Establishment and Evaluation of 7 Machine Learning Models for CHD Risk Prediction in Patients With HHcy

This study utilized 7 machine learning algorithms, namely logistic regression, XGBoost, LightGBM, random forest, decision tree, KNNs, and stacking ensemble, to develop risk prediction models for CHD in patients with HHcy based on 6 core predictors: age, weight, hypertension, continuous drinking history, APTT, and carotid plaque. In the training set assessment, each model exhibited distinct performance characteristics. Notably, the decision tree, random forest, and XGBoost models achieved perfect discrimination (AUC=1.000) and classification metrics (accuracy, sensitivity, specificity, and F_1-score=1.000), indicating potential overfitting, unlike the logistic regression and KNN models. The LightGBM model displayed strong performance with an AUC of 0.987, accuracy of 0.854, and F_1-score of 0.818. Conversely, the stacking ensemble model yielded an AUC of 0.933, accuracy of 0.810, and F_1-score of 0.660, demonstrating inferior performance compared to the aforementioned potentially overfitting models.

During the validation phase, model performance varied notably among different algorithms. The XGBoost model exhibited the highest AUC of 0.802 and an F_1-score of 0.689. The stacking model outperformed others with an AUC of 0.800, the highest accuracy of 0.769, and an F_1-score of 0.625. The LightGBM model achieved an AUC of 0.780 and an F_1-score of 0.648. In comparison, the logistic model yielded an AUC of 0.755 and an F1-score of 0.639. The random forest model attained an AUC of 0.777; however, it demonstrated low sensitivity at 0.355 and an F_1-score of 0.489. The decision tree model, with an AUC of 0.679 and an F_1-score of 0.613, displayed limited generalization ability and was notably impacted by overfitting during training.

During testing, the LightGBM model demonstrated the highest AUC of 0.807, a sensitivity of 0.913, and an F_1-score of 0.636, indicating promising performance. The logistic model yielded an AUC of 0.796, an F_1-score of 0.603, a sensitivity of 0.826, and a specificity of 0.618, striking a balance between prediction accuracy and clinical relevance. In contrast, the stacking model achieved an AUC of 0.802 but exhibited lower sensitivity at 0.478 and an F_1-score of 0.564, suggesting limited generalizability. Although the random forest model achieved the highest accuracy at 0.769, its F_1-score was 0.571. The XGBoost model's performance notably decreased, with an AUC of 0.757 and an F_1-score of 0.523 (Table 3).

[a]AUC: area under the receiver operating characteristic curve.

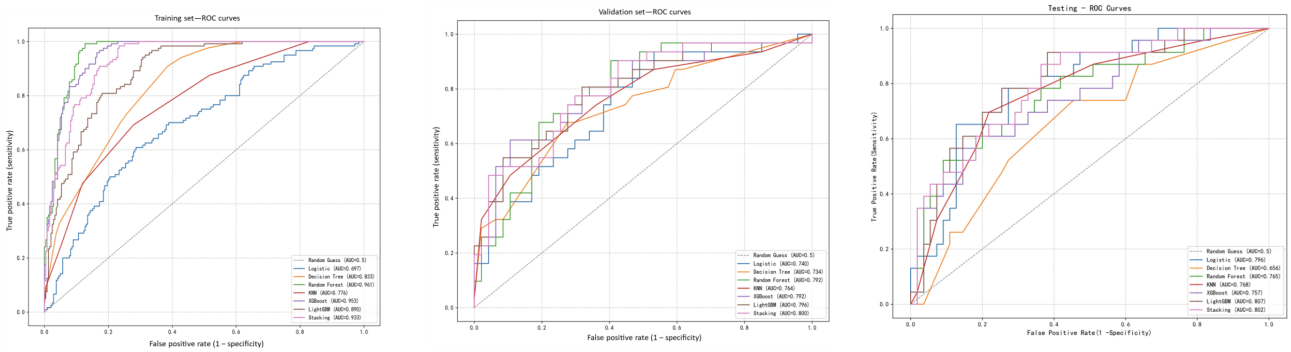
[b]KNN: k-nearest neighbors.

[c]LightGBM: light gradient boosting machine.

[d]XGBoost: extreme gradient boosting.

In conclusion, both the LightGBM and logistic regression models demonstrated consistent performance across the validation and testing phases, indicating their heightened clinical utility.

The performance of the 7 machine learning models (decision tree, KNN, LightGBM, logistic regression, random forest, stacking, and XGBoost) in predicting CHD in patients with hyperhomocysteinemia was evaluated. Performance metrics, such as area under the receiver operating characteristic (ROC) curve (AUC), accuracy, sensitivity, specificity, and F_1-score, were assessed on the training, validation, and test sets. The results indicate consistent discriminative ability and stability across different data partitions, with LightGBM demonstrating superior performance in the test set (AUC=0.807, F_1-score=0.636).



Model Performance Evaluation

Upon analyzing the ROC curves, it was evident that within the training set, the random forest (AUC=0.961), XGBoost (AUC=0.953), stacking (AUC=0.933), and LightGBM (AUC=0.890) models displayed exceptional discriminatory capabilities, indicating potential overfitting. Conversely, the logistic regression model exhibited a comparatively lower AUC of 0.697, while the KNN and decision tree models achieved AUC values of 0.776 and 0.833, respectively (Figure 2A). In the validation set, the stacking model maintained superior performance (AUC=0.800), closely followed by LightGBM (AUC=0.796), XGBoost (AUC=0.792), and random forest (AUC=0.792). The logistic model also demonstrated satisfactory performance (AUC=0.740), surpassing the decision tree (AUC=0.734) and KNN (AUC=0.764) models (Figure 2B). Within the testing set, the LightGBM (AUC=0.807) and stacking (AUC=0.802) models achieved the highest AUC values, trailed

XSL•FO
RenderX

by KNN (AUC=0.768), random forest (AUC=0.765), and XGBoost (AUC=0.757). The logistic regression model also displayed robust discriminatory ability (AUC=0.796), while the decision tree model exhibited the lowest AUC (0.656; Figure 2C).

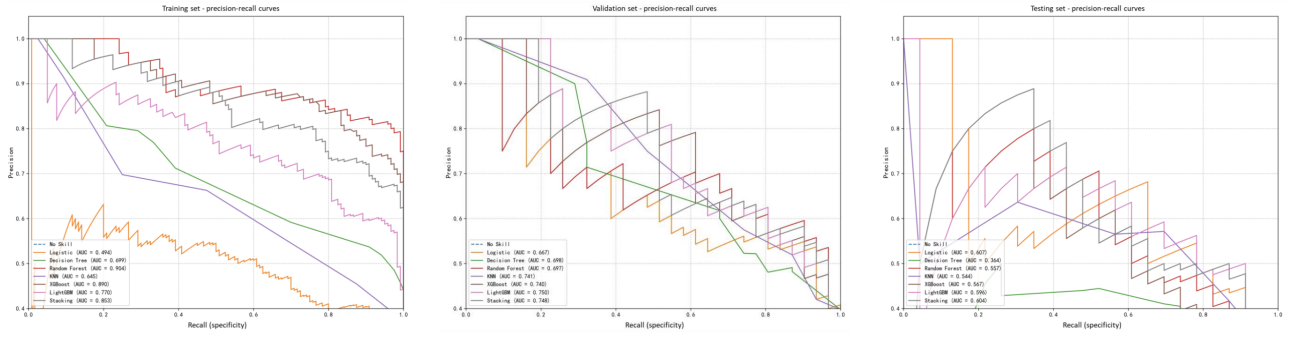


Figure 2. Receiver operating characteristic (ROC) curves of coronary heart disease (CHD) risk prediction models constructed by 7 machine learning algorithms in Hyperhomocysteinemia patients ROC) curves were utilized to assess the discriminative performance of 7 distinct machine learning models, including logistic regression, k-nearest neighbors (KNN), decision tree, random forest, extreme gradient boosting (XGBoost), light gradient boosting machine (LightGBM), and stacking, on various datasets: the training set, validation set, and test set denoted as (A), (B), and (C) respectively. The area under the receiver operating characteristic curve (AUC) was employed as a metric to quantify the models' performance, where increased values are indicative of enhanced capability in discriminating between individuals with CHD and those without.

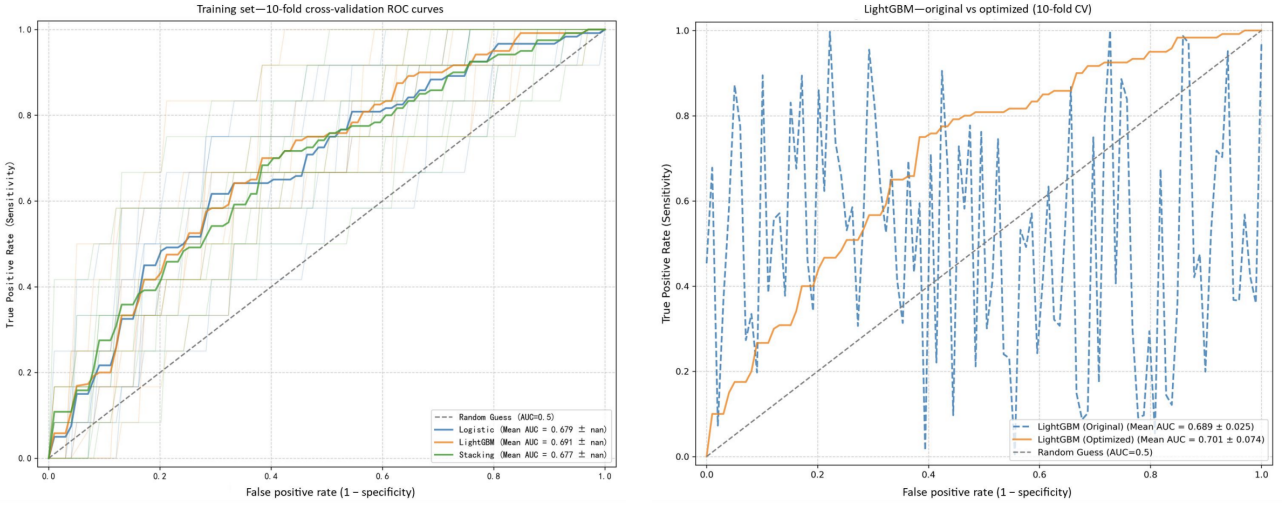
A B C

Upon analyzing the PR curves, distinct variations in model efficacy were evident across the three datasets. In the training dataset, the random forest model exhibited the highest PR-AUC value of 0.904, outperforming XGBoost (0.890), stacking (0.853), and LightGBM (0.770), underscoring its robust classification capability on the internal data. Conversely, the Logistic model displayed limited discriminatory power with an AUC of 0.494, while the decision tree and KNN models achieved PR-AUCs of 0.699 and 0.645, respectively (Figure 3A).

Figure 3. Precision-recall (PR) curves of coronary heart disease (CHD) risk prediction models constructed by the 7 machine learning algorithms. PR curves evaluate model performance in imbalanced datasets, emphasizing precision (positive predictive value) and recall (sensitivity). The results for the training set are displayed in (A), the validation set in (B), and the test set in (C). The PR-AUC (area under the precision-recall curve) is reported for each model, with greater values denoting better classification performance for the positive class (CHD). KNN: k-nearest neighbor; LightGBM: light gradient boosting machine; XGBoost: extreme gradient boosting.

A B C

In the validation dataset, the LightGBM model demonstrated the highest PR-AUC of 0.750, followed closely by stacking (0.748) and KNN (0.741). The XGBoost and random forest models performed comparably with AUCs of 0.740 and 0.697, respectively, whereas the logistic model yielded a PR-AUC of 0.667, and the decision tree model slightly lagged behind with an AUC of 0.698 (Figure 3B).



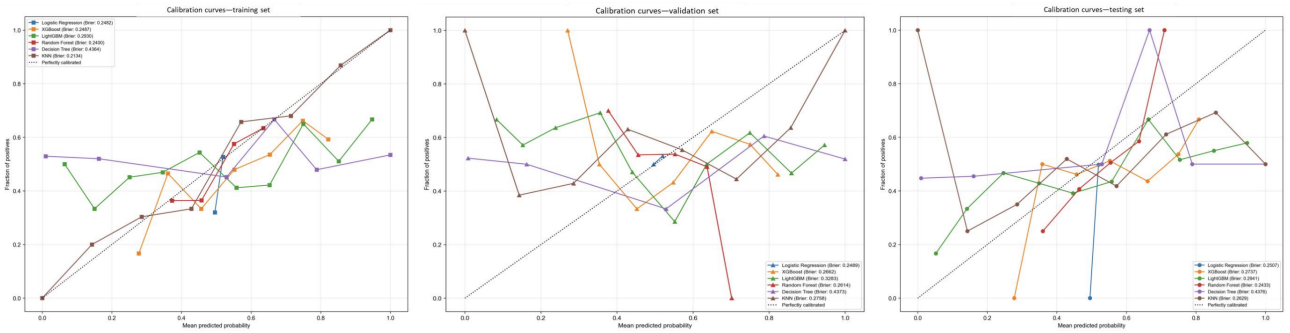
In the testing dataset, the LightGBM (AUC=0.596) and stacking (AUC=0.604) models exhibited moderate PR performance. The logistic model followed with an AUC of 0.607. Conversely, XGBoost (0.567), random forest (0.557), and KNN (0.544) demonstrated slightly lower PR-AUCs, with the decision tree model displaying the weakest performance (AUC=0.364; Figure 3C).

ROC Curve Analysis of Risk Prediction Models Based on 10-Fold Cross-Validation

ROC analysis using 10-fold cross-validation was used to assess the efficacy of 3 leading models: logistic regression, LightGBM, and stacking. As depicted in Figure 4A, during the training phase, the LightGBM model demonstrated the highest average AUC of 0.691, marginally surpassing logistic regression (AUC=0.679) and stacking (AUC=0.677), underscoring its superior discriminatory capability. Additionally, as illustrated in Figure 4B, following hyperparameter optimization, LightGBM's performance was further bolstered, with its mean AUC escalating from 0.689 (0.025) to 0.701 (0.074). This enhancement substantiates LightGBM's resilience across iterations. Consequently, LightGBM was ultimately designated as the preferred model for subsequent analyses.

XSL•FO
RenderX

Figure 4. Receiver operating characteristic (ROC) curve analysis of risk prediction models based on 10-fold cross-validation. (A) ROC curves were generated for the 3 best-performing models, namely logistic regression, light gradient boosting machine (LightGBM), and stacking, through 10-fold cross-validation on the training dataset. LightGBM demonstrated the highest average area under the receiver operating characteristic curve (AUC) of 0.691, with logistic regression and stacking following closely at 0.679 and 0.677, respectively. (B) A comparison of LightGBM performance prehyperparameter and posthyperparameter optimization revealed enhancements. The optimized model exhibited a higher mean AUC of 0.701 (SD 0.074), surpassing the original model's performance of 0.689 (SD 0.025), thus validating its increased stability.

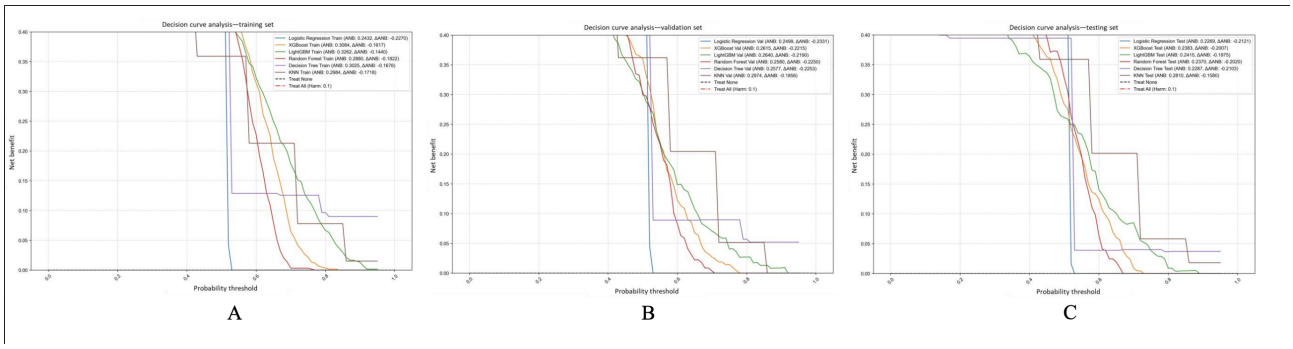


A B

Calibration Curves and Brier Score Analysis

Calibration curves and Brier scores were utilized to assess the alignment between predicted probabilities and observed outcomes across various datasets. In the training set (Figure 5A), all models exhibited moderate calibration performance. The KNN model displayed the lowest Brier score (0.2134), closely trailed by random forest (0.240), logistic regression (0.2482), and XGBoost (0.2487). Within the validation set (Figure 5B), random forest exhibited favorable calibration (Brier score=0.2614), with XGBoost (0.2662) and KNN (0.2758) also demonstrating relatively strong performance. In the test set (Figure 5C), logistic regression demonstrated the most accurate calibration (Brier score=0.2507), followed by XGBoost (0.2737) and KNN (0.2629). While the Brier scores indicated acceptable calibration for multiple models, no single model consistently outperformed others across all 3 datasets. Nevertheless, XGBoost and KNN showcased consistent and favorable calibration performance.

Figure 5. Calibration curves and Brier scores of 6 machine learning models. Calibration curves were utilized to evaluate the concordance between predicted probabilities and observed outcomes of coronary heart disease (CHD) across 3 sets: the training set, validation set, and test set. The diagonal dotted line in the graphs symbolizes ideal calibration, with Brier scores (inset) serving as a measure of prediction accuracy (lower scores indicating improved calibration). Both extreme gradient boosting (XGBoost) and k-nearest neighbors (KNN) models demonstrated consistent calibration performance across all datasets.



A B C

Clinical Utility Evaluation Based on Decision Curve Analysis

Decision curve analysis was used to assess the clinical efficacy of various machine learning models on the training, validation, and test sets. Figure 6 illustrates that the KNN model yielded the highest average net benefit across all 3 datasets (training: 0.2984, validation: 0.2974, and test: 0.281), closely trailed by LightGBM (training: 0.3262, validation: 0.264, and test: 0.2415) and XGBoost (train: 0.3084, validation: 0.2615, and test: 0.2383). These models consistently outperformed the "Treat None" and "Treat All" strategies in terms of net benefit over a broad range of probability thresholds. Notably, LightGBM and KNN consistently demonstrated superior clinical utility, particularly within the 0.3 - 0.7 threshold range, suggesting their potential for guiding personalized preventive interventions in practical healthcare settings.

XSL•FO
RenderX

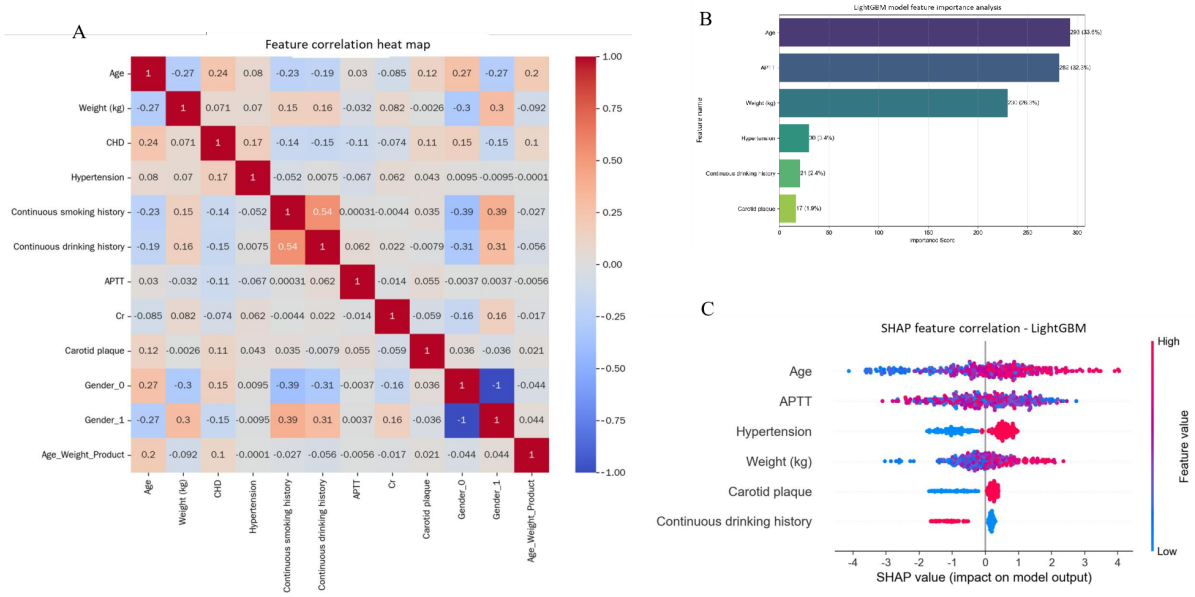


Figure 6. Decision curve analysis (DCA) of 6 machine learning models. The clinical utility of models is assessed by DCA through the calculation of net benefit at different probability thresholds in the training, validation, and test sets. Net benefit is determined as the difference between the proportion of correctly identified cases of coronary heart disease (CHD) and the proportion of unnecessary interventions. K-nearest neighbors (KNN), light gradient boosting machine (LightGBM), and extreme gradient boosting (XGBoost) consistently exhibited superior net benefit compared to strategies of treating all or treating none, especially within the 0.3 - 0.7 threshold range.

SHAP-Based Interpretation of the Optimal LightGBM Model

To enhance the interpretability of the LightGBM model, SHAP values were utilized to assess the significance of individual features on the model's predictions. The feature importance summary plot, derived from the mean absolute SHAP values, identified age, APTT, hypertension, weight, carotid plaque, and continuous drinking history as the primary predictors influencing the risk of CHD in patients with HHcy (Figure 7A). Notably, age and APTT exhibited the most substantial average impact, underscoring their pivotal roles in the model's predictive capabilities.

Figure 7. Shapley Additive Explanation (SHAP)–based interpretation and feature correlation analysis of the light gradient boosting machine (LightGBM) model. (A) A SHAP summary plot displays the average absolute impact of individual features on the prediction of coronary heart disease (CHD) risk, highlighting age and activated partial thromboplastin time (APTT) as the most influential factors. (B) A SHAP dependence plot illustrates the direction (positive or negative) and strength of feature effects on the model's output, indicating that higher age and APTT levels are associated with an increased risk of CHD. (C) A Pearson correlation heatmap of key features demonstrates minimal multicollinearity ($|r|$<0.5 for all features except continuous drinking or smoking history, where r=0.54), thereby ensuring the stability of the model. Cr: creatinine.

The SHAP dependence plot (Figure 7B) illustrates the impact of each feature on the model output in terms of both direction and magnitude. The elevated values of age and APTT were consistently linked to a higher predicted risk of CHD, with hypertension and carotid plaque presence also notably increasing the SHAP value. Notably, the influence of continuous drinking history exhibited variability across individual patient profiles, suggesting potential interactions with other variables.

A feature correlation heatmap (Figure 7C) was generated to evaluate multicollinearity and the interplay among essential features. The heatmap reveals a moderate positive correlation between continuous drinking history and continuous smoking history (r=0.54) and a slight negative correlation between age

XSL•FO
RenderX

and weight (r=–0.27). These findings endorse the incorporation of these variables into the LightGBM model without introducing unnecessary redundancy.

These results demonstrate that the LightGBM model offers both superior predictive accuracy and the ability to reveal the significance and interplay of clinical features. This capability can enhance personalized risk evaluation and targeted preventive measures for coronary heart disease in individuals with HHcy.

Discussion

This research conducted a comparative analysis of 7 machine learning algorithms to forecast the likelihood of CHD in patients with HHcy using authentic single-center electronic health records. The models were developed utilizing 6 fundamental variables (age, weight, hypertension, history of sustained alcohol consumption, APTT, and carotid artery plaque), and their discriminatory capacity, calibration, and clinical applicability were thoroughly assessed across training, validation, and test datasets. The findings revealed that the LightGBM model exhibited superior overall performance, demonstrating the highest AUC (0.807) and a relatively elevated F_1-score (0.636) in the test set, underscoring its promising clinical predictive capability.

A significant discovery is that the model does not depend on variables specific to CHD or HHcy. Instead, it opts for indicators that are commonly available and extensively standardized in routine clinical settings, including coagulation function (activated partial thromboplastin time), arterial structure markers (presence of carotid artery plaques), basal metabolism (body weight), and behavioral aspects (alcohol consumption history). These variables do not necessitate expert image analysis or sophisticated molecular assays, thereby augmenting the model's practicality in primary health care facilities or noncardiovascular disciplines.

Upon applying the SHAP algorithm to interpret the model, we validated that age and APTT are the most impactful variables within the model. Notably, the predictive significance of APTT warrants special consideration. Serving as a marker for the intrinsic coagulation pathway, it could potentially signify a hypercoagulable state within the HHcy population. This pathological characteristic has been identified as a key factor contributing to accelerated atherosclerosis [22]. The SHAP dependence plot and correlation heatmap provided additional confirmation of the minimal collinearity among variables, thereby augmenting the interpretive clarity and reliability of the model.

The stacking model exhibits a high AUC of 0.800 in the validation set; however, its F_1-score decreases to 0.33 in the test set, with a sensitivity of only 0.26, indicating limited generalization ability and a predisposition toward overfitting. Conversely, the LightGBM model demonstrates consistent performance across the training, validation, and test sets, underscoring its robustness in diverse sample scenarios. While the logistic regression model shows a slightly lower AUC, its balanced F_1-score, sensitivity, and specificity underscore its reliability in terms of generalization stability.

In this study, we aim to streamline variable processing by avoiding artificial binning, segmentation, high-dimensional mapping transformations, and the creation of interaction terms. This approach is intended to enhance the model's generalizability across different datasets by minimizing reliance on specific data structures. Additionally, we refrain from using oversampling methods, such as synthetic minority over-sampling technique, to mitigate issues related to feature distribution drift resulting from synthetic sample generation. Instead, we tackle data imbalance by adjusting category weights and optimizing thresholds.

However, this study is subject to several limitations. First, the data were sourced from a singular medical institution, potentially introducing regional, health care–seeking motivation, or detection biases. For instance, individuals with high homocysteine levels who consented to coagulation function tests may exhibit distinct health awareness and disease profiles compared to those who declined the tests. Second, the retrospective design of the study resulted in the exclusion of crucial variables that could impact CHD risk, such as dietary patterns, nutritional status, and renal function. Consequently, the interpretation of changes in serum markers remains inconclusive. Furthermore, the study solely predicted the present CHD status of patients documented in electronic health records. The absence of longitudinal follow-up data precluded the modeling of event timing or disease progression. To address these limitations, future research should integrate prospective cohorts and long-term follow-up data to validate the model's reliability and establish a dynamic risk assessment framework.

In conclusion, the LightGBM model developed in this study exhibits exceptional predictive accuracy and interpretability in individuals with HHcy, offering a robust basis for real-world implementation. We propose its consideration as a potential tool for early CHD risk stratification to aid clinicians in promptly identifying high-risk patients. Subsequent investigations may concentrate on external validation and model refinement in a multicenter context.

Abstract

Background: Coal workers' pneumoconiosis (CWP) is the most prevalent occupational disease that causes irreversible lung damage. Early prediction of CWP is the key to blocking the irreversible process of pulmonary fibrosis. The prediction of CWP based on imaging data and biomarker detection is constrained due to high cost and poor convenience.

Objective: The study aimed to use easily detectable clinical data to construct a prediction model for CWP through machine learning (ML) methods.

Methods: A prediction framework was established using a moderate-sized dataset and multidimensional clinical features, including occupational information, lung function parameters, and blood indicators. Six ML algorithms (light gradient boosting machine, random forest, extreme gradient boosting, categorical boosting, support vector machine, and logistic regression) were trained and evaluated using a stratified 5-fold cross-validation and a held-out test set. Hyperparameter optimization was performed using a unified Optuna-based strategy to ensure fair comparison across models. Model interpretability was assessed using Shapley Additive Explanation on top-performing models. In addition, an ablation analysis was conducted by retraining models after excluding job type to assess the independent predictive value of clinical biomarkers.

Results: All 6 models achieved consistently high predictive performance, and the differences among the top-performing models were small on the test set. After Optuna-based optimization, light gradient boosting machine and categorical boosting achieved high test-set area under curve values (0.974 and 0.975, respectively), while extreme gradient boosting achieved the highest recall (0.926) and F_1-score (0.952). Compared with the baseline models, hyperparameter optimization resulted in only minor performance changes, indicating robust prediction under the current feature set and evaluation protocol. Shapley Additive Explanation analysis consistently identified age, forced expiratory volume/forced vital capacity, and platelet count as key contributors to CWP risk prediction. The ablation analysis further showed that model performance remained strong after removing job type, supporting the independent predictive value of clinical features beyond occupational history.

Conclusions: The research results have confirmed the potential of combining simple multidimensional features with ML algorithms for predicting CWP and provided new ideas for early diagnosis and intervention of patients with CWP.

KEYWORDS

coal workers' pneumoconiosis; disease prediction; machine learning; clinical data; job-type

Introduction

As a traditional fossil energy source, coal has long held an important position in the global energy system. A large amount of respiratory coal dust can be generated during coal mining, processing, loading, and transportation and enter the human lungs through diffusion and sedimentation, inducing the occurrence of coal workers' pneumoconiosis (CWP) [1]. The pathogenesis of CWP is complex, characterized by strong concealment in the early stage, high mortality rate in the later stage, and poor quality of life for patients. Once diagnosed, the course of the disease is irreversible and there is currently no

XSL•FO
RenderX

effective cure in clinical practice [2,3]. Early identification of CWP can delay the deterioration of the condition and prevent it from developing into progressive mass fibrosis or respiratory failure.

High kilovoltage X-ray examination is the gold standard for CWP diagnosis. To avoid the problem of overlapping and occlusion of tissue and organ images, computed tomography detection technology has also been used for CWP diagnosis [4,5]. However, the imaging differences among early patients with CWP are not significant, and there are also issues such as high cost, high radiation risk, and convenient equipment use, which collectively constrain the early identification of patients with CWP. At present, the development of biomarker detection technology has significantly improved the clinical feasibility of CWP early screening [6,7]. As a measurable biological indicator, biomarkers can objectively reflect the physiological and pathological status of the body, such as proteins, genes, and metabolites, etc. The research on the expression levels of biomarkers in the serum of patients with CWP is the most extensive, including transforming growth factor-α [8], interleukin-8 [9], noncoding RNA (such as microRNA) [10], and common lipid metabolites such as phosphatidylethanolamines and free fatty acids [11], all of which have been proven to have important guiding significance for early identification of CWP. On the other hand, the occurrence and development of lung diseases usually have an impact on changes in lung microbiota and respiratory flora. MicroRNA expression profiles [12], surfactant-associated protein A and surfactant-associated protein D [13] in bronchoalveolar lavage fluid, and transforming growth factor-β, interleukin-1β, and matrix metalloproteinase-9 in sputum [14], as well as benzene and aldehydes in volatile organic compounds of exhaled breath [15], are also commonly used for early identification of CWP. However, metabolic processes are regulated by multiple factors. The lower specificity and sensitivity reduce the reliability of early screening of CWP through a single biomarker. Meanwhile, the high cost of detecting specific biomarkers also limits the early identification of patients with CWP.

Previous studies have shown that blood routine examination, as an economical, efficient, and easy-to-operate screening method in clinical practice, has important guiding significance for early identification and risk assessment of diseases, especially in mining areas where medical resources are relatively scarce [16,17]. CWP usually leads to lung infections or the occurrence of inflammatory diseases, which are often reflected in lung function, coagulation function, inflammatory markers, etc. This provides the possibility for early identification of patients with CWP [18]. At present, there is a relative lack of research on CWP prediction based on routine clinical blood data. This study aims to develop a low-cost CWP early screening tool based on machine learning (ML) models. By establishing a 3D feature space of occupational exposure history, lung function parameters, and routine blood indicators, and combining 6 algorithms including light gradient boosting machine (LightGBM), random forest (RF), extreme gradient boosting (XGBoost), categorical boosting (CatBoost), support vector machine (SVM), and logistic regression (LR) for comparative analysis of predictive performance. In addition, an Optuna-based hyperparameter optimization strategy was applied to tune the models under a unified evaluation protocol. Finally, the Shapley Additive Explanation (SHAP) method was used to interpret model predictions and analyze the contributions of key parameters such as lung function indicators and blood indicators. The high-precision and interpretable prediction model constructed can provide theoretical basis for early screening of CWP.

Methods

Ethical Considerations

This study was approved by the Second Affiliated Hospital of Xuzhou Medical University ([2024] 082701). Due to the retrospective nature of the study and the use of deidentified data, the requirement for informed consent was waived by the institutional review board. To ensure privacy and confidentiality, all personal identifiers, such as names and national identification numbers, were removed and replaced with unique study IDs before data analysis. No financial compensation was provided to the participants as the data were extracted from routine clinical and physical examination records. Furthermore, we confirm that no identifiable information or images of individual participants are included in this manuscript or its supplementary materials.

Data Sources

Two hundred eighty-seven patients with CWP were admitted to a large tertiary hospital from June 28, 2022, to September 20, 2024. Dust-exposed workers undergoing annual occupational health examinations at the same hospital from 2022 to 2024 were considered as controls. Considering some workers attended examinations in multiple years, records were deduplicated using a unique personal identifier, and only the most recent examination record per worker was retained, yielding 2446 unique controls. These data were retrospectively extracted from the hospital's electronic medical records system and physical examination database. All participants were male, aged between 22 and 90 years, and were employees of a certain mining group. The testing report included common demographic information, job types, and routine biochemical indicators.

The clinical test data of dust-exposed workers and patients with CWP were intersected, and 17 indicators were selected as candidate features. These indicators included job type, age, forced expiratory volume/forced vital capacity (FEV1/FVC), white blood cell count (WBC), absolute neutrophil count (ANC), absolute lymphocyte count (ALC), absolute monocyte count (AMC), absolute eosinophil count (AEC), red blood cell count, hemoglobin, platelet count (PLT), alanine aminotransferase (ALT), glucose, triglycerides, cholesterol, high-density lipoprotein, and low-density lipoprotein. The raw dataset initially comprised 36 job types. However, when categorized by disease status, a highly significant class imbalance was observed that the number of healthy individuals exposed to dust was approximately 8 times that of patients with CWP. This severe imbalance phenomenon can cause the model to lean toward the majority class during training, thereby reducing its ability to recognize diseased samples and affecting the model's generalization performance [19]. Therefore, the original 36 job

XSL•FO
RenderX

titles were first merged into 11 broader job categories based on similarity in work environment and job tasks. And then examined the distribution of CWP cases across these categories and found substantial imbalance (eg, only 1 CWP case among vehicle drivers vs 218 cases among mixed excavation and coal mining workers). To avoid unstable estimates driven by rare categories and to ensure adequate case representation for modeling, we restricted the analytic cohort to 5 job categories with sufficient CWP case counts, including mixed excavation and coal mining workers, excavation workers, coal miners, winch operators, and conveyor operators. After this restriction, the final dataset included 1085 dust-exposed healthy individuals and 271 participants with CWP.

Data Preprocessing

After verification, it was found that FEV1/FVC and low-density lipoprotein had missing values, accounting for 3.68% (50/1356) and 1.48% (20/1356), respectively. In order to avoid the impact of missing values on subsequent analysis and model training, the *k*-nearest neighbor (KNN) algorithm was used to fill in the missing value variables. The KNN imputation was performed within the training data for each fold in cross-validation, ensuring that the test data remained unseen during preprocessing. The specific calculation method is shown in equation (1).

(1)d(xi,xj)∑k=1p(xik−xjk)2

Among them, x_i and x_j, respectively, represent the feature vectors of 2 samples, and x_{ik} and x_{jk}, respectively, represent the *k*th feature of these 2 samples.

The categorical variable job type was processed using one-hot encoding, which converts each category into a binary feature column. Categories include mixed excavation and coal mining, excavation workers, winch operators, conveyor operators, and coal miners. The remaining 15 continuous feature variables were standardized, and each feature was transformed into a distribution with a mean 0 (SD 1) for the model to analyze. Standardization was performed only on the training data, with the same scaling applied to the validation and test sets. The calculation method for the standard score of each feature is shown in equation (2).

(2)Z=x−μσ

Among them, x is a certain value of the feature in the original data, μ is the mean of the feature, and σ is the SD of the feature.

Statistical Analysis and Feature Selection

Statistical analysis was conducted using SPSS Statistics (version 26.0; IBM Corp). The normality of quantitative data was tested using the *K-S* test, and the homogeneity of variance was tested using the Levene test. Data with normal distribution were represented by mean (SD), and intergroup comparison was tested using 2 independent samples *t* test. The data with nonnormal distribution were represented by median (P25-P75), and Mann-Whitney *U* test was used for intergroup comparison. Categorical variables were represented by the number of examples (%), and comparison between groups was conducted using the chi-square test. The difference was statistically significant with $P<.05$. The Least Absolute Shrinkage and Selection Operator (LASSO) algorithm, an embedded feature selection method, was used for regression analysis to identify key feature variables associated with CWP, thereby reducing model complexity and enhancing generalization capability. LASSO regression achieved feature selection by performing α regularization on coefficients, shrinking the coefficients of less important features to 0 [20]. To ensure no information leakage, LASSO feature selection was performed within each fold's training data, and the same selected features were applied to the validation data within each fold. This method was combined with correlation analysis in filtering methods to comprehensively select features.

Construction and Evaluation of ML Models

Six representative ML models including tree-based ensemble learning models (LightGBM, XGBoost, RF, and CatBoost) and traditional classification algorithms (LR and SVM) were used for constructing CWP prediction models. A brief overview of each model's key characteristics and its relevance to this study is provided below.

For tree-based ensemble learning models, XGBoost uses second-order Taylor expansion for high accuracy and speed, incorporates regularization to prevent overfitting, and supports parallel computing for efficient training [21]. LightGBM uses a leaf-wise growth strategy and histogram-based feature discretization for efficiency, with built-in class weight adjustments beneficial for imbalanced datasets [22]. CatBoost uses an ordered boosting strategy for better generalization, directly handles categorical features, and uses a symmetric tree structure to reduce overfitting [23]. RF builds multiple decision trees from bootstrapped samples, randomly selects features at each split, and aggregates predictions through voting for robust classification [24].

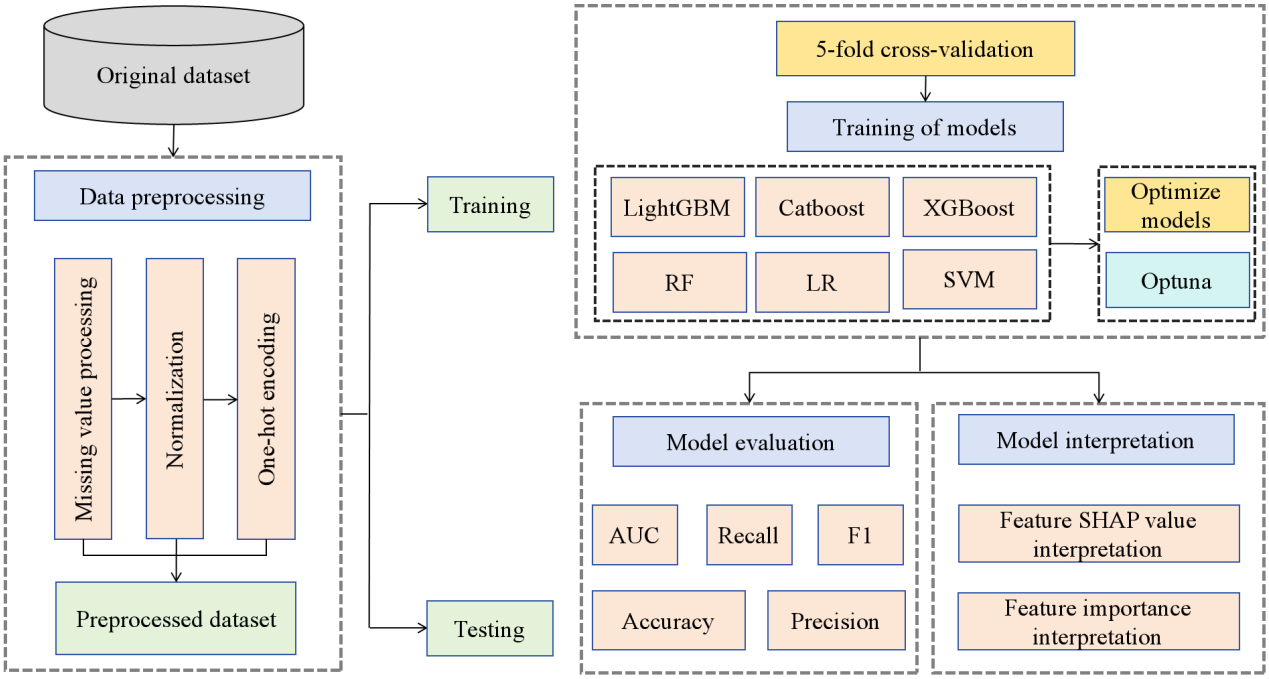
To compare model performance on imbalanced datasets, 2 traditional models were also selected for comparison with the ensemble models. LR as a generalized linear model predicts probabilities using a sigmoid function [25]. SVM finds an optimal hyperplane to separate classes, using slack variables and a radial basis function kernel for inseparable data. Class weights were also incorporated into its objective function for imbalance handling [26]. In this study, class weights were applied in the loss functions of both traditional models to effectively handle the class imbalance issue.

Python (version 3.8.0; Python Software Foundation) software was used for model training and evaluation, randomly dividing the dataset into training and test set in an 8:2 ratio. To further assess model stability, 5-fold stratified cross-validation within the training data was used. In this procedure, the dataset was randomly divided into 5 nonoverlapping subsets. In each fold, 4 subsets were used as the training set, and the remaining 1 subset was used for validation. This process was repeated 5 times, and the average performance across all folds was taken as the evaluation metric. The test set was only used for the final model evaluation, ensuring it remained unseen during model training and hyperparameter tuning. In the process of model training and evaluation, based on the confusion matrix, the performance of the model was comprehensively judged through accuracy, precision, recall, F_1-score value, and the area under

XSL•FO
RenderX

curve (AUC) of the subjects. The corresponding calculation formulas are as follows:

(3)Accuracy=TN+FNTP+FP



(4)Precision=TPTP+FP

(5)Recall=TPTP+FN

(6)F1=2∗precision∗recallprecision+recall

Among them, *TP* represents true positive, *TN* represents true negative, *FP* represents false positive, and *FN* represents false negative. Figure 1 shows the technical roadmap of this study.

Figure 1. The technical roadmap of this study. AUC: area under the curve; CatBoost: categorical boosting; LightGBM: light gradient boosting machine; LR: logistic regression; RF: random forest; SHAP: Shapley Additive Explanation; SVM: support vector machine; XGBoost: extreme gradient boosting.

Results

Results of Statistical Analysis and Feature Selection

Table 1 shows the comparison of basic characteristics between the dust-exposed workers and the patients with CWP. It is found that 13 indicators, including job type, age, FEV1/FVC, WBC, ANC, ALC, AMC, AEC, hemoglobin, PLT, ALT, cholesterol, and glucose, have statistical significance (P<.05) compared between the 2 groups.

Figure S1 in Multimedia Appendix 1 showed the cross-validation curve of LASSO regression. When the α value is low, the model may contain too many irrelevant features, resulting in significant errors (overfitting). When the α value is large, the model may remove too many important features, which also leads to an increase in error (underfitting). At the optimal α value, the cross-validation error is minimized. The LASSO coefficient plot was shown in Figure S2 in Multimedia Appendix 1, which showed that the coefficients of 9 features, including job-type mixed excavation coal, job-type excavation worker, job-type conveyor operator, job-type winch operator, age, FEV1/FVC, AMC, PLT, and ANC, were not 0 at the optimal α value. This indicated the criticality of these features and their significant explanatory power for the target variable; therefore, they should be retained in the final model for prediction.

In order to avoid the problem of multicollinearity caused by strong correlation between features, this study used correlation analysis in a filtering method to comprehensively select features based on the 17 features selected through statistical analysis and LASSO regression screening in the early stage. By calculating the Spearman correlation coefficient matrix (Figure 2), the threshold was set to an absolute value of *r* greater than 0.8, and highly correlated terms in the feature pairs were selected. Based on the absolute value of LASSO regression weights, the features that contribute more to the target were retained, thereby eliminating redundant variables. Specifically, a Spearman correlation matrix was computed on the training data, and pairs with an absolute value of *r* greater than 0.8 were considered highly correlated. For each highly correlated pair, the feature with the larger absolute LASSO coefficient was retained and the other feature was removed. In the current dataset, WBC and ANC showed high correlation (r=0.833); thus, WBC was removed and ANC was retained. After redundancy filtering, 16 nonredundant features were used as inputs for subsequent model development, including job-type mixed excavation coal, job-type excavation worker, job-type conveyor operator, job-type winch operator, job-type coal miner, age, FEV1/FVC, ANC, ALC, AMC, AEC, hemoglobin, PLT, ALT, cholesterol, and glucose.

Evaluation of the CWP Prediction Model

The selected 16 clinical features were input as feature variables into 6 ML models, and 5-fold cross-validation was performed for each model during training. The performance of each model was comprehensively evaluated based on the test-set data, and the output results of each model were organized and are summarized in Table 2. Meanwhile, the visualized results of the data in Table 2 are shown in Figure S3 in Multimedia Appendix 1. From the figure, it can be seen that the AUC of each fold of the 6 models in cross-validation was consistently high (all folds >0.90), indicating that the generalization ability of the 6 models is strong and stable. The AUC values of the 6 models were ranked in descending order as CatBoost (0.979), LightGBM (0.978), XGBoost (0.976), RF (0.972), SVM (0.968), and LR (0.967). This result indicated that the performance of ensemble learning models on imbalanced datasets was superior to traditional models, verifying the advantages of ensemble learning models in dealing with such problems [27]. Taking into account accuracy, precision, recall, and F_1-score, both the LightGBM and RF models achieved the highest accuracy (0.982), precision (1), and F_1-score (0.951), while the LR model had the highest recall (0.926). Therefore, based on the overall performance across multiple evaluation indicators, LightGBM and RF were preliminarily considered as top-performing predictive models.

In order to further improve the predictive performance and to ensure a fair comparison among candidate models, this study used the Optuna algorithm to optimize the hyperparameters of all 6 ML models (LightGBM, CatBoost, XGBoost, RF, LR, and SVM) under the same optimization budget, and also conducted 5-fold cross-validation during training. The output results of each optimized model were summarized in Table 3, and the visualized results were shown in Figure S4 in Multimedia Appendix 1. The results showed that the AUC of each fold in cross-validation was consistently high (all folds >0.90), indicating that the generalization ability of the 6 models was strong and stable. After applying an equivalent hyperparameter optimization strategy, the overall performance of the 6 models remains high and the differences among the top-performing models were small. Specifically, CatBoost and LightGBM achieved high test-set AUC values (0.975 and 0.974, respectively). In addition, XGBoost achieved the highest recall (0.926) and F_1-score (0.952) on the test set. Compared with the baseline results, hyperparameter optimization led to only small changes in performance. Overall, the 6 models maintained consistently high performance under the current evaluation protocol.

Table . Performance evaluation of optimized models.

Model	Accuracy	Precision	Recall	F_1-score	AUC[a]
LightGBM[b]-Optuna	0.982	1	0.907	0.951	0.974
CatBoost[c]-Optuna	0.982	1	0.907	0.951	0.975
XGBoost[d]-Optuna	0.982	0.98	0.926	0.952	0.969
RF[e]-Optuna	0.974	0.961	0.907	0.933	0.968
LR[f]-Optuna	0.952	0.847	0.926	0.885	0.968
SVM[g]-Optuna	0.967	0.925	0.907	0.916	0.962

[a]AUC: area under the curve.

[f]LR: logistic regression.

[g]SVM: support vector machine.

Model Interpretability

In order to gain a deeper understanding of the impact of various clinical features on the model's prediction results, this study used the SHAP method to conduct interpretability analysis on the 2 representative top-performing models LightGBM-Optuna and CatBoost-Optuna. The calculation method was shown in Equation 7.

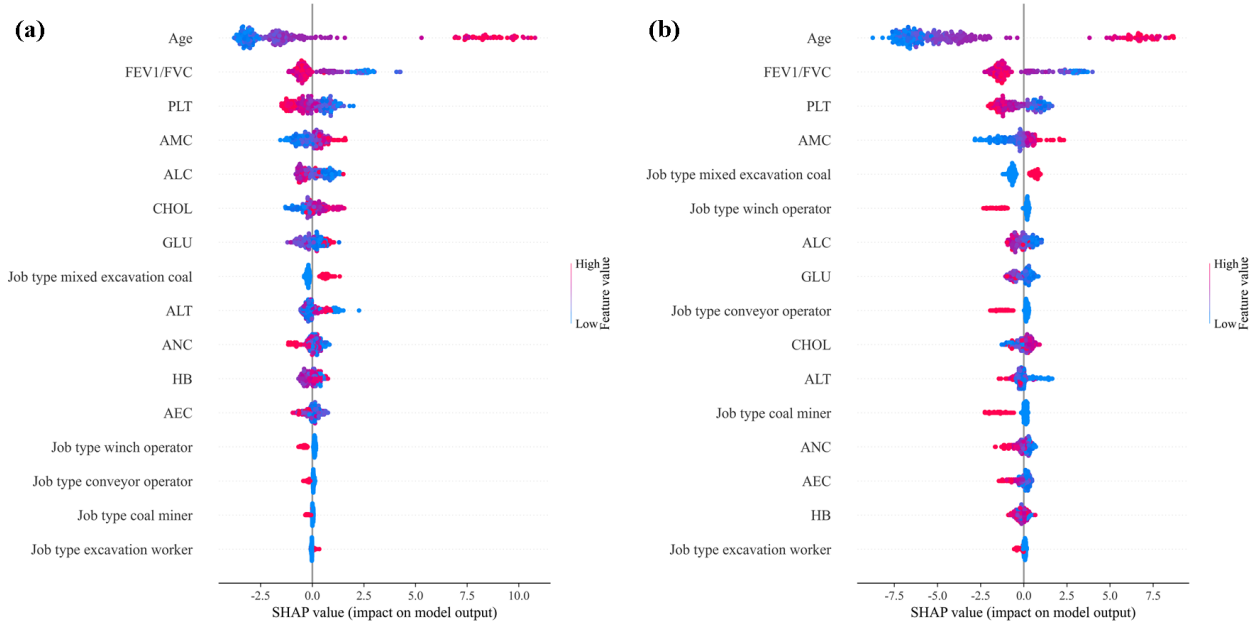
$$(7)\text{SHAP}(y)= \text{SHAP}(\text{base})+\sum_{i=1}^{n}\text{SHAP}(xi)$$

XSL•FO
RenderX

Among them, *SHAP (base)* is the baseline value of the entire model, and *SHAP* (x_i) is the contribution of each sample to the final prediction result.

The summary results of SHAP values are shown in Figure 3, which displayed the distribution of SHAP values for 17 input feature variables. Each point in the figure represented a feature, and the position of the point represented the SHAP value of the feature, which was the contribution of the feature to the model output. If the SHAP value is positive, it indicates that the feature increases the risk of disease and has a positive impact on the output results. Conversely, if it is negative, it indicates that the feature reduces the risk of disease and has a negative impact on the output results. In addition, the color range from blue to red reflects the actual value of the feature, with red indicating high values and blue indicating low values. The darker the color, the stronger the impact of the feature on the target variable. Overall, both models showed consistent patterns in feature effects. Age is the most influential variable, and higher age values were mainly associated with positive SHAP values, suggesting that older individuals tended to have a higher predicted disease risk. In contrast, higher values of FEV1/FVC were mostly distributed on the negative side, indicating that better lung function (higher FEV1/FVC) was related to a lower predicted risk. PLT showed a similar tendency, with higher values generally corresponding to negative SHAP values. On the other hand, higher AMC values tended to correspond to positive SHAP values, indicating a positive association with increased predicted risk. These results suggested that the model predictions were largely driven by age-related factors and lung function indicators, together with selected hematological and biochemical variables.

Figure 3. Summary chart of SHAP values. (a) LightGBM-Optuna; (b) CatBoost-Optuna. AEC: absolute eosinophil count; ALC: absolute lymphocyte count; ALT: alanine aminotransferase; AMC: absolute monocyte count; ANC: absolute neutrophil count; CHOL: cholesterol; FEV1/FVC: forced expiratory volume/forced vital capacity; GLU: glucose; HB: hemoglobin; PLT: platelet count; SHAP: Shapley Additive Explanations.



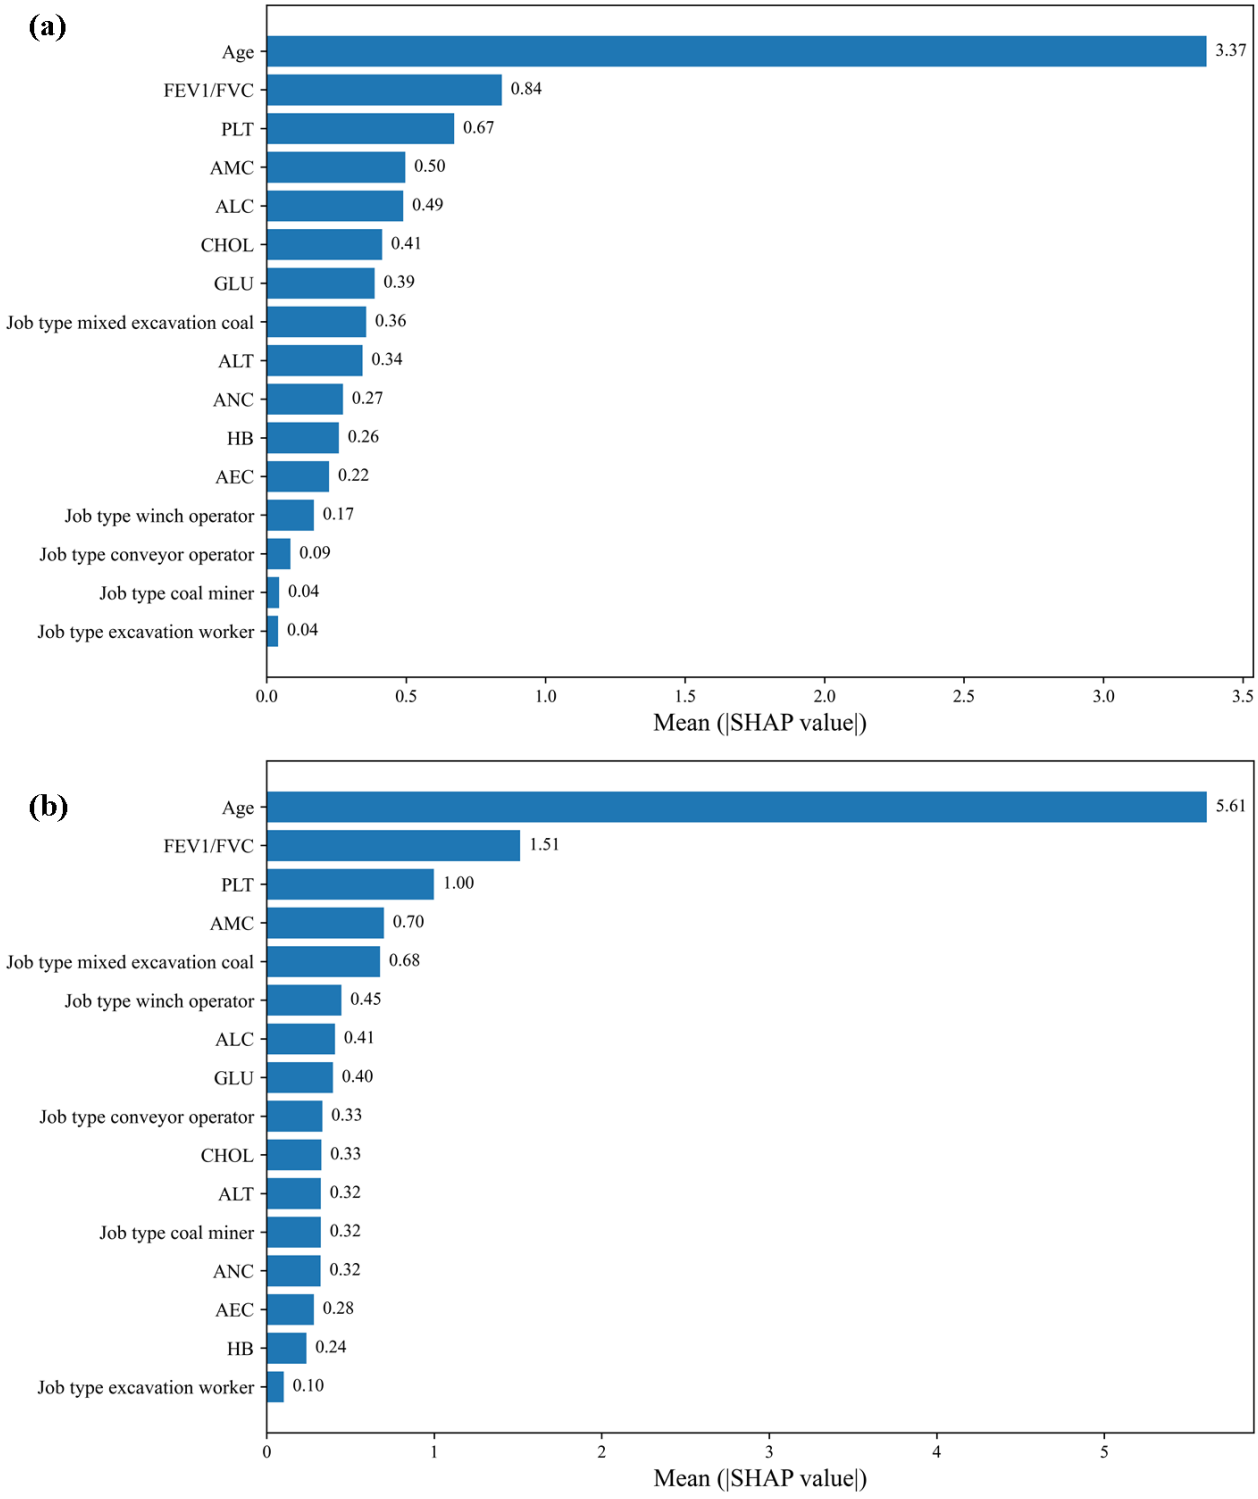


Figure 4 showed the SHAP feature importance matrix, which arranged the average SHAP absolute value of each feature from high to low. The horizontal axis represented the contribution value, and the larger the value, the greater the contribution to the model results. In both the Optuna-tuned LightGBM and CatBoost models, age showed the highest contribution, followed by FEV1/FVC and PLT, which indicates that these variables play the most important roles in the prediction of CWP risk.

RenderX

Figure 4. Matrix diagram of SHAP feature importance. (a) LightGBM-Optuna; (b) CatBoost-Optuna. AEC: absolute eosinophil count; ALC: absolute lymphocyte count; ALT: alanine aminotransferase; AMC: absolute monocyte count; ANC: absolute neutrophil count; CHOL: cholesterol; FEV1/FVC: forced expiratory volume/forced vital capacity; GLU: glucose; HB: hemoglobin; PLT: platelet count; SHAP: Shapley Additive Explanation.

To further examine how the top 3 influential features affect the model output, SHAP dependence plots were generated (Figure S5 in Multimedia Appendix 1). As shown in the dependence plot for age, the SHAP values generally increase with age, and the risk contribution became more pronounced after approximately 55 - 60 years, suggesting that older age was associated with a higher predicted disease risk. For FEV1/FVC, lower values correspond to higher SHAP values, indicating an increased risk, whereas higher values (approximately 85% - 100%) were associated with SHAP values close to zero or negative, suggesting a lower predicted risk. Similarly, the PLT dependence plot showed that lower PLT levels tended to contribute positively to disease risk, while higher PLT values (approximately 250 - 350×10^9/L) were more often associated with negative SHAP values, indicating a reduced predicted risk.

Discussion

Principal Findings

In clinical research, it is very common for medical records to have missing values in a certain examination due to the complexity of data collection and individual differences among different patients. By calculating the Euclidean distance between samples, KNN interpolation can identify *K*-neighboring samples that are most similar to missing values and then use the average feature information of neighboring samples to fill in the missing values, effectively restoring the integrity of the data [28]. As a categorical variable, the values of job type do not have a sequential relationship, and categories with larger values do not necessarily have greater weights than categories with smaller values. In order to enable ML models to better capture the relationship between feature variables and target variables, single hot encoding was applied to categorical features in this study [29]. The remaining 15 characteristic variables are all continuous features, but their units and ranges of values vary greatly. For example, PLT is measured in unit ×10^9/L and has a wide range of variable values, while glucose is measured in unit mmol/L and has a smaller range of values. This inconsistent scale may lead to the model being more sensitive to certain features with larger numerical ranges during training and ignoring other features with smaller scales, thereby affecting the training effectiveness of the model. Standardizing irregular continuous variables is often the key to solving such problems [30].

Feature selection is a crucial step in ML applications, aimed at selecting the most relevant features to the target variable in order to improve model performance and interpretability [31]. The common feature selection methods mainly include embedded, wrapped, and filtered methods [32]. As an embedded feature selection method, LASSO uses regression analysis to screen out key feature variables related to CWP, reducing model complexity and improving model generalization ability. In this study, LASSO regression analysis is applied to compress the coefficients of some unimportant features to 0 by performing α regularization on the coefficients, thereby achieving feature selection [20]. The preprocessed dataset still suffers from class imbalance, with the number of dust-exposed workers without CWP being about 4 times that of patients with CWP. Regarding the issue of class imbalance, commonly used methods in model construction include data sampling and ensemble learning [33]. In order to preserve the distribution characteristics of the original data as much as possible and avoid the bias and noise that may be introduced by data oversampling methods [34], ensemble learning models were used to handle imbalanced data in this study. Specifically, we selected decision tree-based ensemble learning models such as LightGBM, RF, CatBoost, and XGBoost and compared them with traditional LR and SVM models.

To ensure a fair comparison among candidate models, this study adopted a unified hyperparameter optimization strategy based on Optuna. Optuna is a Bayesian optimization framework that uses a tree-structured Parzen estimator to efficiently explore the hyperparameter space by prioritizing promising regions. Under the same optimization budget and the same stratified *k*-fold cross-validation protocol, all 6 models were tuned and evaluated consistently. The results show that after optimization, all models achieved consistently high cross-validated performance, while the differences among the top-performing models remained small on the held-out test set. This finding suggests that the current feature set and evaluation setting already provide strong predictive ability, and further improvements are more likely to depend on feature refinement or decision strategy rather than extensive hyperparameter tuning. In addition, the top-performing models show comparable overall performance, but each presents advantages under different evaluation priorities. Specifically, models such as LightGBM and CatBoost demonstrate stronger overall discrimination, whereas XGBoost tends to perform better when recall- or F_1-related sensitivity is emphasized. Therefore, LightGBM and CatBoost were both retained as top-performing models for subsequent interpretability analysis. Job type reflects different dust exposure scenarios in coal mining and therefore contributes to CWP risk prediction, which is consistent with epidemiological evidence [35]. The concentration, particle size, and composition of coal dust have a significant impact on the pathogenesis and prevalence of CWP [36,37]. The different working scenarios in coal mines in the same region also have a significant impact on the prevalence of CWP. The excavator workers are mainly responsible for developing tunnels, and the cut rocks are rich in free silica. The pathogenicity of silica dust is much higher than that of coal dust, which can lead to more severe pulmonary fibrosis (silicosis) and a shorter onset period [38,39]. Coal miners mainly come into contact with coal dust (carbon-based dust), which has relatively weaker pathogenicity compared to silica dust and slower disease progression. At the same time, the excavation face is a temporary work site, and the ventilation and dust removal facilities are usually not as complete as those in the coal mining face, resulting in greater difficulty in dust control [40]. Mixed workers for excavation and coal mining are exposed to silica dust and coal dust simultaneously, and the synergistic effect of the 2 types of dust may accelerate lung damage [41,42].

To examine whether the clinical variables provide predictive value beyond occupational history, we conducted an ablation analysis by retraining the baseline models after removing the job-type variable. Because hyperparameter tuning led to only minor changes in performance, using baseline models for this analysis was sufficient to evaluate the independent contribution of clinical variables. The results of each model are summarized in Table 4, which showed that model performance remained highly robust. For example, the AUC of LightGBM only slightly changed from 0.978 (with job type) to 0.973 (without job type), indicating that the physiological signals captured by clinical features and biomarkers are major contributors to the model's predictive capability.

Table . Ablation analysis of model performance without job type.

Model	Accuracy	Precision	Recall	F_1-score	AUC[a]
LightGBM[b]	0.982	1	0.907	0.951	0.973
CatBoost[c]	0.978	0.98	0.907	0.942	0.977
XGBoost[d]	0.982	1	0.907	0.951	0.978
RF[e]	0.982	1	0.907	0.951	0.976
LR[f]	0.963	0.893	0.926	0.909	0.969
SVM[g]	0.974	0.98	0.889	0.932	0.971

[a]AUC: area under curve.

[b]LightGBM: light gradient boosting machine.

[c]CatBoost: categorical boosting.

[d]XGBoost: extreme gradient boosting.

[e]RF: random forest.

[f]LR: logistic regression.

[g]SVM: support vector machine.

This finding is also supported by the SHAP interpretation results. The decrease in FEV1/FVC reflects impaired lung function, while the corresponding increase in SHAP value suggests that ventilation function may be an important feature of CWP. This is consistent with the results of existing studies suggesting that alveolar-arterial oxygen gradient in lung function can be used as a predictor of CWP [43]. Platelets, as important cells for hemostasis and coagulation, play a role by participating in systemic inflammatory and immune responses, providing new therapeutic targets for inflammatory diseases [44]. For example, a previous study found that lower PLT levels were associated with a higher risk of developing severe *mycoplasma pneumoniae* pneumonia [45]. Due to the important role of platelets in inflammation and tissue repair, this phenomenon may be related to inflammation or weakened immune function leading to lung damage. These findings emphasize the importance of clinical features in CWP risk assessment and provide new perspectives for a deeper understanding of the pathogenesis of CWP.

Despite its contributions, this study has several limitations. First, the cohort was derived from a single center and a specific occupational group, which may introduce regional or selection bias and limit generalizability to other settings. Second, although model performance was evaluated rigorously, interpretability remains limited and warrants further investigation. Most importantly, smoking history was not available in the retrospective physical examination records. Because smoking is a major confounder for both lung function and inflammatory biomarkers, part of the observed discrimination may reflect unmeasured differences in smoking behavior rather than CWP status alone. Furthermore, differences in physical demands and lifestyle factors associated with distinct job roles could potentially influence certain biomarkers. While our analysis indicates strong independent predictive value for the biomarkers, future studies should consider more granular lifestyle adjustments.

Conclusions

This study developed a ML-based model for CWP prediction using multidimensional clinical features. The 6 candidate models achieved consistently high performance, and Optuna-based tuning resulted in only small changes, suggesting robust prediction under the current protocol. SHAP analysis identified age, FEV1/FVC, and PLT as key contributors to CWP risk prediction. Moreover, ablation analysis showed that the models remained highly accurate even without job type, indicating that clinical biomarkers provide strong predictive signals beyond occupational information. These results support the potential of routine clinical data for early CWP screening and intervention.

Abstract

Background: Artificial intelligence (AI) is increasingly applied to health care, yet concerns about fairness persist, particularly in relation to sociodemographic disparities. Previous studies suggest that socioeconomic status (SES) and sex may influence AI model performance, potentially affecting groups that are historically underserved or understudied.

Objective: This study aimed to (1) assess algorithmic bias in AI-driven dementia prediction models based on SES and sex (biological sex), (2) compare the utility of an individual-level SES measure (the Housing-Based Socioeconomic Status [HOUSES] Index) versus an area-level measure (the Area Deprivation Index) for bias detection, and (3) evaluate the effectiveness of an oversampling technique (the Synthetic Minority Oversampling Technique for Nominal and Continuous features) for bias mitigation.

Methods: This study used data from two population-based cohorts: the Mayo Clinic Study on Aging (n=3041) and the Rochester Epidemiology Project (n=19,572). Four AI models (random forest, logistic regression, support vector machine, and Naïve Bayes) were trained using a 5-year observation window of structured electronic health record data to predict dementia onset within the subsequent 1-year window. Fairness and model performance were assessed using the balanced error rate (BER) across intersecting SES-sex subgroups. The Synthetic Minority Oversampling Technique for Nominal and Continuous features algorithm was applied to the training data to balance the representation of SES groups.

Results: Across both cohorts, individuals with lower SES generally exhibited higher BERs (worse performance) than high SES groups, confirming the presence of bias. In the MCSA cohort, males with high SES, as indicated by the HOUSES Index, consistently exhibited the lowest BERs across all evaluated models. Balancing the training data based on a specific SES measure showed a trend toward reducing the BER disparity when evaluated using that same measure. However, this targeted improvement demonstrated nonuniversal benefits; in some cases, it exacerbated disparities when evaluated using other, unbalanced SES measures. This pattern suggests that fairness interventions are not universally beneficial across different definitions of the protected attribute. While the balancing approach improved fairness in model performance for lower SES groups, it often came at the cost of a slight reduction in overall model performance. However, an exception was observed in the MCSA cohort when balancing based on the HOUSES Index using logistic regression, support vector machine, and Naïve Bayes, where the performances of both the high and low SES groups improved.

Conclusions: This research highlights the importance of incorporating sociodemographic context into AI modeling in health care. The choice of SES measure may lead to different assessments of algorithmic bias. The HOUSES Index, as a validated individual-level SES measure, may be more effective for bias mitigation than area-level measures. Future AI development should integrate bias mitigation strategies to ensure models do not reinforce existing disparities in health outcomes.

Introduction

In 2024, Alzheimer dementia affected approximately 6.9 million people in the United States, and this number is projected to escalate to 13.8 million by 2060. This growth places an immense burden on patients and their families, society, and the health care system, manifesting in an estimated 18.4 billion hours of unpaid care annually, valued at US $346.6 billion [1]. Despite this considerable prevalence, cognitive impairment, including mild cognitive impairment (MCI) and dementia, often goes undetected in clinical settings. Diagnoses frequently come late in the cognitive decline process, reducing opportunities to enhance patients' quality of life and exacerbating existing health disparities. Ongoing research in health care seeks to leverage artificial intelligence (AI) to enhance dementia prediction.

The rapid advancements in computing power, data storage, and predictive analytics have significantly accelerated the integration of AI tools into the US health care system [2]. By 2014, 97% of nonfederal acute care hospitals had adopted a certified electronic health record (EHR) [3]. As of January 2025, the US Food and Drug Administration has approved more than 1000 clinical AI applications [4]. This foundational shift has enabled the widespread adoption of AI. AI-powered solutions have already demonstrated transformative potential in health care.

Beyond diagnostics, AI research continues to explore ways to address health disparities, such as reducing unexplained pain disparities through image-based algorithms in underserved populations [5]. However, alongside these advancements lies the critical challenge of mitigating biases inherent in AI systems. Studies have revealed that AI algorithms trained on biased data can perpetuate health disparities, particularly among underresourced and understudied populations [6-9]. For example, a race-based algorithm for estimating kidney function produced higher estimates for Black patients than for White patients, resulting in delayed referrals for organ transplants among Black individuals [10]. Such findings underscore the ethical imperative to scrutinize differential model performance by socioeconomic status (SES) and other social determinants of health (SDOH), which have profound implications for underserved populations and care delivery. SES, as a core component of SDOH, plays a pivotal role in shaping health outcomes through biological, behavioral, and environmental pathways [11-20].

Recent studies have highlighted the pervasive issue of bias in health care AI systems, particularly SES. For instance, a 2019 study [21] defines algorithmic bias in health care as the application of an algorithm that compounds the challenges affecting underserved groups across SES, race, background, religion, sex, or disability, thereby amplifying disparities in health systems. The authors discuss how AI can inadvertently perpetuate and exacerbate challenges faced by underserved populations if not carefully designed and implemented. Another study outlines various elements of potential bias in the development and implementation of AI algorithms in health care. It emphasizes that such biases can propagate stereotypes and discrimination, further marginalizing underserved populations and contributing to socioeconomic health care disparities [22]. Similarly, research indicates that lower SES is associated with poorer predictive model performance, potentially due to incomplete or inaccurate EHR data [23].

In addition to SES disparities, sex differences have emerged as a critical factor influencing AI model performance in dementia prediction. Research indicates that females often exhibit more severe cognitive impairment and experience a faster rate of cognitive decline compared to males at the onset of Alzheimer disease [24]. Sociodemographic factors, such as lower education levels and SES, disproportionately affect older female individuals, increasing their risk for dementia [25-27]. Predictive models for cognitive decline, such as Cox regression, demonstrate varying performances across sexes, indicating potential biases in predictive accuracy [28]. Additionally, transfer learning approaches have revealed that cognitive deficits in female individuals, once detected at the MCI stage, tend to deteriorate more consistently over time, whereas male participants exhibit a wider variety of declines across multiple cognitive functions [29].

Despite these findings, there remains a significant gap in strategies to mitigate biases in AI models. While some studies have proposed methods to detect and quantify such biases, comprehensive approaches to address and correct them are limited [30]. Our study seeks to fill this gap by not only examining the relationship between SES, sex, and AI model performance in dementia prediction but also implementing oversampling techniques to ensure adequate representation of socioeconomically disadvantaged groups. By doing so, we aim to reduce disparities in model performance across different SES groups, thereby enhancing fairness in AI-driven health care solutions.

Methods

Study Population

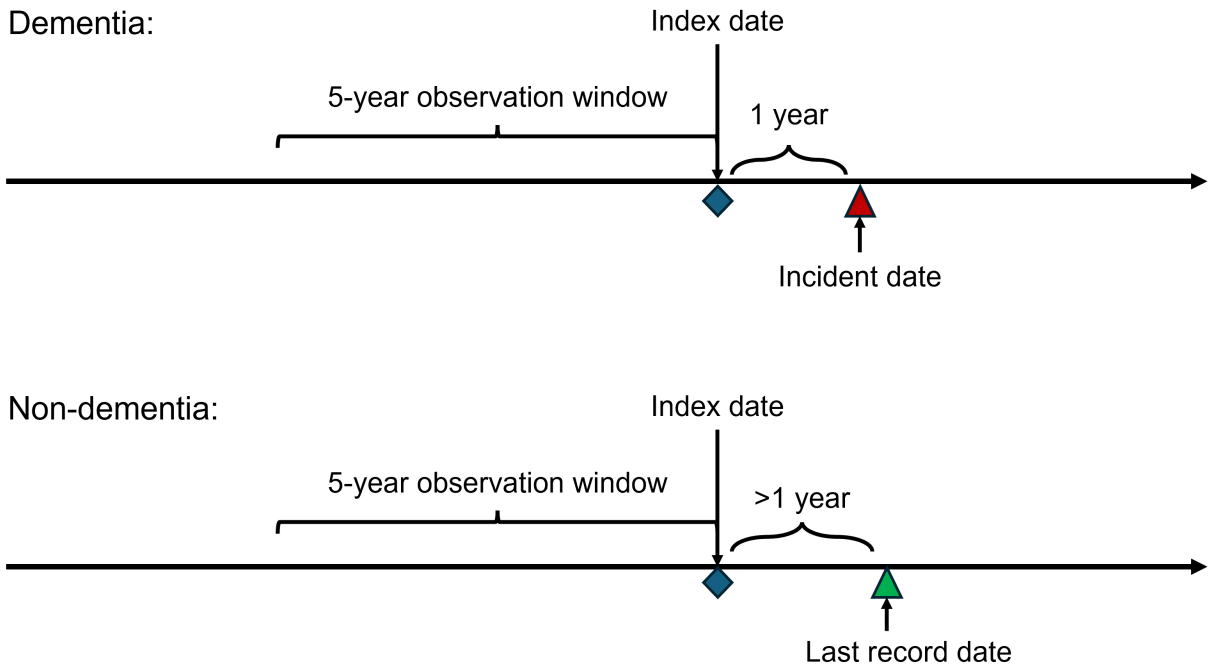
In our study, we used 2 cohorts. First, we studied individuals participating in the Mayo Clinic Study on Aging (MCSA) [31]. The MCSA, which commenced in 2004, is a population-based research study focused on investigating the epidemiology of MCI, dementia, and related biomarkers (N=5890; dementia, n=682, 11.6%; and non-dementia, n=5208, 88.4%). Participants for the study were chosen randomly from among persons living in Olmsted County, Minnesota, at the time of recruitment. These participants completed detailed cognitive assessments, including the Clinical Dementia Rating scale, a full-scale neurological evaluation, and various neuropsychological tests. Using established criteria, a consensus committee made diagnoses, classifying participants as cognitively unimpaired, having MCI, or having dementia. MCI diagnostic criteria have been disclosed in previous publications [32], and dementia diagnoses adhered to the criteria laid out in the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition* [33].

Second, we studied a larger cohort of persons living in Olmsted County, MN, between 2004 and 2020, derived from the Rochester Epidemiology Project (REP) medical records linkage system (N=290,528; dementia, n=8,205, 2.8%; and non-dementia, n=282,323, 97.2%) [34]. The onset of dementia

XSL•FO
RenderX

was identified by the date of the first diagnosis code (*International Classification of Diseases [ICD], Ninth or Tenth Revision code*) received between 2004 and 2020.

Socioeconomic Measures



We assessed potential biases in model performance using two residence-based SES measures: the Area Deprivation Index (ADI) [35] and the Housing-Based Socioeconomic Status (HOUSES) Index [36]. The ADI is a multidimensional evaluation of a person's socioeconomic conditions at the census block group level. We used both national-level and state-level ADI rankings. The national-level ADI rankings were used to divide participants into two groups: those in the higher ADI quartile group (76-100) were considered to reside in an area with high socioeconomic deprivation (hereafter, low SES), and those in the ADI group (0 - 75) were considered the referent group (hereafter, high SES). Similarly, the state-level ADI ranking was categorized into two groups: ADI (8-10) for low SES and ADI (0 - 7) for high SES. The HOUSES Index is a housing-based SES indicator, derived from an analysis of 4 specific variables related to a housing unit. The bottom quartile was considered low SES, and the remaining quartiles were considered high SES. The HOUSES Index was only used in the MCSA cohort because it is not available for the REP cohort. By incorporating both the HOUSES Index and ADI measures, our study aimed to evaluate and compare their effectiveness in identifying SES-related biases in the performance of AI models. In addition to quantifying bias in model performance based on SES, our study also considered sex.

Prediction Timeline Window

Our goal was to use records from the past 5 years (observation window) to forecast whether a patient would be diagnosed with dementia in the following year (prediction window).

For both cohorts, we applied consistent inclusion and exclusion criteria. For patients with dementia (case), the incident date was the date of dementia onset. We excluded patients whose age at the incident date was less than 50 years. The index date (point for prediction) is set to 1 year before the dementia incident date. We performed frequency matching for age between participants with dementia and participants without dementia. For patients without dementia (control), we assigned index dates to match age with cases—that is, patients without dementia at the index date have a similar age distribution to patients with dementia at their index dates. As shown in Figure 1, the 5-year period preceding the index date serves as the observation window. The 1-year period following the index date is the prediction window for both groups. We exclude patients with no record within the observation window. We also exclude patients without dementia who do not have at least 1 year of follow-up after their index date (whose last record date is not at least 1 year after the index date).

Figure 1. Timeline overview for dementia and non-dementia patients. For patients with dementia (cases), the index date is set 1 year before their diagnosis. For patients without dementia (controls), the index date is assigned to match the age distribution of the cases. The model uses a 5-year observation window preceding the index date to predict the onset of dementia within the subsequent 1-year prediction window.

Assessing AI Bias Across Different SES and Sex Categories

Four machine learning algorithms were selected to capture a variety of model classes commonly used in clinical prediction tasks, allowing for an assessment of whether observed bias patterns were robust across different algorithmic assumptions and complexities. The selected models were (1) logistic regression (LR), a well-established, interpretable linear model that serves as a standard baseline in clinical research; (2) support vector machine (SVM), a powerful kernel-based method capable of learning complex, nonlinear decision boundaries; (3) random

XSL•FO
RenderX

forest (RF), a nonlinear ensemble of decision trees that is robust to overfitting and can implicitly capture complex interactions between features; and (4) Naïve Bayes (NB), a simple yet efficient probabilistic classifier based on Bayes' theorem with strong independence assumptions. This selection enables a more comprehensive evaluation of how algorithmic bias manifests across linear, nonlinear, ensemble, and probabilistic modeling paradigms. We trained and tested the 4 AI models to predict the incidence of dementia in the following year.

The experimental process begins with preprocessing the data. The 5-year observation period is divided into five 1-year windows. During each 1-year window, patients may have multiple visits. For each visit, we extracted ICD-9 and ICD-10 codes, categorized the codes using the Clinical Classifications Software (CCS) [37], which groups diagnoses and procedures into clinically relevant categories and then generated a one-hot–encoded vector representing the CCS categories for the visit. We computed the element-wise sum of all visit vectors within each 1-year window. To robustly distinguish between years with no visit and years with visits but no relevant diagnoses, we used a missing indicator method. For 1-year windows where a patient had no visits, the corresponding annual vector was filled with zeros. Concurrently, we introduced 5 binary features, one for each year of the observation window, setting the feature to "1" to explicitly flag a year with no visits and "0" otherwise. Finally, we formed the final input vector by concatenating the 5 annual vectors, sex, age at the index date, and the 5 created binary visit-indicator features. Our primary objective was to assess the baseline performance and bias of models built only on the most common, structured data elements that are widely available for nearly all patients within a standard EHR system.

In this study, we developed and evaluated 4 AI models for each cohort. We randomly partitioned the dataset into two subsets: 70% for training and 30% for testing. Within the training set, we used a 5-fold cross-validation strategy to identify the optimal parameters for each model, thereby ensuring robust performance estimates and minimizing the risk of overfitting. After determining the best-performing configuration for each model, we retrained the model on the entire training set and subsequently evaluated its performance using the 30% test set. All model development and evaluation procedures were conducted independently within each of the 2 cohorts. We did not perform cross-cohort validation.

Within each cohort, and for each model, we then conducted subgroup analyses by comparing performance across different sex groups and among various SES-sex subgroups. This approach was used to identify potential differences in predictive bias.

To assess the fairness of these models, we used the balanced error rate (BER) [23], defined as the unweighted mean of the false-positive rate (FPR) and the false-negative rate (FNR), as follows:

$$BER=\frac{FPR+FNR}{2}$$

The FPR, also referred to as 1−specificity, represents the proportion of negative instances that are incorrectly classified as positive. Formally,

$$FPR=\frac{\text{False positive (FP)}}{\text{True negative (TN)}+\text{False positive (FP)}}$$

The FNR, also referred to as 1−sensitivity, represents the proportion of positive instances that are incorrectly classified as negative. Formally,

$$FNR=\frac{\text{False negative (FN)}}{\text{True positive (TP)}+\text{False negative (FN)}}$$

By incorporating both the FPR and FNR, BER captures imbalances in how models treat positively and negatively labeled individuals, allowing us to identify potential disparities or biases in the predictive performance.

To assess the variability and reliability of the BER estimates, we calculated bootstrap CIs for each SES-sex group:

1. Bootstrapping procedure: We generated 1000 bootstrap samples by randomly resampling with replacement from the original test datasets.
2. BER calculation: For each bootstrap sample, we calculated the BER.
3. CI estimation: The distribution of the bootstrap BERs was used to compute the 95% CI, providing an estimate of the uncertainty around the BER.

To assess statistical differences in model performance (BER) between SES-sex groups, we conducted a series of pairwise 2-tailed *t* tests with a significance threshold of 0.05. The Levene test was used to assess variance homogeneity, with the Welch *t* test applied for unequal variances and the standard *t* test for equal variances. Each test was performed independently to evaluate a specific contrast (eg, low vs high SES within a sex group). To correct for the increased risk of type 1 errors (false positives) due to multiple comparisons, we applied the Benjamini-Hochberg procedure. For each of the 4 AI models, we collected the *P* values from all pairwise *t* tests performed for that model and applied the Benjamini-Hochberg correction to this complete set of *P* values. This method controls the false discovery rate at our chosen significance level of 0.05. All reported statistical significances for pairwise comparisons are based on the results of this false discovery rate correction.

In addition to these pairwise comparisons, a separate baseline analysis was conducted to contextualize the performance of all subgroups relative to a single reference point. For this analysis, the "male in high SES" subgroup was designated as the baseline category. We then calculated the difference in BER for all other sociodemographic subgroups by comparing their BERs to the BER of this baseline group. This method provides a consistent benchmark for evaluating the performance disparities relative to the reference group.

Reducing SES-Related Bias

To address disparities in AI model performance related to SES, we implemented the Synthetic Minority Oversampling Technique for Nominal and Continuous features (SMOTE-NC) [38]. SMOTE-NC is a variant of an oversampling technique designed to generate synthetic examples in datasets that include both continuous and categorical variables. This method is

XSL•FO
RenderX

particularly useful in addressing imbalances in datasets, which can lead to biased model performance.

In the context of our study, we applied SMOTE-NC to balance the representation of understudied SES groups within our training dataset. This process preserved the ratio of dementia cases and controls in the cohort (Tables 1 and 2). We set the number of neighbors parameter to 5 and used a fixed random seed of 42. This process ensured that the distribution of SES groups in the training dataset was balanced, without introducing synthetic examples into the test set. Following the oversampling, the AI models were retrained on the balanced dataset using the same cross-validation strategy. To assess the effectiveness of SES balancing, we compared the performance (BER) of models trained on the oversampled datasets with those trained on the original, imbalanced datasets.

Ethical Considerations

The study was approved by the institutional review boards (IRBs) of the Mayo Clinic (20 - 004498) and the Olmsted Medical Center (028-OMC-20). The need for informed consent was waived for the study. Approval for the MCSA (IRB number 14 - 004401) was also obtained from the IRBs of the Mayo Clinic and Olmsted Medical Center in Rochester, Minnesota. Participants of the MCSA provided written informed consent before participation. The MCSA informed consent and the study's IRB protocol allow secondary analysis without additional consent. All data were accessed and analyzed within secure and institutionally approved computing environments. No individual identifiers were presented in the manuscript. The results are reported only in aggregate form, ensuring that patients cannot be identified. No compensation was provided to participants, as this study involved the retrospective analysis of medical records.

RenderX

Results

Cohort Characteristics

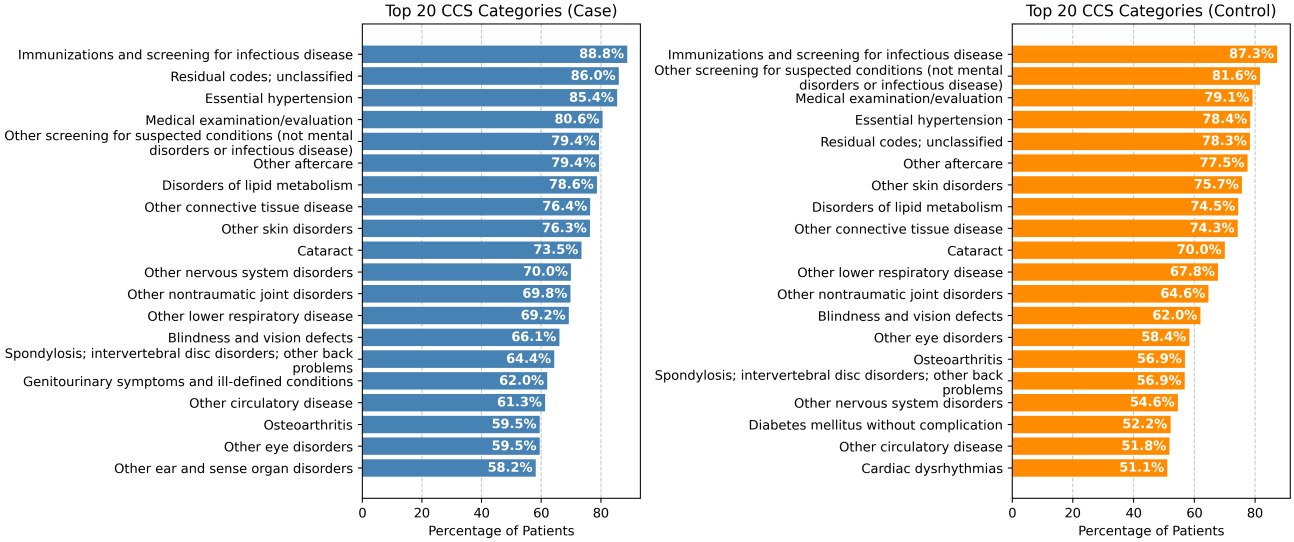

Table 1 presents the participant characteristics for the MCSA cohort. Approximately 21% (652/3041) of cases were categorized as low SES based on the HOUSES Index, 4% (129/3041) were categorized based on the national-level ADI, and 25% (774/3041) were categorized based on the state-level ADI. To understand the relationship between SES measures, we assessed the concordance between the HOUSES Index and both ADI measures in the MCSA cohort. There was limited overlap between the classifications. Among those identified as low SES by the HOUSES Index, only 12.0% (78/652) were concurrently classified as low SES by the national-level ADI, and 40.0% (261/652) were concurrently classified as low SES by the state-level ADI. This lack of concordance indicates that while these metrics all aim to measure disadvantage, they identify distinct subpopulations.

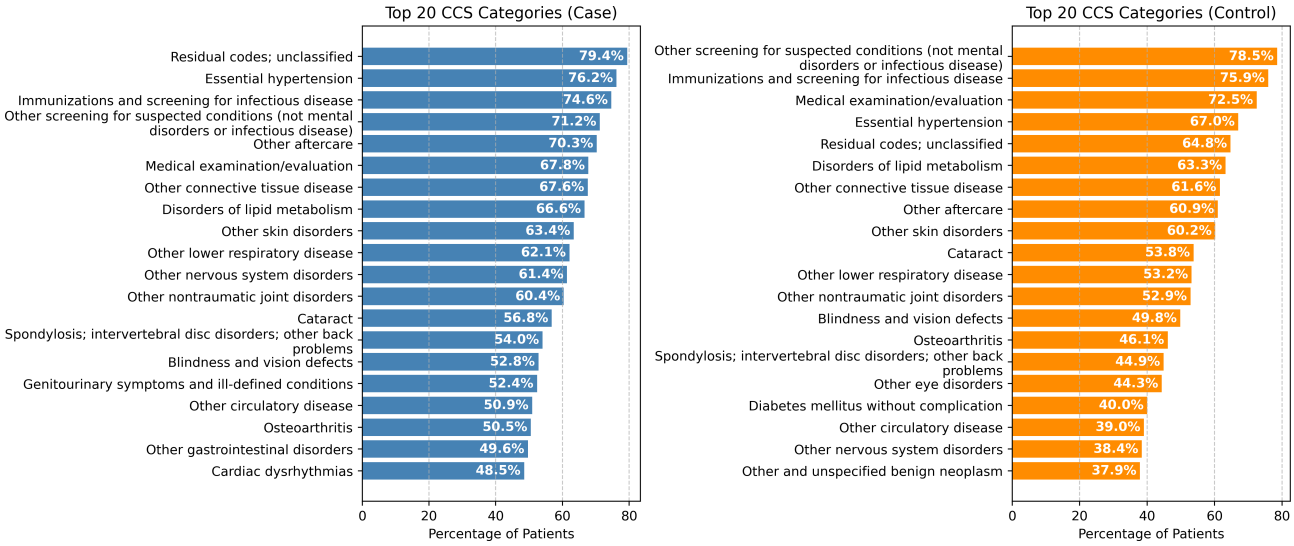
Table 2 summarizes the participant characteristics for the REP cohort. SES analyses indicate that approximately 6% (1095/19,572) of cases were classified as low SES using the national-level ADI, and 27% (5274/19,572) of cases were classified as low SES using the state-level ADI (the HOUSES Index is not available in the REP cohort). SES measure distributions were similar for controls in both populations.

The average number of visits during the 5-year observation window was 93.3 (SD 65.0) for patients with dementia and 79.5 (SD 62.7) for patients without dementia in the MCSA cohort, and 76.2 (SD 70.4) and 55.8 (SD 52.2), respectively, in the REP cohort. We also assessed data completeness by calculating the average number of years missed, defined as the count of years within the 5-year observation window where a patient had no recorded visits. When analyzing the combined population of patients with dementia and patients without dementia, most SES measures indicated that the low SES group exhibited a higher average number of years missed compared to the high SES group. In the MCSA cohort, the high SES group averaged 0.12 missed years compared to 0.17 missed years for the low SES group based on the HOUSES Index. Similarly, the national-level ADI showed 0.13 missed years for the high SES group and 0.16 missed years for the low SES group, while the state-level ADI showed a divergent pattern, with 0.14 missed years for the high SES group compared to 0.11 missed years for the low SES group. A consistent pattern emerged in the REP cohort, where the national-level ADI showed averages of 0.54 missed years for the high SES group and 0.71 for the low SES group, and the state-level ADI showed 0.54 for the high SES group compared to 0.59 for the low SES group.



Figures 2 and 3 show the top 20 CCS categories that appear among cases versus controls, ordered by the percentage of patients who had those CCS categories in the MCSA cohort and the REP cohort, respectively. In both cohorts, more patients with dementia visited for “essential hypertension” than patients without dementia during the 5-year observation period (MCSA: 85.4% vs 78.4%; and REP: 76.2% vs 67.0%). Similarly, more patients with dementia visited for “other nervous system disorders” than patients without dementia during the same period (MCSA: 70.0% vs 54.6%; and REP: 61.3% vs 38.4%).

Figure 2. Top 20 Clinical Classifications Software (CCS) categories that appear among cases versus controls during the 5-year observation period, ordered by the percentage of patients who had those CCS categories in the Mayo Clinic Study on Aging cohort.

Figure 3. Top 20 Clinical Classifications Software (CCS) categories that appear among cases versus controls during the 5-year observation period, ordered by the percentage of patients who had those CCS categories in the Rochester Epidemiology Project cohort.

Bias Measurement

Table 3 presents a comparison of BERs for AI-based dementia prediction models stratified by SES, as indicated by both the ADIs and the HOUSES Index in the MCSA cohort. The first 2 rows compare BERs among males, the next 2 rows compare BERs among females, and the final 2 rows compare BERs for both males and females combined. Between each pair of rows, superscript letters denote statistically significant differences in BER for the low SES group compared to the high SES group (based on Benjamini-Hochberg–corrected $P<.05$): “h” indicates a significantly lower BER, “i” indicates a significantly higher BER, and “j” indicates no statistically significant difference. Across all evaluated models, individuals (males and females combined) with low SES, as measured by both the ADIs and the HOUSES Index, consistently exhibited higher BERs. When focusing on males only, those with low SES similarly demonstrated higher or equal BERs across models. However, for females, the patterns differed: in nearly all evaluated models, females with low SES, as indicated by the national-level ADI, consistently showed higher BERs, while female participants with low SES, as indicated by the state-level ADI, showed comparable BERs. In contrast, those with low SES as measured by the HOUSES Index consistently exhibited lower or equal BERs.

Table 4 compares BERs within each AI-based dementia prediction model among SES-sex subgroups in the MCSA cohort. We selected “male in high SES” as the baseline category. For each model, the table displays how the BERs for “male in low SES,” “female in high SES,” and “female in low SES” compare to this baseline. “Lower” indicates a lower BER than the baseline, “higher” indicates a higher BER, and empty cells signify no statistically significant difference. From the table, it is evident that males with high SES, as indicated by the HOUSES Index, consistently exhibited the lowest BERs across all evaluated models. Furthermore, males with high SES measured by the 2 ADIs showed the lowest BERs in almost all models, with the exception of the RF when using the national-level ADI and the NB model when using either the state-level or national-level ADI.

Table 5 presents a comparison of BERs for AI-based dementia prediction models stratified by SES—as indicated by both ADIs—in the REP cohort (the HOUSES Index was not available in the REP cohort). In every evaluated model except NB, individuals (combining both males and females) with low SES, as determined by both ADIs, consistently exhibited higher BERs. When focusing on females only, those with low SES similarly demonstrated higher BERs across almost all models, with the exception of the NB model when using the state-level ADI. Furthermore, males with high SES showed lower BERs in almost all models, with the exception of the NB model when using either the state-level or national-level ADI.

Table 6 compares BERs within each AI-based dementia prediction model among SES-sex subgroups (using the same approach as Table 4) in the REP cohort; we selected "male in high SES" as the baseline category. From the table, most of both males and females with low SES exhibit higher BER compared to males with high SES. Furthermore, females with high SES, as indicated by the national-level ADI, exhibited higher BER compared to males with high SES. However, females with high SES, as indicated by the state-level ADI, exhibited the lowest BERs across almost all the evaluated models except for the NB model.

