scientific publications is at the core of bibliometric research on evolving trends [1] and supports evidence synthesis addressing key questions in clinical and public health decision-making [2].

Abstract classification, the first step in many review processes, typically requires two independent reviewers to minimize errors and bias, with a third resolving disagreements [3,4]. This procedure is time-consuming [5] and creates a considerable burden for review teams in projects addressing broad questions.

Advances in artificial intelligence (AI) have introduced new opportunities to reduce workload, especially for abstract and title screening tasks [6]. Two main categories of AI tools have been used to date. The first includes machine learning algorithms trained directly for a specific classification task. This approach has demonstrated good and reproducible performance [7] but it lacks versatility and requires task-specific training. The second category involves prompting large language models [8,9]. While they are highly versatile and not dependent on task-specific training, their performance can vary depending on the prompts provided, sampling parameters, and their use requires substantial

XSL•FO
RenderX

computing power, or a paid private Application Programming Interface (API).

Zero-shot classification models [10] represent a third, less explored option with potential advantages. These language models, constrained to assigning a probability to a label for a given text, are fine-tuned on large datasets of labeled data. They subsequently develop natural language inference capabilities allowing them to categorize text into user-defined labels without domain-specific training. Although they can be further fine-tuned, we focus here on generalist zero-shot models that are widely available and not trained on a specific domain. They are simple to use, require minimal computational resources, have no tunable input hyperparameters beyond the label set, and have broad applicability. They therefore offer both the versatility required for abstract screening and the reproducibility needed in research. Previous studies have reported encouraging results in classifying texts [10] and heterogeneous results have been reported for abstract screening in systematic reviews [11].

In our study, we use abstracts of randomized clinical trials in rheumatology as a case example to evaluate the performance of openly available, generalist, zero-shot classification models in classifying types of interventions against a human gold standard. As a benchmark, we compare its performance with the lightest version of Llama 3 available at the time of the study (8 billion parameters).

Methods

We used an existing database of all primary reports of RCTs published in rheumatology between 2009 to 2022. Full details about search methodology can be found in a published report [12] (Multimedia Appendix 1).

Data Extraction

One reviewer with no previous experience in evidence synthesis or rheumatology (SC) extracted information of RCTs according to the type of intervention. A second reviewer with experience in evidence synthesis (DBG) and rheumatology reviewed the data classification of the first reviewer. Disagreements were resolved by a trained rheumatologist (MI). The classification obtained was considered the gold standard.

The type of intervention, pharmacological or nonpharmacological (*drug or non-drug intervention*) was extracted for each abstract. RCTs assessing nondrug interventions [13,14] were further categorized as: Behavioral, Biological treatments, Delivery of health care services, Device, Education, Exercise therapy, Food/plants/supplements, Procedure, Surgical, Wellness and spa, and Other (Table S1 in Multimedia Appendix 1).

Ethical Considerations

The Geneva Research Ethics Committee exempted the present study from formal ethics review since it is based on publicly available data.

Language Models

Zero-Shot Classifiers

RCTs were classified by type of intervention (“*drug*” or “*non-drug*”) using the two most popular zero-shot classifiers [10] available at the HuggingFace platform [15], namely a classifier based on the DeBERTa model by Microsoft [16,17], and another classifier developed by Meta (*bart-large-mnli, based on BART* [18,19]). Both models have a total size of less than half a billion parameters.

Zero-shot models only require labels to classify the text and provide a probability for each label (Figure 1). Abstracts were assigned to the intervention with the highest probability. To assess whether the wording of the labels could affect the classification performance, we tested seven different label combinations: the first five had two labels (drug intervention/nondrug intervention, drug intervention/other, pharmacological treatment/ nonpharmacological treatment, pharmacological treatment/ other, drug/nondrug), and the last two had the details of the “non-drug” categories (Table S2-S3 in Multimedia Appendix 1).

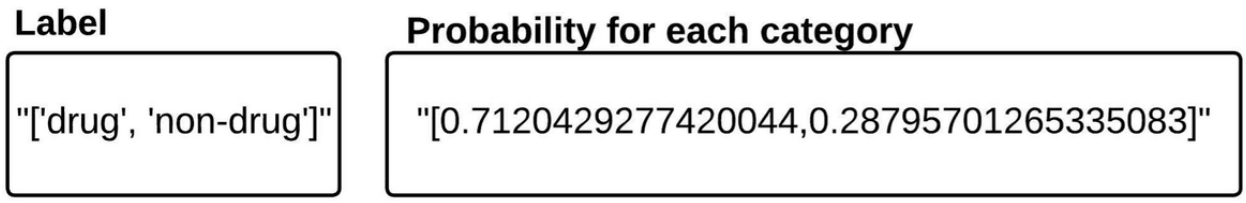

Figure 1a. Output zero shot-model

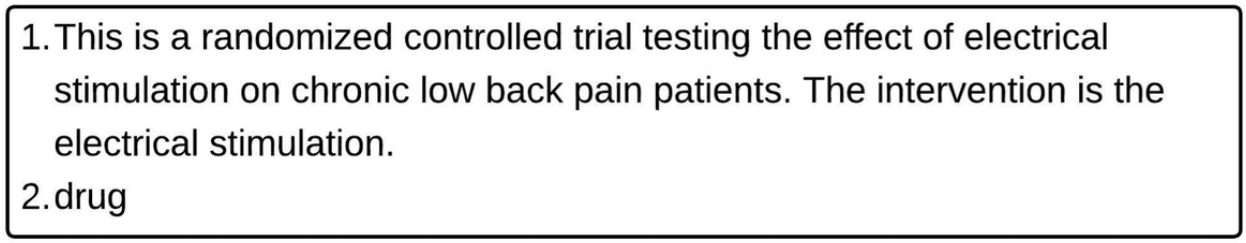

Figure 1b. Output Llama-3

Large Language Models

We used the 8B (8 Billion parameters) version of Meta Llama 3 [20] quantized in 8bit, using a prompt with few-shot prompting with chain-of-thought method [21]. The prompt specified a structured output to extract the answer, asking to provide first an explanation after an "R:" mark, and then the classification after an "A:" mark. Output not properly formatted or providing categories not listed in the initial prompt were considered as missing and were considered as wrong in all performance metrics. The parameters used are based on a previous study [22]: a temperature of 0.3, cumulative probability and most likely next word sampling (top_p and top_k), with top_k=40 and top_p=0.95. Models were run on computer with an NVIDIA Titan X with 12 GB of VRAM, in conjunction with 20G of RAM and a standard CPU. Inference was performed using Python 3.10.4, numpy 1.22.3, pandas 1.4.2, and transformers 4.57.1. The data and prompts used are publicly available in a Gitlab repository [23].

Data Analysis

Performance of each model and of the nontrained reviewer (SC) was assessed using four metrics:

- accuracy, defined as the sum of correct outcomes according to the gold standard divided by the total number of abstracts classified.
- Predictive value for the study being about drugs (PVD), defined as the proportion of abstracts properly classified as drug intervention.
- Predictive value for the study being about nondrugs (PVND), defined as the proportion of abstracts properly classified as nondrug intervention.
- Macro F1, defined as the average of the F1 obtained for the classification of each label (drug and nondrug). F1 is the harmonic mean of the precision and recall.

For all the metrics, the denominator includes all abstracts, even those for which the algorithm provided badly formatted outputs. Data were summarized using frequencies and percentages for categorical variables and median and interquartile range for continuous variables. Model performances were compared to those of the first reviewer.

Confidence intervals were computed using the Wilson method [24]. The analysis was done using R software (version 4.2.0; R Foundation for Statistical Computing) [25].

Results

Of the 1054 RCTs included, 452/1054 (42.9%) assessed drug interventions and 602/1054 (57.1%) nondrug interventions. Among nondrug interventions, the most common were exercise therapy (147/602, 24.4%), procedures (144/602, 23.9%), and delivery of care (88/602, 14.3%) (Table 1).

Zero-shot classifiers took 0.3 Gb of VRAM and around 10 seconds per abstract to run, while the quantized version of Llama3 8B took 10 Gb of VRAM, and 4 seconds per abstract.

The zero-shot classification DeBERTa-based model achieved the highest accuracy using "drug" or "non-drug" categories, with an accuracy of 88.1% (95% CI 86.0% - 90.0%), predictive value for the drug category (PVD) of 80.6% (77.0 - 83.7%) and a predictive value for the nondrug category (PVND) of 96.0% (95% CI 93.9% - 97.3%) and a macro F1 of 88.1% (86.7% - 89.5%) (Table 2, supplementary Tables S4 and S5 in Multimedia Appendix 1), but the accuracy varied substantially

XSL•FO
RenderX

according to the label wording. The BART-based model was less affected by the wording of the labels. The highest accuracy was achieved with the "drug intervention," "non-drug intervention" labels (prompt 1 in Table 2) with an accuracy of 86.9% (95% CI 84.7% - 88.8%), PVD 81.2% (95% CI 77.5% - 84.3%), PVND of 92.2% (95% CI 89.6% - 94.1%) and a macro F1 of 86.8% (85.3% - 88.2%) (Table 2, supplementary Tables S4 and S5 in Multimedia Appendix 1). The approaches based on Llama3 8B and few-shot prompting reached 90.8% (88.9% - 92.4%) accuracy with a prompt requiring a classification into 11 category and providing no context. Less than 2% of the output were not properly formatted and were considered as missing. The predictive values were 89.2% (86.0% - 91.7%) for the drug category and of 92.0% (89.6% - 93.9%) for the nondrug category, reaching a macro F1 of 90.6% (89.3% - 91.9%) (Table 2, supplementary Tables S4 and S5 in Multimedia Appendix 1). Adding context (prompt 1 vs 2, or prompt 3 vs 4) improved the performance of the LLM classification only for the two-category approach, where the confidence intervals of accuracy did not overlap (prompt 3: 89.3%; 87.3% - 91.0%) vs prompt 4: 85.5%; 83.2% - 87.5%). Using only two categories yielded a lower PVD but a higher PVND compared to 11-category prompts.

Table . Interventions assessed in the 1054 rheumatology RCTs[a] included in this study.

Intervention	RCTs (N=1054), n (%)[b]
Drug interventions	452 (42.9)
Nondrug interventions	
Exercise therapy	147 (13.9)
Procedure	144 (13.7)
Delivery of health care services	88 (8.3)
Device	50 (4.7)
Food/plants/supplements	45 (4.3)
Education	31 (2.9)
Surgical	27 (2.6)
Wellness and spa	22 (2.1)
Behavioral	19 (1.8)
Biological treatments	16 (1.5)
Other	13 (1.2)

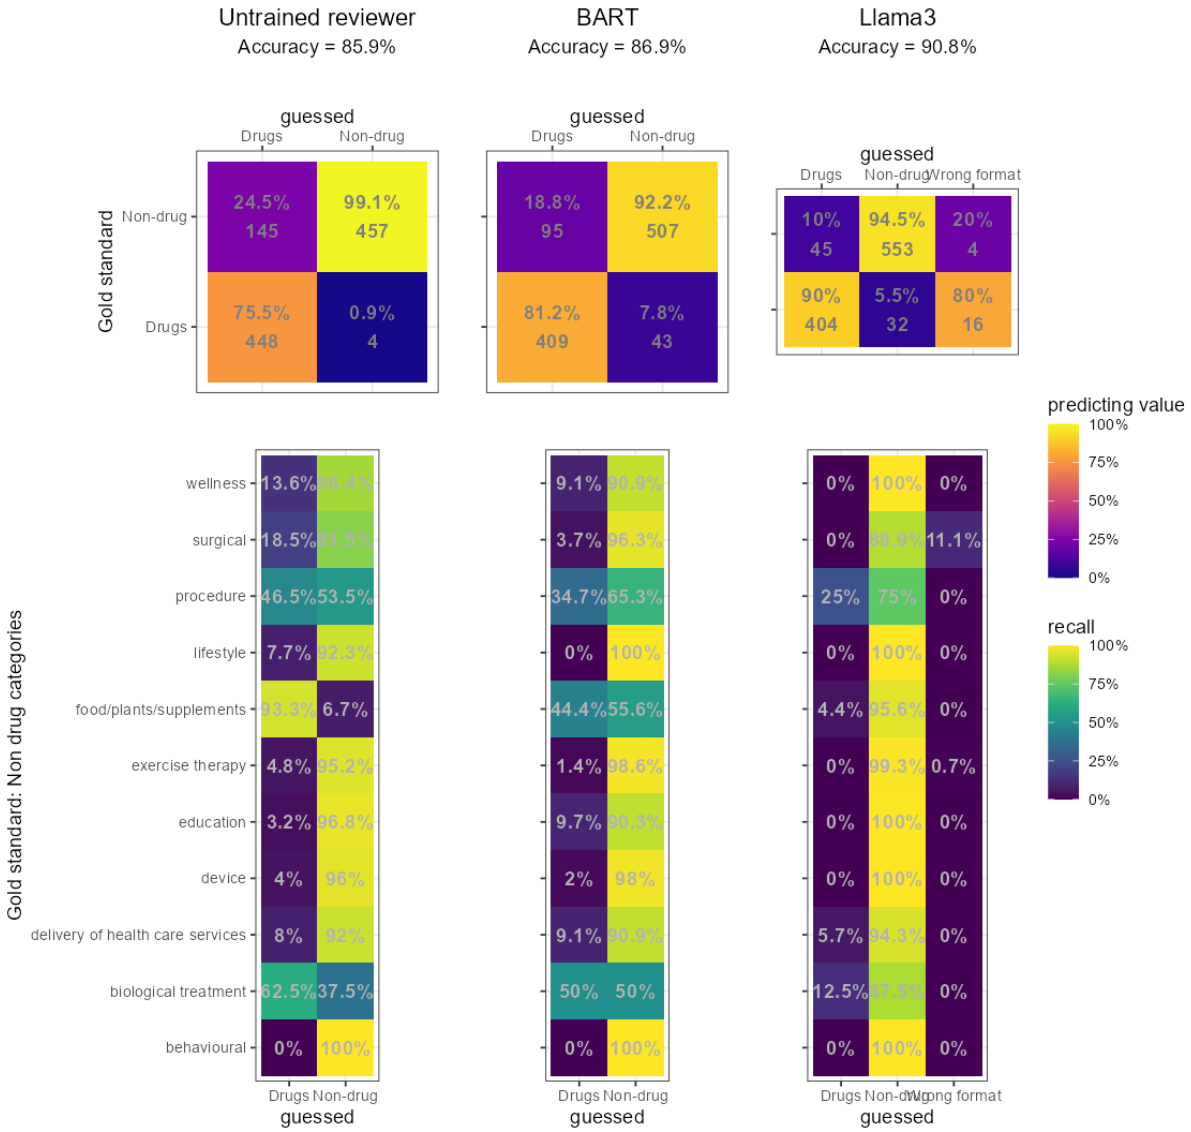
[a]RCT: randomized controlled trial.

[b]Detailed information about the labels used are in supplementary Table S2, and in supplementary table S3 in Multimedia Appendix 1 for prompts.

[c]Sum of correct outcomes according to the gold standard divided by the total number of abstracts classified.

[d]Proportion of abstracts properly classified as drug intervention.

[e]Proportion of abstracts properly classified as nondrug intervention.



[f]Average of F1 for each label. F1 is the harmonic mean of precision and recall.

The nontrained reviewer reached 85.9% accuracy (95% CI: 83.6% - 87.8%), with a PVD lower than those obtained with AI models (75.6%; 95% CI: 72.0% - 78.9%) but a higher PVND (99.1%; 95% CI 97.8% - 99.7%). When looking specifically

XSL•FO
RenderX

at nondrug interventions, both the nontrained reviewer and BART had suboptimal performance for trials involving procedures (eg, intra-articular injections), food compounds, vitamins, supplements, or biological treatments. These misclassifications were not resolved by using explicit labeling of all nondrug categories (labeling strategies 6 and 7, see supplementary table S2 in Multimedia Appendix 1). Llama3 8B, aided by detailed prompts, properly classified food/supplements as nondrug and performed better in general at classifying drug interventions (Figure 2, supplementary table S6 in Multimedia Appendix 1).

Figure 2. Performance metrics when classifying abstracts between "drug" or "non-drug" interventions, for the untrained reviewer (left column), the BART-based zero-shot classifier (middle column) and Llama3 8B model (right column).

When testing the zero-shot classifiers on the eleven categories of nondrug intervention, the classifier performed globally poorly with discrepant results between categories, with some, such as "surgical," reaching as high as 92.6% (95% CI 76.6% - 97.9%) accuracy, when others such as "wellness" or "device" had a zero or close to zero accuracy (see Table S7 in Multimedia Appendix 1 for full details).

Discussion

Principal Findings

Our study found that zero-shot classifier models can reach 85% - 90% accuracy on a simple binary classification task and 85% macro F1, despite not being trained on medical or rheumatology-specific data. Meta's BART model was the least sensitive to changes in label phrasing and produced the best overall performance when using simple two-category labels. Its accuracy was comparable to that of an untrained human reviewer and slightly lower than that of Llama 3 8B. Given its ease of use and small computational footprint, BART is a practical option for abstract classification tasks in resource-limited settings.

Both zero-shot classification models struggled to classify RCTs testing procedures, food/supplements, or biological treatment as drugs. These interventions resemble drug-based treatments (eg, supplements, biologics) or involve drugs administered through procedures, yet differ by requiring specialized expert

XSL•FO
RenderX

actions (eg, injections, ultrasound guidance). This nuance created difficulties for both the zero-shot models and the untrained reviewer. Adjusting label phrasing did not resolve these errors, likely because zero-shot models cannot use detailed task instructions. For Llama3 8B, the effect of prompt design was more nuanced: providing context improved accuracy only in the two-category setting, while the number of categories influenced the balance between predictive values for drugs and nondrugs. It is expected that more advanced LLMs may reduce such misclassifications when provided with explicit explanatory prompts. Zero-shot classifiers were unable to reliably handle multi-label or more complex classification tasks, for which high-performance LLMs remain more suitable.

Comparison to Prior Work

Our results align with studies evaluating RCT abstracts using trained machine learning models [26], or prompt-based LLMs [27], which suggest these methods could supplement a reviewer for simple classification tasks. Recent work [28] shows that bigger models (Llama3 70B) can reach 95% accuracy on the same classification task, albeit at substantially greater computational cost, and that aggregating outputs from multiple LLMs can exceed human-level performance. Nevertheless, expert reviewers remain essential to supervise the process and prevent inappropriate exclusion or misclassification of studies [29].

Strengths and Limitations

This study analyzed over 1000 rheumatology RCT abstracts, enabling precise estimates of model performance. It also examined the details of the subtypes of nondrug interventions, to allow a good understanding of where humans and LLM models misclassify. The zero-shot models presented are free to use, available and stable for more than three years, running on standard computers. Besides, we provide the prompts and data used in our study, enabling replication of our methods in different medical fields.

Several limitations should be noted. First, we evaluated only a single, simple binary classification task within rheumatology. Thus, the present results may not generalize to other fields or to multi-label tasks. Second, LLMs are prone to a rapid development and better performance could be obtained using more recent models. Finally, the reference human performance is based on a single untrained reviewer, which may not reflect broader human variability, though the observed error rate aligns with typical rates reported for systematic review screening [30].

Conclusion

Zero-shot classification models can classify with accuracy similar to a scientist untrained in evidence synthesis, perform well on simple classification tasks, while not requiring specific training for the scientific domain or high-performance computing. These tools have the potential to facilitate classification processes of systematic reviews or bibliometric studies by replacing one reviewer for simple classification tasks.

Abstract

Background: Concept mapping (CM) is a widely used mixed method research approach for structuring and visualizing complex ideas across various fields, such as the health sciences. A critical bottleneck in the CM process is the idea synthesis phase, which remains labor-intensive, subjective, and consequently challenging to scale for large datasets.

Objective: In this study, we propose IdeaDistiller, a semiautomated solution based on semantic clustering to optimize the idea synthesis step while maintaining methodological rigor through a human-in-the-loop approach.

Methods: Using 9 health care–related datasets in English and Swedish, we systematically evaluated different embedding models, dimensionality reduction techniques, and clustering algorithms to identify robust and reproducible parameter settings for the proposed approach. IdeaDistiller clusters participant-generated ideas based on semantic similarity to identify similar ideas with different wording, suggests representative and unique ideas per cluster, and provides coherence scores and sorted outputs to aid manual validation.

Results: Our findings suggest that IdeaDistiller may substantially reduce the manual effort involved in idea synthesis while preserving quality and transparency. However, human expertise remains indispensable for validating and refining cluster outputs.

Conclusions: Integrating semiautomated methods into the CM workflow offers significant potential for improving the efficiency, scalability, and rigor of the CM process. Building on our work will enable the exploration of larger multilingual datasets and integration into future CM studies.

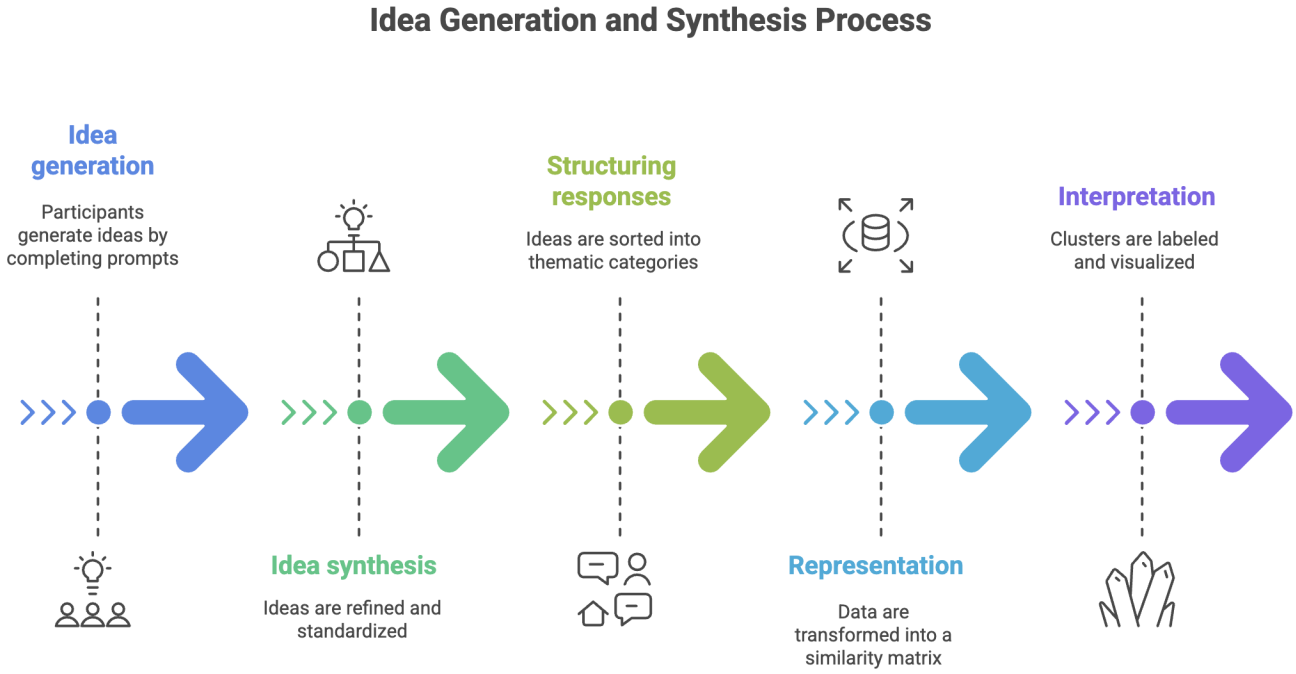
KEYWORDS

concept mapping; semantic clustering; topic modeling; bidirectional encoder representations topic modeling; BERTopic; human-in-the-loop; qualitative research automation

Introduction

Background

Concept mapping (CM) is a structured research method designed to visualize and organize thoughts, ideas, or knowledge concerning a specific topic by creating graphical representations of concepts and their interrelationships [1]. Widely used in disciplines such as education, psychology, health sciences, and other social sciences, CM is an integrative mixed methods research methodology for exploring and analyzing complex conceptual domains. It includes both qualitative and quantitative data collection and analysis in sequential steps, where each step builds on the previous one, as described below [2]. One of the strengths of this method is the active involvement of stakeholders throughout the process. Depending on the project and the research question, the participants can be more or less involved in all stages described in the following sections [3].