Table 7 presents a comparison of the relative differences in BERs between low and high SES groups, as indicated by both the ADIs and the HOUSES Index, across the 4 AI-based dementia prediction models in the MCSA cohort. The relative difference (value close to 0 is perfectly balanced between low and high SES groups), calculated as (low SES' BER−high SES' BER)/high SES' BER, was first shown for the baseline case with no dataset balancing. Subsequently, the relative differences after balancing the training dataset (separately using national-level ADI, state-level ADI, and the HOUSES Index) are displayed. Within each model and SES measure, if the difference postbalancing was lower than the baseline, the corresponding cell is marked with "i"; otherwise, it is marked with "j". As indicated by "h" in the table, balancing the training dataset using any one of the 3 SES measures was associated with narrower BER differences between high and low SES groups when stratified by that same SES measure. However, in several cases, most notably with the LR and RF models under national-level ADI balancing, the relative difference shifted from positive to negative. This shift indicates an inversion of the disparity, whereby the low SES group achieved a lower BER than the high SES group. Furthermore, when the training dataset was balanced using one SES measure but performance was stratified by another SES measure, BER differences were similarly reduced across nearly all cases. The exceptions occurred when SES was stratified by national-level ADI and the training dataset was balanced by state-level ADI or the HOUSES Index under the RF model or when the training dataset was balanced by national-level ADI but evaluated using the HOUSES Index with the SVM and NB models. For instance, balancing the training data on the HOUSES Index increased the BER disparity measured by the national-level ADI from 8.38% to 30.37% with the RF model. This pattern suggests that fairness interventions are not universally beneficial across different definitions of the protected attribute.

Table 8 presents the same comparison as in Table 7 but for the REP cohort. Similarly, as indicated by footnote "g" in the table, balancing the training dataset using any one of the 3 SES measures consistently reduced the BER differences between high and low SES groups when stratified by that same SES measure. A similar pattern of disparity inversion was observed, where balancing on the national-level ADI for the RF model and the state-level ADI for the SVM model also resulted in negative relative differences.

Discussion

Principal Findings

Our study demonstrates socioeconomic bias in AI-driven dementia prediction models. Across both the research cohort (MCSA) and the real-world cohort (REP), the combined male and female population with lower SES consistently exhibited higher BERs compared to their higher SES counterparts, except when using the NB model in the REP cohort. This discrepancy suggests that AI models, when trained on imbalanced SES datasets, may not generalize well across different socioeconomic groups, potentially reinforcing existing health care disparities. The findings highlight important differences in bias detection across SES measures. Both the ADI and the HOUSES Index were effective in identifying disparities, but they capture different aspects of socioeconomic disadvantage. The HOUSES Index, which is based on housing data, identified a more nuanced variation in model performance. In contrast, the ADI (both national-level and state-level rankings), which is derived from census block group–level data, showed broader disparities but may be less sensitive to individual economic conditions.

One important factor contributing to the observed differences in performance between high and low SES groups is the imbalance in their representation within both cohorts. Individuals from higher SES groups significantly outnumber those from lower SES groups. This skewed distribution can have a direct impact on model performance, as AI algorithms trained on predominantly high SES individuals may not adequately capture the health-related patterns of populations with low SES.

A key implication of this imbalance is that AI models become optimized for the majority (high SES) group, leading to lower accuracy and higher BERs for the understudied (low SES) group. Machine learning models inherently learn patterns based on the data they are exposed to, and if the majority of training samples come from high SES individuals, the model is likely to develop a bias toward their health characteristics and health care access patterns. This bias can manifest in the form of increased BER for participants with low SES. Furthermore, disparities in health care access and utilization between SES groups can compound these biases. Traditionally, it is argued that individuals from higher SES backgrounds have more comprehensive and consistent health records, whereas individuals with lower SES may experience gaps in care that lead to incomplete medical histories [23]. Our findings support this view: the low SES group exhibited a higher average number of years with missed visits compared to the high SES group, as reported in the Results section.

Another important observation is the interaction between SES and sex. In the MCSA cohort, high SES male participants generally exhibited the lowest BERs. In the REP cohort, however, the results depended on the specific SES measure used: high SES female individuals tended to have the lowest BERs when stratified by the state-level ADI, whereas this pattern was not observed with the national-level ADI. This discrepancy between cohorts may result from MCSA's active recruitment and retention process, which likely selected for a subgroup of male participants with higher health literacy and more complete records than the general population—a selection bias less present in the passive data collection of the REP cohort. Furthermore, within the REP cohort, the fact that high SES female individuals did not exhibit this advantage under the national-level ADI highlights the differential validity of SES measures. Broader metrics such as the national-level ADI may fail to capture localized resource variations that drive health outcomes for female participants, nuances that are better reflected by more granular measures such as the state-level ADI.

To address these disparities, we applied the SMOTE-NC to balance the SES representation in the training data. This approach narrowed the observed SES-related disparities in BERs, demonstrating that balanced data distributions can improve AI model fairness. However, the effectiveness of this technique varied across SES measures—while balancing based on the HOUSES Index and state-level ADI consistently reduced BER disparities, national-level ADI balancing sometimes led to unintended increases in BER differences for certain models. This may indicate that the national-level ADI lacks the necessary resolution to distinguish SES levels within specific states effectively. Unlike the state-level ADI or the HOUSES Index, the national-level ADI may not adequately represent the local socioeconomic context required for effective data balancing. Furthermore, the limited concordance observed between the HOUSES Index and the ADI measures may explain why oversampling based on one measure resulted in disparities in the others.

While our balancing approach improved fairness in model performance for lower SES groups, it often came at the cost of a slight reduction in overall model performance. In some cases, this intervention led to an inversion of bias, resulting in the models performing better on the low SES group than the high SES group. The trade-off between fairness and predictive accuracy is a known challenge in AI-driven health care apps, and our results highlight this issue. Most balancing strategies led to improved performance for the low SES group while slightly decreasing overall predictive accuracy. However, an exception was observed in the MCSA cohort when balancing based on the HOUSES Index using LR, SVM, and NB, where both the high and low SES group performances improved. This suggests that housing-based SES metrics, such as the HOUSES Index, may be more effective for bias mitigation than area-level measures such as the ADI.

Beyond statistical significance, it is crucial to consider the clinical importance of these performance disparities. For instance, in the MCSA cohort, the NB model using the HOUSES Index yielded a BER of 39.3% for the high SES group compared to 46.2% for the low SES group. While this represents a modest absolute difference of 6.9 percentage points, its impact at a population level is substantial. In a hypothetical clinical screening scenario involving 1000 patients from each SES group, this disparity would translate to an additional 69 patients from low SES backgrounds being misclassified compared to their high SES counterparts. Such a systematic difference in accuracy, when deployed at scale, could further disadvantage already underserved populations in clinical care. Patients from socioeconomically disadvantaged backgrounds would be

XSL•FO
RenderX

disproportionately subject to the consequences of misclassification, including delayed diagnosis and intervention in the case of false negatives, or unnecessary, costly, and anxiety-inducing follow-up procedures in the case of false positives. This quantification highlights how seemingly small statistical biases can manifest as meaningful clinical harms.

Limitations

While this study provides valuable insights, it is important to recognize limitations. First, although our study cohorts (MCSA and REP) represent Midwestern populations with a dominant White demographic, they are not representative of the broader US population [39]. Therefore, the findings regarding SES- and sex-based bias warrant validation in more representative populations. Second, our AI models do not include certain important clinical factors, such as cognitive test scores, functional assessments, or advanced biomarkers, in dementia prediction. Instead, we focused on commonly available variables in real-world clinical settings because the primary goal of this study was to investigate AI bias rather than to maximize predictive accuracy. Third, relying on ICD codes to identify dementia cases in the REP cohort introduces potential ascertainment bias. In real-world settings, socioeconomic barriers to care may prevent low SES individuals from obtaining a formal diagnosis despite the presence of disease. Consequently, these undiagnosed individuals are liable to be misclassified as not having dementia. This specific form of label noise likely inflates the apparent error rates (specifically false negatives) for low SES groups independent of algorithmic performance. Fourth, the requirement for a 5-year observation window and subsequent follow-up may inadvertently exclude individuals with fragmented care. This selection factor suggests that the performance disparities reported here may underestimate the full extent of algorithmic bias. Additionally, while SMOTE-NC consistently reduced numerical BER disparities, the statistical significance of this reduction was not formally tested. These findings should be interpreted as descriptive evidence of fairness improvement. Finally, we did not consider temporal validation of the AI models over time, particularly in the REP cohort (real-world data). Health care systems are dynamic, and evolving diagnostic criteria for dementia and changes in ICD coding practices may lead to concept drift. Consequently, the models' utility for predicting dementia risk in future patient populations requires further investigation. Nonetheless, our main objective was to assess the SES-driven AI model bias rather than to optimize prediction performance, and our findings successfully demonstrate the influence of SES on AI bias in dementia prediction.

Future Work

In this study, BER was selected as the primary metric for evaluating model performance and fairness. This metric is particularly well suited for classification tasks with imbalanced classes, such as dementia prediction, because it gives equal importance to errors made on the understudied and majority classes, unlike standard accuracy. Our use of BER aligns with a fairness goal of achieving parity in overall error rates between demographic subgroups. However, it is important to acknowledge that "fairness" is a multifaceted concept, and no single metric can capture all its dimensions. Alternative fairness criteria could have been used, each with different implications. Future work should extend this analysis by evaluating these models against a broader suite of fairness metrics to provide a more holistic assessment of their performance trade-offs. We should also investigate whether differences in health care utilization patterns contribute to these variations, as female individuals may engage with health care services differently than male participants, potentially influencing AI model predictions.

Our further research should explore advanced fairness-aware algorithms that optimize both fairness and predictive accuracy, ensuring that model improvements do not disproportionately benefit or disadvantage any subgroup. Additionally, our future work should evaluate alternative debiasing strategies beyond oversampling, such as model recalibration and adversarial learning, to address structural biases inherent in the data.

Conclusions

This study underscores the biases in AI models predicting dementia, with performance disparities observed across SES and sex groups. Individuals from lower SES backgrounds consistently experienced less accurate predictions, as reflected in higher BERs. These disparities suggest that AI models trained on real-world health care data may inadvertently reinforce patterns of underservice among certain populations, underscoring the need for fairness-aware modeling approaches.

Comparisons between SES measures revealed that the HOUSES Index and ADI capture different aspects of socioeconomic disadvantage, with the HOUSES Index potentially offering more granularity at the individual level. The observed sex-based disparities in model bias further emphasize the intersectionality of SDOH, highlighting the importance of multidimensional fairness evaluations in AI-driven health care applications.

Ultimately, this research reinforces the ethical imperative to integrate sociodemographic factors into AI model development and evaluation. Addressing these biases is essential for promoting fair AI-driven solutions in dementia risk prediction, where early and accurate diagnosis is critical for patient outcomes.

Abstract

Background: Nephrolithiasis affects approximately 15% of the population and often remains undetected in asymptomatic individuals. Current diagnostic approaches rely on imaging tools, such as ultrasound or computed tomography, which are costly, operator dependent, or involve radiation, making them unsuitable for large-scale screening. A standardized, practical, and low-cost screening strategy for early identification of clinically significant kidney stones is still lacking.

Objective: This study aimed to develop a low-cost, rapid screening model for clinically significant nephrolithiasis using machine learning (ML) and simple clinical parameters.

Methods: We conducted a multihospital retrospective study using data from 3 hospitals in Kaohsiung, Taiwan (2012‐2021). Adults without renal colic were included. ML models were trained and tested using 10 routine variables: sex, age, BMI, gout, diabetes, estimated glomerular filtration rate, urine pH, red blood cell count, specific gravity, and bacteriuria. Multiple ML algorithms were trained and evaluated, and the best-performing model was selected based on the area under the receiver operating characteristic curve and the area under the precision-recall curve. To assess model interpretability, Shapley value analysis was performed to determine the relative importance and contribution of each variable to the model's predictive performance.

Results: Among 6528 participants, the best-performing model achieved an area under the receiver operating characteristic curve of 0.968 (95% CI 0.956‐0.980), an area under the precision-recall curve of 0.936 (95% CI 0.918‐0.953), a sensitivity of 0.873 (95% CI 0.841‐0.904), and a specificity of 0.947 (95% CI 0.935‐0.959). Shapley value analysis identified urine red blood cell count, estimated glomerular filtration rate, and urine specific gravity as the 3 most influential predictors.

Conclusions: This ML-based model enables efficient, noninvasive, and large-scale kidney stone screening using routine health data. It can be integrated into health checkups or telemedicine platforms to facilitate early detection and proactive management. Although the model was developed using an Asian population, future validation in diverse cohorts is warranted to confirm its generalizability.

Introduction

Approximately 10% of the global population faces a lifetime risk of developing kidney stones [1], and the prevalence of this disease has been steadily rising over the past two decades [2,3]. The most common symptoms include flank pain and hematuria, and kidney and ureteral stones are significant risk factors for chronic kidney disease [4]. A study reported that in the year 2000 alone, the total medical expenditure for treating kidney and ureteral stones in the United States reached US $2.1 billion [5].

Currently, there is no effective tool available for kidney stone screening. Renal ultrasonography is the most commonly used method for detecting kidney stones in clinical settings and emergency departments [5]. While it is a convenient and radiation-free technique, its accuracy is highly dependent on the operator's skill, thus requiring trained medical professionals for both operation and interpretation. As a result, its use in large-scale screening would demand substantial health care manpower [6,7]. In contrast, abdominal computed tomography (CT) is considered the gold standard for diagnosing kidney and ureteral stones [8]. However, due to its high radiation exposure and limited accessibility for routine or large-scale screening, CT is not suitable for asymptomatic populations or frontline outpatient use [9]. Therefore, existing imaging tools are impractical for large-scale screening of kidney stones. Developing a simple, cost-effective, and accessible screening tool would be highly beneficial for the early detection of kidney stones and for timely medical decision-making.

We previously developed an artificial intelligence (AI) algorithm that uses routine health checkup data, including urine routine and blood creatinine, to preliminarily predict the presence of kidney stones larger than 2 mm in overweight individuals (BMI ≥25 kg/m^2) [6]. This tool has shown potential for use in kidney stone screening. In this study, we aimed to build upon our prior success by leveraging machine learning (ML) techniques and routine health data to further develop a clinically applicable AI model that can predict clinically significant kidney stones in all patients—not limited to those with BMI >24 kg/m^2. The models will be validated using patient cohorts from multiple hospitals.

Methods

Description of Participants

In this cohort study, clinical data were retrospectively collected from three hospitals located in Kaohsiung, Taiwan: Kaohsiung Medical University Hospital, Kaohsiung Municipal Ta-Tung Hospital, and Kaohsiung Municipal Siaogang Hospital. The data collection period spanned from January 2012 to March 2021.

Patients were categorized into 2 groups based on the presence or absence of nephrolithiasis measuring ≥2 mm. This classification followed the methodology of our previously published ML-based nephrolithiasis screening model developed for overweight and obese individuals [6]. In accordance with prior urological literature, stone fragments smaller than 2 mm are considered clinically insignificant, as they are unlikely to cause stone-related events or require intervention [7]. Therefore, a cutoff of 2 mm was adopted in this study to define clinically significant nephrolithiasis. The presence of stones of 2 mm or larger was confirmed using abdominal CT or a combination of renal ultrasonography and plain abdominal radiography (KUB: kidney, ureter, and bladder), consistent with our prior study protocol [6]. Patients were excluded if they experienced renal colic at the time of data collection, had undergone kidney transplantation, had indwelling foreign bodies in the upper urinary tract (eg, ureteral stents or percutaneous nephrostomy tubes), were receiving renal replacement therapy (hemodialysis or peritoneal dialysis), were aged younger than 18 years, or lacked complete medical records. For model development, data from January 2012 to December 2019 were used for training and validation. An independent test cohort comprising data collected between January 2020 and March 2021 was used for the clinical evaluation of model performance.

Ethical Considerations

This study was approved by the Institutional Review Board of Kaohsiung Medical University Hospital (KMUHIRB-E(I)-20210331) and conducted in accordance with the principles outlined in the Declaration of Helsinki. The requirement for informed consent was waived due to the retrospective nature of the study and the minimal risk to participants. All data were obtained from existing electronic health records and were fully deidentified before analysis. No personally identifiable information was accessed by the researchers, and data access was restricted to authorized study personnel only. No compensation was provided to participants, as no direct contact or intervention was involved in this retrospective study.

Variables and Data Processing

A total of 10 predictor variables were included for model development, categorized into sociodemographic, health-related, and clinical domains. The categorical response variable indicated the presence (1) or absence (0) of nephrolithiasis ≥2 mm. Sociodemographic variables included age (numeric) and sex (categorical: male=1 and female =0). Health-related variables comprised BMI (numeric with 2 decimals) and a history of diabetes mellitus and gout (both categorical: with=1 and without=0).

Clinical variables included five parameters derived from urine and blood tests:

1. Urine specific gravity (SG; numeric with 3 decimals)
2. Urine pH (numeric with 1 decimal)
3. Bacteriuria (categorical: present =1, absent =0)
4. Urine red blood cell (RBC) count (treated as a numeric variable; details described as follows): In Taiwan, urine RBC counts are commonly reported in terms of a range (eg, 6 - 10 RBCs per high-power field [HPF]), with the lowest range being "0 to 2 RBCs per HPF." In this study, the urine RBC data we collected consist of the following ranges: 0 to 2, 3 to 5, 6 to 10, 11 to 25, 26 to 50, 51 to 99, and 100 or greater. As such, it may be treated as a categorical variable in this study. However, to accommodate various range scales used by different hospitals and make the model

XSL•FO
RenderX

universally applicable, we adopted the mean of the reported ranges (eg, 8 for the range 6 - 10 RBCs per HPF) as the corresponding urine RBC count and treated the variable as numeric (continuous). The exceptions to the rule are the range of "0 to 2" and the ranges whose mean values exceed 100. For the 0 to 2 range, the value 0 is assigned. This is due to an American Urological Association guideline, which defines microhematuria as "3 or more RBCs per HPF on microscopic examination." Therefore, 0 to 2 RBCs per HPF is generally considered as no hematuria. On the other hand, patients with macroscopic hematuria generally have their urine RBC counts reported as "100 or more RBCs per HPF," or a range with a mean value exceeding 100, or something equivalent to that effect. As such, for ranges whose mean values exceed 100 RBCs per HPF, we applied the capped value of 200 to maintain consistency across the dataset [10].

5. Estimated glomerular filtration rate (eGFR), numeric with 1 decimal, calculated using the Isotope Dilution Mass Spectrometry–traceable Modification of Diet in Renal Disease equation: eGFR (mL/min/1.73 m^2)=175×$(Scr)^{-1.154}$×$(age)^{-0.203}$×(0.742 if female) [8]

For descriptive statistics, the Fisher exact test was used for categorical variables (eg, sex, history of diabetes mellitus, and history of gout), and the Mann-Whitney *U* test was applied for numeric variables (eg, age, BMI, eGFR, urine SG, urine RBC count, and urine pH) between patients with and without nephrolithiasis. To verify the similarity between the training and testing datasets, we compared feature distributions by calculating category percentages for categorical variables and means with SDs for continuous variables. All statistical analyses were performed using the Statistical Package for the Social Sciences for Windows (version 24.0; IBM), and *P* values of less than .05 were considered statistically significant.

Model Development, Fitting, and Evaluation

ML methods were used to build the models [9]. The logistic regression, the k-nearest neighbors algorithm, the support vector machine, and the random forest (RF) algorithm were used as the standard methods for comparison, while an artificial neural network (ANN) model was developed for deep learning classification. All standard models were implemented in Python using the scikit-learn library (version 1.1.3; scikit-learn developers) with recommended settings. The respective algorithms for each method were run using the recommended parameters [11,12].

For the ANN, implemented in Python, the 10-fold cross-validation protocol was performed on the training set to produce 10 models, each structured as a 9-layer fully connected neural network. These models were averaged into 1 final model. To address the imbalance between stone-positive and stone-negative cohorts, the synthetic minority over-sampling technique, as well as the approach of assigning different weights to the 2 patient groups, was adopted when training our models. In addition, a pronounced sex imbalance among the patient cohorts was observed. To ensure equitable accuracy for the 2 gender groups, 2 separate cutoff thresholds were identified for male and female patients. The 2 thresholds were then standardized to 0.5 by applying gender-specific rescalers to the averaged outputs. The resulting combined structure served as the final ANN model with a unified threshold of 0.5. Additional information is provided in Figure S1 in Multimedia Appendix 1.

Data between January 2012 and December 2019 were used for model training and validation. The data were randomly divided into a training dataset (75%) and a validation dataset (25%). Model training was performed using the training data, while validation data helped identify overfitting or bias. Data registered after January 1, 2020, formed the testing dataset (ie, the holdout dataset) for independent evaluation of model performance. Performance on the testing data was assessed by various metrics, including the area under the receiver operating characteristic (ROC) curve (AUROC), the area under the precision-recall (PR) curve (AUPRC), and net benefit by the decision curve analysis. The optimal thresholds for standard models were based on the Youden index [13] from their respective training ROC curves. For the ANN, the classification threshold was preset at 0.5. These thresholds were used to calculate sensitivity, specificity, positive predictive value, and negative predictive value on the validation and testing sets. Model calibration analysis was also performed to assess how accurately the output probabilities of the models reflect the true likelihood of outcomes.

To examine model stability and fairness across different patient subgroups, additional analyses were performed by individual variables (eg, sex, diabetes, gout, bacteriuria, urine RBC count, age, BMI, and eGFR), where model performance metrics (area under the curve [AUC] and accuracy) were calculated independently for each subgroup.

Importance of Feature Variables

To evaluate the predictive power of each feature variable, their relative impact on the ANN model output was assessed by applying the Shapley value analysis [14]. Features with notably high impact were selected, and an ANN model was trained using only these variables. The performance of the model was compared with that of the full-variable ANN model to assess whether key features alone provided sufficient predictive power.

Results

Characteristics of Study Participants

In the training dataset, 1243 (33.11%) participants had nephrolithiasis, and 2511 (66.89%) participants were without nephrolithiasis of 2 mm or greater, among a total of 3754 (100.0%) participants. The validation dataset had 414 (33.09%) participants with and 837 (66.91%) participants without nephrolithiasis of 2 mm or greater, among a total of 1251 (100.0%) participants. The testing dataset had 400 (26.26%) participants with and 1123 (73.74%) participants without nephrolithiasis of 2 mm or greater, among a total of 1523 (100.0%) participants. The characteristics of the participants in these 3 sets are described in detail in Tables 1 and 2. Statistical similarity among the 3 sets was observed. It is also observed that the mean values (or the "percentages," in the case of binary variables) of the variables we selected are statistically different between participants with and without nephrolithiasis. The

XSL•FO
RenderX

Fisher exact and Mann-Whitney *U* tests were applied to verify the statistical significance of these differences, and the resulting *P* values are also reported in Tables 1 and 2.

Model Performance

The ANN model we developed demonstrated strong discriminatory power in identifying participants with kidney or ureteral stones, using only limited information typically collected at an initial clinical visit. It achieved validation and testing AUROCs of 0.970 and 0.968 and validation and testing AUPRCs of 0.960 and 0.936, respectively. Using a cutoff value of 0.5, the model showed high sensitivity, specificity, positive predictive value, and negative predictive value in both validation and testing sets, with overall correction rates of 92.3% and 92.7%, respectively. These performance measures indicate that the model achieved a good balance in identifying both positive and negative cases and is able to render both high precision and high recall.

The performance of models obtained using standard methods appeared to be somewhat inferior to that of the ANN model, with the exception of the RF algorithm, which performed equally well. The logistic regression, k-nearest neighbors, and support vector machine (linear kernel) models had testing AUROCs of 0.933, 0.916, and 0.910, respectively, and testing AUPRCs of 0.822, 0.876, and 0.790, respectively. The RF model achieved AUROC and AUPRC of 0.965 and 0.934, which are almost the same as those of the ANN model. The overall correction rate was 90.5%. Despite the high AUROC and AUPRC scores, the RF model showed unbalanced performance between sensitivity and specificity, a pattern also observed in the other conventional models.

Table 3 summarizes the performance data of these 5 models. Figure 1A-C presents their training, validation, and testing ROC curves, while Figure 2A-C presents the respective PR curves.

Regarding the practical relevance of models' predicted probabilities, the results of decision curve analysis and model calibration analysis are shown in Figure 3A-C and Figure 4A-C, respectively. Figure 3 indicates that all models rendered higher net benefits than those of the baseline strategies ("treat all" and "treat none") over a large range of threshold probabilities. Among them, the performance of the ANN and RF models appeared to be superior to the others over the validation and testing datasets. Figure 4 indicates that the predicted probabilities of all models were somewhat deviated from the actual events. As such, despite exhibiting good performance for identifying nephrolithiasis, further calibration of the model outputs appears to be required. To further evaluate the robustness and generalizability of the ANN model, subgroup analyses were conducted based on demographic and clinical characteristics.

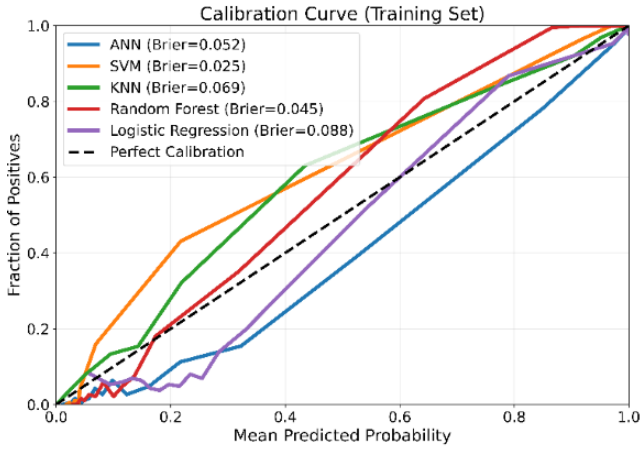

Fig. 4A

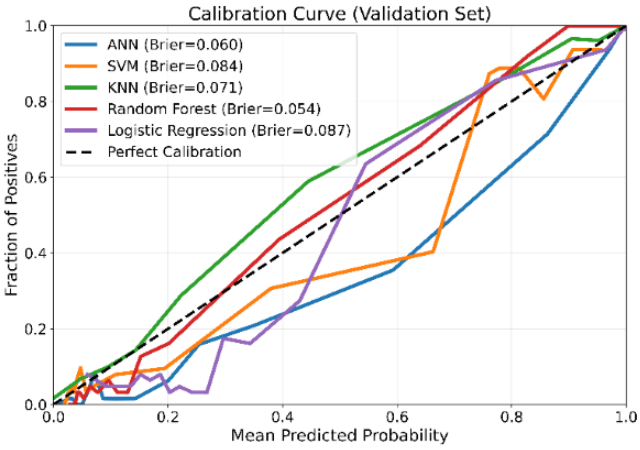

Fig. 4B

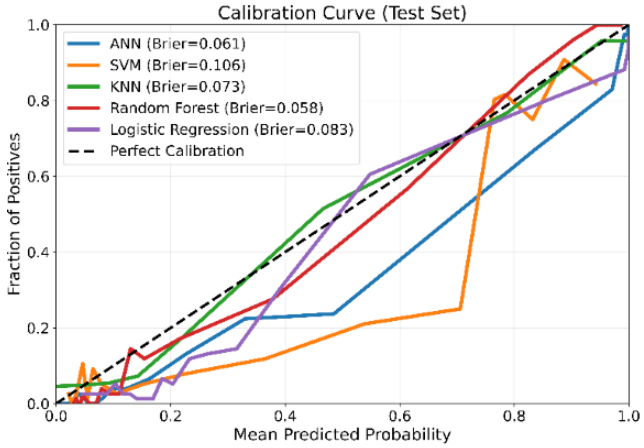

Fig. 4C

In the subgroup analysis, the ANN model achieved an AUC of 0.965 and an accuracy of 0.917 in male patients and an AUC of 0.970 and an accuracy of 0.936 in female patients. Similar consistent performances were observed across other subgroups. In patients with diabetes, the model achieved an AUC of 0.961 and an accuracy of 0.890, whereas in those without diabetes, the AUC and accuracy were 0.963 and 0.930, respectively. In patients with gout, the model reached an AUC of 1.000 and accuracy of 1.000, while in those without gout, the AUC was 0.967, and the accuracy was 0.926. For patients with bacteriuria, the AUC was 0.967, and the accuracy was 0.926, compared with 0.968 and 0.929 in those without bacteriuria. Among urine RBC subgroups, the AUC and accuracy were 0.915 and 0.942 for 0 to 2 RBCs, 0.936 and 0.866 for 3 to 5 RBCs, 0.950 and 0.908 for 6 to 10 RBCs, and 0.936 and 0.916 for 10 or more RBCs. By age category, the AUC and accuracy were 0.972 and 0.949 for patients aged 18 to 40 years, 0.956 and 0.923 for those aged 40 to 65 years, and 0.916 and 0.907 for those older than 65 years. For BMI subgroups, the model achieved 0.966 and 0.934 for BMI less than 25 kg/m^2, 0.961 and 0.918 for BMI of 25 to 30 kg/m^2, and 0.964 and 0.913 for BMI of 30 kg/m^2 or greater. Finally, among patients with eGFR less than 60, the AUC and accuracy were 0.992 and 0.981, compared with 0.953 and 0.921 for those with eGFR greater than 60.

Importance of Feature Variables

The results of the Shapley value analysis for the ANN model are shown in Figure 5A, which indicates that the predictive power of the model was predominantly driven by three features: urine RBC count, eGFR, and urine SG. An ANN model trained using only these 3 predictors (referred to as “ANN-3P” thereafter, as opposed to “ANN-10P” for the original 10-predictor ANN model) achieved validation and testing AUROCs of 0.954 and 0.943, and validation and testing AUPRCs of 0.938 and 0.891, respectively; the performance is competitive with that of the ANN-10P model. Figure 5B-E displays the ROC and PR curves of the 2 models, and a comprehensive performance comparison is summarized in Table 4. The outstanding performance of the ANN-3P model confirms the predictive power rendered by the 3 key feature variables.

[d]NPV: negative predictive value.

Discussion

Principal Findings

Epidemiological studies indicate that approximately 10% of the global population faces a lifetime risk of developing kidney stones [1], and approximately 80% of those affected experience recurrence after stone treatment [15]. Although kidney stones are not malignant such as cancers, they can cause severe flank pain that often drives patients to seek emergency care [16]. In more serious cases, stones may lead to urinary tract infections, sepsis, and even hospitalization. Furthermore, recent studies have reported a strong association between nephrolithiasis and the development of chronic kidney disease [4]. Despite these risks, most kidney stones are only diagnosed after patients present with symptoms and undergo imaging-based evaluations in clinical settings [17]. Currently, there is no widely adopted, large-scale, low-cost, and simple screening tool available for the early detection of kidney stones [18,19].

In 2024, our team developed an AI-based model using routine health checkup data to screen for kidney stones in overweight and obese individuals. The model achieved excellent performance (AUC=0.96), and its advantages include low cost, rapid computation, minimal computational power requirements, and no need for physician involvement [6]. This enables its application in frontline health screenings to identify high-risk individuals for further evaluation. Building on the success of our previous work, this study extends the application of our AI framework to the general population. Our findings suggest the potential for a scalable, accessible, and noninvasive tool to detect clinically significant kidney stones across diverse patient groups, providing a much-needed advancement in the proactive management of urolithiasis.

In some regions, certain high-end health screening programs incorporate renal ultrasound (US), plain abdominal radiography (KUB), or even CT to detect asymptomatic kidney stones. While US is a fast, user-friendly, and radiation-free imaging modality, its accuracy is highly operator dependent. Studies comparing US with CT have reported widely varying sensitivity (24% - 69%) and specificity (53% - 90%) levels [20-22]. This variability limits its reliability, especially in large-scale screening, as it requires experienced physicians and access to ultrasound equipment, both of which are resource intensive. Plain x-rays or KUB, although useful in identifying some kidney stones, expose patients to radiation (0.7 mSv per scan) [20]. Plain abdominal x-rays (KUB) can identify some radiopaque stones but have limited sensitivity and expose patients to ionizing radiation (~0.7 mSv per scan) [22] . For women of reproductive age, pregnancy status must be considered before imaging. Furthermore, the interpretation of KUB relies on trained radiologists, making it less practical for community-based screening. Currently, abdominal CT is the gold standard for diagnosing kidney and ureteral stones. However, it has notable drawbacks, including significant radiation exposure (10 mSv for standard noncontrast CT and 1 - 3 mSv for low-dose CT) [20,23] and high medical cost [24]. These factors make CT unsuitable for large-scale or repeated screening, particularly in asymptomatic populations. Given the limitations of traditional imaging modalities in mass screening contexts, our AI-based approach offers a compelling alternative. Using only routine clinical parameters from standard health checkups, our model provides a rapid, low-cost, and accessible method for the early detection of kidney stones without the need

XSL•FO
RenderX

for imaging, radiation, or specialized personnel. This has significant implications for population-level screening and preventive nephrology.

To the best of our knowledge, this study is the first to use a large-scale dataset that integrates simple clinical information from both patients with and without kidney stones, applying ML techniques to develop a computer-aided screening tool for detecting stones of various compositions. This approach reflects real-world clinical scenarios and aims to support early detection and decision-making for further diagnostic evaluation. In this study, we expanded upon our previous work by incorporating 10 easily accessible clinical variables to construct an AI-based model capable of identifying individuals at high risk for kidney stones [6]. These variables, readily available during routine health checkups, emergency visits, or outpatient consultations, can be collected and analyzed quickly, with no additional burden on patients or health care resources.

One of the key advantages of this tool lies in its simplicity and cost-effectiveness. Unlike imaging-based diagnostics, which require expensive equipment and specialized interpretation, our AI model only needs a standard internet-connected computer and does not rely on urologists or radiologists for execution. This enhances its feasibility and scalability, particularly in resource-limited settings or rural areas. Conceptually, our AI screening model functions similarly to the fecal occult blood test used for colorectal cancer screening [25]—offering a rapid, noninvasive, and low-cost method to identify high-risk individuals who would then proceed to confirmatory imaging tests such as ultrasound, x-rays, or CT scans.

Furthermore, because our model relies on only 10 standard health checkup parameters, patients do not require any additional testing. This makes the tool highly compatible with existing clinical workflows. Given its accessibility and minimal operational requirements, it could be readily implemented in annual health screenings or even in the follow-up of patients who have undergone treatment for kidney stones [26,27]. By enabling earlier detection of stones—even when they are still small and asymptomatic—the model could facilitate timely intervention, reduce the risk of complications, and simplify surgical management.

Importantly, this approach also holds significant potential for use in telemedicine. By leveraging basic clinical data and our AI software, health care providers could remotely screen for kidney stones in patients living far from medical centers, enabling early identification and reducing the likelihood of emergency presentations. Overall, this screening tool may serve as a practical and scalable solution for improving access to care, minimizing disease burden, and promoting proactive management of urolithiasis across diverse health care settings.

Our AI model is designed as a practical screening tool to identify kidney stones using only routine blood and urine data collected during health checkups. In real-world workflows, it can be seamlessly integrated into existing laboratory information systems, allowing automated risk predictions once test results are available. For individuals with a high predicted probability of nephrolithiasis, clinicians can proceed with confirmatory imaging such as ultrasonography or CT for diagnosis, while those with low risk can safely avoid unnecessary imaging. This stepwise approach facilitates early detection and appropriate resource allocation. Furthermore, it should be noted that the algorithm only uses laboratory data from routine urinalysis and no additional (expensive) tests are required. As such, the extra cost for using our algorithm is minimal, making it highly affordable. Early identification enables timely lifestyle interventions or pharmacologic prevention, potentially reducing emergency visits and treatment costs associated with advanced stone disease.

The variables selected in our model were based on previously validated clinical factors strongly associated with nephrolithiasis. Although several of these factors showed significant differences (P<.001) between cases and controls, which may contribute to potential overestimation of model performance, we minimized this bias by applying stratified sampling and reweighting techniques during model training. Consistently high AUC and accuracy values across all subgroups further support the robustness and generalizability of our model.

As every participant in this study underwent imaging confirmation to verify the presence or absence of stones, conducting multiethnic and cross-national validation would require substantial resources and logistical coordination. Therefore, this work focuses on an Asian cohort as an initial step. Although our dataset was comprehensive—comprising a large number of patients from multiple hospitals—and we further validated the model using an independent testing cohort in a clinical trial setting, one important limitation must be acknowledged. All patients included in this study were of Asian ethnicity. As a result, the predictive performance of our AI model may be limited when applied to populations of different racial or ethnic backgrounds. Differences in genetics, diet, and environmental factors could potentially affect the clinical presentation and risk profiles of kidney stone disease. To reduce racial and environmental bias, variables known to vary with ethnicity or diet—such as urinary calcium, oxalate, citrate, or lifestyle factors—were excluded. Instead, our model incorporated clinically relevant indicators of stone risk, including hematuria, bacteriuria, and serum creatinine. These features are biologically plausible and less population dependent, suggesting that the model may be applicable across diverse groups, although future international validation is warranted to confirm its performance. Future research should focus on collecting and integrating data from diverse populations to further refine and recalibrate the model. This will be essential to enhance the generalizability and global applicability of the AI-based kidney stone screening tool.

Conclusions

In this multihospital study, we developed an ML-based model that accurately identifies clinically significant kidney stones using only 10 routine clinical and urine parameters. This low-cost, noninvasive tool enables large-scale, manpower-free screening and can be readily integrated into health checkups or telemedicine, offering a practical solution for early detection and proactive management of nephrolithiasis.

Abstract

Background: The Cox proportional hazards (CPH) model is a common choice for analyzing time-to-treatment interruptions in patients on antiretroviral therapy (ART), valued for its straightforward interpretability and flexibility in handling time-dependent covariates. Machine learning (ML) models have increasingly been adapted for handling temporal data, with added advantages of handling complex, nonlinear relationships and large datasets, and providing clear practical interpretations.

Objective: This study aims to compare the predictive performance of the traditional CPH model and ML models in predicting treatment interruptions among patients on ART, while also providing both global and individual-level explanations to support personalized, data-driven interventions for improving treatment retention.

Methods: Using data from 621,115 patients who started ART between 2017 and 2023, in Kenya, we compared the performance of the CPH with the following ML models—gradient boosting machine, extreme gradient boosting, regularized generalized linear models (Ridge, Lasso, and Elastic-Net), and recursive partitioning—in predicting first and multiple treatment interruptions. Explainable surrogate technique (model-agnostic) was applied to interpret the best performing model's predictions globally, using variable importance and partial dependence profiles, and at individual level, using breakdown additive, Shapley Additive Explanations, and ceteris paribus.

Results: The recursive partitioning model achieved the best performance with a predictive concordance index score of 0.81 for first treatment interruptions and 0.89 for multiple interruptions, outperforming the CPH model, which scored 0.78 and 0.87 for the same scenarios, respectively. Recursive partitioning's performance can be attributed to its ability to model nonlinear relationships and automatically detect complex interactions. The global model-agnostic explanations aligned closely with the interpretations offered by hazard ratios in the CPH model, while offering additional insights into the impact of specific features on the model's predictions. The breakdown additive and Shapley Additive Explanations explainers demonstrated how different variables contribute to the predicted risk at the individual patient level. The ceteris paribus profiles further explored the time-varying model to illustrate how changes in a patient's covariates over time could impact their predicted risk of treatment interruption.

Conclusions: Our results highlight the superior predictive performance of ML models and their ability to provide patient-specific risk predictions and insights that can support targeted interventions to reduce treatment interruptions in ART care.

Introduction

The Cox proportional hazards (CPH) model has long been a foundational tool for time-to-event analysis, widely used in health care research to examine treatment interruptions, including among patients on antiretroviral therapy (ART). The CPH model is a favorable choice due to its straightforward interpretability; its coefficients can be easily understood as hazard ratios, which quantify the relative effect of each covariate on the likelihood of an event, offering clear insights for clinical decision-making and risk assessment [1,2]. In addition, its flexibility in handling time-dependent covariates allows it to incorporate variables that change over time, providing a more accurate reflection of patient dynamics [3-5]. Our previous work [6] focused on using time-dependent covariates within the CPH model to enhance its application in modeling the complex patterns of multiple treatment interruptions in patients on ART, aiming to capture the nuanced and changing influences on treatment adherence.

Despite its popularity, the CPH model has limitations. A key disadvantage is its handling of high-dimensional data with many covariates, as it can be prone to overfitting and may yield unreliable results due to multicollinearity [4]. This risk is particularly pronounced in time-dependent CPH models, where changing covariates can amplify the potential for erroneous inferences [4]. In addition, as a semiparametric model, it does not fully specify the baseline hazard function, potentially limiting its ability to capture complex, nonlinear relationships [7]. These limitations highlight the need for more flexible modeling approaches, especially when working with complex health care datasets with nonlinear, time-varying, or high-dimensional characteristics.

Machine learning (ML) models are increasingly used in time-to-event analysis due to their ability to capture complex, nonlinear relationships at scale. In HIV and ART research, however, most survival ML applications such as random survival forests and gradient boosting primarily rely on baseline or time-invariant covariates, limiting their ability to reflect the dynamic nature of ART care. Although some methods, including recursive partitioning (RP), have been adapted to incorporate temporal structures and time-varying effects [8-10], support for fully time-varying covariates remains limited in many survival ML frameworks. RP provides a flexible alternative by modeling nonlinear effects and interactions with time-varying covariates, yet its application to large-scale, longitudinal ART cohorts has been limited. In addition, advances in model interpretability have made ML models more explainable, helping to bridge the gap between predictive accuracy and practical applicability. Through methods such as permutation importance, partial dependence plots, and Shapley Additive Explanations (SHAP) values [11-13], ML models now provide insights into variable importance and individual predictions, making them increasingly useful for clinical decision-making and patient-centered care.

The aim of this paper is first to compare the performance of traditional CPH model and ML models in predicting treatment interruptions among patients on ART. This comparison aims to evaluate whether ML models, with their flexibility in handling nonlinear relationships and time-dependent covariates, can provide more accurate and reliable predictions than the CPH model. Second, provide clear, intuitive explanations for the predictions at both the global level to understand overall patterns and key risk factors and the local level for individualized predictions for a patient. By combining predictive accuracy with interpretability, this study aims to support health care providers in identifying patients at high risk for treatment interruption and in implementing personalized interventions to enhance treatment retention.

Methods

Study Population and Data

The analysis used longitudinal, deidentified electronic medical record (EMR) data from patients initiated on ART between January 1, 2017, and November 30, 2023, across 2156 facilities in all 47 counties of Kenya. Eligible patients had at least 2 follow-up visits or drug pickups after ART initiation, were followed for more than 28 days postinitiation, and had returned to care if they had experienced an initial treatment interruption.

Data Preprocessing and Definitions

The preprocessing, cleaning, feature engineering, and covariate definitions are detailed in our previous work [6]. Treatment interruption was defined as no ART drug pickup and no clinical contact for greater than 28 days after the last expected contact [14]. Time-invariant covariates included age, gender, education, marital and employment status, noncommunicable disease, baseline regimen, and ART initiation year, while time-varying covariates were adherence, alcohol intake, World Health Organization stage, viral load, clinical stability assessment, regimen line, multimonth dispensing (MMD), differentiated service delivery (DSD) model, and prevention with positives package. Full list of covariates and description is included in Table S1 in Multimedia Appendix 1. A key preprocessing step included creating an “unknown” category for categorical variables with missing data. Engineered features included the COVID-19 pandemic period—dummy variable to indicate the COVID-19 pandemic; missed appointment—failure to attend a scheduled visit within 1-3 days of the scheduled date; defaulted appointment—failure to attend a scheduled visit within 4-28 days; and the duration of treatment interruption—average duration of any treatment interruption before a patient returned to care.

Analysis and Models

We performed 2 sets of modeling, that is, time-invariant model, for first-ever treatment interruption, and a time-varying model, for multiple interruptions. The data structure differs between the models: in a time-invariant model, covariates were fixed, with 1 row per patient containing the time to interruption and interruption status. In a time-varying model, covariates change over time, with multiple rows per patient representing different time intervals and multiple interruption statuses.

Our base reference model was the traditional CPH model. The time-invariant CPH assessed the effect of fixed covariates on time to first interruption, with an assumption that the hazard ratio remains constant over time, while the time-varying allowed

XSL•FO
RenderX

covariates to change over time, capturing the dynamic effects of these covariates on the hazard at different intervals.

Our choice of ML models was based on algorithms with the ability to fit time-varying covariates and their computational feasibility at scale. We evaluated 3 classes of algorithms: boosting methods for their efficiency and predictive performance, regularized shrinkage models for handling multicollinearity and improving generalization, and RP for its ability to capture nonlinear relationships and interactions while remaining interpretable. Although random survival forests are widely used in survival analysis, their computational demands and limited support for fully time-varying covariates constrained their applicability in this study. The trained models are as described:

- Gradient boosting machine (GBM): an ensemble learning method that builds a series of decision trees, where each new tree corrects the errors of the previous ones. It is powerful for time-invariant survival analysis due to its ability to handle complex, nonlinear relationships and improve predictive accuracy by minimizing loss iteratively.
- Extreme gradient boosting (XGBoost): an optimized version of GBM, known for its speed and performance, especially with large datasets. It is well suited for our analysis due to its efficiency, scalability, and ability to manage missing data, offering robust predictions in survival tasks. The Accelerated Failure Time model was trained for a time-varying dataset.
- Regularized generalized linear models: Extends traditional regression models with regularization techniques—Ridge (L2), Lasso (L1), and Elastic Net (a combination of both)—to prevent overfitting and handle multicollinearity. These models are beneficial in time-invariant survival analysis for selecting relevant covariates while improving model generalization, especially with high-dimensional data.
- Recursive partitioning (LTRCtrees/Rpart): Uses decision trees to model survival data, splitting the dataset based on covariates to form homogeneous subgroups. It is advantageous due to its interpretability and ability to handle nonlinear relationships without making parametric assumptions.

We initially trained each model using default hyperparameters as a baseline, followed by hyperparameter tuning through a 10-fold cross-validation over a grid of parameter combinations. The optimal set of hyperparameters was selected based on the highest Harrell's concordance index (C-index) score, reflecting the study's primary objective of ranking patients by treatment interruption risk. The optimal parameter sets were then used for final model training. All analysis and modeling were performed using R Statistical Software (version 4.4.0; R Foundation for Statistical Computing).

Model Evaluation

We evaluated model performance using an 80:20 train-test split (including the Cox models to ensure comparability). Likewise, a 10-fold cross-validation was performed on the train set, and models were trained on k-1 folds and validated on the remaining fold, repeating this process 10 times, with each fold serving as the validation set once.

Final model evaluation and comparison were performed using the C-index, a widely used metric for assessing the performance of survival models. The C-index measures the model's ability to correctly rank pairs of observations based on survival times, with values ranging from 0.5 (random prediction) to 1.0 (perfect ranking). We calculated the C-index for each model on both the training and test sets to evaluate predictive accuracy. This approach ensured that the models performed well during training and on validation data, providing a reliable measure of generalizability. Furthermore, to assess the sensitivity and uncertainty of the predictive performance measures, we conducted 200 bootstrap resampling iterations to estimate the IQR distribution of the scores for our best performing model.

Model Interpretability

To interpret our model predictions, we used the DALEX package in R [15] and applied 2 levels of model-agnostic explanation, that is, model level global explanations—using permutation variable importance and partial dependence plots, and individual-level explanations—using variable attribution—breakdown and SHAP values and ceteris paribus (CP) analysis.

Global-Level Explanations

The global-level explanations are listed as follows:

1. Variable importance: Using a permutation-based approach, we assessed how removing the effect of selected variables through multiple permutations impacts model performance.
2. Partial dependence profiles: We explored the effects of selected variables by examining how the model's predicted values change as a function of individual variables, based on randomly selected observations.

Individual-Level Explanations

The individual-level explanations are listed as follows:

1. Variable attributions: This explains how a model's prediction for a single observation differs from the average prediction and distributes the difference among explanatory variables. We applied two methods: (1) Breakdown additive attribution, a procedure that decomposes the model's prediction into contributions from each explanatory variable. (2) SHAP, the averaging of variable attribution values over all (or several) possible orderings to show their individual impacts.
2. CP profiles: This explores how the model's prediction changes when the value of a single explanatory variable is altered, while keeping all other variables constant.

Ethical Considerations

This study was reviewed and approved as nonhuman subject research by the institutional review boards of the University of Maryland, Baltimore (HP-00108126), and the Aga Khan University Nairobi (2023/ISERC-94 (v2)). The analysis used secondary EMR data that were fully deidentified prior to receipt by the study team in accordance with Kenya's Data Protection

XSL•FO
RenderX

Act and institutional guidelines; therefore, written informed consent was not required.

Results

Our dataset comprised 621,115 unique patients on ART, with 432,041 first treatment interruption events and 959,170 multiple treatment interruption events. Data were split into an 80:20 ratio for the training and test sets, respectively. The hyperparameters for each model, along with the final parameter combinations used in the final model, are shown in Table 1. The predictive performance of ML models and their comparison with the CPH are shown in Table 2 and Figure 1, summarized by the estimated C-index scores and 95% CIs for both the train and test sets.

[a]N/A: not applicable.

[b]Ridge—applies L2 regularization which penalizes the sum of the squared coefficients and is effective in cases where multicollinearity is present in the predictor variables.

[c]Elastic-Net regression—applies a combination of L1 and L2 regularization.

[d]Lasso—applies L1 regularization which can shrink some coefficients to zero, effectively performing feature selection.

Coxph	0.7873 (0.7865 - 0.7881)	0.7886 (0.7871 - 0.7903)	0.8757 (0.8754 - 0.8761)	0.8755 (0.8748 - 0.8762)
glmnet—Lasso	0.7801 (0.7793 - 0.7809)	0.7797 (0.7780 - 0.7813)	0.7747 (0.7741 - 0.7754)	0.7745 (0.7732 - 0.7758)
glmnet—Ridge	0.7799 (0.7791 - 0.7807)	0.7794 (0.7778 - 0.7810)	0.7816 (0.7810 - 0.7821)	0.7812 (0.7800 - 0.7824)
glmnet—Elastic-net	0.7801 (0.7793 - 0.7809)	0.7796 (0.7780 - 0.7812)	0.7795 (0.7789 - 0.7801)	0.7793 (0.7780 - 0.7805)
gbm	0.5765 (0.5758 - 0.5773)	0.5764 (0.5749 - 0.5780)	0.5334 (0.5330 - 0.5337)	0.5335 (0.5328 - 0.5342)
Xgboost	0.7157 (0.7149 - 0.7165)	0.7143 (0.7127 - 0.7157)	0.8351 (0.8346 - 0.8356)	0.8347 (0.8338 - 0.8357)
LTRCtrees	0.8115 (0.8108 - 0.8123)	0.8105 (0.8091 - 0.8120)	0.8918 (0.8915 - 0.8921)	0.8901 (0.8895 - 0.8907)

In the time-invariant analysis, the glmnet models—Lasso, Ridge, and Elastic-Net—produced comparable results to the CPH model, with train C-index values ranging from 0.7799 to 0.7801 and test C-index values ranging from 0.7794 to 0.7796. XGBoost performed slightly worse than the CPH model, while the GBM model had the lowest performance. The LTRCtrees model outperformed all other ML models and the CPH model with a C-index value of 0.8115 for the train set and 0.8105 for the test set. The LTRCtrees model remained the top performer in the time-varying analysis with a C-index of 0.8918 for the train set and 0.8901 for the test set. XGBoost was the next best performing ML model and slightly comparable with the CPH model. We further evaluated the best-performing model (ie, LTRCtrees), using a 200-bootstrap resamples; the C-index interquartile range remained stable across resamples.

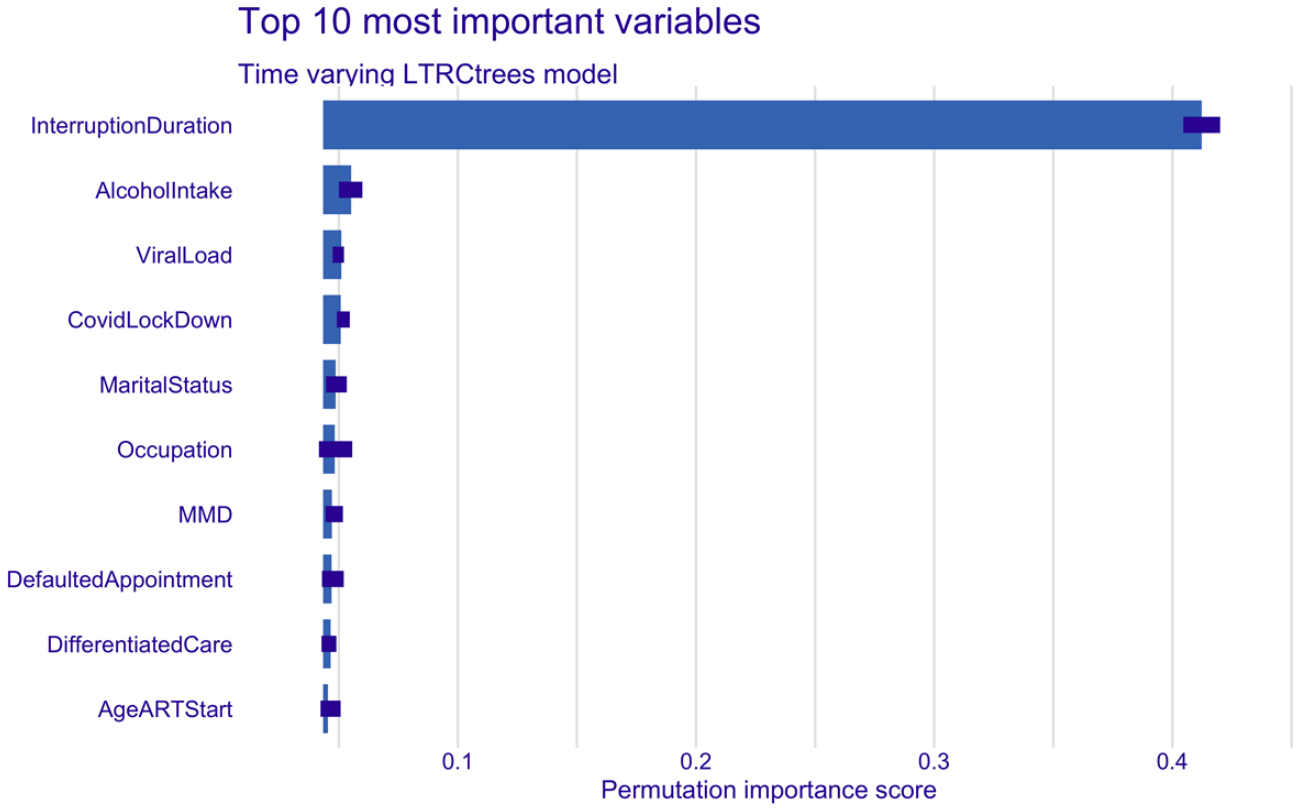

Figures 2 and 3 show the permutation-based variable importance for the top 10 variables in both the time-invariant and time-varying models. MMD emerged as the most important variable in the time-invariant model, while the duration of treatment interruption was most important in the time-varying model. In addition, variables such as viral load, ART start year, stability assessment, baseline regimen, and occupation were consistently ranked among the top 10 most influential variables in both models. The permutation-based variable importance results were similar to the ranking of the absolute values of the coefficients of the CPH models (Table 3). MMD, missed and defaulted appointments, year of ART initiation, occupation, and stability assessment consistently ranked among the top 10 variables in both the time-invariant LTRCtree and CPH models. In the time-varying models, duration of interruption, MMD, year of ART initiation, baseline regimen, and occupation were consistently top influencers in both LTRCtree and CPH models.

<30 days	N/A	N/A	29.94 (29.63-30.26)	<.001
30-197 days	N/A	N/A	19.63 (19.51-19.75)	<.001
180-364 days	N/A	N/A	8.15 (8.08-8.23)	<.001
365 days or more	N/A	N/A	2.85 (2.82-2.88)	<.001

[a]N=number of observations in the train dataset, that is, 80% of the entire dataset; events=number of treatment interruptions.

[b]Concordance=0.79 (se=0).

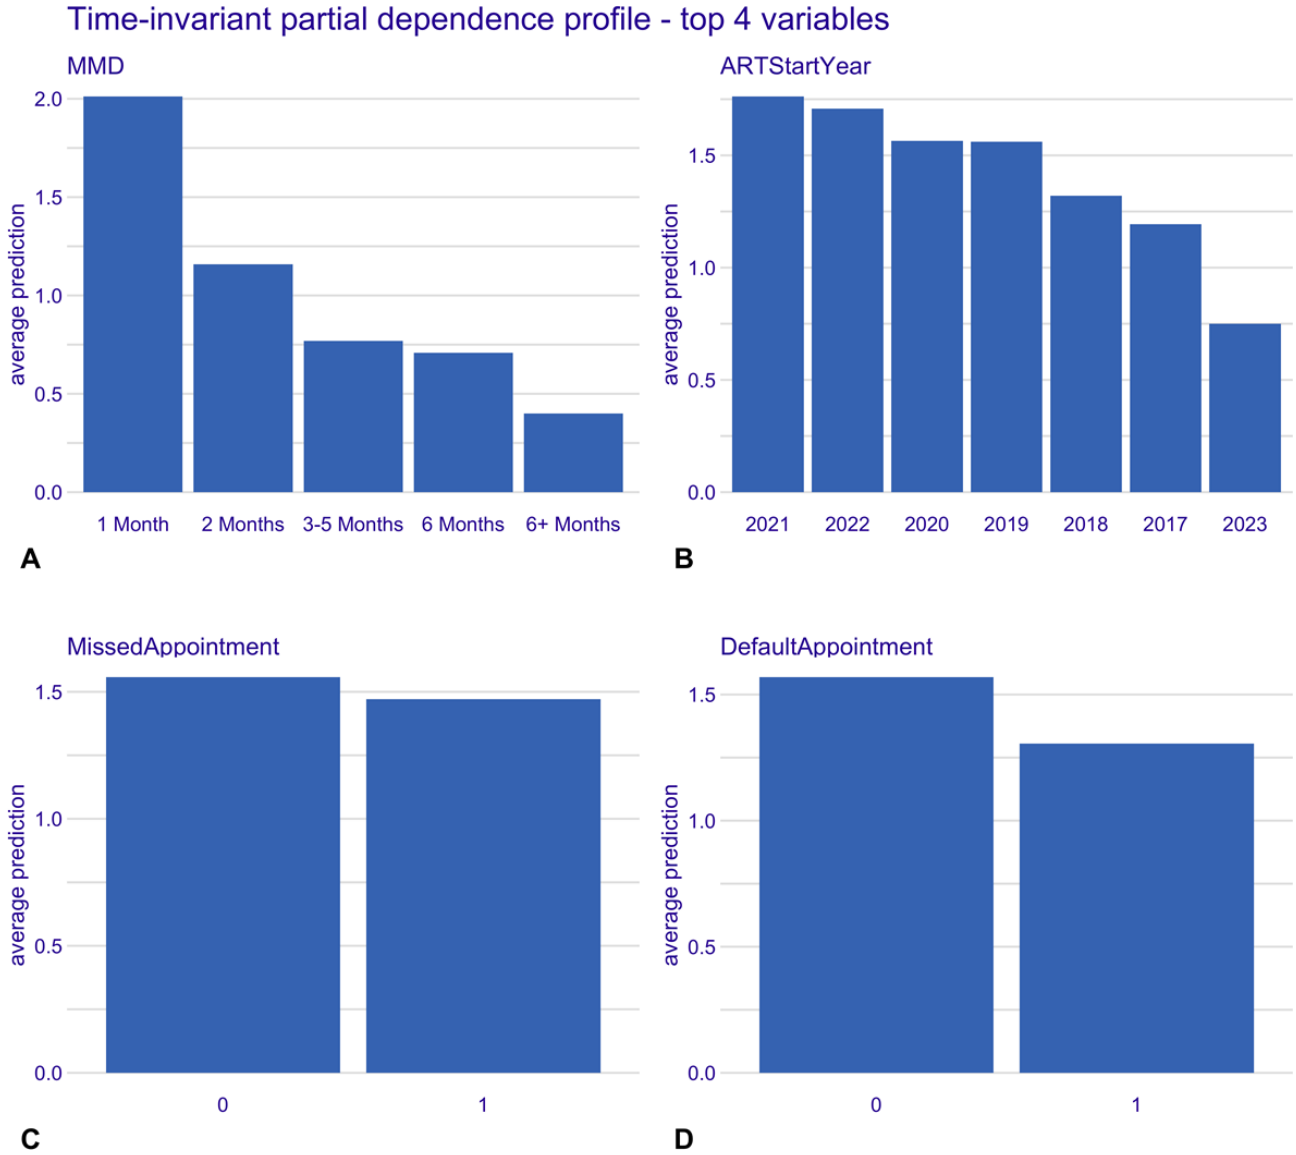
[c]Concordance=0.88 (se=0).

[d]ART: antiretroviral therapy.

[e]NRTIs: nucleoside analog reverse transcriptase inhibitors.

[f]PI: protease inhibitor.

[g]INSTI: integrase strand transfer inhibitor.



[h]NNRTI: nonnucleoside analog reverse transcriptase inhibitor.

[i]N/A: not applicable.

The full results of the time-invariant and time-varying CPH models are included in Table S2 in Multimedia Appendix 1. The partial dependence plots for the top 4 variables from both models are displayed in Figures 4 and 5. These plots show the average predicted risk for each of these variables. Short dispensing interval (MMD of 1 month), initiating ART in 2021, and having not missed or defaulted on an appointment were associated with higher predicted risks of first treatment interruption. Conversely, longer dispensing intervals (6+ months MMD), initiating ART in 2023, and having missed or defaulted on an appointment had a lower predicted risk of first treatment interruption. Short interruption durations (<30 days), unknown viral load, separated marital status, and unspecified alcohol use were all associated with higher predicted risk of multiple treatment interruption, while having no prior interruptions (ie, interruption duration of zero), lower viral load (<200), and no alcohol consumption showed lower predicted risk of multiple treatment interruption.

Figure 5. Time-varying model; partial dependence plots for top 4 variables. Panels show the marginal effect of each variable on the average predicted risk of treatment interruption. (A) Treatment interruption duration, (B) viral load count, (C) alcohol use, and (D) marital status.

To examine individual-level predictions for the time-invariant model, we randomly selected 2 observations from the dataset: one representing a patient (labeled "patient A") who experienced a first treatment interruption, and another representing a patient (labeled "patient B") who did not experience an interruption by the end of the follow-up period.

The row labeled "intercept" represents the overall average prediction value (1.516) for the model—baseline prediction (Figure 6A). The subsequent rows show how the mean prediction changes when a specific covariate is fixed. Green bars indicate an increase in the risk of treatment interruption, while red bars show a decrease in the risk. The final row (prediction), shown with a blue bar, displays the overall mean value and change, giving the final predicted risk of treatment interruption for the patient. Patient A had a high predicted risk of treatment interruption, with a risk score of 2.051, which is 0.535 points higher than the model's average prediction (Figure 6). Covariates influencing this prediction are short MMD intervals (1 month), viral load of 200 - 999, did not receive a prevention with positive package, not defaulted on appointment, non–COVID-19 pandemic period, aged 25 - 34 years at the start of ART, and baseline regimen of 2NRTIs + NNRTI. Patient B, on the other hand, had a low predicted risk (0) of interruption, largely driven by the long MMD interval (6+ months), enrolled in the DSD fast-track model, and had prior missed and defaulted appointments contributing to a reduced risk (Figure 7).

XSL•FO

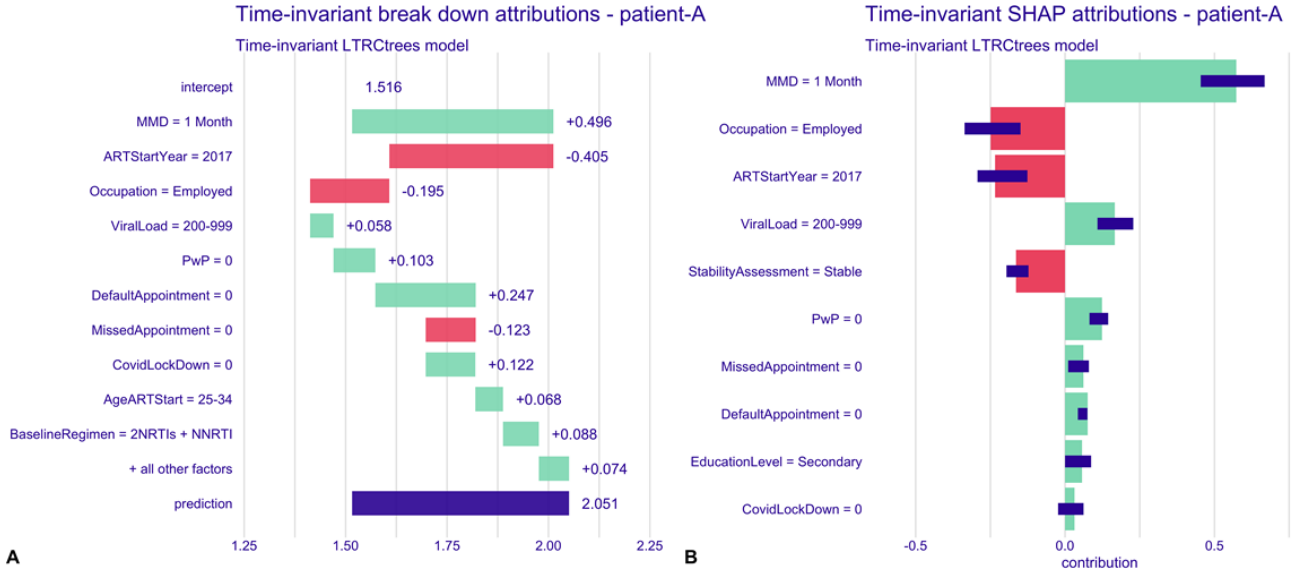
Figure 6. Time-invariant model breakdown and SHAP attribution plots for patient A. **(A)** Breakdown plot decomposing the model prediction into cumulative covariate contributions. Intercept—model's overall average prediction value; green bars, with (+) sign indicate increased risk of treatment interruption; red bars, with (−) sign indicate decreased risk of interruption; and blue bar, "prediction" is the individual predicted risk of interruption for the patient. **(B)** SHAP plot summarizing the direction and magnitude of individual covariate effects on the predicted risk of treatment interruption. Note: variable labels shown in the plots represent categorical levels of the corresponding covariates; see Table S1 in Multimedia Appendix 1 for full description. ART: antiretroviral therapy; MMD: multimonth dispensing; NNRTI: nonnucleoside analog reverse transcriptase inhibitor; NRTIs: nucleoside analog reverse transcriptase inhibitors; PwP: prevention with positives package; SHAP: Shapley Additive Explanations.



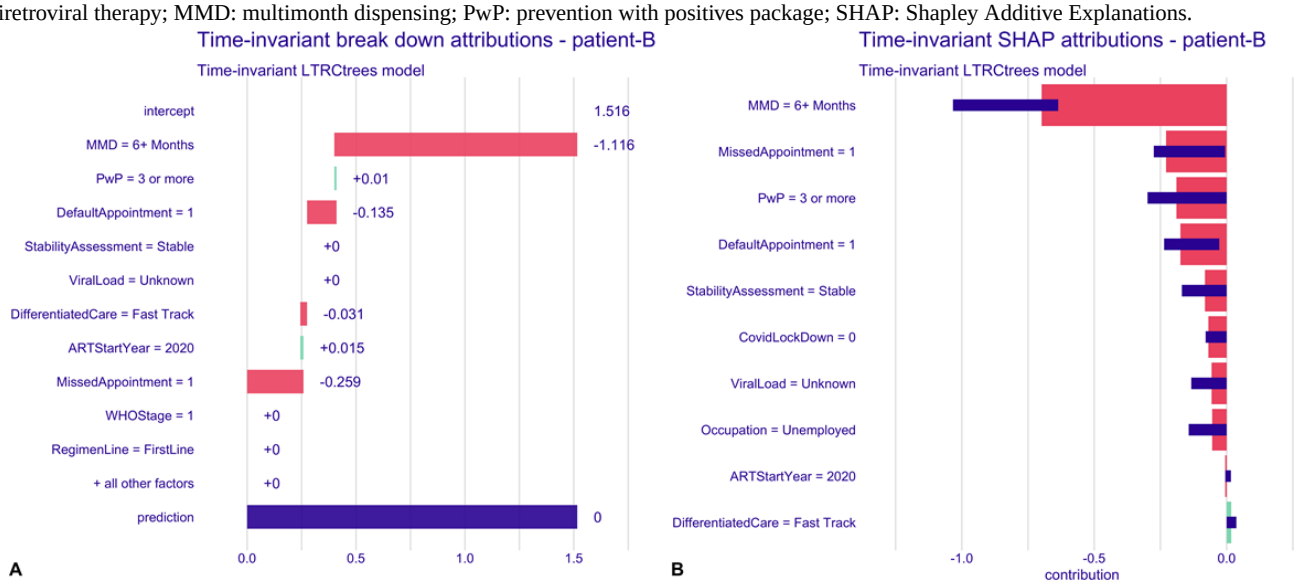


Figure 7. Time-invariant model breakdown and SHAP attribution plots for patient B. **(A)** Breakdown plot decomposing the model prediction into cumulative covariate contributions. Intercept—model's overall average prediction value; green bars, with (+) sign indicate increased risk of treatment interruption; red bars, with (−) sign indicate decreased risk of interruption; and blue bar, "prediction" is the individual predicted risk of interruption for the patient. **(B)** SHAP plot summarizing the direction and magnitude of individual covariate effects on the predicted risk of treatment interruption. ART: antiretroviral therapy; MMD: multimonth dispensing; PwP: prevention with positives package; SHAP: Shapley Additive Explanations.

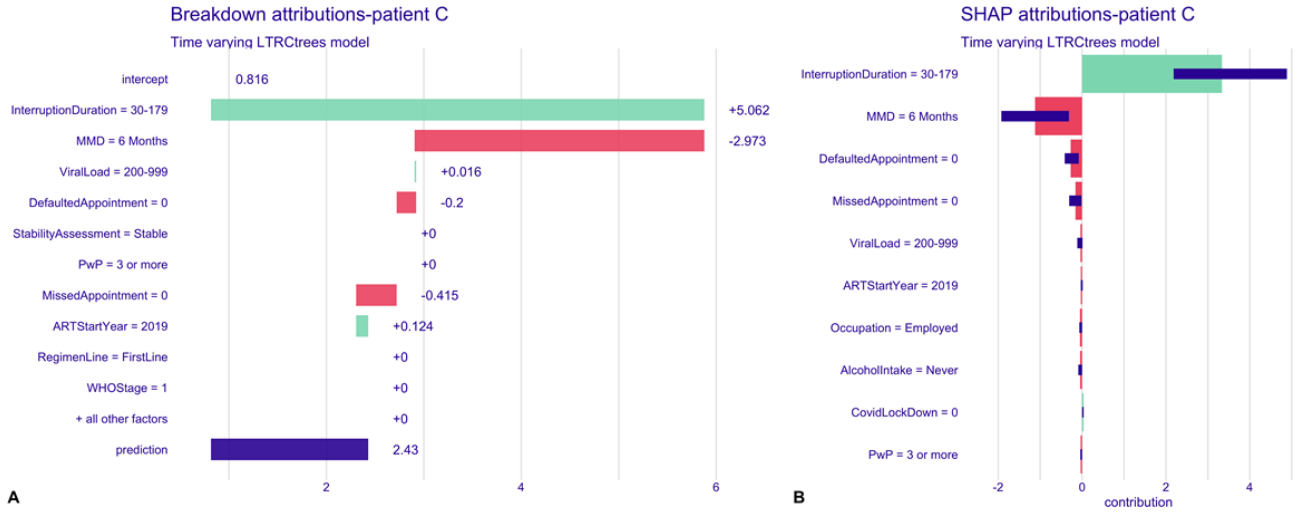
The right plots of both Figures 6 and 7 show the SHAP plots for the patients, where the SHAP values represent the computed mean attribution across 25 random orderings of the explanatory variables. The red bars indicate an average increase in risk, while the green bars show a decrease in risk. The violet box plots summarize the distribution of the attributions over the 25 orderings. The plots reveal similar influential variables as in the breakdown attributions, with a slight reordering of importance and the inclusion of additional variables—such as education level and stability assessment for patient A, and COVID-19 pandemic period for patient B.

To examine the time-varying model's prediction for a single time-interval instance for a patient, we randomly selected 2 patients: patient C, who had experienced 1 or more interruptions and subsequently returned to care; patient D, who had no history of treatment interruption. Figure 6 shows the breakdown and SHAP attribution plots for a single time interval for patient C. After considering all variable contributions, the final predicted risk of subsequent treatment interruption for this patient was 2.43, which is 1.614 points above the average prediction. The key covariate contributing to this risk prediction is the patient's previous interruption duration (duration of 30 - 179 days). In contrast, being on a 6-month MMD interval and having not

XSL•FO
RenderX

missed or defaulted on any appointments were associated with a lower risk of subsequent interruptions. The SHAP plot reflects similar variable contributions (Figure 8B). The predicted risk of treatment interruption for patient D was 0.181, which is 0.635 lower than the average model prediction (Figure 9A). Key covariates contributing to this reduced risk include no prior treatment interruptions (interruption duration of zero), being on a 3 - to 5-month MMD interval, having a viral load between 200 and 999 cp/mL, the COVID-19 pandemic period, no defaulted appointments, good adherence, and starting ART between the ages of 35 and 44 years. SHAP plots (Figure 9B) further highlighted covariates associated with a lower risk for this patient.

Figure 8. Time-varying model, breakdown, and SHAP attribution plots for patient C. **(A)** Breakdown plot decomposing the model prediction into cumulative covariate contributions. Intercept—model's overall average prediction value; green bars, with (+) sign indicate increased risk of treatment interruption; red bars, with (−) sign indicate decreased risk of interruption; and blue bar, "prediction" is the individual predicted risk of interruption for the patient. **(B)** SHAP plot summarizing the direction and magnitude of individual covariate effects on the predicted risk of treatment interruption. ART: antiretroviral therapy; MMD: multimonth dispensing; PwP: prevention with positives package; SHAP: Shapley Additive Explanations.



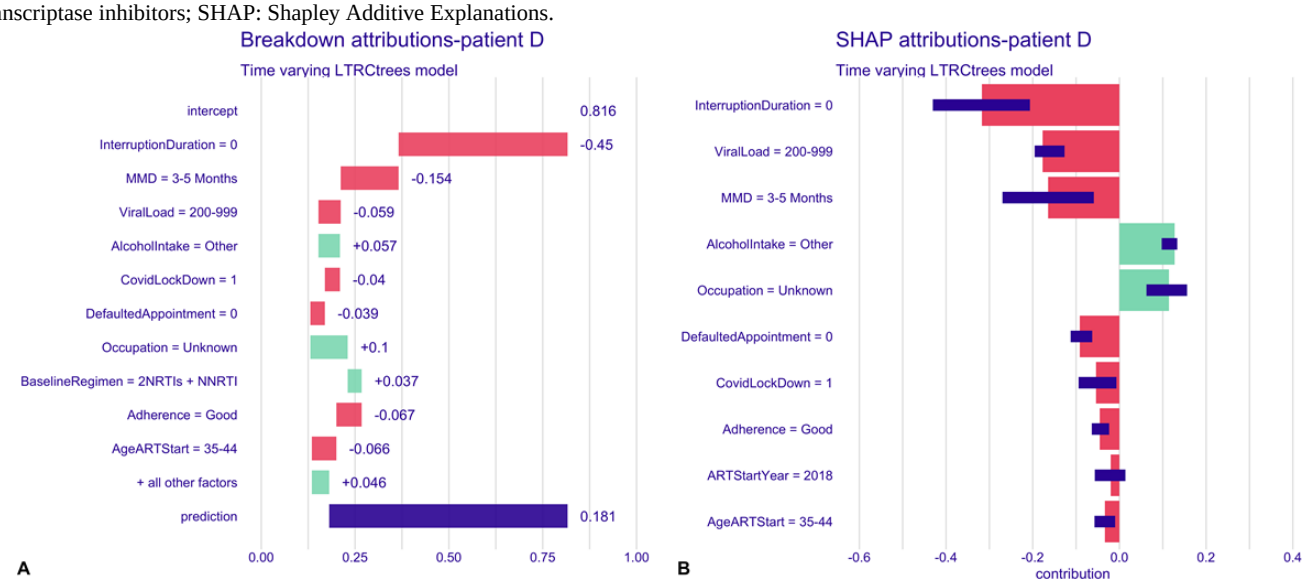


Figure 9. Time-varying model, breakdown, and SHAP attribution plots for patient D. **(A)** Breakdown plot decomposing the model prediction into cumulative covariate contributions. Intercept—model's overall average prediction value; green bars, with (+) sign indicate increased risk of treatment interruption; red bars, with (−) sign indicate decreased risk of interruption; and blue bar, "prediction" is the individual predicted risk of interruption for the patient. **(B)** SHAP plot summarizing the direction and magnitude of individual covariate effects on the predicted risk of treatment interruption. ART: antiretroviral therapy; MMD: multimonth dispensing; NNRTI: nonnucleoside analog reverse transcriptase inhibitor; NRTIs: nucleoside analog reverse transcriptase inhibitors; SHAP: Shapley Additive Explanations.

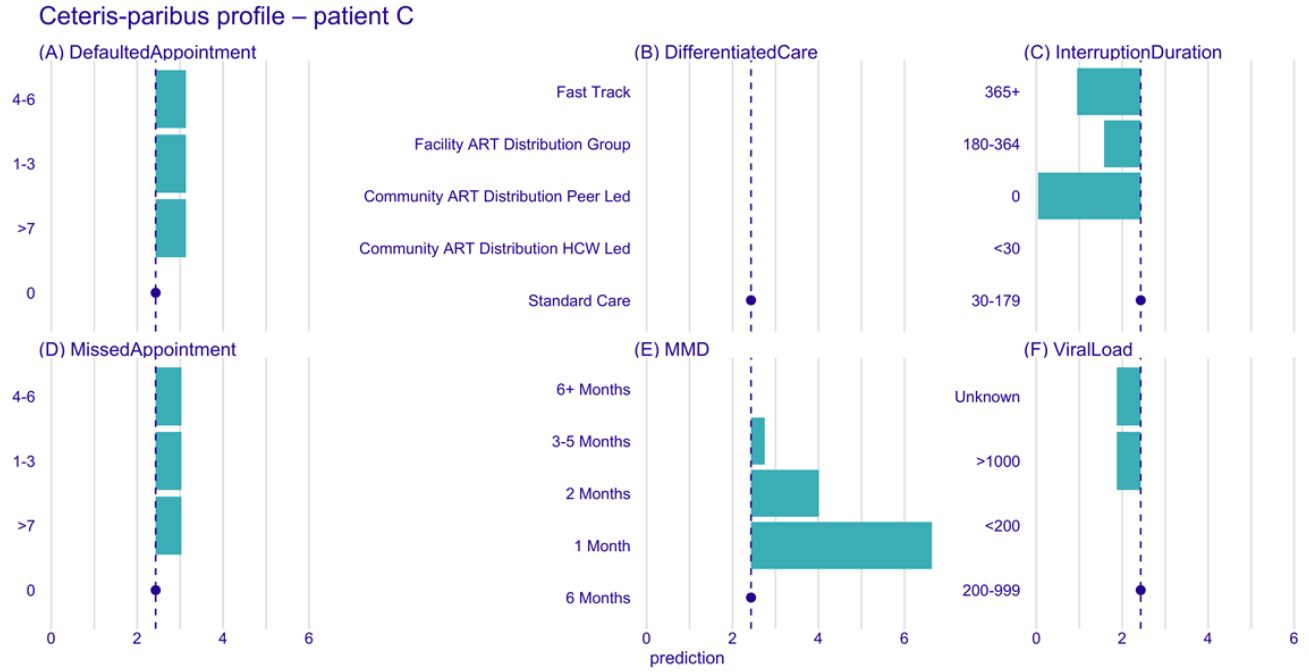
Using CP profile plots, we further examined how the model's predictions for these patients would shift if key covariates—such as the duration of the previous interruption, viral load, DSD model, MMD, missed appointments, and defaulted appointments—were altered. This allowed us to explore how changes in time-varying covariates impact the risk of multiple treatment interruptions. The blue dot and dotted line in the CP plot (Figures 10 and 11) represent the values of the covariates and the corresponding prediction for the patient. Each green bar in the plot shows the predicted change in value and direction for a specific covariate, with bars pointing to the right of the dotted line indicating an increased risk of interruption and bars pointing to the left indicating a decreased risk.

XSL•FO
RenderX

Figure 10. Ceteris paribus profile plots for patient C. Panels show the marginal effect of changes of each variable on the predicted risk of treatment interruption. (A) Defaulted appointments, (B) differentiated care model, (C) interruption duration, (D) missed appointments, (E) multimonth dispensing duration, and (F) viral load. Blue dot is the value of the covariate; blue dotted line corresponding prediction for the patient; green bars—predicted change in value and direction for a specific covariate; and bars right of the dotted line indicate increased risk, while those to the left indicate decreased risk. ART: antiretroviral therapy; HCW: health care worker; MMD: multimonth dispensing.



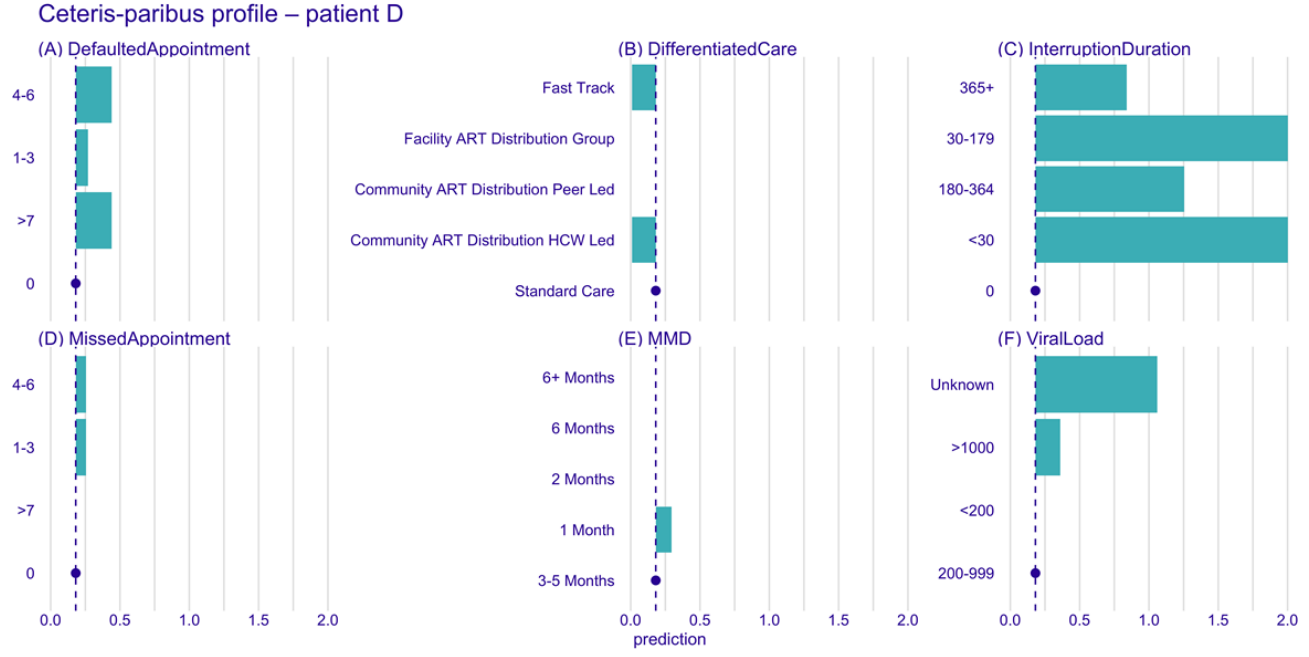


Figure 11. Ceteris paribus profile plots for patient D. Panels show the marginal effect of changes of each variable on the predicted risk of treatment interruption. (A) Defaulted appointments, (B) differentiated care model, (C) interruption duration, (D) missed appointments, (E) multimonth dispensing duration, and (F) viral load. Blue dot is the value of the covariate; blue dotted line corresponding prediction for the patient; green bars—predicted change in value and direction for a specific covariate; and bars right of the dotted line indicate increased risk, while those to the left indicate decreased risk. ART: antiretroviral therapy; HCW: health care worker; MMD: multimonth dispensing.

The CP plot (Figure 10) for patient C indicates that their risk of future treatment interruptions would increase significantly if they were to miss or default on an appointment or be placed on a shorter MMD interval. However, the predicted risk remains unchanged if they were to transition across different DSD models. The future risk of treatment interruption would increase for patient D if they miss or default on an appointment, had an increase in their viral load, were placed on a 1-month MMD interval, or experienced a treatment interruption, irrespective of how long it took to return to care (Figure 11). Transitioning from their current standard care DSD model to fast track or community ART distribution health care worker–led models would slightly reduce the risk of interruption.

Discussion

Principal Findings

We compared the traditional CPH model with 6 different ML models to predict the risk of treatment interruption in 621,115 patients receiving ART in 256 facilities across all 47 counties in Kenya. The analysis was conducted in 2 parts: time-invariant models for predicting time-to-first treatment interruptions and time-varying models for predicting time-to-multiple treatment interruptions. Model evaluation was performed using an 80:20 train-test split, and Harrell's C-index was applied to compare the performance of the models on both the train and test sets. Prediction from the best-performing model was then interpreted at both global and individual levels.

The RP model outperformed all other models in both the time-invariant and time-varying analyses. It achieved C-index values of 0.8115 for the train set and 0.8105 for the test set in the time-invariant model, and 0.8918 for the train set and 0.8901 for the test set in the time-varying model. These results align with findings from previous studies that have compared CPH models with ML models, demonstrating the effectiveness of RP models in survival analysis. Previous studies have reported C-index values ranging from 0.63 to 0.96, primarily from ML models such as GBM, random survival forest, and survival support vector machines in predicting survival for patients with cancer [16-19]. Other studies that focused on predicting treatment interruptions in patients on ART had typically reported metrics such as sensitivity, specificity, and area under the curve, with values ranging between 61.9% and 76.0% [20-24]. Few of these studies have incorporated time-varying covariates [16,25]. Even when compared with prior studies that evaluated ML models against CPH [17], our RP approach achieved higher discrimination, with C-index values of 0.8105 and 0.8901 compared with reported XGBoost performance of approximately 0.73. Notably, our study stands out as one of the few to apply RP within a time-varying survival framework, effectively constructing a survival tree that accommodates time-varying covariates.

The RP method offers flexibility in detecting complex interactions without assuming proportional hazards. They automatically select covariates and split points, allowing more adaptive modeling of survival times [26]. This method is advantageous for identifying nonlinear relationships and interactions, making it particularly useful in our case where covariate effects changed over time. The RP model also had the advantage of simple hyperparameter tuning and faster computational times compared with the other ML models we evaluated. We attempted to train a random survival forest model but were unsuccessful due to the large computational resources and extensive time required to handle our large dataset. Likewise, the widely used randomForestSRC R package does not currently support time-varying covariates directly. While random forests are known for their high predictive performance, their significant computational requirements make them less practical for real-world applications [16].

To ensure that our results were fully comparable with the traditional CPH, we implemented a cohesive framework for explaining the ML predictions with meaningful insights. Using a model-agnostic [15] explainer framework, we gained detailed insights into how specific variables influenced individual-level predictions and overall global outcomes, similar to the interpretations provided by hazard ratios in the CPH model. The explainer framework offers additional advantages by capturing complex, nonlinear relationships that traditional CPH may overlook.

On a global level, the permutation-based variable importance from the RP model was similar to the ranking of the absolute values of the coefficients of the CPH model for both time-invariant and time-varying models. In addition, the effects of the selected covariates we considered in the partial dependence plots were consistent with the direction of hazard ratios in the CPH model. This combination of techniques offers diverse insights into our model predictive performance. They reveal the most significant effects and risks associated with treatment interruption across various covariates without the assumptions of linearity, hence capturing potential nonlinear effects that traditional CPH models might overlook. Overall, these methods provide more comprehensive global explanations, particularly for complex variable interactions.

Further exploration using breakdown attribution and SHAP plots reveals how individual variables influence each patient's predicted risk within specific time intervals. On a global level, the time-invariant model was primarily influenced by MMD. Considering this at the patient level, the breakdown and SHAP plots provide detailed insights into how MMD increases or decreases risk, explaining why patient A was at a higher risk than patient B based on MMD. In addition, these plots highlight the most influential covariates for predicting the risk of a first treatment interruption for each patient, emphasizing individual variability in risk factors. For the time-varying model, we furthered the instance-level exploration using CP profiles. These plots provided insights into how a patient's predicted risk would change if certain variables were adjusted. For example, with patient C—who has no history of treatment interruption—we explored the predicted risk of an interruption if the patient were to miss or default on an appointment, transition to a less intensive DSD model, or receive a different drug-dispensing interval. In contrast, for patient D—a patient with a history of interruptions—the focus was on understanding how the predicted risk of another interruption might change if they transitioned to a less intensive care model, adjusted their dispensing interval, or missed an appointment. The changes highlighted for each patient provide actionable insights to guide transitions between DSD models and targeted interventions to prevent treatment interruptions. Following ART initiation, CP profiles can identify patients whose interruption risk under standard care would decrease with earlier DSD enrollment or longer dispensing intervals. For patients returning to care after an interruption, CP profiles quantify how changes in follow-up intensity or MMD duration influence recurrent interruption risk, supporting tailored rather than routine care. These scenario-based insights align with recent World Health Organization and global guidance [27,28] emphasizing person-centered, targeted care packages for patients reengaging in treatment.

XSL•FO
RenderX

Bringing the various components together, our model could be integrated into an EMR system to predict a patient's risk of treatment interruption in real time. This integration would allow the model to continuously process each patient's historical data, current visit date, and next scheduled visit date, creating a new data point for each interaction. With each visit, the EMR system would automatically update risk predictions, enabling health care providers to proactively identify high-risk patients before interruptions occur. The Kenya EMR currently includes an ML module that generates interruption risk scores based on a limited set of patient-centric covariates. By leveraging our model's broader range of covariates, the current system can be optimized for improved prediction accuracy and comprehensive risk assessment.

Limitations

Our study had some limitations. First is the issue of missing data, as highlighted in our previous work [6]. This was addressed by creating an "unknown" category for affected variables, given that the data were not missing at random. Variables with more than 60% missingness, such as baseline and follow-up CD4 counts, were excluded, which may have introduced bias. Sensitivity analyses comparing complete-case models with alternative "unknown" category specifications were conducted in prior work [6] and showed consistent results. Multiple imputation was not considered, given data were not missing at random. Second, while the explainer we used is model-agnostic, it lacks built-in support for survival-specific metrics such as Brier score and area under the curve. Survex explainer is specifically designed for survival models, but it currently does not support the LTRCtrees package or time-varying survival models. A potential work-around could be treating the model as a classification task, focusing on whether there was an interruption or not within a specified fixed time, although this approach will sacrifice the temporal dimension of survival analysis or future studies can consider implementing other Survex-supported algorithms with the ability to fit time-varying covariates. Finally, generating breakdown and SHAP attribution profiles for individual predictions was computationally intensive, particularly for SHAP, which may limit real-time EMR use. However, subsampling across observations or feature permutations can substantially reduce computational cost while preserving accurate SHAP approximations.

Conclusions

Our study compared the predictive performance of the traditional Cox model with 6 different ML models for predicting the risk of treatment interruptions in patients on ART. Overall, our results demonstrate that ML models outperform the traditional Cox model, with RP, in particular, effectively capturing nonlinear effects and complex interactions without relying on proportional hazards assumptions, making it well suited for time-varying survival analyses. Our model-agnostic explanation aligns well with the Cox model results while also offering additional, patient-specific insights for targeted interventions. The combination of enhanced predictive performance and interpretability demonstrates how ML models can effectively support patient-centered care strategies to reduce the likelihood of treatment interruptions in ART.

Acknowledgments

The authors acknowledge the technical inputs of Davies Kimanga (Centers for Disease Control and Prevention—Kenya) and Jacob Odhiambo (The Palladium Group Kenya) during the early phases of the study design. The authors also acknowledge the following staff of The Palladium Group Kenya, that is, Mary Gikura, Kennedy Muthoka, Ashley Odhiambo, and Evans Munene, for their support with data access and validation. Finally, the authors also thank members of the INSIGHT technical working group from CIHEB Kenya—Sam Wafula, Rebecca Wangusi, Patrick Awuor, Violet Makokha, Dinah Nakhanu Mamai, Sarah Nzioka, and Emmah Momanyi—for their valuable contribution and insights into the Kenya treatment program.

Abstract

Background: Rib fractures are present in 10% - 15% of thoracic trauma cases but are often missed on chest radiographs, delaying diagnosis and treatment. Artificial intelligence (AI) may improve detection and triage in emergency settings.

Objective: This study aims to evaluate diagnostic accuracy, processing speed, and technical feasibility of an artificial intelligence–assisted rib fracture detection system using prospectively collected data within a real-world, high-volume emergency department workflow.

Methods: We conducted an observational feasibility study with prospective data collection of a faster region-based convolutional neural network–based AI model deployed in the emergency department to analyze 23,251 real-world chest radiographs (22,946 anteroposterior; 305 oblique) from April 1 to July 2, 2023. This study was approved by the Institutional Review Board of MacKay Memorial Hospital (IRB No. 20MMHIS483e). AI operated passively, without influencing clinical decision-making. The reference standard was the final report issued by board-certified radiologists. A subset of discordant cases underwent post hoc computed tomography review for exploratory analysis.

Results: AI achieved 74.5% sensitivity (95% CI 0.708-0.780), 93.3% specificity (95% CI 0.930-0.937), 24.2% positive predictive value, and 99.2% negative predictive value. Median inference time was 10.6 seconds versus 3.3 hours for radiologist reports (paired Wilcoxon signed-rank test W=112 987.5, P<.001). The analysis revealed peak imaging demand between 08:00 and 16:00 and Thursday-Saturday evenings. A 14-day graphics processing unit outage underscored the importance of infrastructure resilience.

Conclusions: The AI system demonstrated strong technical feasibility for real-time rib fracture detection in a high-volume emergency department setting, with rapid inference and stable performance during prospective deployment. Although the system showed high negative predictive value, the observed false-positive and false-negative rates indicate that it should be considered a supportive screening tool rather than a stand-alone diagnostic solution or a replacement for clinical judgment. These findings support further clinician-in-the-loop studies to evaluate clinical feasibility, workflow integration, and impact on diagnostic decision-making. However, interpretation is limited by reliance on radiology reports as the reference standard and the system's passive, non-interventional deployment.

Introduction

Digital health technologies, particularly artificial intelligence (AI), are increasingly used to address diagnostic delays in high-acuity clinical settings. In emergency departments, timely identification of injuries is essential, yet radiographic interpretation remains constrained by heavy workloads and the inherent complexity of imaging—especially for subtle findings such as rib fractures.

Rib fractures are a frequent consequence of thoracic trauma, occurring in 10% - 15% of trauma patients and often indicating more serious underlying injuries [1-3]. When missed, they may lead to inadequate pain management, delayed respiratory support, pneumonia, or even preventable intensive care unit admissions. Beyond clinical harm, undetected fractures also carry medicolegal implications and increase health care costs.

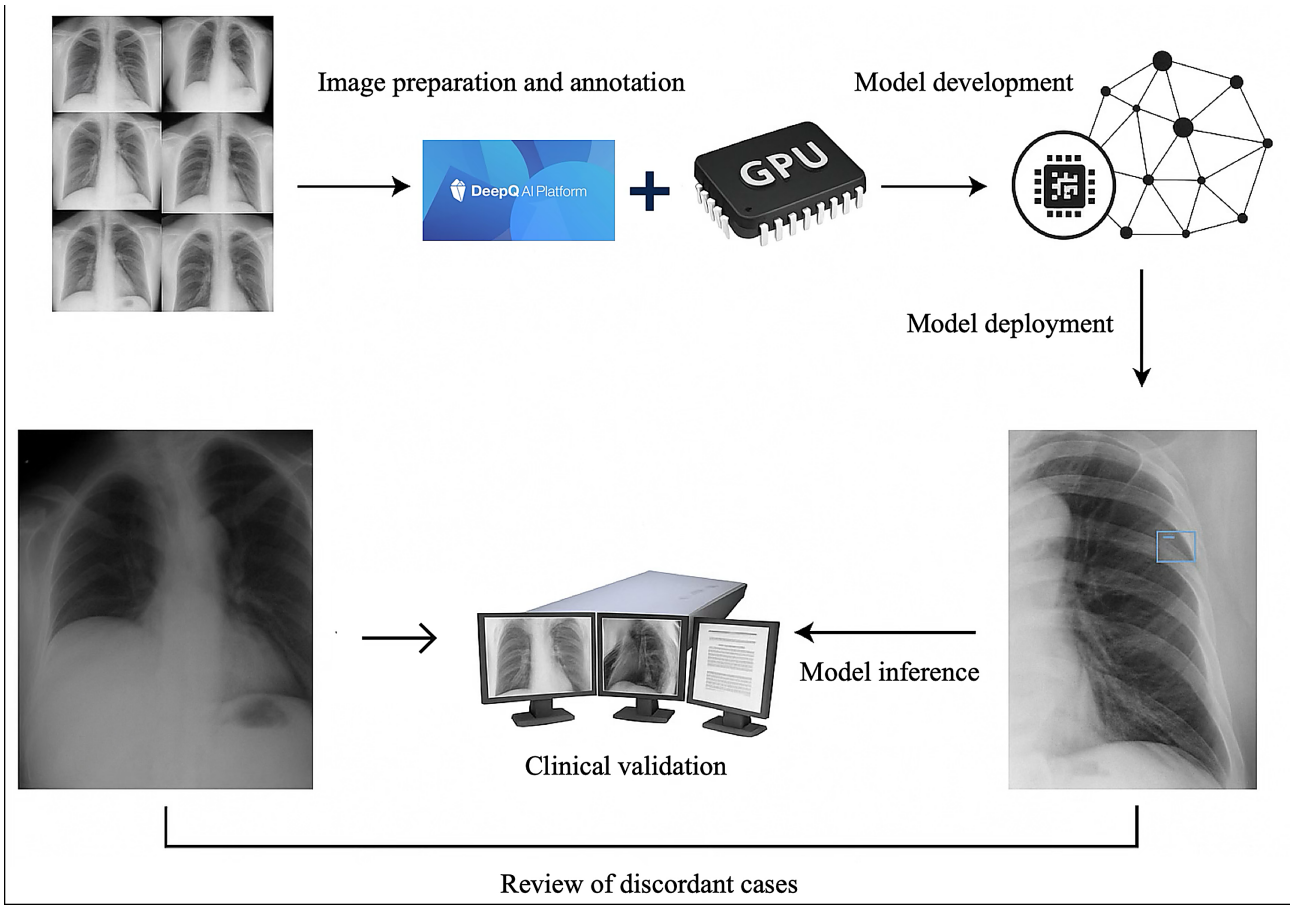
Despite their significance, rib fractures are notoriously difficult to detect on chest radiographs (CXRs)—the first-line imaging modality in most emergency departments—due to overlapping anatomical structures and subtle fracture lines. Reported sensitivities for radiologist detection can be as low as 15%, with up to half of fractures potentially missed in high-volume settings [4,5]. Although computed tomography (CT) and ultrasound can improve accuracy, they are resource-intensive and not always feasible for frontline triage [6-8]. These limitations highlight an urgent need for AI-driven tools that can assist clinicians by rapidly identifying suspected rib fractures in routine CXRs, enabling more effective prioritization and timely intervention.

Recent advances in AI, particularly deep learning, have demonstrated strong potential in automating image analysis tasks across medical domains, including dermatology, ophthalmology, and pulmonary imaging [9-11]. Deep learning models, especially convolutional neural networks, can automatically extract complex image features and have shown superior performance compared to traditional machine learning methods in various image classification tasks [11-13]. Transfer learning further enables the adaptation of pretrained convolutional neural networks—originally developed for natural images—for medical image classification tasks, including bone fracture detection [14,15].

Although prior studies have applied deep learning to rib fracture detection with promising results, most were retrospective, limited in scale, and did not assess feasibility in operational emergency department workflows [7,16,17]. These proof-of-concept efforts did not address the practical barriers to integrating AI into emergency radiology workflows, such as inference latency, system interoperability, or artifact handling.

To address this gap, we conducted an observational feasibility study with prospective data collection, evaluating an AI model for rib-fracture detection on CXRs. The system was passively deployed in parallel with routine emergency department imaging workflows using real-world data, without influencing clinical decisions. This design allowed the assessment of diagnostic performance, processing speed, and operational characteristics within standard clinical workflows.

Methods



Study Design

The observational feasibility study protocol was reviewed and approved by the Institutional Review Board of MacKay Memorial Hospital (IRB No. 20MMHIS483e) prior to the initiation of data collection. MacKay Memorial Hospital is a tertiary referral and level 1 trauma center in northern Taiwan. The AI system functioned passively in real time without influencing clinical decisions or patient management. As the system functioned in a noninterventional, observational manner, prospective trial registration was not required.

From April 1 to July 2, 2023, all chest and rib radiographs acquired in the emergency department were automatically processed by the AI system in near-real-time. Both standard CXRs and rib-only views acquired during the study period were automatically analyzed, as both modalities are routinely used for suspected thoracic trauma. During the study period, a temporary 14-day graphics processing unit (GPU) hardware outage occurred, during which radiographs were not processed in real time; these examinations were excluded from turnaround time analysis but retained for diagnostic accuracy, as formal radiology reports were available. No additional exclusion criteria were applied beyond the 14-day system outage; all eligible emergency radiographs during the study period were included in the analysis. The system operated passively alongside routine clinical workflows, without influencing clinical decisions. AI-identified suspected rib fractures were highlighted using bounding boxes on a backend interface, which was accessible only for research evaluation and remained hidden from the clinical care team (Figure 1).

Ethical Considerations

This study was approved by the Institutional Review Board of MacKay Memorial Hospital (IRB No. 20MMHIS483e) and conducted in accordance with the Declaration of Helsinki. Informed consent was waived because the study involved secondary analysis of routinely acquired, deidentified clinical imaging data, and the AI system operated passively without influencing patient management.

All data were deidentified prior to analysis and processed on secure institutional servers with access limited to authorized research personnel. No compensation was provided to participants. All images included in the manuscript were fully anonymized, and no identifiable patient information is disclosed.

Consistent with the approved observational study design, all AI outputs—including discordant cases—were withheld from treating clinicians and did not influence patient management.

AI Model Development

CXRs were retrospectively collected from the hospital picture archiving and communication system (PACS) for model training. All images were deidentified and preprocessed using histogram equalization and image inversion to improve fracture conspicuity. Fracture locations were annotated using bounding boxes by a board-certified emergency physician with 18 years of clinical experience via the DeepQ AI platform [18].

A deep learning model was developed using PyTorch (v1.13) with GPU acceleration. The architecture was based on faster region-based convolutional neural network (R-CNN) [19], incorporating a ResNet-50 backbone for feature extraction, a region proposal network for candidate region generation, and a classification head for fracture detection.

The dataset comprised 2079 CXRs (1065 fracture-positive and 1014 normal) collected between 2010 and 2020. Images were randomly divided into training (80%) and validation (20%) sets at the image level, as each radiograph represented an independent study. When multiple images were obtained from the same patient encounter, each radiograph was treated as an independent sample. Data augmentation—including random rotation, flipping, brightness, and contrast adjustment—was applied to improve generalization. To address the inherent class imbalance given the low fracture prevalence, class-weighted loss and oversampling of fracture-positive images were employed.

Model Validation

Model performance was assessed on a hold-out test set of 262 CXRs containing 724 expert-annotated rib fractures. Evaluation metrics were reported at both the case and object levels.

At the case level, the unit of analysis was the radiographic study. A study was considered positive if at least 1 rib fracture was detected, regardless of the number of fractures present. The model correctly identified fractures in 230 of 257

XSL•FO
RenderX

fracture-positive studies, achieving a sensitivity of 89.5%. With only 8 false-positive cases, precision reached 96.6%, yielding an overall F_1-score of 0.93.

At the object level, performance reflected per-lesion detection accuracy. The model correctly localized 680 of 724 annotated rib fractures (recall=94.0%) and generated 55 false-positive boxes. The mean average precision at an intersection-over-union threshold of ≥0.5 was 0.65, indicating robust lesion-level localization (Table 1).

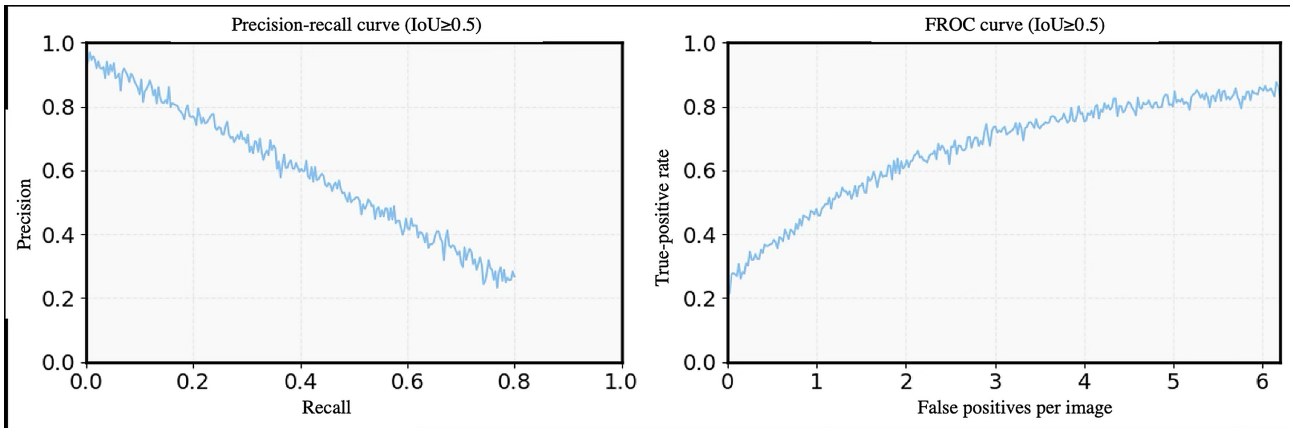

Table . Dataset composition and performance of the artificial intelligence (AI) model using retrospective emergency department chest radiographs, including case-level detection and object-level localization (intersection-over-union [IoU]≥0.50).

Category and metric	Value
Dataset	
Total images	262
Ground-truth boxes	724
Case-level detection (%)	
Sensitivity (recall)	89.6
Precision	96.6
F_1-score	0.93
Object-level localization	
Recall	94.0%
mAP[a] (IoU≥0.5)	0.65

[a]mAP: mean average precision.

Curve-based analyses further characterized the model's detection behavior (Figure 2). The precision-recall curve (Figure 2A) maintained precision ≥0.90 until recall fell below 0.55 (precision-recall area under the curve=0.65), demonstrating high reliability across a broad sensitivity range. The free-response receiver operating characteristic (FROC) curve (Figure 2B) showed true-positive rates of 0.77 at 1 false positive per image and 0.88 at three, representing practical trade-offs between sensitivity and alert frequency in potential clinical deployment.

Figure 2. The performance of the artificial intelligence (AI)–assisted rib fracture detection model was evaluated in the retrospective model development and validation dataset using emergency department chest radiographs. (A) Precision-recall curve demonstrating case-level detection performance at an intersection-over-union (IoU) threshold of ≥0.50 (area under the curve=0.65). (B) Free-response receiver operating characteristic (FROC) curve showing lesion-level sensitivity as a function of false positives per image, with localization performance assessed at the same IoU threshold (mean average precision=0.65; recall=94%).

Prospective Evaluation of AI Model in Emergency Department Workflow

The trained model was prospectively evaluated in parallel with clinical workflow, performing automated inference on incoming emergency radiographs. During the automated inference process, all incoming radiographs were standardized and resized to a fixed resolution of 512×512 pixels. The prospective evaluation cohort (April-July 2023) was temporally and operationally independent from the retrospective training and validation dataset (2010-2020), and no patient overlap existed between the 2 cohorts. During the prospective evaluation phase, all chest and rib radiographs from emergency department encounters were automatically processed by the AI system without disrupting clinical workflows. The bounding box outputs were logged for research analysis but were not disclosed to radiologists or used for patient management.

RenderX

Performance Assessment Using NLP-Derived Labels

To evaluate AI performance in the real-world setting, output was compared to formal radiology reports issued by board-certified radiologists. A rule-based natural language processing (NLP) pipeline was developed to extract structured rib fracture labels (positive, negative, or ambiguous) from free-text reports. The algorithm combined keyword detection (eg, “rib fracture,” “fx”) and negation handling (eg, “no evidence of,” “no definite fracture”).

To validate NLP accuracy, a random sample of 200 radiology reports was manually reviewed by 2 emergency physicians blinded to both NLP and AI results. The NLP classification achieved 96.5% agreement (193/200) with manual review, with a Cohen κ of 0.91, indicating excellent concordance. Most discrepancies were due to ambiguous language or complex negation structures (Table 2).

Table . Confusion matrix comparing natural language processing (NLP)–extracted radiology report labels with manual expert review in a randomly selected subset of 200 emergency department chest radiographs, used to assess labeling accuracy in the retrospective dataset.

Manual review	Fracture present	Fracture absent	Ambiguous	Total (NLP prediction)
NLP: fracture present	95	2	1	98
NLP: fracture absent	3	90	2	95
NLP: ambiguous	1	2	4	7
Total (manual review)	99	94	7	200

Formal radiology reports served as the primary reference standard for AI evaluation. This approach may have underestimated AI sensitivity because CT confirmation was not performed systematically. In select discordant cases—where the AI flagged fractures not documented in the reports—subsequent CT scans confirmed some of these findings. These discrepancies were retrospectively reviewed to investigate potential underreporting by radiologists. While informative, these exploratory adjudications were not used as a universal reference standard due to inconsistent CT availability. Nonetheless, radiology reports remained the definitive benchmark for all performance metrics. Additionally, the selected misclassified cases were examined to identify recurring patterns of diagnostic oversight among frontline physicians.

Targeted Adjudication of Discordant Cases

To further explore potential underreporting within the report-based reference standard, we performed a focused review of discordant cases in which the AI system flagged suspected rib fractures not documented in the corresponding formal radiology reports. Because not all discordant cases had confirmatory CT imaging, an illustrative subset of 11 cases was selected based on the availability of same-encounter chest CT and clinical relevance for qualitative adjudication. Each case was reviewed to determine whether the AI-predicted fractures corresponded to true fractures confirmed on CT. These adjudications were exploratory and intended to contextualize the potential clinical value of AI detection beyond the report-based benchmarking.

Data Analysis

Case-level performance was assessed at the radiographic study (accession) level by comparing AI outputs to NLP-derived labels from radiology reports. A study was considered positive if at least 1 image within the same examination was flagged as having a rib fracture by the AI system; otherwise, the study was classified as negative. Key metrics included sensitivity, specificity, accuracy, positive predictive value, negative predictive value (NPV), and F_1-score. Ninety-five percent CIs were calculated using nonparametric bootstrap resampling (1000 iterations). The results were summarized in confusion matrices and diagnostic performance plots.

Statistical Analysis

All statistical analyses were performed using Python 3.11 (pandas v2.2, scikit-learn v1.4) and R 4.3.2. Continuous variables were reported as mean (SD) or median with IQR. Categorical variables were summarized as counts and percentages. A 2-tailed P<.001 was considered statistically significant.

This study was reported in accordance with the Checklist for Artificial Intelligence in Medical Imaging (CLAIM) guideline, with the completed checklist provided as Checklist 1.

Results

Study Cohort

From April 1 to July 2, 2023, all chest and dedicated rib radiographs acquired in the emergency department were automatically processed by the AI system in a parallel workflow, yielding 23,251 imaging studies from 20,908 unique patient visits. Population demographics are summarized in Table 3. The mean age was 55.9 years (SD 22.3; range 0 - 106), with 10,770 (51.5%) male and 10,138 (48.5%) female patients. A radiologist review identified 589 rib-fracture cases (prevalence 2.8%).

XSL•FO
RenderX

Table . Demographic and clinical characteristics of patients in the emergency department included in a prospective observational study of artificial intelligence (AI)–assisted rib fracture detection (April 1-July 2, 2023).

Characteristic	Value
Total cases	20,908
Age (y), mean (SD; range)	55.9 (22.3; 0 - 106)
Sex, n (%)	
Male	10,770 (51.5)
Female	10,138 (48.5)
Radiologist-confirmed rib fractures, n (%)	589 (2.8)

AI Model Performance

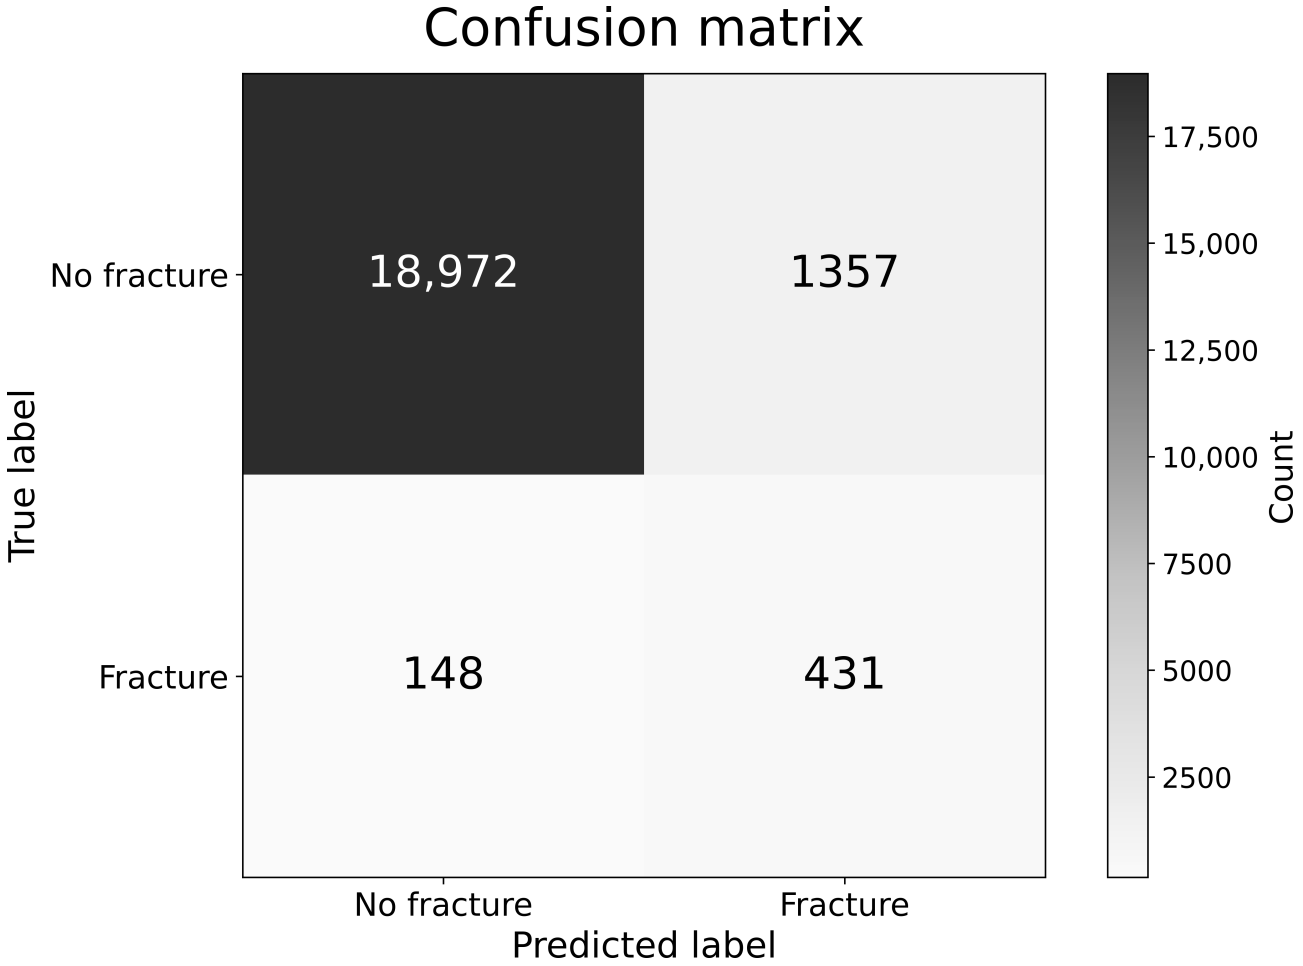
AI model outputs were compared on a per-case basis against structured rib-fracture labels derived from board-certified radiology reports. At the selected operating point—corresponding to approximately one false-positive per image on the FROC curve—the system achieved a sensitivity of 0.745 (95% CI 0.708 - 0.780) and specificity of 0.933 (95% CI 0.930 - 0.937). Positive predictive value was 0.242 (95% CI 0.223 - 0.262), and negative predictive value was 0.992 (95% CI 0.991 - 0.994). The overall F_1-score was 0.365 (95% CI 0.340 - 0.390) with an accuracy of 0.928 (Table 4).

Table . Case-based diagnostic performance of an artificial intelligence–assisted rib fracture detection system in a prospective observational emergency department study[a].

Metric	Estimate (95% CI)
Sensitivity	0.745 (0.708 - 0.780)
Specificity	0.933 (0.930 - 0.937)
PPV[b]	0.242 (0.223 - 0.262)
NPV[c]	0.992 (0.991 - 0.994)
F_1-score	0.365 (0.340 - 0.390)
Accuracy	0.928 (N/A[d])

[a]Performance metrics are reported with 95% CIs using final radiologist reports as the reference standard.

[b]PPV: positive predictive value.



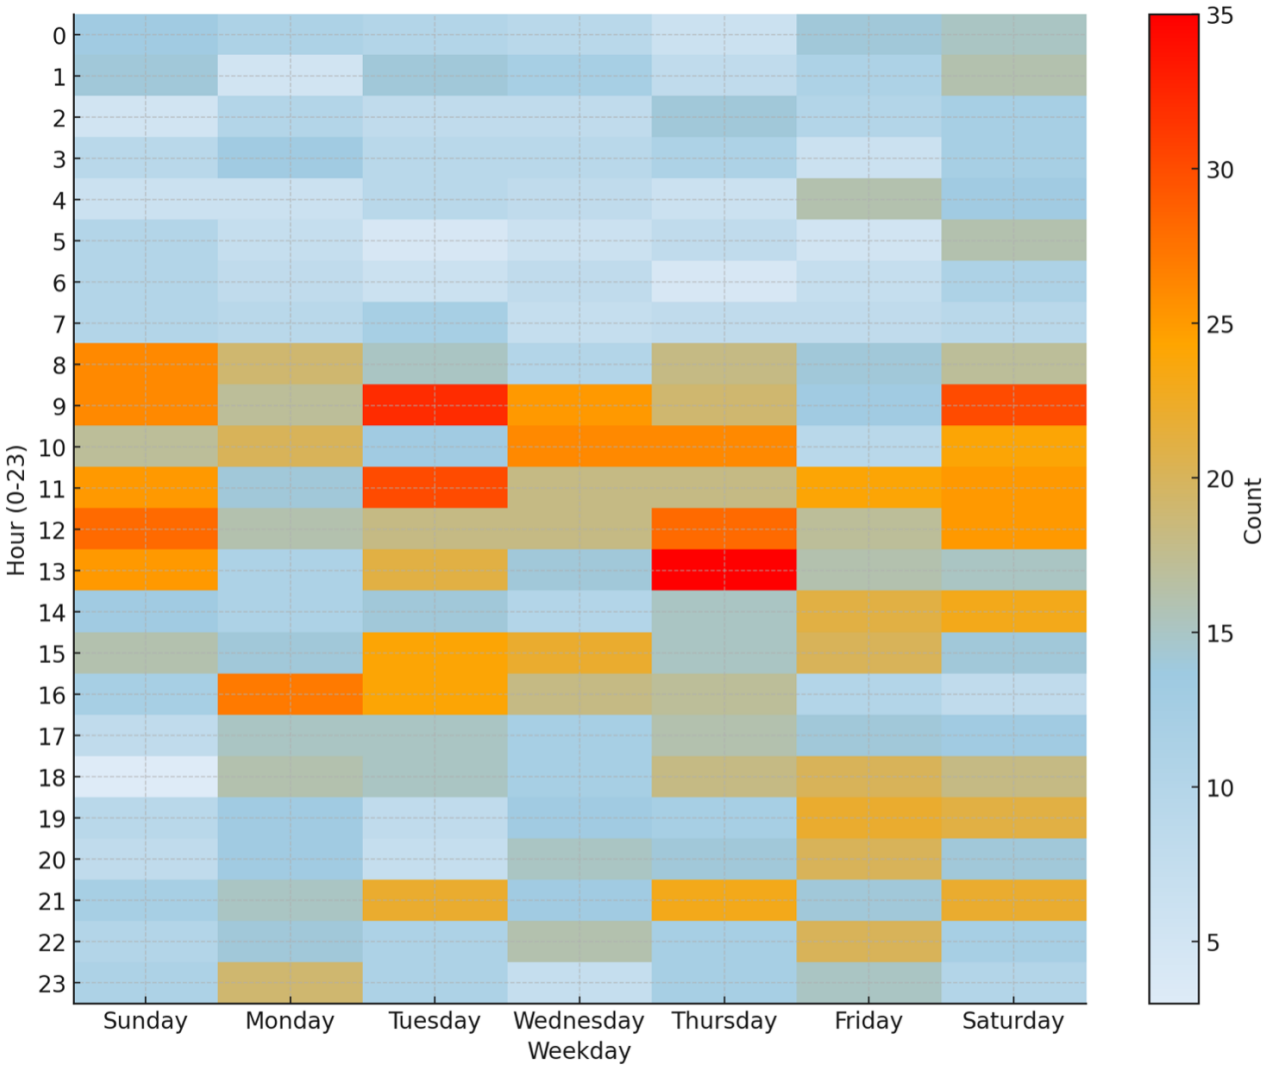
[c]NPV: negative predictive value.

[d]N/A: not available.

As shown in Figure 3, the AI system correctly identified 431 (74.5%) fracture-positive cases while producing 1357 (6.1%) false positives and 148 (0.7%) false negatives across 23,251 studies. This distribution demonstrates the model's high true-negative count (n=18,972, 93.3%) and its strong negative predictive value during deployment in the emergency department. No temporal drift or learning curve effects were observed, as the deployed model remained fixed throughout the study period.

XSL•FO
RenderX

Figure 3. Case-level confusion matrix of the artificial intelligence (AI)–assisted rib fracture detection system during prospective emergency department deployment, using final radiologist reports as the reference standard. Darker blue indicates a higher number of cases (count), as shown in the color bar.



Imaging Workload Patterns

Analysis of imaging demand revealed predictable diurnal and weekly patterns, with peak volumes between 08:00 and 16:00 daily and secondary surges on Thursday to Saturday evenings. Demand was the lowest between 00:00 and 07:00 across all days of the week (Figure 4).

XSL•FO
RenderX

Figure 4. Heatmap illustrating the temporal distribution of chest radiograph imaging workload by hour of day and weekday during prospective emergency department deployment. Color intensity represents the number of chest radiographs acquired per hour, highlighting peak imaging periods across weekdays and weekends.

Inference Turnaround Time

A total of 19,641 paired cases were included to compare AI inference and radiologist report turnaround times. As shown in Table 5, the AI system achieved a median processing time of 10.6 seconds per image (IQR 9.0 - 14.0; range 3 - 35 s), compared with a median of 3.3 hours (IQR 1.31 - 4.80; range 0.08 - 72 h) for radiologist reports. This represents a more than 1000-fold reduction in turnaround time. Figure 5 illustrates this disparity using boxplots on a logarithmic scale. A paired Wilcoxon signed-rank test confirmed that AI inference was significantly faster than radiologist reporting (W=112,987.5; P<.001). This median reporting time reflects the full clinical workflow, including overnight and backlog delays typical of high-volume emergency radiology settings.

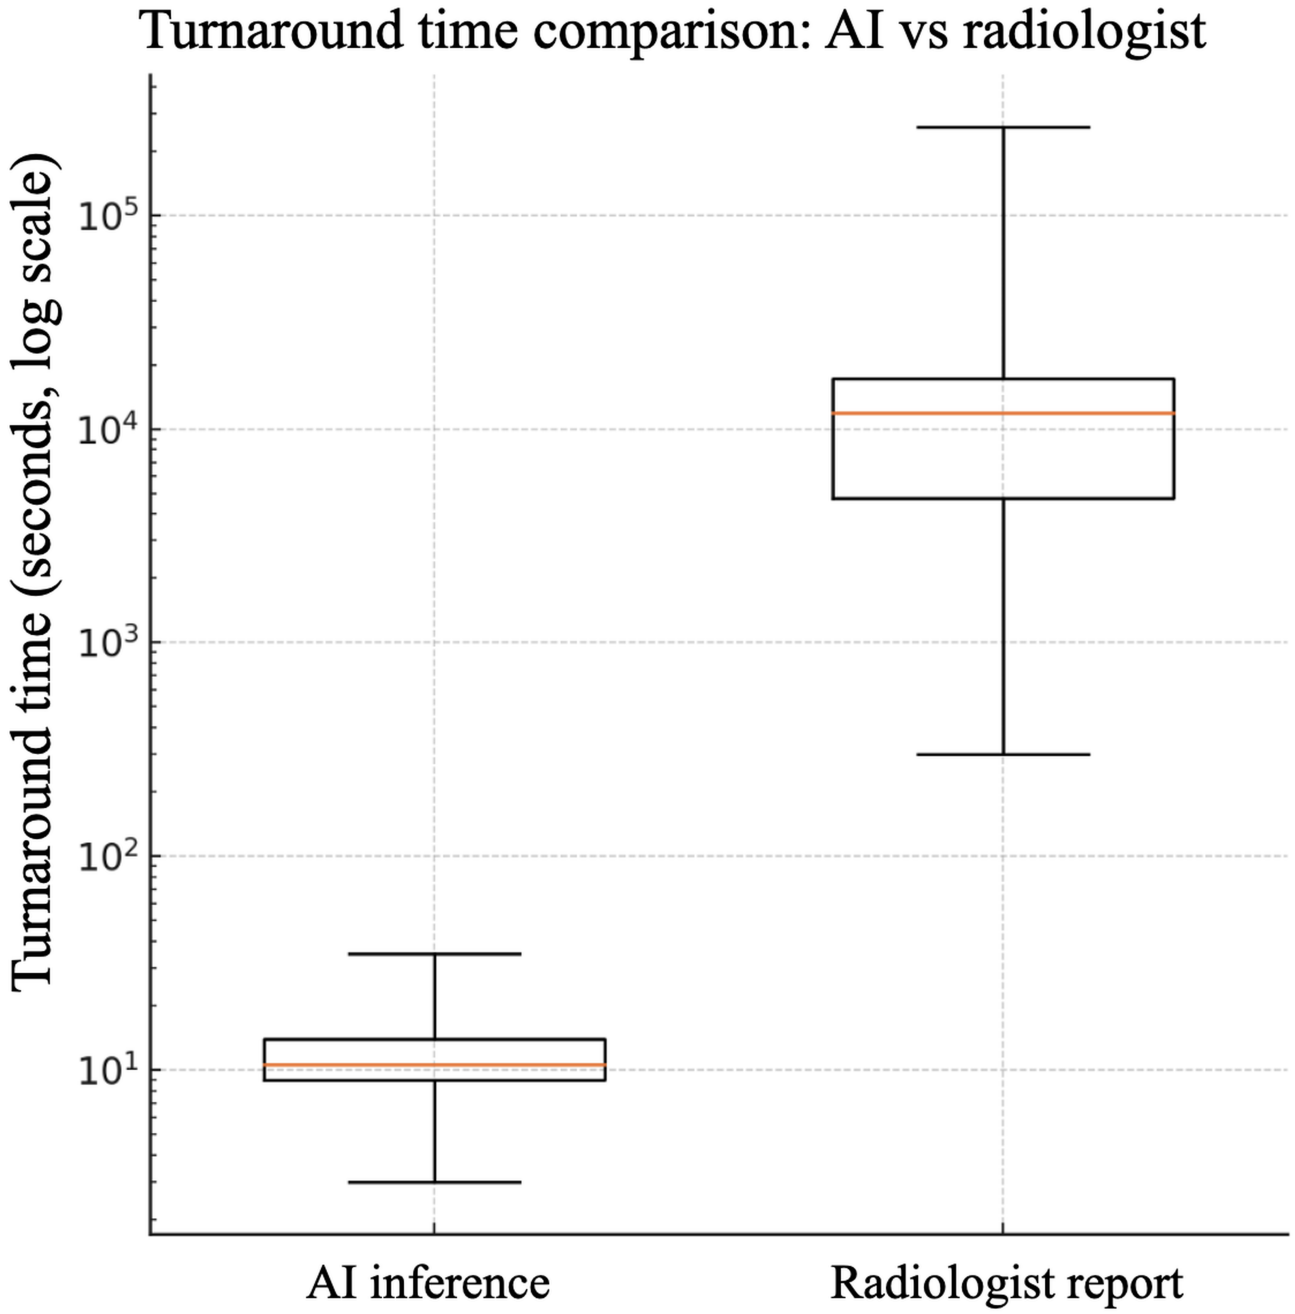


Table . Turnaround times for artificial intelligence (AI) inference versus radiologist reporting during prospective emergency department deployment (n=19,641)[a].

Metric	AI inference time (s)	Radiologist report time (s)
Mean	10.9	10,877
Standard deviation	3.0	4008
Median (50%)	10.6	11,880
IQR (25% - 75%)	9.0 - 14.0	4728 - 17,280
Min	3.0	300
Max	35.0	259,200

[a]Times are summarized using descriptive statistics, including median and interquartile range.

XSL•FO
RenderX

Figure 5. Comparison of turnaround times between artificial intelligence (AI) inference and radiologist reporting during prospective emergency department deployment (April 1-July 2, 2023). Boxplots on a logarithmic scale illustrate differences in processing time distributions between real-time AI inference and routine clinical reporting.

This processing speed highlights the potential of AI-assisted triage systems to complement radiology workflows by rapidly identifying cases for prioritized review, especially in high-volume emergency settings.

System Reliability

During the prospective evaluation of the AI system operating in a parallel clinical workflow, the AI platform experienced 1 service interruption—from 27 April to 10 May 2023—caused by GPU overload that halted all inference operations. A total of 3610 studies acquired during this 14-day outage were excluded from the turnaround time analysis but retained in the diagnostic accuracy evaluation (their formal radiology reports remained available). Following hardware replacement, full functionality was restored on 11 May, and no further outages occurred over the remainder of the study period.

Illustrative Review of Discordant Cases

To further evaluate the AI system's potential diagnostic value beyond report-based benchmarking, a targeted adjudication was conducted on 11 representative discordant cases in which the AI system flagged suspected rib fractures not described in the corresponding radiology reports (Table 6). Among these, 7 cases (cases 1 - 7) were subsequently confirmed as true fractures on CT ("AI-CT concordant"), indicating that several AI-labeled false positives in the report-based analysis represented true fractures missed in the reference standard. The remaining 4 cases (cases 8 - 11) were confirmed negative on CT, primarily attributable to nonfracture anatomical structures or imaging

XSL•FO
RenderX

artifacts. Including these CT-confirmed fractures as true positives would modestly increase the model's effective sensitivity and positive predictive value, highlighting the underestimation inherent in report-based benchmarking.

Table . Targeted post hoc computed tomography (CT) adjudication of representative discordant cases in which artificial intelligence (AI) flagged suspected rib fractures not described in the corresponding radiology reports during prospective emergency department deployment.

Case	AI output	Radiologist report	Emergency physician	Outcome	Note (AI significance)
1	Flagged right rib fracture	No fracture	Noted with POCUS[a]	CT-confirmed	Triage value, prompting clinicians to perform US[b]
2	Flagged right rib fracture	No fracture	Missed	CT-confirmed	AI-CT concordance
3	Flagged left fifth rib fracture	No fracture	Missed	CT-confirmed	AI-CT concordance
4	Flagged rib fracture post chest tube	No fracture	Missed	CT-confirmed	Chest tube artifact did not impair detection
5	Flagged lower-rib fracture	No fracture	Missed	CT-confirmed	AI-CT concordance
6	Flagged fracture near hardware	No fracture	Missed	CT-confirmed	Detected fracture adjacent to surgical hardware
7	Flagged fracture under scapular shadow	No fracture	Missed	CT-confirmed	AI-CT concordance
8	Flagged fracture at scapula border	No fracture	No fracture	False positive	Scapular margin misidentified
9	Flagged rib fracture at bra clasp	No fracture	No fracture	False positive	Bra hardware artifact
10	Flagged fracture at chest tube marker	No fracture	No fracture	False positive	Chest tube marker misinterpreted
11	Flagged fracture (image noise)	No fracture	No fracture	False positive	Image noise

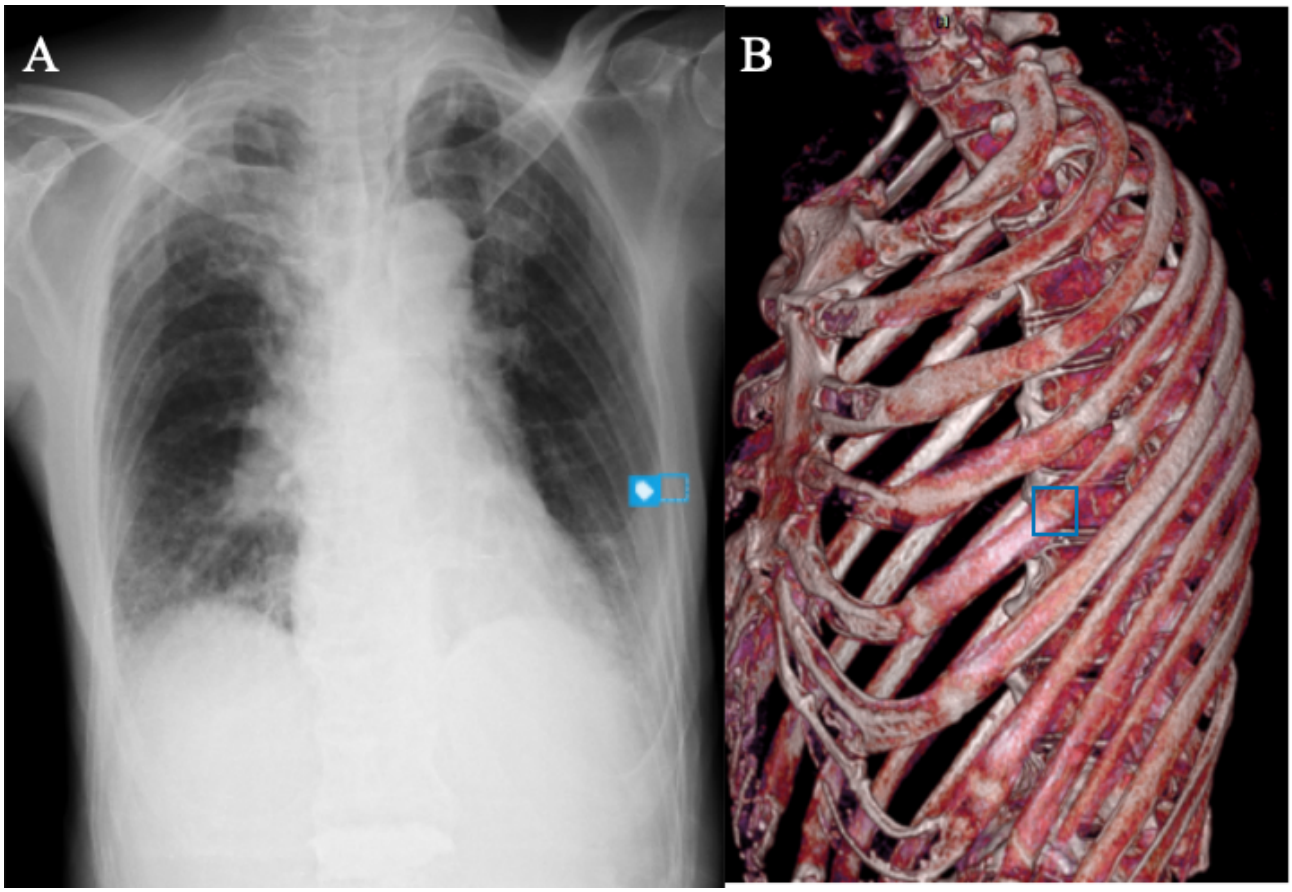
[a]POCUS: point-of-care ultrasound.

[b]US: ultrasound.

In one representative case (Case 3), the AI system correctly identified a subtle nondisplaced fracture of the left fifth rib that was not documented in the radiology report but later verified on 3D CT reconstruction (Figure 6). In contrast, Figure 7 illustrates the main sources of false positives, including scapular margin misinterpretation, chest-tube hardware artifacts, and motion-induced noise.

XSL•FO
RenderX

Figure 6. Representative true-positive rib fracture detected by artificial intelligence (AI) and confirmed by computed tomography (CT) during prospective emergency department deployment. (A) Chest radiograph showing an AI-flagged fracture of the left fifth rib that was not described in the initial radiology report. (B) Corresponding CT image confirming the fracture at the same anatomical location.



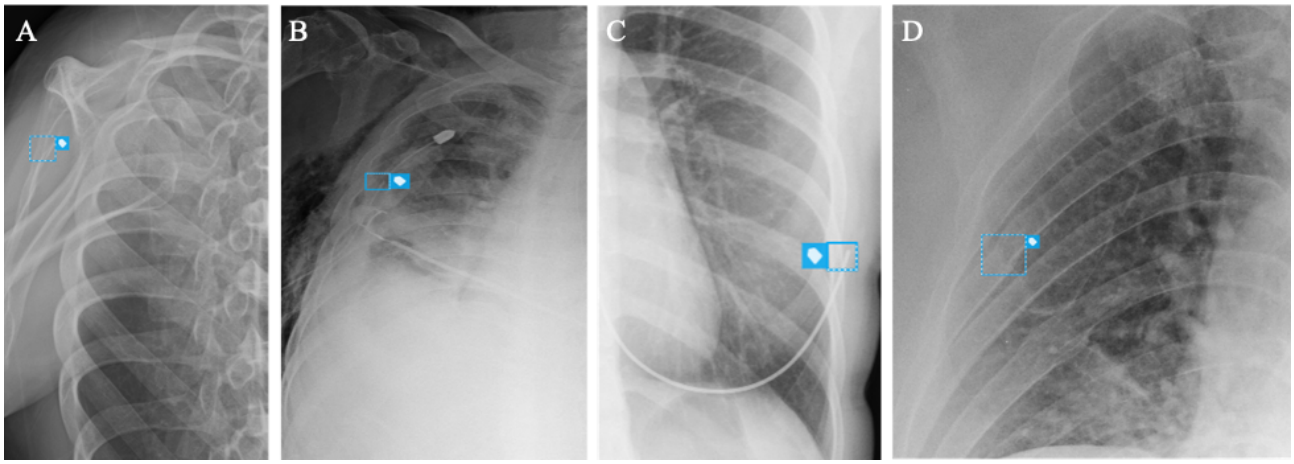


Figure 7. Representative false-positive detections generated by an artificial intelligence (AI)–assisted rib fracture detection system during prospective emergency department deployment. The examples illustrate common sources of false-positive signals on chest radiographs. (A) Scapular margin overlap misinterpreted as a rib fracture. (B) Chest tube marker misidentified as a rib discontinuity. (C) Bra hardware producing a linear opacity mimicking a fracture. (D) Image noise and low-contrast regions leading to spurious detection.

This targeted CT adjudication underscores the potential of AI-assisted screening to augment clinical vigilance by identifying subtle or overlooked fractures, while also emphasizing the need to improve artifact robustness and optimize false-positive suppression for practical clinical integration.

Common Pitfalls in Frontline Rib Fracture Detection

Our review of discordant cases identified 3 principal drivers of missed rib fractures by emergency physicians: first, non-thoracic presenting complaints (eg, catheter malfunction or abdominal pain) led interpreters to focus on unrelated findings and overlook subtle rib breaks; second, the absence of classic chest pain—patients describing only mild discomfort or a vague “pop”—lowered clinical vigilance for nondisplaced fractures; and third, competing urgent injuries (facial, limb, or soft-tissue

XSL•FO
RenderX

trauma) diverted attention from the chest, resulting in underappreciated fractures.

Discussion

Principal Findings

In this observational feasibility study using real-world emergency department imaging data, we demonstrated that a faster R-CNN–based AI system can operate in parallel with routine clinical workflows to provide near-instantaneous rib fracture triage without influencing patient care. During a 3-month evaluation period, the model automatically processed 23,251 CXRs with a median inference time of 10.6 seconds per image, achieving a turnaround time reduction exceeding 3 orders of magnitude compared with formal radiologist reporting, while maintaining 74.5% sensitivity and 93.3% specificity. These findings position AI as a potential automated screening aid capable of rapidly identifying low-risk examinations and generating signals that could inform future prioritization strategies. The observed discrepancy between the 10.6-second AI inference time and the 3.3-hour radiologist turnaround time reflects a critical clinical bottleneck in busy emergency departments. Although these metrics represent different stages—technical processing versus final clinical documentation—the delay in official reporting highlights the diagnostic gap AI aims to address. In this context, near-instantaneous AI alerts may support case prioritization before formal reporting, although no clinician-facing alerts were implemented in this study.

However, the current findings primarily demonstrate technical feasibility rather than full clinical feasibility, as the AI system operated passively without direct clinician interaction. Future clinician-in-the-loop evaluations will be necessary to assess workflow integration, usability, and impact on diagnostic behavior or patient outcomes.

Although the system's positive predictive value was relatively low (24.2%), this trade-off aligns with its design as a triage support tool rather than a stand-alone diagnostic system. In high-volume emergency departments, the ability to rapidly identify examinations with a low likelihood of fracture is crucial. The model's high NPV of 99.2% allows clinicians to focus on a smaller, higher-risk subset of cases, thereby improving efficiency and reducing cognitive load. Given the observed sensitivity of 74.5%, false-negative cases remain possible, and the system should not be used as a stand-alone rule-out mechanism or as a substitute for clinical judgment.

Comparison to Prior Work

Similar findings have been reported by Yao et al [20], who demonstrated that deep learning systems with high NPV on chest CT can reduce radiologists' workload by effectively identifying nonfracture cases. A recent systematic review by van den Broek et al [21] further emphasized the triage value of AI in fracture detection, underscoring its potential across multiple imaging modalities.

Our AI system also demonstrated robust performance across circadian and weekly imaging surges, with peak volumes observed between 08:00 and 16:00 and during Thursday to Saturday evenings. However, a 14-day GPU hardware outage during the study period highlighted a real-world challenge of maintaining the AI system's reliability in clinical environments. This incident underscores the need for infrastructure redundancy, real-time monitoring, and failover protocols—key considerations for sustainable AI deployment. These practical aspects of AI deployment remain underreported in most published studies [22].

Compared with prior approaches such as the PACS-AI platform [23], our system offered full automation, operating continuously in real time and without the need for manual image selection. This better reflects the demands of frontline emergency radiology. Herpe et al [24] demonstrated improved diagnostic accuracy with PACS-integrated AI for limb fractures; however, their study did not evaluate scalability or autonomous triage capability under high-throughput conditions. In contrast, our study incorporated prospective data collection within a real-world emergency department workflow, allowing the assessment of AI performance, reliability, and operational feasibility under authentic clinical conditions.

Focused adjudication of discordant cases revealed that the AI system correctly identified rib fractures that were missed by both radiologists and emergency physicians in 7 cases, all subsequently confirmed on follow-up CT ("AI-CT concordant"). These findings highlight the potential of AI to strengthen diagnostic vigilance in complex clinical scenarios. While prior studies—such as Zhou et al [25]—have shown that AI can detect rib fractures overlooked in initial CT interpretations, with confirmation on follow-up imaging, these investigations have largely centered on CT-based workflows. Although CT is highly sensitive, its routine use is limited by concerns over radiation, cost, and logistics. In contrast, our CXR-focused approach targets the most widely used imaging modality in acute care, offering a more scalable and practical solution for real-world emergency triage. Notably, Brady et al [26] have emphasized that diagnostic errors and discrepancies are not uncommon in radiology, with daily error rates estimated at 3% - 5%, reinforcing the importance of AI as a complementary tool to enhance diagnostic accuracy.

Four false-positive cases revealed predictable pitfalls, including the misinterpretation of scapular margins, chest-tube hardware, and motion artifacts. Similar findings were reported by Sun et al [27], who noted frequent false positives in an AI model for rib fracture detection on CXR, often due to anatomical overlap and imaging artifacts. These results support the need for artifact-aware retraining and preprocessing optimization to reduce false alerts and improve clinical integration.

This targeted CT adjudication further highlights the complementary role of AI in identifying subtle or overlooked fractures and underscores the inherent limitation of using report-based labels as the reference standard in real-world studies.

Future Directions

In addition, integrating AI-generated alerts into emergency radiology workflows will require careful calibration of alert thresholds to minimize false positives and prevent alert fatigue

XSL•FO
RenderX

among clinicians. Human-centered design, interface refinement, and iterative feedback from end users will be critical to achieving effective and sustainable adoption.

While most prior prospective studies have emphasized diagnostic performance or radiologist feedback, our findings extend beyond these metrics to include diagnostic efficacy, operational resilience, and system failure contingencies. These real-world insights support the feasibility and clinical value of embedding AI into routine emergency department workflows. Recent work has highlighted the importance of not only measuring accuracy but also assessing robustness across patient and workflow variability [28]. Furthermore, the need for deployment frameworks that address hardware resilience, continuous quality monitoring, and interpretability safeguards is increasingly recognized as essential for sustainable AI adoption in high-acuity settings [29].

Recent reports and position statements have highlighted a persistent gap between the promising diagnostic performance of AI systems and their limited demonstrated clinical benefit. Robust, prospective, and randomized clinical studies remain urgently needed to justify large-scale implementation [30,31]. Even high-performing AI models (area under the curve≈0.85) have failed to surpass standard clinical practice in improving patient outcomes [32,33]. These findings reinforce ongoing concerns that most AI or machine learning devices, despite regulatory authorization, are primarily validated using retrospective data and therefore remain susceptible to selection bias, distributional shift, and overestimation of generalizability [34,35].

Clinical decision-making in emergency care is inherently multimodal: physicians integrate imaging findings with the mechanism of injury, examination, and vital signs to guide judgment. In contrast, this AI system analyzes images in isolation and is designed not to replace but to support clinicians as a rapid screening aid—enhancing vigilance in high-volume, high-pressure environments where missed fractures may occur. Incorporating multimodal clinical data in future models could further improve diagnostic relevance and workflow integration.

Although this was an observational feasibility study, it represents one of the largest evaluations of an AI-assisted rib fracture detection system in real-world emergency radiology. The findings demonstrate that such a system can provide meaningful diagnostic support, maintain consistent performance at scale, and potentially enhance patient safety. Future implementation should therefore shift from technical to clinical feasibility, focusing on clinician-in-the-loop impact studies, PACS-integrated trials, and workflow efficiency assessments. Although user perception was not formally assessed, informal feedback from emergency physicians indicated strong interest in AI-supported flagging—particularly for subtle fractures and during periods of high patient volume.

Future research should prioritize prospective, multicenter studies to validate generalizability and quantify AI impact on workflow, resource utilization, and patient outcomes. Model improvements—including artifact-aware retraining, expanded fracture coverage in challenging scenarios such as subtle or anatomically obscured fractures, and continuous learning—will be critical to enhance diagnostic precision. Finally, building infrastructure resilience and integrating effective alert management into radiologist workflows are essential for sustainable clinical adoption.

Limitations

First, this single-center observational study may limit generalizability to other institutions with different imaging protocols, patient populations, or workflow environments. Second, during retrospective model development, training and validation were performed at the image level rather than the patient level. This may have resulted in optimistic internal validation estimates due to potential within-patient similarity, which likely contributes to the observed performance gap between retrospective validation and prospective real-world deployment. Additionally, stratified performance analyses by age group and sex were not performed due to the low prevalence of rib fractures in certain subgroups, particularly pediatric patients. Similarly, the small fraction of oblique views (approximately 1.3%) prevented a dedicated analysis by imaging view, as the limited sample size would yield unstable estimates for these specific cohorts.

The prospective evaluation period also did not include winter months. Seasonal variation in trauma mechanisms or imaging artifacts may influence fracture detectability in certain settings; therefore, caution is warranted when generalizing these findings across different seasonal contexts.

Additionally, the use of a 512×512 resolution for model inference represents a technical trade-off; while it facilitates rapid processing, the associated downsampling may limit the detection of very subtle cortical disruptions.

Third, using radiology reports as the reference standard—while pragmatic—may underestimate the AI system's true performance, as subtle or occult fractures can be underreported in clinical practice. A focused CT review of representative discordant cases further supported this concern, revealing instances where AI-predicted fractures were subsequently confirmed as true fractures on CT. This approach likely yielded conservative performance estimates, since NLP-derived labels may not capture subtle fractures identified by AI or CT.

Regarding the study design, although post hoc adjudication is generally more appropriate for hypothesis generation than for definitive performance reassessment, modifying the reference standard after study completion may introduce bias. Accordingly, in this study, performance evaluation was anchored to the contemporaneous clinical reference standard used in routine practice. More comprehensive adjudication strategies—such as consensus radiologist review of AI-positive, report-negative cases—may provide additional insights when implemented within a separately designed study.

Finally, because AI predictions were not disclosed to clinicians, we did not assess downstream clinical outcomes, including changes in diagnostic behavior, time to intervention, or patient management. As for the data pipeline, although we used NLP to extract rib fracture labels from radiology reports, which may introduce misclassification in ambiguous cases, the pipeline demonstrated high agreement with manual review (κ=0.91).

XSL•FO
RenderX

Given the observed 3.5% discrepancy rate, any residual label noise propagating through the large-scale dataset may introduce modest uncertainty into performance estimates. However, the substantial sample size (n=23,251) is expected to attenuate the impact of such noise, supporting the stability of the resulting confidence intervals for large-scale clinical benchmarking.

Conclusions

In this observational feasibility study, we evaluated a faster R-CNN–based AI system deployed in parallel with clinical workflows to automatically detect rib fractures on CXRs using real-world emergency department data. Although AI outputs were not visible to clinicians, the system processed over 23,000 studies with high throughput, achieving 74.5% sensitivity and 93.3% specificity and delivering results within seconds—over 1000 times faster than formal radiologist reports.

These findings demonstrate strong technical feasibility of real-time AI-assisted rib fracture detection in emergency radiology. While clinical decisions remained unaffected during this observational phase, future studies should validate clinical feasibility through clinician-in-the-loop evaluation, PACS integration, and workflow optimization to address potential alert fatigue and false-positive management.

Acknowledgments

We thank the emergency department, radiology department, and information technology teams for their support during system deployment and data extraction. Generative artificial intelligence tools were used solely for language editing and grammar checking. All scientific content, analyses, interpretations, and conclusions were developed by the authors. The artificial intelligence system evaluated in this study was deployed on the DeepQ AI platform as a technical deployment environment. The authors have no financial, employment, or equity relationship with DeepQ Technology or HTC, and the platform was used solely for noncommercial research purposes.

Funding

This research was financially supported by National Science and Technology Council, Taiwan, under Grant No. NSTC113-2221-E-038 - 006

Data Availability

The imaging data analyzed in this study are not publicly available due to institutional regulations and patient privacy protections. Deidentified data may be made available from the corresponding author upon reasonable request and subject to institutional review board approval.

Abstract

Background: Opioids are a widely prescribed class of medication for pain management. However, they have variable efficacy and adverse effects among patients, due to the complex interplay between biological and clinical factors. Pharmacogenetic testing can be used to match patients' genetic profiles to individualize opioid therapy, improving pain relief and reducing the risk of adverse effects. Despite its potential, the pharmacogenetic testing uptake (use of pharmacogenetic testing) remains low due to a range of barriers at the patient, health care provider, infrastructure, and financial levels. Since testing typically involves a shared decision between the provider and patient, predicting the likelihood of a patient undergoing pharmacogenetic testing and understanding the factors influencing that decision can help optimize resource use and improve outcomes in pain management.

Objective: This study aimed to develop machine learning (ML) models, identifying patients' likelihood of pharmacogenetic uptake based on their demographics, clinical variables, medication use, and social determinants of health.

Methods: We used electronic health record data from a single center health care system to identify patients prescribed opioids. We extracted patients' demographics, clinical variables, medication use, and social determinants of health, and developed and validated ML models, including a neural network, logistic regression, random forest, extreme gradient boosting (XGB), naïve Bayes, and support vector machines for pharmacogenetic testing uptake prediction based on procedure codes. We performed 5-fold cross-validation and created an ensemble probability-based classifier using the best-performing ML models for pharmacogenetic testing uptake prediction. Various performance metrics, uptake stratification analysis, and feature importance analysis were used to evaluate the performance of the models.

Results: The ensemble model using XGB and support vector machine–radial basis function classifiers had the highest *C*-statistics at 79.61%, followed by XGB (78.94%), and neural network (78.05%). While XGB was the best-performing model, the ensemble model achieved a high accuracy (32,699/48,528, 67.38%), recall (537/702, 76.50%), specificity (32,162/47,826, 67.25%), and negative predictive value (32,162/32,327, 99.49%). The uptake stratification analysis using the ensemble model indicated that it can effectively distinguish across uptake probability deciles, where those in the higher strata are more likely to undergo pharmacogenetic testing in the real world (320/4853, 6.59% in the highest decile compared to 6/4853, 0.12% in the lowest).

XSL•FO
RenderX

Furthermore, Shapley Additive Explanations value analysis using the XGB model indicated age, hypertension, and household income as the most influential factors for pharmacogenetic testing uptake prediction.

Conclusions: The proposed ensemble model demonstrated a high performance in pharmacogenetic testing uptake prediction among patients using opioids for pain. This model can be used as a decision support tool, assisting clinicians in identifying patients' likelihood of pharmacogenetic testing uptake and guiding appropriate decision-making.

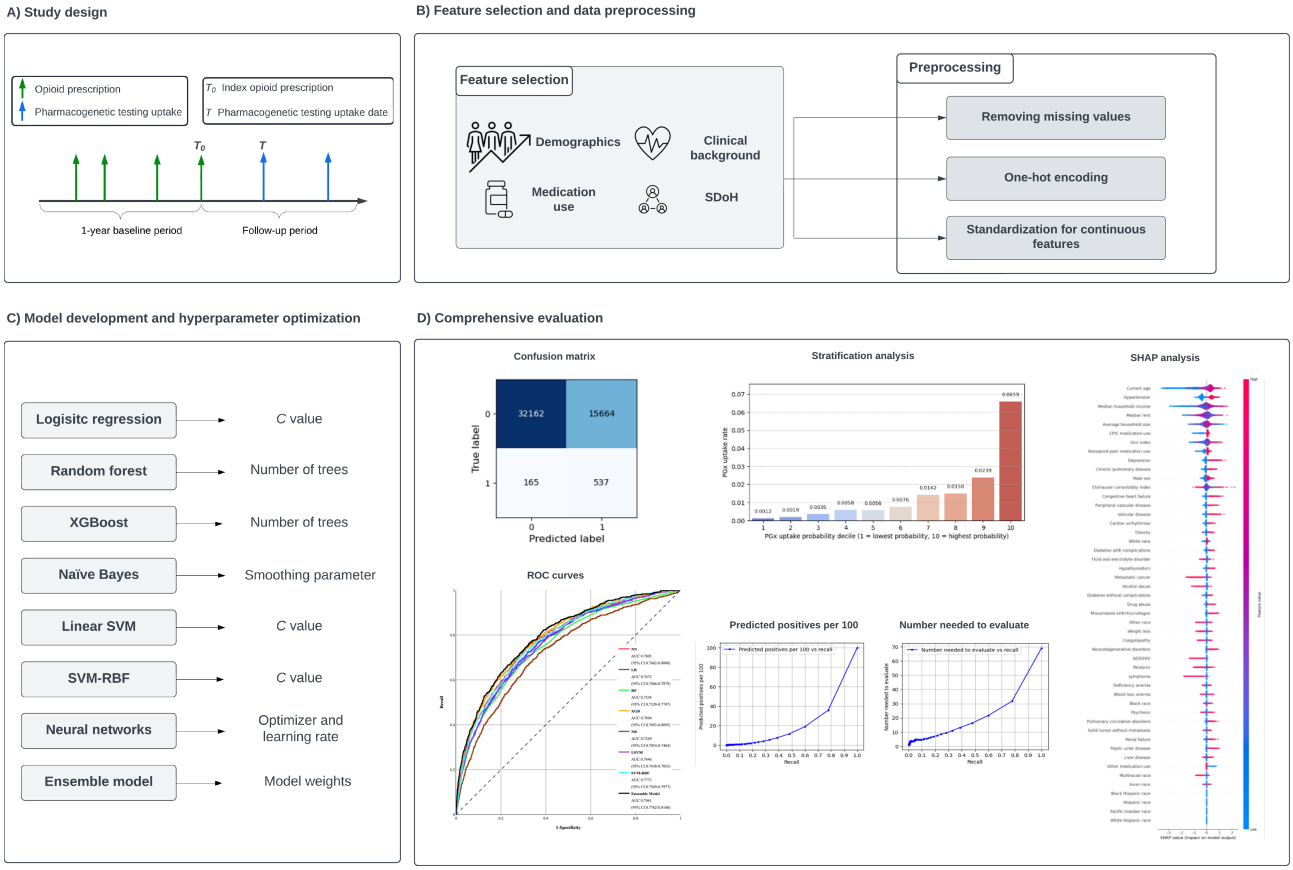
ensemble model; ML; machine learning; opioids; opioid prescription; pain management; pharmacogenetic testing

Introduction

Opioid prescribing presents a complex therapeutic challenge due to variable efficacy and the risk of adverse effects, often resulting in a trial and error approach for prescription. These variations in opioid response often arise from interindividual differences in pharmacokinetics and pharmacodynamics, influenced in part by genetic variations [1]. Over recent decades, pharmacogenetic testing has emerged as a promising strategy to tailor opioid therapy to an individual genetic profile, with the goal of enhancing pain relief, minimizing adverse effects, and improving overall patient outcomes. Several opioids, including codeine, tramadol, hydrocodone, and oxycodone, are metabolized to varying extents by cytochrome P450 family 2 subfamily D member 6 (CYP2D6), which is an enzyme involved in the metabolism of many drugs [2]. A pragmatic trial demonstrated improved composite pain intensity outcomes with CYP2D6-guided pain management, highlighting the potential benefits of personalized therapy based on pharmacogenetic testing [2]. Based on the current evidence, the Clinical Pharmacogenetics Implementation Consortium (CPIC) provides guidelines on using CYP2D6 genotype results for prescribing tramadol, hydrocodone, and codeine [2]2 yet their real-world impact depends on whether patients offered pharmacogenetic testing actually complete it. In opioid prescribing contexts, uptake hinges on perceived use and timing, out-of-pocket costs, health literacy, trust, social context, and clinician offering practices, as well as workflow constraints that differ across acute, perioperative, and chronic pain settings.

Electronic health records (EHRs) contain rich information relevant to testing acceptance: prior and current opioid exposures, pain diagnoses, comorbidity burden, care setting, prescriber specialty, monitoring and follow-up patterns, previous laboratory or genetic testing, and engagement with the health system. Machine learning (ML) such as neural network (NN), random forest (RF), and logistic regression (LR) can synthesize these heterogeneous and high-dimensional features [3] to produce calibrated, patient-level probability estimates of pharmacogenetic testing uptake at the moment testing is offered. Such predictions could help health systems, including patient care teams and insurers, tailor communication (eg, language, framing, and channel), select appropriate clinical checkpoints (such as before initiating certain opioids or at dose escalation), and allocate resources where they are most likely to improve test uptake without adding unnecessary burden. These predictions may be especially valuable for patients who are expected to benefit most from testing (though this was not the focus of this study), enabling patient care teams to dedicate additional resources to support uptake in this population.

Prior work has developed ML predictive models to support uptake for vaccines [4], cancer screening [5], and genetic counseling [6]; however, pharmacogenetics-specific models for opioid-related testing are scarce, and few studies evaluate calibration, clinical use, fairness, and workflow integration together. In this study, we aimed to predict the likelihood that patients receiving opioid prescriptions will undergo pharmacogenetic testing after an offer in routine care. We hypothesized that ML models could accurately predict the likelihood of pharmacogenetic testing uptake among opioid-prescribed patients by identifying patterns in demographic, clinical, and health care use factors associated with testing behavior under current practice conditions. Our objectives were to achieve strong discrimination and predictive performance of the ML models, and reliable model calibration through patients' stratification in subgroups based on the predicted probability of test uptake. We emphasized model explainability to support clinician understanding and sought to identify factors influencing the likelihood of pharmacogenetic testing uptake in opioid therapy. Ultimately, we aimed to complement, rather than replace, clinical judgment, potentially facilitating better use of pharmacogenetic testing for precision pain management. By focusing on actionable predictions at the point of offer, this paper may help programs deliver the right message through the right channel at the right time: improving test uptake, informing safer opioid prescribing, and advancing equitable delivery of pharmacogenetic testing.



Methods

Overview

The overall ML pipeline for pharmacogenetic testing uptake prediction is shown in Figure 1. The pipeline involves 4 steps, including study design, data preprocessing and feature selection, model development, and comprehensive evaluation. Each step involves several tasks that are critical to building and evaluating the final predictive model. The details of each step are described in this section.

Figure 1. Overall machine learning pipeline for pharmacogenetic testing uptake prediction. CPIC: Clinical Pharmacogenetics Implementation Consortium; ROC: receiver operating characteristic; SDoH: social determinants of health; SHAP: Shapley Additive Explanations; SVM: support vector machine; SVM-RBF: support vector machine–radial basis function; XGBoost: extreme gradient boosting.

Ethical Considerations

We used real-world deidentified EHR data available from the University of Florida Health Integrated Data Repository (IDR) to develop the models. These data included information on patients' demographics, clinical variables, and medication use from 2011 to 2023. The study was conducted in compliance with ethical standards and was approved by the University of Florida Institutional Review Board under the reference number IRB202301927. This study is a secondary analysis of existing deidentified EHR data, and the approved IRB covers secondary analyses without additional consent. Therefore, no informed consent was obtained.

Study Design

Patients' age range was 1 to 89 years, and we did not exclude any patients based on age. Patients were included if they were aged between 18 and 89 years and had an opioid prescription order for noncancer treatment from 2011 to 2023. Patients were stratified into an intervention group (patients with a minimum of one pharmacogenetic testing order) and a control group (those with no history of pharmacogenetic testing order). We used current procedural terminology codes to determine patients' pharmacogenetic testing. To create the cohort for ML model development, we defined the index dates separately for intervention and control groups. The index date for the intervention group was defined as the most recent date of an opioid prescription prior to pharmacogenetic testing. The index date for the control group was defined as the earliest date of opioid prescription. All baseline covariates were collected in the 1-year period prior to the index date. The outcome was a binary target variable, indicating whether the patient was in the intervention or control group based on their pharmacogenetic testing record. If a patient was in the intervention group, their outcome value was encoded as 1 and otherwise 0.

Feature Selection and Data Preprocessing

We selected four different categories of features for our study sample: (1) demographics, (2) clinical history, (3) medication use, and (4) social determinants of health (SDoH). Demographics included age, sex, and race, where age was continuous, sex was binary, and race was multicategory which was one-hot-encoded to get separate binary inputs for each racial group and prevent the ordinality assumption by the model. We used the *International Classification of Diseases, Ninth Revision* (*ICD-9*) and *International Classification of Diseases, Tenth Revision* (*ICD-10*) codes to determine the clinical history variables, including a diagnosis of AIDS/HIV, alcohol abuse, blood loss anemia, cardiac arrhythmias, chronic pulmonary disease, coagulopathy, systolic (congestive) heart failure, deficiency anemia, depression, diabetes with complications, diabetes without complications, drug abuse, fluid and electrolyte disorder, hypertension, hypothyroidism, liver disease, lymphoma, metastatic cancer, neurodegenerative disorders, obesity, paralysis, peptic ulcer disease, peripheral vascular disease, psychosis, pulmonary circulation disorders, renal failure, rheumatoid arthritis or collagen, solid tumor without metastasis, valvular disease, and weight loss. Furthermore, we

XSL•FO
RenderX

included the Elixhauser comorbidity index [7] to calculate the overall health care burden for each patient. In addition, the SDoH information included the average household size, Gini index as a measure of income inequality, median household income, and median gross rent, all linked to the University of Florida Health EHR based on year and ZIP code using the Agency for Healthcare Research and Quality SDoH database [8]. We removed all the missing data, so all patients had complete information for model development.

Model Development and Hyperparameter Optimization

We adopted a comprehensive strategy for model development using LR, extreme gradient boosting (XGB) [9], RF [10], support vector machine (SVM) [11] with linear and radial basis function (RBF) kernels (ie, linear support vector machine [LSVM] and SVM-RBF), and NN to capture predictive performance across a wide range of models for pharmacogenetic testing uptake prediction. LR was first developed due to its ability to capture linear relationships in the data and providing baseline performance. Similarly, the naïve Bayes (NB) model was developed due to its simplicity and effectiveness in high-dimensional spaces. However, considering LR's and NB's limitations in capturing complex nonlinear relationships, we trained tree-based models, including XGB and RF, given their ability to capture nonlinear interactions that may be critical to accurately predicting the pharmacogenetic testing uptake. LSVM and SVM-RBF were developed to capture high-dimensional complex interactions among input features. Finally, the NN was trained to explore more complex interactions among features that may be missed by traditional models.

To train the models, we randomly partitioned the data with a stratified 80/20 train/test split. To mitigate the risk of overfitting and get the best performance out of ML models, we conducted 5-fold cross-validation. For LR, we tuned the hyperparameter *C* with values of 0.01, 0.1, 1, and 10. To tune NB, we used smoothing parameters ranging from 10^{-9} to 10^{-5} with 10x increments. Both XGB and RF models were tuned with 100, 200, 300, 400, and 500 trees to explore the effect of different numbers of trees on performance. LSVM and SVM-RBF were optimized with *C* values equal to 0.01, 0.1, 1, and 10. Finally, NNs were trained with all possible combinations of various optimizers and learning rates. The optimizers included stochastic gradient descent [12], Adam [13], and Nadam [14], and learning rates ranged from 10^{-5} to 10^{-1} with 10x increases. The best hyperparameters were selected based on the highest area under the receiver operating characteristic curve (AUC) or *C*-statistics achieved on the training set during the cross-validation process.

We trained all the models using the best-performing hyperparameters and evaluated their performance on the test set. Notably, we used a balanced class weighting approach, assigning proportionally higher weights to the minority class, to decrease the risk of overfitting when training each of the models. As an additional analysis, we used the synthetic minority over-sampling technique (SMOTE) [15] with a 1:1 class ratio between minority and majority samples, creating a balanced dataset for model training and evaluation. To improve the performance and enhance generalizability of the models, we created a weighted probability-based ensemble classifier. We used a grid search optimization procedure, searching for the best combination of model weights, conditioned on having a total sum of weights equal to 1. The ensemble model achieving the highest AUC or *C*-statistics was selected as the final best model for pharmacogenetic testing uptake prediction.

Comprehensive Evaluation

We followed TRIPOD+AI (Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis + Artificial Intelligence) guidelines [16] to evaluate the performance of ML models. AUC or *C*-statistics demonstrates the discriminative ability of the model, considering the trade-off between sensitivity and specificity at different threshold values. DeLong test [17,18] is used to identify whether there is a statistically significant difference between AUC values. Accuracy provides the overall performance of the model by calculating the proportion of true negative and true positive cases compared to all the samples in the data. However, this measure may be misleading for rare events and not suitable for highly imbalanced datasets. To address this, we calculated specificity, which measures the model's ability to correctly identify true negative cases and recall or sensitivity, indicating the model's performance for identifying true positive cases. Since model performance may not be optimal, we used the Youden index [19-21] to obtain the best performing classification threshold for each model, where the highest value of "specificity+sensitivity-1" is achieved. To further evaluate model performance for real-world applications, we calculated the number needed to evaluate and predictive positives per 100 patients, showing how many predictions must be made to identify 1 actual positive case and the number of pharmacogenetic testing uptake predictions per 100 individuals, respectively. Moreover, we did stratification analysis, where pharmacogenetic testing uptake probabilities were categorized into 10 deciles in ascending order and the percentage of actual pharmacogenetic testing uptake in the data was identified in each decile to evaluate the ability of the model in identifying more uptakes in the higher strata. In addition, we used the Shapley Additive Explanations (SHAP) [22] analysis to report feature importance and identify the features that are most influential to pharmacogenetic testing uptake.

Results

Patient Characteristics

We used data from the University of Florida Health IDR with patients from a wide range of demographic and clinical backgrounds. The data included a total of 455,773 patients, 7645 (1.68%) with a recorded pharmacogenetic testing and 448,128 (98.32%) without. After removing 160,914 further patients who had no opioid prescription, there were 294,859 patients using opioids in the cohort. We further excluded patients with no race information and SDoH variables (after matching with the Agency for Healthcare Research and Quality database). Overall, the final cohort included 242,640 patients, where 3510 (1.45%) had a recorded pharmacogenetic testing uptake and 239,130 (98.55%) did not. The cohort had an average age of 58 (SD 17.47) years, a gender distribution comprising 41.49%

XSL•FO
RenderX

(100,670/242,640) as male participants and 58.51% (141,970/242,640) as female participants, and a racial distribution of 64.94% (157,567/242,640) White individuals, 28.77% (69,810/242,640) Black individuals, and 6.29% (15,263/242,640) belonging to other racial groups (ie, Hispanic, White Hispanic, Black Hispanic, Asian, Pacific Islander, American Indian, Multiracial, and other). In addition, the cohort had an average household size of 2.58 (SD 0.28), a Gini index of 0.45 (SD 0.05), and an average median income of US $46,324. Table 1 presents the key sociodemographic characteristics of patients in the cohort. Moreover, the distribution of patient characteristics in the training and test sets is provided in Table 2.

Table . Sociodemographic summary of patients.

Characteristics	Pharmacogenetic testing	Nonpharmacogenetic testing	*P* value[a]

Model Performance

The ROC curves of all models and their corresponding AUC or *C*-statistics with 95% CIs are provided in Figure 2. The ensemble model achieved the highest *C*-statistics of 79.61% using 0.7 and 0.3 weights for XGB and SVM-RBF, respectively. In contrast, NB achieved the lowest *C*-statistics at 72.49%. Other models had comparable *C*-statistics, equal to 75.38% (RF), 76.72% (LR), 76.46% (LSVM), 77.73% (SVM-RBF), 78.05% (NN), and 78.94% (XGB). Additionally, the DeLong test results indicated that there was a statistically significant difference ($P<.05$) between the *C*-statistics of the ensemble model and all other classifiers, showing its higher performance is less likely to be due to chance.

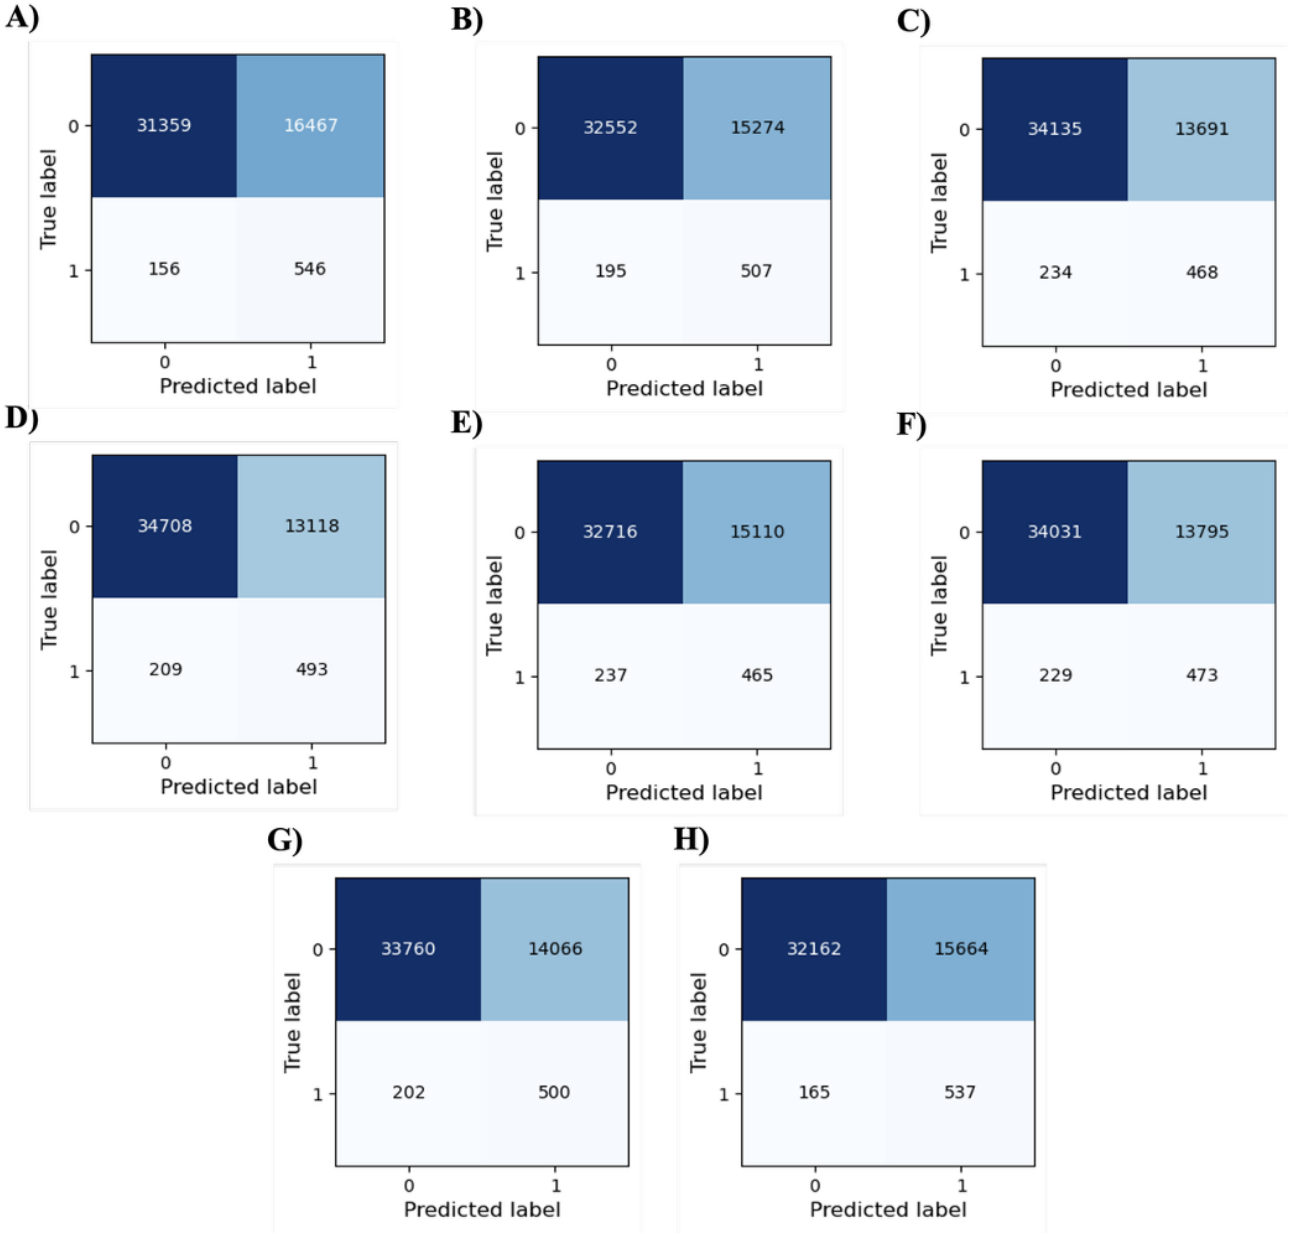

Figure 2. Receiver operating characteristic curves of developed models. AUC: area under the receiver operating characteristic curve, LR: logistic regression, LSVM: linear support vector machine, NB: naïve Bayes, NN: neural network, RF: random forest, SVM-RBF: support vector machine–radial basis function, XGB: extreme gradient boosting.

Since model performance was not optimal, we used the Youden index [19-21] to obtain the best performing classification threshold for each model. Figure 3 portrays the confusion matrices for all developed models based on their Youden index threshold. Table 3 provides a summary of performance for all developed models. Accuracy representing the proportion of correctly classified cases was highest for XGB (35,201/48,528, 72.54%), followed by RF (34,603/48,528, 71.31%), LSVM (34,504/48,528, 71.10%), and SVM-RBF (34,260/48,528, 70.60%). Other classifiers had 65% to 70% accuracy with the ensemble model having an accuracy of 67.38% (32,699/48,528).

Ensemble	67.38	76.50	67.25	99.49	3.31	79.61

[a]NPV: negative predictive value.

[b]PPV: positive predictive value.

[c]AUC: area under the receiver operating characteristic curve.

[d]NN: neural network.

[e]LR: logistic regression.

[f]RF: random forest.

[g]XGB: extreme gradient boosting.

[h]NB: naïve Bayes.

[i]LSVM: linear support vector machine.

[j]SVM-RBF: support vector machine–radial basis function.

To assess the model performance in identifying true positive cases (ie, those with a recorded pharmacogenetic testing uptake) and true negative cases (ie, those without a recorded pharmacogenetic testing uptake), recall and specificity were calculated. Recall values ranged from 66.24% (465/702) to 77.78% (546/702) with the NN model achieving the highest recall and the ensemble model achieving 76.50% (537/702). Specificity values ranged from 65.57% (31,359/47,826) to 72.57% (34,708/47,826), with the XGB model achieving the highest specificity. To further assess models' performance in distinguishing between true positives and true negatives, negative predictive value (NPV) and positive predictive value (PPV) were calculated. NPV values ranged from 99.28% (32,716/32,953) to 99.51% (31,359/31,515) with the NN model having the highest NPV, while PPV values ranged from 2.99% (456/15,575) to 3.62% (493/13,611) with XGB achieving the highest value. To evaluate model fairness, we used the ensemble model to calculate the performance metrics across different racial groups (Table 4). All the metrics, except NPV, exhibited notable variations across different racial groups with AUC ranging from 74.31% to 83.29%, and accuracy from 65.11% (20,592/31,629) to 79.15% (205/259).

Table . Performance metrics of developed models across racial groups[a].

Race group	Accuracy	Recall	Specificity	NPV[b]	PPV[c]	AUC[d]
White	65.11	75.27	64.95	99.44	3.11	77.73
Black	70.34	81.59	70.18	99.61	3.88	83.29
Multiracial	79.15	75.00	79.22	99.51	5.36	74.31
Asian	74.90	66.67	75.00	99.46	3.15	82.69
Other	78.27	60.87	78.45	99.47	2.94	82.32

[a]The performance metrics were reported using the testing data for the racial groups with at least 4 samples in the positive class (ie, pharmacogenetic testing uptake)

[b]NPV: negative predictive value.

[c]PPV: positive predictive value.

[d]AUC: area under the receiver operating characteristic curve.

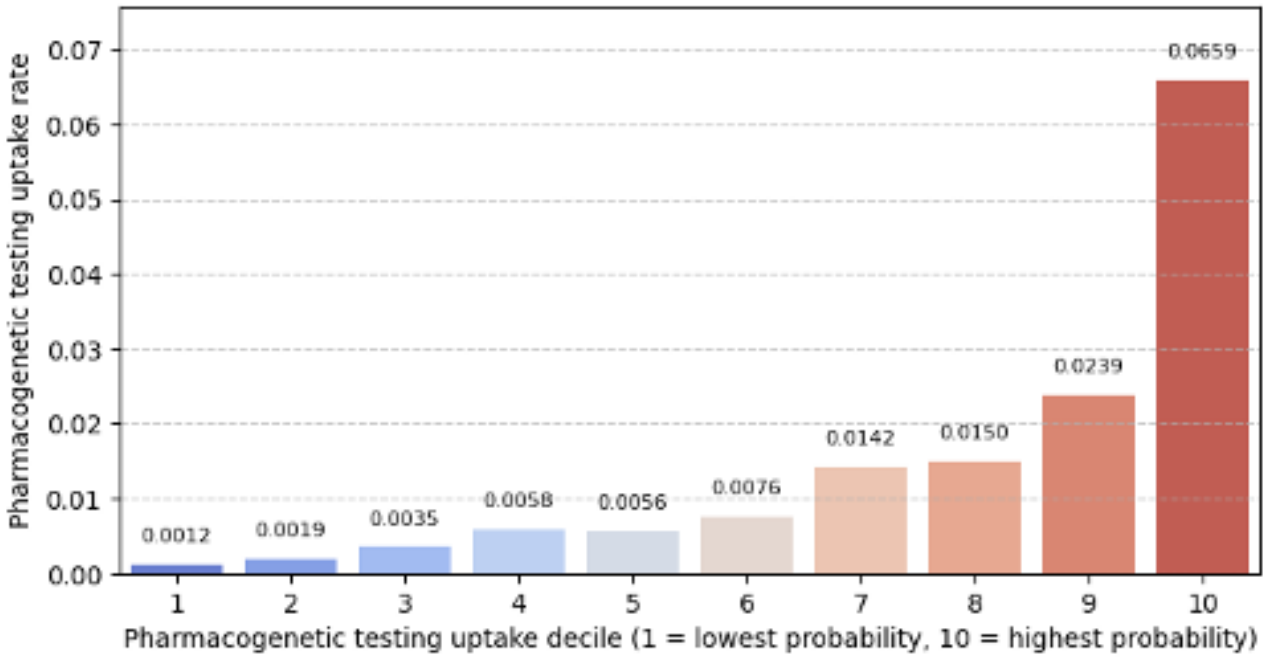
The SMOTE results, including ROC curves and performance metrics measured at the Youden index are provided in Multimedia Appendix 1. The results did not show any improvement, and the overall performance significantly reduced. The best-performing model was the ensemble model with 73.63% AUC, which is lower than the AUC without SMOTE (ie, 79.61%). All other models demonstrated a notable decrease

XSL•FO
RenderX

in AUC and other performance metrics, especially accuracy, specificity, and NPV.

Stratification analysis results are presented in Figure 4. The analysis was performed by dividing the predicted probabilities of pharmacogenetic testing uptake into deciles and calculating observed uptake rates within each to assess performance across the probability groups. The lowest decile was decile 1 with the lowest probability values, while decile 10 represented the highest probability values. Within each decile, observed uptake rates were calculated to plot against the probability deciles. The observed event rates demonstrated an increasing trend across the probability deciles (except for the 5th). The event rate in the highest probability decile was 6.59% (320/4853) while 0.12% (6/4853) in the lowest decile.

Figure 4. Stratification analysis for the probability of pharmacogenetic testing uptake.



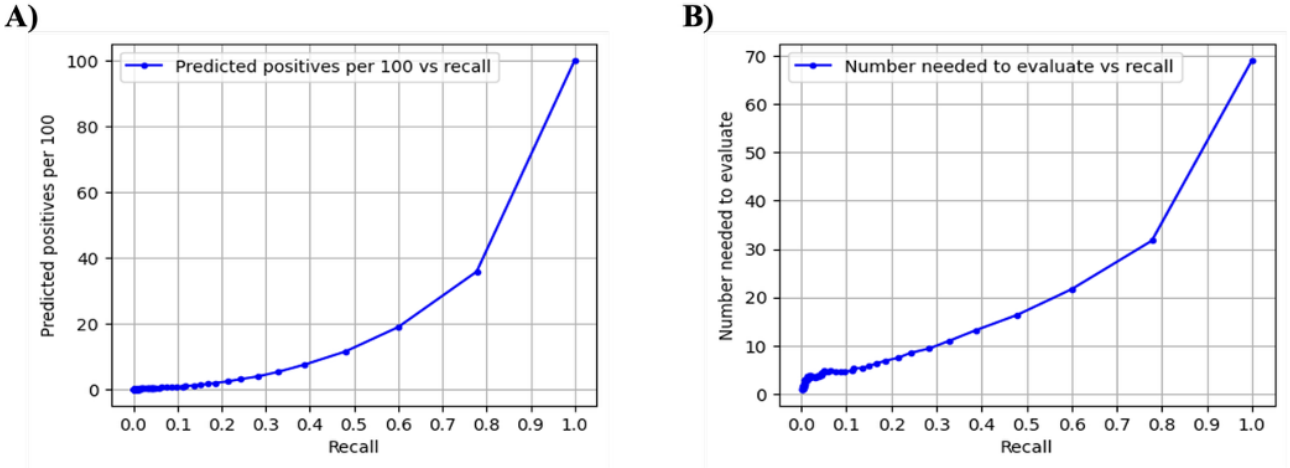


Figure 5 demonstrates the plots of recall values against predictive positives per 100 and the number needed to evaluate. Predictive positives per 100 represent the number of individuals per 100 who are predicted to undergo pharmacogenetic testing across different recall values. The number needed to evaluate indicates the number of individuals that need to be assessed by the model to find 1 true positive (ie, recorded pharmacogenetic testing uptake).

Figure 5. Recall versus (A) predicted positives per 100 and (B) number needed to evaluate.

SHAP analysis for feature importance using the XGB model has been shown in Figure 6. Age had the highest impact on pharmacogenetic testing uptake, where older patients are more likely to undergo pharmacogenetic testing. Hypertension and median household income were the next most important features, both associated with a higher likelihood of pharmacogenetic testing uptake. Other SDoH factors were among the top 7 important factors for pharmacogenetic testing uptake. In contrast, racial group variables (ie, Hispanic, Pacific Islander, and White Hispanic) had the lowest influence on the outcome.

Discussion

Principal Findings

ML has widely been used in pharmacogenetics, where investigations focused on using genetic information to predict drug response [23,24]. However, this is the first study to develop ML models for predicting probability of the use of pharmacogenetic testing using clinical and nonclinical factors such as demographics, comorbidities, medication history, and SDoH. It highlighted the potential of using ML methods to improve the use of pharmacogenetic testing, especially in pain management with opioid medications. The results of this study demonstrated that the ensemble model achieved the highest AUC compared to other models for pharmacogenetic testing uptake prediction. Although the XGB model, when evaluated at its Youden index, performed better than other models in terms of accuracy, recall, specificity, and NPV, we selected the ensemble model as the final classifier. This was because the ensemble model harnesses the strengths of both high-performing XGB and SVM-RBF models for prediction, ultimately improving the performance for pharmacogenetic testing uptake prediction. Overall, the ensemble model proves to be a viable tool for accurately predicting pharmacogenetic testing uptake, supporting more informed, data-driven decision-making.

Several methodological considerations must be addressed when interpreting these promising results. The primary goal of our study was to predict pharmacogenetic testing uptake, which is a clinically favorable outcome. In this scenario, NPV represents the ability of the model to correctly predict no pharmacogenetic testing uptake out of all no-uptake predictions. While our study showed a very high NPV (32,162/32,327; 99.49%), a low NPV could lead to negative consequences, including resource misallocation, alert fatigue, and missed clinical opportunities for those who need pharmacogenetic testing uptake for more effective treatment. In contrast, PPV represents the accuracy of the model in correctly predicting pharmacogenetic testing uptake out of all positive predictions. Thus, a lower PPV leads to lower trustworthiness of positive predictions and inadequate resource allocation to patients who are wrongly predicted to undergo pharmacogenetic testing. Since our data was highly imbalanced with a low percentage of patients having a recorded pharmacogenetic testing uptake, we used a balanced class weighting approach for final model development, assigning proportionally higher weights to the minority class (ie, pharmacogenetic testing uptake). However, the model achieved a much lower PPV compared to NPV. To address this issue, threshold moving was used as a strategy to balance clinical context and consequences of false positives compared to false negatives. Since lowering and raising the threshold can decrease or increase PPV and NPV, the optimal threshold should be selected based on the trade-off between minimizing the consequences of misallocated interventions (ie, higher NPV) and maximizing clinical opportunities for patient care (ie, higher NPV). Overall, the high NPV in our study based on the Youden index could be advantageous in decision-making, as it allows for the allocation of more resources and encouragement plans for patients predicted not to undergo pharmacogenetic testing.

We conducted a comprehensive feature importance analysis to enhance model interpretability and clinical acceptance. The SHAP value analysis using the XGB model highlighted the contribution of each feature to individual predictions, enhancing the model's clinical credibility and trustworthiness. The most influential features were age, hypertension, and household income, suggesting that these features require more attention for increasing pharmacogenetic testing uptake among patients. As mentioned, pharmacogenetic testing uptake is not necessarily due to opioid prescribing and could be due to prescribing of other medications and participation in a research project, potentially affecting the study results. Thus, although the results demonstrate the model's transparency and clinical use, more research is needed before integrating the model into a real-world decision support system. While the SHAP diagram ranks features based on their overall importance, it is crucial to examine critical factors for each patient on a case-by-case basis when making decisions.

Beyond individual prediction, we evaluated the model's ability to stratify patients into meaningful pharmacogenetic testing uptake categories. The uptake stratification analysis showed that the ensemble model effectively differentiated patients across pharmacogenetic testing uptake deciles, with higher uptake probabilities corresponding to higher observed uptake rates. Such an analysis can assist decision-makers in categorizing patients into different deciles based on their likelihood of pharmacogenetic testing uptake and prioritize those in lower deciles (less likely for the pharmacogenetic testing uptake) for optimal resource allocation and improved access to testing. It is important to recognize that stratification analysis often relies on predefined thresholds (ie, 10% in this study) to categorize probabilities into deciles, which may not be optimal for real-world decision-making.

The implementation of the pharmacogenetic testing uptake prediction model addresses the barriers to pharmacogenetic testing in opioid therapy. Our models accurately predict the likelihood of pharmacogenetic testing uptake but do not identify patients who clinically require or should receive testing (this was not the objective of this study). The models capture associations between demographic, clinical, and social determinants with testing behavior under current practice patterns, not clinical appropriateness. This distinction is important as the predictions reflect existing health care access and use patterns rather than evidence-based treatment recommendations. The predictive patterns we observed, favoring older patients with multiple comorbidities and greater health care access, largely reflect existing health care use behaviors and socioeconomic factors rather than clinical need or potential for improved outcomes. Consequently, this model should not be interpreted as a clinical decision support tool for determining which patients should receive pharmacogenetic testing. Rather, the primary applications of this model lie in health care operations and policy rather than direct clinical care. By providing the probability of pharmacogenetic testing uptake at the individual patient level, health systems can identify patients less likely to receive guideline-recommended testing and target barrier-reduction efforts. Insurers can use uptake predictions to forecast costs, allocate resources to underserved populations,

XSL•FO
RenderX

and design coverage policies that promote equitable access to precision medicine. Such predictions could be particularly useful for patients predicted to benefit from testing (not the focus of this study), allowing care teams to prioritize resources to promote uptake in this population. By quantifying uptake likelihood, the model supports data-driven decisions about resource allocation and coverage policies to move beyond trial-and-error opioid prescribing toward more systematic, evidence-based pain management.

Our study has several limitations. First, it is notable that although the study used PPV as a performance metric, it is highly dependent on outcome prevalence and may not generalize across different patient populations or clinical settings, reducing its applicability in decision-making. Second, this study used various clinical and demographic variables to develop more-informed ML models. However, the underrepresentation of certain racial groups, such as Hispanic and Pacific Islander, could potentially affect models' outcomes. This raises concerns about the bias and fairness issues, as ML models may exhibit lower performance for these groups compared to others. Third, while the study incorporated SDoH information as potential predictors of pharmacogenetic testing uptake, this information was based on ZIP code-level data, which may lack the necessary granularity required for precise prediction. Detailed individual-level data on variables such as income, education, and household size could enhance the model's reliability and improve the accurate identification of each feature's contribution to the outcome. Fourth, the model's performance may not directly translate to external populations with varying demographic and clinical backgrounds. Specifically, the model was trained on data from a single EHR system, including minority racial groups, and the results may not be applicable to other racial groups. Therefore, caution is warranted when interpreting the model's outcomes for these populations. Finally, some of the patients in the data who had a recorded pharmacogenetic testing uptake were part of a clinical trial where the cost of testing was covered. This would potentially influence the ability of the model to identify the true impact of patients' economic and income status on undergoing pharmacogenetic testing. To demonstrate the model's broader applicability, future work should focus on external validation using independent datasets from different health systems and identification of patients who are more likely to benefit from testing. This would help evaluate the model's robustness and clinical use for real-world decision-making.

Conclusions

Pharmacogenetic testing is a viable tool for matching patients' genetic profiles to suitable opioids for pain treatment. This study proposed ML models for pharmacogenetic testing uptake prediction using data from an EHR system. Results demonstrated that the ensemble ML model combining XGB and SVM-RBF classifiers achieved the highest AUC at 79.61%, making it a reliable prediction model for pharmacogenetic testing uptake prediction. Additionally, the uptake stratification and feature importance analysis using SHAP values further indicated the model's use for real-world applications. Following further validation using an external dataset, this model can be integrated into a data-driven decision support system, enabling health systems and insurers in resource planning and health equity assessment to optimize pain management and improve patient outcomes.

Abstract

Background: There is a lack of venous thromboembolism (VTE) risk prediction models based on gene expression information.

Objective: This study aimed to construct a VTE prediction model based on whole blood gene expression profiling, by performing a comprehensive analysis of 20 machine learning (ML) algorithms.

Methods: Two transcriptome datasets containing patients with VTE and healthy controls were obtained by searching the Gene Expression Omnibus database and used as the training and validation sets, respectively. Feature selection for model construction was performed on the training set using the least absolute shrinkage and selection operator and random forest, followed by the selection of the intersection of the chosen features. Subsequently, recursive feature elimination was applied to further refine the selected features. The selected features underwent model construction using 20 ML algorithms. The performance of the models was evaluated using various methods such as receiver operating characteristic and confusion matrix. The validation set was used for external model validation.