CM Methodology

After the initial preparation stage, the CM methodology typically comprises the following sequential stages, as shown in Figure

XSL•FO
RenderX

1. Normally, idea synthesis is part of idea generation, but for clarity in this study, it is defined here as an additional step in the process.

Figure 1. Process of concept mapping methodology.

Idea Generation

The research team formulates a focused research question, typically structured as an incomplete sentence or prompt. Participants individually complete this sentence, usually generating between 1 and 5 responses, referred to as ideas. Given the volume of data collected, a subsequent idea synthesis process is necessary to manage and refine the input so that the ideas are manageable for the sorting step.

Idea Synthesis

Idea synthesis involves a series of refinement steps to produce a concise yet representative set of ideas for further analysis, referred to as the set of unique ideas for the study. This process includes eliminating identical or highly similar ideas, preserving unique and relevant contributions, removing off-topic ideas, and segmenting complex or compound ideas into more granular units. Additionally, grammatical and typographical corrections are applied to standardize the text. The overarching goal is to reduce the initial set of ideas to a manageable number, typically no more than 100 distinct ideas, while preserving the conceptual breadth and diversity of the original input [1,4].

Structuring the Ideas

A subset of participants individually sorts the unique ideas into thematic categories, ensuring that each idea is placed in only 1 category. This process can be done manually or, as in most cases, using designated card-sorting software. Participants also assign descriptive labels to the categories they create.

Representation

The sorting data are transformed into a similarity matrix that captures how often pairs of ideas are grouped. Multidimensional scaling is then applied to represent these similarities or dissimilarities on a 2D plane. The multidimensional scaling output is subjected to hierarchical cluster analysis to develop a hierarchy of clusters. The research team reviews successive cluster solutions to determine the optimal number of clusters, selecting the most meaningful and interpretable configuration while balancing sufficient yet manageable detail [5]. Depending on the project, participants can also be part of this stage, as well as in the final step, interpretation.

Interpretation

Clusters are labeled based on the category names suggested during sorting. The final concept map visually presents the ideas' spatial coordinates and delineated clusters, offering a structured and interpretable visualization of the conceptual domains.

The principal objective of CM is to provide a clear, visual representation of a conceptual space and set of ideas, thereby enhancing the understanding of underlying structures and relationships among the ideas. A defining characteristic of CM is the active engagement of stakeholders at multiple stages of the research process, including data collection, analysis, and interpretation, making it highly compatible with participatory research methodologies [3].

Despite its structured framework, CM poses a number of challenges. Criticisms, even from the originators, include the potential for subjectivity and bias, particularly during qualitative phases, as well as the method's high demands on time and resources for researchers and participants [6]. The idea synthesis phase is particularly concerning, as it involves refining, consolidating, and preparing ideas for subsequent sorting and analysis [4].

While the core CM methodology is well-established, the growth of large-scale, digitally mediated data collections necessitates

XSL•FO
RenderX

more efficient, rigorous, and partially automated approaches to the idea synthesis step.

Related Work

The idea synthesis phase in CM has traditionally relied on manual, labor-intensive procedures conducted by research teams through iterative consensus-building exercises. A range of approaches has been documented in the literature. For instance, Ashe et al [7] describe a multistage process in which individual review of items was followed by several collaborative meetings to finalize the list of unique ideas. Similarly, Windsor [8] employed 5 independent coders to identify redundancies, after which consensus was reached on the items to retain. Hassmiller Lich et al [9] introduced a more advanced strategy by comparing an initial set of 830 ideas with a final curated set of 97 to assess representativeness. Pantha et al [2] conducted a review indicating that while approximately one-third of studies provided an explicit rationale for their sample size, three-quarters described their idea synthesis process in detail. However, concerns about methodological transparency remain. For example, McLinden [10] criticized the often insufficient reporting of synthesis procedures, arguing that such omissions hinder the ability to evaluate the representativeness and validity of the final idea sets. These studies underscore the variability in practice and the need for more standardized and transparent approaches to idea synthesis in CM research.

Despite growing awareness of the importance of rigorous idea synthesis, inconsistencies persist in methodological reporting and implementation. Even though digital technologies have enabled larger-scale data collection, they have also further compounded the challenges and increased the burden on researchers to conduct transparent and methodologically sound synthesis. While Kane and Trochim [1] emphasized that CM relies on a combination of technological support and human qualitative judgment—a "high-tech, high-touch" approach—there is a growing need for methods that blend automation with interpretive rigor without compromising the qualitative depth of the process.

To address all the aforementioned challenges, this study presents the development and evaluation of IdeaDistiller, a semiautomated tool designed to support the idea synthesis phase of CM. By leveraging machine learning techniques, our approach aims to reduce researchers' burden, enhance methodological transparency, and preserve qualitative depth. We demonstrate the tool's utility through a series of exploratory benchmarks across diverse English and Swedish datasets, providing a framework for more efficient and reproducible conceptual analysis in large-scale studies.

Methods

Design Rationale and Requirements

Recognizing that idea synthesis is inherently a qualitative task requiring nuanced judgment, we adopted a human-in-the-loop (HITL) approach, integrating automated techniques with expert oversight. This strategy aligns with the recommendation by Kane and Trochim [1] that, while technology can support the CM process, human interpretive engagement remains essential. We acknowledge that the distillation of ideas is not a discovery of an objective "ground truth" but rather a subjective interpretive process in which granularity and categorization depend on the researcher's perspective. Overall, we aimed at developing a tool that fulfills the following requirements:

- Redundancy reduction: identifying and eliminating duplicate or semantically similar ideas to minimize repetition within the idea set.
- Semantic alignment: assessing and organizing ideas by measuring their semantic similarity to each other.
- Preservation of unique contributions: safeguarding novel and valuable ideas to maintain the richness and diversity of participants' input.

Our approach is based on the principle that all ideas can be clustered into semantically coherent groups, where each group consists of ideas conveying the same or a similar idea in different formulations, and the main idea for each group is distinct from all other groups. Creating such a clustering enables the researcher to subsequently extract one representative idea from each group, ensuring that all extracted ideas collectively represent the diversity of the complete dataset.

We explored several approaches to clustering ideas based on their semantic similarity. In the following sections, we describe the data, clustering methods, and evaluation metrics used, as well as the output created to facilitate the easy integration of human feedback.

Datasets

This study used data from various independent CM studies. Each dataset comprised two components: (1) the complete set of raw ideas provided by participants and (2) the manually identified set of unique ideas, which served as the reference for evaluating the performance of the computational methods developed.

In total, 9 datasets were analyzed: 6 in English and 3 Swedish datasets. The English datasets cover diverse topics within the health and health care domains, including obesity, stress, medical services [11], drug abuse [12], and aspects of suicide screening [13]. The datasets covering the first 3 topics originally contained Spanish ideas collected from Latino participants in Cincinnati; however, their English translations were used in this study. The Swedish datasets addressed cancer rehabilitation [14], the support structures available to patients and their families (the "Kraftens hus" initiative) [15], and the use of development plans as a tool in patient care [16].

Before clustering, exact duplicate entries, which were particularly frequent among shorter ideas, were removed as they would not contribute additional unique ideas. However, within our approach, it is possible to retain duplicates to allow for a quantitative follow-up analysis.

Table 1 provides an overview of the datasets, along with their sizes and the number of manually identified unique ideas. The datasets vary in thematic focus, language, participant demographics, and dataset size, providing a robust basis for evaluating the generalizability and performance of the proposed computational approach.

XSL•FO

Table . Datasets used in the study.

Dataset	Language	Original ideas[a]	Unique ideas
Obesity	English	406	100
Stress	English	670	97
Medical services	English	697	96
Drug abuse	English	162	75
Results of suicide screening	English	462	80
Important parts of suicide screening	English	415	80
Cancer rehabilitation	Swedish	525	67
Cancer support center	Swedish	121	72
Development plans	Swedish	375	100

[a]Number of original ideas after the removal of duplicates.

Semantic Clustering

Semantic similarity identifies latent patterns within textual datasets by uncovering recurring groups of words that represent underlying themes or topics. Traditional methods, such as latent Dirichlet allocation [17,18], primarily rely on word frequency statistics to discover topics, which makes them limited in their ability to find semantic similarity in sentences with very different wording. Therefore, our approach builds on the BERTopic (bidirectional encoder representations topic modeling) framework [19-21], a technique that incorporates textual relationships and semantic meaning.

BERTopic follows a flexible pipeline comprising several steps. Since our primary interest lies in grouping each idea into a semantically coherent cluster, we focus on the first three stages of the pipeline: (1) embedding the ideas into a dense vector space, (2) reducing the dimensionality of the embedding space, and (3) clustering the embedded original ideas to form semantically related groups.

The core principle of BERTopic is embedding sentences into a high-dimensional embedding space to transform textual data into dense vector representations before clustering them. Semantic similarities between texts are reflected by their proximity in the vector space. These embeddings allow for a more nuanced understanding of similarity beyond simple word counts. In this study, we used several different pretrained embedding models, adapted to different languages, to create the sentence embeddings.

Through this process, all ideas are assigned to clusters, each containing original ideas with similar semantic meanings. CM researchers can then extract one or more representative ideas from each cluster. Each of the 3 mentioned steps offers multiple methodological choices, and we selected the specific methods that showed the most robust results across our exploratory study. While this process provides a good starting point, manual refinement is still needed. To simplify this task for the researcher, we additionally sort all ideas based on their cluster assignment and the semantic similarity between the clusters; that is, we organize the clusters such that those covering similar themes are positioned closer together in the output. To achieve this, we applied hierarchical clustering to the topic representations and used the resulting dendrogram to order the output.

Evaluation Metrics

Standard evaluation metrics for topic modeling, such as coherence scores and perplexity, assess the semantic consistency and interpretability of the identified topics. In our case, however, the availability of manually curated unique ideas from previous CM studies enabled more targeted evaluation measures. Rather than measuring "correctness" in an absolute sense, these metrics quantify the degree of alignment between the computational output and a specific, human-led reference synthesis. To quantify the performance of IdeaDistiller, we developed 2 coverage-based metrics that assess the alignment between the computationally generated clusters (without human refinement) and the expert-identified unique ideas. These metrics are based on the heuristic that an optimal alignment with the reference standard would produce as many clusters as there are unique ideas, with 1 unique idea representing each cluster. Therefore, the metrics used consider the overlap between computational clustering and curated unique ideas, which is the number of clusters containing at least 1 unique idea. The 2 metrics are defined as follows:

$$\text{Coverage of clusters to unique ideas} = \text{overlap}_{n_unique_ideas}$$

where n_unique_ideas represents the total number of manually curated unique ideas. This metric evaluates the proportion of unique ideas represented by the computational clusters. In other words, this metric tells us how many of the unique ideas we would obtain if we extracted exactly 1 unique idea from each cluster and how many this computational approach would miss:

$$\text{Proportion of clusters with unique ideas} = \text{overlap}_{n_clusters}$$

where n_clusters is the total number of computationally generated clusters. This metric assesses the proportion of clusters containing at least 1 manually identified unique idea, highlighting the extent to which the computational clusters align with expert curation. A value below 1 indicates clusters without a unique idea, which can be either due to suboptimal clustering (ie, the additional clusters do not consist of new ideas but should be a part of another cluster containing a unique idea) or due to

XSL•FO
RenderX

the clustering identifying new aspects that the human evaluator has not considered.

As an example, consider a scenario with 100 clusters and 96 unique ideas, where 62 clusters contain at least 1 unique idea. In this case, the 2 metrics are calculated as follows:

$$\text{Proportion of Clusters with Unique Ideas} = \frac{62}{100} = 0.62$$

$$\text{Coverage of Clusters to Unique Ideas} = \frac{62}{96} \approx 0.65$$

This example indicates that 38% (38/100) of clusters do not contain a manually curated unique idea, while 35.41% (34/96) of unique ideas are not captured when extracting 1 idea per cluster. Together, these metrics provide a comprehensive assessment of the representativeness and completeness of the clustering results. It is important to note that a lack of perfect correspondence (values below 1) does not necessarily indicate "error" by the model. Because unique ideas in CM are interpretive and dependent on the researcher's chosen level of granularity, discrepancies may represent valid alternative structures. Therefore, these metrics should be interpreted as a measure of how closely the IdeaDistiller mimics the specific synthesis decisions made by previous expert researchers.

While these 2 metrics aim to evaluate the results from 2 different perspectives, we applied the pipeline by choosing the number of clusters to be equal to the number of manually curated unique ideas, which resulted in identical values for both metrics. Therefore, in the following, we will report only one of the metrics.

Topic Coherence

Although coherence was not used to select the best-performing model, we computed a coherence score for each idea to support researchers during the manual evaluation phase. In our setting, coherence measures the degree of semantic similarity among all ideas within the same cluster, with higher coherence indicating greater internal consistency. This score can help assess how well an idea fits within its assigned cluster, allowing for special focus on ideas with low coherence scores during the postcomputational or refinement phase. In practice, we computed embeddings for all individual ideas using a pretrained sentence-BERT (bidirectional encoder representations from transformers) model [22]. The coherence score of each idea is then calculated as the cosine similarity between its embedding and the mean embedding of all ideas in its assigned cluster.

Generated Output

Our approach, IdeaDistiller, produces an output file designed to support CM researchers during the idea synthesis phase. This file includes a comprehensive table listing all participant ideas alongside the results of the computational analysis, facilitating manual review and refinement.

The output contains the following components:

- Cluster labels: each idea is accompanied by an assigned cluster label, indicating the group to which the idea belongs based on semantic similarity.
- Sorting: to aid manual evaluation, the ideas are sorted according to their cluster assignments (ie, similar ideas should appear close to each other in the file), and clusters are organized based on semantic similarity. This structure enables researchers to easily assess whether adjacent clusters are sufficiently similar to warrant merging, potentially representing them with a common, unique idea.
- Suggested unique ideas: the file provides a computationally suggested representative idea for each cluster. When available, original, manually curated, and unique ideas are also included for comparison. This feature is useful when applying the tool to previously filtered datasets or when evaluating the alignment between manual judgments and computational outputs.
- Coherence scores: semantic coherence scores are provided for each idea, offering insights into the internal consistency and quality of the clustering process. A low coherence score for an idea may indicate a poor fit within its assigned cluster and can prompt further review and adjustment.

These outputs offer researchers a structured foundation for conducting a comprehensive evaluation and refinement of the results to finalize the idea synthesis process.

Ethical Considerations

All projects that contributed data for this work have been ethically assessed and/or approved. Further details can be found in the respective manuscripts [11-16]. For this study, permission to use the data was granted by the data collectors, and no actual outcomes are reported. The data were used exclusively for the development and testing of the tool and are neither required for its further use nor can they be retrieved from the tool.

Results

As outlined in the *Datasets* section, the datasets used vary in characteristics such as size, topic, language, and participant demographics. This diversity allows us to evaluate the usefulness and generalizability of the proposed approach under diverse conditions.

Experiments and Parameter Selection

Sensitivity Analysis and Parameter Exploration

Given that a definitive "ground truth" for idea synthesis is rarely available in real-world research contexts, our experimental grid is intended as a sensitivity analysis. We aimed to demonstrate the robustness of the IdeaDistiller framework across a wide range of configurations, rather than to nominate a single "optimal" model for all future applications. We aimed to maintain a one-to-one correspondence between clusters and unique ideas and selected the number of clusters to match the number of unique ideas in each dataset using the metrics described above.

Using BERTopic, we explored different parameter configurations for the three main components of the computational pipeline: (1) embedding models, (2) dimensionality reduction methods, and (3) clustering algorithms.

The specific parameters and methods tested are summarized in Table 2. The total number of experiments conducted per dataset is as follows:

XSL•FO
RenderX

Total experiments=(Number of clustering algorithms)×(Number of embedding models)×(Number of dimensionality reduction methods×Number of dimensions)

Accordingly, the datasets for the experiment are as follows:

- For the English datasets: 3×3×(2×9)=162 experiments per dataset
- For the Swedish datasets: 3×2×(2×9)=108 experiments per dataset

This allowed us to assess the impact of different parameters and evaluate performance under diverse configurations. Our results showed that no single parameter configuration consistently yielded the best performance across all datasets, reflecting the heterogeneity of the datasets.

Table . Overview of the different parameter settings that were tested.

Parameters	Options
Clustering	• K-means clustering, agglomerative clustering, and spectral clustering.
Embedding	• English: fastText[a], SentenceTransformer, Flair[b] • Swedish: KB-BERT[c], SentenceTransformer
Dimensionality reduction	• Truncated SVD[d], PCA[e] (with dimensions varied from n=2 to n=10)

[a]fastText: Facebook artificial intelligence word embedding model.

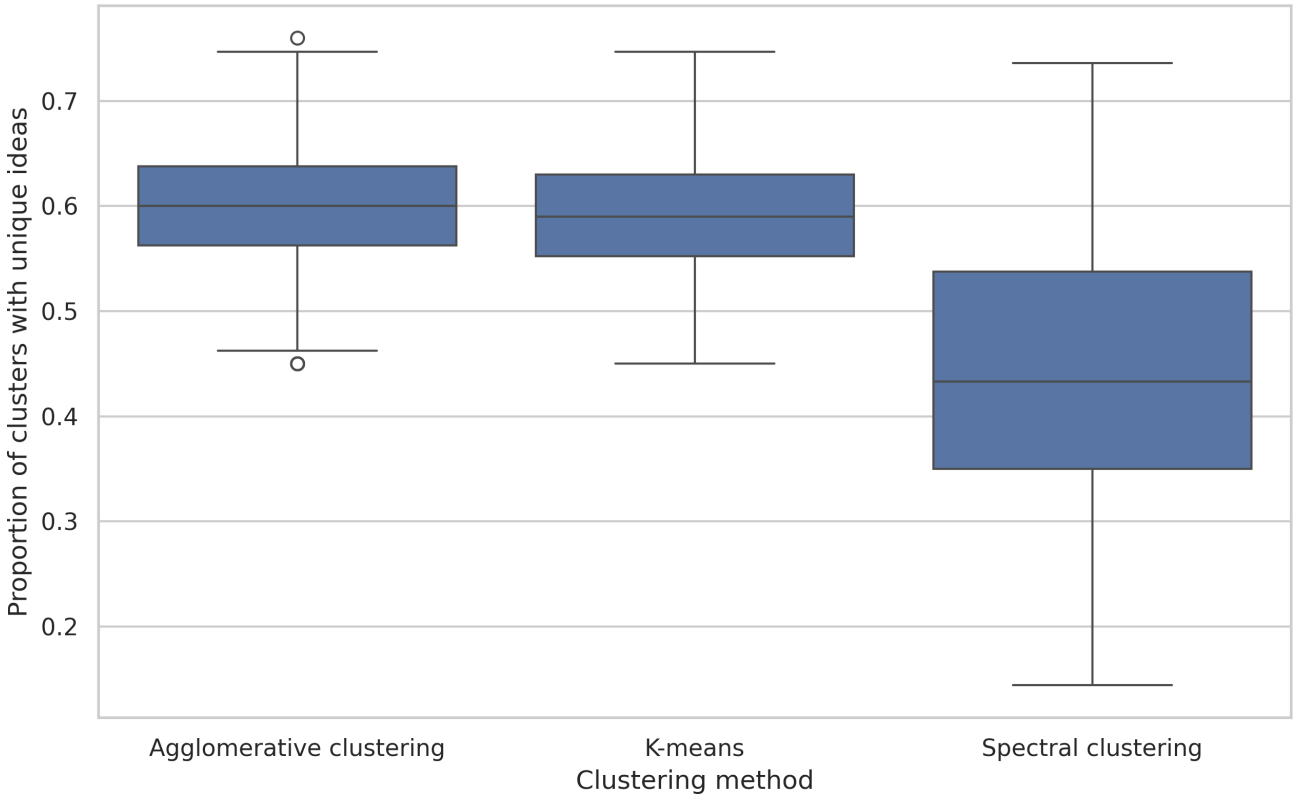
[b]Flair: natural language processing embedding framework.

[c]KB-BERT: Kungliga Biblioteket bidirectional encoder representations from transformers.

[d]SVD: singular value decomposition.

[e]PCA: principal component analysis.

Clustering Algorithm Selection



We evaluated multiple clustering algorithms to determine the most suitable method for our approach. We explored hierarchical density–based spatial clustering of applications with noise due to its ability to discover clusters of varying densities without requiring a predefined number of clusters. However, initial trials resulted in very high numbers of clusters and outliers, reflecting the complexity of the dataset. We, therefore, concluded that the absence of explicit control over the number of clusters rendered hierarchical density–based spatial clustering of applications with noise less appropriate for our application.

Overall, we compared the performance of 3 clustering algorithms across all datasets: k-means, agglomerative clustering (with Ward linkage), and spectral clustering.

As illustrated in Figure 2, spectral clustering appeared to show less stable performance and tended, on average, to yield lower results compared with the other methods. In contrast, k-means and agglomerative clustering seemed to perform at broadly similar levels across the experiments. These impressions are based on visual inspection of the box plots and should, therefore, be interpreted with appropriate caution.

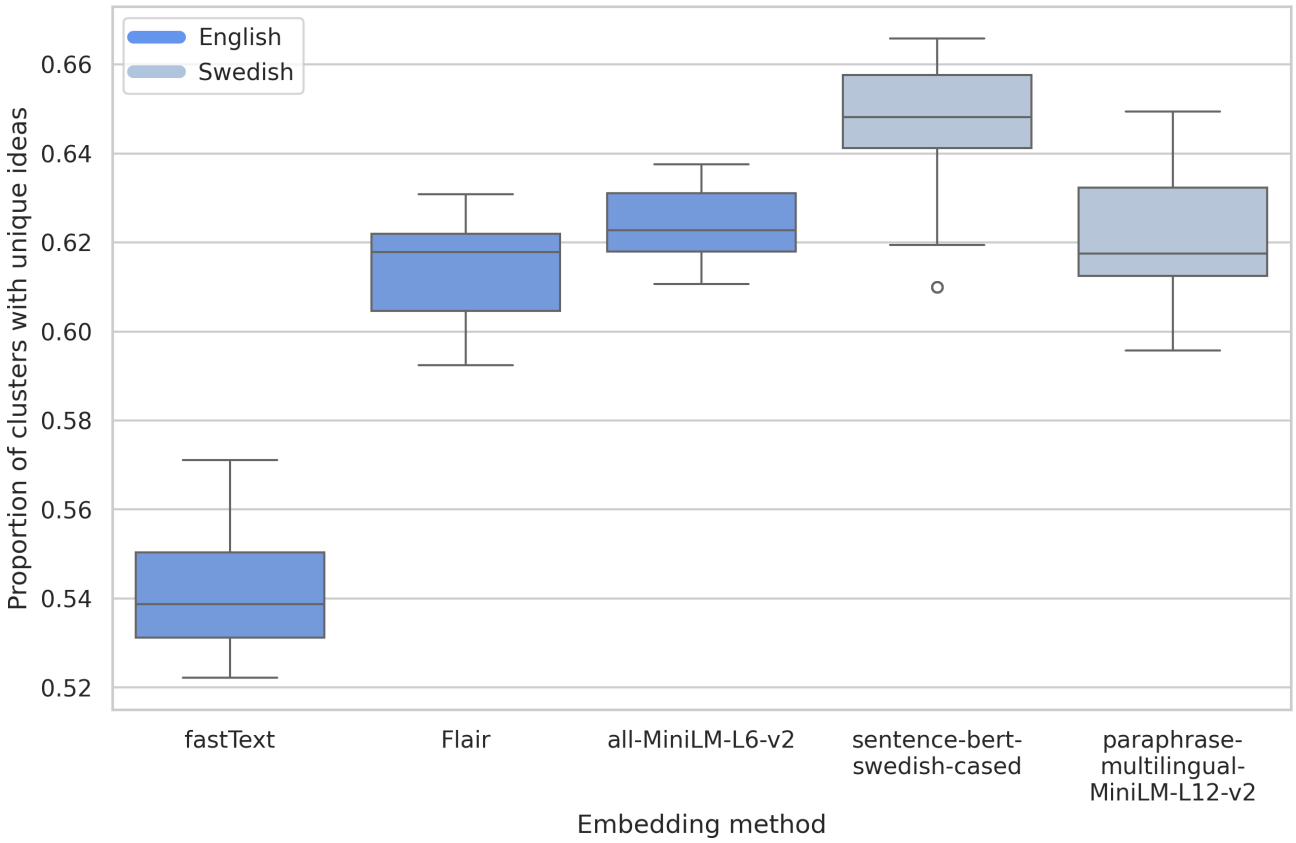
XSL•FO
RenderX

Figure 2. Box plots of the 3 clustering algorithms (k-means, agglomerative clustering, and spectral clustering) showing their proportions of clusters with unique ideas.