Results: The final results demonstrated that all algorithm models, except for k-nearest neighbor, exhibited good performance in VTE prediction. External validation data indicated that 9 algorithm models had an area under the curve greater than 0.75. The confusion matrix analysis revealed that the algorithm models maintained high specificity in the external validation cohort.

Conclusions: This study used 20 ML algorithms to construct VTE prediction models based on whole blood gene expression information, with 9 of these models demonstrating good diagnostic performance in external validation cohorts. The above models, when used in conjunction with D-dimer, may provide more valuable references for VTE diagnosis.

Introduction

Venous thromboembolism (VTE) is a prevalent thrombotic disorder in clinical practice, consisting primarily of deep venous thrombosis and pulmonary embolism. VTE remains a major global health burden, affecting approximately 10 million people annually and ranking among the most common vascular diseases worldwide [1]. The pathogenesis of VTE is considered to be

XSL•FO
RenderX

multifaceted and intricate, encompassing a multitude of factors, including but not limited to congenital genetic factors, malignancies, pregnancy in women, surgical trauma, and the use of oral contraceptives [2,3]. Despite the existence of relatively comprehensive prevention and assessment systems, the high mortality rate associated with VTE remains a significant concern among clinical practitioners. According to a study by Heit et al [4], the short-term (30-d) survival rate for deep vein thrombosis is approximately 94.5%, whereas the short-term survival rate for pulmonary embolism is only 66.8%.

In clinical practice, the diagnostic modalities most frequently used for VTE include D-dimer measurement, ultrasonography, and venography [5]. Among these methods, venography is considered the gold standard for diagnosing VTE. However, due to its invasive nature and the potential risk of contrast-induced renal impairment and allergic reactions, its clinical application is limited [6]. The limitations of ultrasonography include its subjectivity and difficulty in detecting deep venous thrombosis [7]. D-dimer testing is known to lack specificity, as elevated D-dimer levels may be caused by conditions such as infection, autoimmune diseases, pregnancy, and childbirth, leading to a higher likelihood of false positive results [8]. Therefore, it is crucial to construct a VTE risk prediction model with high performance.

With the advancement of science and technology, artificial intelligence (AI) has become a widely studied and highly regarded field in recent years, particularly in the medical domain. As one of the methods for achieving AI, machine learning (ML) algorithms have tremendous potential in medical research [9-11]. The aim of this study was to construct a VTE risk prediction model based on whole blood gene expression information, using a comprehensive analysis of 20 ML algorithms and external validation, with the goal of providing a reference for clinical decision-making and VTE prevention. These models are not only designed to differentiate between existing VTE cases and controls, but also intended to detect high-risk patients in early or asymptomatic stages, thereby serving as predictive tools that may assist in clinical decision-making before definitive diagnostic imaging is performed.

Methods

Data and Source

The gene expression data of patients with VTE and healthy controls were retrieved and downloaded from the Gene Expression Omnibus (GEO) database and used as the training and validation groups, respectively, in this study. The GSE19151 dataset was used as the training set, while the GSE48000 dataset served as the validation set. Both datasets were generated using the Affymetrix Human Genome U133 Plus 2.0 microarray platform (GPL570). Table 1 shows the basic information of the 2 datasets, GSE19151 and GSE48000. The GSE19151 dataset comprises gene expression data from 70 patients with VTE and 63 healthy controls [12]; the GSE48000 dataset contains gene expression data from 107 patients with VTE and 25 healthy controls [13]. Data analysis was performed using the *Scikit-learn* (sklearn) module in Python (version 3.6; Python Software Foundation).

Feature Selection

Least absolute shrinkage and selection operator (LASSO) regression analysis method was developed by Robert Tibshirani [14]. The principle of this method is to construct a penalty function to achieve the goal of shrinking regression coefficients and refining the model. While the principle of feature selection using random forest (RF) is mainly based on evaluating the contribution of each feature in the RF on each tree. In this study, we used the mean decrease in Gini impurity to measure feature importance in the RF model. The above 2 methods were used to select modeling features in the training set, and the intersection analysis was subsequently performed to reveal the features selected by both methods. This intersection strategy was designed to combine the strengths of both linear (LASSO) and nonlinear (RF) approaches and to reduce potential selection bias by focusing on consistently selected features. Although this intersection approach may sacrifice sensitivity, it enhances stability and reduces overfitting risk in high-dimensional settings. All feature selection procedures were performed exclusively on the training dataset to prevent information leakage from the validation data. The results were then visualized by a Venn plot.

Recursive Feature Elimination for Model Simplification

The main idea of the recursive feature elimination (RFE) method is to repeatedly construct models and remove the most significant features, ranking the features according to the order in which they are eliminated. To achieve a more streamlined model without compromising performance, the features selected by the aforementioned method were further screened and simplified using the RFE method in our study.

Construction of a VTE Risk Prediction Model Using 20 ML Algorithms

After completing the feature selection process, this study constructed the model using commonly used ML algorithms in the field, which included the following: adaptive boosting, artificial neural network, bagging, Bayesian ridge, decision tree, elastic net, extra tree (extremely randomized trees), gradient boosting, k-nearest neighbors (KNN) algorithm, LASSO, linear

XSL•FO
RenderX

LASSO, linear regression, logistic regression, naïve Bayes, RF, ridge regression, ridge cross-validation (ridge regression with cross-validation), stochastic gradient descent, support vector machine, and voting (voting classifier). The algorithm code is taken from the sklearn website [15]. All models were constructed using 5-fold cross-validation.

External Validation of the Model

In this study, GSE48000 was used as the external validation cohort to evaluate the generalization ability of the 20 ML models, ensuring the reproducibility of the model. The performance of the external validation was evaluated by the receiver operating characteristic (ROC) curve. All feature selection and model training were exclusively performed on the training dataset. The final trained models were then directly applied to the validation dataset without any retraining or adjustment, thereby ensuring a true external validation.

Decision Curve Analysis

To evaluate the potential clinical use of the constructed models, we performed decision curve analysis (DCA) across both internal and external evaluation settings. The net benefit for each model was calculated using the standard formula:

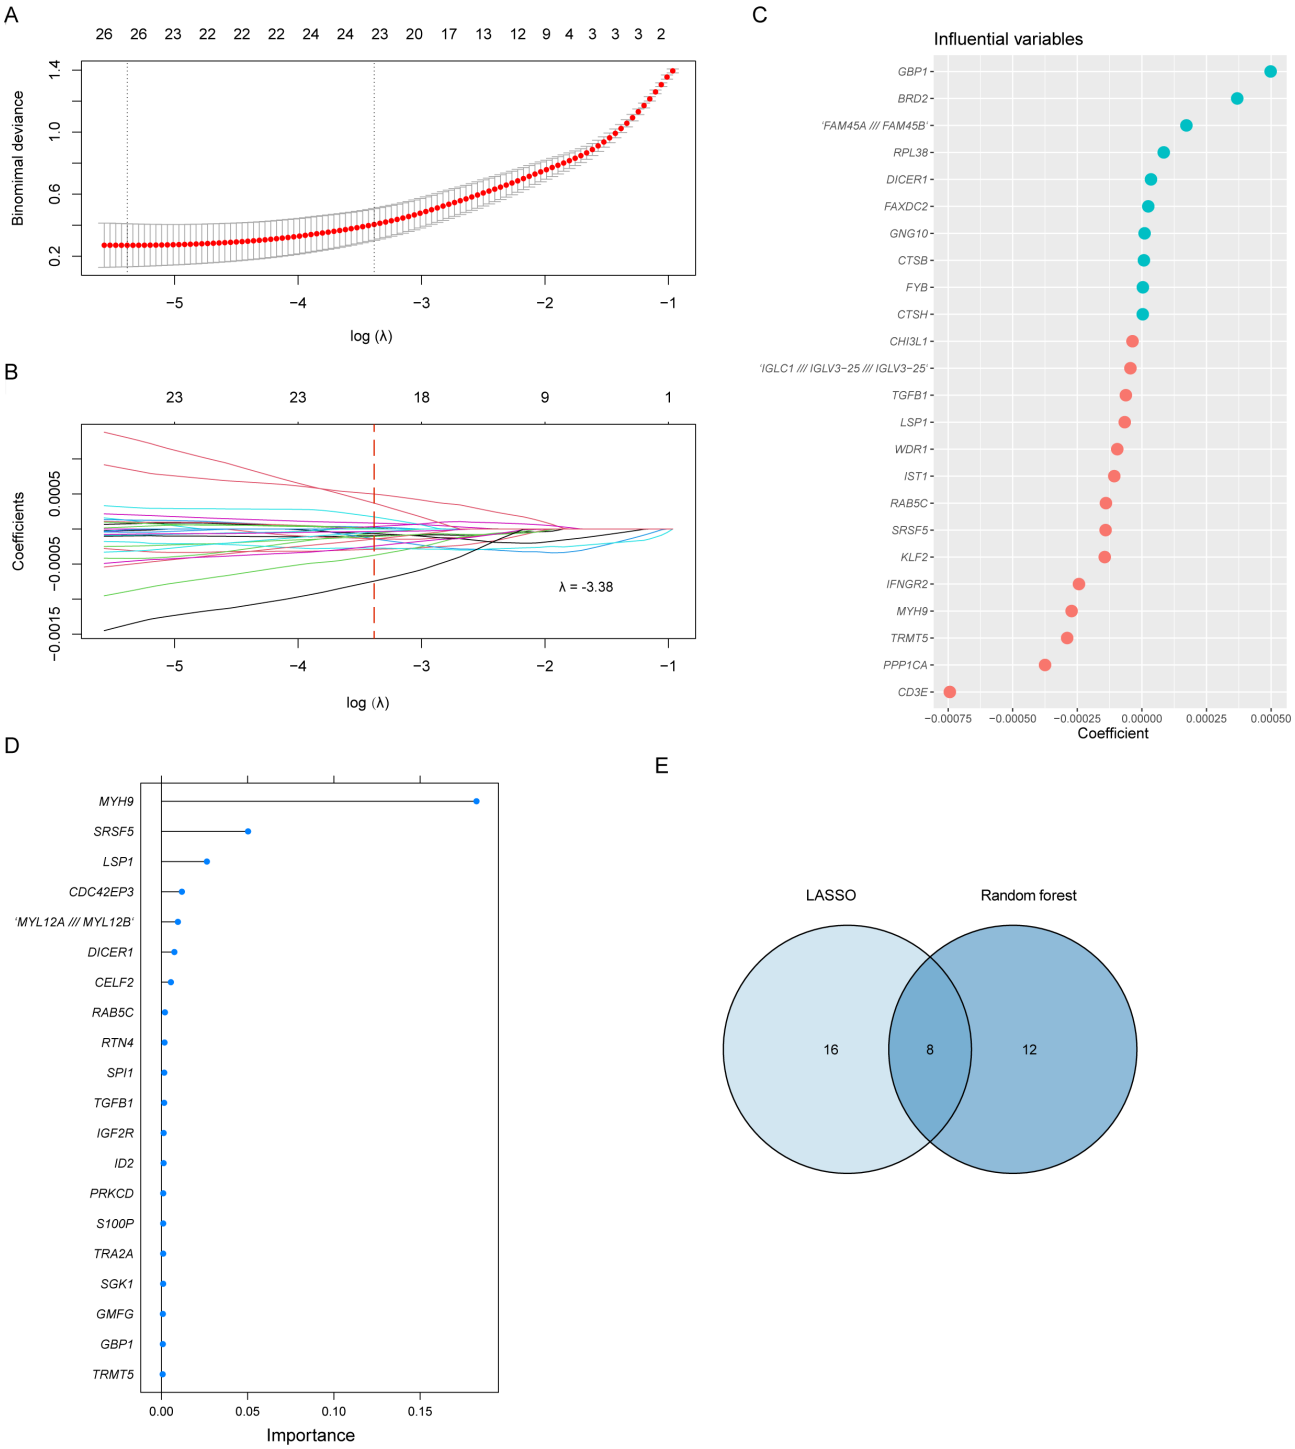
NetBenefit=TPN-FPN*PT1-PT

where TP and FP denote the numbers of true and false positives at a given threshold probability, and *n* is the total number of samples. DCA was conducted over a range of clinically relevant threshold probabilities from 0.05 to 0.5. The decision curves were generated using Python with appropriate packages compatible with sklearn.

Ethical Considerations

This study involved secondary analysis of publicly available, deidentified transcriptomic datasets obtained from the GEO database. As per institutional and GEO data usage policies, such analysis does not require ethical approval or informed consent. For more information, please refer to the GEO data policy [16].

Results



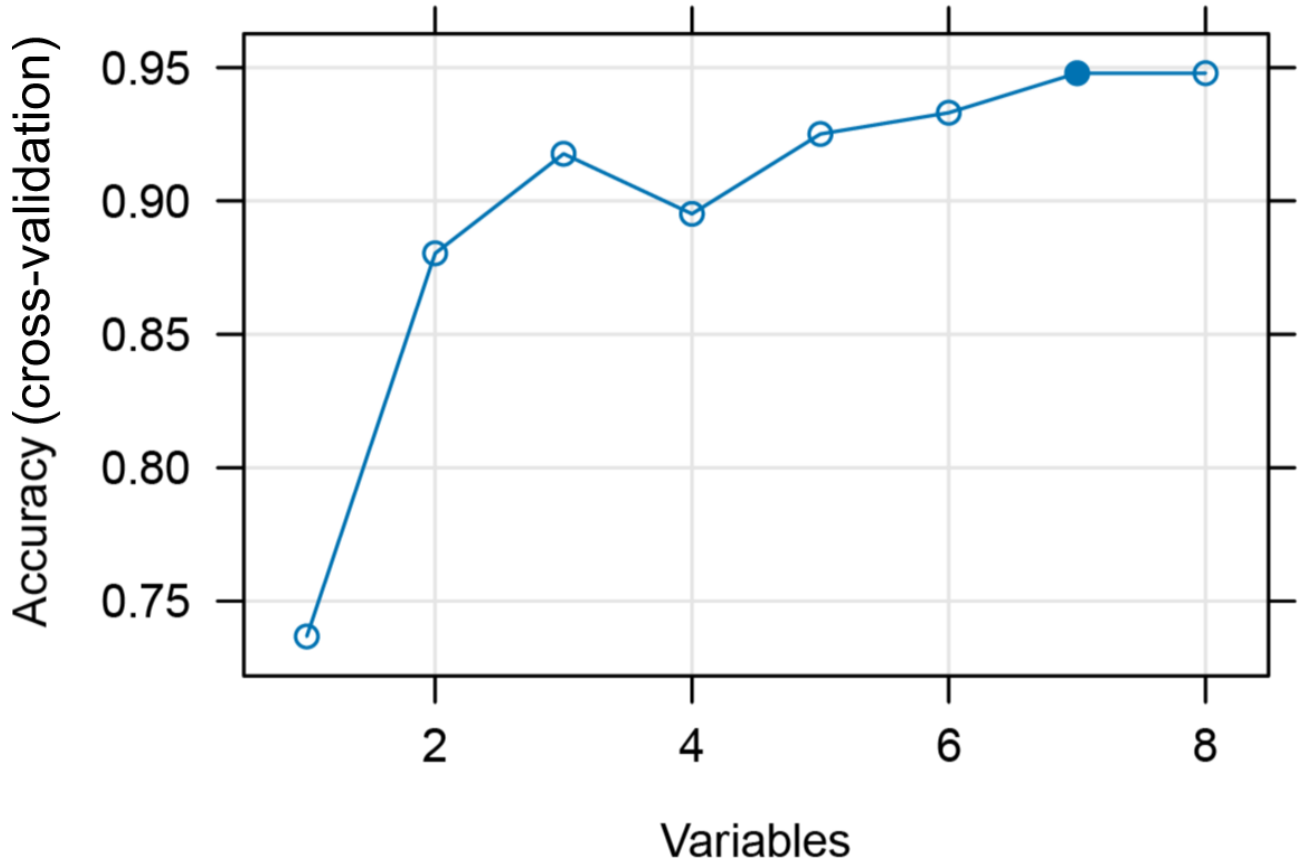
The Features Selected by LASSO Regression and RF

To determine the optimal regularization strength in LASSO regression, we used 5-fold cross-validation to identify the λ value corresponding to the “one standard error rule” (λ_1 se), which balances model simplicity and predictive performance. The regularization path was explored using the LASSO cross-validation function in sklearn, which automatically tests a logarithmic range of λ values. We selected 24 features corresponding to λ=−3.38.

The process of feature selection using LASSO regression is illustrated in Figure 1A and B and Figure 1C illustrates the 24 features selected by LASSO regression and their corresponding coefficients. The screening results of the RF are shown in Figure 1D, where the lollipop plot displays the 20 features selected by RF, with the length of the horizontal axis representing the corresponding importance of each gene. The Venn diagram in Figure 1E shows the intersection of the features selected by LASSO regression and RF methods. The 8 features selected by the intersection analysis are as follows: *TRMT5*, *TGFB1*, *SRSF5*, *RAB5C*, *MYH9*, *LSP1*, *GBP1*, and *DICER1*.

XSL•FO
RenderX

Figure 1. The process of selecting modeling features using least absolute shrinkage and selection operator (LASSO) and random forest methods.



Recursive Feature Elimination to Simplify the Model

The above 8 features were further simplified using the RFE algorithm, which reduces costs and improves the generalizability of the model while removing redundant features. Figure 2 displays the results of the RFE calculations using a line graph. The results indicate that the accuracy of the model in cross-validation no longer significantly changes when the number of features is reduced to 7. The features further refined by the RFE algorithm include 7 genes: *SRSF5*, *MYH9*, *LSP1*, *RAB5C*, *TGFB1*, *DICER1*, and *GBP1*.

XSL•FO
RenderX

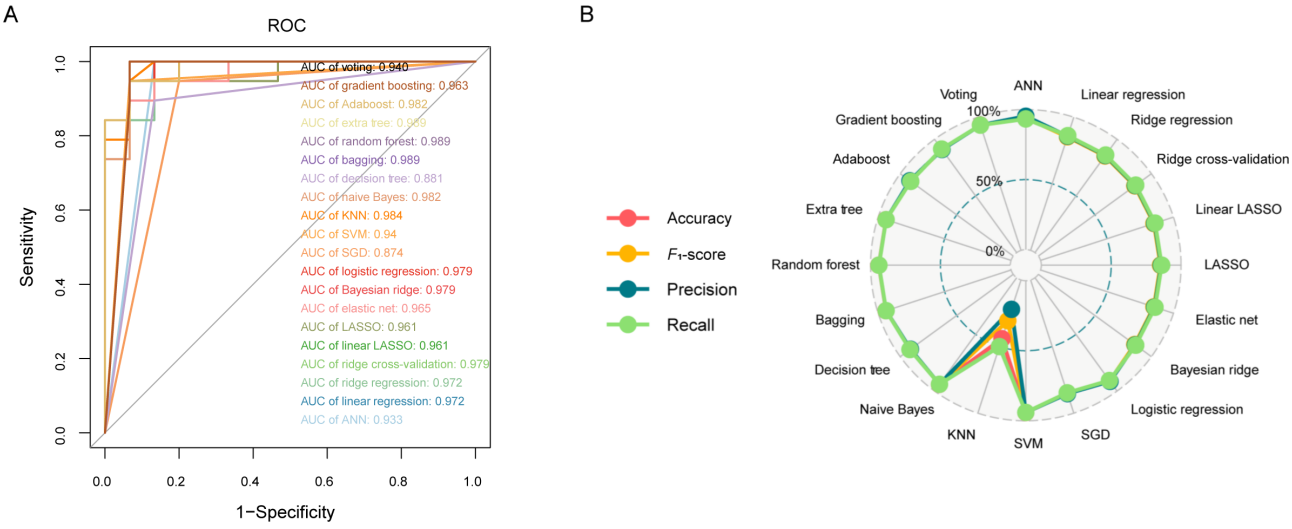
Figure 2. The process of simplifying modeling features using recursive feature elimination.

Construction of VTE Risk Prediction Models Using 20 ML Algorithms

Based on the 7 features selected, our study used 20 commonly used ML algorithms to construct the models and used 5-fold cross-validation to improve the accuracy of model evaluation and reduce random error. Figure 3A displays the ROC curves and corresponding area under the curve (AUC) values of the 20 ML models using different colored lines. Figure 3B depicts a radar chart showcasing the accuracy, F_1-score, precision, and recall for 20 ML algorithms. The accuracy reflects the proportion of correctly predicted samples; precision reflects the proportion of actual VTE cases among samples classified as VTE by the model; recall represents the proportion of VTE cases correctly classified by the model among all VTE samples; the F_1-score is a value used to comprehensively evaluate both recall and precision. As illustrated in Figure 3, most models exhibit an AUC value greater than 0.9, and the radar chart based on 4 parameters evaluation indicates that, except for the KNN model, all other ML models can make relatively accurate predictions for VTE.

XSL•FO
RenderX

Figure 3. Performance comparison of 20 machine learning models using receiver operating characteristic (ROC) curves and radar plots. (**A**) ROC curves and area under the curve values based on 20 machine learning models. (**B**) Radar plots comparing accuracy, F_1-score, precision, and recall across models. AdaBoost: adaptive boosting; ANN: artificial neural network; KNN: k-nearest neighbor; LASSO: least absolute shrinkage and selection operator; SGD: stochastic gradient descent; SVM: support vector machine.



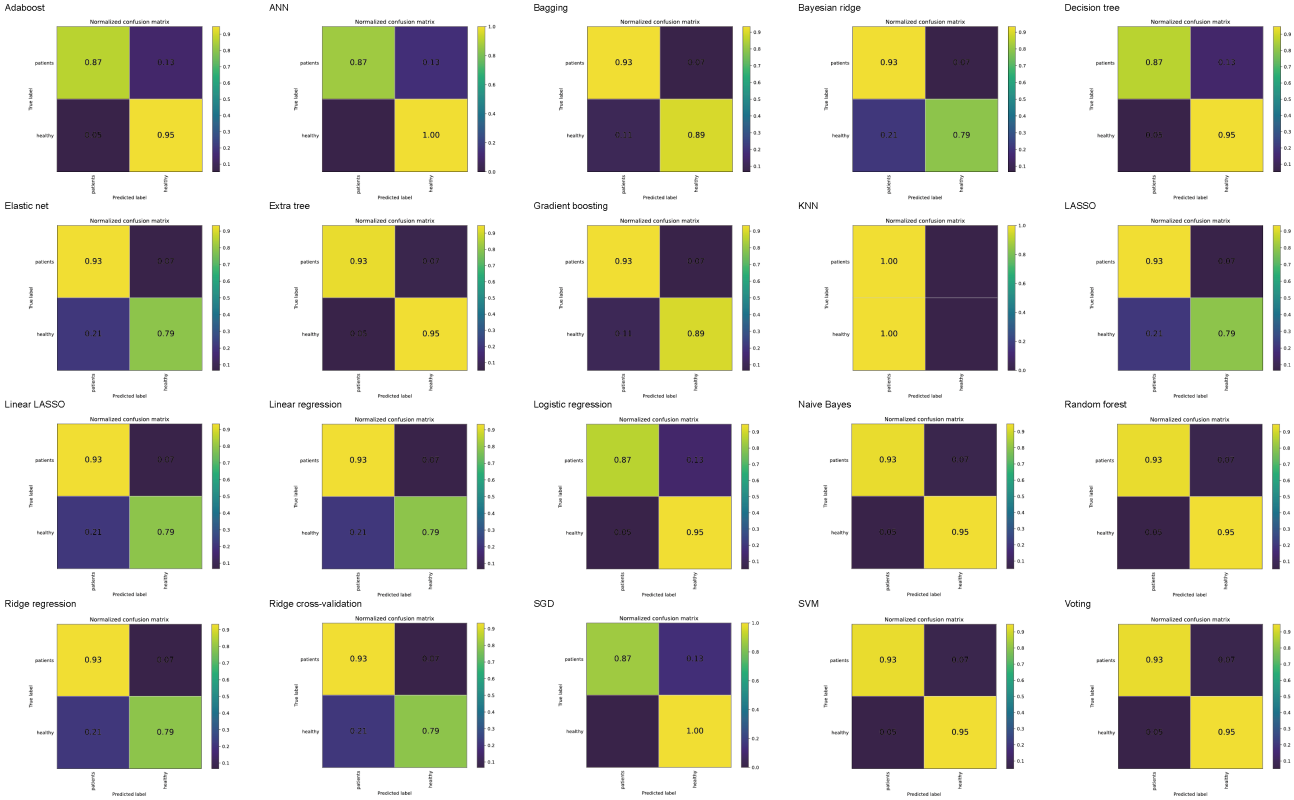


Figure 4 presents the confusion matrices for 20 ML algorithms, among which the sensitivity of all models except for the KNN fluctuated between 87% and 93%, and the specificity fluctuated between 79% and 100%. The findings above indicate that, with the exception of the KNN model, the remaining 19 ML models possess favorable predictive efficacy for VTE. Multimedia Appendix 1 presents the DCA for 20 ML algorithms.

Figure 4. Confusion matrices for 20 machine learning algorithms. The top-left cell indicates the true positive, top-right indicates the false negative, bottom-left indicates the false positive, and bottom-right indicates the true negative. AdaBoost: adaptive boosting; ANN: artificial neural network; KNN: k-nearest neighbor; LASSO: least absolute shrinkage and selection operator; SGD: stochastic gradient descent; SVM: support vector machine.

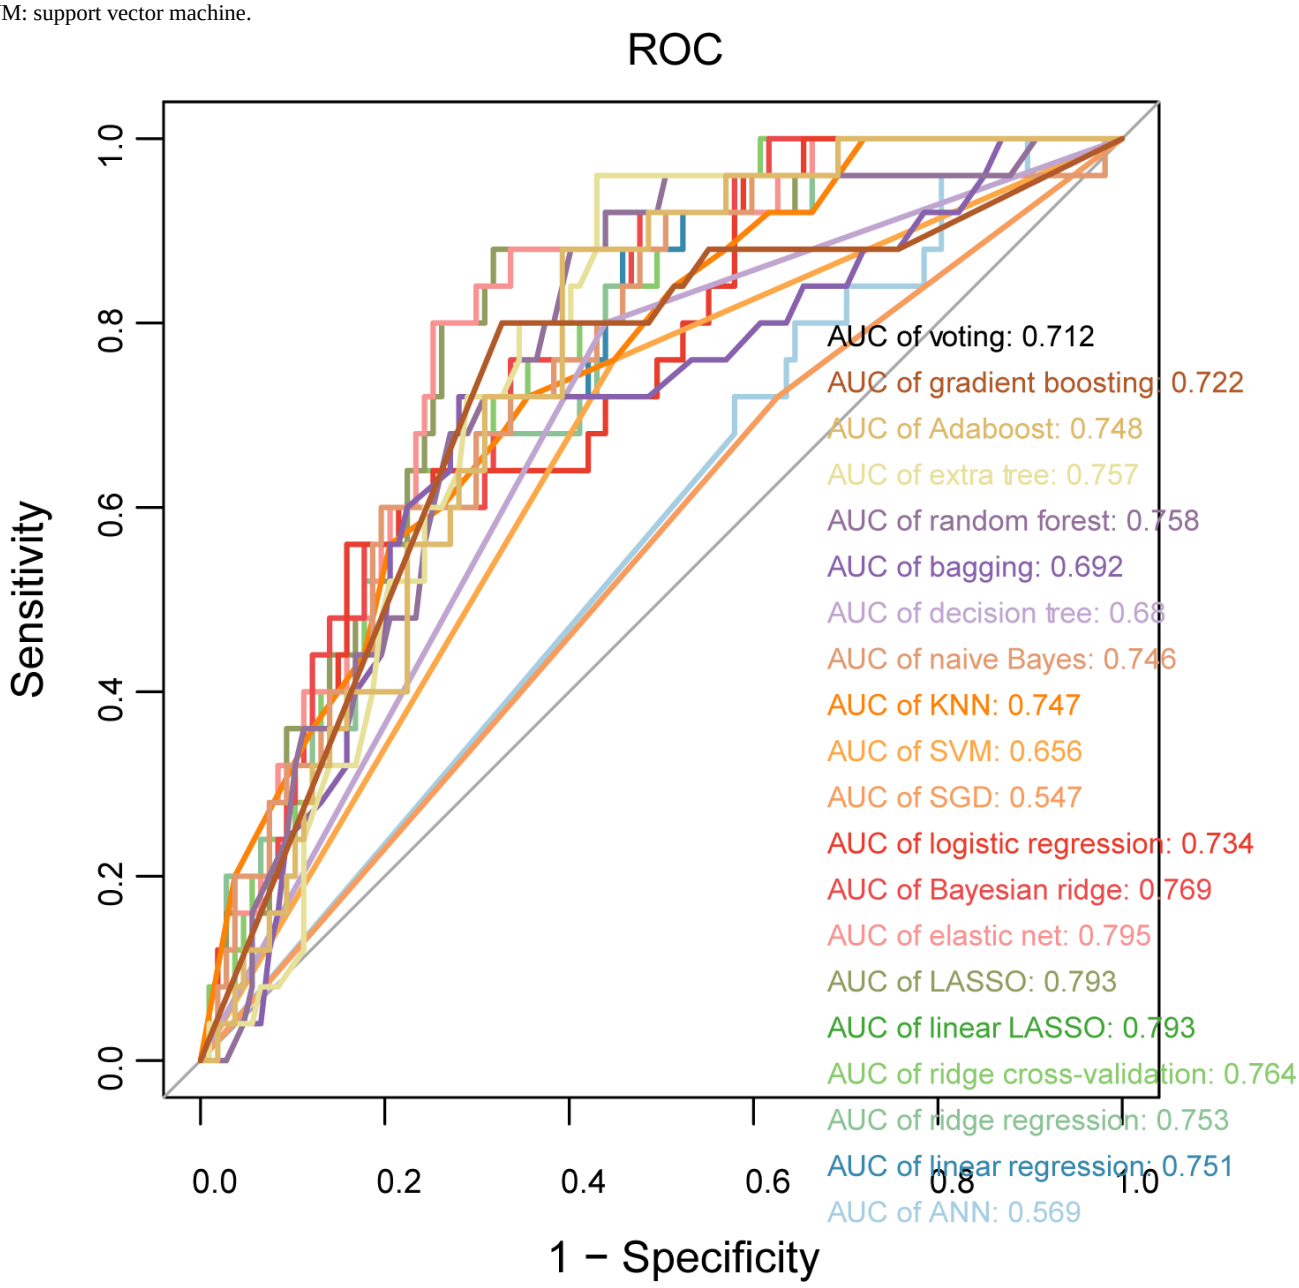
External Validation of the Models

To ensure the reproducibility and generalizability of the model, this study performed external validation of the 20 ML models using the GSE48000 dataset. Figure 5 illustrates the ROC curves and the corresponding AUC based on the external validation dataset. The results revealed a significant decrease in the AUC of all models during external validation, but the AUC of the following 9 models remained above 0.75: extra tree, RF, Bayesian ridge, elastic net, LASSO, linear LASSO, ridge cross-validation, ridge regression, and linear regression. This result indicates that the predictive performance of the models

XSL•FO
RenderX

corresponding to the 9 ML algorithms is relatively stable, and they exhibit strong generalizability.

Figure 5. The external validation receiver operating characteristic (ROC) curve plot for the 20 machine learning models. AdaBoost: adaptive boosting; ANN: artificial neural network; KNN: k-nearest neighbor; LASSO: least absolute shrinkage and selection operator; SGD: stochastic gradient descent; SVM: support vector machine.



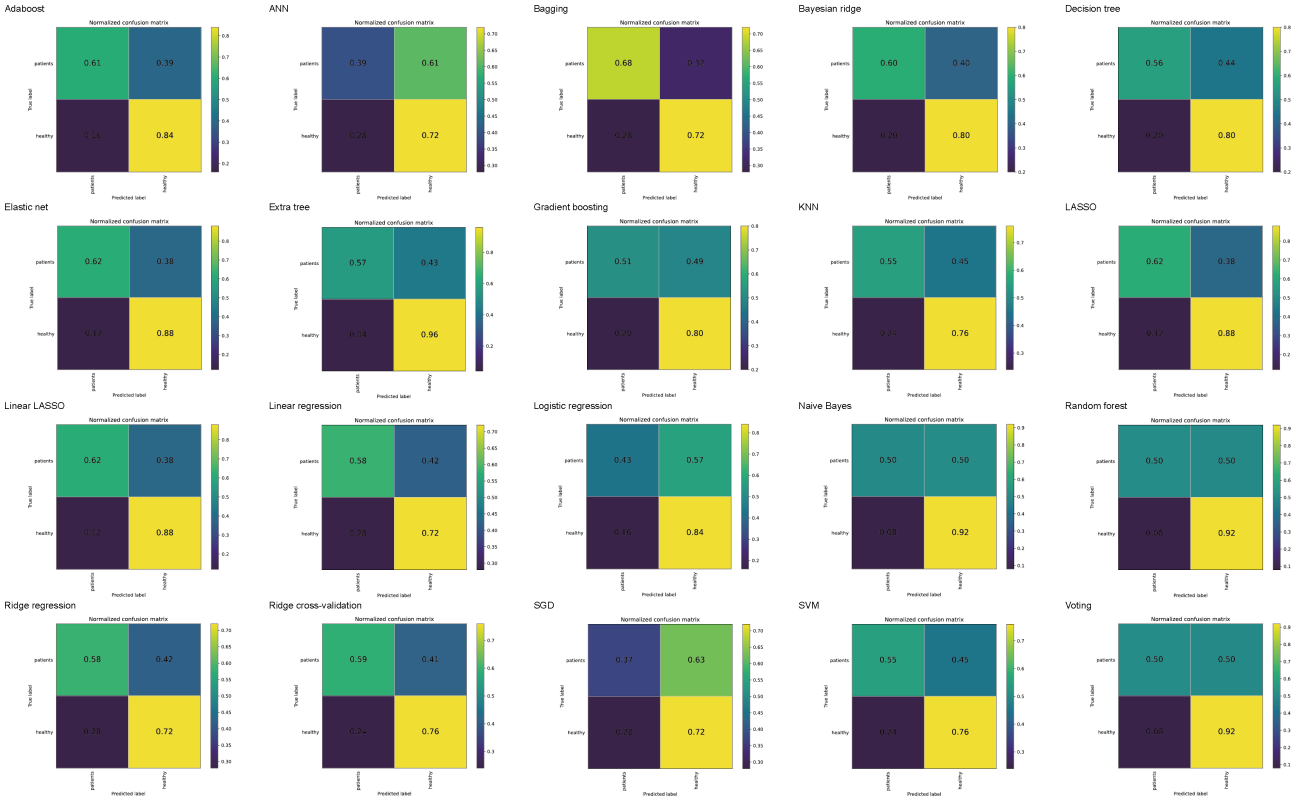


Figure 6 displays the confusion matrices of 20 ML algorithms during external validation. The sensitivity of all models decreased significantly, ranging from 37% to 62%, whereas the specificity remained relatively stable, fluctuating between 72% and 96%. These findings suggest that the models still possess high specificity in the external validation dataset. Multimedia Appendix 2 displays the DCA for 20 ML algorithms in external validation.

AdaBoost: adaptive boosting; ANN: artificial neural network; KNN: k-nearest neighbor; LASSO: least absolute shrinkage and selection operator; SGD: stochastic gradient descent; SVM: support vector machine.

Discussion

Principal Findings

As a rapidly advancing field in computer science, AI has the ability to process vast and intricate medical data for the diagnosis and prediction of potential clinical outcomes [17]. ML, as a component of AI, can extract valuable information and patterns from vast amounts of data through learning and analysis, thereby achieving AI [18]. In the medical field, ML is predominantly used for medical image analysis, disease prediction and risk assessment, health care management, decision support, and drug development, among other applications [19-21]. As the first study to construct a VTE risk prediction model based on whole blood gene expression information, the present research aims to empower the diagnosis of VTE through the use of ML algorithms. It is important to note that the current model was trained and validated only on healthy controls versus patients with VTE and does not assess its discriminative ability in populations with other inflammatory or thrombotic conditions. On the other hand, the external validation results indicate that the models developed in this study are characterized by low sensitivity and high specificity. According to the "No free lunch" theory proposed by Wolpert et al [22], a perfect model does not exist. In other words, if a certain ML model outperforms other algorithms in a particular evaluation metric, it must inevitably sacrifice some performance in other metrics as a trade-off. As a result of this constraint, it is not feasible to determine a flawless ML model as the conclusive outcome. Rather, a more fitting model is chosen by taking into account a comprehensive evaluation of diverse metrics.

At present, the models used for predicting the risk of VTE occurrence are predominantly built upon clinical features. Darzi et al [23] conducted a meta-analysis that included 17 studies, which indicated that VTE may be associated with the following factors: advanced age, elevated C-reactive protein levels, increased D-dimer and fibrinogen levels, tachycardia, thrombocytosis, leukocytosis, fever, leg swelling, malignancy, immobility, infection, and so on. In 2021, Pandor et al [24] conducted a systematic review of 24 VTE risk assessment models to evaluate their predictive performance. The results showed that the *C*-statistic was generally less than 0.7 for all models, with only a few models having favorable *C*-statistics (>0.8). Among these models, sensitivity fluctuated between 12% and 100%, while specificity varied between 7.2% and 100%. Based on the aforementioned findings, the study suggests that the existing VTE risk prediction models have generally weak predictive ability and high heterogeneity, and thus, does not recommend the use of any specific prediction model. Our study is an exciting and innovative attempt to discover modeling features based on gene expression analysis. In the internal validation, most of the models developed in this study exhibited good performance (AUC >0.90), while in the external validation, the data showed that 9 models had an AUC greater than 0.75. Considering clinical applicability, we note that models such as LASSO, ridge regression, and linear regression not only performed well in external validation (AUC >0.75), but also offer the advantages of simplicity, computational efficiency, and interpretability. In contrast, while ensemble models such

XSL•FO
RenderX

as RF and extra trees demonstrated strong predictive power, their black-box nature may pose challenges for clinical interpretation. As such, we believe interpretable models like LASSO may be better suited as candidates for further clinical translation.

The current clinical diagnostic techniques for VTE primarily consist of D-dimer testing, ultrasonography, and venography [5]. Each of the aforementioned 3 diagnostic methods has their own limitations to varying degrees. In 2016, Crawford et al [25] conducted a meta-analysis of 1585 patients from 4 studies and reported that the sensitivity and specificity of D-dimer for diagnosing VTE were 80% to 100% and 23% to 63%, respectively. Although the sensitivity and specificity of D-dimer for diagnosing VTE may vary slightly across different studies, they generally exhibit high sensitivity and low specificity. The main reason for this phenomenon is that various conditions, including trauma, malignancy, and inflammation, can cause an elevation in D-dimer levels, leading to high sensitivity but low specificity in diagnosing VTE using D-dimer testing [26]. In summary, an isolated increase in D-dimer levels is insufficient to establish a diagnosis of VTE. The VTE risk prediction model developed in this study complements D-dimer well in terms of diagnostic performance. Moreover, since both tests use blood samples, they are highly compatible with each other in combination. The high specificity of the developed models, when used in combination with D-dimer testing, can assist clinicians in excluding false-positive cases that may be misdiagnosed as VTE by D-dimer alone. Furthermore, the joint use of the models and D-dimer has the potential to improve the diagnostic accuracy of VTE in patients. This patient population should be regarded as a priority for VTE prevention by clinicians to optimize VTE prevention measures, avoid wastage of medical resources, and achieve greater precision in VTE prevention. A potential clinical application of the gene expression-based models could be in a 2-step diagnostic pathway. For instance, the models may be used as a secondary triage tool following a positive D-dimer result to improve specificity and reduce unnecessary imaging procedures. Alternatively, they could be selectively applied to high-risk subpopulations (eg, older patients, postoperative individuals, or those with cancer) where D-dimer alone may be insufficiently specific. On the other hand, despite encouraging AUC values and specificity in external validation, we acknowledge that the observed sensitivity levels (ranging from 37%-62%) limit the standalone diagnostic capability of the models. This performance pattern may partly result from the significant class imbalance in the validation dataset and potential dataset shift. Importantly, the models are not intended to replace established diagnostic tools, but rather to serve as adjunctive decision aids. Their high specificity may be particularly valuable in ruling out false positives among D-dimer positive patients. Future work may consider ensemble approaches, risk stratification frameworks, or combining these models with clinical parameters to improve sensitivity while preserving specificity.

This study has several limitations. First, the modeling and external validation data were obtained from 2 sequencing cohorts in the GEO database (n=133; n=132), which may be considered a relatively small sample size, and the external validation set also exhibited a notable class imbalance (107 VTE vs 25 controls), which may have contributed to the observed reduction in sensitivity. Second, as the model has not yet been implemented in clinical practice, and both datasets were derived from US populations without detailed ethnicity annotations in the GEO records, its predictive performance in real-world clinical settings and across diverse ethnic backgrounds remains unverified. Third, we used a sequential feature selection strategy combining LASSO, RF, and RFE, aiming to enhance robustness and reduce dimensionality. However, we acknowledge that this approach may introduce complexity and the potential risk of overfitting, particularly when applied to algorithms that already incorporate internal regularization mechanisms. This redundancy could limit generalizability. Moreover, although some of the best-performing models in this study are inherently nontransparent, several interpretable models (eg, LASSO and logistic regression) were also included to ensure interpretability and practical applicability. In future work, we aim to further improve the explainability of complex models by using Shapley Additive Explanations or Local Interpretable Model-Agnostic Explanations–based interpretation frameworks, thereby enhancing their clinical interpretability and reliability. Future studies may benefit from alternative feature selection strategies, such as embedded or end-to-end feature learning methods within specific model frameworks, and from incorporating formal calibration analyses to improve clinical interpretability and reliability.

Conclusions

The current study used ML algorithms to construct 20 VTE risk prediction models based on whole blood gene expression information. Notably, 9 of these models displayed favorable diagnostic performance in the external validation dataset. Thus, these models, in conjunction with D-dimer, have the potential to serve as a valuable reference for the clinical diagnosis of VTE.

Abstract

Background: Accurate classification and grading of lymphoma subtypes are essential for treatment planning. Traditional diagnostic methods face challenges of subjectivity and inefficiency, highlighting the need for automated solutions based on deep learning techniques.

Objective: This study aimed to investigate the application of deep learning technology, specifically the U-Net model, in classifying and grading lymphoma subtypes to enhance diagnostic precision and efficiency.

Methods: In this study, the U-Net model was used as the primary tool for image segmentation integrated with attention mechanisms and residual networks for feature extraction and classification. A total of 620 high-quality histopathological images representing 3 major lymphoma subtypes were collected from The Cancer Genome Atlas and the Cancer Imaging Archive. All images underwent standardized preprocessing, including Gaussian filtering for noise reduction, histogram equalization, and normalization. Data augmentation techniques such as rotation, flipping, and scaling were applied to improve the model's generalization capability. The dataset was divided into training (70%), validation (15%), and test (15%) subsets. Five-fold cross-validation was used to assess model robustness. Performance was benchmarked against mainstream convolutional neural network architectures, including fully convolutional network, SegNet, and DeepLabv3+.

Results: The U-Net model achieved high segmentation accuracy, effectively delineating lesion regions and improving the quality of input for classification and grading. The incorporation of attention mechanisms further improved the model's ability to extract key features, whereas the residual structure of the residual network enhanced classification accuracy for complex images. In the test set (N=1250), the proposed fusion model achieved an accuracy of 92% (1150/1250), a sensitivity of 91.04% (1138/1250), a specificity of 89.04% (1113/1250), and an F_1-score of 90% (1125/1250) for the classification of the 3 lymphoma subtypes, with an area under the receiver operating characteristic curve of 0.95 (95% CI 0.93 - 0.97). The high sensitivity and specificity of the model indicate strong clinical applicability, particularly as an assistive diagnostic tool.

Conclusions: Deep learning techniques based on the U-Net architecture offer considerable advantages in the automated classification and grading of lymphoma subtypes. The proposed model significantly improved diagnostic accuracy and accelerated pathological evaluation, providing efficient and precise support for clinical decision-making. Future work may focus on enhancing model robustness through integration with advanced algorithms and validating performance across multicenter clinical datasets. The model also holds promise for deployment in digital pathology platforms and artificial intelligence–assisted diagnostic workflows, improving screening efficiency and promoting consistency in pathological classification.

KEYWORDS

deep learning; lymphoma; U-Net; pathological subtype; automated diagnosis; medical image analysis; artificial intelligence; AI

Introduction

Lymphoma is a malignant tumor originating in the lymphatic system, with a steadily increasing global incidence. On the basis of its clinical features and histological characteristics, lymphoma can be classified into various subtypes, with Hodgkin lymphoma and non-Hodgkin lymphoma being the most prevalent [1,2]. Accurate classification and grading of lymphoma are critical for clinical treatment and prognostic evaluation [3]. Conventional diagnostic approaches rely on the visual

XSL•FO
RenderX

examination of tissue sections by pathologists under a microscope, a process that is labor-intensive and influenced by subjective judgment. Diagnostic accuracy is often limited by the pathologist's expertise and technical proficiency and by sample quality [4,5]. With the advancements in medical imaging and computational technology, artificial intelligence (AI) techniques such as deep learning have been gradually introduced into medical image analysis [6], showing great potential in automated image segmentation, feature extraction, and disease diagnosis [7].

Deep learning, particularly convolutional neural networks (CNNs), has achieved significant success in medical image analysis, offering new approaches for automated lymphoma diagnosis [8,9]. Among them, the U-Net architecture, a specialized form of convolutional neural network, has demonstrated notable effectiveness in segmentation tasks by enabling precise delineation of lesion areas and producing high-quality inputs for subsequent classification and grading [7,10]. Despite these advancements, several challenges persist in the automated analysis of lymphoma histopathology images [11]. Minimal morphological differences between subtypes and the inherent complexity of lesion regions increase classification difficulty [12]. Moreover, the performance of existing deep learning models remains highly dependent on large volumes of annotated data. Limited datasets and overfitting remain a pressing challenge [13,14]. Therefore, developing a deep learning model that can effectively improve the accuracy of lymphoma pathological image classification and grading has become a critical research direction in medical image analysis [15].

Recent studies have shown that pathological diagnosis of lymphoma is associated with considerable interobserver variability, with consistency coefficients (κ values) ranging between 0.55 and 0.70. Misclassification frequently occurs among morphologically similar subtypes, including follicular lymphoma (FL) and mantle cell lymphoma (MCL). Previous research has applied CNNs and other machine learning models for automatic classification of pathological images, such as Inception-V3–based models for breast cancer image analysis or residual network (ResNet)–based models for predicting lung cancer types and molecular features. These studies highlight the substantial potential of AI in assisting pathological diagnosis. However, research specifically focused on the classification of lymphoma pathological subtypes remains limited and often restricted to individual subtypes or single-model architectures. There is still a lack of systematic validation of hybrid deep learning models for fine-grained classification across multiple lymphoma subtypes.

This study aimed to achieve automated segmentation, subtype classification, and grading of lymphoma pathological images by integrating deep learning techniques, including the U-Net model, attention mechanisms, and residual networks (ResNet), all of which are established deep learning approaches [4]. This research has significant clinical and practical implications. Deep learning models have the potential to significantly improve the accuracy of lymphoma pathological diagnosis, reduce human-related diagnostic errors, and provide more objective and consistent diagnostic results [16]. Automated systems can also process large volumes of pathological slides at high speed, offering an efficient auxiliary tool for pathologists, accelerating the lymphoma diagnostic workflow, and reducing patient waiting times. Moreover, precise identification and grading of lymphoma subtypes may contribute to the development of personalized treatment strategies, allowing for more tailored treatment plans and improving treatment outcomes and survival rates [17].

The primary objective of this study was to explore and evaluate the application of deep learning techniques in classifying and grading lymphoma pathological subtypes. An automated image analysis system was constructed based on the U-Net architecture. Through deep learning methods such as image segmentation, feature extraction, and classification prediction, this study sought to accurately identify different lymphoma subtypes and achieve effective grading. In addition, this study used cross-validation techniques to assess the stability and accuracy of the proposed model. A comparative analysis with traditional pathological diagnostic methods was conducted to verify the model's clinical feasibility. Ultimately, this study aimed to provide effective technical support for the early diagnosis of lymphoma, advancing the application and development of AI into the field of medical pathology.

Methods

Data Collection and Preprocessing

A total of 620 high-quality histopathological images representing 3 major lymphoma subtypes were collected from The Cancer Genome Atlas (TCGA) and The Cancer Imaging Archive (TCIA). The number of samples per subtype was approximately balanced. Inclusion criteria required complete pathological annotations and clearly defined tissue structures. Images exhibiting severe artifacts, incomplete labeling, or low resolution were excluded. All slides were stained with hematoxylin and eosin and resized to 512 × 512 pixels to ensure model compatibility. No stain normalization was applied.

The image data in this study primarily consisted of standardized lymphoma tissue section images captured using high-resolution digital scanners and stored in TIFF or PNG format. Image preprocessing steps included denoising, contrast enhancement, and image normalization. Gaussian filtering was used to reduce noise, whereas histogram equalization was used to enhance contrast and improve the visibility of lesion regions. All images were uniformly cropped and resized to ensure consistent input data quality for the network. These preprocessing procedures were implemented to improve data quality and model classification accuracy (Figure S1 in Multimedia Appendix 1).

Feature Extraction From Image Data

This study used the U-Net architecture to conduct image segmentation, enabling precise identification of lesion areas and the generation of high-quality segmentation maps. Subsequently, ResNet was used for feature extraction and classification. The residual learning structure in ResNet enabled the capture of deep pathological features from the segmented images, thereby improving classification accuracy and supporting automated grading of lymphoma subtypes. During

XSL•FO
RenderX

training, 5-fold cross-validation was used to optimize model hyperparameters and reduce the risk of overfitting. The Adam optimization algorithm was used in conjunction with a learning rate decay strategy to enhance training stability and convergence (Figure S2 in Multimedia Appendix 1). The training dataset was randomly divided into 3 subsets, with 70% allocated to the training set and 15% each allocated to the validation and test sets.

Model Construction and Training

The model used in this study was based on the standard U-Net architecture, enhanced by integrating ResNet residual modules and attention mechanisms. To achieve subtype classification and grading of lymphoma, the combined use of U-Net and ResNet allowed for effective image segmentation and deep feature extraction. The cross-entropy loss function was used, and the Adam optimizer with an initial learning rate of 0.001 was adopted to ensure stable model convergence. A learning rate decay mechanism was applied to progressively adjust the learning rate, improving model convergence and training stability (Figure S3 in Multimedia Appendix 1). The model can automatically extract and learn features of different lymphoma subtypes and grades from images through this training process, enabling efficient classification and accurate grading of new images.

To further justify the selected model architecture, a comparative evaluation was conducted against several classic CNN frameworks widely used in medical image analysis (Table S1 in Multimedia Appendix 1). Fully convolutional networks offered advantages in simplicity and computational efficiency but demonstrated limited sensitivity in detecting small lesions and boundary structures in pathological images. SegNet achieved reliable semantic segmentation performance but often resulted in detail loss during the upsampling stage due to its deconvolutional design. DeepLabv3+, which uses atrous convolution and multiscale feature fusion, significantly improved segmentation accuracy but introduced increased model complexity, computational cost, and reduced interpretability in clinical settings. In contrast, the hybrid deep learning framework proposed in this study—featuring a U-Net backbone, ResNet residual connections, and attention mechanisms—achieved a better balance among segmentation accuracy, training stability, and interpretability. It is particularly well-suited for the classification and grading of lymphoma images characterized by blurry boundaries and high subtype heterogeneity.

Model Evaluation and Optimization

Model performance was evaluated using multiple metrics, including accuracy, recall, precision, and F_1-score, to assess classification effectiveness. The receiver operating characteristic curve and the area under the curve (AUC) were used to further evaluate the model's discriminative ability. To prevent overfitting and enhance generalization capability, the model incorporated dropout layers and data augmentation techniques. Augmentation strategies included image rotation, translation, and flipping, which increased the diversity of the training data and improved model robustness. During training, the performance on the validation set was monitored in real time to identify and preserve the model with the best generalization ability for subsequent testing (Figure S4 in Multimedia Appendix 1).

Traditional Pathology Baseline and Metric Sources

To establish a reproducible baseline for comparison with traditional pathological diagnosis, we conducted a randomized crossover washout reading study. Six board-certified pathologists with ≥5 years of professional experience were enrolled. From the 620 cases included in this study, a subset of 180 (29%) was stratified by subtype, center, and diagnostic difficulty to form the reading set. The reference standard (ground truth) was determined by 2 senior pathologists independently, with any discrepancies resolved by a third expert adjudicator. Each reader completed case interpretation under 2 study arms: unassisted and AI-assisted (with U-Net–generated segmentation masks and posterior probability and attention cues displayed). The order of arms and case sequence was computer randomized, with a washout period of at least 2 weeks, and the readers were blinded to previous assessments. The primary endpoint was case-level accuracy. Secondary endpoints included sensitivity, specificity, F_1-score, AUC, mean average precision (mAP), weighted κ, and single-case reading time. Segmentation performance was evaluated using case-level dice coefficient and intersection over union (macro- and microaveraged). Classification and grading were assessed at the whole-slide image level; patch-level probabilities were aggregated via attention pooling, and classification thresholds were determined on the validation set using the Youden index and subsequently fixed for the test set. For statistical analyses, the DeLong test was used to compare AUCs, whereas the McNemar test was applied to paired proportions (accuracy, sensitivity, and specificity). The 95% CIs were estimated via the bias-corrected and accelerated bootstrap method (1000 iterations), and Holm-Bonferroni correction was used for multiple comparisons.

Image Data Analysis Methods

Image data analysis focused on 2 primary tasks: image classification and subtype grading. First, deep CNNs based on U-Net and ResNet were used to analyze histopathological slide images. These architectures effectively captured cellular morphology and tissue-level structural features, enabling accurate differentiation among lymphoma subtypes. For subtype grading, the analysis extended beyond subtype identification to include the evaluation of lymphocyte distribution, morphological variation, and lesion heterogeneity within the image (Figure S5 in Multimedia Appendix 1). To ensure accuracy in classification and grading, the image analysis methods integrated traditional medical imaging analysis techniques with deep learning approaches using automated and manual annotation strategies.

Statistical Analysis and Result Validation

Following model construction, statistical methods were used to validate its performance comprehensively. In addition to conventional classification evaluation metrics, a confusion matrix was used to analyze the model's prediction results in detail, identifying errors such as false positives and false negatives. The average accuracy of the model was calculated through multiple repeated experiments, and k-fold cross-validation was used to ensure the robustness of the results.

XSL•FO
RenderX

Furthermore, 2-tailed *t* tests or ANOVA were conducted to analyze differences among models, ensuring that the selected model demonstrated superior performance in lymphoma subtype classification and grading tasks (Figure S6 in Multimedia Appendix 1).

Feature Analysis and Subtype Differentiation

Feature analysis was conducted using the U-Net and ResNet architectures to extract and differentiate cellular and tissue-level characteristics from histopathological images. Key features, including tumor cell morphology, tissue architecture, and cellular distribution, were effectively captured to support the accurate identification of lymphoma subtypes and enhance understanding of histological variation among them.

U-Net provided precise segmentation of lesion regions, whereas ResNet enabled efficient feature extraction and supported deeper network training. The combination of these 2 architectures facilitated the recognition of complex spatial relationships between cells and tissues, contributing to improved classification accuracy.

In addition, statistical analysis methods are crucial in evaluating model performance. Metrics such as sensitivity, specificity, precision, and recall were calculated to comprehensively assess the performance of different models in classifying lymphoma pathological subtypes. Confusion matrices and receiver operating characteristic curve analyses were also used to evaluate each model's predictive effectiveness, providing deeper insights into the strengths and limitations of the models in identifying various subtypes.

Ethical Considerations

All histopathological images used in this study were obtained from publicly available databases (TCGA project and TCIA). All datasets underwent strict anonymization procedures before public release and complied with the relevant ethical policies and data sharing regulations. No new patient samples were collected during the course of this research. Therefore, additional ethics approval was not required. This study adhered to the ethical principles outlined in the Declaration of Helsinki and its subsequent amendments. Access to the image data is available under the open access policies of TCGA and TCIA or upon request from the corresponding author.

Results

Effect Analysis of Data Preprocessing and Image Quality Enhancement

In this study, the quality of lymphoma pathological slide images directly affected the performance of the deep learning model. Therefore, multiple image preprocessing techniques, including Gaussian filtering for noise reduction, histogram equalization, and image normalization, were applied to improve image quality. Figure 1 illustrates the visual differences between raw and preprocessed images. In the preprocessed images, background noise was substantially reduced, edges appeared sharper, and lesion regions became more prominent. These enhancements facilitated clearer visualization of pathological features and improved input consistency for model training. During subsequent deep learning model training, the preprocessed images exhibited higher segmentation accuracy and lower error rates. A detailed dataset analysis was also conducted to assess sample distribution. Table 1 presents the number of samples in the training, validation, and test sets, along with the specific distribution of each class, providing crucial data support for subsequent model training.

Figure 1. Visualization of data preprocessing effects. This figure showcases the effects of different preprocessing stages on the same lymphoma image slide: (A) the original image; (B) the denoised image processed through Gaussian filtering; (C) the contrast-enhanced image after histogram equalization; and (D) the normalized image, showing clearer edges and details.

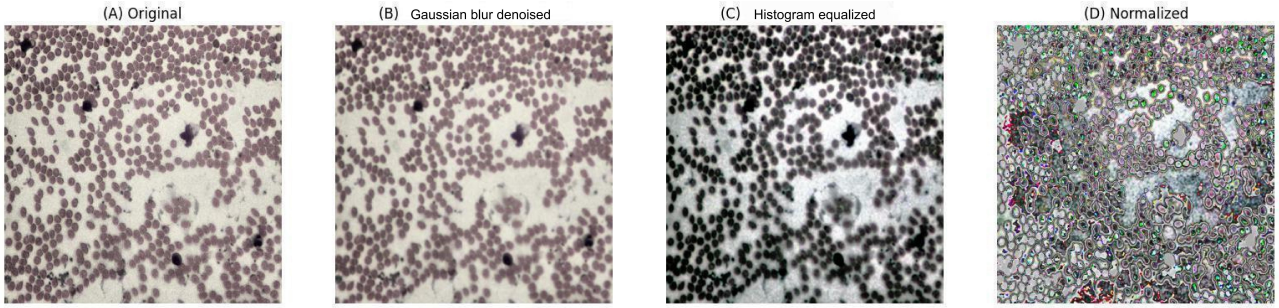

Table . Distribution of dataset samples—the number of samples in the training, validation, and test sets along with their corresponding categories.

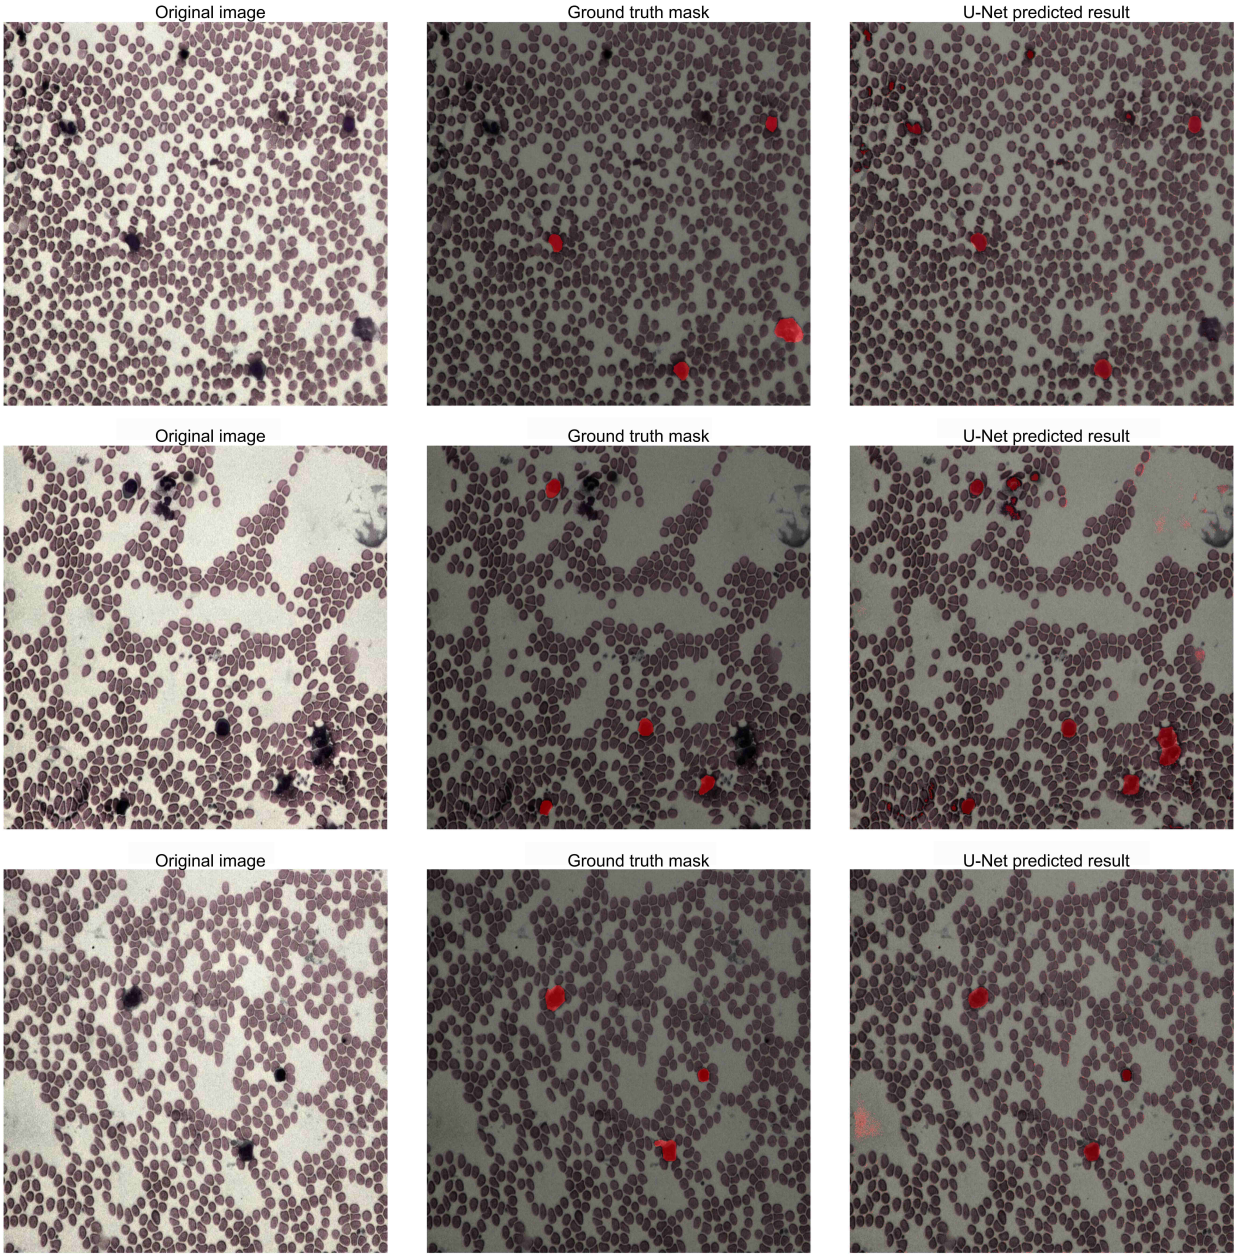
Dataset	Number of immune cell samples	Number of epithelial cell samples	Number of matrix cell samples	Total
Training set	4000	3000	2500	9500
Validation set	500	400	350	1250
Test set	500	400	350	1250
Total	5000	3800	3200	12,000



XSL•FO
RenderX

To evaluate the impact of image preprocessing on model performance, a comparative experiment was conducted using both unprocessed and preprocessed images. The results showed that unprocessed images achieved only 77.12% (964/1250) accuracy in the segmentation task, with poor edge detection quality, slower model convergence, and a substantially higher error rate. In contrast, preprocessed images achieved a segmentation accuracy of 84.4% (1055/1250), demonstrating clearer delineation of lesion boundaries and exhibiting a noticeably faster training speed (Table S2 in Multimedia Appendix 1). These findings highlight the importance of preprocessing steps such as Gaussian filtering, histogram equalization, and normalization in significantly enhancing segmentation performance.

Performance of the U-Net Model in Image Segmentation

The application of the U-Net architecture in image segmentation demonstrated strong performance in accurately segmenting lesion areas in lymphoma pathological slides, significantly outperforming traditional methods. Figure 2 illustrates the performance of the U-Net model in segmentation tasks. During training and validation, the U-Net model achieved a segmentation accuracy exceeding 85.04% (1063/1250) on the test set, with a recall rate of 88% (1100/1250). These results confirmed the capability of U-Net in handling complex medical images, particularly lymphoma pathological slides. Effective segmentation of lesion areas provided high-resolution input data for downstream tasks, including subtype classification and pathological grading.

Figure 2. U-Net image segmentation results. This figure shows the performance of the U-Net model on the image segmentation task for lymphoma pathological slides. Segmented regions are marked in different colors to distinguish lesion areas from healthy tissue.

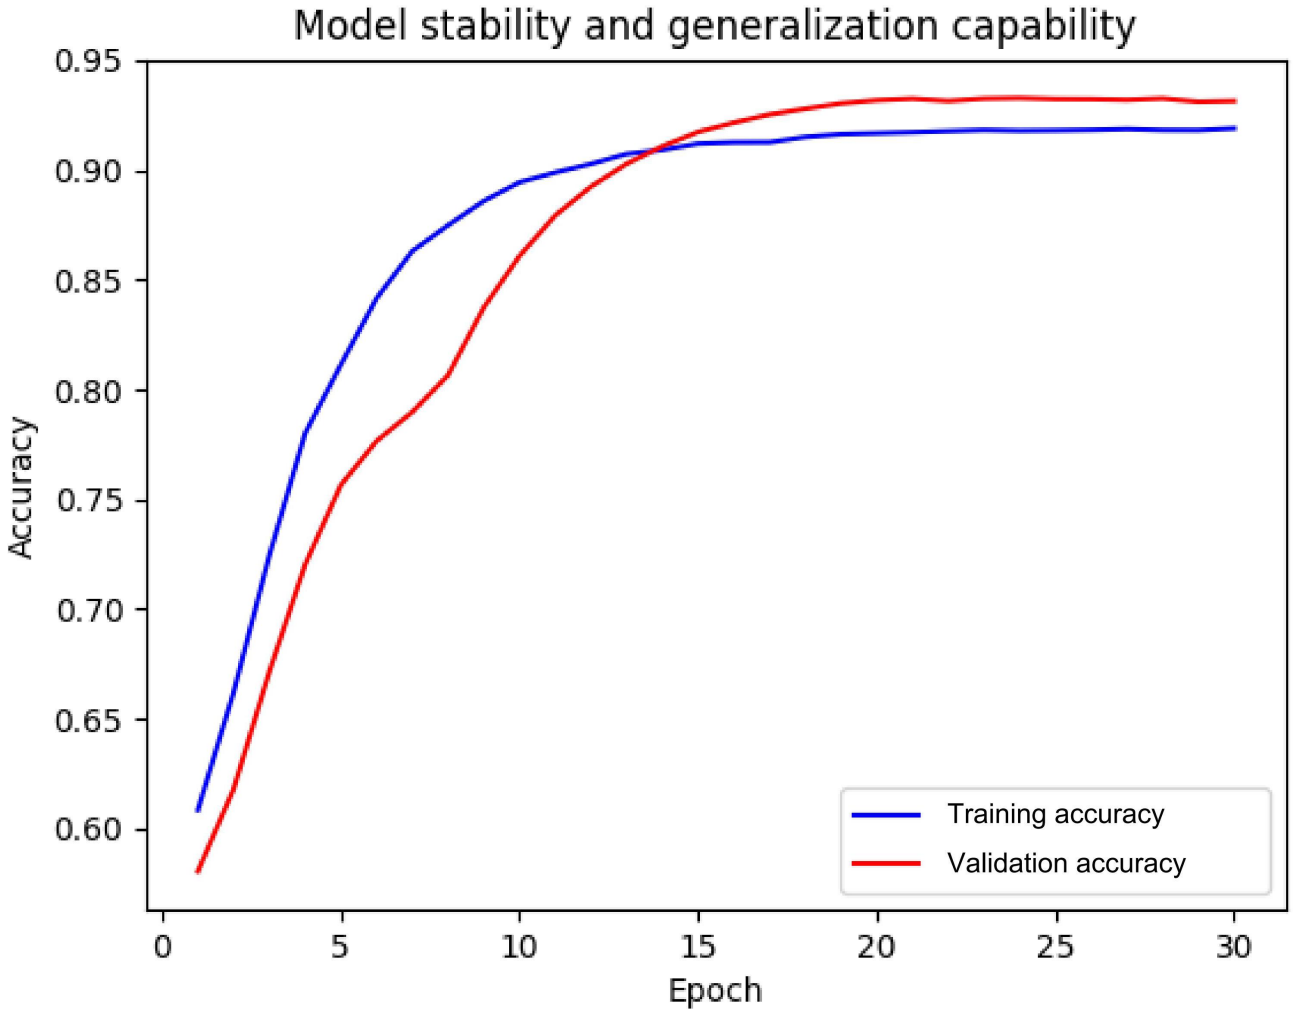
Analysis of the Synergistic Effects of Attention Mechanisms and ResNet

Integrating attention mechanisms with ResNet for feature extraction and classification markedly enhanced model performance. Figure 3 shows the results of lymphoma subtype classification using the combined model. Incorporating the attention mechanism enabled the network to concentrate on diagnostically relevant image regions, thereby reducing errors in differentiating morphologically similar subtypes. Meanwhile, the residual structure of ResNet effectively mitigated the vanishing gradient problem and facilitated the learning of complex image features. Compared with traditional CNNs, the classification accuracy of the proposed deep learning model increased from 81.04% (1013/1250) to 91.04% (1138/1250), representing an improvement of approximately 10 percentage points.

Figure 3. Analysis of attention mechanism and residual network (ResNet) synergy. This figure compares model performance in subtype classification tasks: (A) results of a traditional convolutional neural network and (B) results after incorporating attention mechanisms and ResNet, showing significant improvement in accuracy. CLL: chronic lymphocytic leukemia; FL: follicular lymphoma; MCL: mantle cell lymphoma.



Evaluation of Model Stability and Generalization Capability

To evaluate the stability and generalization capability of the model, 5-fold cross-validation was performed. The model demonstrated high consistency across the 5 independently partitioned training-validation subsets with only minor fluctuations in accuracy (Figure 4). During cross-validation (N=10,750 samples), the model achieved an average accuracy of 90% (9675/10,750), confirming its robustness and reliability. Even under small-sample conditions, the model maintained high predictive accuracy, indicating good generalization ability and strong resistance to overfitting.

XSL•FO
RenderX

Figure 4. Analysis of model stability and generalization capability. This figure shows the accuracy changes during 5-fold cross-validation. The blue line represents the training set, and the red line represents the validation set. The figure shows stable and minimal fluctuations in model performance across different data splits.

Analysis of Lymphoma Subtype Classification Results

To evaluate the performance of the deep learning model in lymphoma subtype classification, classification results on the test set were analyzed using accuracy, precision-recall curves, and mAP as evaluation metrics. The results showed that the model achieved a classification accuracy of 98% (1225/1250) when distinguishing FL, chronic lymphocytic leukemia, and MCL. Additionally, the precision-recall curve demonstrated a high AUC, and the mAP reached 97%, indicating strong overall classification performance. Multiclass analysis revealed that most classification errors occurred between subtypes with similar morphological characteristics, such as FL and MCL (Figure 5). The incorporation of a feature enhancement module significantly improved the model's ability to extract critical features from key regions, leading to a nearly 5% increase in classification performance.

XSL•FO
RenderX

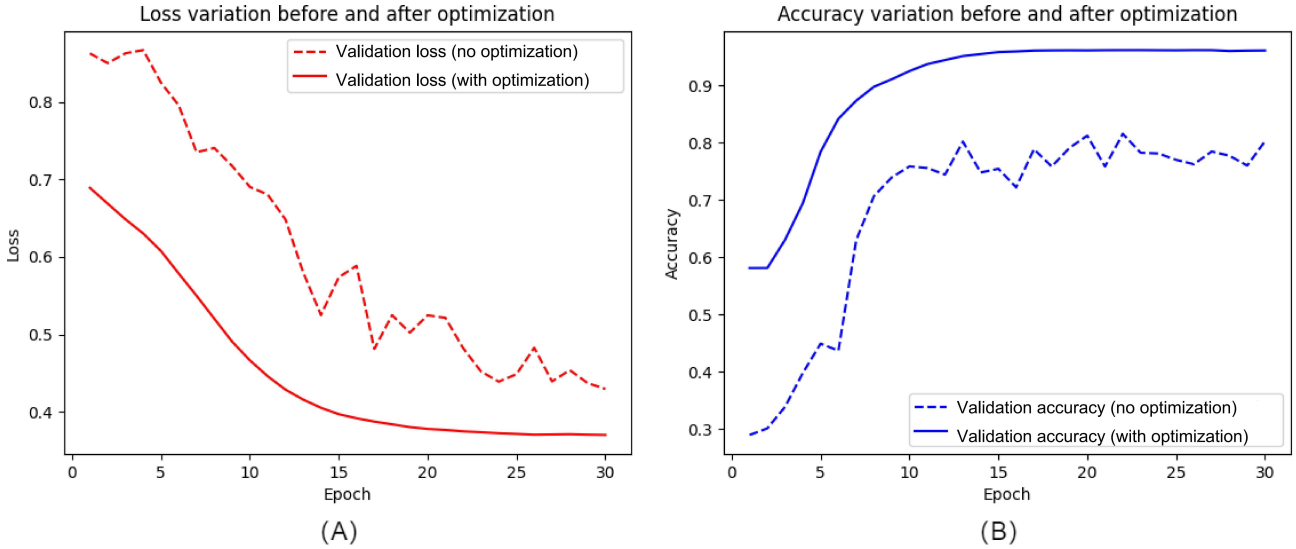
Figure 5. Evaluation of lymphoma subtype classification performance. This figure shows the model's performance in subtype classification, including (A) accuracy, (B) precision-recall curve, and (C) mean average precision (mAP), reflecting comprehensive performance in multiclass classification tasks. CLL: chronic lymphocytic leukemia; FL: follicular lymphoma; MCL: mantle cell lymphoma.

XSL•FO
RenderX

Under 5-fold cross-validation (total sample size: n=10,750), the model achieved an average classification accuracy of 90% (9675/10,750; SD 1.9%), an F_1-score of 90% (9673/10750; SD 2.3%), and an AUC of 0.95 (SD 0.015) across the 3 lymphoma subtypes, all statistically significant (=0.004). In terms of subtype performance, the model demonstrated the highest sensitivity for FL at 94.2% (393/417), followed by chronic lymphocytic leukemia at 90.6% (378/417), whereas the performance for MCL was relatively lower at 87.3% (363/416), which may be attributed to the blurred boundaries and higher heterogeneity typically observed in MCL images. As this study primarily focused on model architecture and performance evaluation, interpretability tools such as gradient-weighted class activation mapping were not incorporated. Future work will include model interpretability analyses to enhance its clinical applicability.

To evaluate the superiority of the proposed model across different deep learning architectures, we systematically compared the fusion model with several mainstream CNN-based frameworks (Table S3 in Multimedia Appendix 1). The results showed that traditional fully convolutional networks and SegNet underperformed in the detection of small lesions and boundary delineation, with overall accuracies of 81.04% (1013/1250) and 83.52% (1044/1250), respectively—significantly lower than those of U-Net and its improved variants (P=0.006). DeepLabv3+ achieved improved segmentation accuracy (dice coefficient=83.9%) but suffered from increased training complexity and limited interpretability. In contrast, U-Net demonstrated stable performance in both segmentation and classification tasks (dice coefficient=85.5%; accuracy=1099/1250, 87.92%). The further incorporation of attention mechanisms and ResNet led to continuous performance gains, and the final fusion model achieved the best results in segmentation dice coefficient, classification accuracy, and AUC (dice coefficient=89.7%; accuracy=1150/1250, 92%; AUC=0.95), with statistically significant differences (P<). These findings indicate that the proposed fusion model provides a significant advantage in multisubtype classification and grading tasks.

Comparative Analysis With Traditional Pathological Diagnosis Methods



Compared to traditional pathologists' manual slide review methods, the deep learning model in this study demonstrated significant advantages in classification and grading tasks of lymphoma pathology images. Figure S7 in Multimedia Appendix 1 shows a comparison of accuracy between the deep learning model and the average accuracy of pathologists. Under conditions involving small sample sizes or diagnostically complex subtypes, the model maintained consistent performance and achieved higher classification accuracy than pathologists. Particularly in images with rich details or blurred edges, the deep learning model reduced human error and improved diagnostic efficiency, highlighting its potential application in clinical practice. To ensure fairness in comparison, all participating pathologists were mid- to senior-level professionals with more than 5 years of diagnostic experience in hematopathology (Figure S7 in Multimedia Appendix 1). Diagnoses were conducted in accordance with the World Health Organization classification guidelines and the expert consensus on pathological diagnosis of lymphoma. Each pathologist independently reviewed the same set of blinded slide images, and no communication was allowed during the review process. Final diagnostic results were determined through majority consensus. This selection protocol was designed to reflect the average diagnostic level of experienced pathologists in routine clinical practice.

Model Optimization and Accuracy Improvement Strategies

To improve model accuracy and stability, a series of optimization strategies were implemented, including learning rate decay, data augmentation, and dropout regularization, which significantly improved model performance. Figure 6 illustrates the performance changes of the model under different optimization strategies. The model gained greater diversity during training through the use of data augmentation, effectively improving its generalization capability. The incorporation of dropout layers effectively mitigated overfitting by reducing model reliance on specific neurons, allowing the network to maintain high accuracy on new datasets.

This figure illustrates the impact of optimization strategies (learning rate decay, data augmentation, and dropout regularization) on model training: (A) changes in the loss function before and after optimization and (B) changes in accuracy before and after optimization, showing improved accuracy.

Discussion

Principal Findings

This study explored the application of deep learning techniques, particularly the U-Net model, in classifying and grading lymphoma pathological subtypes. The results showed that deep learning models significantly improved the efficiency and accuracy of automated lymphoma diagnosis. By integrating U-Net for image segmentation with ResNet for feature extraction, a robust diagnostic system was developed capable of differentiating Hodgkin lymphoma from non-Hodgkin lymphoma and accurately predicting lesion grades. Notably, the proposed deep learning model demonstrated significant advantages in segmentation accuracy, classification accuracy, and model stability. These results validated the potential of deep learning in medical image analysis, especially in disease diagnosis and clinical decision support systems.

U-Net exhibited outstanding performance in image segmentation tasks. Its precision in delineating lesion regions highlighted its ability to process complex pathological features. Lymphoma lesion regions often display irregular morphology and poorly defined boundaries, which limit the effectiveness of conventional manual segmentation methods. U-Net, through the hierarchical feature extraction capabilities of CNNs [15], enabled automated and accurate segmentation of lesion areas while minimizing subjective variability. The model achieved an accuracy exceeding 85.04% (1063/1250) on the test set, significantly improving the efficiency of lesion recognition and extraction [9].

However, despite the excellent performance of the deep learning model, several challenges were encountered, particularly regarding data scarcity and annotation quality. The acquisition of pathological images of lymphoma remains difficult, particularly for high-quality annotated data, which may impact model training effectiveness and generalization ability [7]. To address this issue, this study used strategies such as data augmentation and cross-validation [18] to improve the robustness and accuracy of the model. Nevertheless, inconsistencies in data quality, particularly the subjective differences among pathologists during annotation [19], may still affect model training and prediction. Future work could benefit from the development of standardized annotation protocols and the construction of larger, high-quality datasets to further refine model performance.

To optimize model accuracy and stability, several techniques were incorporated, including attention mechanisms, ResNet-based residual learning, and comprehensive data augmentation. The use of attention modules enabled the model to more precisely focus on diagnostically relevant regions within the pathological images, thereby reducing the influence of irrelevant features and enhancing subtype classification accuracy. ResNet's residual structure effectively mitigated the common issue of vanishing gradients in deep networks, enhancing the model's ability to learn complex pathological features. These optimization strategies significantly improved the model's performance in lymphoma subtype classification, achieving a classification accuracy of 92% (1150/1250) and a grading accuracy of 89.04% (1113/1250).

Compared to traditional pathological diagnostic methods, deep learning models offer distinct advantages. Traditional pathology relies on pathologists' experience and technical expertise, making the diagnostic process vulnerable to subjectivity and relatively inefficient when analyzing complex histological images [20]. In contrast, deep learning models can process large volumes of images quickly and provide efficient and objective diagnostic results [21]. Comparative analysis with manual slide review by pathologists revealed that deep learning models exhibited higher accuracy in handling complex and detail-rich images. Specifically, deep learning models reduced human error and improved diagnostic efficiency in lesion segmentation and subtype differentiation [6,22,23].

Despite the robust performance of deep learning models, several technical limitations remain. First, deep learning models' "black-box" nature presents a significant challenge, especially

XSL•FO
RenderX

in clinical settings, where physicians tend to favor interpretable diagnostic methods. Future research should focus on enhancing model interpretability by using visualization techniques and traceability analysis, allowing clinicians to better understand the rationale behind model predictions. Second, although the model achieved high accuracy in feature extraction and classification tasks, minor errors may still occur in subtype classification and grading, particularly when morphological differences between subtypes are subtle. Improving the model's performance in analyzing complex pathological images remains a key direction for future research.

In summary, this study confirmed the immense potential of deep learning technologies in lymphoma pathological image analysis and provides robust technical support for the automated diagnosis of clinical lymphoma. With ongoing advancements in computational methods, the application of deep learning in medical imaging analysis will become more extensive and profound. Such progress will play a vital role in developing personalized treatment plans, evaluating therapeutic efficacy, and improving patient survival rates, thereby providing substantial clinical value. The successful application of the proposed approach not only accelerated the diagnostic workflow but also provided clinicians with precise and efficient diagnostic tools, promoting greater automation and enhanced analytical capability in pathological image analysis.

Conclusions

This study demonstrated the significant potential of deep learning techniques, particularly the U-Net model, in lymphoma pathological subtype classification and grading. By combining U-Net for image segmentation and ResNet for feature extraction, an efficient and accurate diagnostic framework was developed capable of distinguishing Hodgkin lymphoma from non-Hodgkin lymphoma and precisely predicting the grades of lesions. The proposed model achieved strong performance in segmentation accuracy, classification accuracy, and model stability, validating the potential of deep learning technologies in medical imaging analysis, especially in disease diagnosis and clinical decision support.

As the core of this research, the U-Net model exhibited exceptional performance in segmenting pathological regions, effectively addressing challenges such as irregular morphology and blurred boundaries in lymphoma tissues. These capabilities significantly improved segmentation efficiency and accuracy, providing high-quality input data for subsequent classification and grading tasks. Additionally, integrating attention mechanisms and ResNet further optimized feature extraction and classification capabilities, achieving a classification accuracy of 92% (1150/1250) and a grading accuracy of 89.04% (1113/1250).

Despite the encouraging results, certain limitations remain. The limited availability of annotated lymphoma pathological images and inconsistencies in labeling quality may affect the model's training effectiveness and generalizability. Although data augmentation and cross-validation were used to improve robustness, variability in annotation and the scarcity of high-quality labeled data continue to pose challenges. In addition, the deep learning model's "black-box" nature limits its interpretability, which affects clinical acceptance and the transparency of decision-making. Moreover, the dataset used in this study was primarily derived from publicly available databases with a relatively limited sample size and without multicenter or real-world clinical validation, which may introduce sampling bias and increase the risk of overfitting. The model also exhibited relatively lower recognition performance for morphologically ambiguous subtypes such as MCL, suggesting that further optimization is needed to address highly heterogeneous lesions. Future work should focus on expanding the dataset with multicenter cohorts, integrating the model into digital pathology workflows as a clinical decision support tool, enhancing interpretability through visualization-based modules, and addressing ethical and regulatory challenges to ensure the safe and responsible application of AI technologies in health care settings.

In summary, this study demonstrated the outstanding performance of U-Net–based deep learning models in analyzing lymphoma pathological images. These techniques significantly improved diagnostic efficiency and accuracy while offering clinicians effective and reliable decision support tools. As AI technology continues to evolve, deep learning models are expected to play an increasingly important role in medical imaging analysis, offering robust support for developing personalized treatment plans and enhancing patient outcomes, thereby advancing medical imaging analysis toward greater automation and intelligence as shown in Multimedia Appendix 2.

Abstract

Background: The pathological and physiological state of patients with intracerebral hemorrhage (ICH) after minimally invasive surgery (MIS) is a dynamic evolution, and the traditional models cannot dynamically predict prognosis. Clinical data at multiple time points often show the characteristics of different categories, different numbers, and missing data. The existing models lack methods to deal with imbalanced data.

Objective: This study aims to develop and validate a dynamic prognostic model using multi–time point data from patients with ICH undergoing MIS to predict survival and functional outcomes.

Methods: In this study, 287 patients who underwent MIS for ICH were retrospectively collected on the day of surgery, days 1, 3, 7, and 14 after surgery, and the day of drainage tube removal. Their general information, vital signs, laboratory test findings, neurological function scores, head hematoma volume, and MIS-related indicators were collected. In addition, this study proposes a multistep attention model, namely the MultiStep Transformer. The model can simultaneously output 3 types of prediction probabilities for 30-day survival probability, 180-day survival probability, and 180-day favorable functional outcome (modified Rankin Scale [mRS] 0-3) probability. Five-fold cross-validation was used to evaluate the performance of the model and compare it with mainstream models and traditional scores. The main evaluation indexes included accuracy, precision, recall, and F_1-score. The predictive performance of the model was evaluated using receiver operating characteristic (ROC) curves; its calibration was assessed via calibration curves; and its clinical utility was examined using decision curve analysis (DCA). Attributable value analysis was conducted to assess the key predictive features.

Results: The 30-day survival rate, 180-day survival rate, and 180-day favorable functional outcome rate among 287 patients were 92.3%, 88.8%, and 52.3%, respectively. In terms of predictive efficacy for survival and functional outcomes, the MultiStep Transformer model showed a remarkable superiority over traditional scoring systems and other deep learning models. For these three outcomes, the model achieved areas under the receiver operating characteristic curves (AUROCs) of 0.87 (95% CI 0.82-0.92), 0.85 (95% CI 0.77-0.93), and 0.75 (95% CI 0.72-0.78), with corresponding Brier scores of 0.1041, 0.1115, and 0.231. DCA confirmed that the model provided a definite clinical net benefit when threshold probabilities ranged within 0.06-0.26, 0.04-0.5, and 0.21-0.71.

XSL•FO
RenderX

Conclusions: The MultiStep Transformer model proposed in this study can effectively use imbalanced data to construct a model. It possesses good dynamic prediction ability for short-term and long-term survival and functional outcome of patients with ICH undergoing MIS, providing a novel tool for individualized assessment of prognosis among patients with ICH undergoing MIS.

KEYWORDS

intracerebral hemorrhage; minimally invasive surgery; dynamic features; prognosis prediction; deep learning

Introduction

Intracerebral hemorrhage (ICH) accounts for 10%-15% of all stroke cases [1,2]. It is the leading cause of death and disability worldwide [3], characterized by [4] high morbidity, disability, and mortality rates. Conservative medical treatment of ICH exhibits limited efficacy [5]. Surgery for the removal of hematoma may improve the functional outcome of patients [6]. However, Surgical Trial in Intracerebral Haemorrhage (STICH) [7] and Surgical Trial in Intracerebral Haemorrhage II (STICH II) [8] confirmed the failure of craniotomy in improving functional outcomes among patients with ICH.

Recently, minimally invasive surgery (MIS), characterized by limited trauma, rapid recovery, and other advantages, has received increasing attention. Minimally Invasive Surgery Plus Alteplase for Intracerebral Hemorrhage Evacuation Phase 3 (MISTIE Ⅲ) [9] demonstrated the safety of minimally invasive hematoma evacuation combined with alteplase thrombolysis. The Early Minimally Invasive Removal of Intracerebral Hemorrhage (ENRICH) [10] trial reported that MIS can improve the functional outcomes of patients with lobar ICH at 180 days. Although the ENRICH trial provided encouraging evidence regarding the efficacy of MIS, not all patients with ICH can benefit from this approach. The uncertainty surrounding the therapeutic efficacy of MIS poses challenges for assessing the prognosis of patients.

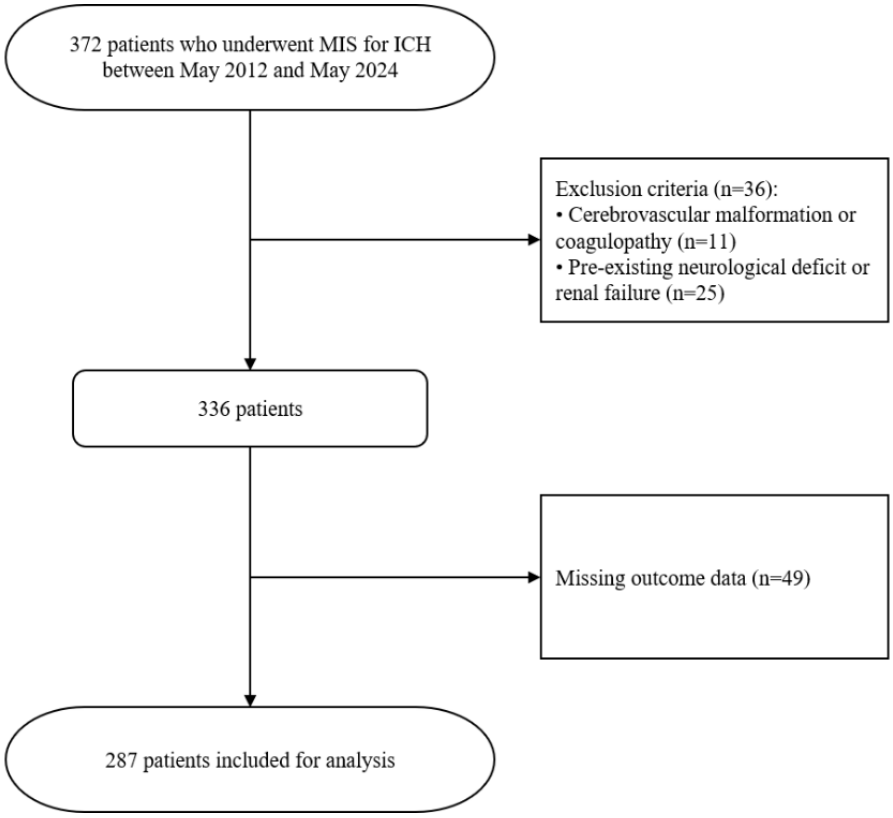
Moreover, the condition of patients with ICH is a dynamic process. Although some tools have been used to predict death or functional outcome in patients with ICH [11-17], these predictions are mostly based on data at admission or a single time point, which cannot reflect the dynamic changes of the disease and also limit the accuracy of prognostic assessment. Electronic health records (EHRs) containing abundant data reflect the pathological and physiological state of dynamic changes in patients with ICH undergoing MIS. However, data extracted from EHR, without systematic organization, exhibits characteristics such as variable quality, high dimensionality, heterogeneity, temporality, and incompleteness [18], posing significant challenges for predictive modeling. Therefore, this study aimed to leverage multitime point, imbalanced data from patients undergoing MIS for ICH to develop a dynamic prognostic model and validate its performance in predicting survival and functional outcomes.

Methods

Study Design and Population

Patients with ICH who underwent MIS for ICH in the Department of Neurology, Tongji Hospital, Tongji Medical College, Huazhong University of Science and Technology were enrolled in this study. Clinical and imaging data were collected retrospectively on the day of surgery, 1, 3, 7, and 14 days after surgery, and on the day of drainage tube removal. A deep learning algorithm was used to construct a dynamic prognostic model and validate the effect of the model.

In total, 372 patients undergoing MIS for ICH between May 2012 and May 2024 were selected. Among them, 11 cases of ICH caused by cerebrovascular malformation and coagulopathy, 25 cases with a history of neurological deficit and renal failure, and 49 patients with missing outcome data were excluded, and data from 287 patients were analyzed. A flowchart for the patient selection process is shown in Figure 1.



The inclusion criteria were as follows: (1) patients with spontaneous acute ICH in basal ganglia or lobar regions based on cranial computed tomography (CT), who underwent stereotactic intracranial hematoma puncture and drainage surgery after admission; (2) ICH hematoma volume 20-100 mL; (3) age 18-80 years old; (4) surgery within 1 week of onset; and (5) survival for at least 7 days after admission.

The exclusion criteria were as follows: (1) coagulation disorders, such as thrombocytopenia and significant abnormal coagulation indexes caused by hepatitis; (2) traumatic ICH; (3) intracranial infection and other diseases leading to a significant increase in intracranial pressure; (4) previous severe heart, liver, kidney, or lung diseases or functional failure; (5) previous history of neurological dysfunction; (6) ICH was caused by structural abnormalities of the cerebral blood vessels (eg, arteriovenous malformations, intracranial aneurysms, vasculitis, and moyamoya disease); and (7) ICH was caused by brain tumor or cerebral infarction and was treated with thrombolytic therapy.

The model was developed and validated in accordance with the TRIPOD-AI (Transparent Reporting of a multivariable prediction model for Individual Prognosis Or Diagnosis–Artificial Intelligence) checklist.

Figure 1. Patient selection flowchart. ICH: intracerebral hemorrhage; MIS: minimally invasive surgery.

Data Sources and Collection

We electronically extracted clinical data from the EHR of Tongji Hospital, Tongji Medical College, Huazhong University of Science and Technology. Data were collected on general information, vital signs, laboratory test findings, neurological function scores, and MIS-related metrics, such as the time from onset to surgery and the duration of drainage tube placement, along with established neurological scales: the ICH score, Glasgow Coma Scale (GCS), National Institutes of Health Stroke Scale (NIHSS), and the functional outcome in patients with primary intracerebral hemorrhage (FUNC) score. Rapid segmentation and volume calculation of hematomas on cranial CT images were conducted using 3D Slicer.

Follow-up and Clinical Outcomes

Follow-up was conducted via telephone call. The primary outcome was all-cause mortality at 30 days. Secondary outcomes included all-cause mortality at 180 days and functional outcome at 180 days. The outcomes were assessed using the modified Rankin Scale (mRS), which was transformed into a binary variable, favorable functional outcome (mRS 0-3) and unfavorable functional outcome (mRS 4-6) [19,20]. The assessment was conducted by 2 medical doctors (JW and YS), with discrepancies being resolved through arbitration by a senior physician (PZ).

Data Processing and Statistical Analysis

Missing values in this study were predominantly attributed to the absence of imaging features at certain time points, whereas clinical features (vital signs, laboratory studies, etc) were fully documented. Instead of imputing the missing imaging features, the model automatically ignored the corresponding time points via an attention mechanism and completed representation learning and outcome prediction solely based on available temporal imaging features and comprehensive clinical features. To ensure a consistent input structure across patients and time points, we adopted a simple zero-imputation strategy during preprocessing. For patients with missing measurements at specific time points (eg, when certain laboratory tests or clinical assessments were not performed on a given day), the corresponding feature values were set to zero. All features were standardized before model training so that zero-imputed values lie within a well-defined range and are distinguishable from typical observed values.

For continuous variables, intergroup comparisons were conducted using the *t* test. The chi-square test was used for categorical variables. Data are presented as median (IQR), mean (SD), and range. A *P* value of <.05 was considered statistically significant.

Model Development and Training

Modeling Strategy

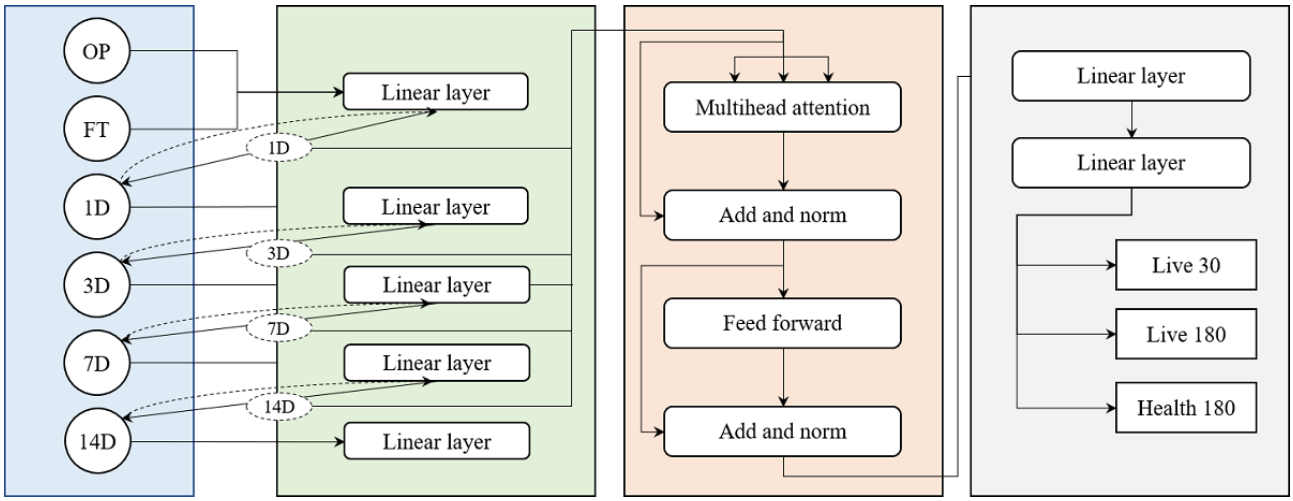
The changes of clinical indicators after MIS for ICH reflect the dynamic changes of individual status. Reasonable modeling of time series data dependence and cross-time point information interaction is of high importance for survival and prognosis prediction. We collected a data series of patients' multidimensional clinical measures: , where x^{1d}, x^{3d}, x^{7d}, x^{14d} denote the characteristics at 1, 3, 7, and 14 days after surgery, respectively. x^{ft} denotes fixed features (eg, gender and age) that do not change over time. x^{op}denotes the characteristics of the day of surgery. In particular, since not all individuals had

XSL•FO
RenderX

the same drainage tube removal time, the corresponding characteristics were introduced separately.

Our objective was to learn a mapping function $f: X \rightarrow \gamma$, where γ {0,1}represents the survival and prognosis labels, specifically defined as 30-day survival, 180-day survival, and 180-day favorable functional outcome. Crucially, we aimed to establish a mapping function capable of predicting both future data and the final labels from postoperative data of any given day. For instance, when input with first-day postoperative data x^{1d}, the model was meant to successfully predict subsequent data x^{3d}, x^{7d}, x^{14d} and the final ternary label γ. The problem was a multistage, multi–time point, and multivariate time series classification task.

Since the clinical indicators at each time point in X were not entirely consistent, it was not feasible to establish a unified model for cyclic prediction at each time point. Available machine learning or deep learning models exhibit limited capability in handling variable dimensional feature data [21].



To address this, we proposed a MultiStep Transformer model designed to capture nonlinearly evolving clinical features over time and manage the cross-influences existing between different time points.

MultiStep Transformer Model Architecture

In the MultiStep Transformer model, we introduced a multistage feature prediction module and a time-sharing embedding mechanism. It cooperated with the transformer encoder to realize the reinforcement modeling of multi–time point sequences. Specifically, we constructed a multilayer feature prediction module to predict and train each prognostic data separately. Finally, the Transformer encoder was used to predict 30-day survival probability, 180-day survival probability, and 180-day favorable prognosis probability. The overall process of the model is shown in Figure 2.

The MultiStep Transformer model was able to receive data at any time point as input and output for 3 types of prediction probabilities. The model framework is as follows:

Figure 2. Model diagram.

Multistage Feature Cycle Prediction Module

The core idea of the multistage feature cycle prediction module was to use the information of current and previous time points to recursively infer the feature expression of missing or future time points, which was formulated as

Here, $LR_t(\cdot)$represents a linear mapping layer specific to the t-th time point, responsible for establishing recursive dependencies among the time-series features. This design effectively mitigated the challenges of incomplete clinical data and the isolation of temporal features, thereby enhancing the ability of the model to capture temporal evolutionary trends.

Time-Sharing Feature Embedding

In view of the large difference of input data dimensions and strong heterogeneity of feature distribution at different time points, an independent linear mapping layer was designed:

The high-dimensional projection of the input at each time point was conducted to eliminate the difference in input dimensions and ensure the consistency of the sequence dimensions of the input of the transformer encoder. In addition, the independent mapping parameters W_t and d_t captured the unique statistical characteristics of time points and improved the adaptability of the model to the information of different stages.

Transformer Encoder Structure and Time-Series Dependence Modeling

Through the self-attention mechanism, the transformer encoder flexibly modeled the interactive dependencies between all positions in a sequence. It overcame the limitations of traditional recurrent neural networks and possessed the capabilities of parallel computation and long-range dependency capture. In our framework, the same temporal feature sequence was used simultaneously as the query, key, and value in the self-attention operation. This design allows feature extraction to be performed directly on the observed sequence without forcing all patients to have the same number of time points and therefore naturally supports variable-length temporal inputs.

XSL•FO
RenderX

Input sequence: concatenate the embedding vectors at all time points to form an input sequence:

Here, t= 6 represents the number of input feature layers, and B denotes the batch size for each training or inference step. The experimental framework supports arbitrary combinations of time points as input, for example using only Day-1 data or Days 1, 3, 7, and 14, depending on data availability and clinical requirements.

Encoding process: the multilayer stacked transformer encoder consisted of multihead self-attention and a feed-forward network. A single layer was formulated as

Where the same sequence serves as Q, K, and V in the self-attention module. The model performs multistep, progressive computation; features from earlier time points are encoded first, and then information from subsequent time points is gradually integrated. After multilayer coding, the model comprehensively considered the influence between different time points and its feature correlation, and the output sequence was expressed as:

$$Z = \text{TransformerEncoder}(H) \quad (6)$$

The encoding vector Z^d at the final time point of the sequence was taken as the representation of the comprehensive temporal dynamic state of patients.

Survival Prediction Head

The final classification layer was mapped using single-layer linearity:

Here, σ denotes the sigmoid activation function for generating binary classification probability outputs. The output data format was (30 live, 180 live, and 180 heal), representing the probability of 30-day survival, 180-day survival, and 180-day favorable functional outcome, respectively.

Training and Prediction Processes

For model training, data were input uniformly, and the model was trained step by step. Specifically, features from all time points $X = \{x^{ft}, x^{op}, x^{1d}, x^{3d}, x^{7d}, x^{14d}\}$were input into the model. The model first processed the features $[x^{ft}, x^{op}]$ through the linear layer LR_{1d} to compute  , and calculate the loss using x^{1d}, followed by backpropagation to optimize LR_{1d}. Subsequently, stepwise prediction and optimization were conducted sequentially based on the mapping layers in the multistage feature prediction module. All features, including known inputs and predicted outputs, were combined into a complete feature sequence  . Finally, the transformer encoded all temporal features to obtain the patient's dynamic state representation Z, which was then classified using a linear layer.

During inference, given the first i temporal features X_i (eg, $X_i = \{x^{ft}, x^{op}, x^{1d}, x^{3d}\}$), the model applied masking to the existing feature time points based on the number of feature layers and directly computed subsequent features  , finally predicting survival and prognosis (30 live, 180 live, and 180 heal).

Model hyperparameters were selected empirically based on preliminary experiments on the training folds. The network was optimized using the Adam optimizer with a fixed learning rate of 0.001 and trained for 200 epochs per fold. We used the cross-entropy loss for outcome prediction, combined with the feature prediction loss for intermediate temporal features in the multistage prediction module. The batch size, number of transformer layers, hidden dimensions, and dropout rate were tuned within a reasonable range to balance model performance and overfitting risk.

Model Evaluation

The predictive performances of different models and scores were compared using accuracy, precision, recall, and F_1-score. The predictive performance of the model was evaluated by the area under the receiver operating characteristic curve (AUROC). Calibration curves were plotted to assess the consistency between the predicted probabilities and the observed outcomes of the model. In addition, decision curve analysis (DCA) was performed to evaluate the clinical utility of the model.

Model Interpretation

To gain insight into the decision-making process of the model, we used attribution values, a technique used to quantify how much each input feature contributes to the output of the model. Attribution values revealed the importance of clinical characteristics in predicting the outcome and helped us determine which characteristics had the greatest impact on the model's decision-making process.

Ethical Considerations

This study was approved by the Medical Ethics Committee of Tongji Hospital, Tongji Medical College, Huazhong University of Science and Technology (TJ-IRB202502129). Given the retrospective nature of the study and the absence of any direct interaction with participants, informed consent was exempted by the ethics committee, and no compensation of any form was provided. This study adheres to the ethical principles outlined in the Declaration of Helsinki.

Results

Baseline Characteristics of the Study Population

The mean age of the 287 patients was 53.2 (10.6) years, and 67.9% of the patients were male. Their 30-day survival rate was 92.3%, their 180-day survival rate was 87.8%, and the rate of favorable functional outcome at 180 days was 52.3%. The presence of intraventricular hemorrhage, GCS, NIHSS, ICH score, and FUNC score showed significant differences across the 3 groups of patients (Tables S1-S3 in Multimedia Appendices 1-3).

XSL•FO
RenderX

Evaluation of the Model Performance

Due to variations in clinical assessment items across different time points, the feature categories at each time point were not entirely consistent. In the collected dataset, there were 48 features on the day of surgery, 47 features on postoperative days 1 and 3, a total of 46 features on postoperative day 7, a total of 10 features on postoperative day 14, and 15 features on the day of drainage tube removal (feature labels are in Multimedia Appendix 4). Based on feature dimensions of the patients, we constructed a MultiStep Transformer model with 4 feature prediction modules.

Given the limited sample size (287 patients) and single-center design, we adopted a 5-fold cross-validation scheme for internal validation. The entire cohort was randomly partitioned into 5 approximately equal subsets. In each iteration, one subset was held out as the validation (test) set, and the remaining 4 subsets were used for model training. This process was repeated 5 times so that each subset served as the validation set exactly once. Model performance metrics were averaged across the 5 folds and reported together with their SDs, providing an estimate of variability and robustness. The outcome labels were not evenly distributed across classes. To mitigate the impact of class imbalance, we ensured that the proportion of outcome categories in each fold of the cross-validation was approximately consistent with that of the full cohort by using stratified splitting according to the target labels. In addition, class weights inversely proportional to class frequencies in the training data were applied in the loss function to reduce bias toward the majority class. This strategy helped the model to learn more balanced decision boundaries across different outcome categories.

We calculated the confusion matrices of the results to obtain accuracy, precision, recall, and F_1-score. Regarding the prediction results, actual labels were defined as follows: true positive (TP), positive labels correctly predicted; false positive (FP), negative labels incorrectly predicted; true negative (TN), negative labels correctly predicted; false negative (FN), positive labels incorrectly predicted. The evaluation metrics were calculated as follows:

For comparison, we selected the commonly used deep learning models, including temporal convolutional network (TCN), gated recurrent unit (GRU), and transformer. Table 1 presents the comparison of prediction performance between the MultiStep Transformer model and each deep learning model.

live_180	88.80 (3.24)	93.99 (1.68)	93.22 (3.90)	93.55 (1.20)
heal_180	80.13 (3.68)	81.16 (2.13)	82.02 (6.05)	81.42 (2.82)

[a]GRU: gated recurrent unit.

[b]TCN: temporal convolutional network.

The proposed method achieved the best performance in terms of accuracy, recall, and F_1-score for the 3 categories of outcomes. The accuracy of the MultiStep Transformer model was 92.43 (1.68) for 30-day survival, 88.80 (3.24) for 180-day survival, and 80.13 (3.68) for 180-day favorable functional outcome, respectively.

Furthermore, we separated the 4 scores (GCS, NIHSS, ICH score, and FUNC score) from the data to predict the three categories of outcomes. The FUNC score is associated with the volume of hematoma, but there were some missing data, and it could not be combined with the other scores for classification. We compared the single-score classification and the combined classification of scores (ICH score, GCS, and NIHSS),

XSL•FO
RenderX

respectively. We also used support vector machine (for classification). Using the same 5-fold cross validation, their confusion matrices were calculated to obtain the corresponding indicators (Table 2).

As can be seen, the NIHSS predicts the best results of the traditional scores for 30-day survival. The FUNC score was superior to the other 2 scores in the accurate classification of 180-day survival and 180-day favorable functional outcome. It significantly improved the prediction of 180-day favorable functional outcome, indicating that the FUNC score was better at predicting the long-term prognosis of patients. The combination of the ICH score, GCS, and NIHSS features significantly improved 30-day survival prediction, but the FUNC score still exhibited some advantages in long-term prediction.

Figure 3 presents a comparison of classification accuracy between the MultiStep Transformer model, traditional scoring methods, and other deep learning models. The results indicated that compared to either traditional scoring methods or other deep learning models, our proposed method offers superior performance in both short-term and long-term predictions of the 3 outcome categories. Furthermore, the MultiStep Transformer model yielded the smallest SD (eg, mean 92.43, SD 1.68 for accuracy in 30-day survival prediction), reflecting its consistent performance across different data subsets, enhanced stability, and strong generalization capability.

Figures 4A, D, and G present the receiver operating characteristic (ROC) curves of the model for different outcomes, namely 30-day survival, 180-day survival, and 180-day favorable functional outcome. The model achieved AUROCs of 0.87 (95% CI 0.82-0.92), 0.85 (95% CI 0.77-0.93), and 0.75 (95% CI 0.72-0.78) for these 3 outcomes, respectively.

Furthermore, the calibration curves demonstrated good calibration performance of the model (Figures 4B, E, and H), with corresponding Brier scores of 0.1041, 0.1115, and 0.231, respectively. DCA indicated that the model yielded a net benefit when the threshold probabilities ranged within 0.06-0.26, 0.04-0.5, and 0.21-0.71, respectively (Figures 4C, F, and I). The above findings confirm that this model exhibits favorable generalizability.

Model Interpretation

In this study, we used deep neural networks to classify clinical data for predicting patients' outcomes. Specifically, we visualized the attribution values calculated by the model alongside the corresponding input feature values in the same diagram to interpret the model's decision-making mechanism.

The attribution values indicated the contribution of each clinical feature to the model's output. The feature importance was relatively similar between postoperative day 1 and day 3, while some changes emerged in the key clinical features affecting predictions by days 7 and 14 (Figure 5).

The horizontal axis in Figure 5 represents the indices of the input features as discrete integers, facilitating the identification of specific features. The left vertical axis denotes the attribution values, displayed with blue bars that illustrate each feature's relative contribution to the output. The right vertical axis corresponds to the original feature values, plotted as a red dashed line to visualize the correspondence between attributions and raw data. This integrated plot helps identify the most influential features on the model's predictions, enabling a more comprehensive understanding of the model's behavior.

Figure 5. Visualization of attribution values of features.

Discussion

Principal Findings

This study reports the construction process and model performance of the MultiStep Transformer model, a novel deep learning model that can dynamically predict short-term and long-term survival and functional outcome in patients with ICH undergoing MIS. The experimental results showed that the model significantly outperformed the mainstream deep learning models (GRU, TCN, and transformer) and traditional clinical scores (GCS, NIHSS, ICH score, and FUNC score) on the 3 prediction tasks of 30-day survival, 180-day survival, and 180-day favorable functional outcome.

In patients undergoing MIS for ICH, neurological functions, vital signs, imaging findings, and laboratory parameters are subjected to continuous changes, generating substantial clinical data. However, temporal data in EHR present challenges, including irregular recording intervals and variable sequence lengths across individuals. Meanwhile, most of the previous studies have conducted predictions at fixed time points, whereas many clinical scenarios necessitate continuous outcome updates with the emergence of new data [22]. Therefore, it is essential to develop a dynamic model to process variably dimensional features. This approach not only addresses the needs of clinical practice but also allows personalized management of patients.

The MultiStep Transformer model incorporates innovative designs to address common challenges in real-world clinical data, such as missing time points, heterogeneous feature dimensions, and inconsistent sampling frequencies.

First, multistage feature prediction addresses data missingness. Through layered stepwise linear mapping, the model not only imputes missing values at certain time points but also enhances temporal dependencies among features, thereby improving the accuracy of predictions.

Second, time point–specific embedding resolves dimensionality inconsistency. Independent linear embedding layers ensure unified representation of heterogeneous input data, strengthening the generalizability of the model.

XSL•FO
RenderX

Third, the self-attention mechanism of the transformer captures long-range dependencies. Compared to traditional recurrent neural networks, the transformer architecture more effectively learns complex nonlinear dependencies and interactions across several time points.

Finally, we visualized feature importance through attribution values. The values revealed which clinical features played a pivotal role in the final predictions. A higher attribution value of a feature suggested a greater influence on the model's decision-making. The MultiStep Transformer model successfully captured the dynamic shifts of key perioperative features during MIS, thereby enhancing the interpretability of the model and its credibility in clinical practice.

Comparison With Prior Work

TCN is a feedforward network architecture that models time series by stacking convolutional layers [23]. Under the constraint of convolutional layers, it can effectively prevent information leakage. Multilayer convolution can also capture local time dependence and short-term dynamic changes in multi–time point clinical data. GRU is a type of recurrent neural network, which uses a gating unit to control the memory and forgetting of information. It has a relatively small number of parameters and high training stability and can model the dependence from local to global. For clinical data with multiple time points, GRU can better extract cross-temporal global features [24]. With the attention mechanism as the core, Transformer can model the relationships between any time points in a sequence in a global scope [25], making it suitable for dealing with long sequences and complex temporal patterns. In addition, it has good parallel computing ability and can effectively use global information.

Compared to the mainstream deep learning models, the MultiStep Transformer model offers full usage and efficient modeling of complex imbalanced time-series data by introducing a multistage feature cycle prediction module, time-sharing embedding mechanism, and transformer encoder structure. Besides, the modular design of the MultiStep Transformer model enables adaptation to flexible inputs, supports dynamic input time points, and is suitable for clinical scenarios with different monitoring frequencies, thereby improving its practicability.

In 30-day survival prediction, GRU, TCN, and transformer achieved 100% precision, indicating rare false positive errors, but their low recall suggests many missed diagnoses. The MultiStep Transformer exhibited a significant improvement in recall and F_1-score, suggesting a more accurate identification ability while avoiding excessive conservatism. The performance of all models decreased with the prolongation of prediction time, but the MultiStep Transformer still showed a high F_1-score in 180-day survival prediction, with greatly improved recall. These findings imply that it is more sensitive in long-term prediction and not overly conservative. In the prediction of a favorable functional outcome at 180 days, all models performed worse compared to their performance in survival prediction, highlighting the challenges in predicting functional outcomes. The MultiStep Transformer was the only model with a recall of more than 80%, indicating that it was more advantageous in identifying patients with a greater chance of recovery.

Traditional scoring systems are widely used in clinical practice due to their simplicity and have demonstrated considerable value in predicting the outcomes of ICH. For predicting mortality, the ICH score achieved AUROCs of 0.83-0.84, while the FUNC score showed AUROCs of 0.79-0.83. In predicting functional outcomes, the ICH score attained AUROCs of 0.77-0.82, compared to 0.76-0.78 for the FUNC score [26]. When predicting death or severe disability, the NIHSS score yielded an AUROC of 0.796, the GCS score achieved an AUROC of 0.650, and the ICH score revealed an AUROC of 0.674 [27]. By comparison, the model developed in this study demonstrated superior predictive performance. For the prediction of 30-day survival, 180-day survival, and 180-day favorable functional outcome, the model achieved AUROCs of 0.87 (95% CI 0.82-0.92), 0.85 (95% CI 0.77-0.93), and 0.75 (95% CI 0.72-0.78), respectively. Meanwhile, calibration curves and DCA confirmed that this model has excellent calibration performance and definite clinical benefit. Furthermore, the inherent limitations of traditional scoring systems are becoming increasingly apparent. McCracken et al. indicated that nearly two decades after its introduction, the predictive accuracy of the ICH score may no longer be sufficient for contemporary clinical practice, necessitating adjustments and optimization [28]. More importantly, the clinical guideline "Guidelines for Neuroprognostication in Critically Ill Adults with Intracerebral Hemorrhage" emphasizes that no single score or clinical variable should be used as the sole basis for prognostic judgment at 3 months or beyond [29]. Accordingly, factors such as preoperative functional status, surgical complications, and intervention timing should be comprehensively considered when developing assessment tools for patients undergoing surgery [30]. The dynamic prognostic model developed in this study aligns with this philosophy. From a clinical perspective, accurate prediction of long-term functional outcomes is crucial for rehabilitation planning and patient communication. For predicting 180-day functional outcomes, the most challenging task, our model achieved an F_1-score of 81.42%, significantly surpassing traditional scoring systems (maximum 71.56%), suggesting its substantial potential in guiding rehabilitation strategies.

Limitations

There are some limitations to this study. First, this study was a single-center retrospective study with a small sample size, which constitutes the most critical methodological limitation. Population heterogeneity, treatment variability, and fluctuations in data quality may potentially compromise model performance. Although our dataset, spanning over ten years and including medical records from both local and nonlocal patients, confers a certain degree of representativeness, and despite rigorous cross-validation for model performance evaluation, single-center data are inevitably influenced by institutional clinical protocols and inherent biases of retrospective data collection. This poses a distinct challenge for dynamic models, whose generalizability is limited by institutional variations in feature distributions and missing patterns. Second, the puncture needle used in MIS leads to artifacts in CT images, which will affect the accurate calculation of hematoma volume. Third, the model only predicted binary outcomes, such as survival or death, favorable

XSL•FO
RenderX

prognosis, and unfavorable prognosis, but could not predict the specific mRS score. The prediction ability of the functional outcome was not comprehensive enough. Finally, we collected clinical data at a few time points, which may have affected the performance of the model. In the future, more clinical data at more time points can help train the model more effectively.

Future Work

All features incorporated into this model are derived from routine clinical practice in MIS for ICH, eliminating the need for additional data collection efforts. Meanwhile, the model supports continuous integration of the latest data and dynamic updating of prediction outcomes, which can precisely match the time-varying characteristics of ICH progression and the clinical decision-making needs of MIS. Leveraging these advantages, the ideal application of the dynamic prediction model developed in this study is to be embedded in the EHR system, thereby providing clinicians with real-time individualized prognostic predictions to support accurate decision-making. However, its implementation faces obstacles such as technical integration and workflow adaptation. Future work will advance in multiple directions. First, more time-point data will be incorporated to improve the model's performance, and external validation of the model will be conducted in multicenter, prospective cohorts. This is a key step to evaluate its real-world generalizability and promote clinical translation. Second, standardized interfaces will be developed to achieve seamless integration of the model with different EHR systems and ensure real-time data updates. Third, the actual impact of the model on clinical decision-making and final clinical outcomes will be evaluated in real clinical settings, and a replicable workflow solution will be formulated.

Conclusions

Based on clinical data, the MultiStep Transformer model uses deep learning methods to achieve the goal of dynamic, comprehensive, and accurate prediction. It can stably output multiple prediction results in a single prognostic model at the same time. This study explored the individualized management of patients with ICH undergoing MIS, providing a new method for predicting short-term and long-term survival and functional outcomes and bringing a reference for the diagnosis and treatment of ICH in clinical practice.

Abstract

Background: Multiple instance learning (MIL) is widely used for slide-level classification in digital pathology without requiring expert annotations. However, even partial expert annotations offer valuable supervision; few studies have effectively leveraged this information within MIL frameworks.

Objective: This study aims to develop and evaluate a ranking-aware MIL framework, called rank induction, that effectively incorporates partial expert annotations to improve slide-level classification performance under realistic annotation constraints.

Methods: We developed rank induction, a MIL approach that incorporates expert annotations using a pairwise rank loss inspired by RankNet. The method encourages the model to assign higher attention scores to annotated regions than to unannotated ones, guiding it to focus on diagnostically relevant patches. We evaluated rank induction on 2 public datasets (Camelyon16 and DigestPath2019) and an in-house dataset (Seegene Medical Foundation-stomach; SMF-stomach) and tested its robustness under 3 real-world conditions: low-data regimes, coarse within-slide annotations, and sparse slide-level annotations.

Results: Rank induction outperformed existing methodologies, achieving an area under the receiver operating characteristic curve (AUROC) of 0.839 on Camelyon16, 0.995 on DigestPath2019, and 0.875 on SMF-stomach. It remained robust under low-data conditions, maintaining an AUROC of 0.761 with only 60.2% (130/216) of the training data. When using coarse annotations (with 2240-pixel padding), performance slightly declined to 0.823. Remarkably, annotating just 20% (18/89) of the slides was enough to reach near-saturated performance (AUROC of 0.806, vs 0.839 with full annotations).

Conclusions: Incorporating expert annotations through ranking-based supervision improves MIL-based classification. Rank induction remains robust even with limited, coarse, or sparsely available annotations, demonstrating its practicality in real-world scenarios.

multiple instance learning; learning to rank; digital pathology; whole slide image; weakly supervised learning; mixed supervision; data-efficient training

Introduction

With the rise of digital pathology, whole slide images (WSIs) have become essential for computer-assisted diagnosis tasks such as tumor detection, subtype classification, and prognosis prediction [1-3]. Due to their extremely high resolution, WSIs are typically divided into smaller patches before being used in deep learning models. In fully supervised learning settings, this requires patch-level labels—an annotation process that is time consuming and labor intensive due to the scarcity of lesion-containing patches. To reduce the burden of exhaustive labeling, the multiple instance learning (MIL) framework has

XSL•FO
RenderX

emerged as the dominant approach for slide-level prediction. MIL operates in a weakly supervised setting, using only slide-level labels and eliminating the need for detailed patch annotations. Despite this advantage, MIL models still require large datasets to achieve generalizable performance due to a weak supervision signal [4]. In data-constrained settings, MIL training often becomes unstable, leading to a significant reduction in predictive accuracy. To address the limitations of weak supervision, recent studies can be broadly categorized based on the strength of supervision into three main streams: (1) slide-level approaches relying solely on slide labels, (2) pseudolabel-based methods that infer patch-level labels, and (3) expert-guided methods leveraging direct annotations.

Slide-level approaches operate solely with slide-level supervision but aim to improve performance through semisupervised learning, self-supervised learning, or multiresolution architectures [5-12]. For instance, dual-stream multiple instance learning (DS-MIL) introduced a dual-stream architecture that models relationships between high- and low-attention instances to mitigate attention collapse and improve feature discrimination [11]. Hierarchical image pyramid transformer (HIPT) leveraged hierarchical self-supervised vision transformers to capture multiscale contextual information across gigapixel WSIs, demonstrating that strong representation learning can alleviate weak supervision limitations [12]. However, because these approaches still rely only on slide-level labels, the supervision signal remains weak and cannot fully guide the model toward diagnostically relevant regions.

Pseudolabel-based methods generate inferred patch-level labels from attention maps to strengthen the weak supervision signal. A prominent data-efficient training using pseudolabel is clustering-constrained attention multiple instance learning (CLAM), which selects high- and low-attention instances within each slide to form pseudopositive or pseudonegative sets and trains an auxiliary instance classifier [13]. Iterative multiple instance learning proposed an iterative framework that refines both instance and slide representations by retraining the feature extractor with attention-derived pseudolabels, though its performance depends on the stability of the initial MIL attention [14]. In general, pseudolabeling techniques aim to fill the gap in patch-level labels by generating inferred annotations [13-18]. Despite their utility, pseudolabels are inherently noisy, as they are inferred rather than observed. Consequently, MIL pipelines that solely rely on pseudolabels often suffer from degraded performance.

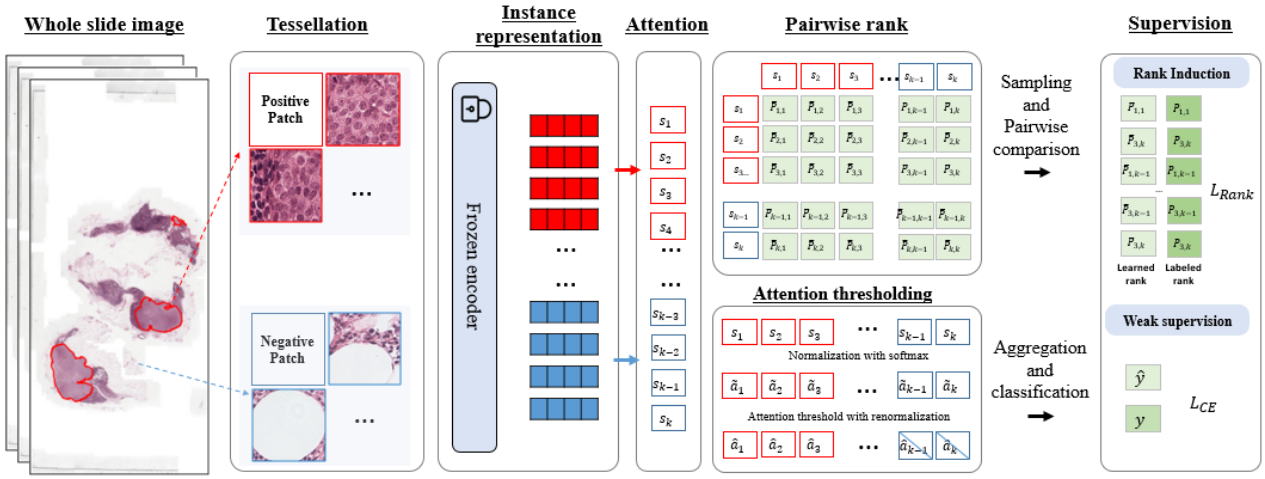
In contrast, expert-guided methods offer a promising way to improve both performance and supervision quality by directly integrating expert annotations. Nevertheless, this approach remains relatively underexplored compared to other categories. A notable study described the attention induction model, which uses pathologist-drawn lesion annotations to guide model attention [19]. However, by enforcing attention scores proportional to the size of the annotated regions, this method inherently biases the model toward larger areas, increasing the risk of overlooking small but clinically critical diagnostic features.

To overcome this limitation, we propose rank induction, a novel MIL framework that introduces a pathology-informed inductive bias. Rather than constraining attention based on region size, rank induction assumes that annotated regions should carry higher diagnostic importance than unannotated ones. By learning relative ranks between patches, our method provides finer-grained supervision, guiding the model to focus on diagnostically relevant areas even when annotations are sparse or training data are limited.

Methods

Problem Definition

We extend the standard MIL framework by incorporating patch-level annotations from pathologists as explicit instance labels, either across all training slides or only a subset. In a typical MIL setting, each WSI is divided into K patches $\{x_1,\ldots,x_K\}$, and only a slide-level label, indicating disease presence, is provided. A slide is labeled positive if at least 1 patch contains a lesion and negative if all patches are normal (for simplicity, we assume a fixed K across slides).



In our extended setting, we additionally use binary labels $\{y_1,\ldots,y_k\}$ at the patch level, where $y_k \in \{0,1\}$, $y_k=1$, if a patch overlaps with a pathologist-annotated region, and $y_k=0$ otherwise. The core inductive bias we introduce is simple but clinically grounded: patches overlapping annotated regions should receive higher attention than unannotated ones. This reflects the assumption that tumor-confirmed regions are more relevant to slide-level diagnosis than those confirmed to be normal.

Rank Induction

As illustrated in Figure 1, rank induction consists of 2 key components: pairwise rank comparison derived from rich annotation supervision and attention thresholding to filter out residual noninformative patches. To implement our ranking-aware attention mechanism, we first define the computation of patch-wise attention. Let z_k denote the feature vector of patch x_k extracted by a backbone feature encoder. We compute a raw attention score s_k from z_k using an attention layer and normalize it using softmax:  . Inspired by RankNet [20], rank induction introduces a ranking constraint that encourages higher attention scores for annotated patches than for nonannotated ones, such that $s_i > s_j$, where s_i is the attention score for an annotated patch and s_j for a nonannotated patch.

XSL•FO
RenderX

Figure 1. Overview of rank induction.

To avoid the normalization constraint of softmax ( ), we apply the ranking loss directly on the raw attention scores $s_i \in R$. We define the pairwise ranking preference using a sigmoid function:

Here, *m* is a margin parameter that enforces separation between positive and negative patches and σ is a scaling factor. We exclude same-class pairs (eg, lesion-lesion or normal-normal) and define the valid pair set: $P = \{(i,j)|y_i = 1, y_j = 0\}$. Let be the ground truth ranking label. The rank loss is defined as:

We jointly optimize the slide-level binary cross-entropy loss and the rank loss:

$$L = L_{BCE} + \lambda L_{rank}$$

where λ is a weighting hyperparameter. For slides without annotated lesions (ie, negative slides), we omit the ranking loss and only apply the slide-level loss.

To mitigate slide-level representation dilution, where a few high-attention lesion patches are overwhelmed by numerous low-attention nonlesion patches during the attention-weighted summation, we apply an attention thresholding strategy during training. Specifically, we threshold the normalized attention weights and then renormalize all (including zero-valued) weights as follows:

Here, *T* is a predefined threshold and *K* is the number of patches. The threshold *T* is introduced to prevent the slide-level representation from being dominated by the large number of negative instances when the bag size is large. For example, in a slide containing 2000 instances with only 10 lesion patches, even if attention is highly concentrated on those few positives, the aggregate contribution from thousands of near-zero attention weights of negative patches can still overshadow the lesion signal, leading to degraded slide representations. By applying *T*, we effectively suppress these noise-like weights and maintain a more balanced representation across instances.

Datasets

We evaluated rank induction on 2 public datasets (Camelyon16 [21] and DigestPath2019 [22]) and an in-house dataset (Seegene Medical Foundation-stomach; SMF-stomach). Textbox 1 provides a detailed description of the datasets used in this study, with sample count statistics summarized in Table 1, which presents the statistics for the 3 datasets.

XSL•FO
RenderX

Textbox 1. Description of the datasets used in this study.

- Camelyon16: this dataset consists of 399 hematoxylin and eosin-stained whole slide images (WSIs) of lymph node sections for breast cancer metastasis detection. It is originally split into 67.7% (270/399) training slides and 32.3% (129/399) test slides. For model development and hyperparameter tuning, we further split the 270 training WSIs into 216 (80%) training slides and 54 (20%) validation slides (an 8:2 split). Each slide includes a slide-level diagnosis and polygon-based lesion annotations provided by expert pathologists. In this study, slides containing metastasis were labeled as abnormal, while negative slides were labeled as normal.
- DigestPath2019: we used the colonoscopy tissue segmentation dataset from the DigestPath Challenge 2019. The dataset originally includes 660 training images and 212 test images with slide-level labels (benign or malignant). However, because the test set is not publicly available, we used only the 660 labeled WSIs. We allocated 20% (132/660) of the slides as the test set and used the remaining 80% (528/660) for training and validation. Specifically, we split the 528 slides into 422 (79.9%) for training and 106 (20.1%) for validation. Each WSI is a JPEG image with an average resolution of approximately 5000×5000 pixels. For consistency, we mapped malignant samples to the abnormal class and benign samples to the normal class.
- SMF-stomach (in-house): we constructed an in-house gastric pathology dataset at Seegene Medical Foundation (SMF). Slide preparation and digitization followed standard operating procedures described by Kim et al [23]. A distinct feature of this dataset, as illustrated in Multimedia Appendix 1, is that at least 3 consecutive tissue sections are placed on a single glass slide; however, pixel-level annotations were not exhaustively applied to every section. A single board-certified pathologist reviewed the slides and provided polygon-based annotations only for representative regions; thus, unannotated tissue sections may coexist within the same WSI. Following the diagnostic criteria of Ko et al [24], lesions were originally categorized as malignant, dysplasia, negative, and uncategorized. We excluded the uncategorized class due to its high heterogeneity. For the binary classification task, we mapped malignant and dysplasia to the abnormal class and negative to the normal class. The final dataset comprised 209 slides, allocated as 120 (57.4%) for training, 30 (14.4%) for validation, and 59 (28.2%) for testing.

Table 1. Dataset statistics (whole slide images).

Dataset	Train		Validation		Test	
	Abnormal	Normal	Abnormal	Normal	Abnormal	Normal
Camelyon16	89	127	22	32	49	80
DigestPath2019	160	262	40	66	50	82
SMF-stomach[a]	81	39	20	10	39	20

[a]SMF-stomach: Seegene Medical Foundation-stomach.

Data Preprocessing

We applied the same preprocessing pipeline to all datasets. First, we performed tissue-background segmentation using the multilevel Otsu algorithm. Each WSI was converted to grayscale and thresholded to generate a binary mask that separated tissue from the white background. We retained only the foreground tissue regions and discarded blank or irrelevant areas.

Next, we tessellated each foreground region into nonoverlapping patches of size 224×224 pixels. For Camelyon16 and SMF-stomach, we extracted patches at 20× magnification, whereas for DigestPath2019, we used the original image resolution.

After tessellation, we computed the tissue coverage ratio for each patch and discarded patches containing less than 5% tissue, as these were considered mostly empty. Finally, we used a ResNet-50 [24] pretrained on ImageNet-1k [25] to extract features from each patch. Specifically, we used the output of the third residual block and applied an adaptive average pooling layer to obtain a 2048-dimensional feature vector.

Statistical Methods

To evaluate rank induction, we designed a series of experiments targeting performance, data efficiency, and annotation use. Our evaluation included 6 different experiment types, which are discussed in the following subsections.

Model Comparison

We trained and evaluated 7 different MIL models on 3 datasets: the baseline attention-based MIL (AB-MIL), the attention induction method, 2 variants of CLAM (single-branch [SB]; multibranch [MB]), DS-MIL, HIPT, and the proposed rank induction method.

Low-Data Regime

To test data efficiency, we trained models on subsets of the training data at 20%, 40%, 60%, 80%, and 100% of the full set. For each fraction, we trained all 7 models (AB-MIL, attention induction, CLAM-SB, CLAM-MB, DS-MIL, HIPT, and rank induction) from scratch and evaluated them on a common held-out test set.

Annotation Granularity

To simulate real-world coarse annotations, we degraded annotation precision by expanding the original lesion masks on Camelyon16 slides. At 40× magnification, we added symmetric paddings of 0, 448, 896, 1344, 1792, and 2240 pixels to each polygon annotation. For instance, a 448-pixel padding at 40× resolution adds 1 patch-width around the lesion, which corresponds to a 224-pixel patch at 20× magnification—potentially including normal tissue and simulating noisy annotations.

XSL•FO
RenderX

Subset-Annotated Slide Setting

In real-world clinical settings, not all slides can be exhaustively annotated. We tested rank induction under partial supervision by varying the proportion of positive slides with patch-level annotations (5%, 10%, 20%, 40%, 60%, and 80%) in the Camelyon16 training set (111 positive slides in total). The remaining positive slides were treated with slide-level labels only. Negative slides, by definition, had no lesion annotations.

Ablation Test

To assess the contribution of attention thresholding, we performed an ablation study with threshold values $T \in \{0,0.25,0.5,1,2,5\}$. The case of $T=0$ served as the reference condition (ie, without attention thresholding). We compared WSI classification performance and the cumulative attention weight assigned to nonlesion patches on the test set to examine how different thresholds affect model behavior.

Attention Localization

To assess interpretability, we compared how different MIL models spatially focus on tumor regions in Camelyon16. This is not a dense pixel-wise segmentation map; rather, it is a ranking over discrete patches, with scores defined for all patches in the slide [13]. Because no established gold standard protocol exists for evaluating such attention maps, we quantified spatial alignment between attention and expert lesion annotations using 3 metrics: intersection over union (IoU), Dice score, and pointing game [25]. For each WSI, we ranked all patches by attention weight and then selected only the top α% relative to the number of tumor-annotated patches in that slide ($\alpha \in \{1, 5, 10, 20, 50, 75, 100\}$). To ensure that the ideal case could always achieve a score of 1, IoU and Dice score were computed by sampling up to the number of tumor-annotated patches, whereas the pointing game was evaluated by sampling from all patches in the slide. We then computed IoU and Dice score between the selected high-attention patches and the tumor-annotated patches, averaged over positive test slides. We also measured the pointing game by calculating a hit rate, defined as whether at least 1 of the top α highest attention patches fell within the annotated tumor region (classified as a hit). For all malignant test slides, localization accuracy was defined as hits divided by the sum of hits and misses.

For model evaluation, we computed area under the receiver operating characteristic curve (AUROC), area under the precision-recall curve (AUPRC), and accuracy for slide-level classification. All results were averaged over a 10-fold Monte Carlo cross-validation. We assessed statistical significance using the Mann-Whitney *U* test, with *P* values <.05 considered statistically significant.

Experiment Details

We implemented the models in Python using the PyTorch deep learning framework. WSI data preprocessing was carried out with OpenSlide, OpenCV, and Pillow libraries. Visualization of attention maps and result plots was generated using Seaborn and Matplotlib libraries (specific version information for each library can be found in the GitHub repository). The training and experiments were run on a computing system with a pair of NVIDIA A100 graphics processing units (80 GB memory each) and an Intel Xeon Gold 6338N central processing unit (128 cores, 2.20 GHz) with 512 GB of RAM. Additionally, because the original implementation of attention induction was not publicly available, we reimplemented the method based on the descriptions provided in the paper. Our implementation is available to facilitate reproducibility [26].

For optimization, we used the Adam optimizer with a learning rate of 2×10^{-4} and a weight decay of 1×10^{-5}. We trained each model for up to 200 epochs using an early stopping criterion: if the validation loss did not improve for 7 consecutive epochs (after an initial 20-epoch warmup period), training was stopped. In practice, most models converged well before 200 epochs under this criterion. For all MIL benchmarks, the ResNet-50 backbone was frozen during training. Crucially, we used a frozen ResNet-50 backbone for all MIL benchmarks. Although methods such as DS-MIL and HIPT typically leverage self-supervised pretraining or hierarchical encoders, we used ResNet-50 as the feature extractor for this experiment. This ensured a direct comparison of the MIL aggregation strategies themselves, isolating their performance from the variations in pretrained feature representations.

We set the rank loss hyperparameters as follows: the scaling factor $\sigma=1$ and margin $m=1$ in the pairwise probability formula, and the rank loss weight $\lambda=1$. In each training iteration, to limit memory use and ensure computational efficiency when computing the rank loss, we randomly sampled up to 1024 positive and 1024 negative patches per slide. The attention threshold *T* was set to 1.

Ethical Considerations

This study used both publicly available deidentified datasets (Camelyon16 and DigestPath2019) and a private clinical dataset (SMF-stomach). The Camelyon16 and DigestPath2019 datasets consist of fully deidentified WSIs, publicly released for research under their respective challenge licenses; therefore, no institutional review board (IRB) approval or informed consent was required for their use. For the SMF-stomach dataset, this study was approved by the IRB of the Seegene Medical Foundation (SMF-IRB-2024-015). Given the anonymous and deidentified nature of the retrospective pathological images, informed consent was not required.

Results

Model Performance

We compared rank induction against 6 representative MIL benchmarks: AB-MIL, attention induction, CLAM, DS-MIL, and HIPT, regarding slide-level classification performance. On Camelyon16, rank induction achieved an AUROC of 0.839 (SD 0.050) and an AUPRC of 0.850 (SD 0.042), outperforming all baseline methods with consistently low variance (Table 2). We observed similar performance trends on the DigestPath2019 dataset. Although all models performed well due to the dataset's relative simplicity, rank induction achieved the best results (AUROC=0.995; AUPRC=0.993) with stable variance. On the SMF-stomach dataset, rank induction demonstrated the best performance, achieving an AUROC of 0.875 (SD 0.008) and an AUPRC of 0.937 (SD 0.006). Due to space constraints, the

XSL•FO
RenderX

full accuracy comparison for all datasets is reported in Multimedia Appendix 2.

Data-Efficient Learning With Expert Annotation

To investigate data-efficient training with expert annotation under low-data regimes reflecting real-world constraints, we assessed model performance on Camelyon16 by varying the proportion of training data (Figure 2). With only 20% of the slides, all methods achieved AUROC scores in the range of 0.4 to 0.6, and statistically significant differences were observed between rank induction and the other benchmarks. Among them, rank induction achieved the highest AUROC. At 40% and 60% of the training data size, rank induction significantly outperformed other MIL methods. When trained with 80% of the data, rank induction achieved an AUROC of 0.786 (SD 0.042), surpassing HIPT (AUROC=0.464, SD 0.076), DS-MIL (AUROC=0.709, SD 0.154), AB-MIL (AUROC=0.707, SD 0.186), attention induction (AUROC=0.714, SD 0.193), CLAM-SB (AUROC=0.721, SD 0.180), and CLAM-MB (AUROC=0.847, SD 0.042).

Annotation Granularity

We evaluated model robustness to noisy or imprecise annotations by progressively padding the pathologist-drawn tumor regions on Camelyon16 to simulate coarse lesion markings. Both rank induction and attention induction were trained under each noise condition. With the original annotations (0-pixel padding), rank induction achieved an AUROC of 0.839 (SD 0.050). Even at the highest padding level, its performance declined only slightly to an AUROC of 0.823 (SD 0.050; Figure 3). In comparison, attention induction dropped from an AUROC of 0.742 (SD 0.142) to 0.723 (SD 0.134) as annotation noise increased. Across all levels of annotation coarseness, rank induction consistently outperformed attention induction, although the differences were not statistically significant at some padding levels.

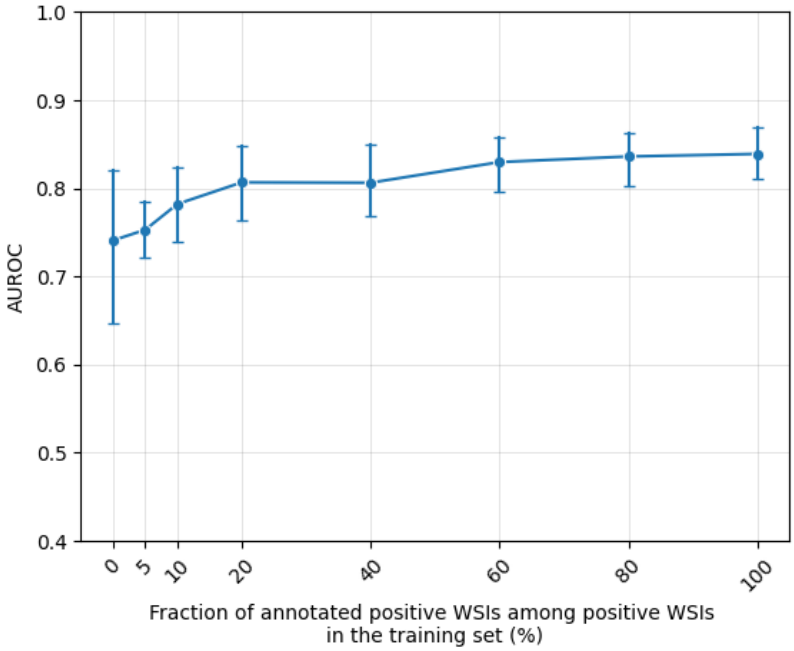
(A) Comparison of slide-level classification performance (area under the receiver operating characteristic curve [AUROC]) between attention induction and rank induction. (B) Representative visualization of the artificially expanded annotations used in the experiment. The thin inner red line indicates the original precise lesion annotation provided by the pathologist (ground truth), while the bold outer red line represents the artificially expanded annotation boundary simulating coarser supervision granularity.



Fraction of Expert Annotation

To simulate real-world scenarios in which annotating all WSIs is infeasible, we evaluated model performance by varying the proportion of annotated positive WSIs in the training set. As a baseline (0% annotation), AB-MIL achieved an average AUROC of 0.741 (SD 0.146; Figure 4). With only 10% (9/89) of positive WSIs annotated in the train dataset, rank induction boosted the performance to an average AUROC of 0.782 (SD 0.070). Increasing the annotation coverage to 20% (18/89) raised the AUROC to 0.807 (SD 0.070), while using all available positive WSIs (N=89) yielded a final AUROC of 0.839 (SD 0.050). Notably, rank induction achieved near-saturated performance with 20% of the annotated data, demonstrating high data efficiency. Moreover, the introduction of even minimal annotation significantly reduced performance variance compared to the unannotated baseline. The performance curve began to plateau beyond approximately 20% annotation coverage, indicating diminishing returns in AUROC gains, while maintaining low variability.

XSL•FO
RenderX

Figure 4. Impact of annotation fraction on area under the receiver operating characteristic curve (AUROC). WSI: whole slide image.

Ablation Test

The impact of varying the attention threshold *T* on model performance and attention distribution is presented in Table 3. As *T* increased from 0 to 2, both AUROC and AUPRC improved steadily, accompanied by a marked reduction in the average sum of attention assigned to nonlesion patches.

Table 3. Effect of attention threshold *T* on whole slide image (WSI) classification performance and sum of attention weight for nonlesion patches.

Threshold	Test dataset (n=129)		Positive WSI in the test dataset (n=49; sum of nonlesion attention), mean (SD)
	AUROC[a]	AUPRC[b]	
0	0.830	0.846	0.465 (0.420)
0.25	0.853	0.878	0.411 (0.434)
0.5	0.869	0.881	0.362 (0.423)
1	0.894	0.905	0.269 (0.387)
2	0.916	0.922	0.178 (0.354)
5	0.909	0.914	0.105 (0.339)

[a]AUROC: area under the receiver operating characteristic curve.

[b]AUPRC: area under the precision-recall curve.

With no thresholding (*T*=0) or low thresholds (*T*<1, where attention distributions remain nearly uniform), the AUROC remained relatively low. This suggests that weakly attended nonlesion patches diluted the slide-level representation. The best performance was observed at *T*=2 (AUROC=0.916; AUPRC=0.922), indicating that moderate thresholding effectively suppresses noise-like, low-value attention weights while preserving discriminative focus. Excessively high thresholds (eg, *T*=5) yielded a slight decline, reflecting an optimal balance near *T*=2.

Attention Localization and Qualitative Analysis

To evaluate the effect of rank induction on attention localization, we examined whether the attention weights were concentrated within expert-annotated regions. Across all 3 localization metrics, rank induction consistently demonstrated greater focus on the annotated areas compared to other MIL methods. At α=5, AB-MIL, attention induction, and rank induction achieved IoU scores of 0.029, 0.023, and 0.031 and Dice scores of 0.056, 0.045, and 0.059, respectively. When α increased to 75, the performance gap between rank induction and the baseline models became more pronounced (Figures 5A and 5B). A similar trend was observed in pointing game accuracy (Figure 5C). Qualitatively, both AB-MIL and attention induction produced noisy attention maps that highlighted not only tumor regions but also large areas of normal tissue, resulting in frequent false positives. In contrast, rank induction generated sharp and well-localized attention maps, accurately delineating lesion areas with minimal off-target activation—closely matching the ground truth annotations. This distinct separation between tumor and normal regions explains rank induction's

XSL•FO
RenderX

superior performance and enhances the interpretability of its predictions (Figure 6).

Discussion

Principal Findings

In this work, we present rank induction, the first method to integrate MIL with expert annotations using pairwise rank constraints. By enforcing a ranking loss that encourages higher attention scores for annotated patches than for nonannotated ones, our approach effectively strengthens the weak supervision signal inherent to MIL frameworks.

We validated rank induction through comprehensive experiments on 2 public datasets and 1 in-house dataset, covering 5 key scenarios: full-data classification, low-data regimes, varying annotation granularity, subset annotation settings, and qualitative visualization. Across all settings, rank induction consistently outperformed baseline methods, including pseudo-labeling approaches and attention induction, while producing more faithful and interpretable attention heat maps.

Notably, the proposed ranking mechanism is model-agnostic and can be used as a versatile module within other MIL architectures. As demonstrated in Multimedia Appendix 3, integrating rank induction into existing methods such as DS-MIL and HIPT consistently improved their performance. In our main experiments, these baseline models (DS-MIL and HIPT) exhibited lower performance than that reported in their original studies. This discrepancy arises because we used a standard ImageNet-pretrained ResNet-50 backbone across all models to ensure a fair comparison of the MIL aggregation strategies themselves, rather than relying on the self-supervised pretraining typically required by those methods. However, even under this constrained setting, incorporating rank induction significantly boosted their classification accuracy, demonstrating the robustness and generalizability of our ranking-based supervision.

Ultimately, these performance improvements stem from bridging weak and strong supervision through informative pairwise constraints that approximate expert guidance. Rank induction is grounded in a simple yet clinically intuitive assumption: models should prioritize annotated regions over nonannotated ones. This inductive bias aligns naturally with domain knowledge in pathology, establishing rank induction as an effective and practical solution for real-world applications.

Real-World Application With Expert Annotations

The pairwise ranking approach in rank induction addresses key challenges associated with expert annotations in real-world settings. In practice, tumor regions often exhibit irregular and heterogeneous morphology with poorly defined boundaries, making precise annotations difficult. Consequently, annotations are frequently coarse or incomplete. Despite this, rank induction maintained robust classification performance even with noisy annotations (Figure 3). This resilience likely stems from the pairwise training mechanism: although some comparisons may involve incorrectly labeled patches, most pairwise relationships remain valid, enabling the model to suppress noise and learn effectively.

Moreover, due to time and resource limitations, only a subset of positive WSIs can typically be annotated in clinical workflows. In such scenarios, extracting maximum value from limited expert input is critical. Unlike attention induction, which relies on assigning exact attention weights to individual patches, rank induction leverages a larger number of patch-pair comparisons from the valid pair set P, which grows quadratically with the number of annotated patches. This design allows the model to achieve near-saturated performance even with partial annotations (Figure 4).

Although pseudolabeling offers an alternative when expert annotations are unavailable, as seen in methods such as CLAM, it introduces uncertainty by relying on the model's own predictions. These pseudolabels are inherently noisier than expert supervision and can lead to cascading errors. In contrast, rank induction avoids this risk by grounding supervision in verified expert annotations, leading to more stable and accurate slide-level predictions, especially in low-data or noisy-label conditions.

Comparison of Fully Supervised Learning and Rank Induction

In scenarios where exhaustive patch-level annotations are available for all WSIs, fully supervised learning remains a strong baseline. Using the same training settings as our MIL models, a patch-level convolutional neural network with a fine-tuned ResNet-50 backbone and max-pooling aggregation achieved an AUROC of 0.892 on Camelyon16. This result outperformed the AUROC of 0.839 achieved by rank induction, which utilizes a frozen backbone and MIL-based aggregation. This result illustrates the upper bound of fully supervised performance given complete expert annotations and domain-specific fine-tuning (Multimedia Appendix 4).

However, in realistic clinical environments, exhaustive annotation is rarely feasible. When only 10% (9/89) of positive WSIs were annotated in the train dataset, the fully supervised model trained on this subset achieved an AUROC of 0.729. In contrast, rank induction, using the same 10% of patch-level annotations and leveraging slide-level labels from the remaining 90%, achieved a higher AUROC of 0.775. The key difference lies in how each method handles unannotated slides. Fully supervised models are limited to the annotated subset and cannot benefit from weak labels. Rank induction, by integrating both patch- and slide-level supervision through pairwise ranking constraints, makes effective use of all available data, even with sparse annotations.

These findings highlight a clear trade-off: while fully supervised learning performs best under ideal, fully annotated conditions, rank induction offers a more practical and annotation-efficient alternative. Its ability to generalize from partial supervision makes it especially suitable for real-world digital pathology applications, where annotations are incomplete or expensive.

Limitations

Our study has several limitations. First, although we validated our method on 3 datasets, including 1 in-house dataset (SMF-stomach), the diversity of organs and pathologies remains limited. Specifically, the SMF-stomach dataset was collected from a single institution, which may introduce biases related to specific staining protocols or scanner characteristics. To fully assess cross-domain robustness, future work should include

XSL•FO
RenderX

evaluation on larger, multicenter cohorts with diverse scanners. Nonetheless, the inclusion of Camelyon16 partially addresses this concern, as it contains slides from multiple medical institutions, providing evidence of generalization.

Conclusions

In summary, rank induction provides a practical and effective solution for improving slide-level classification in digital pathology by bridging weak and strong supervision via pairwise ranking constraints. By leveraging only sparse expert annotations, it achieves a strong balance between annotation efficiency and model performance, outperforming traditional MIL and pseudolabeling approaches, particularly in low-data or noisy-label settings.

Although fully supervised learning may yield higher accuracy when exhaustive annotations are available, rank induction offers a more scalable and annotation-efficient alternative for real-world use. Its robustness with limited annotations and its ability to highlight diagnostically relevant regions underscore the potential of rank-based supervision to improve both model interpretability and generalizability across diverse clinical environments.

Abstract

Background: Delirium is a frequent postoperative complication among patients who have undergone cardiac surgery and is associated with prolonged hospitalization, cognitive decline, and increased mortality. Early prediction of delirium is therefore critical for initiating timely interventions.

Objective: This study proposes the development and validation of a machine learning–based model to predict postoperative delirium in patients undergoing cardiac surgery during intensive care unit (ICU) care, facilitating the early detection of individuals at high risk of delirium and supporting clinicians in the deployment of targeted preventive strategies.

Methods: This study extracted data on postoperative cardiac surgery patients who remained in the ICU for more than 24 hours from the Medical Information Mart for Intensive Care IV version 2.0 (MIMIC-IV 2.0) database and the eICU Collaborative Research Database (eICU-CRD). The MIMIC-IV 2.0 cohort was randomly divided into a training set and an internal validation set in a 7:3 ratio, whereas the eICU-CRD functioned as an independent validation cohort. We used data from the first 24 hours of ICU monitoring to model the likelihood of delirium over the entire ICU admission period. Delirium was identified by a positive Confusion Assessment Method for the Intensive Care Unit evaluation (ie, score ≥4). We built predictive models by using logistic regression, support vector classifier, extreme gradient boosting (XGB), and random forest classifiers. Their performance was assessed via the area under the receiver operating characteristic curve, accuracy, sensitivity, positive predictive value, negative predictive value, and F_1-score.

Results: The analysis involved 2124 patients from the MIMIC-IV 2.0 database and 2406 from the eICU-CRD. A set of 57variables was selected to construct the predictive models. Among the various machine learning models tested, the XGB model demonstrated the best performance for delirium prediction during internal validation. As for external validation, the model achieved an area under the receiver operating characteristic curve of 0.75, indicating strong discriminatory ability. The most important predictive features identified by the model included hospital length of stay, minimum Glasgow Coma Scale score, mean blood pressure, Sequential Organ Failure Assessment score, weight, urine output, heart rate, and age.

Conclusions: The XGB model with strong predictive capability for ICU delirium after cardiac surgery was developed and externally validated. This model offers essential technical support for building real-time delirium alert systems and enables ongoing risk stratification and evidence-based decision-making within the ICU environment.

Introduction

Delirium is an acute neuropsychiatric syndrome commonly associated with encephalopathy, acute cerebral dysfunction, and states of confusion, particularly following surgical procedures [1-4]. In patients undergoing cardiac surgery, the incidence of postoperative delirium has been reported to range from 10% to 40% [5-7]. This condition is linked to a variety of adverse outcomes, including heightened pain perception, depression, cognitive impairment, and increased mortality [8,9]. Currently, the assessment of patients' arousal can be conducted using standardized tools such as the Richmond Agitation-Sedation Scale and the Confusion Assessment Method for the Intensive Care Unit (CAM-ICU) to identify different types of delirium with distinct characteristics [10-12]. Despite the existence of standardized instruments, the diagnosis of delirium frequently depends on the patient's subjective assessment of their condition. If the occurrence of delirium in patients could be predicted within a short period, it will substantially reduce the aforementioned risks.

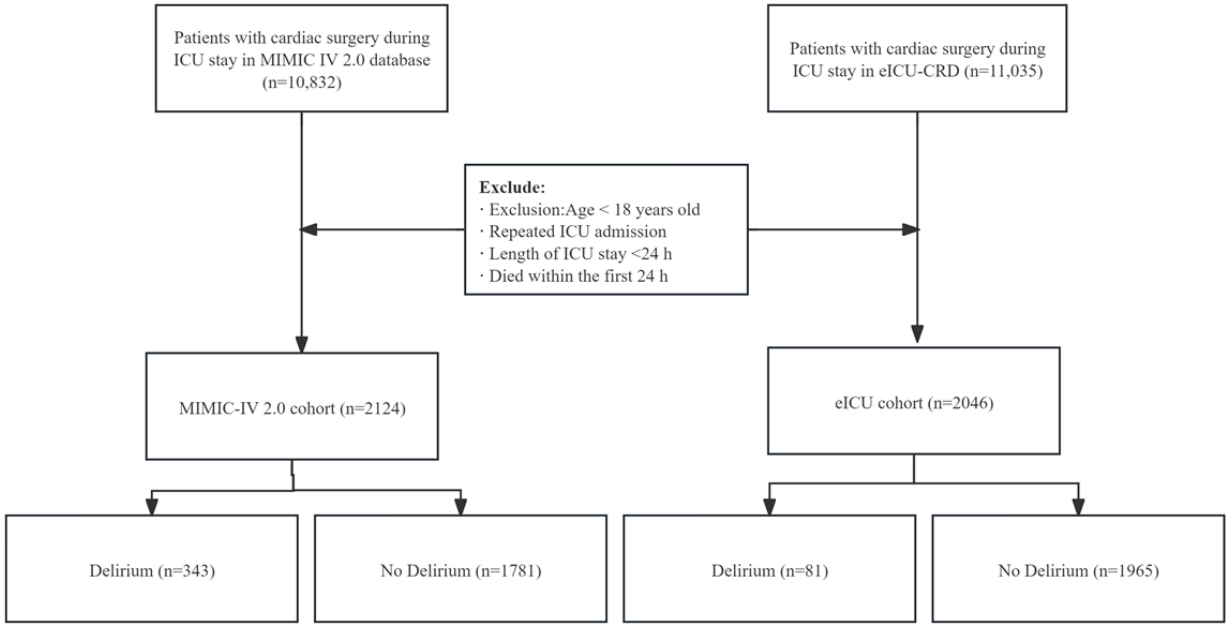
Machine learning (ML), a branch of artificial intelligence, has driven notable progress across numerous domains of health care [13,14]. One such area where ML has shown its potential is in the postoperative surveillance with cardiac surgery, offering more information to predict delirium [15,16]. It has the potential to improve patient health care outcomes [17,18]. Compared to traditional data analysis techniques, ML models can provide more intricate predictions and perform real-time monitoring using objective data from all patients [19-21]. Furthermore, recent research has also used ML to forecast the near-term mortality rates of patients after cardiac operations. For example, Nistal-Nuño [22] constructed an extreme gradient boosting (XGB)–based predictive model to estimate 24-hour postoperative mortality following cardiac surgery. The outcome demonstrated that XGB attained an area under the receiver operating characteristic curve (AUC) of 87.5%, signifying the model's exceptional performance in forecasting intensive care unit (ICU) mortality, notably surpassing other models. Zhang et al [23] assessed an ML model, comparing it to existing severity-of-illness systems to develop a real-time tool for predicting death. However, no correlation-predictive models using ML have been developed for patients who experience delirium after cardiac surgery.

In this study, we created and verified 4 models using ML techniques to anticipate the occurrence of delirium and facilitate identification. Furthermore, we enhanced the interpretability of the results by prioritizing the independent variables according to their predictive significance.

Methods

Ethical Considerations

This study used data from 2 publicly available critical care databases: Medical Information Mart for Intensive Care IV version 2.0 (MIMIC-IV 2.0) database and eICU Collaborative Research Database (eICU-CRD). Both databases were approved by the institutional review boards of the Beth Israel Deaconess Medical Center and the Massachusetts Institute of Technology. As all data were fully deidentified before release, the requirement for individual informed consent was waived in accordance with the Declaration of Helsinki and applicable regulations. All team members underwent certified training in "Data or Specimens Only Research" to comply with ethical regulations governing dataset access.



Study Population

This study used 2 publicly available critical care databases to develop and validate a predictive model. The training dataset was sourced from MIMIC-IV 2.0, which includes 76,943 ICU admissions recorded at Beth Israel Deaconess Medical Center (Boston, Massachusetts, United States) between 2008 and 2019 [24]. For external validation, we used the eICU-CRD, which contains deidentified data for over 200,000 patients admitted to 208 US hospitals between 2014 and 2015 [25]. Both databases contain structured clinical data, including demographics, vital signs, laboratory test results, procedures, medications, and outcomes. We included adult patients (aged ≥18 years) who underwent major cardiovascular surgeries, such as coronary artery bypass grafting, heart valve repair or replacement, combined procedures, or other surgeries involving cardiopulmonary bypass.

We applied consistent inclusion and exclusion criteria across both datasets to ensure cohort comparability and data quality. Inclusion criteria required patients to meet the age threshold and have documented cardiovascular surgery. We excluded patients who had ICU stays shorter than 24 hours (to ensure sufficient observation data), missing essential demographic or outcome variables, or delirium recorded within the first 24 hours of ICU admission (to preserve the prediction time window). Although the 2 datasets differ in time range and hospital coverage, we aligned the study population by applying uniform definitions for surgical type and using a standardized 24-hour observation window. Figure 1 summarizes the baseline characteristics of the 2 cohorts.

XSL•FO
RenderX

Figure 1. Schematic representation of the study design. eICU-CRD: eICU Collaborative Research Database; ICU: intensive care unit; MIMIC-IV 2.0: Medical Information Mart for Intensive Care IV version 2.0.

Delirium Assessment

Delirium served as the primary outcome, identified on the basis of a positive CAM-ICU assessment (score ≥4) and consistent diagnostic coding. The observation window was the first 24 hours after ICU admission, during which patient data were collected for modeling. If at least one positive delirium assessment occurred at the time of prediction, the patient was considered delirious.

Data Extraction and Processing

The clinical data were retrieved and extracted using the structured query language, with pgAdmin 4 serving as the administrative platform for PostgreSQL. The prediction model included just clinical and laboratory characteristics that were accessible on the initial day of admission to the ICU, with patients being recognized by their unique ID numbers. The predictors consisted of the following variables— (1) demographics: age, gender, ethnicity and weight; (2) vital signs: heart rate, mean blood pressure, respiratory rate, systolic blood pressure, and temperature; (3) laboratory analysis: hemoglobin level, platelet count, white blood cell count, lactate and urine output; (4) severity scoring: Glasgow Coma Scale (GCS) and Sequential Organ Failure Assessment (SOFA) scores; (5) comorbidities: myocardial infarction, congestive heart failure, peripheral vascular disease, cerebrovascular disease, dementia, chronic pulmonary disease, rheumatic disease, peptic ulcer disease,diabetes (with control, without control), paraplegia, renal disease, malignant cancer, severe liver disease, and AIDS; (6) medications: opioids, barbiturates, benzodiazepines, acetaminophen, antipsychotics, anticoagulant, antihistamines, diuretics, anesthesia, and anticholinergics; (7) treatment measures: emergency admission, first care unit, last care unit, renal replacement therapy, invasive ventilation, length of ICU stay.

Missing Data Management

Variables exhibiting a missing value rate exceeding 10% were omitted to prevent potential bias. Variables with less than 10% missing values were subjected to multivariable imputations [26].

Data Balance

The dataset showed a marked imbalance, with notably fewer positive delirium cases compared with negative ones, which caused the model to lean toward predicting the majority (negative) class. To mitigate this issue, we used the Synthetic Minority Oversampling Technique to artificially augment the number of positive samples, thereby achieving a more balanced class distribution and enhancing the model's ability to generalize.

Feature Selection

The feature selection process involved using the recursive elimination of features approach of the random forest [27]. This method was used to identify the most optimal combinations of predictive variables. By examining the weight of features and their correlation and after stratified 10-fold cross-validation, final features were selected based on importance scores, correlation analysis, and cross-validation results. This process reduced dimensionality while preserving predictive power.

Model Development and Hyperparameter Tuning

The MIMIC-IV 2.0 dataset (N=2124) was randomly split into a training set (1487/2124, 70%) and a testing set (637/2124, 30%), whereas the eICU-CRD dataset was used as an external validation cohort. We developed prediction models using 4 widely adopted ML algorithms. Logistic regression was implemented for binary classification using maximum likelihood estimation [28]. Random forest, an ensemble learning method, combined multiple decision trees through majority voting to

XSL•FO
RenderX

enhance predictive performance [29]. XGB used a gradient boosting framework to iteratively build strong learners from weak ones [30]. Support vector classifier aimed to find the optimal hyperplane in a high-dimensional space for classification [31]. Bayesian optimization was used to identify optimal hyperparameters for each model, improving training efficiency and performance [32].

Model Performance Evaluation

To comprehensively assess the discriminatory performance of the prediction models, we used the receiver operating characteristic (ROC) as the primary evaluation metric. Additional metrics included accuracy, positive predictive value, negative predictive value, and sensitivity. We also reported the F_1-score, the harmonic mean of precision and sensitivity, to reflect the balance between these two metrics. Together, these indicators were used to evaluate the clinical applicability of each model in stratifying the risk of postoperative delirium among cardiac surgery patients. Shapley Additive Explanations (SHAP) was used to investigate the interpretability of the final predictive model.

Statistical Analysis

All statistical analyses were conducted using Stata 17.0 and SPSS (version 27.0; IBM Corp). Frequencies and percentages were used to summarize categorical variables, with comparisons made via the chi-square test. The distribution of continuous variables was assessed using the Shapiro-Wilk test. Normally distributed data were reported as mean (SD) and compared using independent 2-tailed *t* tests. Skewed data were summarized as median and IQR and analyzed using the Mann-Whitney U or Kruskal-Wallis test, based on group composition. Statistical significance was determined using 2-sided tests, with a threshold of $P<.05$.

Results

Baseline Characteristics

A total of 2124 patients from the MIMIC-IV 2.0 database were included in the final analysis. Among them, 16.1% (343/2124) of cardiac surgery patients were diagnosed with delirium during their hospital stay, occurring after the first day of ICU admission. In the external validation cohort, an analysis was conducted on 2046 cases obtained from the eICU-CRD, of whom 3.81% (81/2046) developed delirium during the same postoperative period, also defined as after the first ICU day. In these patients with delirium, maximum heart rate, minimum mean blood pressure, minimum hemoglobin level, minimum platelet count, maximum white blood cell count, urine output, minimum GCS score, SOFA, and length of ICU stay showed a notable disparity between the two different groups. Tables 1-3 present a concise summary of the comparison of fundamental traits, vital signs, and laboratory analysis between patients with and without delirium. According to the data, patients with delirium are predominantly male, typically older, and have longer hospital stays with higher severity scores upon admission. Additionally, factors such as weight loss, decreased urine output, and decreased mean arterial pressure may all exacerbate the likelihood of delirium in patients.

Model Performance Evaluation

Using 4 ML algorithms, we developed predictive models to assess the risk of postoperative delirium in cardiac surgery patients, leveraging electronic health record data for early identification of high-risk individuals. Figure 2 presents ROC curves of all models, allowing a systematic comparison of their discriminative performance. Among the models, XGB demonstrated the best overall predictive performance, achieving the highest AUC for identifying patients at risk of delirium. The random forest classifiers also exhibited strong performance, although slightly lower than that of the XGB model. Notably, both XGB and random forest classifiers maintained high predictive accuracy, indicating good model generalizability. In contrast, support vector classifier and logistic regression models showed substantially lower discriminative power. To further validate the clinical applicability of the XGB model, model performance was assessed using several evaluation metrics,including accuracy, sensitivity, positive predictive value, and negative predictive value (Table 4). Furthermore, the corresponding confusion matrices illustrating these metrics are displayed in Figure 3.

The model was externally validated using the eICU-CRD, a large-scale critical care dataset incorporating records from 208 hospitals, to assess its performance on independent data. The XGB model maintained strong discriminative performance in ROC analysis, with high AUC values confirming its reliability across institutions (Figure 4). The model was further rigorously validated through precision-recall analysis and calibration curves (Figures 5A and B).

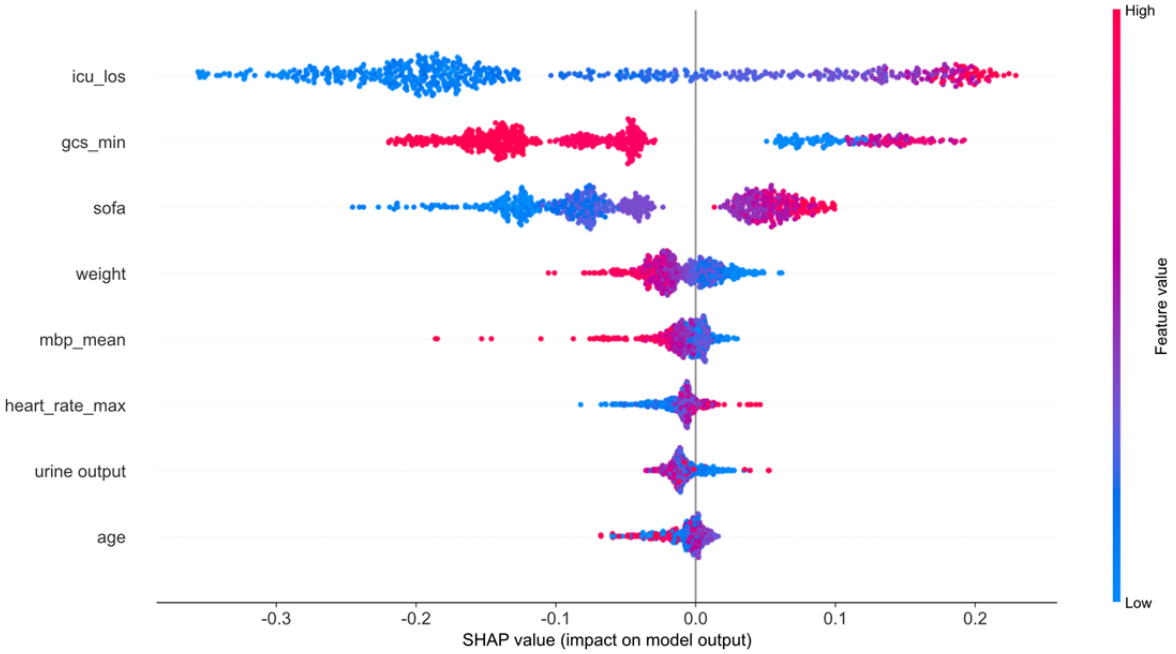
Variable Importance



The predictive contribution of each variable to postoperative delirium varied among cardiac surgery ICU patients. The XGB algorithm was used to estimate variable importance and highlight the top predictors influencing model accuracy. The top predictors included length of stay in ICU, lowest GCS score, age, mean blood pressure, SOFA score, weight, heart rate and urine output (Figure 6). To further interpret the influence and directionality of these features on model predictions, we generated SHAP summary plots (Figure 7). These visualizations provide a detailed explanation of how individual features contributed to the model output, offering insights into their relative impact and potential clinical relevance.

Discussion

Principal Findings

In this large-scale retrospective study, we developed and validated an ML model to predict postoperative delirium, a common and burdensome complication after cardiac surgery, with reported incidence rates ranging from 18% to 52% [33-35]. The XGB-based model, trained on the MIMIC-IV 2.0 dataset, demonstrated excellent performance in internal validation (AUC=0.91) and maintained strong discriminative power in external validation using the eICU-CRD dataset (AUC=0.75). Key predictors identified by the model included length of stay in ICU, min GCS score, mean blood pressure, SOFA score, weight, urine output, heart rate, and age. As far as we are aware, this study presents one of the earliest ML models that are developed to predict delirium in a diverse population of cardiac surgery patients. Importantly, our model relies on routinely available clinical data from the first 24 hours of ICU admission, enabling early identification of high-risk patients throughout their ICU stay. This early-warning capability offers a critical window for timely intervention, allowing clinicians to implement targeted strategies at the earliest stages of delirium onset. The model's high temporal relevance and wide applicability support its potential use in guiding personalized care plans and improving patient outcomes.

Comparison With Previous Work

Among existing tools for predicting postoperative cognitive complications, the CAM-ICU score remains the most widely used [36-38]. However, its applicability may be limited in certain surgical contexts or patient subgroups. Some individual populations require more tailored analysis, and it is important to note that CAM-ICU may not capture the full spectrum of delirium severity, potentially compromising its construct validity [12,39,40]. Therefore, balancing feasibility and validity in specific clinical settings is essential. Our ML approach addresses these limitations by offering a data-driven, individualized risk assessment that adapts to patient heterogeneity and enables broader clinical applicability.

Furthermore, this study incorporated SHAP to enhance the interpretability of the XGB model. SHAP provides a transparent and traceable explanation framework for individualized risk prediction of delirium, allowing visualization of how each feature influences the model's output in both direction and magnitude [41,42]. This helps clinicians better understand the rationale behind specific predictions. Through SHAP analysis, we identified a set of clinically relevant predictors closely associated with patient deterioration, including length of stay in ICU, lowest GCS score, age, mean blood pressure, SOFA score, weight, urine output, and heart rate.

The XGB model demonstrated superior predictive performance, its clinical value extends beyond accuracy—it lies in its ability to inform real-time decision-making. Future research should focus on integrating these key features into dynamic clinical monitoring and intervention workflows. For instance, early abnormalities in high-impact variables, such as lowest GCS score, mean blood pressure, or urine output could trigger automated alerts within electronic health record systems, enabling real-time risk stratification. Additionally, individualized SHAP-based explanations could support patient-centered clinical strategies, facilitating a closed-loop "early warning–targeted intervention" model. This approach may ultimately enhance early prevention and improve outcomes in postoperative delirium management.

Strengths and Limitations

This study has several notable strengths. First, model development was based on large scale, real-world data from 2

XSL•FO
RenderX

publicly available critical care databases (MIMIC-IV 2.0 and eICU-CRD), which offer extensive clinical information and robust sample sizes, thereby increasing the trustworthiness and general applicability of our findings. Second, as far as we are aware, this is the earliest known study to apply ML techniques for predicting postoperative delirium in a broad cardiac surgery cohort. This tailored approach enables more accurate risk stratification by accounting for individual variability across surgical subtypes. One notable strength of our model lies in its exclusive use of routinely available clinical data obtained within the first day of ICU stay, eliminating the need for additional or specialized testing. The use of early time-series features to quantify dynamic changes in key physiological indicators allows real-time risk estimation with high clinical practicality and timeliness. From a translational perspective, the model demonstrated a sensitivity of 77% in identifying high-risk patients early, providing a valuable window for initiating preventive interventions. These proactive measures have the potential to reduce ICU length of stay, lower per-patient hospitalization costs, and minimize readmission risk, ultimately interrupting the cascade of adverse outcomes often associated with postoperative delirium. Finally, by focusing on the first day of ICU data, the model creates a strategic opportunity for timely clinical action, supporting the implementation of early, targeted strategies aimed at mitigating symptom progression and reducing complication rates.

Our study has several limitations. First, we acknowledge that our findings may be racially biased against White patients and the applicability to other populations may be limited due to the database being derived from Western countries. Second, the use of open public databases to obtain data may introduce missing data bias, which is unavoidable. Third, as this study is retrospective and observational in nature, selection bias is inevitable. Specifically, the collection of retrospective data depends on existing medical records that may vary in completeness and accuracy due to differences in clinical documentation practices and data entry habits. Such inconsistencies can result in missing or inaccurate key clinical information, which in turn affects the quality of data used for model training. Moreover, retrospective studies lack the ability to actively intervene in or control the research process, making it difficult to eliminate the influence of confounding variables. This limitation weakens the strength of causal inferences drawn from the analysis. Additionally, our model has not yet undergone prospective clinical validation, which limits its current applicability in real-world clinical practice. Prospective validation, ideally conducted under well-controlled trial conditions and standardized workflows, is essential for evaluating the predictive performance and robustness of the model in diverse clinical settings. Without this step, there remains a risk that the model's actual performance may deviate from the retrospective findings, particularly when applied to different health care systems or patient populations.

Conclusions

We constructed and assessed an effective predictive model targeting postoperative delirium in patients admitted to the ICU after cardiac surgery. This model leverages routinely available patient information from the initial 24-hour ICU stay to estimate the risk of delirium throughout the hospitalization period. Given its reliance on readily available early-stage variables, the model has the potential to serve as a practical and accessible risk stratification tool for health care professionals and patients when selecting optimal cardiac treatment strategies.

Acknowledgments

The authors gratefully acknowledge the institutional review boards of Beth Israel Deaconess Medical Center and the Massachusetts Institute of Technology for providing authorization to use data from the Medical Information Mart for Intensive Care IV version 2.0 database and eICU Collaborative Research Database.

Funding

The authors have not declared a specific grant for this research from any funding agency in the public, commercial, or not-for-profit sectors.

Data Availability

The datasets used and analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

HH contributed to study design, data extraction, methods, data analysis, and manuscript preparation. YW, QZ, JW, and LL contributed to data interpretation and data analysis. Abstract

Background: Machine learning models are increasingly used to predict patients at risk of high health care usage for targeted interventions.

Objective: This study aimed to evaluate the predictive performance of multiclass ensemble models across different levels of health care usage and assess their potential application through real-world economic impact analysis.

Methods: A total of 4 previously developed binary classification models (base learners)—boosted trees, multivariate adaptive regression splines, multilayer perceptron, and logistic regression—were extended using a stacking ensemble approach. These base learner models generated individual-level predicted probabilities, which were used as inputs to build multiclass prediction models forecasting usage across defined strata: length of stay (LOS) of <7, 7-13, 14-29, and ≥30 days, and emergency department (ED) visits of <3, 3-4, 5-9, and ≥10 visits. In total, 3 ensemble algorithms were evaluated: random forest, boosted trees, and linear support vector machines. Ensemble models were trained on registry data from 2020-2021 and temporally validated on 2021-2022 data. Performance was assessed using multiclass area under the receiver operating curve, accuracy, and confusion matrix–derived metrics. Economic impact was estimated via Monte Carlo simulations using inpatient billing data, assuming a 20% cost reduction in the following year.

Results: The models were trained on 108,886 patients and validated on 111,004 patients. Among all ensemble configurations, boosted tree models regardless of base learner achieved the highest performance, with multiclass area under the receiver operating curve scores of 0.6877 (95% CI 0.6927-0.7255) for LOS and 0.7601 (95% CI 0.7301-0.7654) for ED visits, and corresponding accuracies of 0.6522 (95% CI 0.6465-0.6579) and 0.7457 (95% CI 0.7405-0.7508), respectively. In the validation set, these models correctly assigned 30.3% of inpatient LOS and 39.8% of ED visits to the correct class, identifying 77% of future inpatient users and 73.9% of future ED users. Economic impact analysis for LOS identified the boosted tree model with logistic regression base learner as dominant, achieving a simulated average cost reduction of SGD $152 million (US $111 million), SGD $2.4 million (US $1.75 million; 1.5%) more than the next best model using a multilayer perceptron base learner.

Conclusions: Ensemble models can effectively predict multilevel health care usage and potentially generate meaningful cost savings when applied to real-world settings. These models may support targeted interventions and guide planning and budgeting in diabetes-related population health programs.

KEYWORDS

diabetes mellitus; healthcare utilization; population health management, machine learning; artificial intelligence; economic analysis; decision analysis; Monte Carlo simulation

Introduction

Health care expenditure in high-income countries is rising [1], with chronic diseases (specifically diabetes mellitus) being a leading contributor. Diabetes accounts for approximately 15% of health care expenditure in the United States [2], 9% in the European Union [3], and 11% in Singapore [4]. It is a significant cause of cardiovascular disease, kidney failure, eye disease, peripheral vascular disease, and neuropathy, all associated with substantial morbidity, mortality, and higher health care costs.

Health care spending is also highly skewed, with a small proportion of patients incurring most costs [5]. Efforts to identify high-need, high-cost (HNHC) patients—typically the top 5% of usage or cost—have led to predictive models using regression and machine learning [6]. However, the clinical utility of these models remains uncertain, as few studies assess their net benefit compared with not using them [6-8]. Furthermore, the potential to reduce costs among the top decile or 5% of high-cost patients is smaller than commonly assumed [9], possibly due to heterogeneity in patient characteristics and usage patterns, variability in group membership over time, and a small proportion who are amenable to cost-reducing interventions [5,9,10]. Focusing narrowly on the highest users may also overlook many individuals with future health care needs outside this group.

Building on these insights, our previous study expanded the predictive focus beyond traditional HNHC patients by developing binary classification models to predict inpatient and emergency department (ED) usage across various thresholds for patients in the Singapore Health Services Diabetes Registry (SDR), a clinical database of over 130,000 patients with diabetes [11]. In this study, we extended that work by creating separate multiclass ensemble models for inpatient bed days and ED visits. We validated these models, evaluated their relevance for population health program development, and analyzed their potential economic impact using real-world financial data [7,8]. Our goal is to develop clinically actionable predictive models that can be integrated into broader diabetes-related population health initiatives.

Methods

Study Design and Population

This study used data from the SDR spanning 2020-2022, comprising 2 datasets: 2020-2021 and 2021-2022. The 2019-2020 dataset, previously used to develop the binary classification models [11], was excluded from the current analysis to prevent overfitting. Each dataset (2019-2020, 2020-2021, and 2021-2022) was constructed as a cross-sectional snapshot based on a fixed 1-year prediction window. Patients could appear in multiple datasets across years if they continued to meet inclusion criteria for entry into the registry [12]; however, within each dataset, only 1 record per patient per year was used. Multiple visits within the same year were aggregated to derive annual service-level usage metrics (eg, total inpatient bed days and total ED visits).

Predictor Variables

Individual-level predicted probabilities from the binary classification models, which reflect the predicted likelihood of future usage, were used as predictor variables in the corresponding ensemble models (ie, length of stay [LOS] probabilities for the LOS ensemble model and ED probabilities for the ED ensemble model). Additionally, current-year LOS or ED visits were also included as predictors. Full details on predictor variables for the binary models are provided in Table S1 in Multimedia Appendix 1 and our previous publication [11]; briefly, they include age, gender, ethnicity, housing type, comorbidities (eg, hypertension, hyperlipidemia, and chronic kidney disease), diabetes-related complications, and mean glycated hemoglobin.

Outcome Variables

Multiclass ensemble models were developed to predict usage for LOS and ED visits across 4 classes each. For LOS, the classes were <7 days, 7-13 days, 14-29 days, and ≥30 days. For ED visits, the classes were <3 visits, 3-4 visits, 5-9 visits, and ≥10 visits.

Inclusion and Exclusion Criteria

Patients aged 18 years or older with type 2 diabetes mellitus were included. Patients with missing variables were excluded, as data imputation was not performed, and most machine learning algorithms used in this study do not natively support missing values.

Handling Unbalanced Data

Class imbalance negatively affected model performance in previous studies, and random upsampling outperformed the synthetic minority oversampling technique [11]. We applied random upsampling using the ‘upSample’ function from the *caret* package [13] to achieve equal representation across all classes in the training dataset (ie, an equal number of patients across all classes).

Machine Learning Models

Previously developed binary classification models from the multi-institutional SDR were used to predict total inpatient LOS and ED visits over a calendar year [11]. Predictions were made across 3 thresholds in the 2 outcomes: LOS of ≥7, ≥14, and ≥30 days; and ED attendance of ≥3, ≥5, and ≥10 visits.

We used the best-performing binary classification models from our previous work, which were trained using the 2019-2020 dataset as base learners: boosted trees, multivariate adaptive regression splines, multilayer perceptron, and logistic regression [11]. For each base learner type, 3 separate binary models were developed to predict inpatient LOS of ≥7, ≥14, and ≥30 days, and ED attendance of ≥3, ≥5, and ≥10 visits, respectively. The

XSL•FO
RenderX

individual-level predicted probabilities from these binary models were then used as inputs (meta-features) in a stacking ensemble model designed to classify patients into 4 mutually exclusive outcome categories (LOS: <7, 7-13, 14-29, ≥30 days, and ED: <3, 3-4, 5-9, ≥10 visits).

Stacking was selected over voting-based methods for its ability to learn optimal weights for combining base learner outputs, rather than treating all models equally or assigning manual weights [14]. Furthermore, 3 algorithms were tested as meta-learners: random forest, boosted trees, and linear support vector machines (SVMs). All models were developed in R (version 4.3.1; R Core Team) using the *tidymodels* package [15].

The 2020-2021 dataset was used to train and test the ensemble models, with a 75:25 split. Models were then temporally validated on an unseen 2021-2022 dataset. Each dataset represented a patient-year observation with a fixed 1-year prediction horizon. All predictor variables, including inpatient bed days and ED visits, were derived exclusively from the preceding calendar year to predict usage in the subsequent year, ensuring that no future information was used at the time of prediction and avoiding look-ahead bias. While patients could appear in multiple datasets across years, training and validation were temporally separated to ensure that predictions were evaluated on future, unseen patient-year data, consistent with real-world deployment for chronic disease management. To ensure consistency and reproducibility, we used default hyperparameters for all base learners and meta-learners.

Explainability

We did not conduct explainability analysis for the ensemble models, as previous analyses of the base learner models with model-specific variable importance scores, permutation feature importance plots, and partial dependence plots demonstrated consistent and predictable behavior [11]. The ensemble models' transparent construction from base learner outputs rendered additional explainability analysis unnecessary.

Performance Indicators

Model performance was assessed using multiclass area under the receiver operating curve (AUROC; one-vs-rest approach), and accuracy (95% CI) was calculated using the DeLong method (via the pROC package) for AUROC and the confusionMatrix function (from the caret package) for accuracy. Confusion matrices were analyzed, and new metrics specific to our 4-class prediction task were developed for population health programs (Figure 1). Additional metrics, including sensitivity, specificity, positive predictive value, negative predictive value, and balanced accuracy, are detailed in the Multimedia Appendix 1.

These new metrics were designed for population-level interventions using the prediction models. Our priorities were maximizing correct predictions, followed by identifying users, and minimizing unnecessary predictions (ie, patients predicted to have usage but who ultimately did not). Maximizing correct predictions minimizes underpredictions, overpredictions, and missed cases. Increasing identified users enables interventions to reach more patients with future needs, while minimizing unnecessary predictions enhances program efficiency by reducing resources spent on patients unlikely to use services.

Figure 1. Confusion matrix in a 4-class problem and related evaluation variables.

Labels	Inpatient bed days	Emergency Department Visits
0	< 7 days	< 2 visits
1	7 - 13 days	3 - 4 visits
2	14 - 29 days	5 - 9 visits
3	≥ 30 days	≥ 10 visits

Variable	Description	Formula
Total	All patients in the prediction	$= A + B + \cdots + P$
Users	All actual users	$=$ Total $- (A + E + I + M)$
Correct predictions	Ratio of correct predictions (*among patients with actual usage*) to all users	$= \frac{F + K + P}{\text{Utilizers}}$
Underprediction	Ratio of underpredictions (*among patients with actual usage*) to all users	$= \frac{G + H + L}{\text{Utilizers}}$
Overprediction	Ratio of overprediction (*among patients with actual usage*) to all users	$= \frac{J + N + O}{\text{Utilizers}}$
Unnecessary predictions	Ratio of predicted users (*among patients with **no** actual usage*) to all patients with ***no*** usage	$= \frac{E + I + M}{A + E + I + M}$
Missed cases	Ratio of predicted nonusers (*among patients with actual usage*) to all users	$= \frac{B + C + D}{\text{Utilizers}}$
Identified users	Ratio of predicted users (*among patients with actual usage*) to all users	$=$ Correct predictions + Underprediction + Overprediction

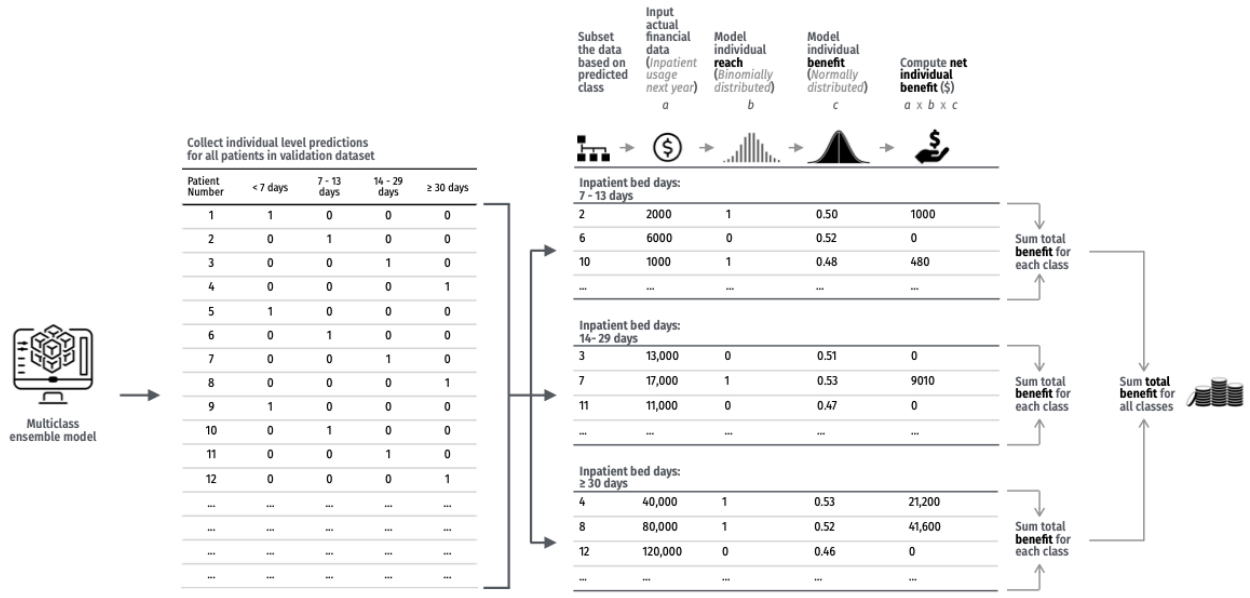
Economic Impact Analysis of the Models

We assessed the potential economic impact of the top 5 ensemble models with the largest proportion of correct predictions for inpatient bed days. Using individual-level inpatient cost data, we modeled hypothetical cost reductions to simulate the financial implications of targeted intervention. These simulations assume that accurately predicted patients would receive effective interventions that reduce future inpatient costs. Cost savings were not attributed to the prediction alone, but to downstream programs triggered by the prediction.

In total, 2 key parameters were incorporated—reach and benefits, both factors important to population-level impact. Reach was defined as the proportion of patients within a predicted usage class who would receive the intervention [16], while benefits referred to the hypothetical percentage reduction in future inpatient costs among those reached, attributable to the intervention.



We used total inpatient costs (in Singapore dollars and the equivalent United States dollars [US $], presubsidies) for each calendar year, using the conversion rate of SGD $1=US $1.370, which is accurate as of 1 June 2022. We assessed model performance using fixed effects and Monte Carlo simulations with 10,000 iterations to account for random effects. “Total benefit” was defined as the simulated reduction in inpatient costs in the following year, enabling us to compare models and identify the dominant one. A schematic of the economic impact analysis model is provided in Figure 2, with parameters detailed in Table S2 in Multimedia Appendix 1.

In the fixed effects model, we modeled the benefit at a uniform 50% cost reduction for all identified patients—an optimistic scenario to benchmark maximum potential impact. In contrast, the Monte Carlo simulations modeled a more conservative and realistic benefit at an average cost reduction of 20% across all classes, with stochastic variation applied using a normal distribution.

Real-world programmatic use was further simulated by varying reach across usage tiers: average reach levels were set at 90% for the highest usage class, 70% for the middle class, and 50% for the lowest classes, each with a 5% variance. For example, the reach for the highest users ranged from 85% to 95% across simulations. This tiered approach reflects potential operational realities: patients predicted in the highest usage class are fewer in number and more likely to be prioritized and successfully engaged by targeted interventions. In contrast, lower usage classes include larger populations, making it less feasible to reach all patients in practice. To account for individual variability in intervention uptake, reach levels were also modeled using a binomial probability distribution.

From the Monte Carlo simulations, we identified the dominant model as the one with the highest median cost savings. To explore uncertainty and assess the robustness of this selection, we performed parameter sensitivity analysis stratified by usage class. Specifically, we varied the reach and benefit parameters in 10% intervals (ranging from 10% to 90%), resulting in 81 unique parameter combinations. For each combination, 1000 Monte Carlo runs were conducted to account for stochastic variability. The distribution of cost savings across simulations was analyzed, and results were visualized using the *plotly* package [17] to provide an interactive and detailed view of model performance under different programmatic scenarios.

Figure 2. Schematic of economic impact analysis model.

Reporting Checklist

We reported our study using the Transparent Reporting of a multivariable prediction model for Individual Prognosis or Diagnosis + Artificial Intelligence (TRIPOD+AI) checklist (Multimedia Appendix 2) [18].

Ethical Considerations

Ethics approval was obtained from the Singapore Health Services Centralized Institutional Review Board before initiating this study (reference 2022/2133). As all participant data were deidentified, a waiver for participant consent was also obtained. All procedures were performed in compliance with relevant laws and institutional guidelines.

Results

Characteristics of the Datasets

The demographics, comorbidities, and usage characteristics of the datasets have been previously described [11]. The 2020-2021 and 2021-2022 datasets included 108,886 of 140,859 (77.3%) patients and 111,004 of 137,584 (80.7%) patients from the total SDR cohort, respectively. Total inpatient costs (presubsidies) per annum are summarized in Table 1, and inpatient LOS distributions are illustrated in Figures S1-S3 in Multimedia Appendix 1.

Inpatient usage showed an increasing trend, with gross inpatient bills (unadjusted for inflation) rising from a nominal value of SGD $808 (US $590) million in 2019 to SGD $1.01 billion (US $737 million) in 2022. The proportion of patients with inpatient usage increased from 46,686 of 134,670 (34.7%) in 2019 to 51,228 of 137,627 (37.2%) in 2022, while the average cost per patient rose from SGD $17,321 to SGD $19,704 (US $12,643 to US $14,382). Total inpatient costs were heavily right-skewed (Table S3 in Multimedia Appendix 1) and followed a Pareto distribution (Figure S1 in Multimedia Appendix 1), with the top 10% of patients accounting for 80% of cumulative health care costs and inpatient bed days annually (Figures S1 and S2 in Multimedia Appendix 1). A strong correlation was observed between gross inpatient bills and inpatient bed days (Figure S3 in Multimedia Appendix 1).