We suggest agglomerative clustering as a practical baseline configuration for the pipeline. While k-means is a robust alternative, its sensitivity to random initialization can yield varying outcomes across different runs unless specific measures—such as fixed seeds or multiple restarts—are implemented. We prioritized agglomerative clustering primarily for its inherent determinism, as well as its established use within the field, contributing to its acceptance among researchers. In the following sections, we report the performance based on agglomerative clustering only, excluding the other clustering approaches.

Embedding Models

Embedding models are used to represent sentences as numerical vectors within a high-dimensional space, where the proximity between vectors captures semantic similarity. Various embedding models exist, often tailored to specific languages, which can significantly influence clustering performance.



For the English datasets, we evaluated 3 models: fastText, SentenceTransformer (all-MiniLM-L6-v2), and Flair. For the Swedish datasets, we tested KB-BERT (Kungliga Biblioteket bidirectional encoder representations from transformers; bert-base-swedish-cased) and SentenceTransformer (paraphrase-multilingual-MiniLM-L12-v2).

Our experiments demonstrated that, for the available English datasets, the SentenceTransformer (all-MiniLM-L6-v2) showed the highest mean performance within this exploratory study, as shown in Figure 3, yielding better alignment with the manually curated unique ideas. For our Swedish datasets, KB-BERT (bert-base-swedish-cased) showed the highest performance; however, given the small number of Swedish datasets, these results should be interpreted as indicative rather than definitive (Figure 3). Nevertheless, we selected KB-BERT because its training on Swedish-specific corpora is expected to improve its ability to capture linguistic nuances unique to the language.

In the following sections, we report the performance of the results based on agglomerative clustering combined with the selected embedding models.

Box plots of embedding models showing their proportion of clusters with unique ideas using agglomerative clustering on the English and Swedish languages. fastText: Facebook artificial intelligence word embedding model; Flair: natural language processing embedding framework; MiniLM: miniature language model.

Dimensionality Reduction

Dimensionality reduction is applied to high-dimensional embeddings to reduce computational complexity while preserving the most relevant semantic information. Different techniques emphasize the preservation of distinct aspects of the original data structure, which has an impact on downstream clustering performance.

Although uniform manifold approximation and projection is the default technique in BERTopic and often yields high-quality embeddings, we excluded it from our experiments. While stochastic methods like uniform manifold approximation and projection can be made reproducible through fixed random seeds, we opted for deterministic alternatives (truncated singular value decomposition [SVD] and principal component analysis) to ensure consistent results across different computational environments and versions. This choice was made to prioritize practical deployment and ease of use, and does not imply that nondeterministic methods are theoretically inferior for this task.

Each method was evaluated across a range of dimensions (from n=2 to n=10), with results summarized in Figures 4 to 6-6. Language-specific analyses revealed that for our English datasets, the best performance seemed to be achieved by using truncated SVD with a higher dimensionality (n=10), whereas for the available Swedish datasets, truncated SVD with a lower dimensionality (n=6) showed, on average, slightly better results. However, given the small number of datasets analyzed (6 in English and 3 in Swedish) and the associated variability in the results, we recommend using truncated SVD with a lower dimensionality (n=6) across both languages. This setting seems to provide more robust and stable performance across all the datasets, whereas a higher dimensionality (n=10) exhibited greater variance in clustering quality when considering both English and Swedish datasets.

With these selected methods, the average performance of IdeaDistiller is 0.63 for English datasets and 0.67 for Swedish datasets, meaning that 63% (n=100) and 67% (n=100) of clusters, respectively, contain at least 1 manually curated unique idea, while 37% (33% for Swedish) of the clusters do not contain a unique idea. The latter can be due to suboptimal cluster structure; that is, those clusters could be merged with other existing clusters; however, in some cases, these clusters might provide new, additional perspectives on the topic. These results indicate an existing correlation between manual and computational results, meaning that IdeaDistiller can support the researcher in their analysis. At the same time, they also showcase that the output of IdeaDistiller will need human revision to ensure methodological rigor. The clustered and sorted lists of original ideas produced by IdeaDistiller therefore represent an intermediate step in the idea synthesis process. While this tool does not provide a final solution for idea synthesis, it offers structural assistance and reduces cognitive load on the researchers.

Number of Clusters

In our previous experiments, the number of clusters, *k*, was always set to the number of manually curated unique ideas to evaluate how well IdeaDistiller reproduces these results. With a new CM study, however, this value will not be available, but the researcher might instead use a few standard values. To investigate the effect of different cluster numbers on the results, we varied *k* between 70 and 110 while keeping the suggested options for all other parameters. The results were evaluated using both the proportion of clusters with unique ideas (called proportion) and the coverage of clusters to unique ideas (called coverage), as well as the coherence score, which is independent of the manually curated unique ideas. Figure 7 shows that, due to the way they were constructed, proportion and coverage have an inverse relationship, crossing at the true value of manually curated ideas. The effect of a change in *k* depends on the dataset. Within the considered range of *k*, the change in the proportion score lies in the range of 0.12 to 0.18, while the coverage score shows slightly higher differences, ranging from 0.1 to 0.21 across our datasets. The average coherence score for each dataset monotonically increases with the number of clusters. This is expected, since it measures how closely connected the ideas within a cluster are, with more clusters allowing for better separation of the different aspects covered by the dataset. Based on these results, we generally suggest choosing *k* slightly higher than the number of unique ideas one is aiming for. This way, the user obtains more coherent clusters. At the same time, the clusters become smaller and possibly overlapping in content. To address this, IdeaDistiller provides an output file where the clusters are sorted semantically, such that similar clusters are grouped together and can easily be identified when reviewing the list.

XSL•FO
RenderX

Figure 7. Impact of cluster number (*k*) on proportion, coverage, and coherence scores across 9 datasets.

Coherence Calculation

To provide a concrete example of how coherence scores reflect the semantic unity of the output, Table 3 illustrates a cluster (ID 86) from the English dataset "Stress." The scores represent the cosine similarity between individual statements and the cluster centroid. Higher scores (eg, 0.76) correspond to statements that align closely with the core topic, while lower scores (eg, 0.52) indicate less closely related concepts like "support." This allows researchers to quickly validate the thematic consistency of the tool's output and identify potential outliers.

Table . Representative clusters and associated coherence scores, illustrating semantic proximity to the cluster centroid.

Idea	Coherence score
Look for more information	0.76
Have more information	0.70
More information	0.60
More support	0.52

Illustrative Case Study

We conducted a small audit on one of the English datasets ("Drug abuse") to gain insights into the semantic clusters without unique ideas. We found that, in many cases, these clusters did not contain novel content but slight variations of already selected ideas. However, some of these clusters contained ideas that could be deemed "novel" depending on the focus of the study. One example is 3 statements on background checks ("give background checks when you apply for a license," "background checks on patients," and "ask for consensual

XSL•FO
RenderX

background checks to know if a person is on drugs or has experienced…"), with none of them being included in the list of unique ideas. For the given study, these ideas were considered out of scope and at the same time loosely related to 2 retained unique ideas ("The federal government should run a program that takes convicted drug dealers/users into mandatory rehab" and "Hold addicts accountable for staying clean and away from drugs"). However, depending on the focus of the study, an idea specifically about background checks could be a useful addition. This example illustrates how scope and granularity decisions shape what is included as a unique idea and shows that the tool provides a valuable starting point for idea synthesis. However, it remains independent of these study-specific decisions and therefore does not replace researcher judgment.

Discussion

Principal Findings

This study shows that semantic clustering can be used to support the idea synthesis process in a CM study. For 9 different datasets, IdeaDistiller was able to reproduce expert synthesis with an average alignment of 64%, highlighting both the value of the tool in organizing the original ideas as well as the need for expert involvement in the curation process. The latter is facilitated by providing sorted lists of all original ideas, based on which the results can easily be adjusted.

Topic modeling, specifically BERTopic, has been successfully applied in various contexts, such as Twitter (subsequently rebranded X) tweets [20]. Our study extends these findings and demonstrates the potential to enhance the CM process, specifically the idea synthesis step, using various health care–related datasets. IdeaDistiller, our proposed approach, significantly reduces the manual effort traditionally required to identify and group similar ideas by automating the clustering and thereby presorting the participant-generated ideas. This automation enables researchers to allocate more time to the subsequent analysis and interpretation of ideas rather than the manual data processing phase.

Moreover, the approach provides additional outputs, including coherence scores and semantically sorted clusters, which facilitate a more structured and efficient review process. IdeaDistiller is designed to support CM researchers, while keeping them in control of their own analysis. Extracting final, unique ideas from each cluster still necessitates human judgment, and suggested representative ideas require expert validation, particularly in complex or sensitive domains such as health care.

Our findings align with Prescott et al [23], who argue that while generative artificial intelligence (AI) can significantly reduce time and resource demands, hybrid approaches incorporating HITL validation remain necessary. Similarly, Morgan [24] concludes that although AI tools demonstrate great promise for supporting coding tasks, integrating AI with qualitative data analysis presents challenges. In agreement with Prescott et al [23], human analysts retain a crucial advantage in identifying nuanced meanings and interpreting context-specific themes—an essential skill for rigorous qualitative research.

Integrating an automated step into the idea synthesis process offers substantial benefits for methods such as CM. These include improved scalability for handling larger datasets. We also concur with Chen et al [25], who advocate for using machine learning to identify inconsistencies and ambiguities in qualitative coding. By automating the simpler stages of coding, researchers can allocate their expertise more efficiently to the complex interpretative tasks that require theoretical sensitivity and contextual knowledge—an outcome facilitated by the tool developed in this study.

Limitations

A limitation encountered in this study was the variability in dataset sizes and languages, which posed challenges for optimal parameter tuning. Smaller datasets constrained the ability of machine learning models to generalize effectively. Nevertheless, by using stable parameter settings, we achieved consistent and satisfactory performance across most datasets.

While a HITL approach remains indispensable for analyzing complex qualitative data, developing systems that support and enhance this collaboration is a promising direction for the future evolution of the CM methodology. Further application of the approach across diverse contexts will be necessary to fully understand its capabilities and identify opportunities for improvement.

In summary, our findings suggest that IdeaDistiller can significantly streamline a previously time-consuming step of the CM process, improve scalability, and maintain reasonable accuracy. Nonetheless, human validation remains essential to ensure the quality and relevance of results in real-world applications.

Future Work

In this study, we created IdeaDistiller, a tool trained on previous CM studies. An important next step will be to use and test the tool in further real-life studies across different domains to enable continued evaluation with respect to both usability and the experience of time-saving.

Additionally, advances in explainable AI could be leveraged to improve the interpretability of clustering results by providing insights into how and why specific items are grouped together. For instance, techniques such as attention heatmaps, feature importance scores, or natural language explanations could help domain experts understand the rationale behind each cluster, thereby enhancing transparency, supporting critical evaluation, and increasing trust in the system's outputs.

Overall, the continued development of semiautomated tools, coupled with human expertise, presents a compelling path forward for improving the efficiency, scalability, and methodological rigor of CM and other qualitative research methodologies.

Abstract

Background: The accurate classification of operative notes is essential for surgical outcomes research; however, CPT code classification is notoriously nonspecific for many procedures. In such situations, the operative note (or "dictation") must be reviewed manually, a process that is labor-intensive and unsustainable. Natural language processing demonstrates tremendous potential for improving the efficiency and accuracy of procedure classification from unstructured operative notes. To date, it remains unexplored whether natural language processing can reliably differentiate between complex, multicomponent procedures, such as those involved in the care of cleft lip or palate and craniofacial anomalies.

Objective: This study aims to develop and evaluate a machine learning framework for the automated classification of operative notes for cleft and craniofacial procedures.

Methods: This single-institution, retrospective observational study used operative notes from patients undergoing cleft and craniofacial procedures at a single academic medical center from 2016 to 2024. Each note in the database had been manually classified previously. Notes were preprocessed and vectorized using term frequency-inverse document frequency. A One-vs-Rest classification framework with random forest as the base classifier was developed to categorize procedures at 3 levels: primary procedure type (cleft lip repair, alveolar bone grafting, cleft palate repair, velopharyngeal insufficiency correction, rhinoplasty, and other), procedural subtype (primary vs revision), and specific surgical technique used (eg, Fisher, Mulliken, or rotation-advancement technique for cleft lip repair). Each hierarchical level was developed and evaluated using cross-validation. To improve procedural subtype classification for classes with few samples, synthetic notes were added to the dataset. Area under the receiver operating characteristic curve (AUC), an area under the precision-recall curve, micro- and macro-averaged F_1-scores, and Hamming loss were used to assess model performance.

Results: The dataset comprised 630 operative notes from 311 pediatric patients undergoing cleft and craniofacial procedures between 2016 and 2024, with a mean age of 3.75 (range 0 - 19) years. The primary classification model achieved strong performance in distinguishing procedure types with an AUC of 0.93 (SD 0.04), area under the precision-recall curve of 0.84 (SD 0.05), micro-averaged F_1-score of 0.88 (SD 0.02), a macro-averaged F_1-score of 0.84 (SD 0.03), and a Hamming loss of 0.04 (SD 0.01). Secondary classifiers achieved AUC scores of 1.0 (SD 0.00) for cleft lip revision classification but failed to discriminate between alveolar bone grafting primary and revision procedures (AUC 0.49, SD 0.02). Tertiary classifiers for surgical technique identification showed AUC scores of 0.88 (SD 0.03), 0.89 (SD 0.03), and 0.89 (SD 0.09) for cleft lip, cleft palate, and velopharyngeal insufficiency repair techniques, respectively.

Conclusions: This pilot study demonstrates that machine learning approaches can automate the classification of pediatric craniofacial operative notes across multiple levels of procedural detail. The implementation of such systems could significantly reduce the administrative burden related to surgical research, operations, and quality improvement.

Introduction

Modern health care generates an overwhelming amount of data, ranging from structured information, such as demographic data and laboratory values, to unstructured content, such as clinical notes and radiographic images. While structured data may be readily analyzed using traditional statistical analysis and machine learning approaches for tasks such as disease risk stratification and outcome prediction [1-3], the wealth of clinical information contained in unstructured text data has remained largely untapped due to analytical challenges [4]. In the past, the analysis of unstructured data required manual chart review to extract desired elements and structure them in a spreadsheet or database for later use—a process that is labor-intensive, slow, costly, and subject to human error.

One example of where manual review of text data has been critically important is the review of operative notes (or "dictations") that are recorded by a surgeon after a procedure has been completed. These notes contain essential information on the indication for the procedure (why it was performed), context or historical details about the patient leading to the decision, a description of the technical steps involved in the procedure, a summary of operative findings, and many other details. While standard coding systems, such as Current Procedural Terminology (CPT), can indicate with some generality the type of procedure performed, these codes are notoriously imprecise at representing the critical details about procedures, due to limitations in the codes themselves and variability in coding practices by surgeons and institutions [5]. As a brief example, consider that primary cleft palate repair may be represented by CPT codes 42200, 42205, 42210, and 42235. Revision palatoplasty is ideally coded as 42215, but it may also be coded using the same 42200 and 42205 as a primary palatal repair. Oronasal fistula repair is often coded using 30600, except that it may also be coded using revision palatoplasty codes 42215 or 42235. An alveolar bone graft procedure has no specific code of its own, so it is often coded using the palatoplasty code 42210. There is nothing in the code itself that provides information about which procedure was performed, why it was performed, how it was performed, or what happened during the time it was being performed. It is not the CPT coding system that is at fault, as it was designed for billing purposes and functions adequately in that regard. The problem lies in the fact that researchers have relied upon the CPT code (a structured data field) because it is more easily accessible and analyzable than manually extracting the necessary information from operative notes. Unstructured data have historically been inaccessible, impenetrable, or impractical.

Fortunately, recent advances in natural language processing (NLP) and machine learning have demonstrated promising results in the classification of procedures across various specialties [6-10]. These technologies offer potential solutions using machine learning for automatic procedural classification in fields such as orthopedics, general surgery, neurosurgery, ophthalmology, and anesthesiology, enabling more accurate and efficient clinical data retrieval and analysis. However, the application of these techniques to more complex procedures, such as cleft and pediatric craniofacial procedures, remains largely unexplored [11,12]. A child with a cleft lip or palate or another craniofacial anomaly undergoes operative and nonoperative care, typically coordinated by a multidisciplinary team, in stages spanning 2 decades of the child's life, from birth through young adulthood. For children with some types of clefts, it is typical to undergo 4 to 6 cleft-related procedures in their lifetimes, and sadly, it is not uncommon to encounter patients who have undergone approximately 20 procedures. To decrease the number of anesthetic events for patients, many procedures are combined under the same anesthetic. The surgical techniques used vary considerably based on cleft phenotype, context, and surgeon preference. Such complexity in timing, sequence or staging, type of procedure, technique, coordination of procedures, and so forth makes cleft care the perfect testing ground for the refinement of NLP techniques for the extraction of critical details from the operative note.

In this pilot study, we developed and evaluated a machine learning framework for the automated classification of operative notes across multiple procedure types and subtypes related to cleft care. To address the "black box" nature of machine learning models, we used feature importance analysis to identify the specific textual elements that drive classification decisions. This work has the potential to enhance clinical documentation efficiency, facilitate large-scale quality improvement initiatives, and support comprehensive outcomes research in surgery.

Methods

Data Source

For this study, we extracted operative notes from all patients who underwent cleft and craniofacial procedures at a single institution from 2016 to 2024, comprising 656 operative notes from 312 patients. Operative notes were dictated by the primary surgeon immediately following the completion of the procedure. These notes were stored contemporaneously within the electronic medical record and were periodically aggregated into a condition-specific database as part of the guidelines recommended by the "Standard Set of Outcome Metrics for the Comprehensive Appraisal of Cleft Care" of the ICHOM (International Consortium for Health Outcomes Measurement) [13] and the operational protocol of the Allied Cleft & Craniofacial Quality-Improvement and Research Network (ACCQUIREnet) [14], of which our institution is a member. Within the condition-specific databases, procedures are classified using the ACCQUIREnet Common Data Model. At our institution, this labeling has been performed by an experienced annotator (CJ), a speech pathologist (CCC-SLP), and the Team Coordinator of an American Cleft Palate Craniofacial Association–approved Cleft & Craniofacial Team since 2018. Any uncertainty in procedural classification was resolved by a senior surgeon (ACA) with over 20 years of clinical experience and the director of ACCQUIREnet. Procedural classification was performed for case type (eg, cleft lip repair, cleft palate repair, alveolar bone grafting), subtype or stage (primary repair or revision), and technique. Where operative notes contained the documentation of multiple procedures done in coordination (such as cleft lip repair being done with tip rhinoplasty, or cleft palate revision being done

XSL•FO
RenderX

with sphincteroplasty for speech), each subprocedure was classified separately.

Generation of Synthetic Notes to Augment Dataset

Some procedures were severely under-represented in our dataset. For these procedures, the dataset was augmented using synthetic notes generated by a large language model (LLM). To generate these synthetic operative notes, we used GPT-4o (OpenAI) [15] with a multishot prompting strategy guided by manually anonymized, real operative notes. Example notes were drawn from a separate Duke cleft and craniofacial dataset collected outside the study period to guide the model in reproducing procedure-specific structure and terminology without introducing data leakage. To guide overall structure, 3 representative examples from an internal dataset not used in model development were provided for each procedure while encouraging variation in operative technique and language. Using this approach, we generated synthetic operative notes for cleft lip major revision, cleft lip minor revision, alveolar bone grafting revision, and velopharyngeal insufficiency repair by cleft palate revision with counts matched to the corresponding real-note datasets.

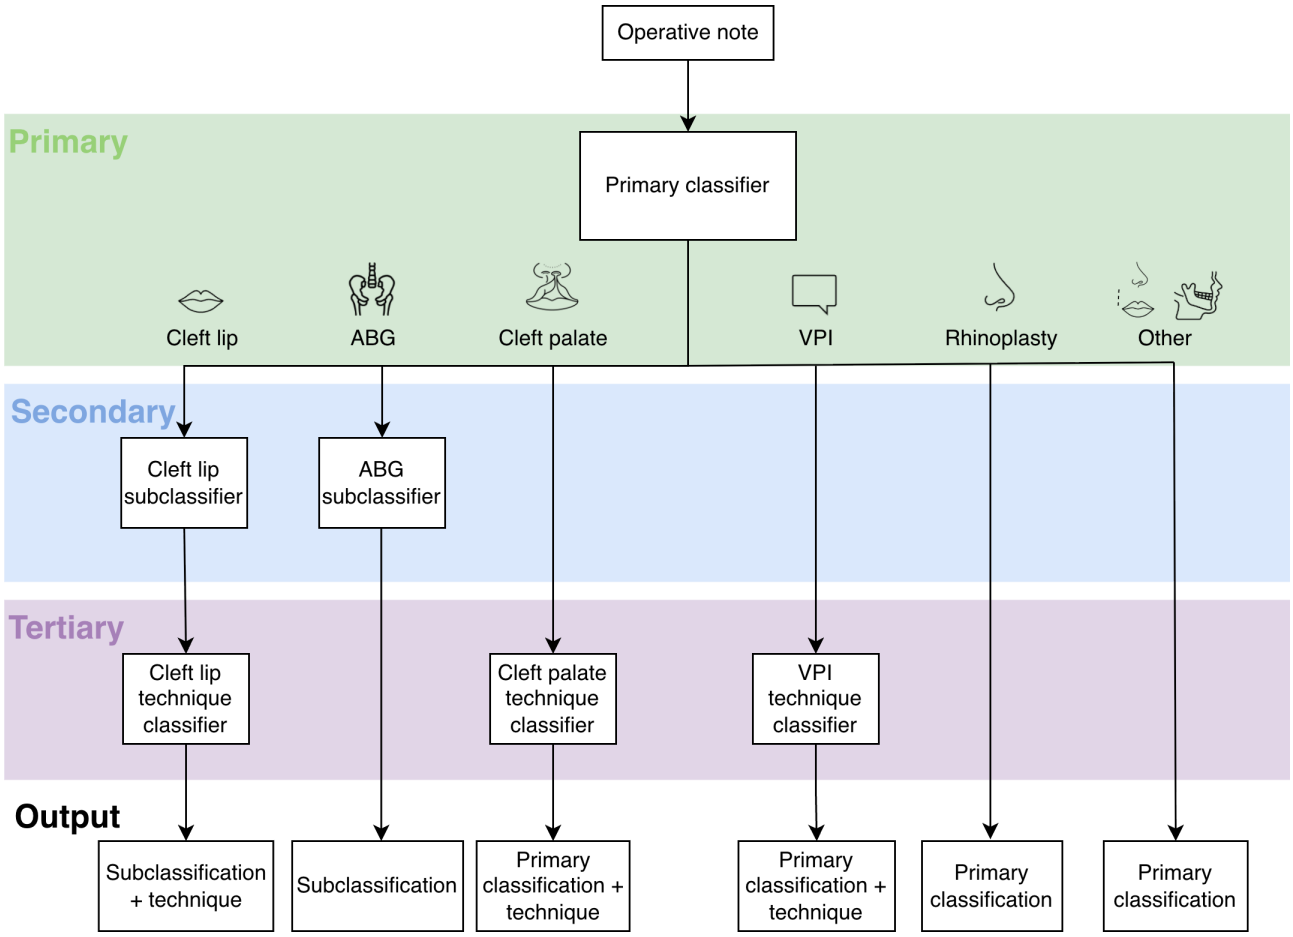
A senior cleft or craniofacial surgeon (ACA) reviewed the synthetic notes to appraise content validity. All notes were rated as being satisfactory in quality and content, similar to what would be found in clinical practice. Criticisms included unnecessary verbosity, slight disorganization in the operative sequence, limited detail in some parts of the operation, and lack of variation with regard to technical complexity or intraoperative events (some cases are harder than others). Notwithstanding, the limitations were actually viewed as advantageous to this project, as they might better simulate the varying quality of notes "in the wild"—for example, what a junior resident or hurried attending surgeon might have dictated.

Synthetic notes were used solely for model development and not for evaluation.

Preprocessing

Operative notes often contain content such as patient history, procedure indications, or other metadata. To isolate clinically relevant content, a custom Python script (version 3.11.9) extracted specific sections of interest (eg, "indications," "operative findings," and "operative details") from the body of each note. This script identified and extracted content preceded by section headers, detected all candidate headers, and then split the note into segments at each detected header. Because the base template is auto-generated by the electronic health record, headings are consistently present; however, certain sections can be overwritten by the surgeon (dictated or typed as free text). The user specified desired content (eg, "operative details") as input, and the script used a combination of exact and fuzzy string matching to identify synonymous headers (eg, "operative technique" or "procedure description"). To improve header recognition consistency across notes, the script optionally supported training for header deduplication using the dedupe library (version 3.0.3), which learns common aliases from the dataset and creates a mapping dictionary [16]. For this process, a separate set of operative notes was used—that is, notes that were not included in the dataset for subsequent vectorization and analysis. Using this mapping, operative notes were split into sections, which were saved for downstream analysis.

The procedure notes were preprocessed to prepare them for NLP analysis. The preprocessing step is crucial for standardizing the text data and reducing noise in subsequent analysis. The medium-sized English-language model from the spaCy NLP library was used for text processing (version 3.8.4). Each operative note underwent tokenization, lemmatization, and filtering to remove punctuation, stop words (such as "the," "a," "and," "in," "of," and "is"), and nonalphabetic characters. Clinically relevant negation terms (such as "no," "not," and "without") were preserved.



Classifier Model Development

The classification framework used a One-vs-Rest (OvR) strategy with random forest as the base classifier. This approach was selected for several compelling reasons. First, OvR decomposes the complex multilabel problem into multiple binary classification problems (one for each procedure type), significantly reducing computational complexity while maintaining high performance. Second, this methodology preserves the interpretability of the model's predictions. Third, OvR classifiers handle class imbalance effectively when paired with appropriate weighting, which was particularly important given the uneven distribution of procedure types in the dataset. Class weighting of the random forest was used to address dataset imbalance, which penalizes the misclassification of minority classes more heavily during the training process. Given the small dataset size of 630 notes, deep learning methods were not likely to be optimal for the task, based on results from prior studies examining sample size requirements for medical NLP classification tasks with deep learning [17,18].

The overall architectural design implements a hierarchical classification framework with 3 levels: primary procedure-type classification, secondary subtype classification for applicable procedures, and tertiary technique classification where sufficient data exist. This hierarchical propagation yields a comprehensive procedural characterization with progressive granularity. The classification architecture is illustrated in Figure 1.

XSL•FO
RenderX

Figure 1. Classification schematic. A primary classifier categorizes an operative note by primary procedure (cleft lip, alveolar bone grafting [ABG], cleft palate, velopharyngeal insufficiency [VPI], or rhinoplasty). A secondary classifier further categorizes cleft lip and ABG procedures into primary and revision procedures. A tertiary classifier categorizes cleft lip, cleft palate, and VPI procedures by technique.

For the primary classifier, we used patient-level grouped 5-fold cross-validation to ensure all notes from each patient remained in either the training or test set, preventing potential information leakage through patient-specific documentation patterns. For secondary and tertiary classifiers, insufficient sample sizes (particularly for minority classes) precluded patient-level grouping while maintaining adequate class representation in each fold. Note-level grouping with 3-fold cross-validation was used for secondary and tertiary classifiers to ensure sufficient representation of minority classes within each fold.

Term frequency–inverse document frequency (TF-IDF) vectorization converted the preprocessed text into a format suitable for machine learning analysis. This technique weights terms based on their frequency within individual documents relative to their occurrence across the entire corpus, effectively capturing the relative importance of specific terms within each operative note. TF-IDF was used for text vectorization due to its interpretability, allowing individual words to be linked to model predictions. Explainability leads to greater physician trust in medical artificial intelligence tools, and understanding how models are making decisions is important prior to incorporating them into clinical and research workflows [19,20]. We also experimented with word embeddings, including Word2Vec and bidirectional encoder representations from transformers, but these approaches yielded similar predictive performance on our tasks. Thus, TF-IDF offered a practical balance of performance and interpretability. To better capture multiterm clinical concepts (such as “water” and “tight” signifying “water-tight closure” of the mucosa in cleft palate repair), as well as negation, we included unigrams and bigrams in our analysis. We also selected only the top 500 features for inclusion in our model. To prevent data leakage, the TF-IDF vectorizer and feature selection were fit exclusively on the training fold during each cross-validation iteration and subsequently applied to the held-out test fold. The resulting TF-IDF matrix served as the feature set for the classification model.

The decision threshold was chosen to optimize F_1-scores, as the F_1-score is a combination of precision and recall, both of which are helpful for different use cases, such as precision for screening cohorts and recall for registry automation. For each fold, the F_1-score at multiple thresholds was calculated, and the optimal threshold was chosen. The average threshold across folds was selected for the final model.

Primary Classification: Procedure Type

For primary classification, a multilabel classification model was developed to automatically categorize operative notes into 5 distinct procedure types common in craniofacial surgery: cleft lip repair, alveolar bone grafting (ABG), cleft palate repair, velopharyngeal insufficiency (VPI) correction, rhinoplasty, and other procedures. “Other” procedures include noncleft and

XSL•FO
RenderX

craniofacial procedures, such as myringotomy and tympanostomy tube placement, as well as cleft and craniofacial procedures with only a small number of procedures recorded, that is, oronasal fistula repair (14 procedures) and orthognathic repositioning (6 procedures).

The model used multilabel classification, as a single operative note frequently described multiple procedure types performed during the same surgery, and it is important to identify combination cases. For example, it is common for a cleft lip repair to be performed alongside a limited-tip rhinoplasty. Unlike traditional multiclass classification, where each instance belongs to exactly one class, multilabel classification allows each operative note to be assigned to any number of relevant categories simultaneously, from zero to all 5 procedure types. This approach reflects the clinical reality of complex craniofacial surgeries, where multiple procedures are often performed during a single operation.

Secondary Classification: Procedure Subtype or Stage

For secondary classification, OvR classifiers that were able to distinguish between subclassifications of procedures were developed. These classifiers were developed in isolation, given ground-truth primary classification. For example, given cleft lip repairs, the classifier could determine whether the procedure was a primary repair or revision. Classifiers like these were developed for cleft and craniofacial procedures in the dataset that had sufficient examples for testing (>1 in the test set). Procedures with enough samples for subclassification include cleft lip and ABG. Procedures such as cleft lip major and minor revisions, as well as revision ABG, had low counts of 4, 5, and 9, respectively. For these procedures, the dataset was augmented using synthetic notes generated by an LLM.

Tertiary Classification: Technique

At the most granular level of our hierarchical framework, a classifier was developed that could distinguish between specific surgical techniques used within procedural subclassifications. This classifier was developed in isolation, given ground-truth primary and secondary classifications. In the context of cleft lip repairs, for instance, the tertiary classifier discriminates between the Fisher, modified rotation-advancement, Mulliken, and other techniques. For cleft palate repairs, the classifier distinguishes between von Langenbeck, Bardach, Veau-Wardill-Kilner, Furlow, Sommerlad, and other palatoplasty techniques. For VPI repairs, the classifier distinguishes between VPI repair by cleft palate revision or sphincteroplasty or pharyngoplasty. Synthetic note generation was used for notes describing VPI repair by cleft palate revision, for which there were only 6 examples.

Model Evaluation

The performance of the classification model was assessed using multiple metrics. To evaluate the model's discrimination ability, the area under the receiver operating characteristic curve (AUC) and the area under the precision-recall curve (AUPRC) were calculated for each procedure type individually. We also report a macro-average across all classes, which provides insight into the model's performance regardless of class prevalence. The balance between precision and recall was assessed by the F_1-score, reported as both micro and macro averages to account for potential class imbalances in the dataset. Additionally, the fraction of incorrectly predicted labels was assessed using Hamming Loss, which is particularly informative in multilabel classification scenarios where partial correctness is meaningful.

All data processing and modeling were implemented in Python 3.11, utilizing scikit-learn (version 1.5.1) for machine learning operations, pandas for data manipulation (version 2.2.3), matplotlib for visualization (version 3.9.2), and spaCy for natural language processing (version 3.8.4). We maintained a fixed random seed to ensure the reproducibility of results.

Ethical Considerations

This work was performed under institutional review board approval (Pro00104806) for participation in the ACCQUIREnet, a multisite collaborative network. Participating sites in the ACCQUIREnet collect standardized outcomes data and variables that were defined according to the ICHOM's Standard Set of Outcome Metrics for the Comprehensive Appraisal of Cleft Care. The ACCQUIREnet is registered with ClinicalTrials.gov as an observational cohort study (#NCT02702869). All adult participants and parents of minor participants provided consent for participation in the data-collection processes of the network. In this work, operative notes and case classifications were reviewed from our single institution (not the entire network). Data processing and analysis were guided by all institutional policies and regulations regarding the protection of personal information, privacy, and human rights.

Results

Dataset Characteristics

The condition-specific database contained 656 operative notes for analysis. Twenty-six notes could not be parsed to extract a procedure description, resulting in a final cohort of 630 notes from 311 patients. The exclusion of the 26 notes resulted in the complete removal of 1 patient from the cohort. Of the 26 notes that could not be parsed, 3 contained unrecognized headers, 8 had no identifiable header, and 15 had improperly formatted headers (eg, lowercase or indistinguishable from body text). These notes represented cleft and craniofacial procedures between 2016 and 2024. Patients had a mean age of 3.75 (SD 4.1, range 0 - 19) years. In 184 instances, multiple procedures were performed during the same anesthetic event. In total, 958 procedures were documented across the 630 notes.

Procedures included the following: 100 cleft lip repair (primary, secondary major, and minor revision), 105 alveolar bone grafting (primary and secondary revision), 104 cleft palate repair, 32 velopharyngeal insufficiency correction (via cleft palate revision, sphincteroplasty, or pharyngoplasty), and 36 rhinoplasty (limited-tip). The 581 "Other" procedures included 191 (32.7%) auditory procedures (audiometry evoked-potential brain response testing, myringotomy and tympanostomy tube placement, and patch myringoplasty), 92 (15.8%) suture removal, 33 (5.8%) dental rehabilitation, 14 (2.4%) oronasal fistula repair, 6 (1%) cranial procedures (suturectomy, cranial vault expansion, and fronto-orbital advancement), 6 (1%) orthognathic repositioning, 5 (0.9%) gastrostomy, and 234 (40.3%) heterogeneous group

XSL•FO
RenderX

of less common interventions spanning multiple specialties, including ophthalmologic (eg, strabismus surgery, cataract extraction), neurosurgical (eg, ventriculoperitoneal shunt placement and revision, Chiari decompression), orthopedic (eg, fracture fixation, spinal fusion), general surgical (eg, exploratory laparotomy, bowel resection), urologic (eg, cystourethroscopy), and cardiothoracic procedures (eg, congenital heart defect repair).

Procedure descriptions averaged 244 words (median 223 words), ranging from 5 to 809 words. The corpus contained 5175 unique tokens, with “patient,” “place,” and “suture” being the most frequent. The type-token ratio of 3.36% indicated substantial lexical repetition and limited vocabulary diversity across operative notes.

Primary Classification Performance

The model demonstrated strong performance in distinguishing procedure types, achieving an AUC of 0.93 (SD 0.04), an AUPRC of 0.84 (SD 0.05), a micro-averaged F_1-score of 0.88 (SD 0.02), a macro-averaged F_1-score of 0.84 (SD 0.03), and a Hamming loss of 0.04 (SD 0.01). The AUC and AUPRC curves are shown in Figure 2.

XSL•FO
RenderX

The curve demonstrates the primary classifier's performance for each procedure type as compared to a no-skill classifier. (B) Precision-recall curve of the primary classifier. ABG: alveolar bone grafting; AUC: area under the receiver operating characteristic curve; AUPRC: area under the precision-recall curve; VPI: velopharyngeal insufficiency.

XSL•FO
RenderX

Secondary Subclassification Performance

In distinguishing subclassifications, such as primary cleft lip repairs versus revisions, the model demonstrated variable performance. Performance was excellent for cleft lip revision, with an AUC score of 1.0 (SD 0.00), an AUPRC of 1.0 (SD 0.0), a micro-averaged F_1-score of 0.96 (SD 0.02), a macro-averaged F_1-score of 0.90 (SD 0.03), and a Hamming loss of 0.06 (SD 0.0) . In contrast, performance for ABG was poor, with an AUC of 0.49 (SD 0.02), an AUPRC of 0.21 (SD 0.14), a micro-averaged F_1-score of 0.61 (SD 0.02), a macro-averaged F_1-score of 0.41 (SD 0.05), and a Hamming loss of 0.39 (SD 0.02), indicating that the model failed to discriminate between primary and revision ABG procedures. Receiver-operating characteristic and precision-recall curves for secondary classifiers are shown in Figure 3. The slight discrepancy between AUC and F_1-score for the cleft lip subclassification model reflects the use of a threshold averaged across folds, which may not be optimal for each individual fold. Cleft palate and rhinoplasty procedures had only 1 category represented in the data (primary cleft palate repair and limited-tip rhinoplasty), and therefore a classifier was not developed due to the lack of real examples for testing. VPI revision subclassification was not possible, as only the VPI technique was recorded in our dataset.

Figure 3. (A) Receiver operating characteristic and precision-recall curves for the cleft lip subclassification model, distinguishing primary versus revision procedures. (B) Receiver operating characteristic and precision-recall curves for the alveolar bone grafting (ABG) subclassification model, distinguishing primary versus revision procedures. AUC: area under the receiver operating characteristic curve; AUPRC: area under the precision-recall curve.

Tertiary Technique Classification Performance

The model for identifying procedure techniques also exhibited good performance, with AUCs ranging from 0.87 to 0.90. The full results are shown in Table 1. Briefly, the cleft lip technique classifier distinguishes between Fisher, modified rotation-advancement, Mulliken, and other techniques. The cleft palate technique classifier distinguishes between von

XSL•FO
RenderX

Langenbeck, Bardach, Furlow, Veau-Wardill-Kilner, Sommerlad, and other techniques. The VPI technique classifier distinguishes between VPI repair by cleft palate revision and sphincteroplasty or pharyngoplasty. In our dataset, only 4 ABG procedures had associated techniques recorded, which was insufficient for developing a reliable classifier. Receiver-operating characteristic and precision-recall curves for tertiary classifiers are shown in Figure 4.

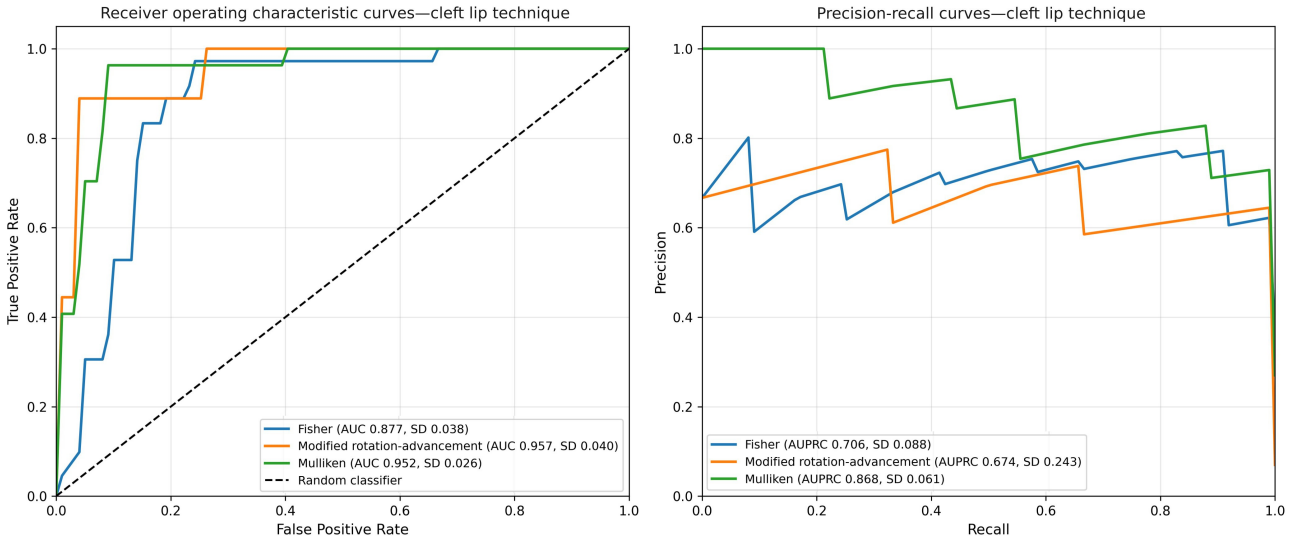
Table . Performance metrics for tertiary classifiers identifying specific surgical techniques[a].

Technique	AUC[b]	AUPRC[c]	F_1-score (micro)	F_1-score (macro)	Hamming loss
Cleft lip, mean (SD)	0.88 (0.03)	0.72 (0.08)	0.77 (0.04)	0.77 (0.06)	0.22 (0.04)
Cleft palate, mean (SD)	0.89 (0.03)	0.67 (0.05)	0.65 (0.05)	0.65 (0.07)	0.36 (0.05)
VPI[d], mean (SD)	0.89 (0.09)	0.97 (0.03)	0.81 (0.01)	0.45 (0.01)	0.19 (0.01)

[a]Metrics for categories with very small sample sizes (eg, velopharyngeal insufficiency repair by cleft palate revision, n=6) should be interpreted with caution, as limited representation in cross-validation may result in unstable estimates.

[b]AUC: area under the receiver operating characteristic curve.

[c]AUPRC: area under the precision-recall curve.



[d]VPI: elopharyngeal insufficiency.

Feature Importance

Feature importance analysis identified key terms contributing to each procedure classification for the primary classifier. The top-ranked words reflected distinct operative terminology across categories. The relative importance values of the top 10 words for each procedure type are shown in Figure 5.

Figure 5. Primary classifier explanations. Top 10 most important term frequency-inverse document frequency (TF-IDF) features for each classification label, based on model coefficients. Bar color reflects normalized importance within each class.

Overcoming Limitations of CPT Coding

To further emphasize the need for cohort definition tools beyond CPT codes, we examined the CPT codes assigned to manually labeled VPI and ABG procedures, which are frequently miscoded due to the limited granularity of CPT coding. Tables 2 and 3 illustrate the heterogeneity of CPT coding for VPI and ABG procedures, respectively, demonstrating the multiple ways identical or highly similar procedures are coded. In total, 32 VPI procedures and 105 ABG procedures were analyzed. Of note, these are two substantially different procedures, and yet the CPT codes overlap due to the generality of the codes, arbitrariness in selecting a code, and possibly even miscoding.

XSL•FO
RenderX

Table . Current Procedural Terminology (CPT) code variability across velopharyngeal insufficiency repair procedures (N=32).

CPT code	Description (if applicable)	Procedures, n (%)
42226	Lengthening of palate and pharyngeal flap	13 (40.6)
42950	Pharyngoplasty (plastic or reconstructive operation on pharynx)	7 (21.9)
42220	Palatoplasty for cleft palate; secondary lengthening procedure	4 (12.5)
42210	Palatoplasty for cleft palate, with closure of alveolar ridge; with bone graft to alveolar ridge (includes obtaining graft)	3 (9.4)
42215	Palatoplasty for cleft palate; attachment pharyngeal flap	2 (6.3)
42225	Palatoplasty for cleft palate; major revision	2 (6.3)
42200	Palatoplasty for cleft palate, soft and/or hard palate only	1 (3.1)

Table . Current Procedural Terminology (CPT) code variability across alveolar bone grafting procedures (N=105).

CPT code	Description (if applicable)	Procedures, n (%)
42210	Palatoplasty for cleft palate, with closure of alveolar ridge; with bone graft to alveolar ridge (includes obtaining graft)	68 (64.8)
40700	Plastic repair of cleft lip/nasal deformity; primary, partial or complete, unilateral	23 (21.9)
42200	Palatoplasty for cleft palate, soft and/or hard palate only	7 (6.7)
42205	Palatoplasty for cleft palate, with closure of alveolar ridge; soft tissue only	4 (3.8)
40701	Plastic repair of cleft lip/nasal deformity; primary bilateral, 1-stage procedure	2 (1.9)
21210	Graft, bone; nasal, maxillary, or malar areas (includes obtaining graft)	1 (1)

Discussion

Principal Findings

This study demonstrates that machine learning approaches can effectively classify operative notes in pediatric craniofacial surgery with high accuracy across multiple levels of granularity. The primary classification model achieved strong performance (AUC 0.93, SD 0.04) in distinguishing between 5 distinct procedure types common in craniofacial surgery. Secondary classifiers for procedure subclassifications demonstrated variable performance, with AUC scores of 1.0 (SD 0.00) for cleft lip revision and 0.49 (SD 0.02) for ABG. At the most granular level of surgical technique identification, our model maintained good discriminative ability (AUC 0.88, SD 0.03 to AUC 0.89, SD 0.09).

The model for ABG secondary subclassification demonstrated poor performance (AUC 0.49, SD 0.02). This is likely due to substantial overlap in operative and clinical language between primary and revision procedures. In many revision cases, surgeons perform repeat alveolar bone grafting using techniques similar to those used in primary repairs, leading to documentation that does not reliably distinguish initial from secondary procedures. As a result, the textual features available to the model may be insufficient to support accurate subclassification.

The VPI technique classifier demonstrated a notable discrepancy between the micro-averaged F_1-score (0.81, SD 0.01) and the macro-averaged F_1-score (0.45, SD 0.01), indicating a performance imbalance across technique categories. This gap suggests that while the model achieves high overall accuracy, it performs poorly on the minority technique. In our dataset, VPI repairs were categorized as either sphincteroplasty/pharyngoplasty or repair by cleft palate revision, with the latter representing only 6 real examples that required synthetic augmentation. The high micro-F_1-score indicates strong performance on the more prevalent sphincteroplasty/pharyngoplasty category, which dominates the overall metric due to its larger sample size. In contrast, the low macro-F_1-score reveals that the model struggles to correctly identify VPI repairs performed via cleft palate revision, likely due to substantial overlap in operative terminology between these approaches.

XSL•FO
RenderX

Additionally, AUC estimates for these very small classes (eg, VPI repair by cleft palate revision, n=6) are unstable and should be interpreted as exploratory until larger labeled datasets are available. The perfect AUC observed for the cleft lip secondary classifier should also be interpreted with caution. Unlike the primary classifier, this model used note-level rather than patient-level cross-validation due to limited sample size, meaning notes from the same patient or surgeon may have appeared in both training and test sets. The AUC of 1.0 may overestimate real-world generalizability.