Multiclass Model Performance

We developed 12 ensemble models by combining 4 base learner models with 3 ensemble algorithms: random forest, boosted trees, and linear SVM. Detailed performance metrics for all 12 models on the test dataset are provided in Table S4-S6 in Multimedia Appendix 1. We then selected top 5 models for each prediction task based on the highest percentages of correct predictions and identified users (Table 1 and Table S4 in Multimedia Appendix 1), and their performance was temporally validated on the unseen dataset from 2021 to 2022; detailed performance metrics for these models on the test dataset are provided in Tables S7 and S8 in Multimedia Appendix 1.

Boosted tree models outperformed other ensemble algorithms across metrics, including multiclass AUROC, correct predictions, and identified users. While linear SVM models had comparable multiclass AUROC scores to boosted tree models, they showed significantly lower correct predictions, fewer identified users, and more missed cases. Random forest models performed poorly across all metrics.

Boosted tree models demonstrated consistent performance on test and validation datasets, indicating robustness on unseen data (Table 1 and Table S4 in Multimedia Appendix 1). For inpatient bed days, these models correctly assigned approximately 30% of future users to the appropriate category, identified >75% of future users, and generated 30%-32% unnecessary predictions among nonusers. For ED visits, they correctly assigned 36%-39% of future users, identified 70%-75% of users, and generated approximately 25% unnecessary predictions among nonusers.

Economic Impact Analysis of the Models

Results from the fixed effects and Monte Carlo simulations are presented in Table 2 and Figure S4 in Multimedia Appendix 1. The boosted tree ensemble model with logistic regression as the base learner emerged as the dominant model, although other boosted tree models performed similarly. In the fixed effects simulation, the dominant model generated an estimated benefit of SGD $210 (US $153) million. In the Monte Carlo simulations, it produced a median benefit of SGD $152 (US $110) million. Notably, nearly half of the simulations for the dominant model exceeded the 75th percentile of simulations from other models (Table 2 and Figure S4 in Multimedia Appendix 1).

Table 2. Results of fixed effects and Monte Carlo simulations.

Variables	Models				
	Boosted tree with logistic regression as base learner	Boosted tree with MLP[a] as base learner	Boosted tree with MARS[b] as base learner	Boosted tree with boosted tree as base learner	Linear SVM[c] with MLP as base learner
Results for the fixed effects simulation (SGD $)

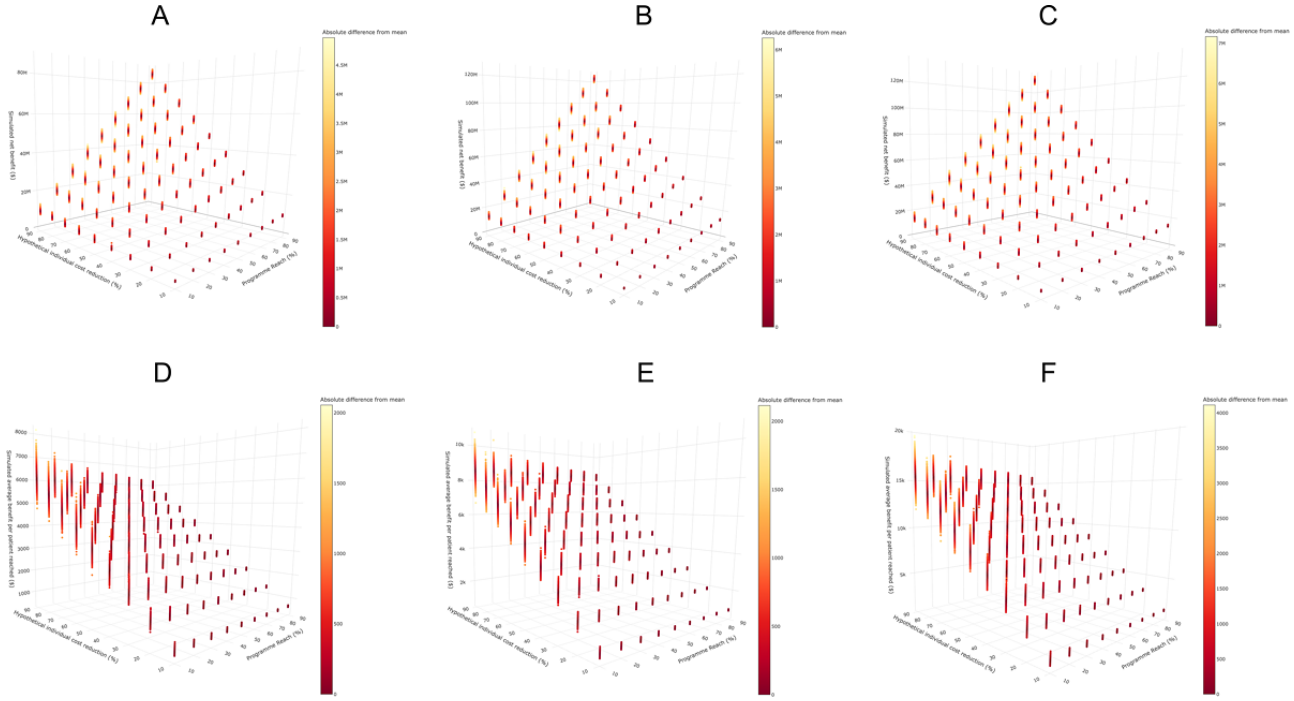
Parameter Sensitivity Analysis



We evaluated the dominant model's performance across various permutations of reach and benefit (Figure 3 and interactive plots available on GitHub [19]). As expected, the net benefit increased with higher individual cost reductions (Figures 3A-3C) and program reach. For predicting LOS of 14-29 days (Figure 3B), with a constant 50% cost reduction, the simulated net benefit ranged from SGD $5.95 to SGD $9.62 (US $4.34 to US $7.02) million at 10% reach, SGD $35.6 to SGD $40.7 (US $26.0 to US $29.7) million at 50% reach, and SGD $66.6 to SGD $70.0 (US $48.6 to US $51.1) million at 90% reach.

With increasing program reach, the range of simulated average benefit per patient narrowed. For LOS of 14-29 days (Figure 3D), with a 50% cost reduction, the average benefit per patient

XSL•FO
RenderX

ranged from SGD $3708 to SGD $5814 (US $2707 to US $4244) at 10% reach and from SGD $4656 to SGD $4389 (US $3399 to US $3204) at 90% reach. The implications of these findings are further discussed in the Discussion section.

Figure 3. 3D scatterplot for Monte Carlo simulations across various permutations of reach and benefit for the boosted tree with logistic regression as base learner ensemble. (A) Simulated net benefit for prediction 7-13 days; (B) simulated net benefit for prediction 14-29 days; (C) simulated net benefit for prediction ≥30 days; (D) simulated average benefit per patient for prediction 7-13 days; (E) simulated average benefit per patient for prediction 14-29 days; and (F) simulated average benefit per patient for prediction ≥30 days. Readers can refer to the interactive plots on GitHub for higher resolution interactive images.

Discussion

Principal Findings

In this study, we expanded on our previous work by developing multiclass ensemble machine learning models to predict future inpatient LOS and ED visits. The models were evaluated using public health program objectives, analyzing predictions through confusion matrices and performance metrics to identify the best-performing models. Economic impact analysis, incorporating inpatient cost data and program-related simulations, identified the boosted tree ensemble algorithm with logistic regression as the base learner as dominant for LOS. Further testing across analytical parameters confirmed its robustness and practical applicability.

While previous studies focused on binary outcomes with limited evaluation of clinical utility [6,20], our study reframes high health care usage as a multiclass problem, enabling more nuanced predictions across different health care events. By incorporating financial data into the economic impact analysis with Monte Carlo simulations, we model the potential benefits of the model, enhancing its relevance for real-world applications [7,8]. This novel approach to economic impact analysis represents a significant contribution to machine learning in health care and the design of resource-efficient health programs.

Advancing High User Prediction Through Multiclass Modeling and Economic Impact Analysis

Our study advances the prediction and targeting of patients with high health care usage by moving beyond binary classification. While many previous studies have focused on predicting binary outcomes—such as identifying HNHC patients in the top 5% or 10% of usage—this strategy has limited practical utility, as most high users do not remain so over time [9,21,22]. Consequently, there is growing recognition of the need to predict risk across multiple levels of usage, enabling stratified interventions tailored to predicted resource needs [9].

To the best of our knowledge, few studies have applied machine learning to predict health care usage across multiple discrete classes. One recent study using Louisiana Department of Health records built multinomial models to predict clinical service usage (ie, number of clinic visits across 5 classes), and found that tree-based ensemble methods, such as extreme gradient boosting and random forest, consistently outperformed logistic regression, neural networks, and naïve Bayes models—likely due to their capacity to model complex nonlinear interactions in heterogeneous data [23]. Another study within the New York City safety net system developed multiple models to predict acute care usage as both binary and continuous outcomes. Their best-performing model, which predicted the number of acute care days as a continuous variable, successfully identified approximately half of the patients who would go on to have very high acute care use [24].

XSL•FO
RenderX

Our study builds on these approaches in several novel ways. First, we applied a stacking ensemble framework to a multiclass prediction problem, enabling stratification across 4 tiers of inpatient bed days and ED visits. This allows for more granular predictions and targeted interventions, unlike previous work focused solely on binary or continuous outcomes. Second, we introduced custom evaluation metrics derived from confusion matrices (Figure 1) that are directly relevant to population health program planning. Third, we conducted a Monte Carlo–based economic impact analysis, incorporating real-world inpatient cost data to estimate potential cost savings under varying assumptions of reach and benefit. This coupling of predictive modeling with economic simulation offers a practical and policy-relevant contribution to the literature on machine learning for health care resource optimization.

Practical Usage of Ensemble Prediction Models for Future Inpatient Bed Days and ED Visits

Our study predicted LOS and ED usage across 4 tiers, rather than focusing on a specific percentile as is the case in many previous studies [6]. This approach enables tailored interventions based on predicted resource use. The distribution of predictions in the confusion matrix (Tables S4 and S5 in Multimedia Appendix 1), with more predictions in the lower usage tier and fewer in the highest usage tier, suggests that low-cost, scalable interventions (eg, clinical flags, EMR risk prompts, or light-touch monitoring) may be suitable for the lower tier (7-13 inpatient days or 3-4 ED visits) [9,10]. For the middle tier (14-29 inpatient days or 5-9 ED visits), moderately scalable interventions, such as programs involving community nurses or care coordinators, may be effective. Higher-cost, intensive interventions are needed for the highest tier (≥30 inpatient days or ≥10 ED visits), although the scalability is limited.

The new model evaluation metrics we developed address the varying costs of misclassification [25]. Models achieving high correct predictions and low unnecessary predictions enhance program efficiency, while those with more identified users allow interventions to reach more patients, although subsequent recalibration of the intervention may be required downstream. Future health programs using these models should assess patient characteristics and clinical needs at enrollment and during follow-up to ensure appropriate intervention assignment. These metrics may also be adapted for other multiclass problems in health care.

Balancing trade-offs between correct and unnecessary predictions is crucial when selecting the best model. Models with higher correct predictions often had more unnecessary predictions (Tables S4-S6 in Multimedia Appendix 1). Similarly, models with more identified users showed higher unnecessary predictions. This trade-off highlights the need to balance these metrics. Although unnecessary predictions may reduce program efficiency, prioritizing correct predictions and identified users led to greater economic benefits, as shown in our economic impact analyses (Table 2 and Figure S4 in Multimedia Appendix 1). Boosted tree ensemble models, which had higher correct predictions, identified users and unnecessary predictions, and significantly outperformed linear SVM ensemble models.

An important feature of our ensemble models is the tiered distribution of predictions (Tables S4-S7 in Multimedia Appendix 1), with the fewest in the highest tier, followed by the middle, and most in the lower tier. This distribution supports efficient resource allocation: low-cost, scalable interventions can be directed to lower tiers, while high-cost, intensive interventions are reserved for the highest tier—ensuring sustainable deployment of resources.

This stratified output also enables a graduated intervention pathway, starting with risk-appropriate outreach and followed by clinical reassessment to adjust intervention intensity. This flexibility is essential given the modest positive predictive value (13%-14%), even in the highest usage group—a reflection of the complexity and unpredictability of health care use, driven by diverse clinical and social factors.

Nevertheless, our best models identified more than 75% of future high users (≥7 inpatient days), offering valuable opportunities for early engagement. Even if further triage is needed, this early identification is a key step in proactive population health management. Future implementations should incorporate qualitative review or clinical vetting to further optimize targeting and minimize risks of overintervention or alert fatigue.

Implications of Economic Impact Analysis and Parameter Sensitivity Analysis

To our knowledge, this is the first study to conduct an economic impact analysis of predictive models for identifying patients at risk of high health care usage. We selected the best-performing ensemble model for inpatient LOS, leveraging inpatient billing data to assess its real-world potential. The boosted tree ensemble algorithm with logistic regression as its base learner emerged as the dominant model (Table 2 and Figure 3), demonstrating superior performance in both fixed effects and Monte Carlo simulations. Notably, the median simulation outcome for the dominant model exceeded the 75th percentile of other models, indicating that its typical performance surpassed even the best-case scenarios (upper quartile) of the alternatives. This highlights the dominant model's consistency and reliability, despite similar AUROC, accuracy, and evaluation metrics across models.

Findings from the parameter sensitivity analysis provide health care planners with insights into the potential cost savings on different combinations of reach and benefit. Our results show that increasing program reach significantly boosts total benefit, while reducing variability in benefit per patient, especially when more high-cost patients (typically those found in the top cost percentiles) are included. This reflects the Pareto distribution of inpatient costs (Figure S1 in Multimedia Appendix 1), where maximizing program reach is essential for capturing high-cost patients and maximizing the overall net benefit.

While the parameter sensitivity analysis does not explicitly incorporate intervention costs, it serves as a useful planning tool by simulating the financial space available for intervention. For example, in a conservative scenario targeting patients predicted to stay 14-29 days, assuming a 30% cost reduction and 50% reach, projected savings reach SGD $21.0 (US $15.3)

XSL•FO
RenderX

million in a year. This estimate can guide budget planning, allowing programs to allocate resources up to this amount while maintaining a positive return on investment. Future iterations of this analysis could incorporate cost parameters and extend to multiyear projections, enhancing its utility for implementation planning.

Limitations

We acknowledge the potential for selection bias arising from the exclusion of patients with missing variables. Complete case analysis was used because data imputation was not performed, and several of the machine learning algorithms applied in this study do not natively support missing values. Nevertheless, a substantial proportion of the registry was retained: 74.6% (100,500/134,670) of eligible patients were included in training the binary base learners, 77.3% (108,886/140,859) in training the stacking ensemble models, and 80.7% (111,004/137,584) in the validation dataset as detailed in our previous study [11]. Patients excluded due to missing data were more likely to have limited interaction with the health care system (eg, no inpatient, ED, or primary care visits), and their exclusion is unlikely to materially affect model performance for predicting higher levels of usage. However, we acknowledge that missingness may be informative, and future work could explore multiple imputation strategies or algorithms that explicitly handle missing data to further assess the robustness and generalizability of the findings.

A methodological limitation is the potential for logical inconsistencies in the predicted probabilities generated by independently trained binary classifiers used as inputs to the stacking ensemble model. For instance, a patient may receive a higher predicted probability for LOS≥14 days than for LOS≥7 days, which violates logical ordering. While these probabilities were not used directly to assign final classes, serving instead as features for a stacking ensemble meta-learner, such inconsistencies could still affect interpretability and calibration. We did not formally assess the prevalence of these inconsistencies in this study. However, we acknowledge this limitation and plan to explore ordinal-consistent modeling strategies in future work, such as classifier chains or ordinal regression frameworks that preserve monotonicity across outcome thresholds.

Additionally, we did not benchmark against simpler baselines, such as heuristic rules (eg, previous year usage) or native multiclass algorithms. Future work could explore these comparisons to better understand the incremental benefits of ensemble architectures in terms of complexity, predictive performance, and operational interpretability.

Another methodological consideration is the absence of hyperparameter tuning, which may have improved absolute model performance. Our objective in this study was to evaluate relative model performance across ensemble strategies and to develop a transparent and reproducible framework. Default hyperparameters were used to ensure consistency and comparability. We acknowledge that in real-world deployment, targeted hyperparameter tuning would likely be performed to further optimize predictive accuracy, and we identify this as a direction for future work.

Relatedly, we did not perform standard decision curve analysis as our multiclass models output discrete class labels corresponding to stratified intervention tiers rather than risk probabilities used for binary decisions. Future work could explore ordinal or multiclass extensions of decision curve analysis that may better reflect stratified care models and potentially enhance decision support performance.

Additionally, in our economic simulations, we also assumed normally distributed variation in intervention benefit; while this was suitable for benchmarking, we acknowledge that future work could explore log-normal or gamma distributions.

A further consideration is the potential impact of pandemic-related disruptions during the study period, which coincided entirely with the COVID-19 pandemic (2020-2022). As the ensemble models were trained and validated on temporally distinct datasets from this period, unmeasured shifts in disease burden and health care delivery—such as deferred elective care, changes in admission criteria, infection control protocols, ED triage processes, and inpatient discharge practices—may have influenced LOS and ED usage patterns. While a detailed exploration of these pandemic-related dynamics is beyond the scope of this study, we acknowledge that they may have affected model performance and limited generalizability to nonpandemic settings. We intend to validate the models using postpandemic data (eg, 2024 onwards) in future work to assess robustness under more stable health care conditions.

Another important limitation is the real-world variability in health care usage among high users; the best models could correctly assign only about 30% of future users to the appropriate category. This variability, likely influenced by regression to the mean and the inherent complexity of the prediction task, highlights the need for additional program measures, such as downstream assessments of predicted patients.

From a pragmatic perspective, not all high users may respond to interventions, and real-world efficacy is likely to vary depending on clinical or social drivers [6]. Our economic impact analyses assumed average cost reductions across usage tiers to facilitate comparative evaluation of ensemble models, but we acknowledge this simplification may not capture the full heterogeneity of intervention effects. Future work could explore stratified modeling based on clinical or social risk profiles when such data becomes available. However, by predicting varying levels of resource use, our models allow for interventions to target patients who may be more amenable to them [9]. This remains an area requiring further research to pinpoint patients with modifiable trajectories [26]. It has been suggested that prediction models should combine quantitative prediction modeling with qualitative assessment for better case identification [6]. In line with this, we plan to explore the use of large language models to analyze unstructured clinical text and better understand social determinants of health [27], supporting a more tailored and prescriptive approach to patient management.

XSL•FO
RenderX

Conclusions

We used binary classification machine learning algorithms to develop ensemble models predicting future health care usage, focusing on inpatient LOS and ED visits. These models were evaluated using metrics relevant to population health programs. Economic and parameter sensitivity analyses of the best-performing models offered valuable insights for designing effective health initiatives. Our ensemble model could be integrated into a diverse decision-making framework, providing tailored recommendations for patients with predicted high health care usage.

Abstract

Background: Accurate segmentation of cartilage from magnetic resonance imaging (MRI) is crucial for the diagnosis and surgical planning of knee osteoarthritis. However, manual segmentation is time-consuming, and conventional computed tomography–based surgical systems are limited by their inability to visualize cartilage.

Objective: This study aimed to develop a clinically targeted deep learning framework, the Swin-UNet conditional generative adversarial network (cGAN), for the automatic segmentation of femoral and tibial cartilage in MRI. We then evaluated its performance against conventional UNet, UNet cGAN, and Swin-UNet baseline models.

Methods: Our dataset comprised 232 knee MRI scans. We conducted quantitative experiments on the proposed Swin-UNet cGAN model and compared the results with those of widely used UNet, UNet cGAN, and Swin-UNet models for femoral and tibial cartilage segmentation, using the Dice similarity coefficient, mean intersection over union, 95th percentile Hausdorff distance, and average symmetric surface distance. All performance metrics were statistically analyzed. In addition, the performance of the Swin-UNet cGAN model was evaluated on an external validation dataset.

Results: The proposed Swin-UNet cGAN achieved the highest mean Dice similarity coefficient and intersection over union scores for both femoral and tibial cartilage segmentation, demonstrating performance statistically comparable to the best-performing baseline (UNet) in the tibia. Regarding distance metrics (average symmetric surface distance and 95th percentile Hausdorff distance), the proposed model significantly outperformed all baselines in the tibia while achieving results comparable to the UNet cGAN in the femur. It also maintained consistently high segmentation performance on both the internal test set and an external validation dataset.

XSL•FO
RenderX

Conclusions: These findings indicate that the proposed Swin-UNet cGAN achieves more accurate knee cartilage segmentation than UNet, UNet cGAN, and Swin-UNet, particularly in terms of boundary accuracy, while maintaining promising generalizability performance across both internal testing and external validation cohorts. This MRI-based deep learning approach addresses critical limitations of computed tomography–based patient-specific instrumentation systems by providing cartilage visualization, potentially improving surgical precision and outcomes in total knee arthroplasty.

Introduction

Knee joint osteoarthritis is a progressive degenerative disorder affecting the articular cartilage, underlying subchondral bone, and surrounding periarticular tissues. It presents with pain, stiffness, and reduced mobility, ranking among the leading causes of disability in adults [1,2]. Timely identification and precise quantification of alterations in cartilage structure and composition are essential for optimal management of knee osteoarthritis [3].

An extensive array of imaging modalities is used in clinical and research settings to deepen understanding of osteoarthritis pathogenesis [4]. Magnetic resonance imaging (MRI) offers superior visualization of cartilage structure and is the modality of choice for assessing cartilage damage and morphological alterations. In addition, MRI provides a noninvasive, radiation-free examination and excels at evaluating overall knee pathology, owing to its superior soft-tissue contrast relative to X-ray and computed tomography (CT) [5].

Quantitative analysis of cartilage morphology depends on accurate medical-image segmentation and visualization of the articular cartilage, with subsequent 3D reconstruction enabling measurement of thickness, volume, and surface area [6]. However, this process is complex and time-consuming, as each image slice must be segmented individually using manual segmentation software [7]. In recent years, deep learning (DL)–based artificial intelligence models, particularly convolutional neural network (CNN) architectures, have been adopted as a cutting-edge solution for knee cartilage segmentation and osteoarthritis diagnosis [8]. CNN-based models have shown strong potential for accurately segmenting cartilage and bone across imaging modalities [9].

Toit et al [9] studied a modified UNet algorithm to automatically segment the femoral articular cartilage in 3D ultrasound images of healthy volunteer knees. Wang et al [10] proposed a novel network, Patch Attention UNet, to enhance knee cartilage segmentation by applying an attention mechanism; it was evaluated on multiple datasets. Recently, generative adversarial networks (GANs) have captivated the research community, with several studies demonstrating that GAN-generated delineations can match manual tracings and materially enhance segmentation performance [11]. Gaj et al [11] developed a conditional generative adversarial network (cGAN) model built on the UNet architecture that delivers fully automated, highly accurate segmentation of knee cartilage and meniscus.

Therefore, our objective was to develop a Swin-UNet cGAN, a tailored adversarial framework merging a hierarchical Swin-UNet generator with a pixel-wise CNN discriminator for 2D segmentation of knee joint cartilage, and to evaluate its performance on both an internal test set and an external validation dataset. We compared the segmentation performance of our proposed model with traditional UNet, UNet cGAN, and Swin-UNet models using the Dice similarity coefficient (DSC), mean Intersection over Union (IoU), average symmetric surface distance (ASSD), and 95th percentile Hausdorff distance (HD95).

We hypothesized that the Swin-UNet cGAN model would achieve the highest performance in segmenting femoral and tibial cartilage.

Methods

Ethical Considerations

This study was approved by the Institutional Review Board (IRB) of Yonsei Sarang Hospital (IRB number 2025-11-002) and Yongin Severance Hospital (IRB number 9-2025-0189). The requirement for informed consent was waived by the IRB owing to the retrospective nature of this study and the use of deidentified imaging data. All procedures involving human participants were conducted in accordance with institutional ethical standards and approved by the relevant IRBs. All patient data were fully anonymized prior to analysis, with no possibility of individual patient identification. Patients received no compensation for the use of their deidentified MRI data in this research. No identifiable patient information or images are included in this manuscript or its supplementary materials.

Dataset

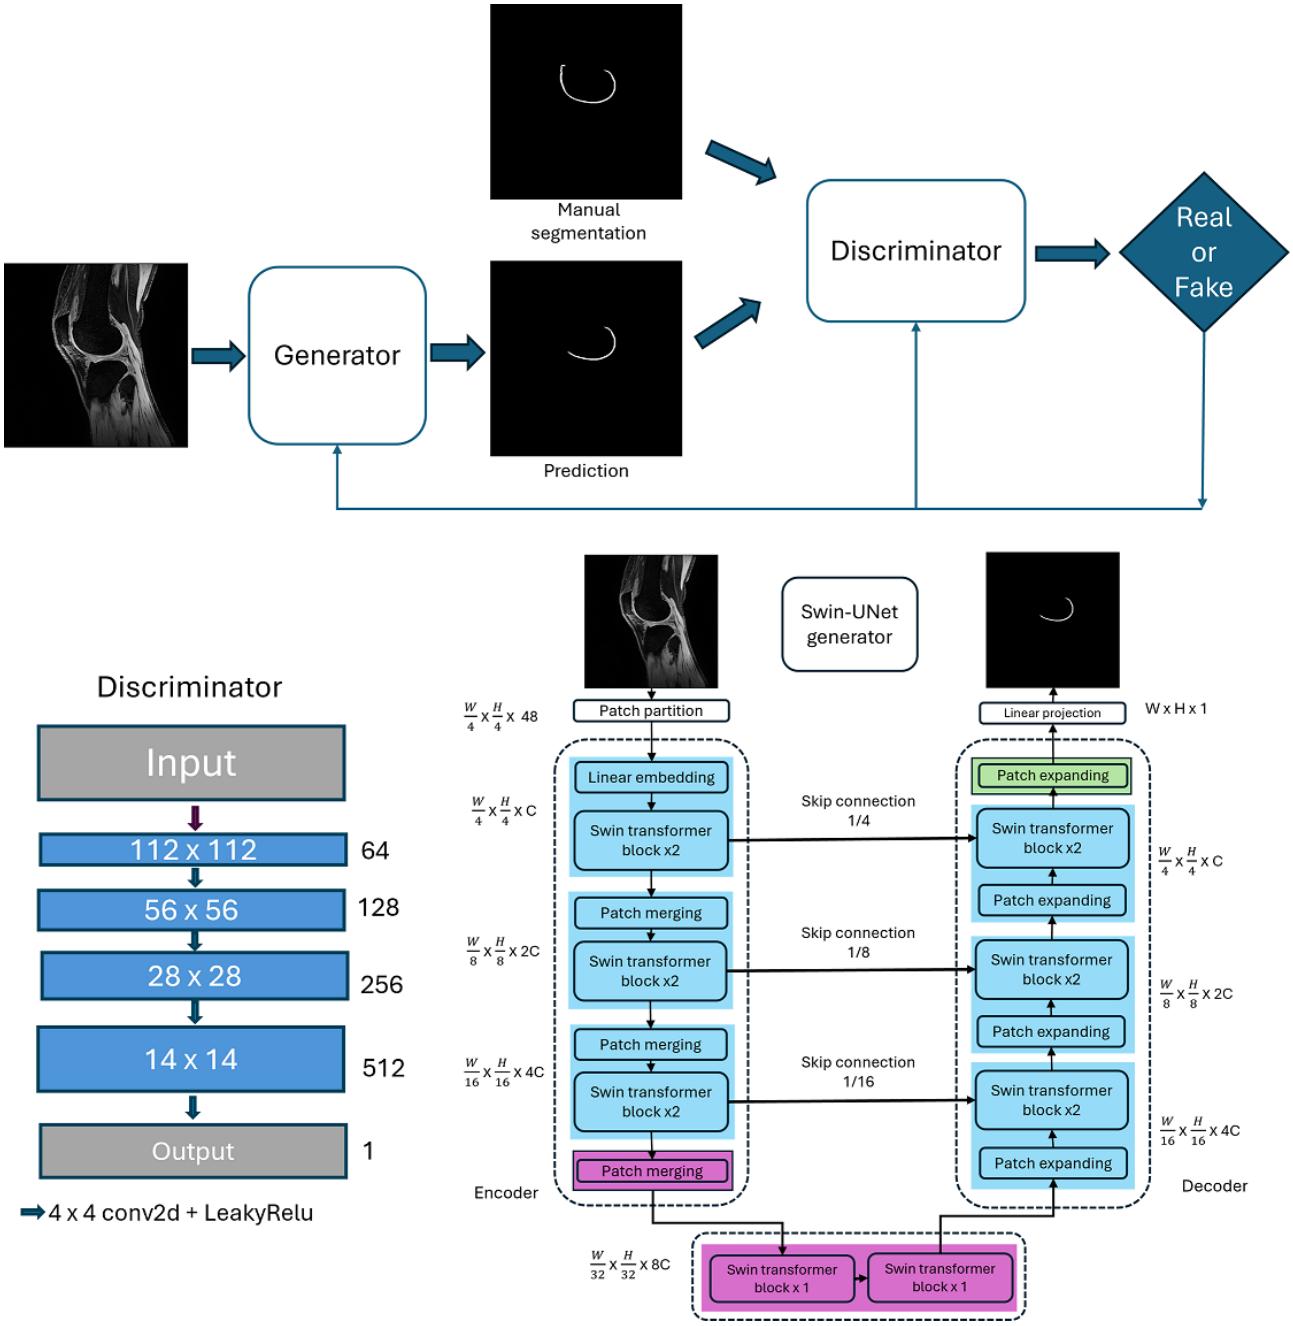
The internal dataset was collected from Yonsei Sarang Hospital and consisted of 232 MRI scans from patients with knee osteoarthritis scheduled for patient-specific instrument (PSI)–guided total knee arthroplasty (TKA) from October 2023 through December 2024. All internal examinations were performed on a 3.0 T system (uMR 770; United Imaging Healthcare) using a 3D high-resolution T2*-weighted gradient-echo sequence (repetition time [TR]/echo time [TE]=17/9.3 ms; flip angle=25°), with a 20-cm field of view and 1-mm thick sagittal slices oriented relative to the posterior femoral condyles. This imaging protocol is commonly used when fabricating PSI [12]. Each scan comprised 90-110 slices. A medical imaging specialist manually segmented cartilage on every slice. The 232 scans were randomly split at the case level:

XSL•FO
RenderX

a total of 162 (70%) scans were assigned to the training set, 35 (15%) scans to the validation set, and 35 (15%) scans to the testing set. For model development, the original 512 × 512 pixel images and their corresponding masks were down-sampled to 224 × 224 pixels.

For external validation, an independent dataset was obtained from Yongin Severance Hospital, consisting of 25 consecutive PSI-guided TKA cases. All external validation knee MRI examinations were performed on a 3.0 T system (SIGNA Premier; GE Healthcare) with a 20-cm field of view and 2-mm thick sagittal slices oriented relative to the posterior femoral condyles. TR and TE were automatically adjusted by the scanner to optimize image quality, with nominal target values of TR/TE=30/11 ms.

Swin-UNet–Based cGAN Model



GAN-based networks usually consist of 2 parts: a generator model that produces synthetic samples from noise with a prior distribution and a discriminator model that acts as a binary classifier to differentiate real data from generated synthetic samples. In this study, the widely used cGAN [13] was adopted for MRI knee bone and cartilage segmentation. In this work, the generator is a mapping function from a source domain image into a segmentation mask, rather than mapping noise to real data as in the original GAN model, and predicts a manual segmentation mask. The cGAN-based model uses the discriminator to judge the quality of segmentation given the source image from the dataset. The binary classifier distinguishes the differences between the manual segmentation mask and the synthetic segmentation mask generated by the generator model, designating them as real and fake samples, respectively. This study introduces a Swin-UNet–based cGAN for knee MRI segmentation [14] to create synthetic masks and a PatchGAN discriminator [15] that learns discriminative features to distinguish generated masks from manual annotations.

Generator of the Swin-UNet–Based cGAN Model

The generator of the knee cartilage segmentation model is a hierarchical Swin Transformer architecture integrated into a UNet-like encoder-decoder structure, as shown in Figure 1. The input image size and patch size are set as 224 × 224 and 4, respectively. The C-dimensional (C=32) tokenized inputs with a resolution of H/4 × W/4 are fed into 2 consecutive Swin Transformer blocks (using a 7 × 7 attention window) to perform representation learning, and the feature dimension and resolution remain unchanged. The patch merging layer reduces the number of tokens (down-samples by 2×) and increases the feature dimension to 2× the original dimension. The encoder repeats this procedure 3 times. The patch merging layer in the encoder divides the input patches into 4 parts and concatenates them together. The feature resolution is down-sampled by 2×, and because the concatenate operation increases the feature dimension by 4×, a linear layer is applied on the concatenated features to unify the feature dimension to 2× the original dimension. The bottleneck consists of 2 Swin Transformer blocks and is used to learn deep feature representation. In the bottleneck, the feature resolution and dimension remain unchanged.

XSL•FO
RenderX

Figure 1. Overall architecture of the proposed network.

The decoder has a symmetrical architecture to the encoder, based on the Swin Transformer blocks. The patch expanding layer in the decoder is used to up-sample the extracted deep features. The patch expanding layer reshapes the feature maps of adjacent dimensions into higher-resolution feature maps, up-sampling by 2×, and reduces the feature dimension to half of the original dimension.

Skip connections are used to fuse the multiscale features from the encoder with the up-sampled features. Both shallow and deep features are concatenated together to reduce the loss of spatial information caused by down-sampling.

Discriminator of the Swin-UNet–Based cGAN Model

The discriminator of the proposed model is a PixelGAN-style convolutional binary classifier of “fake” predicted segmented masks and “real” manually segmented masks. The network input has 2 channels (image + mask) and spatial size H × W. The discriminator network architecture consists of four 4 × 4 convolutional layers with LeakyRelu activation function. Normalization is applied to stabilize the training samples, and Dropout2d prevents the discriminator from overpowering the generator in the early stages and encourages robust feature learning. The final layer is a 4 × 4 stride convolution, which produces a grid of real or fake logits. With 224 × 224 input, the discriminator produces a 13 × 13 authenticity map.

In the proposed model, a linearly increasing adversarial weight schedule was used, with λ starting at 0 after pretraining and gradually increasing to 1×10^{-4} over the GAN training epochs. This prevented gradient shocks and was selected as the most stable λ based on validation stability. Prior to selecting λ, larger values of 5×10^{-4} and 1×10^{-3} were empirically explored;

XSL•FO
RenderX

although these values increased the adversarial influence, they led to unstable training.

Loss Function of the Swin-UNet–Based cGAN Model

The proposed knee cartilage segmentation model uses a combination of supervised segmentation loss and adversarial losses. If segmentation performance mainly relies on adversarial loss, the output segmentation mask might not always share the same global structure as the manually segmented mask [16-19]. For traditional segmentation losses, the DSC and cross-entropy can be applied as loss functions for the generator network to improve performance by decreasing the distance between generated "fake" and manually segmented "real" masks. The proposed model uses multiple loss functions during training because the training experiments were conducted in multiple stages: generator model pretraining for segmentation mask predictions and overall training of the developed Swin-UNet cGAN–based knee segmentation model. During both the pretraining and overall model training phases, binary cross-entropy (BCE) with logits loss  is adopted as the primary segmentation loss.

where yi is the ground truth mask of the real samples and  is the mask predicted by the generator network. For adversarial loss, a hinge loss formulation is applied to improve training stability.

The discriminator network is trained using hinge loss to improve classification of real and fake sample data. For real mask samples, the discriminator is set to output values greater than 1; for fake samples, output are less than –1. The overall loss is computed as the mean of the 2 hinge components. The overall discriminator loss can be written as follows.

In the proposed model training, a gradient penalty was implemented to stabilize training by penalizing deviations in gradient norm from 1. Finally, the generator's overall loss is composed of the total segmentation loss and a weighted adversarial loss.

For the proposed model training, the Adam optimizer was used with a learning rate of 1×10^{-4} for the transformer-based generator and 5×10^{-5} for the patch-based discriminator networks, with a weight decay of 1×10^{-5}. To maximize the prediction results of the segmentation model, the generator was first pretrained for 30 epochs using only the segmentation loss (BCE with logits loss). After pretraining, adversarial training was performed for 40 epochs using a combination of segmentation and adversarial losses. During overall model training, adversarial weight λ_{adv} increased linearly until it reached the final value of 1×10^{-4}. Training of all experimented models was performed using an NVIDIA GeForce RTX 4090 24 GB graphics processing unit.

Evaluation Metrics

The performance of the knee cartilage segmentation models was compared with that of the Swin-UNet segmentation model, the UNet-based GAN segmentation model [11], and the traditional CNN-based UNet model using the DSC, IoU, HD95, and ASSD. The DSC represent the overlap between the predicted and ground truth masks. A DSC of 1 (or 100%) represents perfect overlap, whereas a value of 0 indicates no overlap between the ground truth and predicted masks.

The mean IoU metric is calculated by dividing the area of intersection of the predicted and ground truth masks by the area of the union of 2 masks.

The Hausdorff distance (HD) measures the extent to which 2 subsets of a metric space differ. Because HD is sensitive to outliers, the 95th percentile (HD95) is frequently used instead. By considering the 95th percentile of distances, HD95 provides a more robust measure of boundary conformity, effectively ignoring the most extreme 5% of outliers.

where A and B denote the sets of boundary points for the predicted and ground truth segmentations, respectively; ||a – b|| represents the Euclidean distance between points a and b; and P_{95} denotes the 95th percentile of the accumulated distances.

The ASSD measures the average distance between boundary points, making it highly sensitive to the precise alignment of contours.

where |A| and |B| denote the cardinality of the boundary sets A and B, respectively. All surface metrics (ASSD and HD95) were computed on 224 × 224 masks, the same resolution used for training and inference. Distances were converted to millimeters using the effective in-plane spacing of 0.89 mm/pixel.

Reliability of Manual Segmentation

For consistent and reliable manual labeling of our dataset, DSC and IoU metrics were calculated for intra- and interrater comparisons across femur and tibia segmentations. Two experienced manual data labeling experts, rater A and rater B, segmented the entire dataset. For reliability assessment, MRI data from 30 randomly selected patients were labeled a second time by both raters at a different time of day than the first labeling session. For the final training and test datasets, segmentation masks created by a single expert rater were used for each slice.

XSL•FO
RenderX

Ablation Study

To empirically validate the architectural decisions and hyperparameter configurations of the proposed Swin-UNet cGAN framework, a comprehensive ablation study was designed focusing on 3 critical components. First, model sensitivity to the magnitude of the adversarial loss was evaluated by testing varying adversarial weights ranging from 0.0001 to 0.1 to determine the optimal balance between pixel-wise segmentation accuracy and adversarial shape refinement. Second, to assess the impact of training stability, a constant weight schedule was compared against a linear warm-up strategy, in which adversarial weights increased linearly from zero to the target value over the training epochs. Third, to identify the most effective objective function for segmenting fine cartilage structures within the adversarial framework, standard BCE loss alone was compared with a hybrid objective combining BCE and Dice loss.

Statistical Analysis

Statistical analyses were performed using R (version 4.3.1; R Foundation for Statistical Computing). For multiple comparisons of the results, the normality of the data distribution was first assessed. Data following a normal distribution were analyzed using repeated measures ANOVA, whereas nonnormally distributed data were analyzed using the Friedman test. Post hoc comparisons were conducted using the Bonferroni correction. Inter- and intrarater reliability were evaluated using the DSC. A *P* value of less than .05 was considered statistically significant.

Results

Cartilage Segmentation Results

DSC, mean IoU, ASSD, and HD95 results for femoral and tibial cartilage segmentation are summarized in Table 1.

Table 1. Knee cartilage segmentation results.

Structure and metric	Model, mean (SD)				*P* value
	UNet	UNet cGAN[a]	Swin-UNet	Proposed (Swin-UNet cGAN)	
Femur					<.001
DSC[b] (%)	78.6 (3.1)[c]	80.2 (1.2)[d]	76.5 (4.5)[e]	82 (1.5)[f]	
IoU[g] (%)	69.4 (3.9)[c]	69.9 (1.8)[c]	65.3 (5.2)[e]	71.9 (2.1)[d]	
ASSD[h] (mm)	1.34 (0.32)[e]	0.24 (0.05)[d]	0.58 (0.17)[c]	0.22 (0.08)[d]	
HD95[i] (mm)	5.14 (1.64)[e]	1.25 (0.21)[d]	2.94 (0.96)[c]	1.31 (0.27)[d]	
Tibia					<.001

[a]cGAN: conditional generative adversarial network.

[b]DSC: Dice similarity coefficient.

[c-f]Footnotes c, d, e, and f indicate significant differences between models based on post hoc pairwise comparisons (*P*<.05). Superscript letters follow the journal style (alphabetical order by first appearance) and do not represent a rank order of performance. Means sharing the same footnote are not significantly different.

[g]IoU: intersection over union.

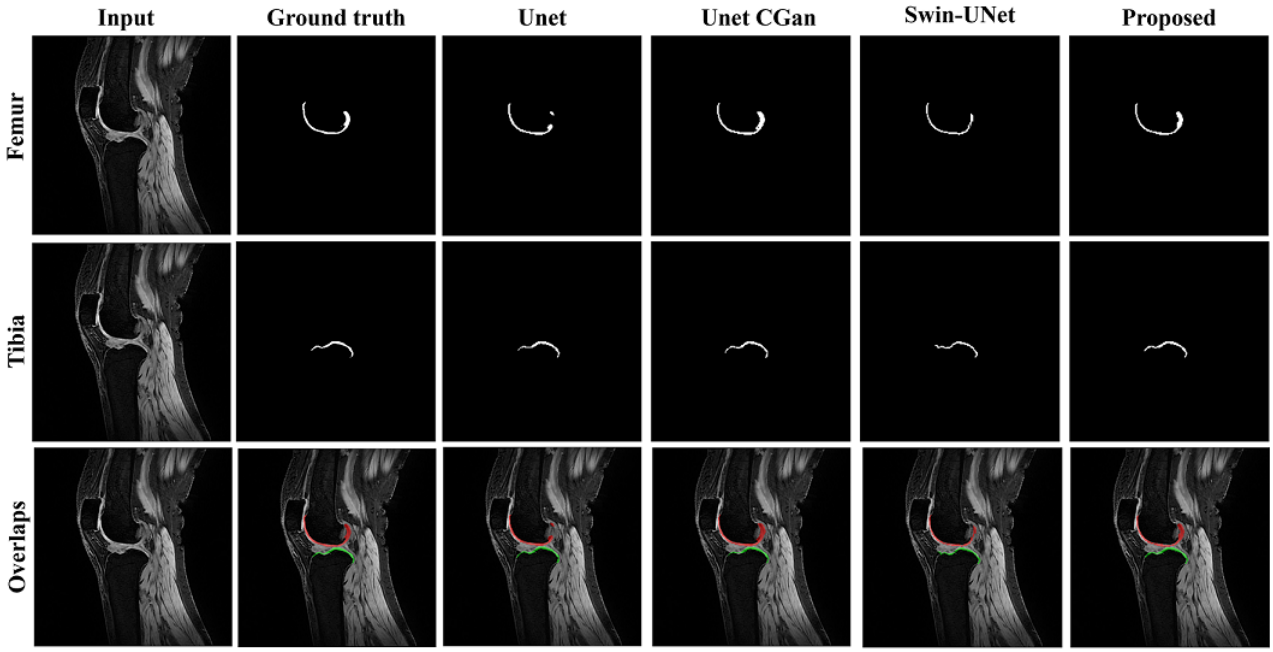
[h]ASSD: average symmetric surface distance.

[i]HD95: 95th percentile Hausdorff distance.

For femoral cartilage, the baseline UNet achieved a mean DSC of 78.6% (SD 3.1%) and an IoU of 69.4% (SD 3.9%), with an ASSD of 1.34 (SD 0.32) mm and an HD95 of 5.14 (SD 1.64) mm. Adding adversarial training in UNet cGAN slightly improved overlap (DSC 80.2%, SD 1.2%; IoU 69.9%, SD 1.8%; *P*<.001 vs UNet) and markedly reduced surface errors (ASSD 0.24, SD 0.05 mm; HD95 1.25, SD 0.21 mm; *P*<.001 vs UNet). Swin-UNet without adversarial training underperformed both UNet and UNet cGAN in overlap metrics (DSC 76.5%, SD 4.5%; IoU 65.3%, SD 5.2%) and showed only intermediate surface accuracy (ASSD 0.58, SD 0.17 mm; HD95 2.94, SD 0.96 mm). The proposed Swin-UNet cGAN achieved the best femoral cartilage segmentation, with a DSC of 82% (1.5%) and an IoU of 71.9% (SD 2.1%; *P*<.001 vs all other models), and significantly lower ASSD and HD95 than UNet and Swin-UNet (*P*<.001), while maintaining surface accuracy comparable to UNet cGAN.

For tibial cartilage, the baseline UNet yielded a DSC of 79.2% (SD 6.3%) and an IoU of 69.7% (SD 7.3%), with an ASSD of 1.05 (SD 1.46) mm and an HD95 of 3.62 (SD 5.62) mm. UNet cGAN preserved similar overlap (DSC 80%, SD 1.8%; IoU 70.1%, SD 2.5%) but substantially reduced surface errors (ASSD 0.32, SD 0.27 mm; HD95 1.46, SD 1.13 mm). Swin-UNet again

XSL•FO
RenderX



showed the weakest performance (DSC 70.5%, SD 8.6%; IoU 59.5%, SD 8.5%; ASSD 0.83, SD 0.83 mm; HD95 3.33, SD 2.89 mm). The proposed Swin-UNet cGAN yielded the highest overall tibial performance, achieving a DSC of 81% (SD 1.7%) and an IoU of 71.1% (SD 2.1%). While it showed significantly higher overlap than both Swin-UNet and UNet cGAN (P<.001), the difference compared with the standard UNet was not statistically significant. Importantly, it yielded the lowest ASSD (0.23, SD 0.15 mm) and HD95 (1.25, SD 0.53 mm) among all models (P<.001 vs all baselines). Taken together, the progression from UNet to UNet cGAN, Swin-UNet, and Swin-UNet cGAN effectively serves as an ablation series that disentangles the contributions of adversarial training and the Swin-Transformer backbone.

The proposed Swin-UNet cGAN achieved highly efficient inference performance. On an NVIDIA GeForce RTX 4090, the average inference time was 16.9 ms per 2D slice, culminating in a total processing time of 1.68 seconds per patient volume. This corresponds to a throughput of approximately 59 slices per second, demonstrating the model's suitability for near-real-time clinical workflows.

Qualitative Comparison of Segmentation Outputs

Figure 2 illustrates qualitative segmentation outputs of the models on unseen test data. The rows correspond to the femur, tibia, and overlaps (segmentation masks overlaid on the input MRI), respectively. The columns display the Input image, ground truth, and predictions from UNet, UNet cGAN, Swin-UNet, and our proposed Swin-UNet cGAN (Ours). As shown in the "Overlaps" row, the proposed model produces the most visually accurate segmentation for both bone and cartilage compared with the baseline models.

Figure 2. Qualitative comparison results of our proposed model and baseline models on the knee cartilage segmentation dataset.

Reliability of Manual Segmentation

Inter- and intrarater agreement calculations for DSC and IoU scores comparing overlap between labeled masks showed high reliability on the original dataset. For intrarater agreement, DSCs for rater 1 and rater 2 averaged 98.9% and 99%, respectively, across femur and tibia. The IoU scores also were high at 98% and 98.3%, demonstrating excellent internal consistency for labeling MRI data. For interrater agreement, the DSC was 95.5% and the mean IoU was 91.9%, indicating greater than 90% agreement between the 2 raters.

External Validation

Quantitative evaluation results on the external validation dataset are summarized. The proposed model demonstrated consistent segmentation performance across both femoral and tibial structures. For the femur, the model achieved a DSC of 73.1% (SD 6.9%) and an IoU of 65% (SD 6.9%). In terms of boundary delineation accuracy, ASSD was 1.30 (SD 0.70) mm and the HD95 was 5.91 (SD 2.93) mm. For the tibia, the model yielded a DSC of 69.7% (SD 7.4%) and an IoU of 62.6% (SD 7.2%). The distance-based metrics showed similar precision to the femur, with an ASSD of 2.16 (SD 0.94) mm and an HD95 of 7.18 (SD 2.64) mm.

Ablation Study on Model Component

A comprehensive ablation study was conducted to optimize the Swin-UNet cGAN configuration, as summarized in Table 2. First, regarding the adversarial weight, a value of 0.0001 yielded the best performance, whereas increasing the weight led to instability and performance degradation. Second, the linear warm-up strategy outperformed the constant schedule, improving tibial metrics and training stability. Although femoral surface errors were marginally higher with warm-up, this trade-off was negligible given the overall gains. Finally, BCE loss alone outperformed the combined BCE + Dice loss, likely because the discriminator sufficiently enforces global shape constraints, making the additional geometric guidance from Dice loss redundant.

Discussion

The most important finding of this study is that the proposed Swin-UNet cGAN model provided overall strong knee cartilage segmentation compared with the baseline UNet, UNet cGAN, and Swin-UNet models. Specifically, our model achieved higher DSC and IoU while maintaining tibial mask overlap comparable to UNet, and demonstrated markedly lower ASSD and HD95 while maintaining femoral surface accuracy comparable to UNet cGAN. These findings confirm our hypothesis that the Swin-UNet cGAN model achieves the highest performance in segmenting femoral and tibial cartilage.

Our results demonstrate that combining hierarchical Swin self-attention with adversarial refinement effectively captures the fine-grained pixel information needed for segmentation of knee cartilage. By embedding the Swin-UNet generator into a cGAN framework, we achieve superior cartilage delineation: the hierarchical self-attention mechanism—leveraging windowed self-attention rather than relying solely on skip connections—accurately traces cartilage boundaries and anatomically curved regions. Moreover, the Swin transformer backbone constructs a multiscale feature hierarchy through patch merging and expansion, enabling the network to integrate both detailed structural cues and broader contextual information more effectively than CNN-based encoders such as UNet.

For femoral cartilage, the proposed Swin-UNet cGAN model showed a statistically significant improvement over all baseline models, including UNet, UNet cGAN, and Swin-UNet, with higher DSC and IoU and markedly lower ASSD and HD95 (P<.05), while maintaining comparable surface accuracy to UNet-cGAN. Notably, for tibial cartilage, UNet-cGAN showed a statistically significant improvement over plain UNet, whereas the difference between the proposed Swin-UNet cGAN and UNet, although numerically larger, did not reach statistical significance. This finding is likely related to the relatively large intercase variability of the UNet baseline and the limited sample size, which reduce statistical power to detect small additional gains. Nevertheless, the proposed model consistently achieved the highest mean performance and the lowest ASSD and HD95, indicating the best overall balance between volumetric overlap and surface accuracy. From a clinical perspective, MRI-based PSI relies on accurate 3D surface reconstruction rather than volumetric overlap alone. Therefore, the substantial reductions in ASSD and HD95 achieved by the proposed Swin-UNet cGAN are particularly meaningful, as they indicate more precise cartilage boundaries that are directly relevant for the design and fit of PSI cutting guides.

An interesting finding of this study is that the plain Swin-UNet achieved lower DSC and IoU than UNet for both femoral and tibial cartilage. This may be explained by the inherent structural advantages of convolutional architectures such as UNet, which are highly effective at extracting local image features and can be trained stably even with relatively small datasets. In contrast, transformer-based architectures such as Swin-UNet are designed to capture long-range global context but typically require large-scale training data to fully learn these relationships. Under the limited knee MRI dataset used in this study, plain Swin-UNet appears to have suffered from overfitting and unstable convergence, resulting in lower performance (76.5%) than UNet (79.2%).

XSL•FO
RenderX

In this context, the effectiveness of the proposed Swin-UNet cGAN becomes more evident. As shown in Table 1, although the standalone Swin-UNet performed poorly, its performance markedly improved to 82% when used as the generator within a cGAN framework, surpassing that of UNet (79.2%). This suggests that adversarial learning, through the discriminator, imposes strong anatomical shape constraints on the generator, thereby compensating for the data dependency of the transformer architecture and enabling more accurate cartilage segmentation.

The disproportionate improvement in surface metrics (ASSD and HD95) compared with overlap metrics (DSC and IoU) can be attributed to the fundamental differences in their sensitivity. While DSC and IoU measure volumetric overlap and are relatively insensitive to minor boundary fluctuations, distance-based metrics such as ASSD and HD95 directly quantify contour delineation precision. Adversarial training in the proposed framework explicitly optimizes boundary realism through the discriminator, thereby yielding substantial gains in boundary precision even when volumetric improvements appear modest.

To benchmark our method against the current state of the art, we evaluated nnUNet on the same dataset (Table S1 in Multimedia Appendix 1). While nnUNet provided competitive volumetric overlap, the Swin-UNet cGAN achieved statistically significant improvements in both DSC (P=.02) and IoU (P=.04). Crucially, nnUNet struggled with boundary precision in severe osteoarthritis cases, yielding high HD95 values (2.55 mm and 2.75 mm for femur and tibia, respectively). In contrast, the proposed model markedly reduced surface errors, achieving HD95 values of 1.31 mm and 1.25 mm (P<.001) and significantly lower ASSD (P<.001). This demonstrates that the adversarial framework offers superior robustness in capturing the fine, irregular boundaries of degenerated cartilage compared with the self-configuring UNet approach.

Previous research by Chen et al [20] demonstrated that using Segmentation of Knee Images 2010 (SKI10) data, their model achieved a 1% to 2% DSC improvement over nnUNet, with results of 89% for femur cartilage and 88% for tibia cartilage. Guo et al [21] created a dataset of 700 MRI scans by pooling data from Osteoarthritis Initiative (OAI; n=200), fastMRI (n=175), SKI10 (n=100), and an internal hospital database (n=225). They trained 4 distinct DL models—UNet, UNet++, residual UNet (ResUNet), and transformer UNet (TransUNet)—on this dataset with corresponding labeled cartilage. Among these, TransUNet showed superior performance, achieving DSCs of 82.3% for femur cartilage and 80.3% for tibia cartilage. Further innovation came from Gaj et al [11], who developed a DL model for cartilage and meniscus segmentation by integrating a conditional GAN with UNet. This approach led to notable performance improvements, with femur cartilage segmentation increasing from 84.2% to 89.7% (a greater than 5% gain) compared with traditional UNet. For tibia cartilage, the method increased medial cartilage segmentation from 77% to 86.1% and lateral cartilage from 86.2% to 91.8%, using OAI data. Gaj et al's [11] work clearly illustrates that cGANs can significantly enhance the capabilities of established models like UNet. A quantitative benchmarking table summarizing the datasets, methods, and metrics of these existing studies is presented in Table 3.

[i]OAI-ZIB: Osteoarthritis Initiative–Zuse Institute Berlin.

[j]HD95: 95th percentile Hausdorff distance.

Beyond spatial overlap assessed by DSC, evaluating boundary precision is crucial for clinical applications such as PSI. Liu et al [22] reported ASSD values of 0.65 mm and 0.73 mm for femoral and tibial cartilage, respectively, using their SUSAN framework. Most recently, Wang et al [10] applied a patch attention UNet (PA-UNet) to the Osteoarthritis Initiative–Zuse Institute Berlin (OAI-ZIB) and SKI10 datasets. Although they achieved competitive DSCs, they reported HD values ranging from 9.1 mm to 18.7 mm, indicating potential challenges in handling outlier boundary pixels.

In this study, the proposed Swin-UNet cGAN demonstrated high surface accuracy, achieving ASSD values of 0.22 mm and 0.23 mm and HD95 values of 1.31 mm and 1.25 mm for femoral and tibial cartilage, respectively. Although direct quantitative comparison is challenging due to differences in datasets, these low error rates suggest that integrating the Swin Transformer with adversarial learning effectively refines segmentation boundaries and may offer superior precision for clinical workflows.

A common limitation observed in prior studies is the use of mixed datasets that combine MRI scans from both healthy individuals and patients without explicitly accounting for osteoarthritis progression. Because knee MRI segmentation is most frequently applied in the context of arthroplasty, we trained our DL model using MRI data from patients diagnosed with Kellgren-Lawrence Grades 3-4 who were already scheduled for TKA. This targeted methodology ensures that our model's findings are highly relevant and directly applicable to real-world clinical scenarios, particularly for patients with advanced osteoarthritis, for whom accurate segmentation is critical for surgical planning and improved patient outcomes.

In addition, a recently published study demonstrated that, compared with training on mixed datasets containing both

XSL•FO
RenderX

healthy participants and patients, training primarily on patient data reduced femoral cartilage DSC from 88.8% to 78.2% and tibial cartilage DSC from 82.7% to 71.6% [10].

In terms of clinical relevance, our results are expected to bring significant advancements not only in quantitative diagnostics during knee arthroscopy but also in computer-assisted surgery, including robotic-assisted TKA. Most contemporary robotic‐assisted procedures are predicated almost entirely on image‐based workflows using CT [23]. However, the patient-specific model is generated exclusively from CT data and includes only the bony anatomy; thus, all registration landmarks must be acquired directly on bone during robot-assisted TKA. Intraoperatively, this requirement necessitates a sharp probe to penetrate the overlying cartilage until the underlying bone surface is reached, ensuring accurate alignment. However, an MRI-derived model inherently preserves the cartilage in its segmentation, facilitating a more straightforward and intuitive registration process.

The clinical impact of incorporating cartilage information has been quantified in several comparative studies [24,25]. Additionally, recent meta-analyses have confirmed that MRI-based PSI demonstrates fewer alignment outliers and superior accuracy compared with CT-based techniques, especially in knees with irregular or worn cartilage [26,27]. The practical implications of the inability of CT to visualize cartilage have led to compensatory measures, such as assuming uniform cartilage thickness or manually removing residual cartilage intraoperatively, potentially compromising surgical precision. In addition, recent studies have shown that CT-based PSI can result in inaccurate alignment in varus deformity knees [28]. According to their study, the authors recommended adding approximately 2 mm of cartilage thickness to the planned lateral tibial resection value in CT-based PSI workflows for patients with varus deformity [28]. However, because cartilage thickness can vary substantially between individuals and across different regions of the joint, artificially increasing the resection thickness by a fixed 2 mm only on the lateral side may introduce design challenges and potential inaccuracies in PSI planning. In contrast, MRI-based PSI directly incorporates patient-specific cartilage thickness, thereby eliminating the need for such heuristic adjustments and potentially overcoming these limitations. Our Swin-UNet cGAN model directly addresses these well-documented limitations by providing accurate, automated segmentation of both femoral and tibial cartilage. This advancement has the potential to eliminate the alignment errors associated with CT-based PSI, representing a significant step toward more precise, reproducible surgical outcomes in TKA.

This study has several limitations. First, we performed segmentation of only the knee joint (distal femur and proximal tibia) cartilage. Future research should expand to include the ligaments and menisci. However, the MRI protocol optimized for PSI fabrication provides a suboptimal evaluation of ligamentous and meniscal structures. Second, the primary training and internal test datasets were acquired on a single 3.0 T MRI system (uMR 770; United Imaging Healthcare) using 1 PSI-optimized 3D T2*-weighted gradient-echo sequence. Although this relatively homogeneous acquisition protocol reduces within-study variability, it may limit the generalizability of our model to other scanner vendors, field strengths, coil configurations, and cartilage-focused imaging protocols beyond those used in this study. External validation was performed on a separate 3.0 T MRI system (SIGNA Premier; GE Healthcare), where segmentation performance was slightly lower than on the internal test set, likely reflecting a degree of domain shift related to differences in slice thickness (2 mm for the external dataset vs 1 mm for the internal dataset), with reduced through-plane resolution and increased partial-volume effects. Nevertheless, the model maintained reasonably high performance on this external cohort, indicating partial robustness to protocol variation. Larger multicenter studies with more heterogeneous MRI protocols and scanner types, together with additional training on datasets acquired with thicker slices and/or explicit domain-adaptation strategies, are needed to further narrow this performance gap and fully establish robustness across diverse clinical environments. Third, the current model uses a downsampled input resolution of 224 × 224 and performs slice-wise 2D segmentation, without explicitly leveraging full 3D spatial context, which is important for volumetric MRI analysis. This resolution choice was primarily driven by the need to manage the high memory complexity of the Swin Transformer backbone within a dual-network GAN framework during training, rather than solely by inference speed constraints. We acknowledge that this downsampling results in an approximate pixel spacing of 0.89 mm, which is relatively coarse compared with thin cartilage structures and may limit the capture of extremely fine details. However, contemporary PSI design workflows for TKA, including most commercial systems, are typically based on sagittal 2D cartilage contours that are subsequently reconstructed into 3D surfaces, making a 2D architecture practically compatible with current clinical and industrial pipelines. While our use of surface-based metrics (ASSD and HD95) provides an indirect assessment of 3D geometric accuracy, future work should extend the framework to 2.5D or 3D architectures with high resolution and directly evaluate interslice consistency and PSI template fit. Fourth, although our proposed model is more advanced than those in previous studies, it exhibited a slightly lower DSC. However, as noted above, this limitation can be attributed to our dataset, which consists of patients (Kellgren-Lawrence grades 3-4) awaiting TKA, where extensive cartilage damage hinders segmentation compared with that in a previous study [11]. Nonetheless, we demonstrated that our Swin-UNet cGAN outperforms the UNet cGAN used in previous studies, even when evaluated on this highly challenging dataset. Future work will explore self-supervised pretraining or advanced augmentation to further improve data efficiency and push performance on small‐sample domains.

The Swin-UNet cGAN integrates hierarchical shifted-window attention into its UNet-style transformer generator and uses a pixel-level CNN discriminator to refine outputs, enabling overall more effective segmentation of fine cartilage structures than the standard UNet, the UNet cGAN, and the Swin-UNet, and this advantage was consistently preserved on an external validation dataset. Clinically, this MRI-based segmentation approach has the potential to address key limitations of current CT-based PSI and robotic-assisted TKA workflows by providing

XSL•FO
RenderX

accurate visualization of femoral and tibial cartilage, enabling more anatomically faithful preoperative models, reducing alignment errors related to unmodeled cartilage thickness, and supporting more intuitive intraoperative registration on the articular surface.

Abstract

Background: Alzheimer disease and related dementias are increasing worldwide, with early detection during the mild cognitive impairment (MCI) stage critical for timely intervention. Driving behavior, which reflects everyday cognitive functioning, has emerged as a promising, noninvasive, and inexpensive digital biomarker when paired with machine learning. However, prior research has often relied on controlled settings, high-level features, or assumptions that fail to capture the sporadic nature of MCI, leaving a gap in modeling naturalistic driving data for robust early detection.

Objective: This study aims to address the limitations of prior work by developing deep learning strategies that leverage driving data collected in a naturalistic setting as digital biomarkers for early detection of MCI.

Methods: Clinically classified participants (8 with MCI and 14 cognitively normal; N=22) drove their personal vehicles under naturalistic conditions for several consecutive days. A total of 3 participants (2 cognitively normal and 1 MCI) withdrew before completing the experiments. In-vehicle sensors recorded GPS, accelerometer, and gyroscope signals, which were segmented into full trips and turning maneuvers. Three modeling strategies were compared: (1) single-view, (2) feature-level fusion, and (3) model-level late fusion. Classification models were trained and evaluated to assess their accuracy, discriminative ability, and participant-level performance.

Results: Models using full-trip data consistently outperformed turn-only inputs, with the best-performing model achieving 78% accuracy and an area under the receiver operating characteristic curve of 77%. Turn-based inputs alone demonstrated limited discriminative power; however, combining them with trip data through late fusion improved performance, though not beyond the full-trip baseline. Participant-level analysis indicated that classification accuracy improved with increased data volume, and trip-wise modeling more effectively captured the episodic nature of MCI than majority-vote aggregation. A frequency-based risk score was proposed as an interpretable and flexible output, enabling practical application in clinical and community settings.

Conclusions: Naturalistic driving behavior offers a scalable and noninvasive approach for early cognitive screening. Deep learning models using full-trip naturalistic driving data show promise for detecting MCI, with fusion strategies providing

supplementary insights. This framework supports proactive, real-world monitoring of cognitive decline, laying the foundation for digital health interventions in dementia prevention.

Introduction

Alzheimer disease (AD) and AD-related dementias are a growing public health concern. In the United States, cases are projected to reach 13.2 million by 2050, placing a significant strain on health care systems and caregivers [1-6]. Worldwide, over 55 million people are affected, with numbers expected to rise to 152 million by 2050 [5,7-9]. The disease progresses gradually, beginning with an asymptomatic phase, followed by mild cognitive impairment (MCI) and eventually dementia [10]. MCI is a transitional stage between normal aging and dementia, involving cognitive but not functional decline [11,12]. Accurate diagnosis at this stage is vital, as early detection allows timely intervention to slow progression and manage symptoms [13-16].

Identifying MCI early is challenging. Current tools, such as neuropsychological tests or biomarkers such as magnetic resonance imaging and positron emission tomography, are clinic-bound, offer only brief cognitive snapshots, and could be invasive, costly, or impractical for large-scale screening [5,6,17]. These methods often miss early MCI, as markers appear later in disease progression [18], highlighting the need for noninvasive, cost-effective biomarkers that support frequent monitoring in real-life settings [5,6,17,19-22]. Recently, spatial navigation deficits and driving behavior have emerged as potential early biomarkers for preclinical AD [23,24]. Tasks such as driving engage multiple cognitive functions in real-world contexts, and even mild impairments can lead to detectable changes in driving patterns [5,6,19,25]. Research shows that older adults with preclinical AD or MCI may limit their driving range, make more navigation errors, and drive more cautiously than cognitively normal peers [25,26]. These driving changes have been linked to AD biomarkers such as elevated amyloid and tau, even when standard cognitive tests are normal [25,27,28]. Notably, such changes can be detected by machine learning (ML) models using in-vehicle sensor data, as demonstrated in studies such as LongROAD [25] and GPS driving [19]. These studies show that ML can accurately identify individuals with MCI or preclinical AD by analyzing patterns in driving behavior such as speed, acceleration, and route choice, often outperforming conventional tools [5,6,19,25], while showing potential for real-time cognitive monitoring through everyday driving.

Despite encouraging progress, ML-based driving diagnostic systems still face key challenges. Many studies rely on simple, high-level features such as trip frequency and duration [19,25], overlooking nuanced indicators such as turn velocity, acceleration patterns, and path deviations that more directly reflect cognitive function. Furthermore, monthly driving records are treated as independent, even when from the same driver, risking data leakage and inflating performance by allowing driver-specific patterns to appear in both training and testing sets. Although recent work has incorporated richer features such as metabolic rate and ensured proper train-test separation [5,6], those studies were conducted in controlled settings with predefined routes, limiting real-world applicability. Additionally, most approaches rely on summary statistics and classical ML models, missing the potential of more powerful deep learning time-series classification techniques. Finally, conventional evaluation frameworks assume MCI symptoms appear consistently across trips, whereas studies have shown that cognitive performance in MCI can vary markedly from day to day, highlighting its sporadic nature [29-31]. Individuals with MCI may only show impairment in a minority of trips, leading models to misclassify them as cognitively normal, yet even occasional MCI-like trips could still serve as an early indicator of cognitive decline.

To address these limitations, this study proposes a new framework that improves both data representation and model evaluation. It shifts from artificial test settings to naturalistic driving by equipping participants' personal vehicles with tracking devices and allowing several days of normal driving, capturing real-world cognitive function. Instead of treating each participant's data as a uniform whole and relying on majority-based classification, the model adopts a granular, context-aware approach, evaluating each trip and turn individually to detect episodic impairments, consistent with the sporadic nature of MCI. Rather than delivering a binary diagnosis, it identifies subtle changes over time and flags individuals for further evaluation, enabling proactive cognitive health monitoring. The framework aggregates binary trip- and turn-level classifications over time to enable longitudinal monitoring and transforms them into a continuous, participant-level risk score (eg, the proportion of trips flagged as impaired). This frequency-based risk score provides a nonbinary, dynamic measure that reflects gradual cognitive change and supports proactive follow-up rather than a 1-time diagnostic label. Specifically, the framework includes a targeted feature-extraction pipeline that segments time-series data from full trips and cognitively demanding turning maneuvers, producing 2 complementary multivariate inputs. Deep learning architectures are then evaluated under 3 paradigms: (experiment 1) single-view modeling of trips and turns, (experiment 2) feature-level fusion, and (experiment 3) model-level late fusion using dual encoders. This design is guided by 3 key research questions.

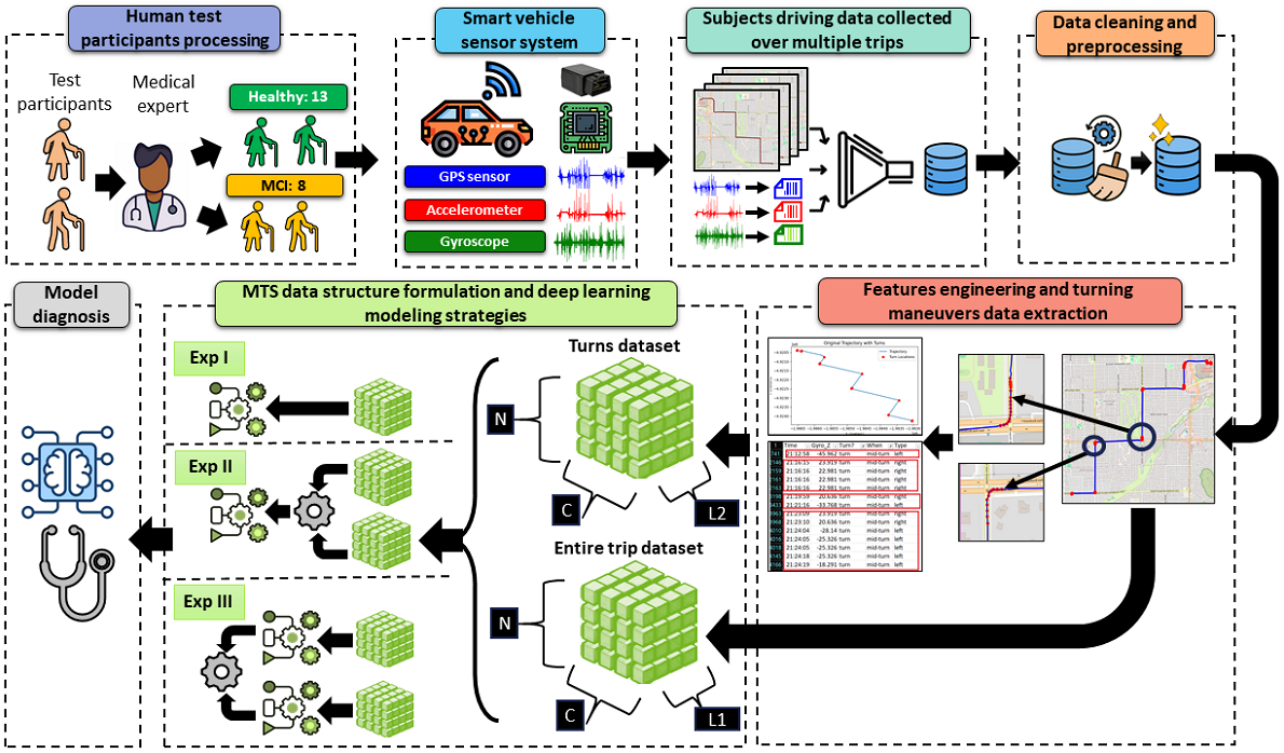
For research question 1 (RQ1), effectiveness in naturalistic settings, can driving-based digital-biomarker strategies that showed promise in previous controlled environments [5,6] remain effective amid the noise and variability of day-to-day, real-world driving?

XSL•FO
RenderX

For research question 2 (RQ2), data handling and representation, what preprocessing and feature-extraction pipeline best transforms raw multisensor driving streams into informative inputs for deep learning?

For research question 3 (RQ3), optimal modeling strategy under data constraints, given current dataset limitations, but also anticipating richer data in future studies, which learning paradigm offers the most robust path forward? To answer this, we decompose this question into three comparative subquestions:

1. Single-view baselines: How well can early MCI be detected when trips and turns are modeled independently?
2. Early (data-level) fusion: Does combining trip and turn data at the feature level improve over the best single-view model?
3. Late (model-level) fusion: Can merging latent representations from trip and turn encoders outperform both single-view and early-fusion models?



The remainder of this paper is organized as follows. The Methods section describes this study's design, materials, and methods used to develop the framework, and the experimental methodology. The Results section presents the outcomes of the conducted experiments. The Discussion section discusses the findings and concludes the paper.

Methods

Study Design

Figure 1 presents an overview of the proposed methodology, which includes participant recruitment with expert cognitive classification, sensor-based driving data collection, preprocessing, feature engineering, and model training and evaluation. Raw sensor streams were cleaned, synchronized, and segmented into 2 complementary multivariate time-series datasets: full-trip sequences and turning maneuvers, used as inputs for subsequent experiments.

Figure 1. Overview of the adopted methodology, illustrating the sequential steps from participant recruitment to model training and evaluation. N denotes the number of samples (trips or turns), C the number of sensor channels, and L_1 and L_2 the interpolated sequence lengths for the trip and turn time-series inputs, respectively. MCI: mild cognitive impairment; MTS: multivariate time series.

Study Participants

To ensure accurate data interpretation, participant diagnoses were conducted in collaboration with a neurologist specializing in AD. Based on cognitive assessments, 13 participants were classified as cognitively healthy and 8 as having MCI. This grouping enabled structured comparison of driving behavior between cognitively normal and impaired individuals. Table 1 summarizes the demographic and medical diagnoses of the participants.

XSL•FO
RenderX

Table 1. Participant demographics and group classification: this study included 21 older adults (ages 65-85 y), with 11 male and 10 female participants. Medical evaluations classified 13 as cognitively healthy and 8 as having MCI[a].

Participant numbers	Age (y)	Sex	Clinical condition
Participant 1	78	Male	MCI
Participant 2	80	Male	Healthy
Participant 3	70	Male	Healthy
Participant 4[b]	72	Female	Healthy
Participant 5	73	Female	Healthy
Participant 6	74	Male	MCI
Participant 7	77	Female	Healthy
Participant 8	87	Female	Healthy
Participant 9	85	Female	Healthy
Participant 10	82	Female	MCI
Participant 11	71	Female	Healthy
Participant 12	72	Female	MCI
Participant 13	65	Male	MCI
Participant 14[b]	75	Male	Healthy
Participant 15[b]	71	Female	MCI
Participant 16	76	Male	Healthy
Participant 17	75	Female	MCI
Participant 18	83	Male	Healthy
Participant 19	76	Male	MCI
Participant 20	80	Female	Healthy
Participant 21	79	Male	Healthy
Participant 22	75	Male	Healthy

[a]MCI: mild cognitive impairment.

[b]Participants withdrew before completing the experiment, leaving insufficient data for their inclusion in the final analysis.

As shown in the table, this study focused on naturalistic driving performance in adults aged 65-85 years, a group at higher risk for cognitive decline. Further, 21 participants were initially recruited, but 3 participants (participants 4, 14, and 15) withdrew before completing the driving experiment, leaving insufficient data for analysis.

Smart Vehicle Telematics System

Each participant's personal vehicle was fitted with a BitBrew on-board diagnostics (OBD) data logger to continuously record naturalistic driving behavior (Figure 2). This advanced telematics device integrates 3 sensors: GPS, accelerometer, and gyroscope. Together, they capture vehicle location, movement, and dynamic behavior, enabling comprehensive real-world driving analysis.

The GPS module tracks the vehicle's location and speed, recording longitude and latitude coordinates and measuring speed in meters per second (m/s) at a frequency of 1 Hz (1 update per second). The accelerometer captures linear acceleration along 3 axes: longitudinal (forward and backward), lateral (side to side), and vertical (up and down), in m/s^2. It detects events such as harsh braking, rapid acceleration, and sharp turns, operating at 24 Hz for high-resolution motion detection. The gyroscope measures angular velocity in radians per second (rad/s) around 3 axes: pitch (tilting forward and backward), roll (tilting side to side), and yaw (rotational movement around the vertical axis). This sensor operates at 24 Hz and provides data on lane changes, skidding, and rollovers.

Participants drove their vehicles freely with no specific instructions, allowing for natural capture of daily driving behavior. Table 2 summarizes the driving periods for each participant, including start and end dates and total duration. All data from the OBD logger was transmitted to an AWS S3 (Amazon Web Services Simple Storage Service) bucket for cloud-based storage and analysis.

Naturalistic Driving Data Collection, Cleaning, and Preprocessing

This naturalistic driving study was conducted in Tempe, Arizona, and extended to nearby cities, including Phoenix, Glendale, Chandler, Scottsdale, and Mesa. Participants drove their personal vehicles, each equipped with a BitBrew OBD data logger, which passively recorded real-world driving behavior. The system continuously captured GPS location, accelerometer, and gyroscope data during each session, enabling a comprehensive analysis of driving patterns without imposing specific instructions or restrictions.

Recorded routes spanned a wide range of road types such as residential streets, highways, and urban roads. The dataset included a variable number of trips per participant, with differences in trip length, duration, and driving conditions reflecting the complexity of real-world behavior. However, sensor data was not always consistent across modalities for the same participant due to device malfunctions, intermittent failures, or temporary disconnections. These issues sometimes caused sensors to stop mid-trip, fail to initiate, or record out of sync, resulting in incomplete or misaligned data. To address these challenges, a structured preprocessing pipeline was applied to ensure that only high-quality, reliable, and synchronized driving records were retained for subsequent analysis.

The first step in preprocessing involved segmenting individual trips from the continuous sensor data stream. Timestamps from the accelerometer, GPS, and gyroscope were analyzed to identify gaps between recordings. If the time difference between consecutive points was less than 1 minute, the data was treated as part of the same trip. Gaps exceeding 1 minute marked the start of a new trip. After segmentation, the data were organized into participant-specific folders, with separate subfolders for each sensor and individual CSV files representing distinct trips.

Although segmentation provided structure, several data quality issues emerged. Sensor malfunctions led to missing data, and differences in recording frequency created synchronization challenges. The accelerometer and gyroscope recorded at 24 Hz, while the GPS operated at 1 Hz, resulting in mismatched data lengths. To resolve this, a cleaning process was applied. A mismatch check flagged any case where the number of trips differed across sensors. When discrepancies were found, the system logged debugging information and excluded incomplete trips. Data from all sensors was merged using shared time attributes such as day, month, hour, and minute. Trips with missing values were flagged, stored separately, and excluded from further analysis. Only complete and synchronized trips were retained. Table 3 shows the number of trips kept for each participant after preprocessing.

XSL•FO

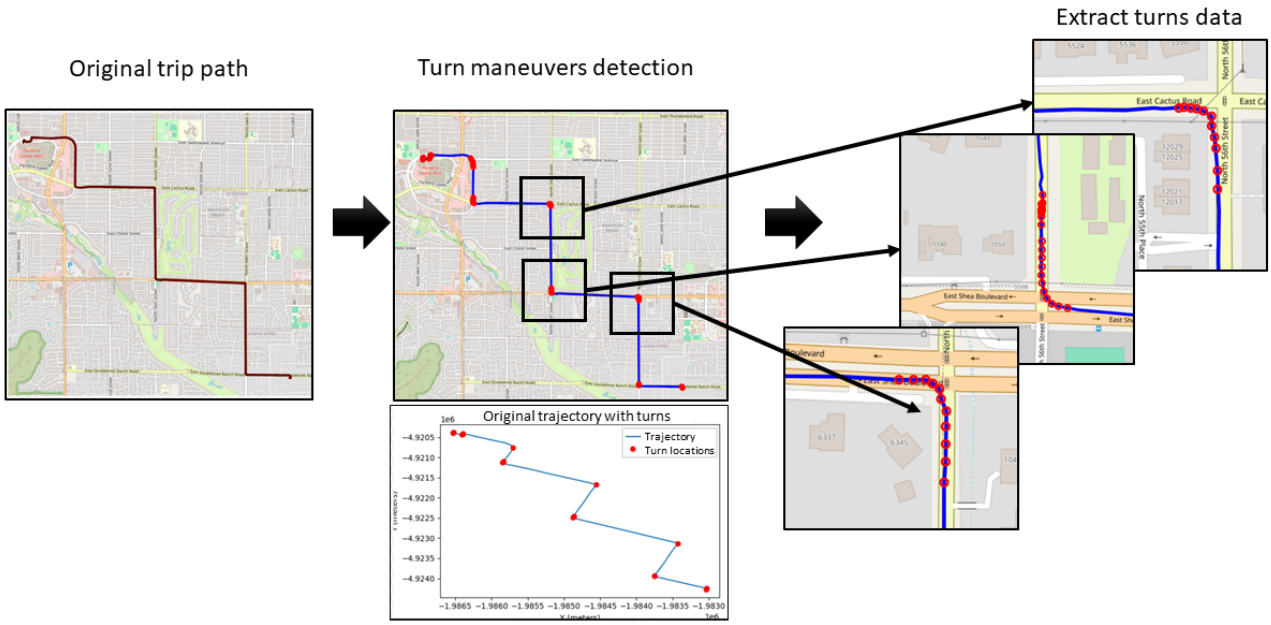
Features, Engineering, and Turning Maneuvers Data Extraction

Turning Maneuvers Data Extraction

Turning a vehicle is a cognitively demanding task involving decision-making, divided attention, working memory, processing speed, and spatial orientation. These functions are often impaired in individuals with MCI and may serve as early biomarkers for AD. Following prior studies [5,6], this work focuses on turning maneuvers, which have shown potential in detecting cognitive decline in standardized controlled experiments. Unlike previous research, this study uses naturalistic driving, where participants follow their routine behavior without instructions. This introduces additional noise into the data, allowing us to test whether turning-related features remain informative under real-world conditions.

Turning detection required converting GPS coordinates from latitude and longitude into Cartesian coordinates for accurate geometric and kinematic analysis. The transformations used are shown in equations 1 and 2. Given a point on the Earth's surface with latitude ∅ and longitude λ, the x and y coordinates were calculated as:



where R is the Earth's radius (approximately 6371 km), and ∅ and λ are expressed in radians.

To identify turning maneuvers, the peak point of each arc path was detected by analyzing the rate of change in x and y rectangular coordinate arrays. By computing the first derivative (dy/dx), the directional changes were captured, with abrupt gradient shifts indicating deviations from straight paths. To filter out gradual curves, various thresholds were tested. It was found that a gradient of 10 degrees (0.174533 radians) reliably captured meaningful turns. However, relying on the gradient alone produced occasional errors. Points where dx=0, resulting in undefined gradients, were discarded. Additionally, turn stamp points with 0 speed, which typically corresponded to stationary periods rather than active maneuvers, were also excluded. Further refinement addressed redundant peak detections within a single turn. In some cases, multiple nearby peaks were

XSL•FO
RenderX

incorrectly classified as separate turns. To resolve this, a smoothing approach was applied. Sequential turn points were merged and replaced by their median index, reducing overlap and ensuring 1 peak per turn event. Once peaks were identified, all surrounding points were extracted by applying a temporal window. Based on empirical observations, a turn maneuver was identified by including all sensor readings occurring 15 seconds before and after the peak point. Accelerometer and gyroscope readings were downsampled to align with the 1 Hz GPS rate by averaging every 24 readings from the higher frequency sensors. Figure 3 illustrates an example of turns extracted from a sample trip.

Figure 3. Illustration of the turn maneuver detection process. The leftmost map represents the original trip path recorded using GPS data. The middle section highlights detected turning maneuvers, marked by red dots, which were identified based on changes in trajectory. The rightmost section zooms in on extracted turn segments, showing detailed turning paths.

Features Engineering (Radial Acceleration)

An additional engineered feature was radial acceleration, which captures how sharply and assertively a driver navigates turns. Higher radial acceleration values may indicate sharper bends or faster speeds, while rapid fluctuations within a maneuver suggest frequent microadjustments in steering and speed. These patterns can reflect reduced motor control and cognitive instability. Radial acceleration was computed by taking the temporal gradient of the gyroscope data along the X, Y, and Z axes. This provided a continuous measure of changes in angular velocity over time, enriching the representation of driver motion. Equations 3-5 show the computation for each axis:

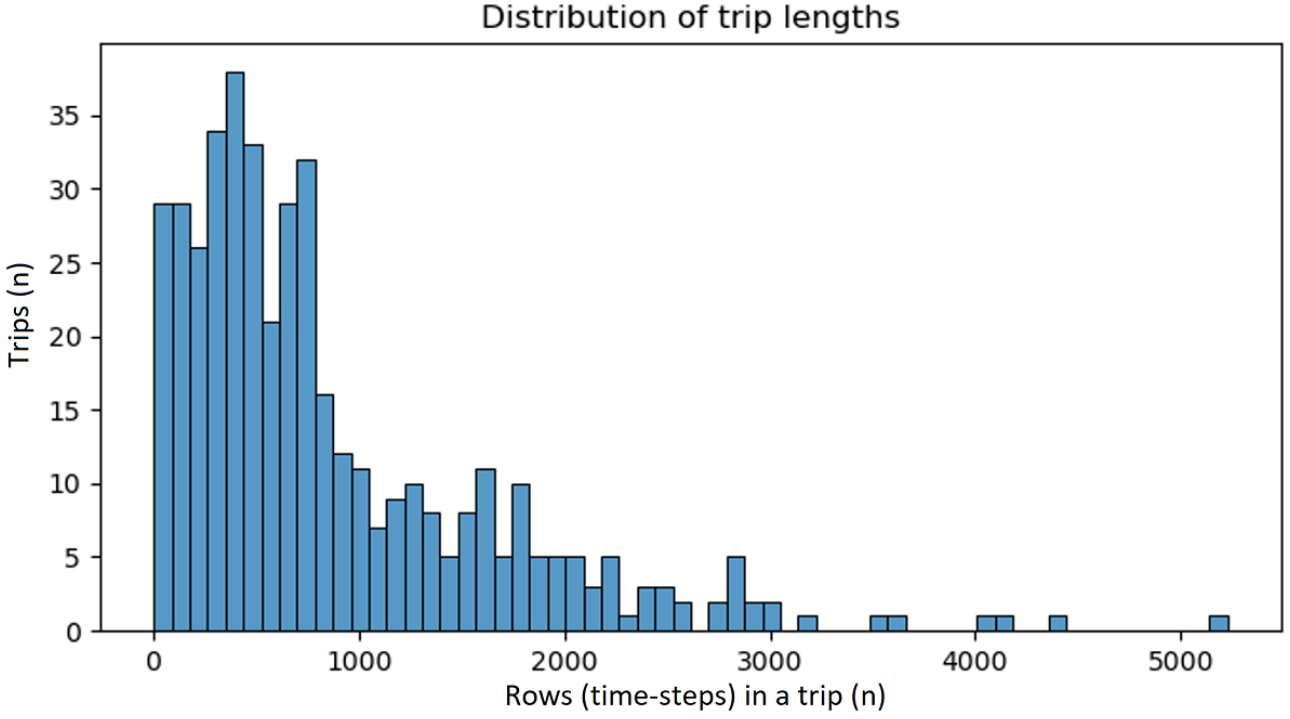
Table 4 summarizes the final set of 10 features used in the input tensor for all models. Each feature represents a specific aspect of motion captured by the GPS, accelerometer, or gyroscope sensors. The Gyro_X_Acc, Gyro_Y_Acc, and Gyro_Z_Acc variables correspond to the angular accelerations derived from the temporal derivatives of the gyroscope signals.

XSL•FO
RenderX

Table 4. Final set of sensor-based features used in the dataset. The table lists the 10 input channels used across all experiments. Each feature captures a different dimension of vehicle motion using raw or derived signals from speed, accelerometer, and gyroscope sensors.

Feature or channel	Description
Speed	Vehicle speed measured in meters per second (m/s)
Acc_X	Linear acceleration along the vehicle's longitudinal axis (forward/backward)
Acc_Y	Linear acceleration along the lateral axis (side-to-side motion)
Acc_Z	Linear acceleration along the vertical axis (up or down motion)
Gyro_X	Angular velocity around the x-axis (roll rate)
Gyro_Y	Angular velocity around the y-axis (pitch rate)
Gyro_Z	Angular velocity around the z-axis (yaw rate or heading change)
Gyro_X_Acc	Angular acceleration around the x-axis, derived from Gyro_X
Gyro_Y_Acc	Angular acceleration around the y-axis, derived from Gyro_Y
Gyro_Z_Acc	Angular acceleration around the z-axis, derived from Gyro_Z

Multivariate Time Series Data Formulation



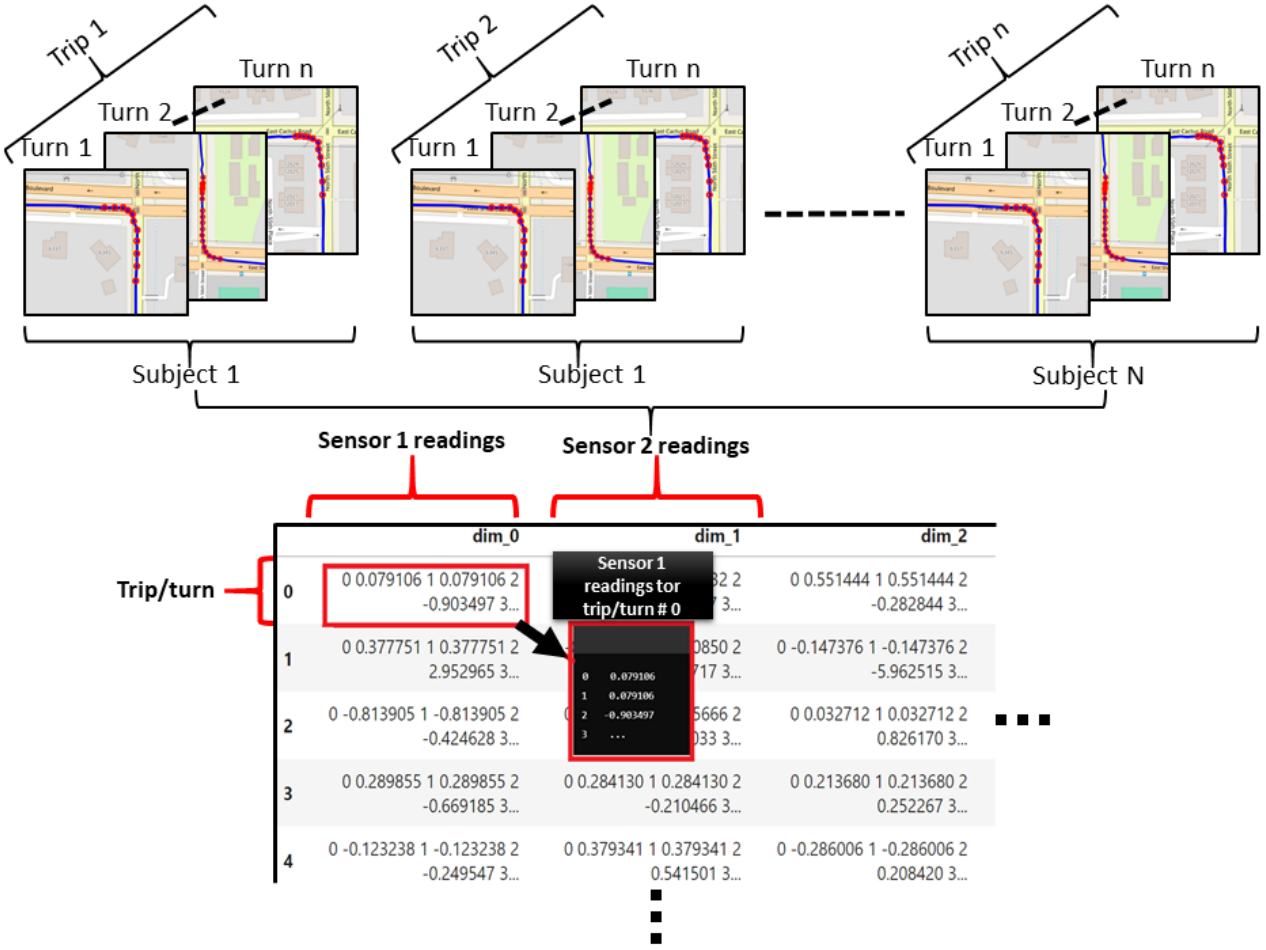
This study used 2 datasets: one capturing entire trip readings and another focused on turning maneuvers. Both were formatted as multivariate time series to preserve the sequential nature of driving behavior. Depending on the dataset, each row represented either a full trip or a turn, and each sensor served as a separate time-dependent variable. To standardize input lengths for model training, sequences were aligned and resampled through interpolation, ensuring uniform temporal resolution across samples.

Time Series Alignment and Interpolation

Trip and turn durations varied widely across drivers, requiring a preprocessing step to standardize time series lengths. Without it, inconsistent sequence sizes would hinder the model's ability to learn temporal patterns. To address this, interpolation was applied to resample all sequences to a fixed number of time points. To select the optimal length, different resolutions were tested by plotting samples and evaluating the balance between data redundancy and information loss. Alignment and interpolation were applied separately to the trip and turn datasets to maintain consistency within each.

For the trip dataset, the distribution of raw sequence lengths (Figure 4) was analyzed, and a target that preserved most trips without excessive compression was selected. This choice was further validated by visually inspecting sensor signals before and after resampling, confirming that key temporal patterns were retained. Based on this process, a fixed length of 1200 points was selected for the trip dataset.

Figure 4. Distribution of trip lengths in the raw dataset. Each bar represents the number of trips with a given sequence length (in time steps). The histogram was used to inform the selection of a standardized interpolation length that balances coverage and temporal resolution.



XSL•FO
RenderX

For the turning maneuvers dataset, the extraction process described in Turning Maneuvers Data Extraction produced segments with a standardized length of 31-time steps by centering each around the turn midpoint and including a fixed number of points before and after. In most cases, this window was fully available, making interpolation unnecessary. However, in rare edge cases, such as turns at the very start or end of a trip, the available context was limited, resulting in shorter segments. These were interpolated to ensure consistency across the dataset.

Final Data Representation

After interpolation, all sensor streams were consolidated into a single structured format. Each trip or turn was represented as a 3D tensor with dimensions N × C × L, where N is the number of trips or turns, C is the number of channels (sensors), and L is the standardized sequence length. Each row corresponds to a distinct trip or turn, columns represent the sensor channels (eg, speed), and the entries hold the sequential readings for the interpolated time steps. Figure 5 shows how all sensor data were aligned and merged into this final format.

Figure 5. Representation of the MTS dataset structure used. Each row corresponds to either an entire trip or a turn, depending on the dataset. The dataset is formatted as a 3D tensor with dimensions (trip or turn, channels [sensors], and sensor readings). MTS: multivariate time series.

Experiments

This section describes the experimental setup and methods used to analyze driving behavior and classify participants based on cognitive status. We hypothesize that naturalistic driving contains digital signatures that can support early MCI detection. The central question is how to best process and model this data to maximize predictive performance. To explore this, we designed 3 experiments based on the same source of driving data but varying in input representation and modeling strategy. By decomposing the problem along 2 dimensions, what part of the data to use (entire trip vs turns) and how to architect the model (single vs multiple inputs or models), we aim to identify which configurations most effectively preserve behaviorally relevant information.