This classification system has several important clinical implications. First, this study provides proof-of-concept that automated classification could substantially reduce the administrative burden on clinical teams. In many studies, traditional coding systems, such as CPT and *International Classification of Diseases* (*ICD*), codes are used for procedural and diagnostic classification. However, CPT coding has been shown to be inconsistent for craniofacial procedures due to inconsistent CPT codes that fail to capture complex techniques [21,22]. The pediatric craniofacial population presents unique documentation challenges due to the longitudinal nature of care, with patients often undergoing multiple staged procedures over many years. CPT codes frequently lack the granularity necessary to distinguish between subtle but clinically significant variations in surgical technique. For instance, CPT code 42200 encompasses multiple distinct approaches to cleft palate repair that have different implications for surgical planning and outcomes research. Additionally, procedures may be coded inaccurately—for example, the correction of VPI or ABG procedures may use a cleft palate repair CPT code. In the case of VPI, revision palatoplasty is one approach for correcting the disorder. In the case of ABG, no specific CPT code exists for bone grafting of the alveolar cleft, so it is conventional to use a “close-enough” CPT code for palatoplasty with bone grafting. The consequence of this “real-world” coding practice has been that manual review was needed to accurately classify complex procedure types. Of course, manual review and classification of operative notes are time-consuming and subject to human error. The substantial variability in CPT coding observed for both VPI and ABG procedures underscores the limitations of billing-based classification systems and highlights the added value of NLP-derived tertiary classifications for capturing clinically meaningful procedural detail. A major goal of this project was to provide an accurate, reliable, efficient, and sustainable method for automating case classification from the unstructured text data of the operative note, allowing for more accurate and efficient cohort identification.

Second, the analysis of feature importance provides insight into the distinctive language patterns that characterize different craniofacial procedures. The terms most strongly associated with each procedure type align with the clinical understanding of these operations, suggesting that the model has learned clinically relevant patterns. This interpretability is crucial for clinical adoption, as it allows surgeons to understand and validate the model’s decision-making process.

Comparison to Prior Work

While prior work applying NLP to operative notes in cleft and craniofacial surgery is limited, related efforts in surgical subspecialties and clinical text classification provide useful points of comparison. A growing body of literature has demonstrated the potential of NLP for classifying surgical procedures based on operative notes, with many studies focusing on predicting CPT codes for billing purposes in fields such as general surgery [23], breast surgery [10], spine surgery [24,25], and pathology [26]. Recently, LLMs have been evaluated for CPT coding in craniofacial surgery given operative notes [27]. However, the accuracies of all 5 models tested ranged between 20% and 40%. These low accuracies suggest that general-purpose LLMs may be poorly suited for granular CPT code classification in highly specialized surgical domains, particularly when models are not trained on domain-specific operative language. Similar findings have been reported in other studies using generalized LLMs, which demonstrate low accuracy in classifying surgical procedures [8,28,29] and CPT modifiers in craniofacial operative notes [30]. Collectively, this work indicates that procedure classification may require models trained on specialized operative notes rather than relying on generalized LLMs alone.

Our work addresses this challenge within cleft and craniofacial surgery—a specialty characterized by complex, multicomponent procedures and longitudinal care spanning years of development—where the precise identification of surgical techniques is crucial for patient outcomes and clinical research. The *hierarchical* approach to classification, moving from procedure *type* (eg, cleft lip repair) to *subclassification* (eg, subtype or stage, such as primary vs revision) to *specific technique* (eg, Fisher anatomic subunit technique), represents a more nuanced and clinically relevant analysis than most previous studies, which typically focus on primary procedure identification or CPT code assignment only. Moreover, our approach does not treat procedural coding as the end goal. Rather, CPT codes serve primarily as a point of comparison. Instead, the proposed model enables more efficient and accurate cohort identification for outcomes reporting and surgical research by capturing both procedure type and detailed operative technique.

Another study highlights the development of a tool, ChartSweep, to automate chart review, which can be used for cohort identification [31]. The study highlights the significant amount of time spent on retrospective chart review compared to an automated tool (8 minutes per patient with manual chart review vs 0.3 minutes per patient with the automated tool for the identification of a radiofrequency ablation cohort). These findings underscore the inefficiency of manual chart review in plastic surgery research. Similar to ChartSweep, our study aims to reduce this burden through automation; however, we specifically address the challenge of classifying cleft and craniofacial procedures, where overlapping and reused operative terminology complicates automated extraction, an area not examined in the prior work.

We additionally apply a synthetic data generation technique to address class imbalance in rare procedure types, demonstrating

XSL•FO
RenderX

a solution to a common challenge in specialty surgical fields with relatively low procedure volumes. Several studies have demonstrated the ability of LLMs to generate satisfactory medical notes. Such synthetic notes have been shown to be sufficiently realistic for downstream analytic tasks, with multiple studies proposing their use as a viable strategy to mitigate data scarcity [32-40]. In this context, our work extends the existing literature by demonstrating the use of synthetic data specifically for hierarchical surgical procedure classification, supporting its role in improving model performance for rare but clinically meaningful procedures.

Limitations

First, our study used data from a single institution, potentially restricting the generalizability of our models to other clinical settings with different documentation practices. Operative notes can vary significantly in structure, terminology, and level of detail across institutions and individual surgeons. To address this concern, future studies should validate these models using multi-institutional data to assess their robustness across different documentation styles. This is planned as future work for the ACCQUIREnet.

Second, surgical notes often rely on templates for documentation efficiency. It is a concern that the model is overfitting to templated data. In this project, the templates for cleft and craniofacial operative notes have changed significantly in the time span encompassed by the study, and operative notes from multiple surgeons are present. This variability does diminish (but does not eliminate) the risk of overfitting. Feature importance analysis identified several highly weighted predictors (eg, phrases such as “wish proceed” and “take operative”) that are not inherently clinical and may reflect aspects of documentation style or templated language rather than surgical technique. This suggests that the model may be partially leveraging institution- or surgeon-specific phrasing patterns. Although variability in note authorship and evolving templates may reduce this effect over time, it highlights a potential limitation related to generalizability, particularly when applying the model to external datasets with different documentation conventions. Training on notes from other institutions will likely be most effective in resolving this issue.

Third, the augmentation of the training data using LLM-generated synthetic notes for procedure subclassification is another potential source of overfitting. Three examples each of cleft lip major revision, cleft lip minor revision, and ABG revision were provided for synthetic data generation. Although the effort was made to select diverse techniques and note styles for these examples, these synthetic notes may, nonetheless, be most similar to the examples provided. In this pilot project, synthetic notes were necessary to explore the feasibility of subclassification for rare procedures. In the future, we will solicit “real-world” operative notes in these categories from across the ACCQUIREnet.

Fourth, our secondary and tertiary classifiers were developed in isolation, given “ground-truth” labeling of preceding classifications. In reality, the hierarchical classification system will need to identify primary, secondary, and tertiary classifications in sequence. Errors in primary classification could permeate into subsequent steps. Therefore, before putting such a system into production, it will be necessary to assess cumulative system accuracy.

Fifth, we excluded a small subset of operative notes that could not be parsed due to missing or nonstandard headers. While this may introduce a minor degree of survivorship bias toward more consistently formatted notes, the proportion excluded was small and unlikely to meaningfully impact overall findings. Future work could incorporate more flexible parsing approaches to further improve robustness to formatting variability.

Sixth, the content validity of the synthetic operative notes was appraised by a senior cleft and craniofacial surgeon (ACA) who is also the corresponding author and lead investigator of this study. As such, this review was internal rather than independent, and the possibility of confirmation bias cannot be excluded. In the future, an independent, blinded clinical review by surgeons unaffiliated with the study would provide stronger evidence of the synthetic notes’ similarity to real-world operative documentation.

Seventh, the ground-truth labels used to train and evaluate all classifiers were generated by a single experienced annotator (CJ), with uncertain cases resolved by a senior surgeon (ACA). Although this annotator has extensive experience in cleft and craniofacial procedural classification, no independent audit was performed on a subset of notes to calculate a formal interrater reliability score. Consequently, the degree of individual annotator bias cannot be quantified, and the possibility that a second annotator would classify some notes differently cannot be excluded. Future work should include independent annotation of a representative subset of notes by a second qualified annotator, with the calculation of a formal interrater reliability statistic (such as Cohen kappa), to better characterize label quality and support confidence in the ground-truth dataset.

Future Directions

Future directions for this research include prospective validation in a clinical setting, expansion to multi-institutional datasets, and incorporation of additional variables from structured data sources. In addition, it is interesting to note that while it is problematic to go from CPT code to procedural classification, as we have shown in this paper, the opposite direction is easy—to derive an appropriate CPT code from a classified case; therefore, an impactful extension of our work may be to improve CPT coding (and thus billing) using NLP-based classification of operative notes.

Conclusions

This study demonstrates the feasibility of automatic classification of pediatric craniofacial operative notes across multiple levels of granularity, from primary procedure identification to specific surgical technique recognition. This study paves the way for further development and deployment of such systems, which could significantly reduce the administrative burden involved in surgical research, operations, and quality improvement.

Abstract

Background: Electronic medical records are a vast and valuable source of information, useful for tasks such as estimating disease prevalence. However, in routine primary care, much of this information is in free-text format rather than in a structured form and, therefore, not readily amenable to analysis. Manual coding of this textual data is both time-consuming and resource-intensive, making it impractical for large datasets. Although powerful open-source language models offer new opportunities for automated coding, their use on short heterogeneous primary care notes, particularly in German-language settings, remains insufficiently studied.

Objective: By providing hands-on guidance for applied health researchers, this study aims to demonstrate the effective and accurate automatic classification of free-text notes using a language model fine-tuned for automated *International Statistical Classification of Diseases, Tenth Revision* (*ICD-10*) coding.

Methods: Building on the extensive Family Medicine Research Using Electronic Medical Records (FIRE) routine database from the Institute of Primary Care at the University Hospital Zurich and the University of Zurich, we trained a large language model–based multilabel classifier on a dataset of 38,728 free-text notes, which had been manually categorized into 47 classes using specific *ICD-10* codes and code ranges or nondiagnostic/ad hoc labels (eg, “unclear diagnosis,” “status post”). We stratified the labeled data into training (70%), validation (15%), and posttraining test (15%) sets, ensuring similar label distributions across these sets. Using the Transformers Python library, we trained the model over 10 epochs and evaluated it on the posttraining test dataset.

Results: Across 48 classes, the FIRE classifier achieved strong performance on the held-out posttraining set, with F_1-scores of 0.85 (micro, overall across all predictions), 0.86 (macro, mean of per-class scores treating classes equally), and 0.84 (weighted, per-class scores weighted by class frequency).

Conclusions: This study demonstrates steps for training open-source large language models and highlights the potential to streamline and scale the extraction of diagnostic information for practical applications. Our model can be robustly deployed, for example, for prescreening and labeling of free-text information, thus potentially reducing the burden of repetitive and error-prone manual handling.

Introduction

Electronic medical records (EMRs) contain rich diagnostic information, but in routine primary care, much of this information is documented in short unstructured free-text format rather than as structured records. As a result, large-scale analysis and reuse of diagnostic data remains challenging, since manual coding of free-text notes is both time-consuming and resource-intensive, making it impractical on a large scale. Therefore, automated assignment of diagnostic codes, in particular from the *International Statistical Classification of Diseases, Tenth Revision* (*ICD-10*), has long been of practical interest for research and health care.

The emergence of powerful open-source language models offers new opportunities to automate text-based diagnosis extraction for research or health care. Transformer-based models like bidirectional encoder representations from transformers (BERT) and generative pretrained transformers have gained traction for *ICD-10* coding of clinical texts, achieving strong performance on English language EMR datasets [1,2]. However, research on the classification of text data into *ICD-10*–anchored classes has been conducted mainly in English [1]. While recent studies demonstrate that domain-adapted transformer models can perform well on non-English clinical texts—including Portuguese [3], French [4], and Spanish [5,6]—the availability of data and pretrained models varies widely across languages. For German clinical texts, resources remain limited, and existing work has largely focused on well-structured, high-quality documents such as discharge summaries or surgery reports. In routine primary care documentation in particular, notes are often short, loosely structured, and heterogeneous. Diagnostic coding may also combine *ICD-10* codes with administrative or primary care–specific systems such as the *International Classification of Primary Care*. These characteristics limit the direct reuse of existing models and underscore the need for approaches that are robust to real-world data and adaptable to local coding practices.

Taken together, these factors—a scarcity of annotated German clinical text datasets from routine care, the predominance of English language research, and the short heterogeneous nature of primary care notes—leave little guidance on how to adapt open-source large language models (LLMs) for routine use in German primary care. To address this gap, our study describes the implementation of a flexible, German-language, multilabel LLM classifier for real-world free-text notes in primary care. Although focused on a German-language dataset, the methodological approach may serve as a blueprint in settings beyond English.

Methods

Data Source: The Family Medicine Research Using Electronic Medical Records Database

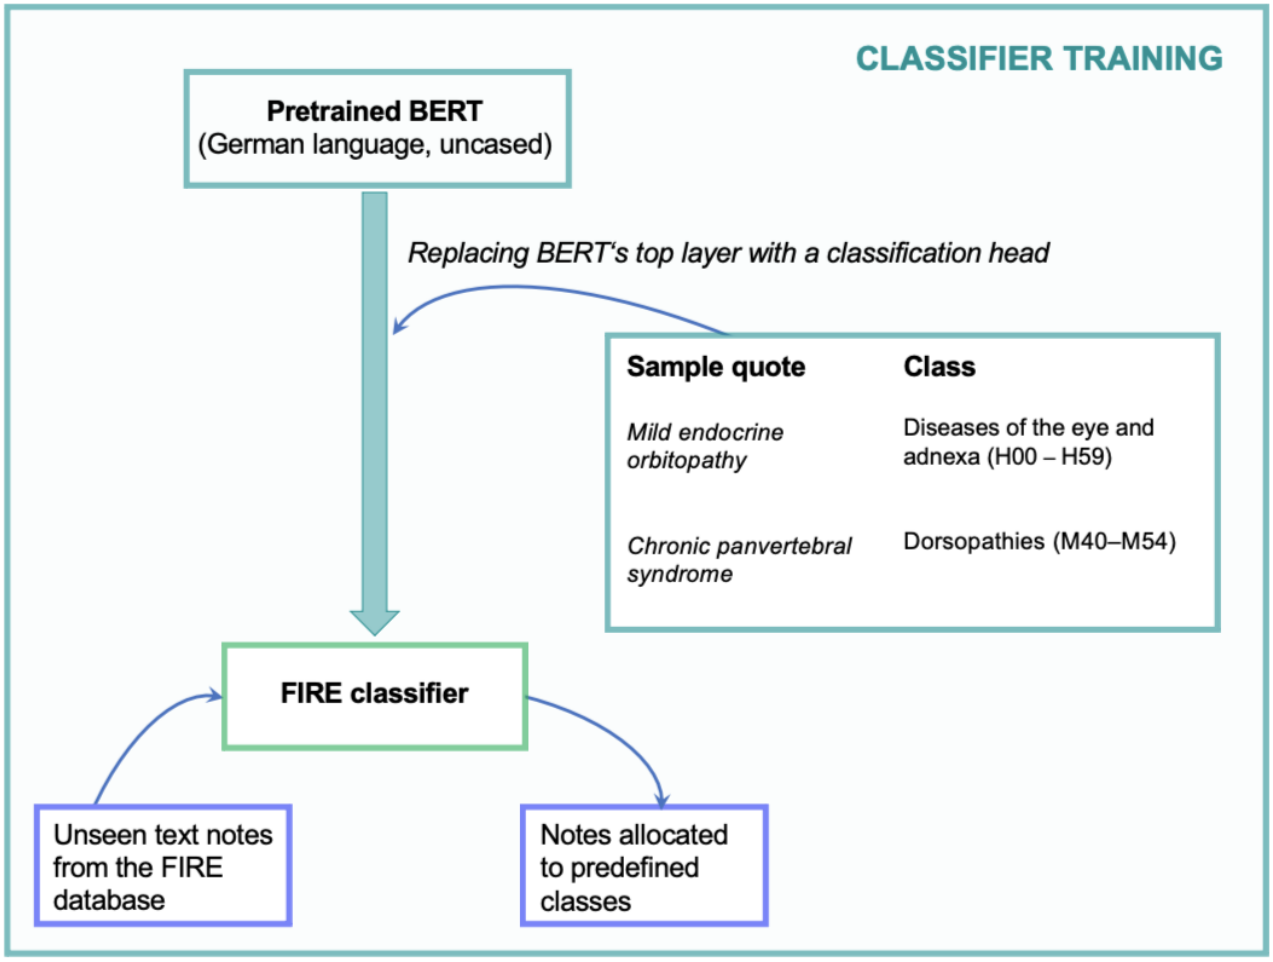
The Swiss Family Medicine Research Using Electronic Medical Records (FIRE) database was initiated in 2009 and has been designed as a basic knowledge base for primary care research through the use of EMRs [7]. So far, the FIRE project has enrolled around 450 general practitioners throughout Switzerland who are willing to contribute their patients' EMRs to the database. General practitioners in the FIRE project routinely document patient encounters—in clinics, at home, or by phone—and records are regularly exported to the FIRE database. The reasons for physician encounters are encoded using the *International Classification of Primary Care, 2nd edition*, albeit not systematically by all participating clinicians. Instead, many participating physicians often include unstructured free-text notes, particularly in the health problems and diagnoses fields, where diagnostic and health care use information is recorded.

Ethical Considerations

The local ethics committee of the Canton of Zurich waived approval for research with the FIRE database because patient data is fully anonymized and, therefore, outside the scope of the Swiss Human Research Act (BASEC-Nr. Req2017– 00797). The study was conducted in accordance with the Declaration of Helsinki and Good Clinical Practice guidelines.

Diagnosis and Problem List Free-Text Notes

This study used manually annotated free-text notes from the diagnosis and problems lists in Swiss general practitioners' EMRs. In Swiss primary care, these lists function as longitudinal note-based records with brief entries summarizing patients' current and past health problems (eg, "hypertension," "low back pain") as well as related events or observations. Each note represents a single, concise observation that persists across consultations, as structured diagnostic coding is not routinely used in Swiss outpatient care.



Training an LLM-Based Classifier for Automated Text Classification

Overview

All analyses and visualizations were performed in Python (version 3.11; Python Software Foundation), using the Jupyter Notebook environment (version 2024.3.2; Project Jupyter). Individual analysis steps and specific Python libraries are detailed in the following sections. The overall procedure is visualized in Figure 1. The Jupyter Notebook containing the Python code and complete model training output is provided in Multimedia Appendix 1.

XSL•FO
RenderX

Figure 1. The figure visualizes the modeling procedure to build the multilabel classifier based on the FIRE dataset. BERT: bidirectional encoder representations from transformers; FIRE: Family Medicine Research Using Electronic Medical Records.

Step 1: Ground Truth Data for Classifier Training

We worked with a total of 53,481 free-text notes, incorporating data from Wallnöfer et al [8] and additional notes annotated thereafter (n=26,501, 49.6%). Wallnöfer et al [8] developed an *ICD-10*–anchored framework comprising 105 diagnostic codes, including both individual *ICD-10* codes and code ranges, as well as a nonspecific "no diagnosis" category. For the present study, a subset of these codes was consolidated into broader groups by combining related diagnostic categories into higher-level ICD classifications, resulting in 44 categories. In addition, three less specific encounter codes not included in the original framework were introduced—"suspected diagnosis," "unclear," and "status post"—bringing the total to 47 categories. Reported interrater reliability for the original codes used in this study—either directly or in aggregated form—ranged from moderate to almost perfect (κ=0.53-0.98); however, these values are not directly transferable to the aggregated categories. For the Wallnöfer et al [8] dataset (n=26,980, 50.4%), two physician raters independently coded the notes (full details are reported in Wallnöfer et al [8]). The remaining 26,501 (49.6%) notes were annotated by a single trained physician.

Step 2: Data Preprocessing

To create a more balanced dataset, we reduced the number of entries for the most heavily overrepresented *ICD-10* code range Z00-Z99 "factors influencing health status and contact with health services," which occurred in 42.5% (n=22,714) of all free-text notes, either alone or in combination with other labels. Specifically, we removed all 14,316 free-text entries assigned exclusively to this code range, reducing the overall dataset to 38,728 free-text notes. As a result, this code range's representation was reduced to 8226 (21.2%), reflecting only those entries where Z00-Z99 appeared alongside other labels.

Step 3: Subdividing the Data Into Training, Validation, and Posttraining Test Data

We then divided the preprocessed dataset (n=38,728) into three parts: 70% (n=27,108) for training, 15% (n=5810) for validation during training, and 15% (n=5810) for final testing. To ensure each class label was proportionally represented in all three sets, we used a stratified splitting process based on the final list of 47 labels, using the *iterstrat* Python package and its MultilabelStratifiedShuffleSplit class for multilabel stratified splitting. In other words, if a particular class made up, for instance, 10% of the entire dataset, it also contained roughly 10% of the training set, 10% of the validation set, and 10% of the posttraining test set.

Step 4: Model Training

To build our classifier, we used a German BERT LLM (dbmdz/bert-base-german-uncased) from the Hugging Face

XSL•FO
RenderX

model hub [9] and replaced its top layer with a classification head to identify the 47 classes in unstructured medical free text. Tokenization was performed using the pretrained tokenizer associated with GermanBERT, a German-language–specific model; no multilingual or custom tokenization was applied (see executed Python script in Multimedia Appendix 1). The model's maximum input length was 512 tokens. No truncation was applied during training or inference, and the model always processed the complete note (median 15 tokens, mean 18 tokens, maximum 111 tokens). Since a single free-text note may belong to multiple categories, we used a multilabel classification approach to allow the assignment of several labels to each note. For model training, we used the Trainer class from the Transformers [10] Python library, which streamlines model training and metric calculation. We set the decision threshold for the binary predictions (true/false) at 0.5 per class.

Step 5: Classifier Evaluation During Training

We monitored evaluation metrics across all 10 epochs throughout training. During each epoch, the model iterated over all training batches, updating its weights via backpropagation based on the binary cross-entropy training loss.

Overall Model Evaluation

After each epoch, we evaluated model quality on the validation set. We first recorded training loss—the average discrepancy between predictions and ground truth on the training data; lower is better. We computed the same metric on the validation set (validation loss) to assess generalization: if validation loss falls and then rises while training loss keeps falling, the model is starting to memorize rather than generalize. We also tracked the microaveraged F_1-score (the harmonic mean of precision and recall), which gives more weight to more frequent classes. In addition, we measured the area under the receiver operating characteristic curve, summarizing how well the model separates positives from negatives across all thresholds (values near 1 indicate excellent separation; values near 0.5 indicate chance performance). Finally, because examples can have multiple labels, we reported subset (exact match) accuracy on the validation set—the fraction of examples for which every label is predicted correctly.

Per-Class Evaluation

Because each free-text note could belong to multiple classes, we examined model performance for each label individually using precision, recall, and F_1-score metrics. These metrics are particularly informative for multilabel classification because they capture how well the model identifies positive cases (recall), avoids false positives (precision), and balances both aspects (F_1-score). Accuracy was not used on a per-class basis, as it is dominated by true negatives in imbalanced datasets and may, therefore, provide a misleading indication of classifier performance.

Step 6: Classifier Evaluation on the Posttraining Test Data

The classifier was subsequently evaluated on the held-out 15% posttraining test set, which had not been used during model training or validation.

Overall Model Evaluation

To provide an overall measure of performance across all diagnostic labels, we calculated the micro-, macro-, and weighted averages of precision, recall, and F_1-score. The microaveraged metrics combine all true and false positives and negatives across labels, capturing the model's overall ability to classify instances correctly. The macroaveraged scores assign equal weight to each label, offering a balanced view that is not influenced by class frequency. In contrast, the weighted average metrics account for label prevalence, summarizing performance in proportion to how often each label occurs in the data.

Per-Class Evaluation

To complement the aggregate measures, the classifier's performance was also examined for each diagnostic category in the posttraining test set. For every label, precision, recall, and F_1-score were computed based on the corresponding ground truth and predicted binary vectors. These per-class metrics highlight how accurately the model distinguishes between individual diagnostic groups, allowing detailed insight into which classes were predicted most reliably and which proved more challenging.

Results

Overview

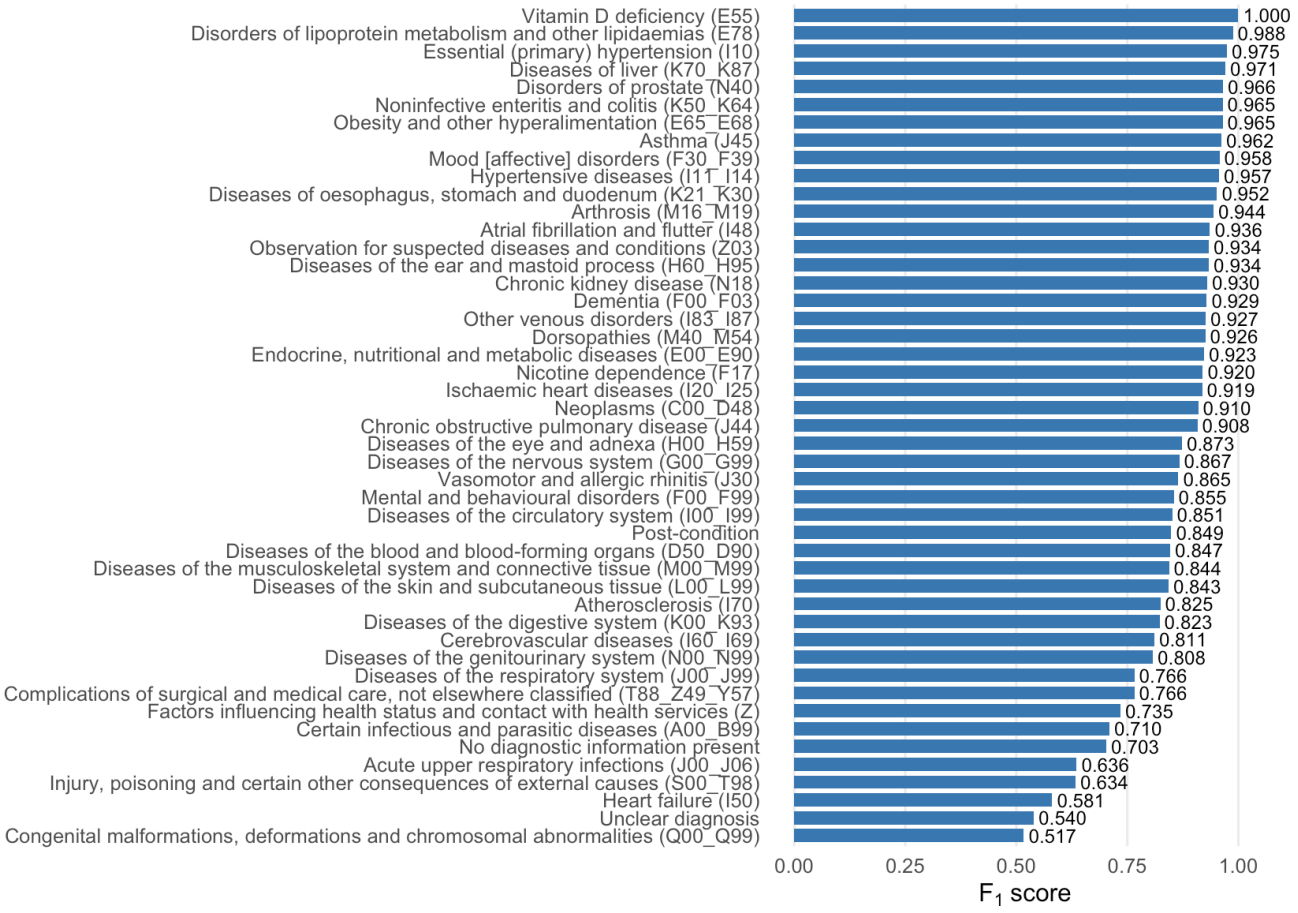
On average, each free-text note was assigned to 1.27 different classes, with the number of classes per free-text note ranging from 1 to 4. The class with the highest number of free-text notes was the umbrella class "factors influencing health status and contact with health services" (Z00-Z99; n=8226). Other classes with particularly high counts included "status post diagnosis" (n=3655) and "diseases of the musculoskeletal system and connective tissue" (M00-M99; n=2883). Conversely, classes such as "dementia" (F00-F03; n=97), "heart failure" (I50; n=116), and "acute upper respiratory infections" (J00-J06; n=163) were among those with the lowest number of free-text notes.

Monitoring Model Metrics

All model metrics during training and for the test data are provided in Multimedia Appendix 1.

Model Metrics During Training

Over the course of 10 training epochs, overall model performance reached a plateau, with the highest F_1-score reaching 0.85 achieved at epoch 10, indicating convergence of model learning. Overall model accuracy at this point was 0.75, and the area under the receiver operating characteristic curve equaled 0.92. The trained FIRE classifier demonstrated robust performance across the majority of classes; specifically, precision during training averaged 0.88 (SD 0.08), recall averaged 0.84 (SD 0.14), and the F_1-score averaged 0.86 (SD 0.11).



Performance on Posttraining Test Data

Across 47 classes, the FIRE classifier achieved strong performance on the held-out posttraining set, with F_1-scores of

XSL•FO
RenderX

0.85 (micro, overall across all predictions), 0.86 (macro, mean of per-class scores treating classes equally), and 0.84 (weighted, per-class scores weighted by class frequency). The classifier achieved the highest performance for "Vitamin D deficiency" (E55) with an F_1-score of 1.0, followed closely by "Disorders of lipoprotein metabolism and other lipidaemias" (E78), "Essential (primary) hypertension" (I10), and "Diseases of liver" (K70-K87), all exceeding 0.97. Strong results were also observed for a range of chronic and metabolic conditions such as obesity (E65-E68), "Asthma" (J45), and "Mood disorders" (F30-F39), with F_1-scores above 0.95. In contrast, performance declined for certain classes with fewer samples or greater diagnostic overlap, such as "Unclear diagnosis" (F_1-score 0.54) and "Congenital malformations, deformations and chromosomal abnormalities" (Q00-Q99; F_1-score 0.52). As displayed in Figure 2, F_1-scores for the posttraining test data were generally high, with variation across the different labels.

Figure 2. Performance of the Family Medicine Research Using Electronic Medical Records (FIRE) classifier on the posttraining test dataset. The bar chart displays the F_1-scores (x-axis) for each diagnostic class (y-axis) predicted by the FIRE classifier on the 15% test posttraining dataset, unseen during training. Larger bars indicate better classification performance.

Discussion

Extracting medical diagnoses or encounters from free-text EMRs or research data still poses critical practice challenges. By using a labeled dataset of ~53,000 records from a nationwide general practice research database, our study developed a classifier to predict appropriate codes in German free-text notes using a locally adapted diagnosis and medical encounter classification system. As such, our study offers insights into not only the challenges but also the potential rewards of creating locally adapted multiclassifier systems for medical free-text notes. Our multilabel classifier showed robust performance in classifying 47 different diagnostic and medical encounter categories during training and on unseen posttraining test data, with varying amounts of available labeled training data across categories. Our multilabel classifier was able to predict around half of the included diagnostic and medical encounter categories with high F_1-scores of 0.8 or greater. These findings showcase the potential usefulness of our classifier approach for systematic use in research.

Therefore, our study demonstrates the feasibility for health care providers to develop locally adapted text classification models designed to meet their unique data requirements and integration needs within operational workflows. We encountered challenges previously discussed in the literature [11], such as predicting a large number of classes simultaneously (a large label space) and dealing with an unbalanced label distribution, in particular with the predominant class "factors influencing health status and contact with health services." Despite preprocessing to mitigate its overrepresentation by removing free-text notes labeled with this class label, its high prevalence persisted due to co-occurrence with other classes, which we did not wish to thin out. This feature, while not ideal, reflects the real-world data scenario and underpins the relevance of our findings.

XSL•FO
RenderX

Importantly, despite these real-world challenges, our classifier maintained commendable performance on both common and rare classes, as well as on new, unseen data, providing valuable insights for health care providers interested in developing custom models amid similar data challenges.

Determining the optimal sample size for training multilabel classifiers remains a topic of debate, as there is no straightforward method such as the power analysis used in hypothesis testing. Our study shows that even for low-frequency classes (ie, with fewer than 100 labeled free-text notes available) such as hypertensive diseases, model performance can still be high. For health care providers looking to develop their own classifiers, our results suggest that the required sample size for each category could be fewer than 100 text samples when training a multilabel classifier of a similar size. However, it's important to note that the required sample size varies depending on how well the classes are defined by specific terms, such as "dementia," versus more ambiguous terms, such as "suspected diagnosis." Generally, our manual error investigation suggested that the quality of data labeling is of crucial importance.

There has been ongoing discussion about shifting toward prompt-based classification and moving beyond manually curated training data by leveraging industry-developed, general-purpose LLMs such as Google's Gemini or OpenAI's ChatGPT. However, a key drawback of currently available powerful general-purpose LLMs, such as OpenAI's GPT-4o, is that they are proprietary, closed-source, and tied to cloud-based paid services operated by large technology companies. This makes them unsuitable for sensitive clinical data, where local processing and data privacy are essential. Nonetheless, in the future, open-source general-purpose LLMs that can be run on local infrastructure are very likely to become more capable.

Our research has several limitations that merit consideration. We used a dataset specifically designed for this use case, which is characterized by its short text notes. Documents of different types, especially those with more extensive content such as admission or discharge summaries, might require alternative methods. For example, researchers dealing with longer documents may need to use models such as Longformer [12], which are designed to process longer text data. Most transformer-based models, including German BERT, typically have a default input constraint of 128 tokens, which can be extended to a maximum of 512 tokens—any text data longer than this is omitted. In the context of the German BERT tokenizer, a token is generally equivalent to a single word. Consequently, training LLMs on longer documents using Longformer models [12] could lead to different results. In addition, the text data was manually labeled by medical school graduates, and labeling may be prone to errors. Errors in data labeling can affect model performance and are a common challenge in the data labeling process. Finally, the predictive results of the model trained in this study are specifically tailored for use at the Institute of Primary Care.

An important consideration when interpreting our results is the *ICD-10* code range Z00-Z99 "Factors influencing health status and contact with health services," which primarily captures contextual or encounter-related information rather than explicit disease entities. In routine primary care documentation, such codes may function as a nonspecific "catch-all" category, particularly when diagnostic certainty is low. To mitigate potential bias, we excluded notes labeled exclusively with these encounter-related categories and retained them only when they co-occurred with disease-related labels, treating them as contextual modifiers rather than stand-alone outcomes. Nonetheless, its continued prevalence reflects real-world documentation practices. Notably, macro- and microaveraged F_1-scores were very similar, suggesting that performance was not driven solely by the dominant encounter-related class. Accordingly, overall performance should be interpreted with an emphasis on macroaveraged metrics and alongside per-class results (Figure 2 and Multimedia Appendix 1, which contains the executed analysis and full per-class results), providing a more balanced view across both common encounter codes and less frequent disease categories. Moreover, predictions of encounter-related codes should be interpreted as reflecting health care use context rather than disease burden, and the classifier should be viewed as a screening tool rather than an autonomous diagnostic system.

Beyond these methodological considerations, an important ethical issue is the potential for residual bias amplification given the imbalanced category distribution, mainly due to the overrepresented encounter-related codes. Although we excluded free-text notes labeled exclusively with encounter-related codes, the high prevalence of this class may still influence model behavior. For this reason, transparency regarding model design, training data, and class-specific performance is essential to support responsible use and clinician adoption. The classifier presented in this study is therefore best suited for screening and structuring heterogeneous clinical free-text notes, rather than as an autonomous diagnostic system, and it should not be used in settings requiring very high precision, such as downstream epidemiological analyses. Future research should focus on improving model explainability to support clinical acceptance and to facilitate the identification of potential biases during deployment.

This study uses supervised multilabel classification, which requires a sufficient number of positive examples per label to learn stable decision boundaries and produce reliable, interpretable performance estimates. We therefore focus on more prevalent *ICD-10* classes. Diagnostic categories with very low prevalence fall into a few-shot or zero-shot regime and cannot be robustly modeled within the same supervised fine-tuning framework. Although we explored prompt-based zero-shot label assignment using an open-source German LLM, performance was inconsistent and substantially inferior to supervised classification. Accordingly, this study concentrates on diagnostic categories with adequate training data for robust supervised model development. Rare conditions remain an important but distinct methodological challenge and may be better addressed through alternative paradigms such as few-shot retrieval-based methods or entailment-based classification.

For classification, we used *bert-base-german-uncased* as a well-established and widely used baseline model to demonstrate

XSL•FO
RenderX

supervised multilabel classification of German free-text notes in primary care. While alternative transformer architectures may offer performance gains, particularly through domain adaptation or different pretraining objectives, systematic comparisons were beyond the scope of this work. Relevant candidates for future evaluation include domain-adapted German biomedical models such as medBERT.de [13], GottBERT [14], and Me-LLaMA 70B [15], as well as alternative pretraining paradigms such as German ELECTRA [16], which has shown strong performance in text classification tasks. In addition, multilingual architectures (eg, the multilingual mBERT [17]) may be of interest for cross-lingual transfer scenarios. Future research would benefit from systematically assessing trade-offs between predictive performance, computational requirements, and deployment feasibility when applying these architectures to real-world clinical settings.

In summary, our study demonstrates the feasibility and benefits of training tailored multilabel text classifiers to categorize diagnostic physician notes in primary care. Combined, our work and documentation of the classifier development process lay a solid foundation for applied researchers and health care providers to leverage their own rich datasets for sophisticated statistical analyses and rigorous research. Moreover, after further validation, such multilabel classifiers could potentially also be used for generating more meaningful, precise, and actionable feedback to the participating general practitioners and thus help them improve the quality of care for their patients. We believe that our work is particularly relevant for health care organizations that accumulate vast amounts of data over time, including rich open text records that often exceed the amount of data typically collected by large research studies in a feasible time frame and budget. For example, many inpatient clinics have extensive longitudinal data, both quantitative and qualitative, including detailed patient histories across multiple admissions. However, our work also underscores the importance of high-quality data labeling and thoughtful integration of artificial intelligence into health care workflows to meaningfully enhance patient care.

Abstract

Background: Clinical data warehouses store large volumes of unstructured text containing valuable information about patients' medical status. Traditional extraction systems based on named entity recognition (NER) identify medical terms but often fail to capture the contextual cues needed for accurate interpretation. Existing approaches to context-aware extraction differ in their reliance on expert annotation, computational power, and lexical resources, leading to uneven feasibility across institutions. Combined with heterogeneity in documentation practices and data-sharing restrictions, these limitations hinder the scalability and reuse of trained models. There is thus a need for practical frameworks that can be deployed and adapted locally within medical institutions.

Objective: This study aimed to introduce the Medical Status Extraction Pipeline (MSEP)**,** a methodological framework that extracts patients' medical status from clinical narratives through sentence classification and supports the local deployment of hybrid extractors, illustrated through an institutional case study.

Methods: MSEP extracts medical status by classifying sentences into predefined categories (presence, absence, or unknown) for each targeted condition. The pipeline combines modules for data selection, expert annotation, and model development, with parameters customizable to different settings. It was applied within our institutional environment on 6 conditions: smoking, hypertension, diabetes, heart failure, chronic obstructive pulmonary disease, and family history of cancer, using 12,119 manually annotated sentences from the eHOP Clinical Data Warehouse (Rennes University Hospital). Three types of extractors were compared: fine-tuned CamemBERT, large language model (LLM) prompt, and a rule-based baseline, evaluated through stratified 3-fold cross-validation, measuring precision, recall, specificity, macro *F*-score, balanced accuracy, as well as manual annotation time and model inference speed.

Results: Among the tested approaches, the CamemBERT-based extractor achieved the best overall performance, with macro *F*-scores above 0.94 for 5 of the 6 medical conditions. The study also highlights that when a medical status is very sparsely represented in the training data, rule-based extractors can outperform learned models (average macro *F*-score 0.94 vs 0.73 for family history of cancer). This shows the pragmatic value of choosing the extraction method according to data availability. Manual annotation time per sentence ranged from 1.2 to 2.9 seconds within the pipeline (2.23 to 4.25 seconds for informative sentences), compared with 7.8 to 16.5 seconds for named entity recognition–based systems. In our institutional experiments, the minimum time to complete all pipeline modules, from dataset construction to final extractor refinement, was 8 hours.

Conclusions: In our institutional case study, MSEP enabled rapid construction of datasets and extractors across multiple clinical conditions while reducing the effort required for local development. Its modular and configurable design allowed the adoption of hybrid extraction approaches and adaptation to different resource settings. These features highlight MSEP's value as a research tool and upstream component that facilitates local deployment of clinical information extraction workflows.

Introduction

In recent years, a substantial amount of clinical data has been collected from numerous patients and stored in clinical data warehouses (CDWs) [1]. These databases represent a valuable resource for clinical research. In many cases, a significant portion of their content exists as free unstructured texts, such as hospital discharge summaries and emergency reports, which can be difficult to process [2]. Nonetheless, these texts contain valuable information about patients' medical status that, once extracted, can be leveraged for clinical and epidemiological research [3-5]. Harnessing these unstructured data requires developing natural language processing (NLP) methods specifically adapted to the medical domain. Extensive efforts have been made in this area, as reflected in shared tasks such as the n2c2 (National NLP Clinical Challenges) competitions, which have addressed problems of extracting patients' family history regarding diseases, smoking, suicide, and drinking [6].

According to a recent review, most NLP approaches for medical information extraction rely on named entity recognition (NER) [2]. At first, rule-based approaches using dictionaries and terminologies to match terms and concepts were proposed [7,8]. However, their reliance on lexical resources and medical expertise for rule construction limits their long-term viability, since rules and vocabularies require regular manual updates to reflect evolving clinical practices. To cope with this, machine learning approaches arose. These methods take advantage of the large amount of medical knowledge in databases and can automate the construction and maintenance of medical information retrieval systems [9]. Its latest branch, deep learning approaches, has improved the ability to capture and use contextual information compared with rule-based and traditional machine learning methods, thanks to their neural network architectures; accordingly, this also makes their performance highly dependent on the availability of sufficient annotated data [10,11].

However, NER-based information extraction approaches present a significant limitation. While NER can effectively extract medical entities (eg, "cancer" and "hypertension"), it cannot capture the contextual information required for a full understanding of the patient's status. A comprehensive assessment involves interpreting the complete syntactic and semantic structure, including subject (patient or family member), predicate (having or not having), and object (the medical condition), to determine whether a condition is present, absent, or mentioned in a familial context [12-14]. Standard NER captures only the object component, necessitating additional processing by context qualifiers to detect negation, temporality, and subject attribution [6,15-17]. Clinical narratives further amplify these challenges, as they are typically unstructured, context-dependent, and institution-specific, with such cues often expressed at the sentence or discourse level [18,19]. For example, in "Tabagisme pendant 7 ans, reprise récente malgré un sevrage en 2020" (Smoking for 7 y, recent relapse despite cessation in 2020), successful interpretation requires resolving the temporal relation between cessation and relapse to infer that the patient is an active smoker, dependencies that standard NER pipelines, which treat entities and assertions separately, struggle to capture. These linguistic characteristics highlight the need for approaches more capable of sentence-level semantic interpretation.

At the same time, developing context-aware information extraction systems can be resource-intensive. The development and evaluation of NER models require extensive expert annotation to label entity boundaries and associated features within large-scale corpora [20], a process made even more laborious by the sparsity of clinically relevant content [21-23]. With the advancement of deep neural networks, embedding fusion techniques have been adopted to enhance context utilization and improve recognition accuracy in NER tasks [24]. However, their cross-domain applicability is limited by high computational cost and reliance on external resources for comprehensive feature engineering. To overcome the limitations of traditional NER pipelines and handcrafted feature engineering, recent research has shifted toward the use of transformer-based pretrained language models that inherently capture richer contextual representations [25]. Encoder-only language models such as BERT [26] and CamemBERT [27] have demonstrated high performance in domain-specific tasks through fine-tuning on relatively small annotated datasets [28]. Decoder-only large language models (LLMs), such as ChatGPT [29] and Mistral [30], can achieve similar goals via prompt engineering without requiring fine-tuning. However, both approaches still depend on domain-specific expertise for model adaptation [31,32], and decoder-only models introduce substantial computational costs that limit their feasibility for routine institutional deployment [33].

Beyond technical constraints, institutional heterogeneity, including differences in documentation practices, terminologies, and privacy regulations, presents major barriers to developing and sharing information extraction systems across institutions [34-36]. Clinical documentation varies widely across institutions, incorporating nonstandard abbreviations, local terminology, and inconsistent formatting [19,37], which hinders the generalizability and scalability of information extraction models, requiring substantial annotation and model adaptation for each use case [19,38]. The sensitive nature of patient data further restricts access to real-world electronic health records and limits the sharing of pretrained models, due to risks of unintended information leakage [39,40]. Consequently, research teams often need to rebuild extraction systems from scratch, even when addressing similar clinical objectives [16,41]. In light of these limitations, there is a critical need for practical, context-aware information extraction systems that can be developed and reused within institutional boundaries.

To address these limitations, we designed the Medical Status Extraction Pipeline (MSEP) as a methodological framework that supports the local development of hybrid approaches for information extraction. MSEP reframes medical status extraction as a sentence classification task, which directly leverages contextual cues such as negation, temporality, and subject attribution while reducing annotation complexity. In addition, by accommodating rule-based methods, fine-tuned language models, and LLM prompting, MSEP allows institutions to select extraction approaches suited to their data availability and computational resources.

XSL•FO
RenderX

To support its interest, the MSEP has been applied to build extractors of patients' status for 6 clinically relevant medical conditions [16,42,43] from a French CDW: smoking, hypertension, diabetes, heart failure, chronic obstructive pulmonary disease (COPD), and family history of cancer. This paper first outlines the steps, functions, and requirements of the MSEP pipeline, along with the materials and tools used. Next, we present the evaluation results of extractors built using MSEP and compare them with different medical information retrieval approaches (rule-based methods and prompt-based LLM extraction). Finally, we discuss the operational benefits of MSEP, particularly reduced annotation effort, and its potential use as an upstream research tool within institutional settings.