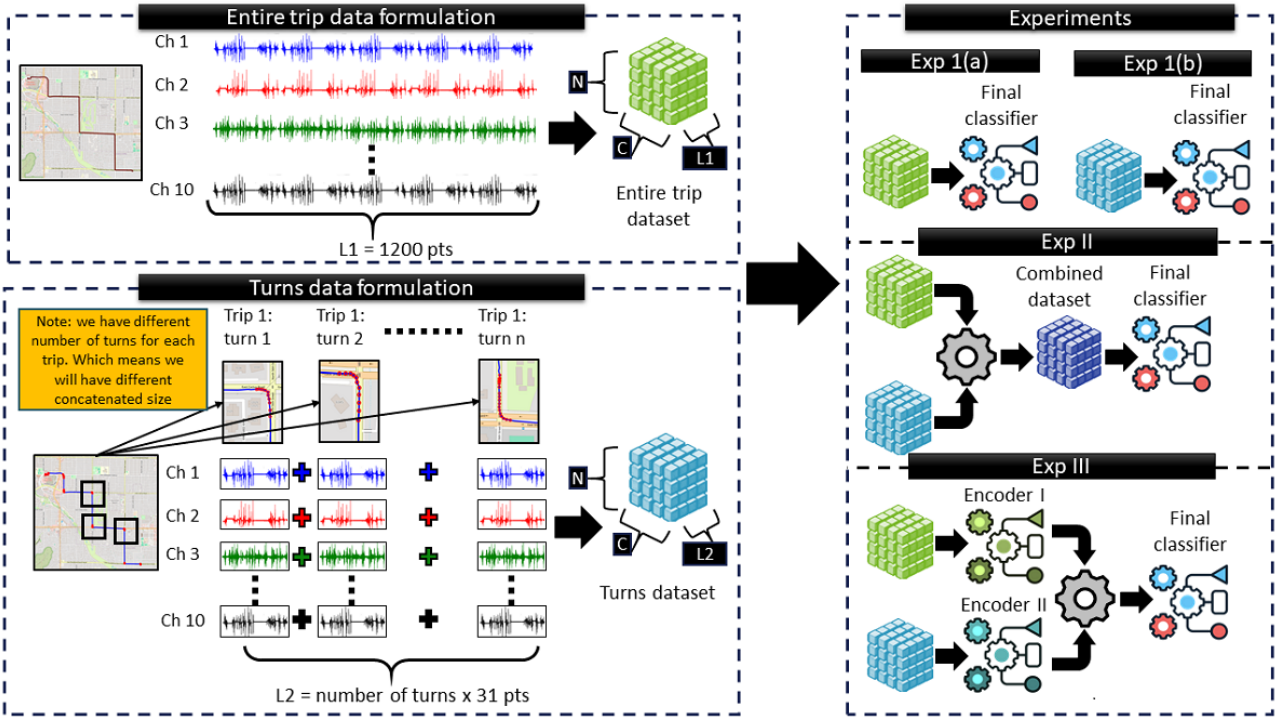
Three main architecture families were used: 1D convolutional neural networks (1D-CNNs), recurrent neural networks (RNNs), and temporal convolutional networks (TCNs); because they align well with the characteristics of naturalistic driving data, which are multivariate, sequential, and temporally dependent. 1D-CNNs were selected for their ability to detect short, localized motion patterns such as rapid accelerations or turning dynamics; RNNs were included to capture longer behavioral trends that unfold over an entire trip; and TCNs were chosen for their ability to model both short- and long-range dependencies efficiently and robustly. Variants within each family (eg, lightweight 1D-CNNs and attention-based RNNs) were explored to identify which architectural style best captures early MCI-related temporal signatures in real-world driving behavior.

XSL•FO
RenderX

All models were trained using a unified configuration to ensure comparability across experiments. The loss function was standard cross-entropy with class weighting applied when needed to address class imbalance. Standard scaling normalization was applied where indicated in the tables. Optimization was performed with AdamW using a learning rate of 1×10^{-3} and a weight decay of 1×10^{-4}. A cosine annealing learning-rate scheduler with T_{max} equal to the number of epochs was used to promote stable convergence. Training was conducted with a batch size of 32 for 200 epochs (reduced from 500 after observing convergence before epoch 200). Dropout was applied only when specified by the architecture variant, as detailed in the appendices.

Table 5 summarizes the details of the experiments, while Figure 6 illustrates the modeling strategies in each.

Table 5. Summary of experimental setups showcasing the data source, feature representation, and modeling paradigm. Sensor channels include speed, linear accelerations (X/Y/Z), angular velocities (X/Y/Z), and derived angular accelerations (X/Y/Z).



Experiment	Data source	Feature representation (input to model)	Predictive-modeling strategy
1(a)	Entire trip only	Multivariate time series (10 raw sensor channels)	Single-view deep models (1D-CNN[a], RNN[b], and TCN[c] variants)
1(b)	Turning maneuvers only	Multivariate time series (same 10 channels, windowed around turns)	Single-view deep models (1D-CNN, RNN, and TCN variants)
2	Trip and turn signals (concatenated)	Feature-level fusion (20-channel time series)	Single model (1D-CNN, RNN, and TCN) trained on fused input
3	Trip and turn signals (separate)	Two parallel 10-channel time series	Dual encoders with late fusion

[a]1D-CNN: 1D convolutional neural network.

[b]RNN: recurrent neural network.

[c]TCN: temporal convolutional network.

Figure 6. Overview of the data formulation and experimental paradigms. The left side shows the data formulation that produces the 2 multivariate inputs used in this study: the entire-trip sensor readings (green) and concatenated turn-segment readings (blue). The right side summarizes how the produced data are used in our experiment, which consists of 3 modeling paradigms: Exp 1 (single-view models trained on trips or turns separately), Exp 2 (feature-level fusion of the 2 inputs), and Exp 3 (dual encoders with late fusion).

Experiment 1: Single Data Representation With Single Model

This experiment evaluates the effectiveness of using a single type of input, either full trips or turn segments, modeled independently (Figure 6). All input data was treated as a multivariate time series and interpolated to a fixed length using 10 sensor channels. For each data type, various model architectures were tested, including 1D-CNNs, RNNs, and TCNs (details in Multimedia Appendix 1). In the full-trip setting (experiment 1(a)), each trip was used as a standalone sequence to capture broad driving behavior. In contrast, the turn-only setting (experiment 1(b)) focused on concatenated turn segments. This experiment isolated a specific behavior

XSL•FO
RenderX

substructure to examine whether it holds predictive power on its own.

Experiment 2: Combined Input With Single Model (Data Fusion)

In this experiment, feature-level fusion was explored by combining full-trip and turn-based inputs into a single tensor, as illustrated in Figure 6. Sensor readings from 10 channels were extracted for the entire trip and interpolated to a fixed length of 1200 time points (L_1) to ensure consistency. Separately, all turn segments from each trip were concatenated and interpolated to the same length (L_1 =1200), despite variability in the number of turns across trips. After alignment, both sequences were concatenated along the channel dimension, resulting in a unified tensor with shape (N, C=20, and L=1200), where N denotes the number of trips and C includes 10 channels from the trip data and 10 from the turn data. As in experiment 1, a range of model architectures was evaluated, including 1D-CNNs, RNNs, and TCNs, using the fused input. The objective was to assess whether the joint modeling of global and localized driving behavior could improve classification performance. Further architectural details are provided in Multimedia Appendix 2.

Experiment 3: Separate Inputs and Models With Late Fusion (Model Fusion)

In the final experiment, a model fusion approach was adopted. Separate models were trained independently on the trip-level and turn-level data. As shown in Figure 6, a total of 2 distinct datasets were prepared for each trip. In the upper branch, the complete 10-channel sensor stream was resampled to a fixed length of L_1 points and passed to encoder 1, where a latent representation of global driving behavior was learned. In the lower branch, all turning maneuvers for the same trip were concatenated, and the resulting sequence was standardized to L_2 points (which differed from L_1) before being input to encoder 2.

Encoders were selected from 3 architectural families, 1D-CNN, RNN, or TCN (for example, DualTinyFCN, DualGRU, and DualTCN), and were trained with separate weights. The latent vectors from both encoders were combined using a late fusion classifier. This allowed the model to integrate complementary global and local driving features while maintaining the independence of each encoder. Further model details are provided in Multimedia Appendix 3.

Model Training Framework

The training framework for all experiments followed a structured procedure. The process began with data preprocessing, where the turning maneuvers dataset was transformed into a 3D tensor representation with dimensions (N, C, and L). To evaluate the model's performance in distinguishing between cognitively healthy individuals and those with MCI, a 7-fold interparticipant cross-validation strategy was implemented. Given the limited sample size, no independent test set was used. Instead, interparticipant cross-validation was adopted to maximize data use while ensuring that the evaluation remained unbiased. Each fold contained a unique set of participants for testing, with the remaining participants used for training, ensuring that no individual appeared in both sets and thereby eliminating any risk of data leakage across folds.

Stratification was handled at the participant level. Each fold maintained an equal ratio of cognitively normal to MCI participants in the validation set. As the models operated on trip or turn-level data (rather than directly on participants), it was not possible to simultaneously stratify the trip or turn samples and preserve strict participant separation. We therefore prioritized participant-level stratification, as it provides a more reliable measure of generalization to unseen drivers, even though the resulting number of trips or turns per class could become imbalanced across folds. To mitigate any resulting class imbalance, balanced accuracy was reported alongside overall accuracy, area under the receiver operating characteristic curve (AUC), precision, and recall to provide a fairer assessment of performance across both diagnostic groups.

Once the dataset was partitioned, each model was trained on the training folds and evaluated on unseen participants in the validation fold. The average metrics across all 7 folds were used to report the final performance.

Evaluation Metrics

To assess the performance of the ML models, multiple evaluation metrics were used. Given the class imbalance in the dataset, relying solely on accuracy could be misleading. Therefore, we used a combination of accuracy, balanced accuracy, AUC, precision, and recall to provide a comprehensive evaluation of model effectiveness.

Accuracy measures the overall proportion of correctly classified instances, but can be biased when the dataset is imbalanced. Balanced accuracy addresses this issue by computing the average recall across both classes, making it a more reliable metric for evaluating performance in cases where 1 class is underrepresented. AUC provides an indication of the model's ability to distinguish between the 2 classes, with higher values indicating better separability. Precision quantifies the proportion of positive classifications that are actually correct, which is particularly important in minimizing false positives. Recall, on the other hand, measures the model's ability to correctly identify positive instances, ensuring that individuals with MCI are accurately detected. The formulas used for computing these metrics are summarized in Table 6.

XSL•FO
RenderX

Table 6. Evaluation metrics and their mathematical formulations.

Metric	Formula[a]	Description
Accuracy		Proportion of correctly classified instances out of all cases.
Balanced accuracy		Average recall for both classes, accounting for imbalances.
AUC[b]	Computed from the ROC[c] curve	Measures the model's ability to distinguish between classes.
Precision		Proportion of correctly identified positive cases among predicted positives.
Recall (sensitivity)		Proportion of actual positives correctly classified by the model.

[a]FN: false negative, FP: false positive, TN: true negative, TP: true positive.

[b]AUC: area under the receiver operating characteristic curve.

[c]ROC: receiver operating characteristic.

Ethical Considerations

A total of 22 participants were initially recruited, informed about the study, and provided written consent. This study was approved by the Institutional Review Board at Arizona State University (STUDY00006547).

Participant privacy and confidentiality were strictly maintained throughout this study. All data were deidentified using unique participant identification codes, and no personally identifiable information was included in any analyses or publications.

Participants received no financial compensation for their participation.

Results

This section reports the performance of the 3 experimental paradigms, single-view modeling (experiment 1), feature-level data fusion (experiment 2), and model-level fusion (experiment 3), evaluated with 7-fold, participant-stratified cross-validation. For every experiment, we averaged accuracy, balanced accuracy, AUC, precision, recall, and F_1-score across folds.

Experiment 1 Results

Experiment 1 examined whether early MCI signals could be more effectively captured from full-trip data or from isolated turning maneuvers when modeled independently. To provide a performance reference, a nontemporal baseline model was first implemented using summarized trip-level statistics from the raw sensor data. For each trip, the mean and SD of the accelerometer (X, Y, and Z), gyroscope (X, Y, and Z), and speed signals were computed, resulting in 14 static features. These features were used to train a random forest classifier, representing a simple benchmark based on conventional telematics features used in earlier driving and cognitive-monitoring studies [19,25]. Table 7 summarizes the cross-validated results for 21 single-view models. The full-trip experiment (1(a)) consistently outperformed the turn-only experiment across all tested architectures. The best performance was achieved by a lightweight convolutional model (TinyFCN without normalization but with class weighting), reaching 78.3% accuracy, 73.6% balanced accuracy, and an AUC of 76.7%. Other strong performers included deeper convolutional models (InceptionTimeSmall) and attention-enhanced recurrent networks (gated recurrent unit, GRU + Attn), suggesting that both paradigms can leverage the extended temporal context of full trips. Channel normalization was found to make results worse.

In contrast, the turn-only experiment 1(b) showed significantly lower performance. The best model in this setting, TinyFCN with normalization, reached only 62.7% accuracy and 56.3% balanced accuracy, a decline of about 16 percentage points compared to its trip-level counterpart. Precision dropped below 45% in most turn-only models, indicating insufficient discriminative power in short maneuver windows. Some architectures (eg, TCN + Attn) achieved high recall (up to 86.4%) by overpredicting the positive class, but at the cost of precision and balanced accuracy. Due to the weak performance of turn-only models, subsequent experiments focused on configurations that included turn data only in combination with full-trip data, either through feature-level fusion (experiment 2) or model-level fusion (experiment 3). This decision avoided further computational investment in a setting that showed limited utility for early AD detection under naturalistic conditions.

Overall, experiment 1 demonstrates that global driving behavior across full trips offers substantially more predictive information than isolated turning maneuvers. Among all architectures,

XSL•FO
RenderX

compact convolutional models such as TinyFCN provided the best balance of performance and efficiency, while recurrent models with attention were also competitive. The performance of full-trip TinyFCN (accuracy ≈78%, AUC ≈77%) serves as the baseline for subsequent fusion experiments.

It is important to note that earlier studies [5,6] identified turn-specific kinematic features as promising biomarkers for MCI. However, those findings were obtained in controlled environments, where participants drove short, predefined routes under standardized conditions. In such settings, turn segments are clearly defined, confounding variables are minimized, and behavioral comparisons are more reliable. In contrast, the present study analyzed turning maneuvers within naturalistic, long-distance trips that varied widely in road conditions, traffic, and route design. As a result, turn segments were shorter, noisier, and occasionally truncated by sensor limitations. These factors contributed to the limited performance of turn-only models and motivated the shift toward combining turn data with richer trip-level context in the remaining experiments.

Experiment 2 Results

In experiment 2, trip and turn signals were concatenated at the feature level, and a single model was trained on the resulting 20-channel input. A total of 4 architectures (TinyFCN, GRU, long short-term memory, and TCN) were evaluated. Their cross-validated performance is reported in Table 8.

Table 8. Cross-validated performance of feature-level data-fusion models (experiment 2). Trip and turn signals were concatenated into a single 20-channel input and evaluated with 7-fold participant-stratified cross-validation.

[f]LSTM: long short-term memory.

[g]TCN: temporal convolutional network.

Overall, performance improved over the turn-only models from experiment 1(b), confirming that global trip context can offset the sparsity of turn data. However, none of the fusion models outperformed the best full-trip baselines from experiment 1(a). The highest accuracy (70%) was achieved by TCN, though its AUC (63%) and balanced accuracy (63%) fell short of the full-trip TinyFCN benchmark. Long short-term memory delivered the highest balanced accuracy (67%), while GRU achieved similar accuracy and recall but lower precision. TinyFCN, which had previously performed best on full trips, dropped to 62% accuracy and 52% AUC, suggesting that feature-level concatenation may impair its ability to model trip dynamics effectively.

These results indicate that early fusion does not offer a reliable method for combining localized and global driving features. While a modest gain in recall was observed, it came at the cost of precision and overall discriminative power. This degradation likely results from the mismatch in temporal characteristics between trips and turns when merged into a single input. These findings support the need for a late-fusion strategy, as explored in experiment 3, where each data type is modeled independently before integration.

Experiment 3 Results

In the final experiment, the trip and turn streams were treated as complementary modalities. Each was processed by a dedicated encoder, and their latent vectors were merged in a late-fusion classifier. Table 9 summarizes the cross-validated results for 7 dual-branch architectures. The dual-encoder strategy outperformed the feature-level fusion models from experiment 2 across all metrics and approached the performance of the best full-trip baselines from experiment 1(a). The highest overall accuracy (75%) was achieved by DualTinyFCN, which also recorded the best AUC (68%) and matched the highest recall (74%). DualTCN with self-attention produced the strongest balanced accuracy (72%) and recall (77%), while maintaining 75% accuracy. DualGRU with a single attention head offered a solid alternative at 73% accuracy and 65% balanced accuracy; its multihead variant improved recall to 84% but at the cost of precision.

XSL•FO
RenderX

Table 9. Cross-validation results for model-level fusion (experiment 3). Each architecture comprises separate trip and turn encoders whose outputs are combined by either concatenation (DualTinyFCN) or a learned gating mechanism (all others).

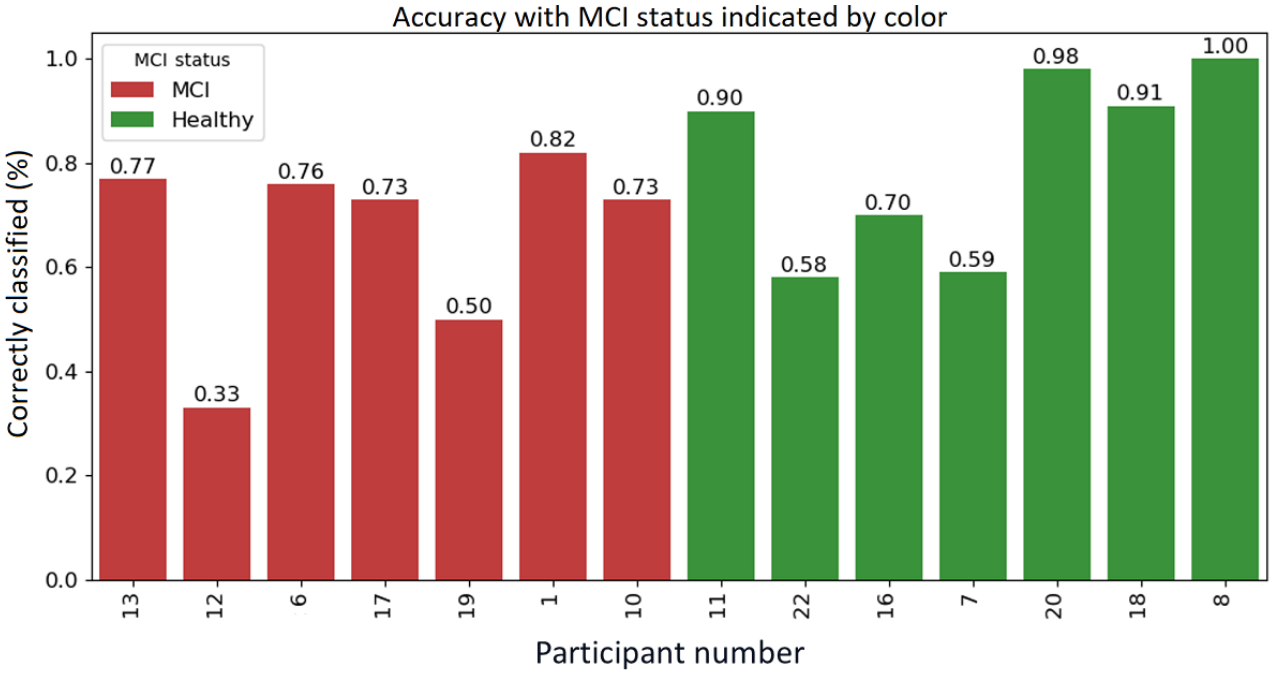
[g]FCN: fully convolutional network

Relative to experiment 2, balanced accuracy improved by 6 to 8 percentage points, and AUC increased by about 5 points, suggesting that separate feature extraction for trips and turns reduced the interference observed with early fusion. While none of the dual-branch models surpassed the single-view TinyFCN baseline from experiment 1(a), the performance gap was reduced to within 4 points, with noticeably stronger recall and class balance.



These results indicate that turning behavior carries useful complementary information, which becomes effective when modeled independently before fusion. However, the late-fusion models still fell short of the trip-only baseline, unlike in earlier studies conducted under controlled driving conditions. A likely explanation is the greater behavioral variability in naturalistic turn maneuvers, where factors such as traffic, shallow bends, truncated segments, and GPS inconsistencies introduce noise that diminishes signal quality. To overcome this, 2 improvements are proposed. First, a more selective turn-extraction method could be implemented to filter out low-information maneuvers (eg, shallow curves or stop-sign rolls) and retain only cognitively demanding turns. Second, the use of an adaptive fusion mechanism, such as a trainable gating or context-aware attention layer, could allow the model to dynamically weigh turn features based on context, rather than relying on fixed integration. These enhancements may help future late-fusion models surpass the trip-only benchmark.

Participant-Level Performance of the Best-Performing Model

To further evaluate model effectiveness, participant-level performance was analyzed using the best-performing model from experiment 1(a), which achieved the highest average accuracy (78%). Figure 7 shows the percentage of correctly classified trips per participant, color-coded by diagnostic group.

XSL•FO
RenderX

Figure 7. Per-subject trip classification accuracy of the best performance model, color-coded by cognitive status (green=healthy, red=MCI). MCI: mild cognitive impairment.

This analysis revealed that trips from cognitively healthy participants were classified more accurately than those from the MCI group. Within the MCI cohort, classification accuracy appeared to correlate with the number of available trips. Participants 12 and 19, who contributed only 3 and 4 trips respectively, showed the lowest accuracies (33% and 50%). In contrast, participant 1, also in the MCI group, provided 28 trips and achieved over 80% accuracy, suggesting that greater data volume improves participant-specific classification performance. These findings support the decision to evaluate trips individually rather than applying a majority-vote rule per participant, as done in previous work. As MCI symptoms tend to appear episodically, a majority-vote approach may misclassify participants with sporadic impairments. For instance, participant 12, clinically diagnosed with MCI, was misclassified on 2 of 3 trips. A majority-vote method would incorrectly label this participant as healthy, masking the sporadic but clinically meaningful deviations this framework aims to detect.

The granular trip-wise approach captures the variability that defines mild impairment and provides a more sensitive early warning mechanism than binary participant-level labels. This variability can be expressed as a frequency-based risk score based on the proportion of trips classified as impaired for each driver. Rather than producing a fixed “MCI” or “healthy” label, the score outputs a continuous risk value between 0 and 1, allowing clinicians to define thresholds for follow-up assessment. The choice of such a threshold will have practical implications. A low threshold (eg, flagging drivers if 10% or more of their trips are classified as impaired) increases sensitivity and supports early detection but may lead to more false positives and unnecessary follow-up. A high threshold (eg, 50%) reduces false positives but risks missing individuals with sporadic lapses (precisely the pattern seen in early MCI). As the risk score is continuous, thresholds can be tailored to specific clinical contexts. For example, high sensitivity may be prioritized in population-level screening, while higher precision may be preferred in specialist clinics. By presenting performance curves across thresholds or reporting AUC values alongside confusion matrices at clinically relevant cutoffs, these trade-offs can be made explicit and support informed deployment of the model in practice.

Trip count was also found to influence the stability of those episodic signals. With fewer than 5 trips, a single misclassified journey can flip a driver’s apparent status, explaining the wide swings in accuracy for participants 12 and 19. As the dataset grows (through additional participants, extended monitoring, or data augmentation), the law of large numbers should attenuate this volatility and sharpen the distinction between truly unimpaired drivers and those with early cognitive change. Overall, these results reinforce the importance of context-aware, trip-level evaluation for detecting early MCI. Rather than relying on binary labels, future implementations should adopt frequency-based risk scoring to translate trip-level outputs into longitudinal, clinically actionable indicators.

Discussion

This study demonstrated the potential of naturalistic driving data as a digital biomarker for early MCI detection. Prior limitations, such as controlled test settings, reliance on summary statistics, and rigid evaluation protocols, were addressed through a framework that embraces real-world variability and context-aware analysis, structured around the 3 research questions posed in the Introduction section.

First, the robustness of driving-based biomarkers under naturalistic conditions was assessed (RQ1). Models trained on full-trip data achieved 78% accuracy (AUC 77%) despite variations in routes, traffic, and sensor noise, while turn-only

XSL•FO
RenderX

inputs underperformed by approximately 16 percentage points. These results affirm that early cognitive change is detectable through naturalistic driving; however, short turning maneuvers alone were found to be too noisy to provide reliable indicators.

Second, to address RQ2, a multistage pipeline was developed to transform raw, noisy, multisensor data into structured model inputs. Signals of varying frequencies were aligned, trips segmented, and interpolation applied to ensure consistency. Turn maneuvers were extracted using a targeted method, yielding maneuver-level data while preserving temporal and sensor fidelity for deep learning.

Third, modeling strategies were compared under current data limitations (RQ3). Single-view models on full-trip data remained strongest. While early fusion of trip and turn data failed to outperform this baseline, late fusion using dual encoders significantly improved balanced accuracy and recall, suggesting that turn cues become useful when learned in a dedicated branch. As larger, cleaner turn datasets are acquired, late fusion is expected to surpass trip-only models, especially with mechanisms that emphasize turns only when informative.

In addition, the participant-level analysis revealed that most misclassifications occurred among MCI drivers with few recorded trips, underscoring the effects of behavioral noise and data scarcity. As MCI is marked by sporadic impairments, traditional aggregate predictions may miss subtle signs. By evaluating each trip and maneuver individually, the proposed approach enables detection of episodic lapses, offering a practical early warning system for clinical follow-up.

Future improvements should focus on refining turn extraction through context-aware filtering, enhancing late-fusion models with adaptive gating or attention mechanisms, and enriching the dataset via increased participation and targeted augmentation. Prospective validation and integration of complementary modalities (eg, eye-tracking and in-cabin audio) may yield a more comprehensive behavioral signature of early cognitive decline. Furthermore, given the relatively small dataset, future work could explore the use of transfer learning from models pretrained on large-scale sensor-based time-series datasets. Models trained on motion, activity recognition, or physiological sensing data capture general temporal and kinematic patterns that overlap with vehicle dynamics such as acceleration and rotation. Fine-tuning such pretrained encoders on naturalistic driving data could improve feature extraction, reduce dependence on large labeled cohorts, and enhance generalization to new drivers or sensing platforms. Incorporating transfer learning in this way would be a practical step toward building more data-efficient and scalable cognitive monitoring systems. Collectively, these efforts may further establish naturalistic driving as a viable and nuanced platform for proactive cognitive health monitoring.

Abstract

Background: Digital health literacy (DHL) is the ability to locate, understand, evaluate, and apply health information in digital environments. It is essential for older adults to effectively engage with contemporary health care. However, existing DHL assessments primarily rely on self-reported measures, which are susceptible to subjective bias and often fail to capture actual performance. There is a need for a comprehensive, data-driven approach that integrates objective performance indicators with self-assessments to accurately predict and explain DHL levels in older adults.

Objective: This study develops and validates a machine learning approach to predict DHL levels in older adults by integrating performance-based and self-assessed evaluations.

Methods: We applied a 2-stage methodological framework using 2 independent datasets. In the first stage, to identify performance-based determinants, we assessed actual digital and information comprehension in a separate pilot cohort of 30 older adults (aged 60-74 years). In parallel, to measure self-reported DHL, we conducted an online survey with a distinct group of 1000 older adults (aged 55-74 years) using the Digital Health Literacy Scale and the Korean version of the eHealth Literacy Scale (KeHEALS). Bayesian linear regression was applied to both datasets to identify significant explanatory variables. In the second phase, we trained and validated a binary classification model to predict KeHEALS levels using the survey dataset (n=1000), leveraging the features identified in the first stage. Five machine learning algorithms were evaluated, and the best-performing model was interpreted using Shapley Additive Explanations (SHAP) analysis.

Results: In the pilot performance-based assessment, using a greater number of electronic devices and having higher educational attainment were positively associated with comprehension, whereas alcohol intake showed a negative association. In the self-assessed survey data, key correlates included interest in health-related apps, self-care confidence, age, smoking, alcohol intake, number of devices used, and exercise frequency. Among the machine learning models, categorical boosting demonstrated the most balanced performance (accuracy 0.785, precision 0.769, F1-score 0.765, area under the receiver operating characteristic curve 0.835), outperforming the dummy classifier (accuracy 0.540). SHAP analysis indicated that self-care confidence, health information search, interest in health-related apps, number of electronic devices used, and exercise frequency were the strongest positive contributors to high-DHL predictions, whereas older age and lifestyle factors (alcohol intake, smoking) contributed negatively.

Conclusions: By explicitly integrating performance-based and self-assessed indicators within an explainable machine learning framework, this study demonstrates that DHL in older adults is influenced by both digital engagement and health management

XSL•FO
RenderX

factors. These findings suggest that the proposed framework can serve as a structured approach for evaluating DHL in older adults and inform the design of personalized digital health interventions in clinical and community settings.

digital health literacy; eHealth literacy; digital health care; mHealth; machine learning

Introduction

Background

The rapid advancement of digital technologies and smart devices has transformed everyday life, particularly in the health care domain. Digital health technologies such as electronic health records, telemedicine, and mobile health (mHealth) apps are increasingly recognized as essential tools for enhancing access to health information, supporting self-management, and improving the efficiency and quality of health care delivery [1]. These technologies empower individuals to better manage their health and facilitate personalized, patient-centered care [2]. Furthermore, community-driven digital health systems have demonstrated their potential to establish sustainable and equitable models of care [3].

However, to fully benefit from digital health technologies, individuals must have a sufficient level of digital health literacy (DHL). DHL refers to the ability to locate, understand, evaluate, and apply health-related information in digital environments to make informed decisions and manage health [4]. Higher DHL levels have been associated with improved health outcomes, including better chronic disease management, engagement in preventive behaviors, increased use of health care services, enhanced quality of life, and reduced risk of depression [5-8]. Furthermore, DHL plays a critical role in narrowing the digital divide and promoting equitable access to health resources across diverse populations.

According to the 2024 Digital Information Divide Survey in Korea, the digital informatization level among older adults corresponded to 71.4% of that observed in the total population. While digital access has largely equalized, reaching 95.3% of the general population's level, their digital competencies and utilization indices were relatively lower (55.9% and 75.0%, respectively) [9]. These scores are more likely the result of cohort effects and differences in the availability of educational opportunities, health status, and social and technical support, rather than problems caused by aging [10,11]. Consequently, interventions aimed at enhancing DHL in older populations should be evidence-based and sensitive to the diversity of digital experiences in later life, focusing on modifiable barriers related to access, education, and available support rather than chronological age alone.

The majority of existing studies have relied on self-assessment surveys to measure DHL [12-17]. However, such instruments often fail to capture psychosocial dimensions, such as social support, and may not accurately reflect individuals' actual digital competencies [18]. This underscores the need for a more comprehensive and empirically grounded approach to DHL assessment. Machine learning offers a robust framework for integrating diverse variables, including sociodemographic characteristics, health behaviors, and psychosocial factors, into multidimensional predictive models capable of capturing complex nonlinear interactions [19].

In this study, we employed a Bayesian estimation method to identify key factors associated with DHL-related outcomes, specifically leveraging a wide range of input features, including psychosocial attributes. Subsequently, we developed machine learning models to predict DHL levels and applied Shapley Additive Explanations (SHAP), an explainable artificial intelligence technique, to enhance the interpretability and transparency of the model's outputs [20]. This 2-stage approach aims to provide a more accurate and comprehensive understanding of DHL in older adults and offers practical insights into the design of personalized digital health education and intervention strategies.

Assessment Tool for Measuring Digital Health Literacy: eHealth Literacy Scale

Norman and Skinner's [21] foundational work conceptualized eHealth literacy as a composite of 6 core literacies: traditional literacy, information literacy, media literacy, health literacy, scientific literacy, and computer literacy. This framework is grounded in the "Lily Model," which categorizes skills into analytical and context-specific domains. As digital health technologies have advanced, the original construct of eHealth literacy has broadened and is now more commonly used within the wider notion of DHL.

At the same time, several conceptual and methodological limitations of the eHealth Literacy Scale (eHEALS) have been identified and should be considered when the instrument is used. As a self-report measure, eHEALS assesses subjective confidence rather than objectively measured performance, so scores may diverge from actual digital and health-related skills [22,23]. Factor-analytic studies have also reported inconsistent dimensional structures across populations and languages, indicating that the underlying constructs may vary by cultural and demographic context and that direct score comparisons or universal cutoffs should be interpreted with caution [24]. Nevertheless, eHEALS has been translated and validated in numerous countries, demonstrates consistently high internal consistency, and remains a pragmatic core instrument for assessing perceived eHealth literacy in large-scale surveys and clinical research [24-33].

Using eHEALS, Berkowsky [17] assessed the DHL levels of adults aged 65 and older in California and examined the impact of sociodemographic characteristics and digital usage patterns. Regression analyses indicated that higher educational attainment, more frequent internet use, and engagement in a wider range of online activities (eg, email, online shopping, social media)

XSL•FO
RenderX

were associated with higher DHL levels, whereas basic demographic variables such as age, gender, and income were not significant predictors. These findings suggest that actual digital engagement may be more critical than demographic background in shaping perceived DHL.

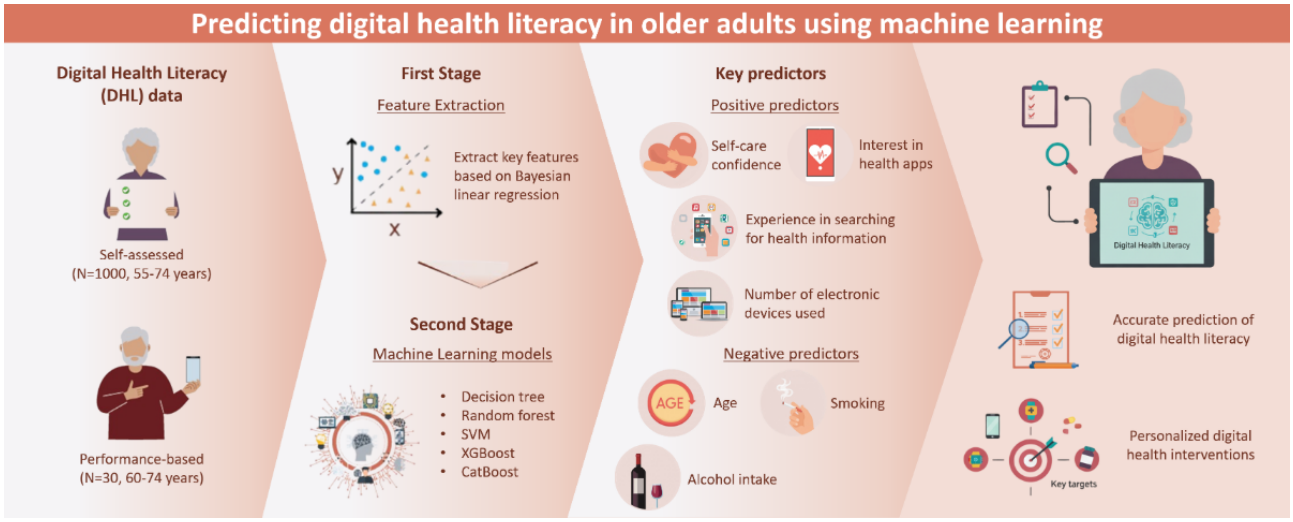
Similarly, Kyaw et al [34] investigated DHL among 434 adults aged 65 and older in urban settings, focusing on the influence of social and digital factors. Their findings revealed that older age was negatively associated with DHL, whereas higher income, extended internet use, and active participation in social media showed positive associations. Notably, older adults who used social media exhibited approximately 4-fold higher DHL levels than nonusers, and those using the internet for more than 3 hours per day demonstrated up to a 35-fold increase in DHL levels. These findings suggest that improving DHL among older adults requires not only the provision of digital technologies but also strategies to promote real-world digital engagement and enhance social participation in digital environments.

Assessment Tool for Measuring Digital Health Literacy: Digital Health Literacy Scale

Early definitions of eHealth literacy focused primarily on individuals' abilities to search for and understand health information on the internet. However, today's digital environment increasingly demands interactive engagement through platforms such as social media, mHealth apps, and telemedicine. Consequently, the concept has evolved into DHL, which encompasses not only information seeking but also the skills to evaluate, apply, and interact with digital health content across diverse platforms [35].

In line with this expanded conceptualization, the Digital Health Literacy Scale (DHLS) was developed as a multidimensional tool to comprehensively measure DHL. The DHLS evaluates competencies across 4 domains: use of digital devices, understanding of health information, use and decision of health information, and use intention [36]. The use of digital devices domain assesses individuals' proficiency in operating digital tools and accessing health-related services. The understanding of health information domain measures the ability to comprehend online content, such as medication instructions and test results. The use and decision of health information domain evaluates both the application of health information in decision-making and the critical judgment of its credibility. The use intention domain captures users' motivation and willingness to engage with digital health platforms and services. It was specifically designed to reflect the behavioral, cognitive, and motivational characteristics commonly observed in older adults, particularly those vulnerable to the digital divide. By independently assessing both digital and health literacy and integrating them into a unified DHL construct, the DHLS facilitates a comprehensive and multidimensional assessment of digital health literacy. This approach helps identify differences in digital health literacy across various skill domains, from basic digital operations to advanced critical thinking, providing actionable insights into the specific competencies that require support among older adults.

Machine Learning Approach for Assessing Digital Health Literacy



Given what we discussed so far, eHEALS and DHLS are widely used self-report measures for evaluating digital health literacy. Most studies employing these tools use univariate analyses to examine the effects of individual variables independently [37-39]. However, because self-assessment instruments are inherently grounded in subjective perceptions, they have substantial limitations in capturing actual performance and real-world information behaviors. This concern aligns with extensive evidence from cognitive and behavioral research demonstrating that self-assessments are often systematically biased and display only modest associations with objective indicators of competence [40]. Moreover, they fail to account for interactions among variables or evaluate the relative importance of each factor [41,42]. These limitations emphasize the need to develop data-driven approaches that use diverse individual-level characteristics to accurately predict DHL.

To address these limitations, this study adopted a comprehensive 2-stage machine learning framework that integrates performance-based and self-assessed indicators of DHL. Machine learning is a statistical approach that predicts and classifies individual conditions by learning complex, nonlinear patterns from multidimensional data [43]. Research suggests that machine learning algorithms, including Extreme Gradient Boosting (XGBoost), random forest, and logistic regression, can identify key sociodemographic factors influencing general health literacy [44]. Existing studies have demonstrated the effectiveness of machine learning in uncovering intricate variable interactions and enhancing predictive accuracy [45-47], reflecting a broader shift toward objective data-driven assessment in health literacy research.

This study integrated performance-based and self-reported assessments to identify key features associated with DHL. Based on these significant features, a prediction model was developed using a machine learning algorithm. Furthermore, we used SHAP to interpret the contribution of each feature, thereby proposing an explainable artificial intelligence approach for medical apps. This approach aims to effectively predict DHL in older adults and provide a foundation for developing personalized intervention strategies (Figure 1).

Methods

Overview

In this study, we designed a 2-stage machine learning framework integrating self-assessed (n=1000) and performance-based (n=30) evaluations (Figure 2). In the initial phase, using a performance-based task, digital literacy and health care information scores were obtained (Figure 2A). Subsequently, Bayesian linear regression analysis was performed to identify explanatory variables significantly associated with DHL (Figure 2B). The performance-based evaluation was employed to enhance the explanatory power of the variables and was excluded from the training phase of the DHL predictive model. In the second phase, using a dataset of 1000 self-assessments and the characteristics identified in the initial phase, we constructed prediction models to classify DHL levels (high vs low; Figure 2C). We conducted comparative evaluations of multiple machine learning models, including decision tree, support vector machine (SVM), random forest, XGBoost, and categorical boosting (CatBoost). In addition, SHAP analysis was used to quantitatively assess the impact of significant variables on DHL predictions, thereby enhancing the interpretation of the model's predicted results (Figure 2D).

Figure 2. Overview of the framework used to predict digital health literacy level. AUC: area under the receiver operating characteristic; CatBoost: categorical boosting; DHLS: Digital Health Literacy Scale; eHEALS: eHealth Literacy Scale; SHAP: Shapley Additive Explanations; SVM: support vector machine; XGBoost: Extreme Gradient Boosting.

Performance-Based Digital Health Literacy

Participants

To evaluate performance-based DHL, we recruited a total of 30 participants aged 60-74 (mean age 69.1 years). Participants were enrolled using a nonprobability snowball sampling strategy facilitated through local community networks. To ensure data validity and minimize potential bias, intermediaries who arranged the initial contact were excluded from participation. Trained research staff (CP and SK) conducted a brief telephone screening to confirm eligibility and then scheduled a home visit. During the visits, researchers provided comprehensive information regarding the study's purpose, procedures, anonymity, data usage, and participants' rights. Written

XSL•FO
RenderX

informed consent was obtained before administration of the behavioral tasks. Participation was voluntary, and all participants were informed that they could withdraw from the study at any time without penalty.

To examine differences in performance-based DHL, participants were divided into 2 groups using the eHEALS cutoff score as the criterion: low DHL (n=15) and high DHL (n=15), based on their Korean version of the eHealth Literacy Scale (KeHEALS) scores, as shown in Table 1 [48]. The 2 groups showed no significant differences in age (mean age: low DHL=68.7 years, high DHL=69.4 years; *P*=.19) or gender (male/female: low DHL=2/13, high DHL=5/10; *P*=.34). In addition, no significant difference was found between the groups in years of education (*P*=.49).

Table 1. Comparison of performance-based sociodemographic variables by DHL[a] level based on the KeHEALS[b] score.

Characteristics	Groups n (%)		Total n (%)
	Low	High	
Gender			
Male	2 (29)	5 (71)	7 (100)

[a]DHL: digital health literacy.

[b]KeHEALS: Korean version of the eHealth Literacy Scale.

Measurements

Participants engaged in content reading focused on digital literacy and health care information, followed by an identification task designed to assess comprehension. Each reading selection comprised 2 or 3 paragraphs and was displayed on a Samsung Galaxy A15 smartphone equipped with a 163.9-mm display (1080 × 2340 pixels). The smartphone was used as the experimental tool to deliver all visual materials for task performance in a controlled viewing environment. During the identification task, participants were asked to indicate whether 10 digital literacy sentences and 10 health care information sentences derived from the readings were true or false. The average time required to complete the assessment did not exceed 30 minutes. To identify key explanatory variables, scores from this identification task were subsequently used in the initial stage of the DHL framework. Before the assessment, demographic information (gender, age, and years of education), psychosocial factors (living arrangements), digital-related factors (interest in health-related apps, health information search, and number of digital devices used), and health-related factors (alcohol intake, smoking, and exercise frequency) were collected from each participant. Interest in health-related apps was measured using a 5-point Likert scale (1=strongly disagree to 5=strongly agree), capturing the degree of interest in using health-related apps in digital environments. Health information search was assessed using a binary (yes/no) item asking whether participants had personally searched for health-related information.

To evaluate participants' overall level of digital health literacy, the KeHEALS was administered. KeHEALS is an 8-item self-report instrument designed to measure individuals' perceived ability to locate, evaluate, and apply electronic health information, demonstrating high internal consistency (Cronbach α=.89) and good test-retest reliability over a 2-week interval (intraclass correlation 0.80). Each item was rated on a 5-point Likert scale ranging from 1 (strongly disagree) to 5 (strongly agree), yielding a total score between 8 and 40, with higher scores indicating greater perceived digital health literacy. Participants were classified into 2 groups using a sample-specific threshold based on the median total eHEALS score of 29 in the entire sample: those with a total score greater than 29 were categorized as having a high level of digital health literacy, whereas those with a score of 29 or below were categorized as having a low level. This classification facilitated subsequent analyses by enabling group comparisons according to participants' perceived competencies in engaging with digital health information.

XSL•FO
RenderX

Self-Assessed Digital Health Literacy

Participants

To evaluate self-assessed DHL for the predictive modeling phase, survey data were collected from 1000 adults aged 55-74 (mean age 63.6 years). All participants were recruited through an online survey platform operated by a survey agency. Recruitment was facilitated via email and website postings. To ensure a representative sample of the general population, stratified quota sampling was employed based on gender and age groups. Each respondent was assigned a unique access link to ensure single participation and eliminate the possibility of repeated submissions. Given the prospective and anonymous nature of this large-scale survey, the requirement for written informed consent was waived by the Institutional Review Board. Participants were first presented with information on the initial survey screen that provided comprehensive details about the study objectives and procedures. Proceeding to the questionnaire was considered to indicate informed willingness to participate.

To examine group-level differences in DHL, participants were classified into 2 groups based on KeHEALS scores: low DHL (n=563) and high DHL (n=437; Table 2). The high-DHL group had a greater proportion of participants in the younger age range of 55-59 (148/437, 33.9%), whereas the low-DHL group included more participants in the 65-69 (242/563, 43.0%) and 70-74 (80/563, 14.2%) age ranges. Age distribution also differed between the groups (mean age: low DHL=64.2 years, high DHL=62.8 years). Differences were likewise observed in gender distribution (male/female: low DHL=257/306, high DHL=243/194). The proportion of males was higher in the high-DHL group (243/437, 55.6%) than in the low-DHL group (257/563, 45.6%), whereas females constituted the majority in the low-DHL group (306/563, 54.4%). Regarding years of education, a marked difference was found between the 2 groups. In the high-DHL group, more than half of the participants (235/437, 53.8%) had obtained a university degree or higher, whereas the low-DHL group had a greater proportion of high school graduates (271/563, 48.1%) and individuals with less than a middle school education.

Table 2. Comparison of self-assessed sociodemographic variables by DHL[a] level based on the KeHEALS[b] score.

Characteristics	Groups, n (%)		Total, n (%)
	Low	High	
Gender			
Male	257 (51.4)	243 (48.6)	500 (100)
Female	306 (61.2)	194 (38.8)	500 (100)
Age (years)			
55-59	134 (47.5)	148 (52.5)	282 (100)
60-64	107 (57.5)	79 (42.5)	186 (100)
65-69	242 (57.9)	176 (42.1)	418 (100)

Community college	62 (50.4)	61 (49.6)	123 (100)
University or higher	180 (43.4)	235 (56.6)	415 (100)

[a]DHL: digital health literacy.

[b]KeHEALS: Korean version of the eHealth Literacy Scale.

Measurements

DHL levels were assessed using the DHLS [36] and KeHEALS [48]. The DHLS consists of 4 subscales: use of digital devices (10 items), understanding of health information (5 items), use and decision of health information (5 items), and use intention (5 items). Participants completed the DHLS questionnaire using a 5-point Likert-type response scale (1=strongly disagree, 5=strongly agree). To determine key explanatory variables related to digital literacy and health care information in older adults, we focused on 3 subscales: use of digital devices, understanding of health information, and use and decision of health information. Based on a sample-specific threshold corresponding to the median total eHEALS score of 29, eHEALS was dichotomized into 2 groups and used as a predictive variable in the machine learning model. Furthermore, we collected demographic information (gender, age, and years of education), psychosocial factors (living arrangements and social support), digital-related factors (interest in health-related apps, health information search, and number of digital devices used), and health-related factors (alcohol intake, smoking, exercise frequency, and self-care confidence). Self-care confidence was assessed as an indicator of health empowerment in older adults using a single item derived from the Korean

XSL•FO
RenderX

Health Empowerment Scale, which measures confidence in making health management decisions [49]. This item was rated on a 5-point Likert scale (1=strongly disagree to 5=strongly agree).

Statistical Analysis

Feature Extraction Based on Bayesian

To identify the most influential factors associated with DHL, we applied Bayesian linear regression to both performance- and survey-based datasets. This approach improves modeling efficiency while enhancing interpretability by incorporating prior-based regularization and probabilistic estimation of regression coefficients, thereby allowing direct assessment of variable importance and uncertainty [50]. Each model was specified separately for each observation unit as follows:

where Y_i is the standardized score of the ith participant; X_{ij} is the value of the jth feature for the ith participant; β_0 is the intercept; β_j is the regression coefficient for each feature; ε_i is the error term; and p' is the total number of features considered.

The likelihood for the observed data was specified as follows:

We assigned weakly informative priors to the model parameters to ensure that posterior inferences were primarily driven by the observed data. Specifically, the intercept term β_0 was assigned a prior distribution $N(0, 5)^2$, and each regression coefficient β_j received an independent prior $N(0, 1^2)$ for j=1, ..., p', reflecting an implicit L2 regularization effect. The SD of the error term σ was assigned a HalfCauchy(2) prior.

Posterior distributions were approximated using Markov chain Monte Carlo sampling. For each model, 4 parallel chains were run, each with 2000 tuning steps followed by 2000 sampling steps. Convergence was assessed by monitoring divergence diagnostics throughout the sampling process.

Feature selection was conducted using a Bayesian inference framework. The dataset was first split into training and test sets, and all feature selection procedures were performed exclusively on the training set. In the performance-based dataset, we separately identified predictors of comprehension scores for digital information and health information. In the self-assessed dataset, feature selection was performed for each DHLS subscale, namely, use of digital devices and health information understanding and utilization. To prevent data leakage during the Markov chain Monte Carlo sampling procedure used for feature selection, all modeling steps were conducted exclusively on the training dataset. Variables were retained only if the 95% highest density interval (HDI) of their posterior regression coefficients β did not include 0, indicating a statistically significant positive or negative association with the outcome variable. These statistically validated features were then used exclusively in subsequent stages to construct the final predictive model for DHL.

Modeling

In this study, final predictive modeling was performed using the self-assessed DHL dataset comprising 1000 participants. The goal of the model was to accurately classify participants into 2 distinct groups: high DHL and low DHL. Before developing the final predictive model, a feature selection process was conducted. This process aimed to identify features strongly associated with both performance-based and self-assessed DHL measures. The resulting feature set was designed to comprehensively represent the various aspects of DHL.

Using this selected feature set, 5 machine learning models—decision tree, random forest, XGBoost, CatBoost, and SVM—were implemented to predict DHL levels [51-55]. During data preprocessing, we applied a structured workflow to handle distinct variable types and used mixed encoding strategies to reflect the measurement properties of each predictor. Nominal categorical variables were encoded using OneHotEncoder. Ordinal variables were generally processed with OrdinalEncoder to preserve their inherent ranking. However, for selected lifestyle variables such as alcohol intake, we applied OneHotEncoder to capture category-specific associations across frequency levels that may not be adequately represented by a single ordered scale. These transformations were integrated into a unified preprocessing pipeline and applied consistently across all data splits, ensuring uniform feature representation and minimizing the risk of data leakage.

For model training and testing, the preprocessed dataset was split into a training set (n=800) and a test set (n=200). The hyperparameters of each model were optimized using the Optuna framework [56], with 10-fold cross-validation applied to the training set to maximize accuracy. Following hyperparameter optimization, to assess generalization performance, each final model was trained on the entire training set and evaluated on the test set.

Performance Evaluation

Model performance in predicting DHL levels was quantitatively evaluated using standard metrics for binary classification, including accuracy, precision, sensitivity, specificity, F_1-score, and area under the receiver operating characteristic curve (ROC AUC). Accuracy indicates the overall proportion of correctly classified cases. Precision reflects the proportion of true high-DHL cases among those predicted to have high DHL. The F_1-score, which is the harmonic mean of precision and recall, provides a balanced metric that is particularly useful under class imbalance. The ROC AUC assesses the model's ability to distinguish between high- and low-DHL cases across varying decision thresholds. Collectively, these metrics offer a comprehensive evaluation of model performance.

Furthermore, to address the "black box" nature of machine learning and ensure clinical transparency, we used the SHAP framework. SHAP is a model-agnostic method based on cooperative game theory that assigns each feature an importance value for a particular prediction. It calculates the Shapley value, which represents the average marginal contribution of a feature across all possible coalitions of features [20]. Unlike traditional feature-importance metrics that provide only a global ranking,

XSL•FO
RenderX

SHAP offers both global and local interpretability. It allows us to quantify not only the magnitude but also the direction of each feature's impact on the model's output.

In the context of our model for predicting digital health literacy, SHAP provides a granular explanation of how specific demographic, interest in digital health care, health management, and psychosocial features influence the classification of an individual into the high-DHL or low-DHL group. This methodology enables visualization of individual and global feature effects, allowing identification of key determinants of DHL and verification of whether the model's learned patterns are consistent with established clinical research on digital health.

Ethical Consideration

This study was reviewed and approved by the Institutional Review Board of the Catholic University of Korea, College of Medicine (survey study approval number MIRB 20230825-007; behavioral task study approval number MIRB 20241014-003), and was conducted in accordance with institutional and national guidelines for research involving human participants. For the web-based survey, an online written information sheet described the study purpose, procedures, minimal-risk nature, anonymity, data use, and participants' rights. Data were collected only from individuals who voluntarily agreed to participate after reading this information, with explicit notice that they could withdraw from the survey at any time without penalty. For the behavioral task study, participants received a written information sheet and provided written informed consent before participation. In the survey study, no personally identifiable information was collected. In the behavioral task study, personal information was collected solely for compensation purposes, stored separately from research data, and destroyed immediately after compensation. In both studies, no personal identifiers were used for analysis or reporting; all analytic datasets were anonymized, encrypted, and stored on secure institutional servers accessible only to the research team. Participants who completed the web-based survey received 500 points (approximately US $0.35) redeemable within the online platform, and participants in the behavioral task study received KRW 30,000 in cash (approximately US $20) as compensation for their time. No identifiable images of participants were included in the manuscript or its multimedia appendix.

Results

Post Hoc Age-Group Comparison of Selected Features

To verify the validity of applying selected features from a small cohort of individuals aged 60 years and older to the 55-59 age group included in the final model during the feature-extraction phase, we divided participants into 2 age groups and performed statistical comparisons of the selected features. The comparison revealed significant demographic and behavioral differences in several variables (Table 3). Modest but statistically significant age-related differences were observed for interest in health-related apps (P=.03), health information search (P=.02), smoking (P=.004), and alcohol intake (P=.007). However, no significant differences were observed in the number of electronic devices used (P=.41), self-care confidence (P=.19), or exercise frequency (P=.86).

Feature Selection From Performance-Based Digital Health Literacy

Feature selection using Bayesian linear regression identified 3 features that were statistically associated with digital information comprehension. The number of electronic devices used showed a strong positive association with comprehension scores (β=.59, 95% HDI 0.21-0.93). By contrast, 2 variables related to alcohol intake were negatively associated with comprehension. Specifically, alcohol intake once a month (β=–1.48, 95% HDI –2.43 to 0.49) and alcohol intake 2-4 times a month (β=–1.05, 95% HDI –1.76 to 0.35) were associated with lower performance in digital literacy tasks.

For health care information comprehension, 2 features were statistically significant. Years of education showed a positive association with comprehension performance (β=.48, 95% HDI 0.10-0.88), indicating that higher educational attainment contributes to better understanding of health-related information. Conversely, alcohol intake 2-4 times a month was again associated with reduced performance (β=–1.03, 95% HDI –1.96 to 0.16). Finally, the features selected from the performance-based DHL were the number of electronic devices used, alcohol intake, and years of education. These selected variables were subsequently used in the second-stage predictive modeling of DHL levels.

Feature Selection From Self-Assessed Digital Health Literacy

The significant predictors associated with 2 DHLS subscales, namely, use of digital devices and health information understanding and utilization, were identified using Bayesian linear regression.

For the digital device utilization subscale, 12 features were statistically significant. Interest in health-related apps was the strongest positive predictor (β=.44, 95% HDI 0.39-0.48). Moreover, several health behavior variables showed positive associations, including abstinence from alcohol intake in the past year (β=.31, 95% HDI 0.09-0.51), alcohol intake about once a month (β=.37, 95% HDI 0.15-0.57), alcohol intake 2-4 times a month (β=.31, 95% HDI 0.11-0.49), alcohol intake 2-3 times a week (β=.26, 95% HDI 0.04-0.52), and being a nonsmoker (β=.19, 95% HDI 0.001-0.37). In addition, self-care confidence (β=.13, 95% HDI 0.03-0.26) was positively associated with digital device use. By contrast, several variables demonstrated significant negative associations with digital device use, including age 70-74 years (β=–.31, 95% HDI –0.50 to 0.11), age 65-69 years (β=–.17, 95% HDI –0.31 to 0.05), number of electronic devices used (β=–.19, 95% HDI –0.26 to 0.13), exercise frequency (β=–.11, 95% HDI –0.17 to 0.05), and years of education (β=–.07, 95% HDI –0.14 to 0.01). Distributions of digital literacy scores by feature values are presented in Multimedia Appendix 1.

For the subscale on health information understanding and utilization, 7 predictors showed statistically significant associations. Interest in health-related apps emerged as the strongest positive predictor (β=.34, 95% HDI 0.27-0.38). Lack of health information search (β=.17, 95% HDI 0.02-0.32), abstinence from alcohol intake in the past year (β=.28, 95% HDI 0.07-0.55), and former smoking status (β=.34, 95% HDI 0.03-0.69) also showed positive associations with health information understanding and utilization. By contrast, negative associations were observed for the number of electronic devices used (β=–.14, 95% HDI –0.21 to 0.07), age 70-74 years (β=–.29, 95% HDI –0.54 to 0.09), and age 65-69 years (β=–.25, 95% HDI –0.41 to 0.11). These variables, including digital information interest and health behavior factors selected from the self-assessed DHL, were subsequently used as input features in the modeling phase.

Predictive Modeling of Digital Health Literacy

The performance of the 5 machine learning models was evaluated and compared using multiple classification metrics, including accuracy, precision, and F_1-score. The detailed results are summarized in Table 4, and the corresponding ROC curves are shown in Figure 3.

To establish a performance baseline given the class distribution, a dummy classifier was evaluated, yielding an accuracy of 0.540. Relative to this baseline, all machine learning models demonstrated improved predictive performance. Among the 5 models, SVM showed strong results, achieving an accuracy of 0.775, a precision of 0.758, and an F_1-score of 0.754. By contrast, the decision tree model exhibited the lowest performance across all metrics, with an accuracy of 0.715, a precision of 0.661, and an F_1-score of 0.716. In addition to standard metrics, ROC curve analysis was conducted to assess the discriminative capability of each model. XGBoost and SVM achieved the highest AUC values (0.850 and 0.841, respectively). Despite these results, CatBoost demonstrated the most balanced and superior overall performance, with an accuracy of 0.785, a precision of 0.769, and an F_1-score of 0.765. Compared with the dummy classifier, CatBoost improved accuracy by 0.245, which was statistically significant (P<.001). This consistently strong performance across primary classification metrics constituted the principal rationale for selecting CatBoost for subsequent SHAP-based post hoc interpretability analysis. These findings indicate that, for DHL prediction, the CatBoost model offers robust and reliable classification performance among the algorithms tested.

Model Interpretation Using SHAP Analysis

The SHAP analysis was conducted to identify the features that contributed most substantially to the model's predictions of DHL levels. Figure 4A presents the mean absolute SHAP values for each feature, indicating their relative importance within the model. The 5 most influential features were self-care confidence, lack of health information search, interest in health-related apps, number of electronic devices used, and exercise frequency. These variables played a central role in distinguishing between high- and low-DHL classifications.

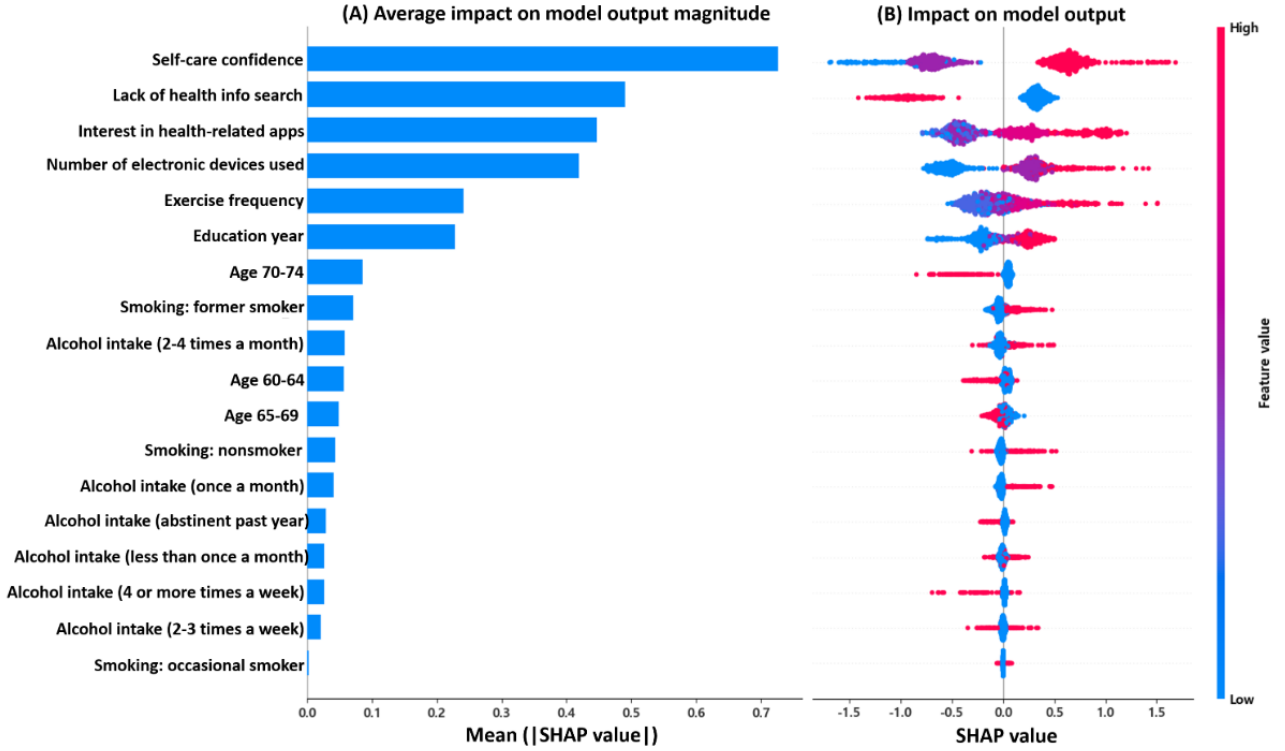

Figure 4B presents a summary plot illustrating the distribution of SHAP values across different feature values. Self-care confidence emerged as the most influential variable, showing the greatest separation between high- and low-DHL predictions. Higher levels of self-care confidence were associated with positive SHAP values, increasing the likelihood of being classified as high DHL. By contrast, lower self-care confidence levels (represented by blue markers) corresponded to negative SHAP values, contributing to low-DHL predictions.

The binary feature representing lack of health information search, derived from one-hot encoding, also demonstrated a

XSL•FO
RenderX

strong effect. Participants who had searched for health information (feature value=0, shown in blue) tended to have positive SHAP values, whereas those who had not (feature value=1, shown in red) exhibited negative SHAP values, indicating a higher likelihood of being classified in the low-DHL group. Similarly, interest in health-related apps and the number of electronic devices used were positively associated with high-DHL predictions. Participants with a greater interest in health-related apps and more frequent use of digital devices showed consistently positive SHAP values, reinforcing their roles as indicators of digital engagement. SHAP values for other contributing factors, including exercise frequency and education level, were relatively small. Age-related features also had comparatively low influence on model predictions; however, the 70-74 age group consistently appeared in association with lower DHL levels, contributing negatively to the prediction outcomes. Overall, the SHAP analysis provided interpretable evidence of how specific behavioral, psychosocial, and demographic features influenced DHL classification, reinforcing both the explainability and practical utility of the CatBoost model in real-world digital health contexts.

Figure 4. Feature importance based on mean Shapley Additive Explanations (SHAP) values according to the contribution of the categorical boosting model to its estimation. (A) Average impact on model output magnitude; (B) Impact on model output.

Discussion

Principal Findings

Digital health literacy, defined as the ability to search for, understand, and apply health-related information in digital environments [4], has emerged as a core competency for effectively navigating modern medical and health care services. As health care delivery models evolve from static information provision to dynamic, user-centered platforms, precise assessment of DHL—particularly among older adults—has become increasingly critical. Accurate measurement of DHL is essential for designing tailored interventions that promote equitable access to health care resources and reduce health disparities.

In this study, we developed an explainable machine learning–based predictive framework to evaluate DHL in a large sample of older adults (n=1000). The framework integrates both performance-based and self-assessed DHL measures and incorporates a range of psychosocial and behavioral variables to identify the most influential predictors contributing to individual differences in digital health literacy.

Selected Features From Performance-Based Digital Health Literacy

To classify participants into 2 DHL-level groups, explainable features were selected based on the intrinsic evaluation criteria of the Bayesian linear regression model. The analysis revealed that, within the performance-based assessment, key predictors included alcohol intake, number of electronic devices used, and years of education. Among these, the number of electronic devices used emerged as the primary positive predictor of digital information comprehension. This finding is consistent with previous studies showing that older adults who use a wider variety of digital devices are more familiar with online health information and demonstrate stronger skills in information search and utilization [57].

Similarly, years of education positively influenced the comprehension of health information. This finding aligns with previous research identifying educational attainment as a key

XSL•FO
RenderX

social determinant of health literacy. Higher educational attainment is generally associated with a greater capacity to comprehend, critically evaluate, and utilize online health information [16,58]. Individuals with higher levels of education are relatively more advantaged in discerning the credibility of health information and translating it into effective communication with health care providers or self-management behaviors, which in turn facilitates greater acceptance and utilization of digital health services [59,60]. A comparative study involving older adults in Korea and the United States likewise identified educational attainment as a consistent predictor of eHealth literacy, while noting that its impact may be moderated by structural and cultural factors within the digital environment [15]. Collectively, these findings underscore the importance of designing digital health interventions that account for educational disparities and incorporate tailored capacity-building strategies for individuals with lower levels of formal education.

By contrast, participants with higher levels of alcohol consumption exhibited significantly lower performance in both digital and health information comprehension, suggesting that lifestyle factors such as alcohol intake may impair information-processing abilities and negatively affect DHL. Moreover, a previous longitudinal study reported that sustained alcohol consumption is associated with cognitive decline, particularly among older women [61]. Taken together, these results indicate that diversity in digital device usage and higher educational attainment contribute meaningfully to actual information comprehension, and that lifestyle behavior management should be considered a critical component of DHL intervention programs.

Selected Features From Self-Assessed Digital Health Literacy

Self-assessed digital health literacy was primarily influenced by interest in health-related apps, age, alcohol intake, number of electronic devices used, and years of education. Additional contributing factors included self-care confidence, smoking status, and exercise frequency. Specifically, perceived competence in using digital devices was associated with greater confidence in health care decision-making, whereas the ability to understand and apply health information was linked to participants' prior health information–seeking behavior.

Among these variables, interest in health-related apps emerged as the most prominent positive predictor of both DHL subscales. Furthermore, a previous study reported that individuals who frequently engage with health care apps and perceive them as useful or reliable tend to demonstrate stronger competencies in locating, evaluating, and applying health information [57]. Interest in health-related apps could reflect more than mere preference, as it represents a motivational factor that enhances digital engagement. Voluntary use of such apps may foster critical components of DHL, including information searching, selection, appraisal, and application. Therefore, interventions designed to improve DHL should extend beyond digital tools and unidirectional health messaging.

In this study, we found that the older the age group, the lower their tendency to evaluate their understanding of and ability to use health information. It has been reported that older adults display a reduced ability to adopt digital technology because of cognitive decline [62]. Moreover, previous studies have found that older adults living alone face both cognitive and emotional barriers when adapting to new technologies [63-67]. Addressing these barriers requires tailored educational strategies that combine practical digital training with emotional support.

The number of electronic devices used and years of education proved to be negatively associated with self-assessed DHL. This finding suggests that greater exposure to digital devices or higher educational attainment does not necessarily translate into higher self-assessed DHL. The strength and nature of the relationship between education and digital health literacy may vary depending on the sociocultural context and the health care and digital infrastructure [68]. In addition, individuals with greater actual abilities may apply stricter self-assessment criteria, reflecting more conservative or critical self-assessment tendencies. A prior finding indicated that older adults may experience increased cognitive load when processing complex health-related information, leading to reduced confidence and lower self-ratings [69].

A similar pattern was observed for health information search. In the feature selection stage, lack of health information search was positively associated with the health information understanding and utilization subscale in the self-assessed survey. By contrast, in the model interpretation stage, the same indicator showed negative SHAP values, thereby decreasing the model's predicted likelihood of high DHL. Individuals who do not search for health information may positively assess their understanding of health information even though they lack it, whereas health information seekers might provide cautious self-assessments despite possessing substantial digital health literacy skills. It is known that self-reported responses do not represent a direct readout of an individual's internal state but are rather the product of complex cognitive processes such as comprehension, retrieval, judgment, and response selection, potentially leading to biased or distorted outcomes [70]. These findings emphasize the constraints of self-reported measures and the imperative to validate subjective data with objective performance metrics [71].

In addition, alcohol intake showed a clear divergence by measurement modality. In the self-assessed digital device utilization subscale, alcohol-related categories were positively associated with utilization scores, including abstinence in the past year, alcohol intake about once a month, and alcohol intake 2-4 times a month. By contrast, in the performance-based DHL tasks, alcohol intake once a month and alcohol intake 2-4 times a month were associated with lower task performance. Prior research in older adults indicates that internet use does not consistently correspond to healthier behaviors and that associations may vary by socioeconomic and lifestyle profiles [72]. A population-based study using CHARLS (The China Health and Retirement Longitudinal Study) 2020 data reported that internet use was associated with a lower likelihood of nondrinking, and this association was partially mediated by social participation [73]. This suggests that digital access may increase opportunities for social activities in which alcohol intake is culturally embedded. Taken together,

XSL•FO
RenderX

performance-based DHL tasks are more closely tied to the cognitive and informational demands of digital health activities and may be more sensitive to alcohol-related decrements. By contrast, self-assessed digital device utilization may reflect a broader lifestyle context rather than objective capability alone.

Development of the Prediction Models

The first stage of the DHL framework identified variables with high explanatory power for both performance-based and self-assessed measures. In the second stage, these selected variables were used to train models predicting DHL levels based on KeHEALS. The model performance evaluation demonstrated that the CatBoost algorithm consistently outperformed the alternative approaches, achieving comparatively high accuracy, precision, and F_1-scores in predicting DHL among older adults (Table 3). Compared with a conventional single decision tree, CatBoost, which effectively handles categorical variables, proved particularly effective for DHL prediction.

To enhance interpretability, a SHAP analysis was conducted on the CatBoost model, providing empirical evidence of the specific factors influencing DHL (Figure 4). The most influential predictors included self-care confidence, lack of health information search, interest in health-related apps, number of electronic devices used, exercise frequency, and years of education. This confirms that the framework successfully integrates both digital and health literacy–related features into a unified predictive model. Among the key predictors, self-care confidence emerged as the single most important predictor, highlighting the strong association between an individual's confidence in making health-related decisions and their DHL level. This finding aligns with prior research reporting that higher eHealth literacy is significantly associated with greater self-efficacy in older adults [74]. This evidence underscores the potential of DHL-focused interventions to enhance broader health management competencies by strengthening decision-making confidence. Furthermore, consistent with the results of the self-assessed DHL, interest in health-related apps reflected an individual's proactive attitude toward information seeking and app utilization, reinforcing the importance of psychosocial factors alongside technical competencies. Accordingly, interventions aimed at improving DHL should combine technical skill development with psychosocial support to enhance motivation for and engagement with digital health tools [75].

In contrast to the preceding factors, a greater number of electronic devices used, higher exercise frequency, and higher educational attainment were paradoxically associated with lower self-assessed scores for use of digital devices and health information understanding and utilization. These results may reflect the subjective biases inherent in self-reports. Self-report measures are constrained by their susceptibility to respondents' memory and cognitive processes, social desirability and consistency motives, and instrument design features such as item wording, response scales, and question order [76-78]. Alcohol intake showed a similar discrepancy. In the self-assessed digital device utilization subscale, abstinence in the past year and infrequent drinking were positively associated with utilization scores. By contrast, similar frequencies of alcohol intake were associated with lower performance in the task-based DHL assessment. This pattern suggests that self-assessed utilization may reflect a broader socioeconomic and lifestyle context, whereas performance-based tasks reflect the cognitive and informational demands required for digital health activities.

Therefore, a multimethod approach that integrates both self-assessments and performance-based evaluations is essential for a comprehensive understanding of DHL, rather than relying solely on self-report data. When variables derived from both measures were incorporated into the machine learning model, SHAP analysis indicated that these factors positively contributed to the classification of the high-DHL group, corroborating the results of the performance-based assessment. This demonstrates that reliance on self-reported data alone may lead to biased inferences or the overlooking of important patterns. By combining multifaceted indicators with explainable machine learning techniques, our study's approach enables more precise identification of the determinants of DHL in older adults and provides practical evidence to inform the design of individualized digital health interventions.

KeHEALS is a broadly used and validated assessment tool, although it yields only a single metric for digital literacy. Therefore, it remains uncertain whether individual vulnerabilities stem from fundamental digital device use, comprehension and appraisal of health information, or demographic and psychosocial factors. By using the detailed subscales evaluated within the DHLS, we can elucidate why a particular individual falls into the low-DHL category according to multidimensional criteria. When these domain-informed features are used to predict KeHEALS levels and the resulting predictions are subsequently examined using SHAP, KeHEALS scores can be analytically decomposed into discrete contributions originating from specific digital and health domains, along with additional contextual factors. This study highlights the limitations of single-score screening instruments and advances personalized interventions by offering explanations of feature importance through SHAP analysis.

This study leverages both performance- and survey-based datasets to bridge the gap between self-reported and actual abilities. Using Bayesian regression, the variables explaining each dimension were identified and integrated into the final DHL prediction model. SHAP analysis further validated the consistency between variable importance in the feature-selection stage and the variables' impact on model learning. This dual-phase approach enabled both ante hoc interpretability—by incorporating transparency into the model design from the outset—and post hoc interpretability, addressing the "black box" issue while retaining explanatory power. Finally, the DHL framework offers practical guidance for assessing users' DHL before implementing digital health interventions. This can be particularly valuable in clinical contexts where evaluation and interpretability are critical, thereby supporting the design of tailored and effective health care strategies for older adults.

Limitations

This study has several limitations that should be noted. First, the performance-based features were identified from a pilot

XSL•FO
RenderX

cohort aged 60-74, whereas the predictive model was trained on a wider age range (55-74 years). Our post hoc comparison revealed that several selected variables differed significantly between the 55-59 and 60-74 age groups, suggesting meaningful demographic and behavioral heterogeneity across age groups. Therefore, the generalizability of the feature-selection process from the small pilot cohort to the younger subgroup may be limited. Future research should employ larger and more diverse samples to enhance the robustness and external validity of the performance-based assessments. Second, because all data collected focused exclusively on older adults in Korea, caution should be exercised when extrapolating the results to populations from different cultural and demographic contexts. Third, the behavioral task was conducted using a single Android smartphone, and all participants were Android users. Thus, familiarity with the Android interface may have been reflected in the digital information comprehension scores and may not fully capture device proficiency among iOS users or across heterogeneous device environments. Fourth, there are inherent limitations related to the measurement scales and variable-processing strategies employed in this study. While offering interpretive simplicity, the binary classification of DHL levels may lead to different outcomes if alternative KeHEALS score thresholds are applied. Furthermore, self-care confidence, which emerged as the primary driver in our predictive model, was assessed using a single-item measure derived from the Korean Health Empowerment Scale. As single-item measures typically exhibit lower reliability and less comprehensive construct coverage than multiitem scales, the high predictive importance of this variable should be interpreted with caution. Additionally, our feature-importance rankings may have been influenced by the mixed encoding strategies used during data preprocessing. Specifically, the use of one-hot encoding for certain lifestyle factors, such as alcohol intake, partitioned these variables into multiple binary features. This approach may have diluted their aggregate predictive power in the SHAP analysis, potentially leading to an artificial deflation of their importance compared with variables maintained as single ordinal features. Finally, actual DHL is likely to exist along a continuous and multifaceted spectrum. Features that demonstrated unexpected associations in the self-assessed DHL analysis, such as the number of electronic devices used, exercise frequency, and years of education, may reflect the inherent limitations of self-report measures or complex interaction effects with other variables. These observations underscore the need for further in-depth analyses to disentangle these relationships.

Conclusions

DHL is a key competency for older adults to effectively navigate modern health care. This study established an explainable machine learning framework that integrates performance-based and self-assessed measures to evaluate DHL. Our findings indicate that using a wider variety of electronic devices and having higher educational attainment were positively associated with performance-based DHL, whereas higher alcohol intake was linked to poorer comprehension. Given the limited sample size of the performance-based pilot, these associations warrant caution and require validation in larger cohorts. In the self-assessed domain, DHL levels were primarily related to interest in health-related apps, age, and self-care confidence. In the predictive modeling stage, the CatBoost model demonstrated superior performance, and SHAP analysis identified self-care confidence and interest in health-related apps as key contributors to high DHL. Overall, by combining performance-based and self-assessed measures, this framework offers a structured and interpretable approach to assessing DHL in older adults and can inform the design of tailored digital health interventions in clinical and community settings.

KEYWORDS

machine learning; wearable device; bipolar disorder; mood disorder; digital mental health

We read the paper "Using Wearable Device and Machine Learning to Predict Mood Symptoms in Bipolar Disorder: Development and Usability Study" by Wu et al [1] with great interest. The integration of wearable data with machine learning to predict mood symptoms is clinically relevant and holds significant potential for real-world applications. However, we would like to highlight specific methodological aspects and possible future directions that could significantly enhance clinical reliability.

Our primary observation concerns the use of weekly mood assessments with backfilling. The authors acknowledged that their labeling method relied on self-rated questionnaires with backfilled mood symptoms for the preceding 7 days, and the participants may not complete these promptly as symptoms emerged, which could affect the accuracy of mood labels. In line with this, we appreciate the intent to minimize patient burden, but using retrospective entry to accurately capture daily mood fluctuations may not be reliable in the context of bipolar disorder. A patient feeling particularly low at the time of filling the weekly scale may unknowingly project that state onto the entire week, and that single net rating may not reflect the preceding days. This may create a risk of labeling daily physiological data with an inaccurate mood state, especially as the wearable data (sleep, activity, heart rate) are collected daily. To address this, future study designs may incorporate ecological momentary assessment, similar to the studies by Schwartz et al [2] and Li et al [3] that used digital biomarkers in studies on mood disorders. Implementing a quick visual check-in once or twice a day, for instance, a 5-point emoji scale with an optional short note, would reduce recall bias and ensure that daily wearable data are mapped against actual daily mood.

Furthermore, physiological markers such as average heart rate and total sleep hours are nonspecific and easily influenced by external stressors, including daily conflicts, work pressure, or life events. Without accounting for these confounding factors, the model risks interpreting situational stress as mood signals. As noted by the authors, heart rate is an index of sympathetic and parasympathetic influences of the autonomic nervous system in both stress and resting states, highlighting the overlap between stress response and mood states. Therefore, including a brief daily measure in future models to capture perceived daily stress would help in differentiating reactive distress from endogenous mood changes.

In conclusion, the integration of wearable biosensors is a promising development. However, we believe that a shift in study design from retrospective weekly aggregates to real-time, context-sensitive monitoring would further maximize the clinical utility of these models.

Acknowledgments

We used the generative artificial intelligence tool Gemini to make minor edits to the manuscript to improve language clarity, which were further reviewed and revised by the authors. The authors take full responsibility for the content of the publication.

Corrigenda and Addenda

Correction: Exploring the Potential of Claude 3 Opus in Renal Pathological Diagnosis: Performance Evaluation

JMIR Publications Editorial Office

Related Article:

Correction of: https://medinform.jmir.org/2024/1/e65033

(JMIR Med Inform 2026;14:e88845) doi:10.2196/88845

Following the publication of "Exploring the Potential of Claude 3 Opus in Renal Pathological Diagnosis: Performance Evaluation" [1], concerns were raised regarding a potential conflict of interest between reviewer X Liu and members of the author list. After review, it was determined that the authors and the reviewer were both affiliated with Sichuan University West China Hospital. This conflict of interest was not disclosed to the editorial office as per journal policy.

This article has been subsequently reassessed by the *JMIR Medical Informatics* editor in chief, who determined that the content of this review did not unduly influence the decision to accept the article. The decision to accept the submission was based primarily on the remaining reviewers' comments and the previous editor in chief's contemporary appraisal of the manuscript.

As such, the JMIR Publications Editorial Office issues this corrigendum to update the Conflicts of Interest statement as follows:

> *Reviewer X Liu was found to have undisclosed conflicts of interest with members of the author list under the terms of JMIR Publications policy. The editor in chief determined that the content of the reviews did not unduly influence the decision to accept the article. The decision to accept the submission was based primarily on the remaining reviewers' comments and the editor in chief's contemporary appraisal of the manuscript.*

We regret that these issues were not identified before publication.

The correction will appear in the online version of the paper on the JMIR Publications website together with the publication of this correction notice. Because this was made after submission to PubMed, PubMed Central, and other full-text repositories, the corrected article has also been resubmitted to those repositories.

Abstract

Background: Advancements in health technology and the adoption of electronic systems in hospital pharmacies have transformed pharmacy practice and service delivery, with patients and health care providers reporting perceived benefits related to patient care and safety. Therefore, it is of paramount importance to seek patients' opinions based on their experiences in receiving outpatient pharmacy services through automated pharmacy systems.

Objective: This study aimed to investigate patients' experiences and explore their satisfaction with outpatient pharmacy services in hospitals using automated pharmacy systems.

Methods: This cross-sectional study used an online questionnaire to assess patients' experiences of outpatient pharmacy services in governmental hospitals in Kuwait where automated pharmacy systems are implemented.

Results: Almost 95% (393/416) of the participants either agreed or strongly agreed that they were totally satisfied with the services delivered through the automated pharmacy systems. Participants reported the perceived benefits of these outpatient pharmacy services, including perceived prevention of medication errors (211/416, 50.7%), time savings (356/416, 85.6%), and easier access to prescription information at any time (249/416, 59.9%).

Conclusions: Patients' experiences with outpatient pharmacy services in automated pharmacy settings were generally positive, reflecting satisfaction with medication collection and service quality.

KEYWORDS

automated pharmacy; pharmacy practice; patient experience; patient satisfaction; e-dispensing; e-prescribing

Introduction

Over the past years, pharmacy practice has undergone significant transformation with the adoption of electronic prescribing (e-prescribing) and electronic dispensing (e-dispensing; hospital information system [HIS]) systems, resulting in numerous advantages within professional practice settings. Notable examples include reductions in medication errors [1-4], time savings [5,6], and increased work efficiency [1,2,6]. However, such systems also present certain challenges. Reported drawbacks include risks to medication safety (eg, unclear or incorrect dosage instructions or strength) [4], technical issues [1,5], and resistance to adoption among staff [1]. Difficult adoption of automated systems has been reported in previous studies and has been attributed to their incapability to execute some functions that were previously completed manually [2,5,6]. The implementation of e-prescribing and/or e-dispensing systems has been extensively examined in the literature, with a focus on evaluating whether their intended purposes have been achieved and whether the anticipated benefits have been realized.

A systematic review of the literature on the barriers and facilitators to implementing an e-prescribing system highlighted the importance of identifying the perceptions of user groups, including pharmacists, managers, and patients [7]. Patients' involvement in the assessment process is essential because the quality of outpatient pharmacy service delivery is ultimately perceived by them; therefore, patient satisfaction can be considered an indicator of success [8,9]. Previous studies have supported the need for future research to evaluate the impact of

XSL•FO
RenderX

integrated e-prescribing and e-dispensing systems [8,10], as the combination of these 2 domains has the potential to improve various aspects of pharmacy schemes and practice [10].

In this study, the term "automated pharmacy" encompasses 2 key domains. The first is the receipt of prescriptions via an e-prescribing system, also referred to as a "pharmacy information system," which is a subset of a much greater HIS. Within such a system, patient data and medication lists are stored electronically. The second component of the "automated pharmacy" concept involves an e-dispensing system, in which electronic cabinets with the drugs on the shelves (most of which are prepackaged) are used to deliver the prescribed medications to the dispensing area. Briefly, the pharmacist receives the prescription from the patient, reviews it to ensure that the medications are accurately prescribed, and uses the e-prescribing system to send the order to the electronic or automated cabinet. The cabinet prepares the medications and delivers them to the pharmacist, who then dispenses them and provides patient counseling.

In Kuwait, there are 6 general governmental hospitals, all of which have transitioned their outpatient pharmacies from manual processes to automated systems. However, the extent of implementation varies across institutions. In some settings, automated dispensing systems are not fully connected to the e-prescribing platform, while in others, the e-prescribing system functions as a stand-alone tool that is not integrated with the HIS or electronic health records.

Following implementation, several challenges arise for staff operating integrated e-prescribing and automated dispensing systems, despite the technological advancements they offer. These challenges include technical difficulties, workflow and organizational issues, and factors related to users' attitudes, adaptation, and readiness to use technology. Such issues can affect the quality of the outpatient pharmacy services delivered to patients, particularly regarding waiting times, the adequacy of medication counseling, availability of medications, and the accuracy of medication dispensing. These challenges highlight the need to explore patients' experiences to understand their perceptions and satisfaction with outpatient pharmacy care in hospitals, which can help identify areas for improving and optimizing service quality.

Within this context, previous studies in Kuwait have examined the perspectives of health care providers regarding the use of HISs in primary care settings [11,12] or secondary care settings [13]. Patients' satisfaction with e-prescribing and electronic health records has also been explored [14,15]. In the existing literature, there is no research in Kuwait that examined patients' satisfaction based on their experiences with integrated automated outpatient pharmacy services. Thus, this study aimed to assess patients' satisfaction with their experiences in receiving outpatient pharmacy services through integrated e-prescribing and e-dispensing systems in the outpatient pharmacies of secondary care governmental hospitals. This enabled the development of recommendations to improve pharmacy practice in Kuwait.

Methods

Study Design, Sample, and Setting

The design of this study was a cross-sectional survey, using a questionnaire developed in Google Forms that was electronically administered to collect data from patients at their convenience between June and July 2024 at the outpatient pharmacies of 4 governmental hospitals in the state of Kuwait. The selected hospitals were Adan, Jahra, Farwaniya, and Jaber Al-Ahmad, which had all adopted and implemented the concept of automated pharmacy, which is using an integrated e-prescribing and e-dispensing system in the outpatient pharmacies.

A Survey Questionnaire

The items of the questionnaire were taken from previous validated studies [16]. Content validity was evaluated by the research team, which included 2 academic staff members from the Pharmacy Practice Department at the College of Pharmacy, Kuwait University, who are experts in their field, and 1 academic staff member from the College of Medicine with expertise in health informatics. This evaluation involved reviewing the questionnaire items to ensure their relevance to the study objectives and their clarity. Several modifications were made to ensure compatibility and appropriateness for the research aim, sample, and setting. The term "medication teaching" was replaced with "medication counseling," as this terminology is commonly used and understood by patients and pharmacy staff in Kuwait. The section "pharmacy place" was removed because it addressed the physical layout of the pharmacy, which was unrelated to the study's aim and objectives. Additionally, 1 item was excluded, which was about "the availability of a private area for counseling," because this service is not consistently provided across outpatient pharmacies in Kuwait and is not applicable to the local setting. A new section was added, which was about "dispensing medications," and was developed from previous studies [17,18] to explore aspects of communication between pharmacists and patients.

Questionnaire Structure

The questionnaire consisted of 40 items and seven sections: (1) time of prescription dispensing (3 items), (2) pharmacist attitudes (5 items), (3) medication supply (5 items), (4) medication counseling (5 items), (5) dispensing medications (5 items), (6) overall impact of automated pharmacy on outpatient pharmacy services (7 items), and (7) sociodemographic characteristics (10 items).

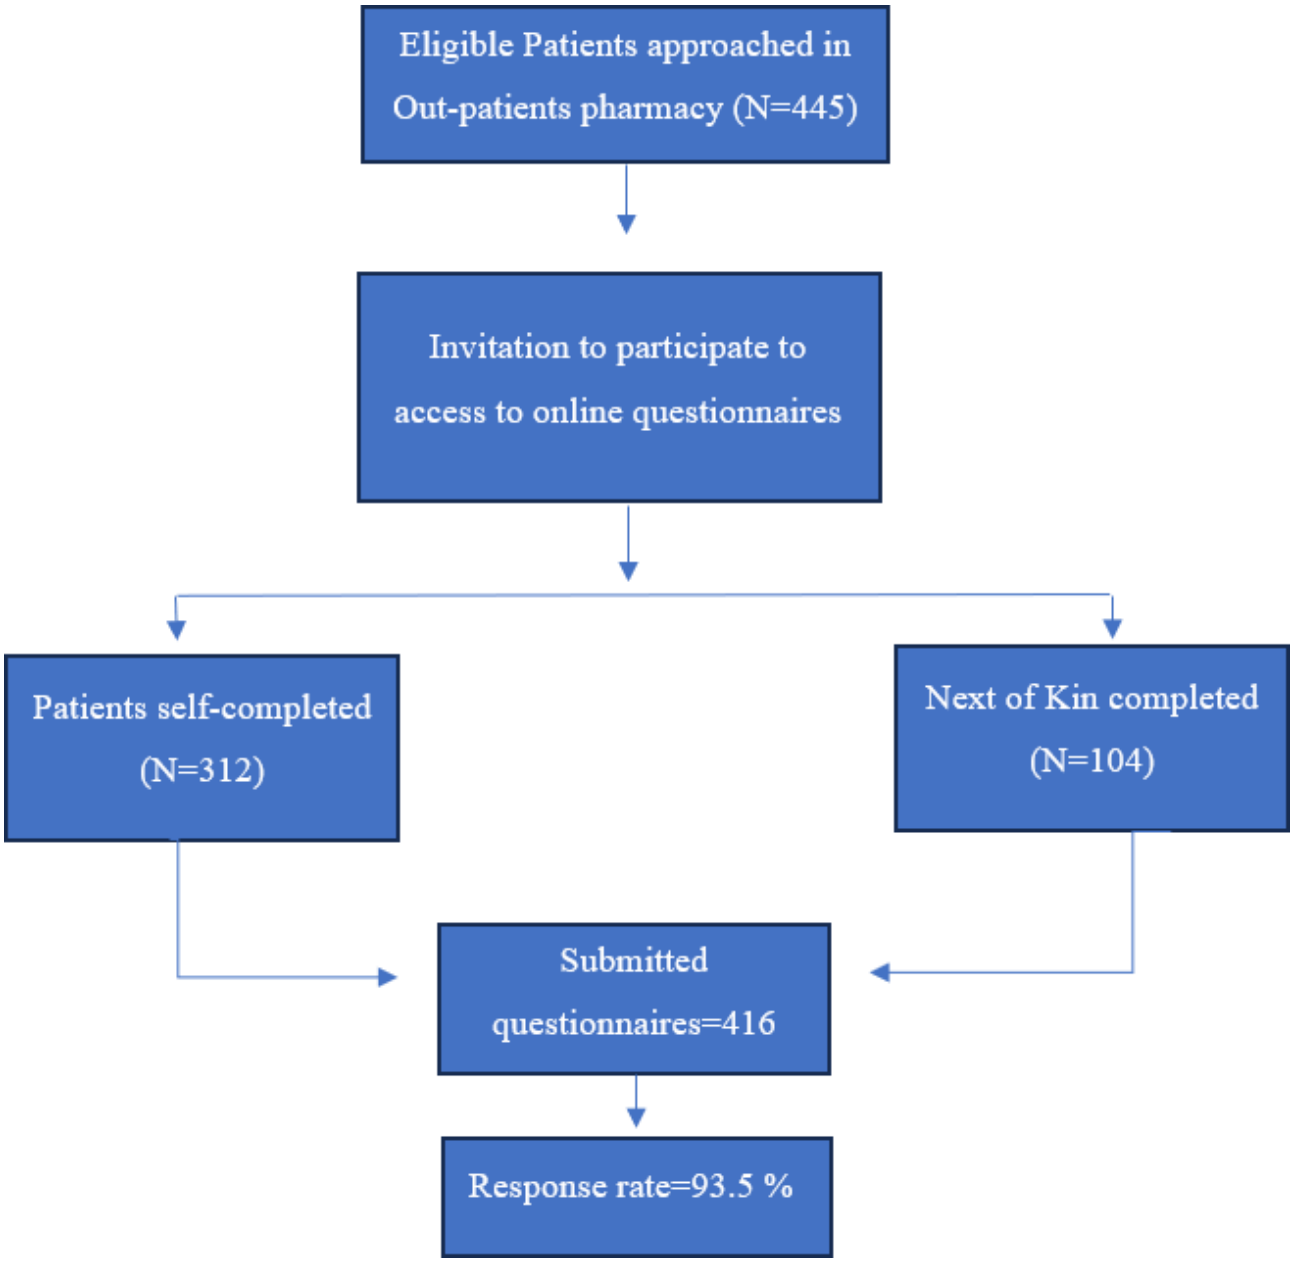
Inclusion and Exclusion Criteria

This study included secondary care hospitals that offer integrated automated outpatient pharmacy services. Patients and/or caregivers who provide close, hands-on care to the patient are familiar with the patient's experiences with outpatient pharmacy services and can offer valuable insights alongside the patients themselves. Eligible participants were those who were able to complete the questionnaire and were therefore invited to take part in the study. Private hospitals and private pharmacies were excluded from this study because they operate under different policies and procedures and do not use integrated e-prescribing

XSL•FO
RenderX

and e-dispensing systems within their outpatient pharmacy services.

Pilot Study



A pilot study was conducted to ensure clarity and readability with 25 patients who were waiting to receive their medications from outpatient pharmacies. The results demonstrated that the questionnaire was easy to understand and well received, confirming its readiness for full-scale distribution.

Recruitment and Data Collection

Patients waiting to receive their medications in the outpatient pharmacy areas were approached and invited to participate voluntarily. The questionnaire was administered to patients using a QR code or via a tablet device, providing direct access to the online questionnaire. No identifying patient information was collected, and responses could not be linked to individual patients. Pharmacy staff were not present while participants completed the survey, which helped maintain anonymity and reduce potential social desirability bias. For patients unable to complete the questionnaire themselves, a next of kin who was familiar with their experience (eg, a spouse, son, or sister) was permitted to respond on their behalf (Figure 1).

The questionnaire was offered in 2 languages, Arabic and English, to accommodate a diverse patient population. The original English version of the questionnaire was translated into Arabic, and the translation was validated using a back-translation method to ensure accuracy and clarity. All patients who met the inclusion criteria were invited to participate. Data collection was undertaken by a group of pharmacy students (n=6) from the College of Pharmacy, Kuwait University. They were available in the waiting areas of the outpatient pharmacies to share the online questionnaire with patients.

Figure 1. The recruitment protocol of the study participants.

RenderX

Construct Validation Using Factor Analysis and Reliability Assessment

The Kaiser-Meyer-Olkin (KMO) test and Bartlett's test of sphericity were used to evaluate sampling adequacy [19]. These tests help determine whether data are suitable for factor analysis. Data factorability was confirmed with a KMO value above 0.50 and a significant Bartlett's test value (P<.05) [19]. Principal component analysis with Promax rotation, an oblique method, was used. Promax was selected because it permits factors to correlate, which aligns with the expected relationships among the constructs [20]. The number of factors was decided based on eigenvalues, scree plots, and explained variance. Exploratory factor analysis was performed with a factor loading cutoff of 0.40 to extract scale dimensions [19,21].

Internal consistency reliability was assessed using Cronbach α coefficient based on a 4-point Likert scale (time of prescription dispensing, pharmacist attitudes, medication supply, medication counseling, and dispensing medications). A Cronbach α value of ≥0.70 was regarded as satisfactory evidence of internal consistency for the new instrument [19,20,22].

Ethical Considerations

Ethical approval for this study was obtained from the The Standing Committee for Coordinating Medical and Health Research prior to data collection (reference number 2352). Participation was voluntary, and informed consent was obtained from all participants before administering the survey. To protect privacy and confidentiality, no personally identifiable information was collected. Surveys were completed anonymously in the outpatient pharmacy waiting area, and participants were informed that they could decline to answer any question or withdraw at any time without any impact on their care or pharmacy services. All collected data were kept confidential, stored securely, and accessible only to the research team. Study findings are reported in aggregate form, ensuring that no individual participant can be identified.

Statistical Data Analysis

Statistical analyses were conducted using IBM SPSS Statistics (version 29; IBM Corp). Descriptive statistics were used to present the data. Categorical variables were presented as frequencies and percentages. To summarize the patients' perspective scores, responses for the questionnaire items were averaged across all items within the category. As an initial exploratory comparison, patient and caregiver perspective scores were compared using the Mann-Whitney U test due to nonnormal score distributions and unequal group sizes.

A normality test for the component scores was undertaken using the Shapiro-Wilk test, which indicated that the data were not normally distributed. Accordingly, results are presented as minimum, maximum, median, and IQR. Nonparametric statistical tests were used to assess associations between component scores and variables of interest, including the Mann-Whitney U test for binary comparisons, the Kruskal-Wallis test for comparisons across multiple groups, Spearman rank correlation for continuous variables, and the chi-square test for trend for ordinal categorical variables.

For analyses based on a priori hypotheses involving comparisons across multiple groups, post hoc pairwise comparisons were conducted following statistically significant Kruskal-Wallis tests, with P values adjusted for multiple comparisons using the Dunn-Bonferroni method. These analyses were planned and considered confirmatory. Effect sizes were reported as rank-biserial correlation coefficients (r_rb) for binary comparisons, epsilon squared (ε^2) for multigroup comparisons, and Spearman correlation coefficient (ρ) for continuous variables.

Multiple linear regression analyses were performed to identify independent factors associated with the overall score across domains of patients' perspectives on automated pharmacy services. Additional association analyses not specified a priori were treated as exploratory and were not adjusted for multiple comparisons; these results are presented for hypothesis generation. Ordinal survey responses were averaged across items within each component to generate composite scores for inferential analyses. Statistical significance was set at P value of <.05.

A sensitivity analysis was conducted to assess the results to potential selection bias arising from voluntary participation and convenience sampling. This analysis examined the possible impact of underrepresentation of less satisfied patients on the study outcomes. Specifically, the patients' perspective score was systematically reduced by 0.3, 0.5, and 1.0 SDs, representing mild, moderate, and severe dissatisfaction scenarios, respectively. These thresholds were selected based on established effect size conventions for continuous outcomes and their application in patient-reported outcome research [23]. For each scenario, the multiple linear regression analyses were repeated using the adjusted outcome variable, while all predictor variables and model specifications remained unchanged.