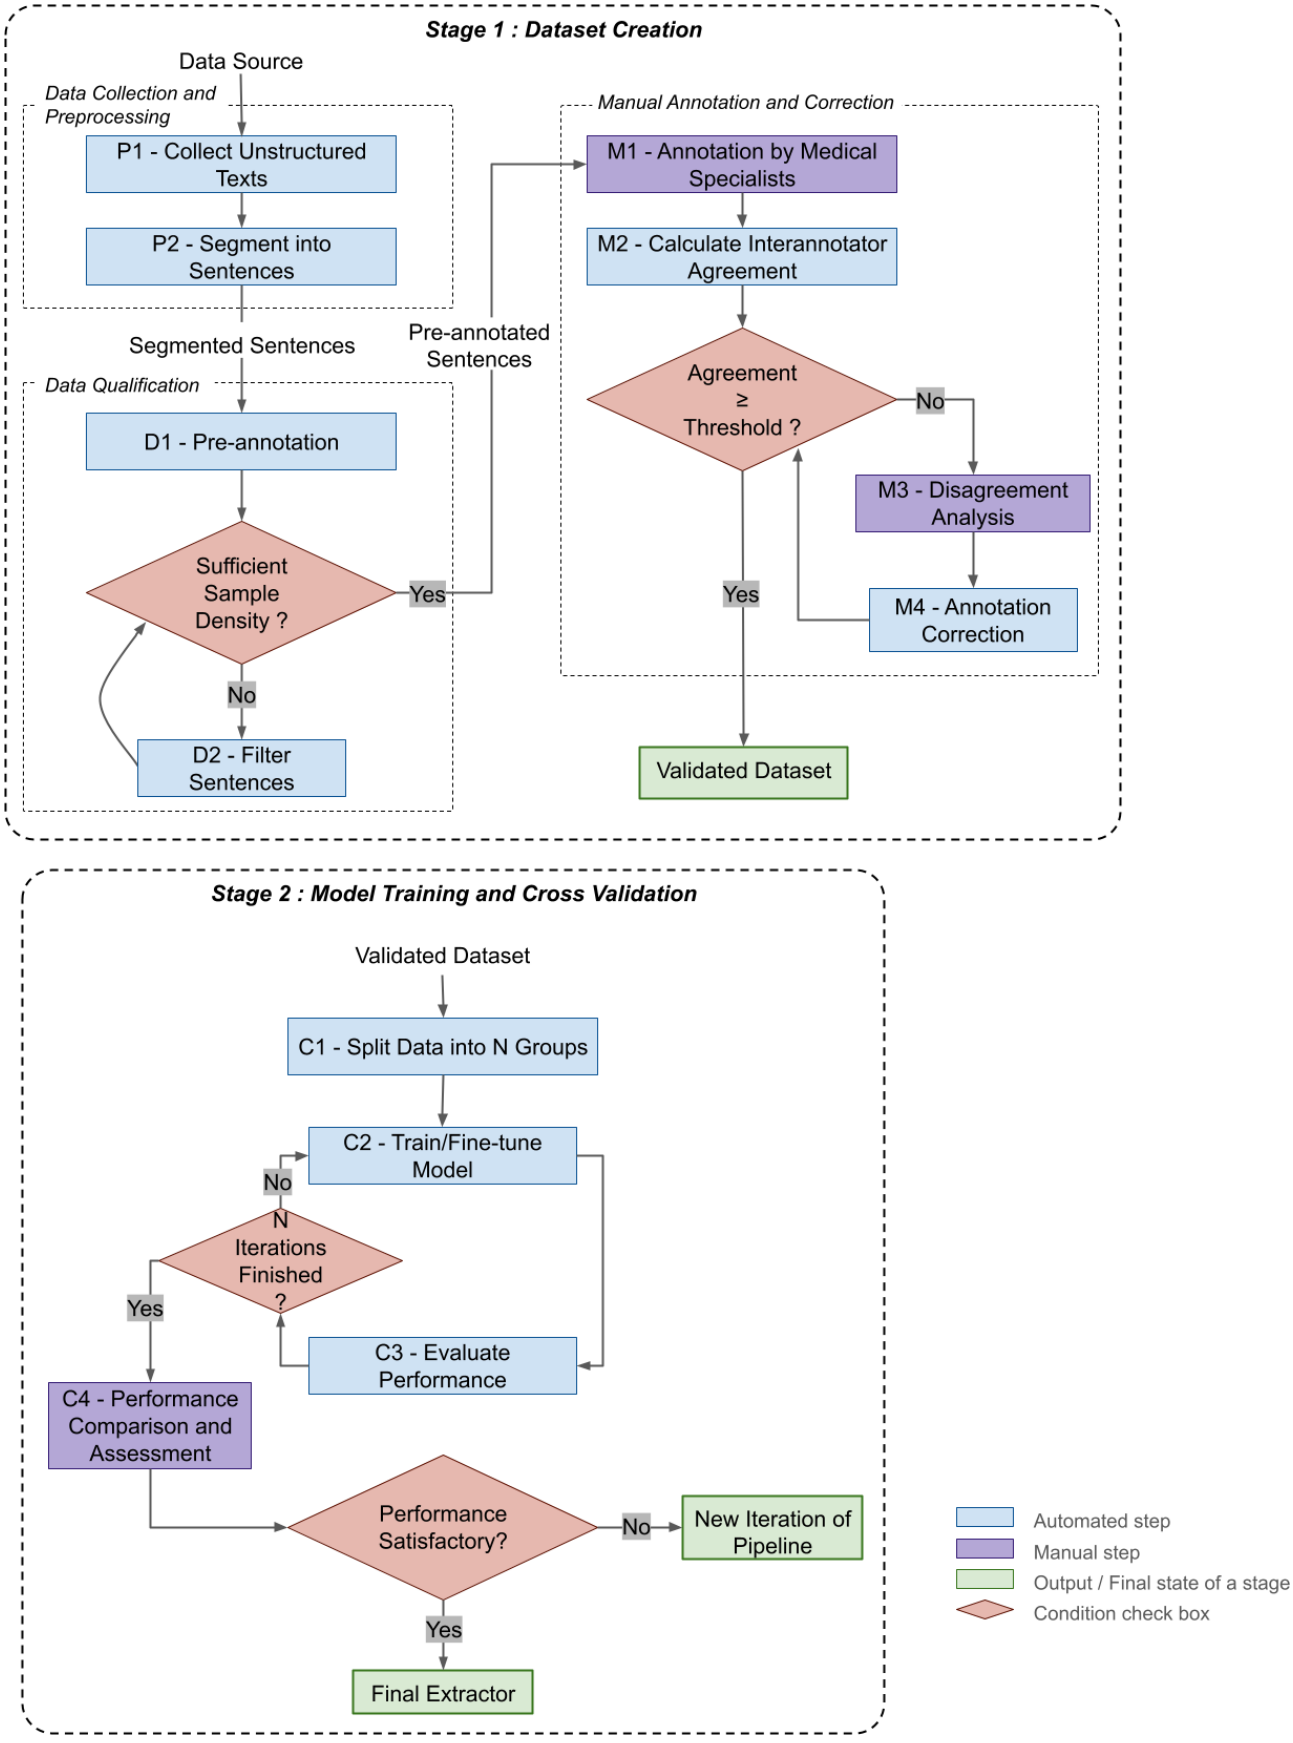
Methods

Overview

The MSEP pipeline classifies sentences in clinical documents as present, absent, or unknown regarding a patient's medical condition. Available as a Python package (repository link in Multimedia Appendix 1), the framework includes configurable parameters that allow its components to be adapted to local research needs and institutional constraints. In the following sections, we first describe the general design of the pipeline and then detail its implementation within our institutional setting.

Ethical Considerations

Ethics approval for data reuse was obtained from the Commission Nationale de l'Informatique et des Libertés (agreement number 2206739). This study was conducted on pseudonymized secondary clinical data provided by the Clinical Data Center of Rennes Hospital. In accordance with French regulations and the guidelines of the Commission Nationale de l'Informatique et des Libertés. Patients were informed of the potential use of their data for research purposes through the hospital's standard information notice. All data were pseudonymized by the Clinical Data Center before being transmitted to the research team. No identifying information was accessible at any stage of the analysis. No compensation was applicable or provided to participants.



Generic Pipeline Design

Overview

The global framework of our method is depicted in Figure 1. The framework consists of two main stages: (1) dataset creation and (2) model training with cross-validation. In order to facilitate the comprehension of the framework, the abbreviations of the steps in the figure are also mentioned in the text.

XSL•FO
RenderX

Figure 1. Overview of the proposed iterative medical status extraction system. This pipeline is primarily designed to extract the status of one medical condition at a time; it may repeat multiple times (iterations) to improve the extractors. This diagram mainly shows the process of the first iteration.

XSL•FO
RenderX

Dataset Creation

Overview

The objective of this stage is to construct the datasets required for training and validating medical status extractors. It involves three processes: (1) data collection and preprocessing, (2) data qualification, and (3) manual annotation and correction.

Data Collection and Preprocessing

Data collection gathers unstructured texts from CDW (P1), which are preprocessed by segmenting into sentences for classification (P2). The output is a corpus of sentences with relevant metadata that maintains the relationship to their source documents.

Data Qualification

The input to the data qualification process is the preprocessed sentence corpus. This phase assesses whether the collected data have appropriate sample density and size for effective model training. Sentences undergo automatic preannotation (D1), preferably using quickly implemented rule-based approaches that match medical status keywords. When preannotating sentences from all documents is impractical due to time and resource constraints, a random subset may be selected. If sample density is low, based on preannotation results, a portion of sentences unlikely to contain medical status information is filtered out (D2). This supervised sampling approach is designed to enhance annotation efficiency and final data quality by optimizing the training sample structure. The output is a preannotated sentence dataset with optimized annotation density and a balanced representation of target medical statuses.

Manual Annotation and Correction

The preannotated sentences serve as input for manual annotation, which requires multiple medical specialists to classify them according to annotation guidelines (M1). Annotators should collaboratively annotate a subset of the sentences to calculate interannotator agreement (M2). If the agreement exceeds the predetermined threshold, the annotations form the training and validation datasets. Otherwise, disagreements are analyzed (M3) to improve guidelines, with corrections applied to the annotated data accordingly (M4). The correction approach depends on the type of disagreements, but preferably through manual review. The disagreements analysis-correction process can be repeated until the interannotator agreement exceeds the threshold. The output is a validated annotated dataset ready for model development.

Model Training and Cross-Validation

The annotated datasets become the input for training or fine-tuning neural network models for medical status extraction. Since the pipeline is designed to extract the status of one medical condition at a time, each corresponding model is trained in a multiclass classification setting, where the possible status labels (eg, present, absent, and unknown) are mutually exclusive. Model stability is assessed through cross-validation by dividing annotated data into several groups (C1), using one group for validation (C3) and the remainder for training (C2) in each session. The number of cross-validation sessions equals the number of groups of data. The data grouping strategy for cross-validation should align with study objectives; for example, testing model stability across different document types requires data partitioning by document type. The extractor's performance metrics across multiple validation sets are assessed and compared with extractors based on other approaches, if available, to decide whether it has stable and state-of-the-art performance (C4). The flexibility of the pipeline configuration allows for easy benchmarking of different models (such as BERT-based models, rule-based systems, or LLM prompts), facilitating comprehensive performance comparison with minimal additional setup.

If the assessment result is positive, the pipeline ends, and the output is a trained medical status extraction model with satisfactory performance.

Iterative Improvement Process

If, according to the assessment step (C4), the extractor does not achieve satisfactory performance (eg, a macro *F*-score below 90%), the pipeline allows for iterative refinement. The definition of "satisfactory" performance may vary depending on the objectives and standards of different research projects.

The iterative process involves both quantitative and qualitative improvements. Quantitatively, additional annotated sentences are incrementally introduced to expand the training and validation datasets. The number of added samples per iteration is not fixed and depends on multiple factors, including the time allocated for manual annotation, the number and availability of annotators, and computing resources.

Qualitatively, the pipeline may be refined by improving preannotation rules, updating annotation guidelines based on annotator feedback, or replacing rules with more accurate extractors from previous iterations for preannotation. The first iteration serves as an exploratory phase to identify bottlenecks, such as insufficient data for certain labels, weak vocabulary coverage in preannotation rules, or annotation inconsistencies, allowing for targeted improvements in subsequent iterations.

Study-Specific Implementation

Data Source and Working Corpus

We used the eHOP CDW from Rennes University Hospital, which contains 80 million unstructured and 430 million structured data elements covering over 1.8 million patients [44]. For this study, we extracted unstructured documents from our previous bladder cancer research dataset [3], obtaining 799,470 documents from 5398 patients. This corpus encompasses diverse medical document types including nursing care reports, medical reports, multidisciplinary follow-up & daily notes, imaging reports, prescriptions, and medication orders (Table 1).

XSL•FO
RenderX

Table . Numbers and ratios of the 9 most frequently found document types (as well as the rest of the 5020 documents in "Other") in our corpus.

Medical document type	Value, n (%)
Nursing care–procedures	329,359 (41)
Medical reports	187,370 (23)
Nursing care–monitoring and vitals	153,865 (19)
Multidisciplinary follow-up and daily notes	54,187 (7)
Imaging reports	31,430 (4)
Prescriptions and medication orders	13,163 (2)
Paramedical care	13,083 (2)
Administrative and admission	6839 (1)
Results and pathology reports	5225 (1)
Other	5020 (1)

Rationale for Extraction Method Design

MSEP is designed as a hybrid framework capable of accommodating different resource-availability scenarios. To assess this flexibility, we evaluated 3 extraction approaches that represent distinct requirements: fine-tuning an encoder-only transformer (high annotation demand and moderate computational cost), rule-based extraction (minimal computation and annotation requirements but substantial reliance on domain expertise), and LLM prompting (low annotation requirements but high computational and expertise demands) [45]. Our experiments focused primarily on encoder-only fine-tuning in order to assess how effectively MSEP can reduce the associated annotation burden in practice, while the rule-based and LLM-prompting approaches served as comparative baselines for low-annotation settings. The rule-based approach is used for preannotation (D1) before fine-tuning, reinforcing the hybrid nature of the MSEP framework.

Regarding the models and tools used in these approaches, CamemBERT was selected for encoder-only fine-tuning strategy because it aligns with the sentence-classification paradigm and has demonstrated strong performance in French NLP tasks [25,46,47]. Furthermore, we opted for the original CamemBERT rather than domain-adapted variants such as CamemBERT-bio [48], as the latter are pretrained on specialized biomedical corpora, which may bias them toward known biomedical tasks and entities [49,50]. Using a general-domain model allows us to evaluate the pipeline's components without relying on domain-specific pretraining and to examine how it behaves in our institutional corpus when applied to varied clinical conditions. For LLM prompting, we used Mixtral-8×7B-v0.1 [51], which offered the strongest performance that could be efficiently supported by our institutional infrastructure (an NVIDIA A100 40 GB GPU). The rule-based extractors were developed using regular expressions and terminology specific to each targeted medical condition, provided by medical experts.

Pipeline Configuration

The pipeline was independently evaluated on 6 medical conditions: smoking, hypertension, diabetes, heart failure, COPD, and family history of cancer. For each condition, we defined 3 possible statuses: "present," "absent," and "unknown," corresponding to confirmed presence, negation, and uncertainty regarding the patient's condition. For the smoking condition, an additional status, "former," was included to indicate that the patient previously smoked but has since quit (Table S1 in Multimedia Appendix 2 provides a detailed definition of medical statuses). Multimedia Appendix 2 contains the annotation guidelines, which give more details about the criteria for annotating the medical status.

We used Spacy's fr_core_news_md model [52] for sentence segmentation (P2) and manually crafted rules based on specialist-provided keywords for preannotation (D1), supplemented by EDS-NLP's negation and family context qualifiers [53] for smoking and family history of cancer. Two medical specialists performed annotations (M1) using the Prodigy interface [54], with Cohen kappa [55] measuring interannotator agreement (M2), which is defined as:

$$(1)\kappa=(Po-Pe)/(1-Pe)$$

where *Po* is the observed agreement and *Pe* is the expected agreement by chance. A threshold of 0.8 was used to determine acceptable agreement.

For CamemBERT-based extractors, we performed a 3-fold stratified cross-validation. The full annotated dataset was randomly partitioned into 3 equally sized folds (C1), preserving the proportion of annotated categories within each fold. Duplicated (identical) sentences were removed before the partition to prevent data leakage across folds. In each of the 3 cross-validation rounds, two folds were used for training and the remaining fold served as the validation set (C2). We trained the CamemBERT-large model [27] with loss weighting to address class imbalance. The weighted cross-entropy loss with class weighting is defined as:

$$(2)L=-\Sigma i\ wi\times\log\ p(yi|xi),wi=N/(C\times Nyi)$$

where $p(yi \mid xi)$ is the predicted probability for the true class *yi* of input *xi*, *wi* is the class-specific weight, *N* is the total number of samples, *C* is the number of classes, and *Nyi* is the number of samples in the class of example *i*. Model performance was evaluated (C3) using precision, recall, specificity, *F*-score on individual status, balanced accuracy, and macro *F*-score on all statuses of a medical condition. Balanced accuracy was defined as:

XSL•FO
RenderX

(3)Balancedaccuracy=(1/C)×Σc[((TPc/(TPc+FNc))+(TNc/(TNc+FPc)))/2]

and macro *F*-score was defined as:

(4)F1macro=(1/C)×ΣcF1(c)

where *C* is the number of classes, and *TPc*, *FNc*, *TNc*, and *FPc* are respectively the true positives, false negatives, true negatives, and false positives for class *c*. This set of metrics is supposed to cover all necessary aspects of evaluation for an information retrieval system according to [56]. For comparison (C4), we evaluated our rule-based extractors and Mixtral-8x7B-v0.1 LLM prompts on the same validation sets used for the cross-validation (C2+C3). To ensure a quite fair comparison, the Mixtral-8x7B prompts were designed using few-shot examples derived from the annotation guidelines, combining basic extraction instructions with expert-crafted example and counter-example sentences embedding specialist-provided keywords and clinical context narration.

Detailed configuration information for each step in MSEP appears in Multimedia Appendix 1. The MSEP python package (repository link in Multimedia Appendix 1) provides configurable modules to realize each step of the pipeline.

Results

Overview

We conducted 2 iterations of the pipeline in our institutional setting to create and refine the extractors, after which most targeted medical conditions reached satisfactory performance (average macro *F*-score>0.94) for our use case. This section presents the results of these iterations, describing implementation paths, dataset characteristics, cross-validation results, and comparisons between our extractors and alternative approaches.

Pipeline Execution and Time Requirements

Figure 2 details the implementation path and time consumption for each medical condition across both iterations.

XSL•FO
RenderX

Figure 2. Steps in the 2 iterations of the pipeline were realized to extract each medical status. The steps within the curly braces mean that they are repeatedly realized within one iteration, and the number after the * marks how many times these steps have been repeated. The color of the steps is consistent with Figure 1; blue means automated steps and purple means manual steps. The type of model used for preannotation (PA) and the interannotator agreement score calculated at step M2 are given underneath the list of steps. The last 4 columns show the total time consumption of preannotation (D1), manual annotation (M1) during both iterations, model fine-tuning during cross-validation (C2), and the total time consumed to go through the pipeline in 2 iterations (Ttl). The time consumption is calculated by hours (h) or by minutes (m), depending on the convenience of data representation. COPD: chronic obstructive pulmonary disease.

Medical condition	Steps (1st iter)	Steps (2nd iter)	Consumed time			
			D1	M1	C2	Ttl
Smoking	P1-P2-D1-D2-M1-M2-C1-{C2-C3}*3-C4 Preannotation: rule-based Cohen kappa: 0.91	P1-P2-D1-D2-M1-M2-C1-{C2-C3}*3-C4 Preannotation: CamemBERT based Cohen kappa: 0.96	1st iter : 8 h 2nd iter : 11 h	10 h	66 m	30 h

Family history of cancer	P1-P2-D1-D2-M1-M2-C1-{C2-C3}*3-C4 Preannotation: rule-based Cohen kappa: 1.0	P1-P2-D1-D2-M1-M2-C1-{C2-C3}*3-C4 Preannotation: rule-based Cohen kappa: 1.0	24 h	4 h	33 m	29 h

Most medical conditions were preannotated using rule-based matching, except smoking status, which was preannotated in the second iteration using a CamemBERT-based extractor fine-tuned from the first, which outperformed the rules. Heart failure annotation during the second iteration initially yielded insufficient interannotator agreement (57%), necessitating disagreement analysis and correcting annotated data. The analysis revealed that the inconsistencies arose from concept confusion among annotators. A list of ambiguous terms was identified and clarified with a medical expert, incorporated into updated annotation guidelines, and used to automatically extract sentences that need revision from all annotations. These

XSL•FO
RenderX

sentences were then reviewed and corrected by the annotators based on the updated guidelines.

Time requirements varied by medical condition and process step. We focused on the 3 most time-intensive steps: preannotation (D1), manual annotation (M1), and extractor training during cross-validation (C2). Preannotation (D1) speed ranged from 0.02 to 0.17 seconds per sentence, with COPD and diabetes being fastest (0.02 s/sentence) and smoking and family history of cancer slowest (0.12 - 0.17 s/sentence). Manual annotation (M1) required 1.2 - 2.9 seconds per sentence when considering all status labels, with diabetes and family history of cancer being the most efficient (1.2 s/sentence) and smoking being the most time-intensive (2.9 s/sentence). After removing the speed bias introduced by quickly dismissed sentences labeled as unknown, annotation speed ranged from 2.23 to 4.25 s/sentence, with hypertension being the fastest and family history of cancer the slowest, indicating that annotation speed is partly driven by sentence complexity and semantic load. Cross-validation training (C2) averaged 5 - 22 min per session (of cross-validation), with COPD training being fastest (5 m/session) and hypertension slowest (22 m/session). Final extractor inference speed ranged from 0.09 to 0.12 s per sentence. Total implementation time across both iterations (Ttl) ranged from 8 hours (diabetes) to 30 hours (smoking). The time consumption and speed of all automatic steps (D1, C2, and inference of extractors) are calculated on a GPU of NVIDIA A100 40 GB graphics card.

Training and Validation Datasets

The first iteration involved quickly preannotating 9997 medical documents and selecting 991 sentences from them for manual annotation. In order to improve extractors' performance by training them with more medical status samples, the second iteration preannotated an additional 18,994 documents, yielding 11,128 sentences for manual annotation. Table 2 shows the distribution of medical status in sentences annotated during each iteration. The training and validation dataset for the 2nd iteration of the pipeline is the combination of all sentences annotated during both iterations (12,119 sentences in total).

Table . Number of samples of different medical status in sentences respectively annotated during the 1st (itr1) and the 2nd (itr2) iteration of the pipeline.

Medical condition	Present		Absent		Former		Unknown		Total	
	itr1	itr2	itr1	itr2	itr1	itr2	itr1	itr2	itr1	itr2
Smoking	75	646	42	211	87	417	787	9854	991	11,128
Diabetes	279	257	29	37	—[a]	—	683	10,834	991	11,128
Hypertension	217	1184	8	30	—	—	766	9914	991	11,128
Heart failure	46	183	41	217	—	—	904	10,728	991	11,128
COPD[b]	22	366	0[c]	1[c]	—	—	969	10,761	991	11,128
Family history of cancer	5	2	0[c]	1[c]	—	—	986	11,125	991	11,128

[a]Not applicable.

[b]COPD: chronic obstructive pulmonary disease.

[c]Status with too few samples for cross-validation.

Sample sparsity was evident for certain status classifications. During the first iteration, most conditions had fewer than 300 samples per status, with absence samples typically fewer than presence samples. No samples were found for the absence of COPD and family history of cancer. We then increased preannotated documents for the second iteration, which successfully increased sample counts for most status classifications, though samples remained limited due to the absence of COPD and both the presence and absence of family history of cancer.

Among the 12,119 sentences, approximately 10% (n=1200) were randomly selected from the medical documents without preannotation, yielding an unbiased subset of 1200 sentences (unfiltered sentences [US]). We compared the distribution of medical statuses in this subset with that of the remaining 10,919 sentences (preannotated filtered sentences [PS]) selected through preannotation to assess the extent of bias introduced by this data qualification process (D1, D2).

Table 3 shows the result of this comparison. For each medical condition, we calculated the proportion for each of its statuses within US and PS, which is defined as:

(5)proportion=c(status)/c(present,absent,former)

XSL•FO
RenderX

Table . Comparison of medical status samples' distribution (%) in 10,919 preannotated filtered sentences (PS) and 1200 unfiltered sentences (US).

Status	Smoking		Diab		Hyper		CHF[a]		COPD[b]		Fam	
	US	PS	US	PS	US	PS	US	PS	US	PS	US	PS
Present	44	49	100	89	100	97.3	33.3	47.1	100	99.7	0	88
Absent	12	17	0	11	0	2.7	66.7	52.9	0	0.3	0	12
Former	44	34	—[c]	—	—	—	—	—	—	—	—	—
Prevalence of relevant statuses	0.75	13.5	0.25	5.49	0.75	13.1	0.25	4.43	0.17	3.54	0	0.07

[a]CHF: congestive heart failure.

[b]COPD: chronic obstructive pulmonary disease.

[c]Not applicable.

where *c*() denotes the total number of samples of one or more statuses in the set. Since the purpose of the data qualification is specifically to reduce the proportion of sentences that do not express any status information (ie, the class unknown), this category was excluded from the computation to avoid inflating the proportions of relevant statuses (ie, present, absent, and former) in the PS and obscuring the assessment of distributional changes. Instead, we report the prevalence of relevant statuses in US and PS to quantify how effectively steps D1+D2 have increased relevant samples' density in PS by filtering out irrelevant sentences (class unknown). This measurement is defined as:

$$(6) \text{prevalence} = c(\text{present}, \text{absent}, \text{former}) / c(\text{present}, \text{absent}, \text{former}, \text{unknown})$$

Across most medical conditions, the distribution of status labels remained stable after the data filtering steps. The proportions of present status for smoking, diabetes, hypertension, and COPD, as well as the absent status for COPD and hypertension, showed only minor deviations between US and PS. A modest shift was observed for the former and absent statuses of smoking, whereas heart failure exhibited a more substantial change in the present status (from 33.3%, 1/3 in US to 47.1%, 228/484 in PS). Larger apparent shifts for rare categories, such as family history of cancer or the absent status of hypertension, reflect the extremely small number (or absence) of these samples in US, making baseline proportions unstable and limiting interpretability. Overall, despite shifts in certain conditions, the relative ordering of status frequencies remained consistent, suggesting preservation of the dominant patterns. Finally, the prevalence values show that the filtering steps substantially increased the density of relevant samples. For most conditions, the proportion of samples in PS was more than 10 times higher than in US (eg, from 0.75%, 9/1200 to 13.45%, 1469/10,919 for smoking, and from 0.25%, 3/1200 to 5.49%, 599/10,919 for diabetes), demonstrating the effectiveness of steps D1+D2 in removing irrelevant sentences while introducing only minor distributional bias.

CamemBERT-Based Medical Status Extractors Evaluation

As a reminder, each extractor was trained in a multiclass classification setting to predict the status of a single medical condition. Evaluation metrics include precision, recall, specificity, and *F*-score for each individual status, as well as balanced accuracy and macro *F*-score aggregated across all statuses. Table 4 presents the performance metrics for the best-performing extractor of each medical condition after the second iteration. Extractors for diabetes and heart failure achieved excellent overall performance (macro *F*-scores of 99% and 96%, respectively). The COPD extractor achieved a macro *F*-score of 99%, although evaluation was limited to the present and unknown classes due to the lack of absent samples. The diabetes, hypertension, and COPD extractors exceeded 98% *F*-score for presence detection. The smoking extractor achieved balanced performance across status classifications (93% - 94% *F*-scores), while the hypertension extractor showed imbalanced performance between presence (98% *F*-score) and absence (86% *F*-score). The extractor for family history of cancer underperformed with only 80% *F*-score for presence detection.

XSL•FO
RenderX

Table . Performance of the best CamemBERT-large based extractors obtained after the cross-validation of the 2nd iteration of the pipeline. For each of the studied 6 medical conditions—smoking, diabetes (diab), hypertension (hyper), congestive heart failure (CHF), chronic obstructive pulmonary disease (COPD), and family history of cancer (fam)—the extractor is evaluated on each of its status (unknown, absent, present, or former) with 4 metrics: *F*-score, precision, recall, and specificity. The macro *F*-score and balanced accuracy are calculated on (and only on) the evaluated status.

Extractor	Smoking	Diab	Hyper	CHF	COPD	Fam
Unknown *F*-score	0.98	0.99	0.98	0.97	0.99	0.99
Unknown Precision	0.99	1.0	0.98	0.96	1.0	1.0
Unknown Recall	0.97	0.99	0.99	0.99	0.99	0.99
Unknown Specificity	0.99	1.0	0.98	0.94	1.0	1.0
Absent *F*-score	0.94[a]	1.0[a]	0.86[b]	0.97[a]	—[c]	—
Absent Precision	0.94	1.0	0.86	0.98	—	—
Absent Recall	0.93	1.0	0.85	0.96	—	—
Absent Specificity	0.99	1.0	0.99	0.99	—	—
Present *F*-score	0.93[a]	0.99[a]	0.98[a]	0.92[a]	0.99[a]	0.80[b]
Present Precision	0.91	0.99	0.98	0.96	0.98	0.67
Present Recall	0.95	1.0	0.98	0.89	1.0	1.0
Present Specificity	0.97	0.99	0.99	0.99	0.99	0.99
Former *F*-score	0.94[a]	—	—	—	—	—
Former Precision	0.93	—	—	—	—	—
Former Recall	0.94	—	—	—	—	—
Former Specificity	0.99	—	—	—	—	—
Macro *F*-score	0.95[a]	0.99[a]	0.94[a]	0.96[a]	0.99[a]	0.89[b]
Balanced accuracy	0.95	0.99	0.94	0.95	0.99	0.99

[a]Status (other than Unknown) whose *F*-score has surpassed 90%.

[b]*F*-score has not surpassed 90%.

[c]Not applicable.

Table 5 presents the results of the 3-fold cross-validation from both iterations. For each medical condition, we evaluated the stability of the extractors by reporting the mean and SD of the *F*-score for each status category, as well as for the overall macro *F*-score, across the cross-validation folds. All extractors demonstrated improved performance after the second iteration. After the first iteration, only the diabetes extractor achieved a macro *F*-score exceeding 90%, while by the second iteration, most condition extractors surpassed this threshold. Hypertension, heart failure, and COPD extractors showed the most substantial improvement (>30%).

XSL•FO
RenderX

Table . Result (average *F*-score, SD) of 3-fold stratified cross-validation with CamemBERT-large based extractors trained during the 1st (iter 1) and the 2nd (iter 2) iterations of the pipeline.

Medical condition	Present *F*-score, mean (SD)	Absent *F*-score, mean (SD)	Former *F*-score, mean (SD)	Unknown *F*-score, mean (SD)	Macro *F*-score, mean (SD)
Iter 1					
Smoking	0.78 (0.02)	0.70 (0.03)	0.88 (0.005)	0.99 (0.02)	0.83 (0.02)
Diabetes	0.89 (0.04)	0.99 (0.01)[a]	—[b]	0.98 (0.004)	0.95 (0.03)[a]
Hypertension	0.94 (0.002)	0 (0)	—	0.97 (0.003)	0.63 (0.003)
Heart failure	0.24 (0.03)	0.14 (0.1)	—	0.71 (0.09)	0.36 (0.05)
COPD[c]	0 (0)	—	—	0.93 (0.04)	0.31 (0.01)
Family history of cancer[d]	0 (0)	—	—	0.99 (0.003)	0.33 (0.001)
Iter 2					
Smoking	0.93 (0.008)	0.93 (0.005)	0.92 (0.01)	0.98 (0.0004)	0.94 (0.003)
Diabetes	0.98 (0.008)[a]	0.98 (0.02)[a]	—	0.98 (0.004)	0.98 (0.01)[a]
Hypertension	0.98 (0.002)[a]	0.85 (0.01)[e]	—	0.98 (0.002)	0.96 (0.009)[a]
Heart failure	0.90 (0.02)	0.95 (0.02)[a]	—	0.97 (0.003)	0.94 (0.003)
COPD	0.99 (0.002)[a]	—	—	0.99 (0.003)	0.99 (0.002)[a]
Family history of cancer[d]	0.55 (0.37)	—	—	0.99 (0.003)	0.73 (0.17)

[a]Average *F*-score more than 95% at detecting medical status other than Unknown (either iteration).

[b]Not applicable.

[c]COPD: chronic obstructive pulmonary disease.

[d]For family history of cancer, with only 7 positive samples across 2 iterations, calculating a SD of 37% for the *F*-score is statistically unstable and potentially misleading regarding the extractor's reliability.

[e]Average *F*-score less than 90% after the second iteration.

Despite these improvements, the family history of cancer extractor achieved only 73% macro *F*-score with 17% instability, primarily due to poor performance in detecting presence (55% *F*-score, 37% instability). The hypertension extractor also showed suboptimal performance for absence detection (85% *F*-score, 1% instability). Due to insufficient samples, absence classification for COPD and family history of cancer could not be trained or evaluated.

To go one step deeper into the assessment of the extractor performances, a post hoc analysis according to document type was conducted. Table 6 reports the average *F*-scores with SD, obtained during three-fold cross-validation during the last iteration of the pipeline, for each medical status across the major clinical document types represented in the dataset.

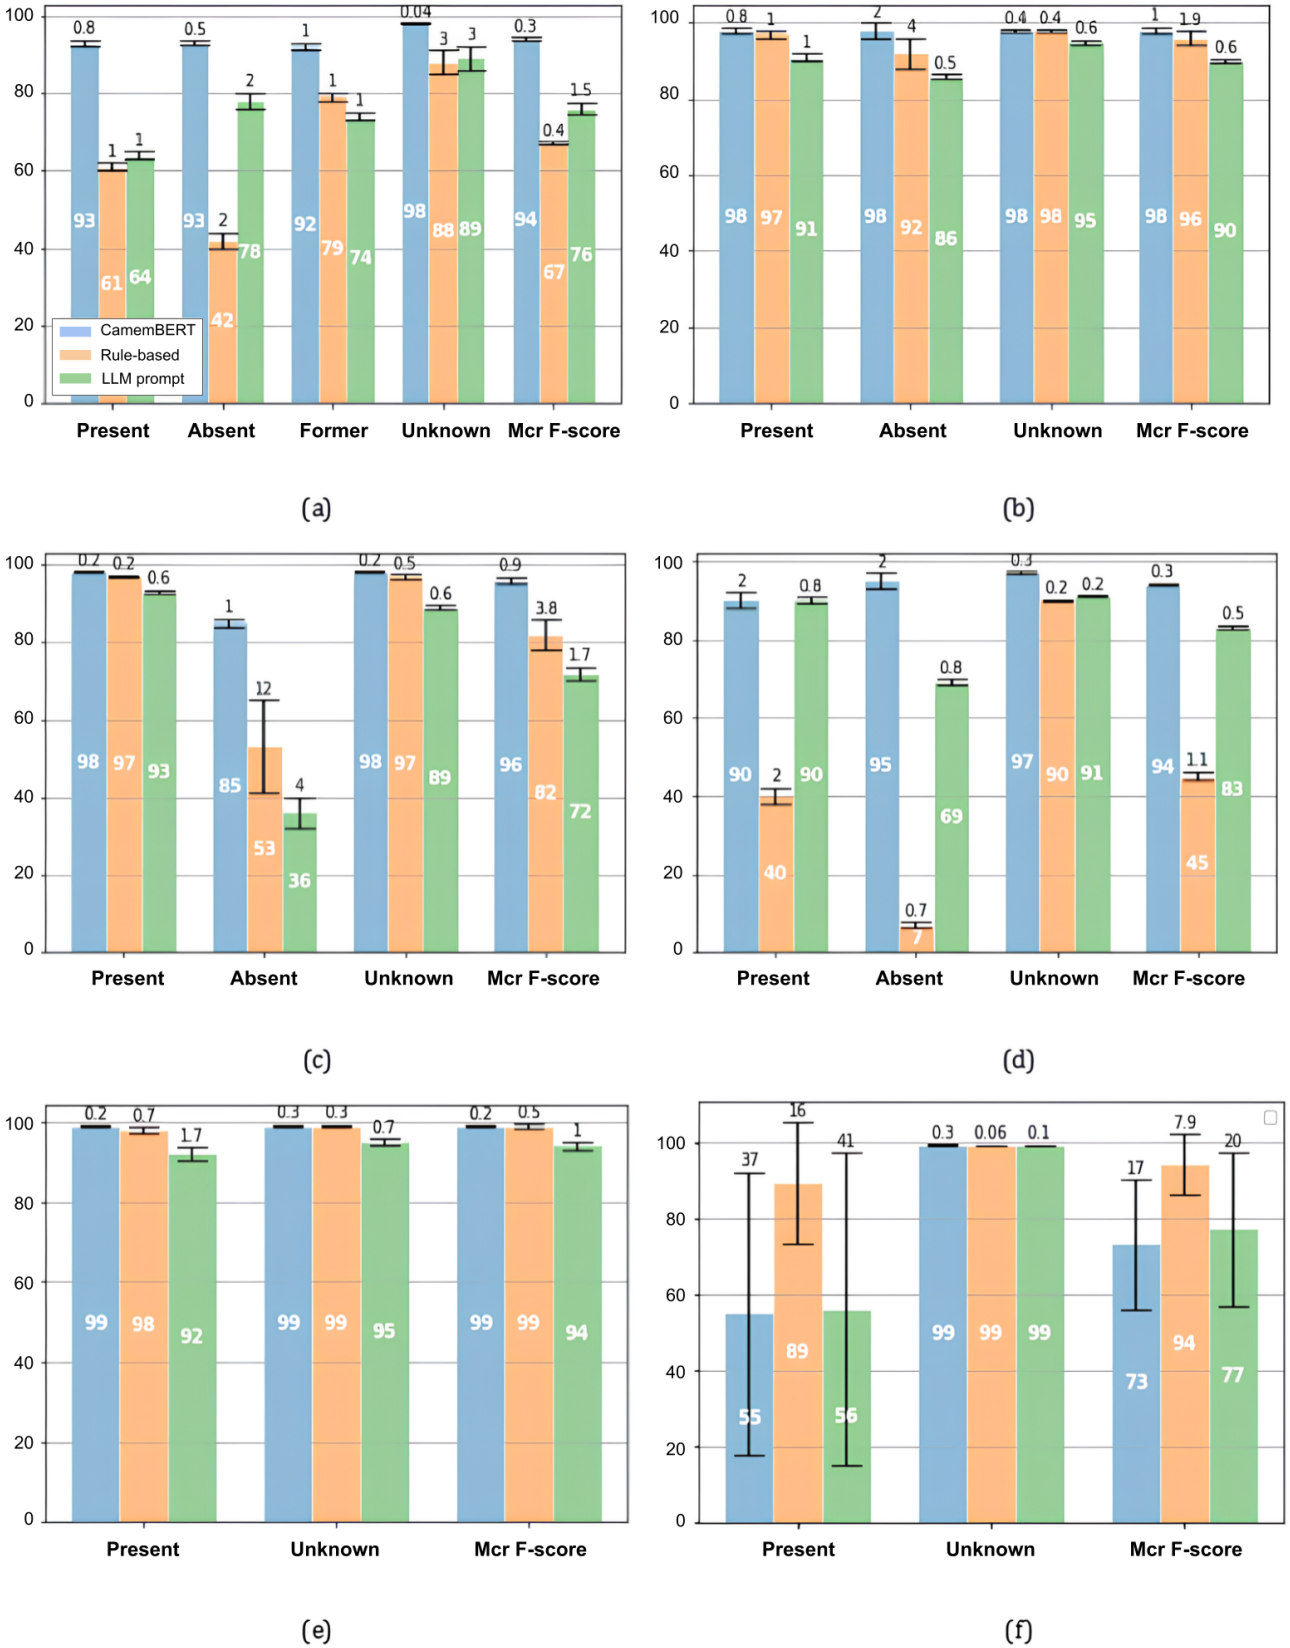
For 72 status–document-type combinations, no sample was retrieved in validation sets, and performance cannot be discussed (marked with an "-"). For the remaining 115 status document-type combinations, we can divide results into 2 categories.



Those with comparable performance (less than 5% decrease) or improvement on specific documents (109/115, 94.8%) and those where a decrease is observed (6/115, 5.2%). In the first category, 79 instances show a score of 1.0 +/– N/A, indicating that only one-fold contains content for evaluation. This perfect performance also suggests that few samples were available for evaluation. In the second category, 2 instances were only evaluated in one fold, and extractors missed the status (ie, for hypertension presence and heart failure presence in the nurse report). For the 4 others (smoking presence and diabetes indifference in paramedical report, absence of heart failure in daily note, and presence of COPD in administration note), a decrease is observed, but performance remains acceptable (>80%). Examination of false positives and false negatives in these 4 cases suggests that most errors stem from the misleading narrative style of clinical notes. For example, in a paramedical report, "OH chronique sevré tabac syndrome dépressif" (Chronic alcohol use weaned tobacco use depressive disorder) was misclassified as former smoking because the boundary between alcohol withdrawal and smoking was unclear. Another sentence, "des atcd cardio,HTA,DT2non traité" (A history of cardiac disease, untreated hypertension, and type 2 diabetes) was misclassified as absence of diabetes because the negation "non" was attached to the diabetes "DT2" rather than to the treatment "traité." The extractor also produces some persistent errors due to the medical complexity of the content, which is challenging even for specialist reviewers; for instance, a sentence in a daily note was misclassified as absent of heart failure because it contains this expression "avec une fraction d'éjection ventriculaire conservée" (with a preserved ventricular ejection fraction), which does not exclude entirely the possibility of having a heart failure. In conclusion, although the representation of entities is very sparse, we observe overall good robustness of the extractors depending on the type of document encountered. To go further, the number of annotated sentences would need to be increased.

Comparison With Alternative Approaches

Figure 3 presents a comparison of the extractors developed using CamemBERT fine-tuning, rule-based methods, and LLM prompting (Mixtral-8×7B-v0.1). As a reminder, all extractors were evaluated on the same validation sets used for the 3-fold cross-validation of CamemBERT-based extractors. For conditions with ample annotated examples, such as smoking and heart failure, CamemBERT-based extractors achieved the highest performance (also confirmed by paired *t* test analysis; Multimedia Appendix 3). In contrast, for conditions with limited training data, rule-based extractors performed comparably to or better than CamemBERT-based models, reflecting their robustness in low-data scenarios. This was particularly evident for family history of cancer, where CamemBERT-based extractors achieved an average macro *F*-score of 0.73 with a cross-validation SD of 17%, while the rule-based approach reached an average macro *F*-score of 0.94 with a substantially lower SD of 7.9%.

XSL•FO
RenderX

Figure 3. Comparison of the performance of extractors based on 3 different approaches: fine-tuned CamemBERT, (**A**) rule-based extraction and large language model prompt query for smoking, (**B**) diabetes, (**C**) hypertension, (**D**) heart failure, (**E**) chronic obstructive pulmonary disease, and (**F**) family history of cancer. The white number on each bar marks the average macro *F*-score percentage, and the number above each bar represents the SD (also percentage) calculated from cross-validation. The performance is evaluated by testing all extractors on the same validation datasets used during the 3-fold cross-validation of the 2nd iteration of the pipeline.

Compared with CamemBERT-based and rule-based extractors, LLM-prompted extractors showed intermediate performance overall but were less efficient in our setting. Using Mixtral-8×7B-v0.1, sentence-level extraction required 12 - 24 seconds per sentence and 35 GB of GPU memory, which is

XSL•FO
RenderX

slower and more resource-intensive than CamemBERT (0.09 - 0.12 s per sentence; 2 GB GPU).

These findings indicate that CamemBERT-based and rule-based methods are the most suitable approaches for our institutional resource constraints, and that no single extraction approach is universally optimal across all clinical scenarios.

Discussion

Overview

This section examines the advantages and limitations of the MSEP pipeline within our institutional setting and explores how its design can support local development of clinical NLP extractors.

Technical Advantages

Efficiency Gains for Clinical Text Annotation

The MSEP pipeline addresses challenges posed by the low density of medical-status information in large institutional corpora, which can hinder the efficient local development of information extraction systems. Its preannotation step helps prioritize sentences with potentially relevant information, and reframing extraction as sentence classification allows annotators to make quicker labeling decisions. Together, these components streamline dataset construction and reduce the operational burden of annotation.

Although our annotators were unavailable for extensive medical entity annotation, preventing a direct comparison of annotation speed in our institution, prior work has shown that sentence classification generally requires less annotation time and effort than word-level NER [57-60]. This is expected, as sentence classification involves assigning a single label to an entire sentence, whereas NER requires annotators to identify multiple entities within a sentence and decide on their boundaries, increasing the complexity and time required for annotation [61]. This improvement in annotation speed is also supported by an empirical comparison with a previous study on NER efficiency [20], as our manual sentence classification ranged from 1.2 to 2.9 seconds per sentence (or 2.23 to 4.25 s per sentence when considering only informative sentences), significantly faster than the 7.82 to 16.48 s reported for NER.

The sentence classification-based extractors also demonstrated faster inference speed than the traditional composite extractors (NER + qualifier). In our study, extractors of rule-based NER combined with EDS-NLP qualifiers were tested for smoking and family history of cancer during the preannotation step of the first iteration of the pipeline. The composite approach (0.17 s/sentence) was notably slower than our CamemBERT-based extractor (0.09 - 0.12 s/sentence) and rules-only preannotation models (0.02 - 0.04 s/sentence). Importantly, this efficiency gain did not compromise performance. Compared with recent medical status extractors, our pipeline achieved comparable or superior results. Our extractors reached *F*-scores of 99%, 95%, 96%, and 99% for diabetes, smoking, heart failure, and COPD, respectively, matching or exceeding performance metrics reported in recent literature [16].

Hybrid, Configurable, and Locally Deployable Pipeline Architecture

The MSEP pipeline was designed as a flexible and configurable framework that enables the local deployment of hybrid extraction approaches across diverse institutional settings. The accompanying Python package (repository link in Multimedia Appendix 1) exposes all key components, such as preannotation models (D1), sentence filtering criteria (D2), cross-validation strategy (C2), and extractor choice, as configurable arguments. This modular design allows researchers to tailor each step of the workflow, including the choice of extraction approach, according to their resource constraints, characteristics of the targeted information, and institutional requirements. For instance, in our experiments, fine-tuned CamemBERT models produced satisfactory performance for most medical statuses, whereas rule-based extractors yielded more stable results for conditions with limited representation in the dataset. This means that the pipeline can be configured to favor rule-based extraction in low-example scenarios. Conversely, in settings with limited annotation resources or domain expertise, the pipeline can be configured to generate LLM prompt-based extractors, which can be readily improved by providing more detailed instructions and examples in the prompts [62].

Our institutional experiments further illustrated the practical feasibility of deploying MSEP within a local clinical setting. First, the full workflow, including preannotation, manual validation, model training, and validation, was applied independently to 6 medical conditions and completed within 99 hours in total (approximately 16.5 h per condition). This was achieved with 2 annotators and a single NVIDIA A100 40 GB GPU, a setup feasible for many medical research institutions. Second, the models were trained and evaluated on a heterogeneous set of clinical documents (including hospital discharge summaries, consultation notes, and reports from multiple specialties). The comparable performance observed across these diverse sources indicates that the workflow can be operationalized effectively within diverse documentation practices at a single institution.

While our current evaluation remains monocentric, MSEP's packaging and explicit parameterization are designed to facilitate reproducible deployment in other institutions. Applying identical configurations on comparable data would be expected to yield consistent results, and extending the approach to multicentric validation represents an important next step toward confirming generalizability and cross-site reproducibility.

Enhanced Monitoring and Optimization Mechanic

The pipeline provides means for evaluating and improving each of its mean processes (data qualification, manual annotation and correction, model training, and cross-validation). Preannotation (D1) allows estimation and supervision on corpus' sample density and medical status' distribution, which can be adjusted by sentence filtering (D2); interannotator agreement calculation (M2) and analysis of annotation disagreements (M3) not only revise the quality of annotated sentences, but also reveal problems in annotation guidelines and improve them accordingly (M4); extractors' assessment and comparison (C4) enables

XSL•FO
RenderX

comprehensive model evaluation and informs decisions on the need for and direction of further improvements.

The iterative nature of our pipeline provides a means for monitoring and optimizing dataset size. By accumulating annotated data gradually and evaluating extractors with cross-validation at each iteration, we can determine when to halt manual annotation, limiting resource expenditure to reasonable levels. We also considered active learning as an alternative approach, where the model selects samples difficult to predict for prioritized manual annotation and updates itself with the received annotation [63]. In theory, this approach can maximize annotation efficiency by prioritizing the most informative samples for model improvement. However, we ultimately rejected it because model updates were disproportionately influenced by status categories with the most samples, and uncertain sample distribution prevented effective loss function weighting. Nevertheless, active learning remains valuable when balanced datasets are available or when sample balancing can be implemented during data acquisition [64].

Importance for Clinical Research

Response to Clinical Text-Mining Challenges

Clinical text mining remains challenging due to the unstructured and context-dependent nature of medical narratives. Our evaluation shows that sentence-level classification, as implemented in MSEP, effectively addresses several of these challenges in practice. The approach demonstrated high accuracy across heterogeneous document types, confirming that the model captures contextual cues, such as negation or temporality, without relying on context qualifiers. Compared with traditional NER-based systems, which require token-level annotation and post hoc context detection, the sentence classification strategy substantially reduces annotation time and complexity. The high *F*-scores obtained for conditions such as smoking and diabetes illustrate that this formulation aligns well with the way medical status is expressed, which is typically at the sentence level rather than through isolated entities.

To our knowledge, there is currently no existing pipeline in the clinical NLP literature that applies sentence classification for medical status extraction. While sentence classification has been explored in other domains, such as sentiment analysis or social media mining, its application to clinical narratives remains underdeveloped and has not yet been systematically assessed for this purpose.

Easy Implementation as a Research Tool for Clinical Studies