Results

Sociodemographic Characteristics of the Study Participants

A total of 445 patients were approached, of whom 416 completed the questionnaire, producing a response rate of 93.5%. The sociodemographic characteristics of the study participants are illustrated in Table 1.

XSL•FO
RenderX

Most participants were female (299/416, 71.9%), Kuwaiti nationals (351/416, 84.4%), younger than 29 years (142/416, 34.3%), and married (258/416, 62.0%). Half of the participants (208/416, 50%) held a bachelor's degree. Regarding pharmacy visits, approximately one-third of the participants visited the pharmacy monthly (161/416, 38.7%), while another third reported visiting 3 or 4 times per year (155/416, 37.3%). Most participants were collecting medications for themselves (312/416, 75%) and had between 1 and 5 medications in their prescriptions (331/416, 79.6%). Dispensing waiting times varied, with the majority of participants waiting 6 - 15 minutes (167/416, 40.1%), followed by those waiting less than 5 minutes (136/416, 32.7%), and those waiting more than 15 minutes (80/416, 19.2%).

Based on the exploratory factor analysis results shown in Table 2, each item with a value greater than 0.40 was assigned to an extracted factor. The KMO value of 0.914 indicated that the data were appropriate for factor analysis, and the value of Bartlett's test of sphericity was significant (χ^2_{231}=5140.38; P<.001). The scree plot indicated a 5-component solution, with all items showing acceptable communalities, and eigenvalues greater than 1.0 were extracted, accounting for 67.27% of the total variance. The reliability of the 22-item factored scale was obtained. The overall Cronbach α for the scale showed excellent reliability (α=0.92).

Table . Results of the exploratory factor analysis.

Component	Item	Factor loadings[a]	Eigenvalue	VE[b] (%)	CVE[c] (%)
Time of prescription dispensing			1.79	8.12	8.12
	1.00	0.83

Time of Prescription Dispensing

The results showed that most respondents agreed or strongly agreed that their prescriptions were dispensed within a reasonable time (364/416, 87.5%; Table 3).

XSL•FO
RenderX

Table . Perceptions of e-prescription and automated dispensing systems in outpatient pharmacies at secondary care hospitals (N=416).

Item	Values, n (%)								Range	Overall median score (IQR)[a]
	Strongly agree	Agree	Disagree	Strongly disagree	Never	Rarely	Sometimes	Many times		
Time of prescription dispensing									1.0-4.0	3.0 (0.5)
1. Receive medications within a reasonable time	136 (32.7)	228 (54.8)	38 (9.1)	14 (3.4)	—[b]	—	—	—		
2. Waiting time is acceptable considering the quantity of prescription medication	115 (27.6)	226 (54.3)	63 (15.1)	12 (2.9)	—	—	—	—		
Pharmacist attitude									4.0-1.2	3.4 (1.0)
3. Pharmacist helped me to get the medications	201 (48.3)	201 (48.3)	9 (2.2)	5 (1.2)	—	—	—	—		
4. Pharmacist helped to solve any problem while getting the medication	168 (40.4)	211 (50.7)	33 (7.9)	4 (1.0)						
5. Pharmacist answered my questions	197 (47.4)	200 (48.1)	18 (4.3)	1 (0.2)						
6. Pharmacist understood the medical case	172 (41.3)	222 (53.4)	21 (5.0)	1 (0.2)						
7. Pharmacist treated me with respect	254 (61.1)	153 (36.8)	5 (1.2)	4 (1.0)						
Medication supply									4.0-1.8	3.2 (0.8)
8. Medication quantity was sufficient	178 (42.8)	214 (51.4)	19 (4.6)	5 (1.2)

22. My medical prescription or information was not received by the pharmacy	—	—	—	—	294 (70.7)	79 (19.0)	32 (7.7)	11 (2.6)		

[a]For each perspective score, responses for the questionnaire items were averaged across all items within the category.

[b]Not applicable.

Most participants (341/416, 82.0%) also found the waiting time acceptable, considering the number of medications prescribed. A statistically significant association (P=.006; chi-square test) was found between the number of medications prescribed and the reported waiting time (Table 4). Patients prescribed 1 - 5 medications were more likely to experience shorter waiting times: 38.8% (118/304) received their medications within 5 minutes, 41.8% (127/304) waited 6 - 15 minutes, and 19.4% (59/304) waited more than 15 minutes.

Table . Association between the number of medications and the waiting time to receive the medications (P=.006[a]; chi-square for trend).

Number of medications	Waiting time		
	≤5 minutes	6-15 minutes	>15 minutes
1-5 items, n (raw %)	118 (38.8)	127 (41.8)	59 (19.4)
6-10 items, n (raw %)	14 (24)	31 (53)	13 (22)
>10 items, n (raw %)	4 (19)	9 (43)	8 (38)

[a]Chi-square test for trend.

XSL•FO
RenderX

In contrast, patients prescribed 6 - 10 medications experienced longer waiting times. Only 24% (14/58) received their medications within 5 minutes, while 53% (31/58) waited 6 - 15 minutes, and 22% (13/58) waited more than 15 minutes. Among those prescribed more than 10 medications, few (4/21, 19%) received their medications within 5 minutes or less, while many (9/21, 43%) waited 6 - 15 minutes, and a similar proportion (8/21, 38%) waited more than 15 minutes, as shown in Table 4.

Pharmacist Attitudes

As shown in Table 3, the results indicated that most participants had positive perceptions of pharmacist attitudes. The majority agreed or strongly agreed that the pharmacists helped obtain their medications (401/416, 96.5%) and assisted them in resolving issues related to medication access (379/416, 91.1%). In addition, a large proportion reported that the pharmacists answered their questions (397/416, 95.5%) and demonstrated knowledge and understanding toward their medical cases (394/416, 94.7%). Furthermore, most participants shared the perspective that the pharmacists treated them with respect and dignity (407/416, 97.9%).

Medication Supply

Most participants found the quantities of medications dispensed to be sufficient (392/416, 94.2%). Additionally, nearly three-quarters (311/416, 74.8%) reported that all their prescribed medications were available in the pharmacy (Table 3). However, a subset of participants (105/416, 25.2%) encountered instances where 1 or more prescribed medications were unavailable. Medication labels were clear and easy to read for most participants (397/416, 95.5%), and the usage instructions were clear and understandable (394/416, 94.8%). Furthermore, the majority expressed satisfaction with the appearance and quality of the medications provided (406/416, 97.6%).

Medication Counseling

The results revealed that the pharmacists performed well in several key areas of patient counseling (Table 3), which included explaining the purpose of medication use (356/416, 85.6%), providing instructions on correct medication dosage (381/416, 91.6%), and dedicating sufficient time to patients during consultations (317/416, 76.2%). However, notable gaps were identified in some specific aspects of counseling. Only half of the participants reported receiving information about the potential side effects of their medications (211/416, 50.7%). Similarly, counseling on proper medication storage was lacking, with approximately half of the participants not receiving such explanations (206/416, 49.5%).

Dispensing Medications

As shown in Table 3, most participants reported that communication challenges with pharmacists and/or physicians rarely or never occurred (329/416, 79.1%). Similarly, errors in the e-prescribing and e-dispensing process were uncommon. Specifically, the majority of participants agreed that rarely or never were prescriptions sent to the wrong pharmacy (402/416, 96.6%), the wrong medication was dispensed (410/416, 98.6%), incorrect instructions were received regarding the medications dispensed (402/416, 96.7%), or the prescription information was not received by the pharmacy (373/416, 89.7%).

Impact of Automated Pharmacy and Overall Satisfaction With Outpatient Pharmacy Services

The participants identified several perceived benefits of the integrated e-prescribing and e-dispensing systems, reflecting their positive impact on outpatient pharmacy services (Multimedia Appendix 1). These perceived benefits included time savings (356/416, 85.6%), perceived prevention of medication errors (211/416, 50.7%), and convenient access to prescription information at any time (249/416, 59.9%).

Also, the results showed high overall satisfaction with the automated outpatient pharmacy services, as 94.5% (393/416) of participants either agreed or strongly agreed that they were satisfied with the services delivered through the automated systems (Multimedia Appendix 2).

The overall median score for the time of prescription dispensing section was 3.0, while the median score for pharmacist attitudes was 3.4. The median scores for the medication supply, medication counseling, and dispensing medications domains were 3.2, 3.0, and 3.8, respectively (Table 3).

Tables 5 and 6 demonstrate the relationships between sociodemographic characteristics and the overall median scores for each questionnaire component. There were significant differences among hospitals, with small effect sizes for the time of prescription dispensing and the dispensing medications scores (ε^2=0.05 and ε^2=0.02, respectively). The median time of prescription dispensing score for Farwaniya hospital was significantly higher than for Adan hospital (3.2 vs 3.0; adjusted P=.03) and Jaber Al-Ahmad hospital (3.2 vs 3.0; adjusted P<.001). The median dispensing medications score for Jaber Al-Ahmad hospital was significantly higher than for Adan hospital (4.0 vs 3.8; adjusted P=.02) and Jahra hospital (4.0 vs 3.8; adjusted P=.04).

[a]Rank-biserial correlation (r_{rb}) for 2-group comparisons, epsilon squared (ε^2) for multigroup comparisons, and Spearman correlation coefficient for continuous variables. Interpretation thresholds: r_{rb}≈0.10=small, ≈0.30=moderate, and ≥0.50=large; ε^2≈0.01=small, ≈0.06=moderate, and ≥0.14=large; and value of P ranges from −1 to +1, P<.1=small, .1-.3=medium, and >.5=large.

[b]Mann-Whitney *U* tests (2 groups), Kruskal-Wallis tests (≥3 groups), or Spearman rank correlation test (continuous variables).

An indirect correlation coefficient of r=−0.13 was present between age and medication counseling score (P=.007). Likewise, there was an indirect correlation between dispensing medications score and education level (r=−0.11; P=.03). All 4 other domains of the questionnaire had scores that were significantly related to the amount of time it took to receive prescriptions (P<.05), with indirect Spearman rank correlation coefficients ranging from −0.15 to −0.46. Furthermore, a significant indirect correlation coefficient of r=−0.11 was found between number of medications and dispensing medications score (P=.03). For other patient characteristics, no statistically significant differences or associations were observed across any of the 5 perspective domains (all P>.05).

All 5 domains of the questionnaire were significantly related to each other (P≤.001), with Spearman rank correlation coefficients ranging from 0.30 to 0.62 (Table 7). The number of medications a patient was prescribed and the amount of time they waited to obtain those prescriptions had a significant association (P=.006), as seen in Table 4. In other words, the amount of waiting time rises as the number of medications increases (from 1 - 5 items to 6 - 10 items or 10 items or more).

The results showed that there is an inverse relationship between medication dispensing waiting time and patient perceptions of automated outpatient pharmacy services, whereas increased waiting times were associated with less satisfaction of pharmacists' attitudes, medication counseling, and dispensing practices.

Table 8 shows the results of the multiple regression model examining patients' perceptions toward automated outpatient pharmacy services, with total perception scores modeled as a function of sociodemographic and other relevant variables. All variables were entered simultaneously to estimate their independent associations. The model was statistically significant (F_{231}=2.32; *P*=.001) and explained 11% of the variance in patients' perceptions. Compared with patients who waited 5 minutes or less, those who waited 6-15 minutes and more than 15 minutes reported significantly lower perception scores (β=−3.70, 95% CI −5.76 to −1.65, *P*<.001 and β=−6.19, 95% CI −8.82 to −3.56, *P*< .001, respectively).

[a]Results from multivariable linear regression using the total score across all key components of patients' perspectives on automated pharmacy as a continuous outcome variable, along with hospital location, age, nationality, gender, marital status, education, number of pharmacy visits in the last year, dispensed medications, time waited to receive medication, and number of medications in the prescription. The regression coefficients (β) represent the mean difference in the overall patients' perspective score associated with each category increase, holding all other variables constant. The 95% CIs and *P* values are reported.

[b]Not applicable.

The results of the sensitivity analyses are shown in Table 9. Across all simulated dissatisfaction scenarios (−0.3 SD, −0.5 SD, and −1.0 SD), the direction, magnitude, and statistical significance of the regression coefficients remained consistent with those observed in the primary analysis (Table 8). In particular, the association between longer waiting times and lower patient perspective scores persisted across all scenarios, with nearly identical regression coefficients and 95% CIs. As expected, the model intercept decreased progressively with increasing downward shifts, reflecting lower assumed overall patient perspectives under more conservative assumptions. The results showed that there were no remarkable changes in the estimated effects of individual predictors, and no variables changed their significance status across the sensitivity analyses.

Discussion

Principal Findings

Studying patients' opinions and satisfaction provides a clear picture of the perceived impact and success of implementing automated pharmacy systems in the real world. Patient feedback can help determine whether the system meets their needs, improves the quality of outpatient pharmacy services, and achieves its intended goals in practice.

The existing literature has shown numerous advantages of using such technology in pharmacy practice. In this context, this study revealed that patients perceived integrated e-prescribing and e-dispensing systems as beneficial to outpatient pharmacy services and expressed overall satisfaction with their experiences of care, as reported by 95% (393/416) of the participants. Participants cited several key perceived benefits, including time savings, perceived prevention of medication errors, convenient access to prescription information at any time, and effective communication between pharmacists and physicians. These findings are consistent with previous studies, which have similarly reported a perceived reduction in medication errors [1-3], time savings in the prescribing and dispensing process [5,6], and increased work efficiency [1,2,6] following the adoption of automated pharmacy systems.

Influence of Sociodemographic Data on Participant Satisfaction

The findings revealed that the satisfaction levels of the participants varied across several sociodemographic groups. This study found an indirect association between age and medication counseling and between dispensing medications score and educational level. This could be explained by the notion that people with higher education levels could have higher expectations of health care services, which could lead to dissatisfaction when these are unmet [24]. Similar findings were found in a previous study [25], which assessed patient satisfaction toward outpatient pharmacy services among outpatients attending public health clinics in Malaysia. The findings revealed that demographic factors (eg, age, education level, self-perceived health status, and general knowledge of pharmacists) significantly influenced patients' perceptions of health care services. Notably, older age and higher education levels were associated with a lower patient satisfaction mean score [25]. Similarly, a study conducted in Pakistan [26] reported that male patients were significantly more satisfied with community outpatient pharmacy services than females. Younger patients (aged 18 - 27 years) exhibited greater satisfaction than older age groups. Illiterate and less-educated individuals showed greater satisfaction levels, while those with higher education levels were less satisfied, likely due to higher expectations. Marital status and occupation also played a potential role, with married individuals showing greater satisfaction and government employees showing less satisfaction. No significant association was observed among students after statistical adjustment [26].

Patients' Satisfaction With Dispensing Time, Pharmacists' Attitudes, and Medication Supply

Although most patients in this study agreed that their prescriptions were dispensed in a reasonable time, the findings revealed that the patients with more medications experienced longer waiting times, suggesting challenges in processing large or complex orders using the automated pharmacy systems.

These findings aligned with those of a previous study into primary health care settings in Kuwait [27], which found that patients' satisfaction was strongly influenced by the timeliness of prescription fulfillment by physicians. Numerous studies have demonstrated that e-prescription systems reduce dispensing times and improve pharmacy workflow [28]. In this context, a study assessed the impact of e-prescription systems on pharmacy workflow and practice in Finland and found a reduction in both median and average delivery times across various prescription types [29]. In particular, the maximum dispensing time with the adoption of e-prescribing systems was shorter in 2012 (6 minutes and 22 seconds) than the time with the use of non–e-prescribing systems in 2006 (12 minutes and 40 seconds). The study concluded that e-prescribing systems significantly improved the efficiency of prescription processing in Finnish community pharmacies [29]. Additionally, a study conducted in Sweden into the impact of integrated e-prescribing systems on pharmacists' practice found that the pharmacists perceived the system as expediting prescription processing and reducing the risk of medication errors [1]. The results showed a positive

XSL•FO
RenderX

correlation between the perceived usefulness of the electronic system for improving work efficiency and medication safety.

This study revealed that the participants were highly satisfied with the pharmacists' attitudes. Nearly all the participants agreed that the pharmacists helped obtain their medications, effectively resolved issues related to medication access, answered their questions, demonstrated knowledge of their medical conditions, and treated them with dignity and respect. These findings were supported by previous studies showing that e-prescribing systems enhance communication between patients and pharmacists [7], patients and prescribers [5], and pharmacists and other health care providers [30,31]. Similarly, a study conducted in Qatar reported comparable levels of satisfaction among participants regarding pharmacists' empathy and communication skills [16]. Furthermore, effective communication, regardless of whether systems are manual or electronic, has been found to significantly contribute to overall patient satisfaction [7,32].

The findings of this study demonstrated statistically significant differences in patient satisfaction across outpatient pharmacies in the 4 general hospitals, particularly regarding medication dispensing speed and pharmacists' attitudes. These site-level variations may reflect differences in staffing levels, staff competencies, workload, maturity of automation, or local operational workflows. For instance, the higher satisfaction with medication dispensing speed observed at Farwaniya Hospital compared with Adan Hospital may be attributable to shorter waiting times, fewer medications per prescription, or more efficient dispensing practices. While patient satisfaction is an important indicator of service performance, it should be interpreted alongside technical and organizational factors to provide a comprehensive understanding of the effectiveness and efficiency of digital pharmacy systems.

The findings of this study indicated that approximately one-quarter of the surveyed participants experienced medication unavailability. Similar findings have been reported by previous studies [33-36], highlighting the need for improved inventory integration to overcome such issues and enhance patient satisfaction. In this context, a study showed that automated drug-dispensing systems carry advantages over traditional systems in improving inventory control and reducing storage errors, resulting in better patient satisfaction [37,38].

The participants in this study were satisfied with the perceived accuracy of the pharmacy's handling of medical prescription information. In support of the claim that prescription accuracy contributes to patient satisfaction, a systematic review study revealed that the integration of e-prescription and e-dispensing systems significantly reduced pharmacy errors [39]. This indicates that the adoption of automated systems may enhance perceived accuracy and is associated with higher levels of patient satisfaction and perceived safety.

Patients' Satisfaction With Medication Counseling and the Dispensing Process

Despite the growing use of e-prescription and e-dispensing systems, challenges remain in their utilization. The findings of this study indicated that the patients reported high levels of satisfaction with medication counseling overall. Specifically, pharmacists were commended for clearly explaining the purpose of medication use, providing accurate dosage instructions, and allocating sufficient time for patients during consultations. However, approximately half of the participants expressed dissatisfaction with the counseling received regarding potential drug side effects and proper medication storage.

A US study into outpatient use of electronic prescriptions found that the use of an e-prescribing system led to lower rates of adverse drug events among patients, suggesting that appropriate counseling on side effects and storage could further reduce such risks [40]. Therefore, in this study, the lack of counseling regarding the side effects of medications and storage conditions indicates a potential gap in quality of practice. This may pertain to numerous reasons, such as a long queue of patients waiting, leading to time pressures, or pharmacists' limited counseling skills, which would affect the quality of the counseling. This shortcoming may reflect the need for additional pharmacist training to improve their counseling skills and not neglect any important information from patient education. Previous research has shown that training physicians in e-prescribing significantly reduces errors and improves workflow, thus indicating that e-prescription systems alone do not resolve counseling-related challenges unless supplemented by targeted education [41]. Addressing these aspects could significantly enhance both patient satisfaction and medication safety.

In addition, despite the automation of the dispensing process, the findings of this study reported longer waiting times for patients with prescribed multiple medications. This association suggests that prolonged waiting times may negatively influence patients' overall perception of outpatient pharmacy domains, including pharmacists' attitudes, medication counseling, medication supply, and dispensing medications. The literature showed that previous studies are consistent with the findings of this study, indicating that waiting time is a critical determinant of patient satisfaction, irrespective of whether outpatient pharmacy services are delivered through conventional or automated systems [38,42,43]. Therefore, the findings revealed that the success of automated outpatient pharmacy services relies not only on technology use but also on efficient workflow that led to suitable time medication dispensing.

This finding highlights the need for process optimization within pharmacy workflows. As with counseling gaps, delays in dispensing may diminish the perceived benefits of automation. Similar studies conducted in Saudi Arabia [38,44] emphasized the value of integrated pharmacy systems while acknowledging the need for region-specific improvements. These studies support the idea that continuous pharmacist education and the implementation of structured feedback mechanisms are essential for identifying and addressing system inefficiencies. By incorporating such strategies, pharmacies can better meet patient expectations and improve the outpatient pharmacy services.

Impact of E-Prescribing and E-Dispensing Systems on Outpatient Pharmacy Services

This study found that most patients reported a positive impact based on their experiences with the medication dispensing process, with pharmacist communication emerging as a key

XSL•FO
RenderX

contributor to patient satisfaction. These findings are consistent with those of a study in Qatar in 2013, which emphasized the importance of pharmacist-patient communication [16]. While pharmacy staff provide irreplaceable expertise in prescription monitoring and dispensing, the integration of electronic systems may help alleviate workload and reduce cognitive burden. Participants perceived that reducing manual tasks enhanced efficiency and contributed to improved patient safety by minimizing the risk of human error [45]. Pharmacists and pharmacy technicians are susceptible to fatigue, stress, and other human limitations, which may compromise dispensing accuracy. In this context, e-prescription systems serve as a valuable support tool that may help mitigate such risks [18,45]. By providing an additional layer of safety and reliability, these systems can contribute to patients' perceptions of positive outcomes and higher satisfaction levels.

The absence of a comparison group involving nonautomated outpatient pharmacies is considered a key methodological limitation of this study. Consequently, the findings cannot isolate the specific effects of automation from other contextual or organizational factors and should be interpreted as reflecting patient experiences within automated pharmacy settings only, which limits their generalizability to other pharmacy models. Future studies using comparative or quasi-experimental designs are needed to evaluate the incremental impact of automation on patient experience and service performance.

Limitations

This study has several limitations. First, it focused exclusively on patients in Kuwait. While the findings provide valuable insights into local users of outpatient pharmacy services, the generalizability of the results to other populations and health care systems may be limited. In addition, the absence of a comparison group involving nonautomated outpatient pharmacies limits the ability to isolate the specific impact of automation.

Second, patient satisfaction data were self-reported, which may have introduced recall or self-reporting bias and may not accurately reflect the actual quality or safety of outpatient pharmacy services. Third, the presence of pharmacy students in the waiting area may have introduced courtesy or social desirability bias, which may have potentially inflated satisfaction scores (approximately 95% agreement), despite private survey completion. The consistently high levels of agreement observed may therefore partly reflect response tendencies rather than true satisfaction levels. Accordingly, future studies should consider alternative data collection approaches or comparative analyses across sites or time periods to better assess this potential bias. Fourth, despite the sensitivity analyses conducted, voluntary participation and convenience sampling may have introduced selection bias, as patients who were more satisfied or more engaged with automated outpatient pharmacy services may have been more likely to participate. Although the sensitivity analyses suggest that potential underrepresentation of less satisfied patients is unlikely to have materially altered the study conclusions, the findings may not be fully representative of all users of automated outpatient pharmacy systems in Kuwait, particularly individuals who actively avoid or disengage from these systems. Fifth, the study was conducted in 4 governmental hospitals and did not include private hospitals or pharmacies, which may differ in service quality, system implementation, and operational policies. Sixth, the cross-sectional design captured perceptions at a single point in time, limiting the ability to assess changes in patient-reported satisfaction over time.

Finally, although responses were obtained from both patients and caregivers, caregivers represented a smaller proportion of the sample (104/416, 25%). An exploratory comparison using the Mann-Whitney *U* test did not detect statistically significant differences between the 2 groups; therefore, further subgroup analyses were not pursued.

Future Research

Future research should link patient-reported perceptions with objective safety and quality indicators, such as medication dispensing error rates, adverse drug events, dispensing accuracy, workflow measures, and prescription turnaround time, to determine whether perceived benefits correspond to measurable improvements in patient outcomes. Longitudinal and mixed methods designs, including qualitative interviews, may provide deeper insight into how and why perceived benefits evolve over time and whether anticipated benefits are realized in routine practice. Methodologically, probability-based sampling approaches should be considered to improve representativeness and reduce selection bias. In addition, remote or independent survey administration and comparative designs across data collection settings may help assess and minimize social desirability bias. Comparative studies involving governmental and private sector hospitals or pharmacies are also warranted, given potential differences in implementation maturity, staffing, workflows, and service policies. Finally, future studies specifically powered to compare patient and caregiver perspectives, alongside technical and organizational assessments, would provide a more comprehensive evaluation of system effectiveness and help identify actionable improvement strategies.

Conclusions

This study demonstrated that integrated e-prescribing and e-dispensing systems offer clear perceived benefits in outpatient pharmacies within governmental hospitals in Kuwait. This is reflected in the positive experiences reported by patients, reflecting overall perceived satisfaction and perceived service performance within the operating systems.

However, the findings also highlight areas requiring improvement to maximize patients' satisfaction toward pharmacy automation systems. The following clinical implications are made:

1. Workflow design optimization: operational strategies should be implemented to improve pharmacy workflow design within automated pharmacy settings to enhance work efficiency, especially for processing lengthy prescriptions and managing drug inventories to reduce dispensing delays, as well as making sure that a counseling area is available for patient education.

XSL•FO
RenderX

2. E-prescribing system enhancement: counseling prompts should be integrated to ensure that important information is delivered completely and properly to patients.
3. Automated inventory management: enhanced inventory control should be implemented, including proactive stock monitoring to clarify what is available and what is near expiry to improve the supply chain management. This is essential because the results showed that approximately 25% (105/416) of patients reported medication unavailability.
4. Staff training: pharmacy staff should receive comprehensive training on best practices for using integrated e-prescription and e-dispensing systems. This would improve patient counseling, interprofessional communication, patient safety, and overall patient satisfaction.
5. Feedback mechanisms: regular collection of feedback from both patients and pharmacy staff should be instituted to identify and address issues related to waiting times, medication availability, and the quality of counseling services.

By addressing these identified gaps, pharmacists can enhance patient satisfaction and improve the overall performance of outpatient pharmacy services supported by integrated digital systems. Strengthening the digital infrastructure and workflow integration would enable hospitals to optimize outpatient pharmacy services and move toward patient-centered digital pharmacy models that support efficient, reliable, and safe medication services. These findings have relevance beyond the study setting and may inform the development of digital outpatient pharmacy services across hospitals in the Arabian Gulf region.

Acknowledgments

The authors would like to thank the students from the College of Pharmacy at Kuwait University who undertook the data collection: Yousef Bahman, Ritaj Alawadhi, Sadeem Almubarak, Nourah Alshammeri, Zainab Moradi, and Sara Alorf.

AI Scribes: Are We Measuring What Matters?

Abstract

Artificial intelligence (AI) scribes, software that can convert speech into concise clinical documents, have achieved remarkable clinical adoption at a pace rarely seen for digital technologies in health care. The reasons for this are understandable: the technology works well enough, it addresses a genuine pain point for clinicians, and it has largely sidestepped regulatory requirements. In many ways, clinical adoption of AI scribes has also occurred well ahead of robust evidence of their safety and efficacy. The papers in this theme issue demonstrate real progress in the technology and evidence of its benefit: documentation times are reported to decrease when using scribes, clinicians report feeling less burdened, and the notes produced are often of reasonable quality. Yet as we survey the emerging evidence base, there remains one outstanding and urgent unanswered question: Are AI scribes safe? We need to know the clinical outcomes achievable when scribes are used compared to other forms of note taking.

(JMIR Med Inform 2026;14:e89337) doi:10.2196/89337

KEYWORDS

artificial intelligence; AI; digital scribes; medical scribes; electronic documentation; patient safety; error prevention

Beyond Efficiency

Early evaluation of any technology naturally focuses on its primary promise, in the case of scribes [1], reducing documentation burden. The studies in this collection confirm that artificial intelligence (AI) scribes deliver on this front. Kanaparthy and colleagues' [2] rapid review found a general trend toward reduced self-reported documentation time and improvements in clinician satisfaction. The comparative analysis by Ha and colleagues [3] demonstrates that current commercial systems can generate reasonable-quality SOAP (subjective, objective, assessment, and plan) notes in about a minute after a 15-minute encounter. These are meaningful findings. Having shown that scribes likely save time in the settings they have so far been evaluated in (eg, primary care and outpatient settings), we can turn to harder questions of safety, clinical reasoning, and wider system-level effects.

Toward Systematic Harm Measurement

How safe are clinical scribes? Do they make errors, what type of errors might see when using digital scribes, and are these errors clinically consequential? What are the causes of errors, and what then are the harm mitigations we need to put into place?

Several papers in this collection begin this work. Ha and colleagues [3] highlight that none of the systems they evaluated are error free. Biro and colleagues [4] have developed and validated an instrument specifically designed to assess the accuracy and safety of AI scribe outputs, an essential foundation since, without standardized measurement, we cannot compare across systems or track changes over time. Their early work confirms that AI scribes do make errors, and some have patient safety implications.

Digital technologies have the capacity to both reduce human error and generate new error classes [5]. This raises another question worthy of further investigation: Are digital scribe errors equivalent to human errors, or do they have different risk profiles? A human might lose attention momentarily; a digital scribe will not fatigue but may misrecognize words through speech recognition errors. An AI might confidently fabricate a medication or symptom that was never mentioned or omit clinically significant details in the pursuit of conciseness, each reshaping the clinical narrative in different ways.

Equally, we should recognize that the status quo carries its own safety risks: clinician burnout and cognitive overload contribute to errors that scribes may help reduce. A complete safety evaluation must weigh new risks introduced by AI against existing risks that the technology may mitigate and consider what analogous error-detection and correction mechanisms we need to build for AI-generated documentation.

Clinical Reasoning When Using a Digital Scribe: An Underexplored Frontier

Perhaps the richest opportunity for future research relates to the quality of clinical care when documentation is outsourced to AI. Note-taking is not merely administrative work. When a clinician summarizes their thoughts into a document, they are actively processing information, prioritizing what matters, and forming and testing hypotheses in real time. The clinical note

XSL•FO
RenderX

is not just a record of the consultation; it is a cognitive artifact that supports clinical reasoning [6].

What happens to this human sense-making process when documentation is delegated to an AI? We may be freeing the attention of clinicians to be more present with patients, or we may be altering how they would normally think. The Y-KNOT (Your-Knowledgeable Navigator of Treatment) implementation study offers an intriguing signal: expert ratings suggested that while most AI-generated drafts were rated positively, around 1 in 6 preanesthetic assessments were judged to have a negative impact on clinical decision-making [7]. As we document faster, are we also documenting differently? Does that difference matter for patient care? If so, can we mitigate the potential for harm, for example, through clinical training or redesigning the user interaction with a scribe to bring clinicians back into the document-and-reason loop?

Ecosystem Perspectives

AI scribes sit at a critical position within a clinical workflow. They determine what gets recorded and how it is structured, which in turn shapes what downstream systems, including other AI tools, will see and act on. In this sense, scribes are a gateway technology, creating data layers that propagate through the health system. As we have argued elsewhere in the context of generative AI more broadly, it is helpful to view these technologies through an ecosystem lens that emphasizes system-level properties over isolated components [8]. With this perspective, we can evaluate the broader scribe ecosystem against system-level dimensions: resilience (how does care adapt when the scribe fails?), sustainability (what happens when cloud-based systems change or disappear?), and service interactions (does optimizing documentation affect other aspects of care?).

The patients in Leiserowitz and colleagues' [9] survey were generally open to an AI scribe when it was framed as supporting clinician focus. Their study also showed one interaction worth monitoring: a meaningful proportion of patients indicated they might withhold sensitive information if an always-listening device was present. Understanding these broader system effects will require looking beyond the scribe itself to the clinical environment it inhabits.

Regulatory Evolution

There are several reasons why we still lack safety evidence. AI scribes have proliferated [10] in part because they sit outside traditional medical device classification [11]. Many commercial scribes skirt the software as a medical device definition of a decision support system and so have evaded regulation. With no regulatory demands for robust safety evaluation, there is little commercial value, it seems, in publishing commercial safety data. The evidence in this collection suggests that we may need new regulatory thinking, not because current systems are demonstrably unsafe, but because they are different. These systems do influence clinical decisions, and unlike traditional medical devices, they are not static; the large language model underlying a scribe may be updated or retrained over time. Regulatory frameworks designed for deterministic, frozen technologies may need to evolve alongside the technology itself. The question is not whether to regulate but how to do so in ways that preserve innovation while ensuring ongoing safety. Potential mechanisms might include postmarket surveillance requirements, mandatory incident reporting for generative medical AI, or periodic re-evaluation as underlying models are updated.

Conclusion

The papers in this theme issue represent important progress. AI scribes appear to deliver on their core promise of reducing documentation burden, and the field is developing increasingly rigorous evaluation approaches. Building on this foundation, we see an opportunity to expand what we measure: systematic assessment of errors and harms, investigation of effects on clinical reasoning, and attention to ecosystem-level dynamics. Documentation burden is real, and technologies that address it are welcome. The next chapter of research can help ensure that the time saved translates into better care.

Abstract

Background: Given the highly heterogeneous biology of breast cancer, a more effective noninvasive diagnostic tool that unravels microscopic histopathology patterns is urgently needed.

Objective: This study aims to identify cancerous regions in ultrasound images of breast cancer via convolutional neural network based on registered grayscale ultrasound images and readily accessible biopsy whole slide images (WSIs).

Methods: This single-center study prospectively included participants undergoing ultrasound-guided core needle biopsy procedures for Breast Imaging Reporting and Data System category 4 or 5 breast lesions for whom breast cancer was pathologically confirmed from July 2022 to February 2023 consecutively. The basic information, ultrasound image data, biopsy tissue specimens, and corresponding WSIs were collected. After core needle biopsy procedures, the stained breast tissue specimens were sliced and coregistered with an ultrasound image of a needle tract. Convolutional neural network models for identifying breast cancer cells in ultrasound images were developed using FCN-101 and DeepLabV3 networks. The image-level predictive performance was evaluated and compared quantitatively by pixel accuracy, Dice similarity coefficient, and recall. Pixel-level classification was illustrated through confusion matrices. The cancerous region in the testing dataset was further visualized in ultrasound images. Potential clinical applications were qualitatively assessed by comparing the automatic segmentation results and the actual pathological tissue distributions.

Results: A total of 105 participants with 386 ultrasound images of breast cancer were included, with 270 (70%), 78 (20.2%), and 38 (9.8%) images in the training, validation, and test datasets, respectively. Both models performed well in predicting the cancerous regions in the biopsy area, whereas the FCN-101 model was superior to the DeepLabV3 model in terms of pixel accuracy (86.91% vs 69.55%; P=.002) and Dice similarity coefficient (77.47% vs 69.90%; P<.001). The two models yielded recall values of 54.64% and 58.46%, with no significant difference between them (P=.80). Furthermore, the FCN-101 model had an advantage in predicting cancerous regions, while the DeepLabV3 model achieved more accurate predictive pixels in normal tissue (both P<.05). Visualization of cancerous regions on grayscale ultrasound images demonstrated high consistency with those identified on WSIs.

Conclusions: The technique for spatial registration of breast WSIs and ultrasound images of a needle tract was established. Breast cancer regions were accurately identified and localized on a pixel level in high-frequency ultrasound images via an advanced convolutional neural network with histopathologic WSI as the reference standard.

Introduction

Breast cancer heterogeneity has induced challenges in treatment planning and follow-up management, which leads to unfavorable outcomes [1,2]. Currently, ultrasound is a widely used diagnostic tool for breast cancer management, particularly valuable in screening, positive diagnosis, and treatment response assessment [3]. However, the biological heterogeneity of breast cancers leads to varied morphological features on ultrasound [4], often resulting in malignancy underestimation and overestimation. Furthermore, there is a heterogeneous response to treatment among patients with breast cancer [5-7]. Curative effect assessment secondary to preoperative neoadjuvant treatment is largely based on cancer volume changes [8], as well as biopsy for further validation [9]. A more accurate noninvasive diagnostic tool that indicates living cancer cells in breast cancer is urgently needed [10-12].

Hematoxylin and eosin (H&E) staining of breast tissue captured via core needle biopsy (CNB) has been introduced to reflect the underlying cellular and molecular information [13-15]. Preoperative diagnosis and curative effect assessment of breast cancer can be undermined by insufficient and nonrepresentative tissue owing to the heterogeneous distribution of breast cancer [16]. Likewise, the partial samples obtained by CNB may not represent the entire lesion [17]. There remains a need for standardized methods or imaging biomarkers available for accurately localizing histopathological cancerous subregions.

The convolutional neural network (CNN), a developed type of deep learning algorithm, has shown remarkable performance in correlating macroscopic imaging and microscopic histopathologic microstructure. A previous study showed that a multimodal radiomics model combining ultrasound and whole slide image (WSI) can effectively distinguish between luminal and nonluminal breast cancers [18]. Other studies have explored using the deep learning algorithm for correlation between magnetic resonance imaging (MRI) and whole-mount specimen images to localize prostate cancer [19]. Theoretically, these approaches may also be applicable in the ultrasound identification and localization of cancerous regions in breast cancer. Nonetheless, few studies have focused on this aspect. The correlation of ultrasound modality and readily accessible biopsy WSI remains open to question.

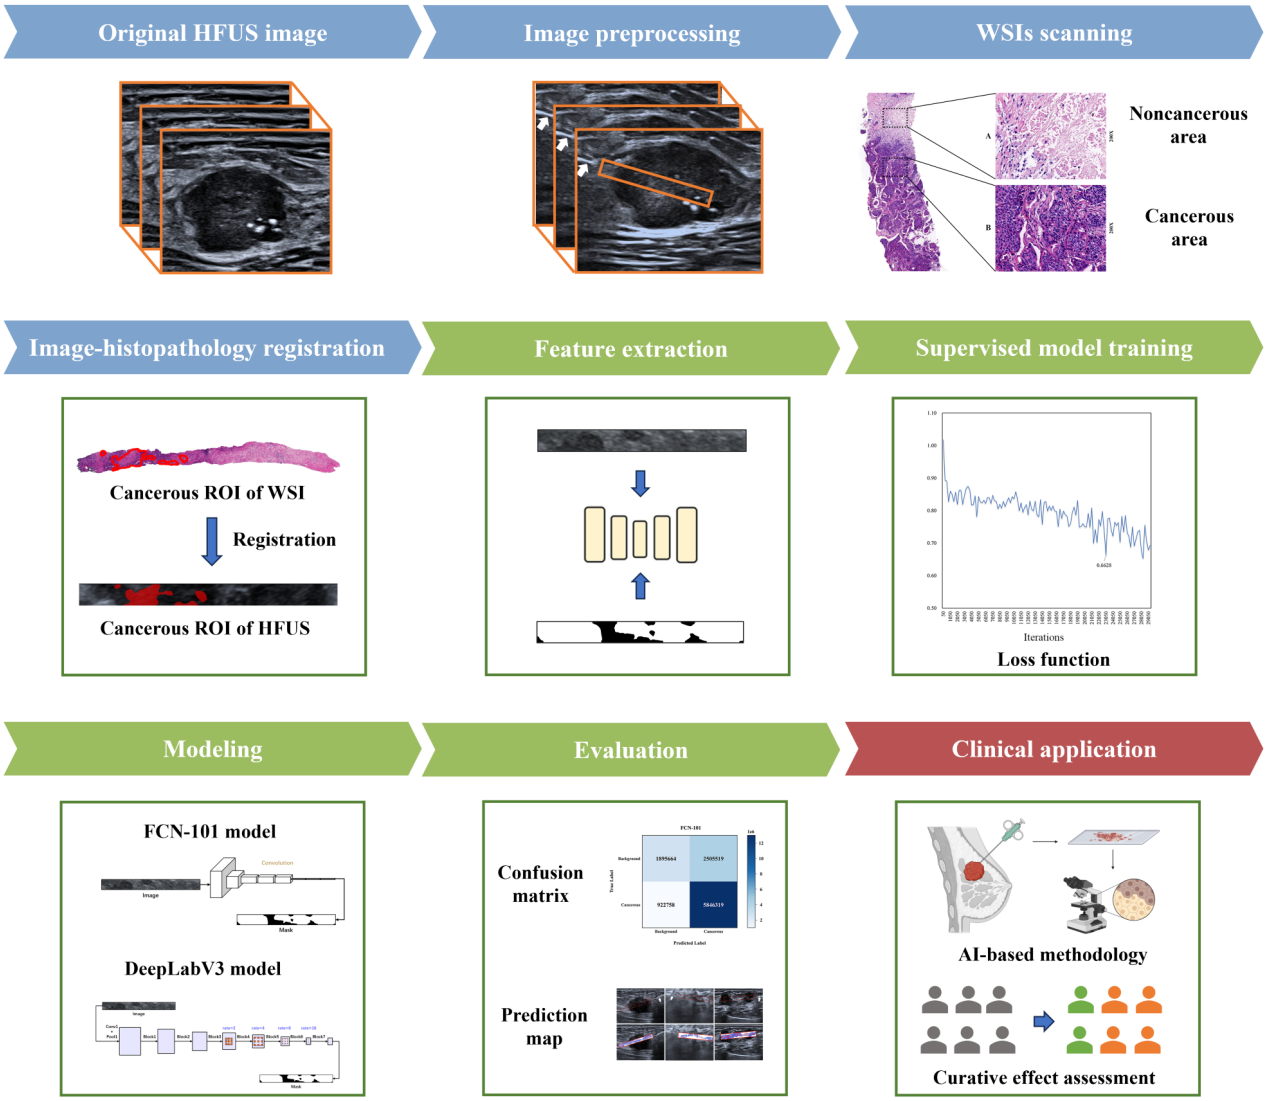
Therefore, this study aims to identify and localize cancerous regions in breast cancer based on a CNN algorithm that integrates high-frequency ultrasound (HFUS) images with WSI histopathology. The predictive performance of the model will be assessed.

Methods

Study Population

Consenting participants were recruited between July 2022 and February 2023 and were included as the training, validation, and test population. The eligibility criteria included the following: (1) index lesion was defined as category 4 or 5 according to the fifth edition of the American College of Radiology Breast Imaging Reporting and Data System (BI-RADS) of ultrasound [20]; (2) index lesion was visible on HFUS, and complete imaging data were stored; (3) underwent ultrasound-guided breast lesion biopsy and the histopathology indicated breast cancer. Participants were excluded if (1) the biopsy specimen was incomplete or inaccessible; (2) the breast ultrasound images were incomplete; (3) there was a history of treatment for breast cancer (surgery, antihormonal therapy, immunotherapy, and radiation therapy); (4) the pathologic diagnosis was incomplete. The study sample included 163 consecutive participants undergoing ultrasound-guided breast biopsy for suspicion of cancer. Of these, three participants whose ultrasound images had poor quality and one who did not provide research consent were excluded. Participants with incomplete, fractional tissue specimens (n=2) and benign histology reports (n=52) were also excluded.

Ultrasound and CNB Examination



The overall design of this study is shown in Figure 1. Expert radiologists with at least 10 years of experience performed breast ultrasound examinations and ultrasound-guided CNB procedures following the standard practice protocol. Location, number, and morphologic characteristics (size, shape, orientation, margin, echo pattern, vascularity, and calcifications) of lesions were identified and categorizations were assigned by the expert radiologists according to the fifth edition of ultrasound BI-RADS [20]. An Aplio i900 Ultrasound System (Canon) with an i24LX8 high-frequency linear probe (frequency range: 8.0 - 18.0 MHz) was used to generate breast ultrasound images. All images were stored in DICOM format for subsequent analysis.

WSI Acquisition

When breast cancer was suspected, an ultrasound-guided CNB procedure was performed by expert radiologists to determine the diagnosis. MAGNUM biopsy instruments (BARD) with disposable core tissue biopsy needles (16G, 22 mm, MN1620, BARD) were adopted. During the procedure, the needle tip was positioned approximately 0.5 cm from the target biopsy region. The radiologists aligned the ultrasound probe and needle to visualize the entire needle tract. Subtle needle deflections were occasionally observed. These deflections were dynamically corrected in real time by adjusting the needle trajectory. The radiologists captured two B-mode HFUS images per biopsy for subsequent registration, including one pre-fire and one post-fire. To ensure the specimens were representative, biopsies were taken by the radiologist from different regions of the lesion, typically 4 - 6 samples, focusing on solid areas on B-mode ultrasound or areas with abundant vascularity on color Doppler flow imaging. When multiple lesions were encountered, the most suspicious lesion for malignancy was chosen for analysis. To facilitate the follow-up spatial registration of ultrasound and histopathologic images, the needle tip side of the biopsy specimen from the index lesion was stained with biological tissue dye (BIOGNOST), depicted in Figure S1 in Multimedia Appendix 1. After 2 to 5 minutes of coloration, the biopsy specimens were placed in 10% neutral buffered formalin for fixation and sent for histopathologic examination.

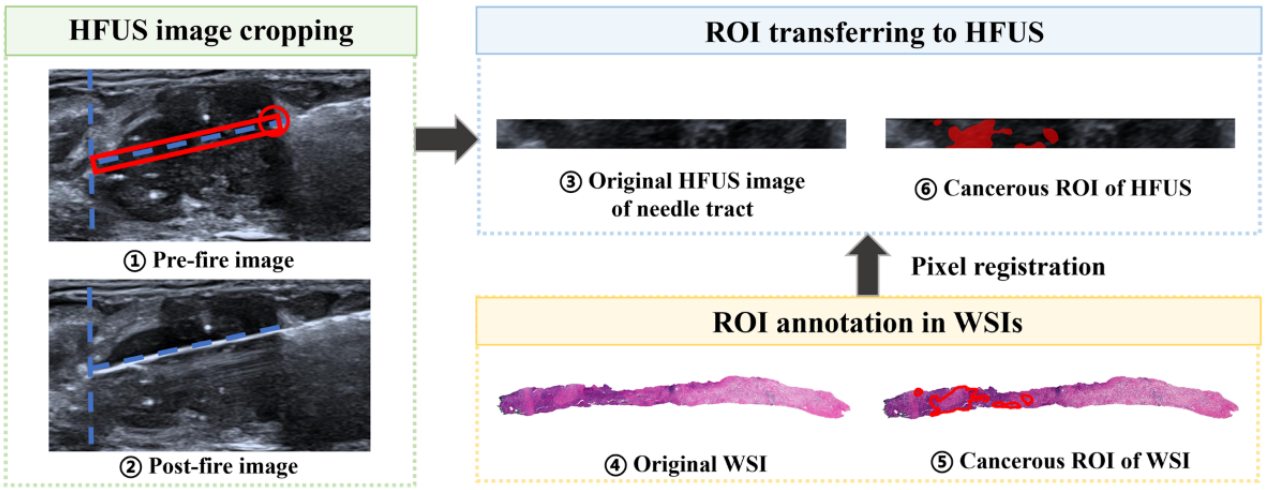
RenderX

Figure 1. Workflow of the proposed cancerous regions identification protocol in this study. First, we got cropped HFUS images and corresponding spatially aligned biopsy WSIs. Second, a registration process was applied to achieve anatomic correlation. Third, the segmentation model was constructed using the FCN-101 and DeepLabV3 architectures. AI: artificial intelligence; HFUS: high-frequency ultrasound; ROI: region of interest; WSI: whole slide image.

The tissue samples were fixed and oriented during the embedding process to preserve the longitudinal axis. Each 3 µm histological slide was then sectioned parallel to the initial needle trajectory, thereby ensuring that the analyzed WSI represented the same gross anatomical plane captured by HFUS. The tissue strips were very small, thus the dimensional changes and distortion introduced by histological processing were assumed to be limited. Each section was stained with H&E. For each participant, all slides stained with H&E were reviewed by two experienced breast pathologists (with 5 y and 10 y of experience), and the histopathologic type was reported. Scanning of the H&E slides was performed using a KFBIO Digital Pathology Slide Scanner (KF-PRO-020) with a 200X objective lens. Representative heterogeneous cancer cell distribution of breast cancer in biopsy WSI is depicted in Figure S2 in Multimedia Appendix 1.

Imaging Registration



The expert pathologist with 10 years of experience used the open-source software QuPath (version 0.4.0) for digital histopathology analysis. The maximal cross-section of the extracted core was used for analysis. Cancer cells were identified based on nuclear atypia and mitotic figures. The regions of interest (ROIs) of cancerous regions were manually outlined on all high-resolution WSI slices, generating a per-pixel cancer cell labeling (Figure 2).

For 4 - 6 samples from one lesion, the expert pathologist selected 1 - 4 specimens for further registration processing. The method for selecting was based on three criteria: (1) intact and well-formed; (2) length matches the needle notch (22 mm); (3) clear and distinguishable staining. For each selected tissue sample, one radiologist with at least 5 years of experience correlated the WSI to two captured B-mode HFUS images. To ensure the spatial registration from WSI to the HFUS images, the radiologist compares the pre-fire and post-fire HFUS images using Photoshop software (version CC 2019; Adobe Inc). In the software, the needle tip position in the pre-fire image was taken as the starting point; actual length of the biopsy specimen was determined by the needle projection distance in the post-fire

XSL•FO
RenderX

image. Then, the radiologist cropped the biopsy area in the pre-fire image for subsequent annotation and analysis. The detailed image cropping process is demonstrated in Figure 2. The HFUS image of the needle tract was then saved in JPG format. The ROIs outlined in WSIs were converted to correlated HFUS images via Labelme software, an open-source image annotation tool (version 5.1.0).

Figure 2. Spatial registration and mapping protocol between HFUS and WSI. We compared the pre-fire image and post-fire image to crop the needle tract in HFUS images. An experienced pathologist manually outlined the cancerous cells on WSI images using QuPath software (version 0.4.0 [21]), which were transferred to the cropped HFUS images, creating the labeled dataset for training. HFUS: high-frequency ultrasound; ROI: region of interest; WSI: whole slide image.

Data Preprocessing

The HFUS images and their ROIs annotation were obtained to establish the CNN prediction model. Open-source libraries including Python (version 3.8.11; Python Software Foundation), Imgviz (version 1.5.1), and Numpy (version 1.21.6) were used to convert the dataset into the standard VOC format. To enhance the robustness and generalization capability of the model, data augmentation strategies, such as random horizontal flipping, rotation, and pixel transformations, were used to increase the generalizability of the model. The dataset was randomly divided into training (n=270, 70%), validation (n=78, 20.2%), and test (n=38, 9.8%) subsets using a 7:2:1 ratio with no overlap between the subsets. Image pixel values were normalized using the *z*-score method to reduce computation burden and accelerate model convergence.

Model Development

The fully automated segmentation CNN model was designed to identify cancerous regions in breast cancer based on HFUS images, with the ROIs in WSI as the reference standard. The independent CNN model was trained with advanced FCN-101 [22] and DeepLabV3 [23] networks as the backbone, separately. During training, the models were adapted using the AdamW optimized algorithm and CosineAnnealing learning rate adjustment curve to improve efficiency. The weighted Dice loss function was used to mitigate the data imbalance during the training process, as plotted in Figure S3 in Multimedia Appendix 1. The iteration parameters with the lowest loss values were chosen, which were 0.6626 for the FCN-101 model and 0.7285 for the DeepLabV3 model. In the fine-tuned process, parameters were selected to construct the segmentation model when the best performance on the test dataset was achieved. Finally, cancerous regions in breast cancer were localized. More details on the CNN model are provided in Multimedia Appendix 1. The source code for our CNN models is available on GitHub [24].

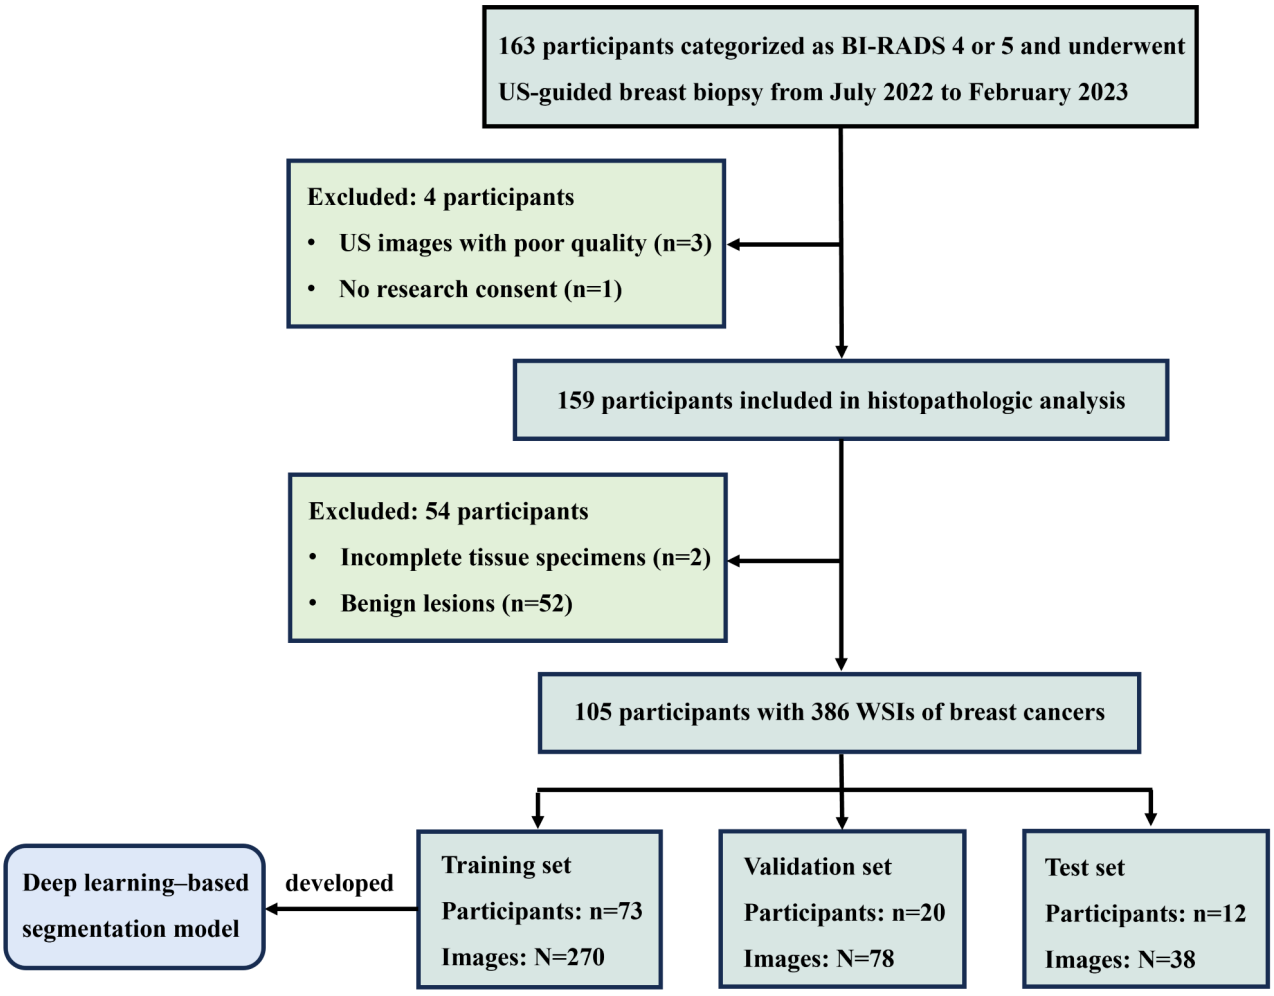
Statistical Analysis

All statistical analysis was conducted with IBM SPSS Statistics 25.0 (version 25.0; IBM Corp), Python (version 3.8.11; Python Software Foundation), and R software (version 4.2.1, R Foundation for Statistical Computing). Continuous variables were exhibited as means (SDs) or medians and IQRs and compared using a 1-sample *t* test or Mann-Whitney *U* test where appropriate. Categorical variables were expressed as counts and percentages and compared through χ^2 tests. To assess and compare the segmentation performance of CNN models based on independent networks, pixel accuracy (PA), Dice similarity coefficient (DSC), mean Intersection over Union, precision, and recall were calculated. These metrics were computed separately for each test image, and the final performance values were obtained by averaging the image-level results across the entire dataset. To avoid inflated degrees of freedom arising from multiple images per participant, a paired-sample *t* test was performed at the participant level to compare the performance of FCN-101 and DeepLabV3 models. Normality of the paired differences was confirmed using the Shapiro-Wilk test. Detailed evaluation metrics were demonstrated in the Supplementary Methods in Multimedia Appendix 1. The confusion matrices were adopted to show the pixel-level classification of cancerous regions and normal tissue based on aggregated raw pixel counts. Two-tailed $P<.05$ was considered statistically significant.

Ethical Considerations

This single-center prospective study involving human participants was approved by the local institutional review board of the First Affiliated Hospital of Sun Yat-sen University (Ethics [2023]842). Written informed consent was obtained from all

XSL•FO
RenderX



participants prior to their inclusion in the study. This study was conducted in accordance with the Declaration of Helsinki and its subsequent amendments. All data were deidentified before analysis to ensure participant privacy. Participants did not receive any financial or material compensation, as all procedures were part of routine clinical care, and the analytical use of the resulting data was clearly explained to participants during enrollment. No identifiable images or personal information are included.

Results

Participant Characteristics

A total of 163 individual participants received ultrasound-guided breast biopsy, and 58 participants were excluded (Figure 3). The final prospective dataset contained 105 participants (mean age, 53.7, SD 11.3 y old; all female) diagnosed as breast cancer with 386 HFUS images of the needle tract. All biopsies ultimately achieved successful targeting and adequate sampling in the 105 participants. Among them, 64 (87.7%), 19 (95%), and 9 (75%) invasive breast cancer and 9 (12.3%), 1 (5%), and 3 (25%) ductal carcinomas in situ were identified in the training, validation, and test subsets, respectively. Characteristics were compared between three subsets in Table 1 and no evidence of a statistical difference was observed, except for vascularity, where internal vascularity of breast lesions was observed in the training dataset (P=.03).

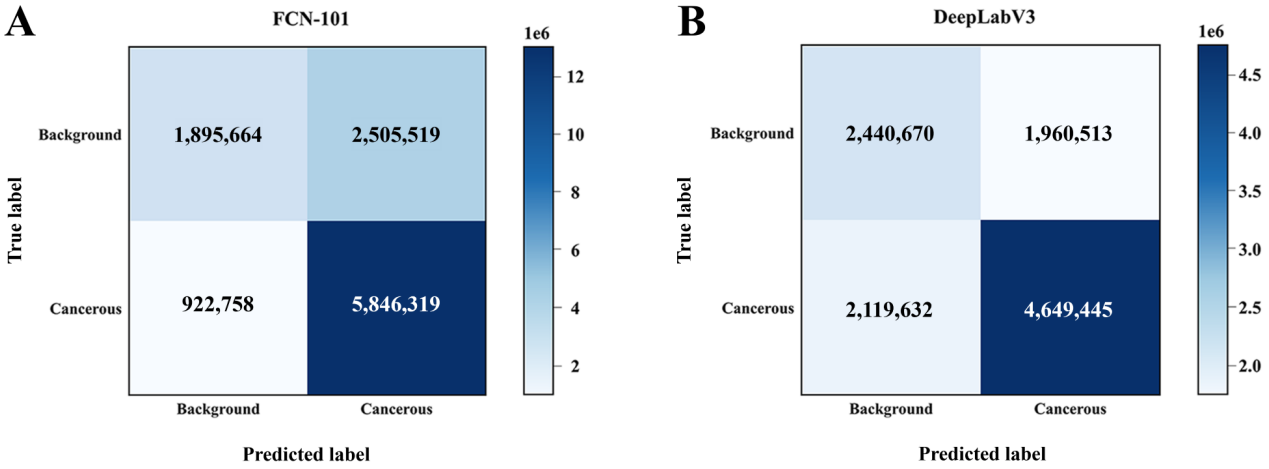
Model Evaluation

The segmentation capacity of the image-based CNN model based on FCN-101 and DeepLabV3 in the test dataset is provided in Table 2. The table presents image-level descriptive statistics, while all inferential comparisons were conducted at the participant level (n=12). In the test dataset, FCN-101 showed higher accuracy (PA: 86.91% vs 69.55%, *P*=.002), similarity (DSC: 77.47% vs 69.90%, *P*<.001), mean Intersection over Union (67.47% vs 60.29%, *P*<.001), and precision (66.01% vs 56.15%, *P*<.001) compared to DeepLabV3. There was no evidence of a difference in recall (54.64% vs 58.46%, *P*=.80) between the two algorithms.

Table . Comparison of prediction performance of FCN-101 and DeepLabV3 models in predicting cancerous regions in breast cancer in the test dataset. All metrics reflect image-level performance and are expressed as percentages. Statistical comparisons (*P* values) were performed at the participant level using paired analyses.

Evaluation metric	FCN-101, % (95% CI)	DeepLabV3, % (95% CI)	*P* value
PA[a]	86.91 (80.30-94.77)	69.55 (65.82-73.99)	.002
DSC[b]	77.47 (70.74-85.88)	69.90 (63.43-75.02)	<.001
mIoU[c]	67.47 (59.70-75.54)	60.29 (54.19-66.57)	<.001
Precision	66.01 (55.69-73.45)	56.15 (48.12-64.17)	<.001
Recall	54.64 (45.57-63.75)	58.46 (49.03-65.66)	.80



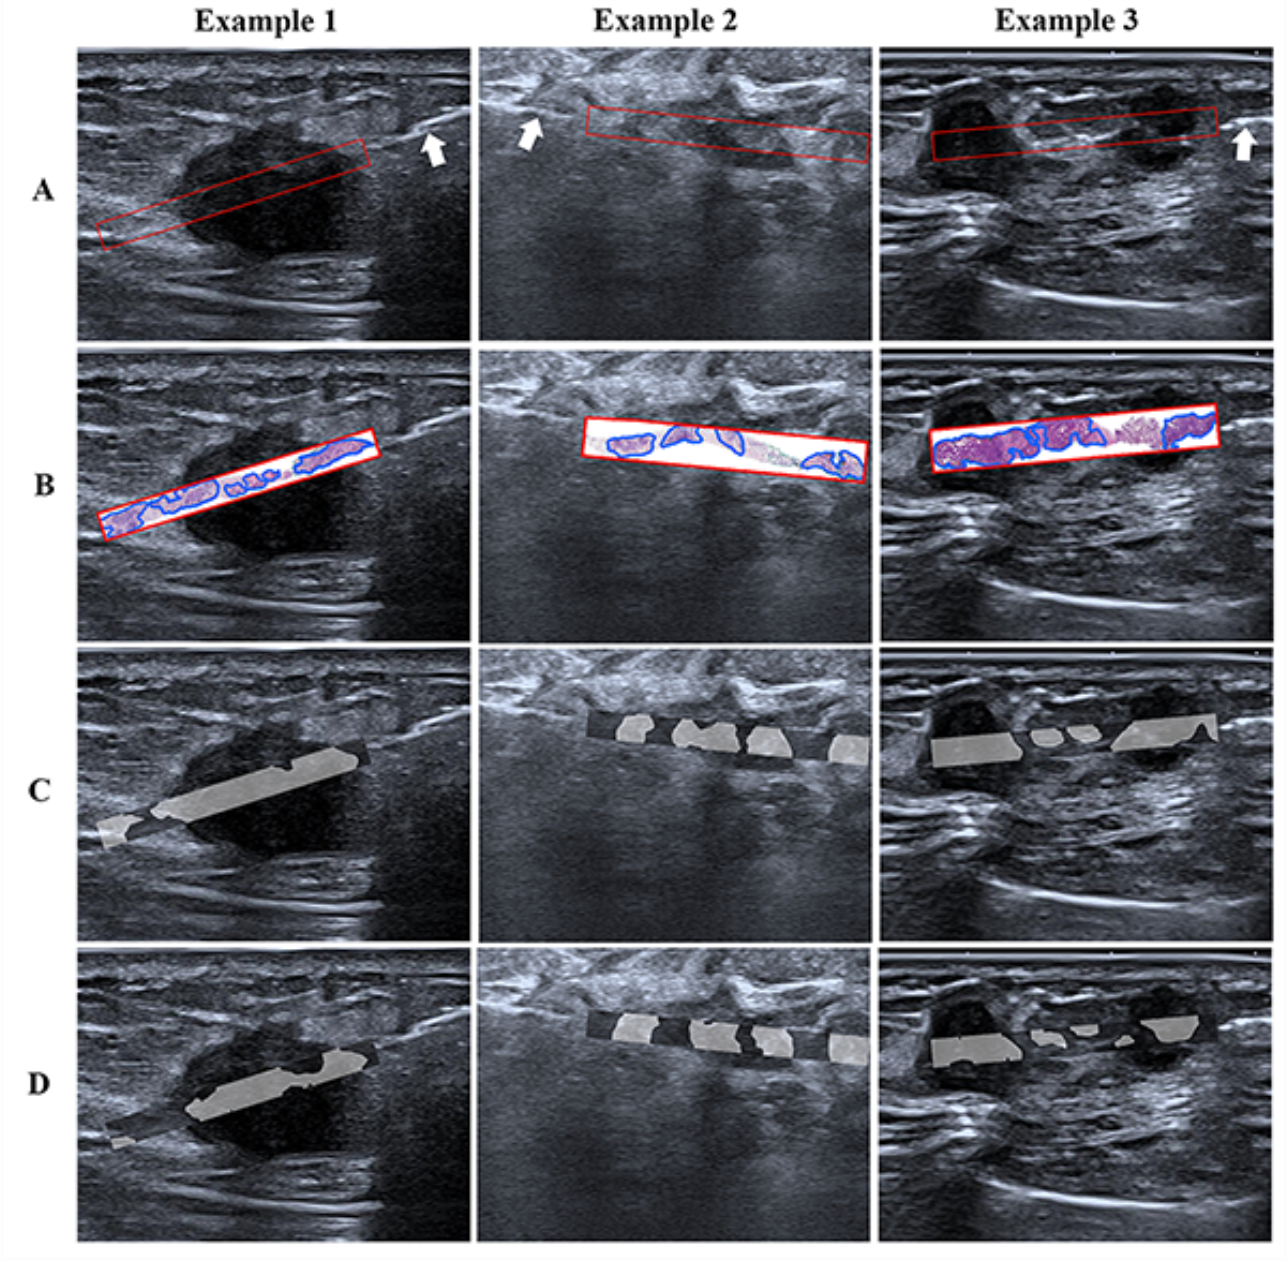
[a]PA: pixel accuracy.

[b]DSC: Dice similarity coefficient.

[c]mIoU: mean Intersection over Union.

The confusion matrix presented in Figure 4 evaluates the pixel categorization capacity, providing further insight into the per-pixel predictions of each model. The results indicated that the FCN-101 model successfully predicted the majority of cancerous pixels (5,846,319 vs 4,649,445 pixels; *P*<.05). However, the DeepLabV3 model demonstrated more accurate predictive pixels in background components (2,440,670 vs 1,895,664 pixels; *P*<.05). Based on the pixel-wise confusion matrices, the recall and specificity of FCN-101 were 86.37% and 43.07%, while those of DeepLabV3 reached 68.69% and 55.46%.

Figure 4. Confusion matrices for predicting cancerous regions. Confusion matrices were applied to summarize pixel-level classification outcomes aggregated across the entire test dataset for (A) FCN-101 and (B) DeepLabV3, indicating discordance or concordance with the ground truth (cancerous cell/background) from WSI results. WSI: whole slide image.



Model Visualization

In the test dataset, the automatic segmentation results of cancerous regions based on the two networks were visually displayed and qualitatively compared with the gold standard to evaluate the predictive performance of the models. Cancerous regions in the CNB biopsy area of three different participants' breast HFUS images were identified and localized in Figure 5, as generated by the FCN-101 and DeepLabV3 models. Cancerous region predictions by the two CNN models align closely with the actual histopathology. Additionally, even in challenging cases with unclear boundaries and mixed internal echoes, as represented in Example 2, both models were able to accurately predict the specific distribution of cancerous regions within the lesions.

Discussion

Principal Results

Breast cancer is a group of highly heterogeneous diseases with varying imaging features. Thus, differential diagnosis through imaging is limited [25,26]. Development and validation of a fast and noninvasive method equal to histologic results is urgently needed. Here, we developed a cancerous region classifier using a deep learning network with true labels from radiology-pathology registration. The FCN-101 model was superior to the DeepLabV3 model in terms of PA (86.91% vs 69.55%; *P*=.002) and DSC (77.47% vs 69.90%; *P*<.001). Recall values were 54.64% and 58.46%, with no significant difference observed between them (*P*=.80). The FCN-101 model excelled in identifying cancerous regions (5,846,319 vs 4,649,445 pixels; *P*<.05), whereas DeepLabV3 was more accurate for normal tissue (2,440,670 vs 1,895,664 pixels; *P*<.05) in pixel-level predictions. In the clinical workflow, the model could segment cancerous regions in grayscale ultrasound images of the breast. The results highlight the model's potential for advancing breast cancer assessment at the microscopic level via ultrasound imaging.

Efforts have been made to establish a methodology pertaining to image-histopathology registration [27-32]. For example, Ward et al [27] and Kwak et al [28] demonstrated accurate alignment between MRIs and digital histopathologic analyses in patients with prostate cancer. In addition, Wildeboer et al [29] established a multiparametric machine learning on ultrasound for histopathology localization of prostate cancer. However, similar research in breast imaging remains limited. In our study, WSIs from CNB provided accessible clinical data suitable for state-of-the-art deep learning algorithms.

XSL•FO
RenderX

Thus, a strength of this study is that we combined accessible CNB tissue samples with real-time ultrasound imaging to facilitate the registration process. The biopsy needle targeted the desired section plane while the tissue sample was obtained at the same level, which was crucial for registration. Moreover, HFUS offers spatial tissue distribution data, enhancing dynamic biopsy procedures and clinical utility. However, subtle registration errors existed; for example, the biopsy needle was deflected when encountering small breast tumors or rigid glandular tissue [33]. To address this, our skilled operators actively mitigated needle deflections. Pre-fire and post-fire ultrasound images were compared to ensure that the extracted tissue precisely corresponded to the visualized ultrasound plane.

Studies have investigated the biopsy efficacy between existing methods. Currently, three image-guided breast biopsy techniques are used: stereotactic-, ultrasound-, and MRI-guided biopsies. Stereotactic biopsy is indicated for calcifications, and MRI-guided biopsy is indicated for lesions visible only on MRI; both primarily assess ductal proliferative lesions. Ultrasound-guided biopsy, however, applies to a broader range of breast lesions [34]. Yashima et al [35] retrospectively compared the positive biopsy rate in 453 patients with 500 lesions that underwent ultrasound-guided core needle biopsy or vacuum-assisted biopsy and reported positive biopsy rates of 61.9% and 72.4% (P=.032), respectively. Unrepresentative CNB specimens might not fully reflect the overall characteristics of the tumor [17]. Although multipoint sampling and repetitive biopsy increased the detection rate, they also increased complications like bleeding, infection, and tumor spreading [36]. Based on this, our model may generate real-time cancer prediction heatmaps, where suspicious regions are highlighted to assist biopsy site selection during CNB sampling. However, prior to clinical use, the proposed approach should undergo rigorous supervision and ethical evaluation to ensure its safety and reliability in guiding biopsy decisions.

The visualized cancerous map was used to enhance the interpretability of the model. Here, we found that distribution maps facilitated the assessment of cancerous regions by highlighting the hypoechoic area in HFUS images (illustrated in Figure 5), which is in accordance with clinical routine. Furthermore, areas of abnormal echogenicity or edges of lesions often corresponded to cancerous regions identified in histopathology, which was also correctly predicted by the deep learning models. Guided by the ultrasound-based CNN algorithm, doctors could identify suspicious regions based on predicted cancerous regions, even in small lesions, helping to ensure sufficient and representative CNB samples for accurate histopathological assessment. However, the model is intended to assist clinicians and cannot replace their judgment in biopsy decision-making.

Notably, there is a discrepancy between the per-image recall and the pixel-level aggregated recall, which can be explained by the scale-dependent nature of these two evaluation strategies. This scale-dependent discrepancy indicates that the current model achieves higher sensitivity for larger tumors, while the detection of small lesions remains more challenging. It highlights an important direction for future optimization aimed at improving detection stability across different tumor sizes.

Although the two models had advantages in predicting cancerous regions, the confusion matrix analysis revealed a relatively low specificity, particularly for the FCN-101 model (43.07%). This indicates the presence of false-positive segmentation, with a proportion of normal background pixels being incorrectly segmented as cancerous. Such oversegmentation may be acceptable in identifying suspicious regions when emphasizing sensitivity. However, in the context of biopsy guidance, such behavior highlights the need for further optimization toward more precise boundary discrimination. Future work will focus on improving specificity through better loss function design, boundary-aware learning, and postprocessing strategies.

Limitations

This study combined registered WSIs and HFUS images to enhance cancerous region recognition in breast cancer, which has not been well-established in the literature. Still, we acknowledge the limitations of this study. First, it is a single-center prospective study with a small and potentially homogenous dataset, which undermines the model's generalizability and heightens the risk of overfitting. Besides, the small sample size in the test set limits statistical power and the generalizability of the prospective findings. To address this, we plan to incorporate data from multiple centers for robust external validation and conduct prospective studies to explore the models' role in assisting breast biopsy and postoperative follow-up after neoadjuvant therapy. Second, the relatively low recall indicates that some malignant regions may be missed; future studies will focus on improving model sensitivity through ensemble and data balancing approaches. Besides, benchmarking against widely adopted baseline models (eg, U-Net) could be performed in future research. Third, there is an absence of molecular subtype or pathological classification analysis and an imbalance of specific subtypes with small sample sizes (ductal carcinoma in situ in the test set). Given that different subtypes and cancer types exhibit distinct morphological features, a subtype-specific analysis could reveal performance differences and lead to refined models optimized for specific subtypes. Fourth, other imaging modalities such as color Doppler flow imaging, elastography, and contrast-enhanced ultrasound also play paramount roles in breast cancer diagnosis. For example, the lower prevalence of internal vascularity in the test set compared with the training set may have influenced model performance. Combining the information from multiple modalities could potentially further improve the performance of the CNN model. Fifth, the ultrasound-histopathology registration was based on biopsy WSIs and ultrasound images of the needle tract. Spatial correspondence should be regarded as approximate, and pixel-level metrics may overestimate the physical precision, which necessitates further refinement and validation via the whole-mount specimen.

Conclusion

In conclusion, we have proposed and evaluated deep learning models to identify cancerous regions in breast cancer in HFUS images through spatial registration of breast biopsy WSIs and HFUS images. This technique is potentially useful in conventional ultrasound examinations and ultrasound-guided breast biopsy procedures.

Abstract

Background: Colorectal cancer liver metastasis (CRLM) presents considerable challenges in both diagnosis and prognosis, as conventional approaches often are limited by subjectivity, variability, and limited efficiency. Recent advances in deep learning have shown great potential for automated extraction of pathological features, offering improved diagnostic accuracy and more reliable prognostic predictions.

Objective: This study aimed to develop and validate a multi-model ensemble deep learning framework (colon cancer liver metastasis network [CLM-Net]) for the automatic recognition and prognostic prediction of CRLM from pathological images, thereby enhancing diagnostic accuracy and clinical applicability.

Methods: A total of 197 pathologically annotated CRLM cases were collected and integrated from publicly available datasets (Kaggle and The Cancer Imaging Archive) to construct high-quality training and independent test sets. CLM-Net was built upon base convolutional neural network architectures including VGG16, DeepLab-v3, and U-Net, incorporating multi-scale atrous convolutions, a squeeze-and-excitation attention mechanism, a conditional random field refinement module, and transfer learning strategies. The framework was comprehensively evaluated using 5-fold cross-validation and independent testing for classification, segmentation, and prognostic prediction tasks. For survival prediction, 1024-dimensional image feature vectors extracted by CLM-Net were analyzed using logistic regression and random forest classifiers, with Kaplan-Meier curves and log-rank tests used for survival analysis.

Results: CLM-Net demonstrated superior performance in pathological image recognition, achieving 94% accuracy, 92% recall, 93% F_1-score, and an area under the receiver operating characteristic curve of 0.96 on the independent test set, outperforming single models. For survival prediction, CLM-Net with multi-scale attention achieved an area under the receiver operating characteristic curve of 0.864. Kaplan-Meier analysis revealed its significantly stronger risk stratification ability compared with VGG16, U-Net, and DeepLab-v3. Precision-recall curves and heatmaps further confirmed the model's high robustness and generalizability in unseen samples. Clinical evaluation by pathologists indicated strong interpretability and diagnostic utility, with a concordance rate of 90%.

Conclusions: The proposed CLM-Net framework, through the integration of diverse deep learning architectures and mechanisms, markedly improved the recognition and prognostic prediction of CRLM, demonstrating excellent generalization and clinical translation potential. Future studies will focus on multi-center validation and integration of multimodal features to further optimize its role in precision medicine.

KEYWORDS

colorectal liver metastasis; deep learning; pathological images; prognostic prediction; model evaluation; integrated learning

Introduction

Colorectal cancer (CRC) is among the most prevalent malignant tumors worldwide, with liver metastasis being a major cause of mortality in affected patients [1-3]. In high-income countries in particular, both the incidence and mortality rates of CRC remain high. According to global cancer statistics, CRC consistently ranks among the top cancers in terms of incidence, and approximately 25% to 50% of patients with CRC will eventually develop liver metastases. Hepatic metastasis not only represents the primary driver of CRC-related death but also markedly affects patient quality of life and treatment efficacy.

XSL•FO
RenderX

Early and accurate diagnosis, as well as reliable prediction of colorectal cancer liver metastasis (CRLM), is therefore essential for improving patient outcomes and guiding personalized therapeutic strategies [4-6]. Deep learning, a leading technology in the field of artificial intelligence, has demonstrated great potential in this area. By leveraging large-scale pathological image datasets, deep learning algorithms can autonomously learn and extract clinically relevant features, thereby enhancing the diagnostic precision and prognostic assessment of CRLM [7,8].

In recent years, the rapid advancement of deep learning technologies has revolutionized medical image analysis [9,10], enabling the efficient interpretation of complex pathological data through automated feature extraction [11]. Despite these advances, substantial gaps remain in the application of deep learning to the diagnosis and prognostic prediction of CRLM. Most existing studies rely on single deep learning models, which often struggle to accurately capture complex pathological features such as tumor boundaries and microarchitectural details. This limitation compromises the precision and robustness of predictive outcomes. Furthermore, how to effectively integrate the strengths of different deep learning algorithms to construct more comprehensive and reliable models remains an urgent challenge [8,12].

In recent years, deep learning techniques have been extensively applied to the diagnosis and prognosis prediction of CRLM. Most existing studies have relied on single-model frameworks—such as U-Net, ResNet, or temporal long short-term memory networks—for lesion segmentation, image classification, or dynamic disease prediction, respectively. However, these approaches often experience limited feature extraction capabilities, an inability to simultaneously address both diagnostic and prognostic tasks, and poor adaptability to the inherent heterogeneity of pathological images. To provide a comprehensive overview of the current landscape, we systematically reviewed representative deep learning-based studies in CRLM analysis, summarizing their specific tasks, data sources, advantages, and limitations (Table S1 in Multimedia Appendix 1). In contrast, the colon cancer liver metastasis network (CLM-Net) model proposed in this study integrates the architectural strengths of VGG16, DeepLab-v3, and U-Net, and incorporates multi-scale feature fusion, squeeze-and-excitation (SE) attention modules, and a conditional random field postprocessing component. These enhancements significantly improve image recognition performance while enabling accurate prognostic prediction and robust clinical applicability, effectively addressing the limitations of existing single-task models.

To overcome these challenges, we designed and developed a novel multi-model ensemble deep learning framework, CLM-Net, designed to enhance both the efficiency and accuracy of pathological image analysis in CRLM. CLM-Net harnesses the strengths of multiple deep learning architectures, including convolutional neural networks (CNNs) (eg, VGG16), segmentation models (eg, DeepLab-v3), and multi-scale processing modules. The model integrates multi-resolution pathological features to enhance representational power and generalizability. In the feature extraction stage, an SE attention mechanism is introduced to strengthen the model's focus on key lesion areas, thereby improving analysis precision. Additionally, the adoption of transfer learning not only accelerates model convergence but also enhances performance on limited-sample datasets.

CLM-Net is designed to address critical challenges in the diagnosis and prognostic evaluation of CRLM by automatically extracting and integrating microscopic features from pathological images, in combination with relevant clinical indicators. This integrated approach provides a highly efficient and accurate prediction tool. The primary objective of this study is to enhance diagnostic precision and prognostic assessment for CRLM, while overcoming limitations of current models in feature representation and overall performance.

This work not only bridges a significant technological gap in the field of CRLM diagnosis and prognosis but also opens new avenues for the development of personalized medicine. By coupling pathological feature extraction with predictive analytics, CLM-Net holds strong potential as a valuable tool in precision oncology for CRLM, contributing to both technological innovation and improved clinical decision-making.

In summary, we propose CLM-Net, a novel deep learning framework that incorporates multi-model ensemble learning, attention mechanisms, and transfer learning to enhance automated recognition and prognostic prediction of CRLM pathology images. We hypothesize that CLM-Net will demonstrate superior performance in diagnostic accuracy, prognostic capability, and generalizability compared with conventional single-model approaches and will be highly endorsed by clinical professionals for its practical utility.

Methods

Ethical Considerations

This study was conducted using publicly available datasets, including the Liver Tumor Segmentation dataset from Kaggle and The Cancer Imaging Archive (TCIA). Because the data are publicly accessible and fully deidentified, institutional review board approval was not required for this retrospective study in accordance with institutional policies of Yongkang First People's Hospital Affiliated to Hangzhou Medical College (policy document available upon request). The study was conducted in accordance with the ethical principles outlined in the Declaration of Helsinki.

All datasets used in this study contain anonymized patient information, and no identifiable personal data were accessed. Therefore, informed consent from individual participants was not required.

The study adhered to principles of data privacy and confidentiality, as only deidentified imaging and clinical metadata were used for research purposes.

No financial or other compensation was provided to participants, as this study did not involve direct patient recruitment or intervention.

Public Data Download and Integration

The pathological image data used in this study were primarily derived from 2 public databases: the Liver Tumor Segmentation Challenge dataset on Kaggle and TCIA. The Kaggle dataset contained 129 CRLM-related histopathological slides with corresponding clinical information, including age, sex, and tumor stage. To further enhance the sample size and diversity, an additional 68 CRLM cases were obtained from TCIA. In total, image data from 197 patients were included. After quality control and image augmentation, a final set of 1000 high-quality images was generated for model training and evaluation.

During preprocessing, low-resolution or unevenly stained images were excluded. All images were resized to 256×256 pixels to meet the input requirements of the model. Annotations were performed by experienced pathologists to ensure the accuracy of metastatic lesions and surrounding regions. Each image was linked to a unique patient identifier to guarantee patient-level independence across training, validation, testing, and prognostic modeling tasks.

Detailed Annotation of Pathological Images

Pathological image annotation was conducted by board-certified pathologists with over 10 years of professional experience. Using Aperio ImageScope software (version 12.3.3; Leica Biosystems, Germany), the experts meticulously annotated tumor regions and liver metastasis features within each slide. In addition, they recorded relevant clinical parameters, including tumor size and morphology, clarity of tumor boundaries with adjacent normal liver tissue, the spatial distribution of tumor-associated macrophages, and the density and localization of immune cells (eg, T cells and B cells) within the tumor microenvironment. All annotation data were saved in XML format to ensure compatibility and efficient parsing by the subsequent deep learning models.

Independent Verification and Annotation Error Control

To ensure annotation accuracy, all pathological images in this study were independently annotated by 2 experienced pathologists. Interrater reliability was assessed using the Cohen κ coefficient. In cases of disagreement, a third senior pathologist reviewed and confirmed the final annotation, ensuring both precision and consistency. To minimize manual annotation errors, the following quality control strategies were implemented:

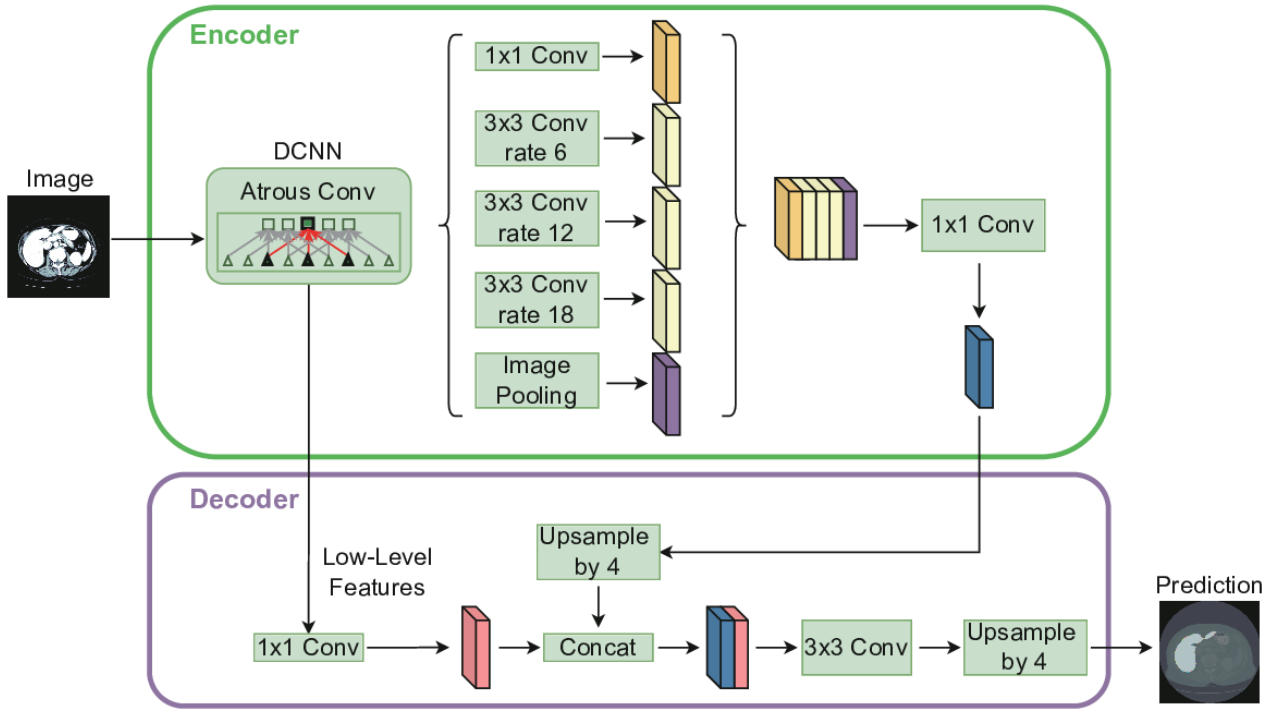
- Dual annotation and cross-validation: Each image was independently annotated by 2 pathologists, and results were cross-verified to reduce single-observer bias.
- Standardized training protocols: All participating pathologists underwent unified training and followed standardized annotation guidelines to ensure interobserver consistency.
- Tool-assisted annotation: Semiautomated annotation tools were used to assist in lesion identification, thereby enhancing both efficiency and accuracy.

These measures collectively ensured high-quality annotations, establishing a robust and reliable dataset for subsequent deep learning model training and analysis.

Application of Data Augmentation Techniques

To improve model generalization across diverse pathological image features, various data augmentation strategies were applied, tailored to the specific requirements of each deep learning architecture. For VGG16, images were first resized to 224×224 pixels using bilinear interpolation to match the model's input specification. Standard normalization was then performed by subtracting the dataset's mean pixel value and dividing by the SD, thereby transforming the pixel distribution to approximate a standard normal distribution. In the case of DeepLab-v3, numerical data were similarly normalized to a mean of 0 and an SD of 1. For textual data inputs, word embedding techniques were used to convert words into dense vector representations using pretrained models such as Word2Vec or GloVe for initialization. For U-Net, input images were also resized and normalized as described above. In addition, random cropping and horizontal flipping were implemented to increase data variability and reduce overfitting. All preprocessing steps were conducted using standard APIs provided by mainstream deep learning frameworks such as TensorFlow and PyTorch. Specifically, the torchvision.transforms module in PyTorch was used for image transformations.

Development of Basic Convolutional Neural Network Models



Several classical CNN models, including DeepLab-v3, VGG16, and U-Net, were used for the classification and segmentation of pathological images. All models were implemented using the PyTorch framework (version 1.7.1; Meta AI, Meta Platforms, Inc). To accelerate convergence and improve generalization, model parameters were initialized with pretrained weights from the ImageNet dataset. Training was conducted using the Adam optimizer, with a learning rate of 1×10^{-4}, a batch size of 32, and 50 training epochs.

DeepLab-V3

DeepLab-v3 is a state-of-the-art semantic segmentation model that incorporates dilated (atrous) convolutions to capture multi-scale contextual information without reducing spatial resolution. Its core component, atrous spatial pyramid pooling (ASPP), applies parallel atrous convolutions with varying dilation rates to extract rich semantic features at multiple scales, thereby enhancing model adaptability to complex structures in histopathological images. The use of dilated convolutions expands the receptive field without increasing the number of parameters or computational cost, enabling more comprehensive feature extraction. DeepLab-v3 follows an encoder-decoder architecture, where the encoder captures high-level semantic features, and the decoder restores spatial details for precise segmentation. Commonly, pretrained backbone networks such as Xception or MobileNet are adopted to serve as feature extractors, followed by the ASPP module and decoder to complete the segmentation task. The model structure is illustrated in Figure 1.

XSL•FO
RenderX

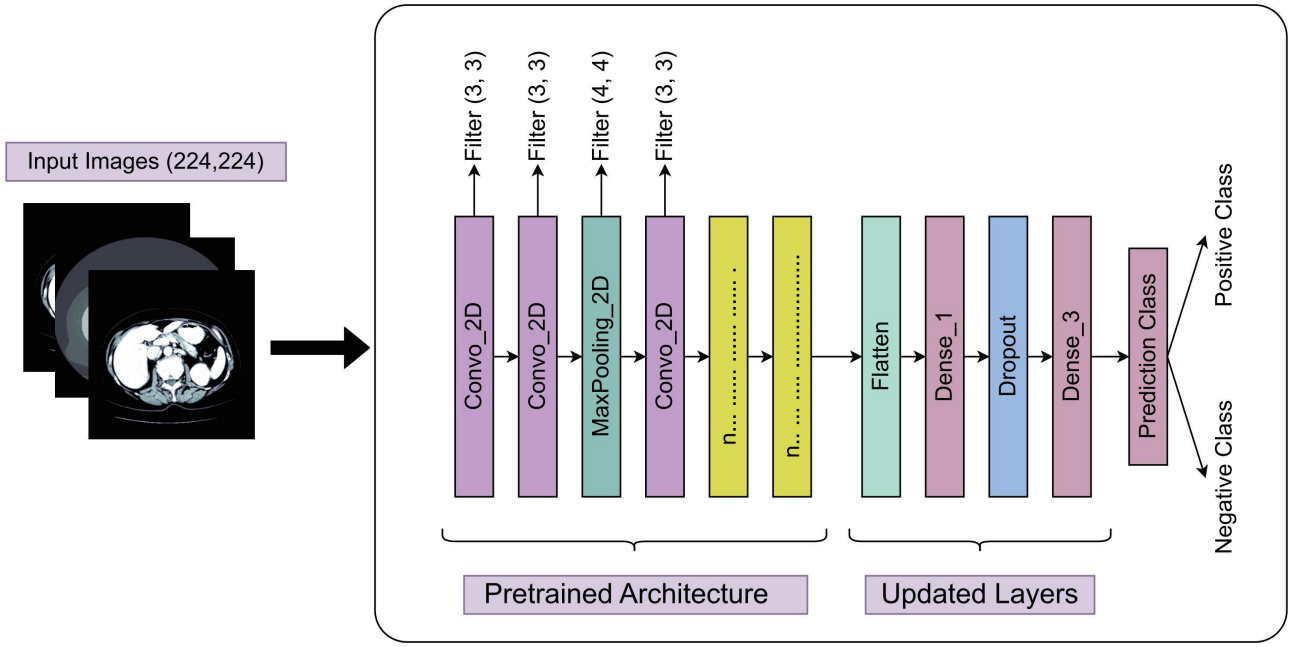


Figure 1. Schematic diagram of the DeepLab-v3 algorithm. DCNN: deep convolutional neural network.

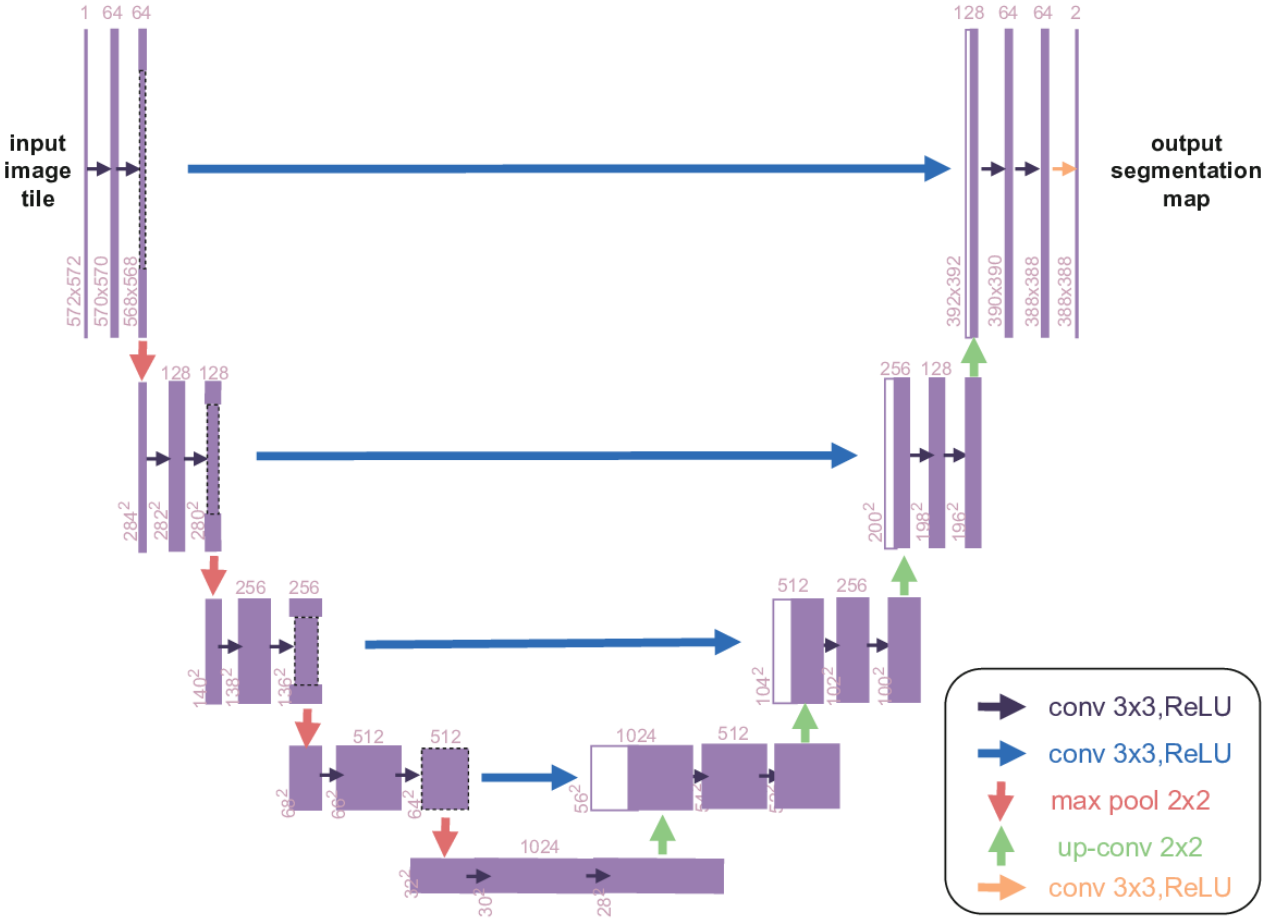
VGG16

VGG16 is a classic deep CNN composed of 16 layers, including 13 convolutional layers and 3 fully connected layers. It captures image features by repetitively stacking 3×3 convolutional kernels and 2×2 max-pooling layers. By using multiple small kernels, VGG16 achieves a larger receptive field while maintaining a relatively low number of parameters and a deeper network structure. Its architecture is straightforward and consistent, with fixed strides in all convolutional and pooling layers, which simplifies network design and optimization. In our study, VGG16 was initialized with pretrained weights from the ImageNet dataset. During training, images were preprocessed by mean subtraction and optimized using mini-batch stochastic gradient descent. The algorithmic framework is illustrated in Figure 2.

Figure 2. Schematic diagram of the VGG16 algorithm.

U-Net



U-Net is a neural network model specifically designed for medical image segmentation, characterized by its U-shaped architecture consisting of a contracting path (encoder) and an expansive path (decoder). A key feature of U-Net is the use of skip connections that merge encoder feature maps with corresponding decoder outputs, thereby preserving spatial

XSL•FO
RenderX

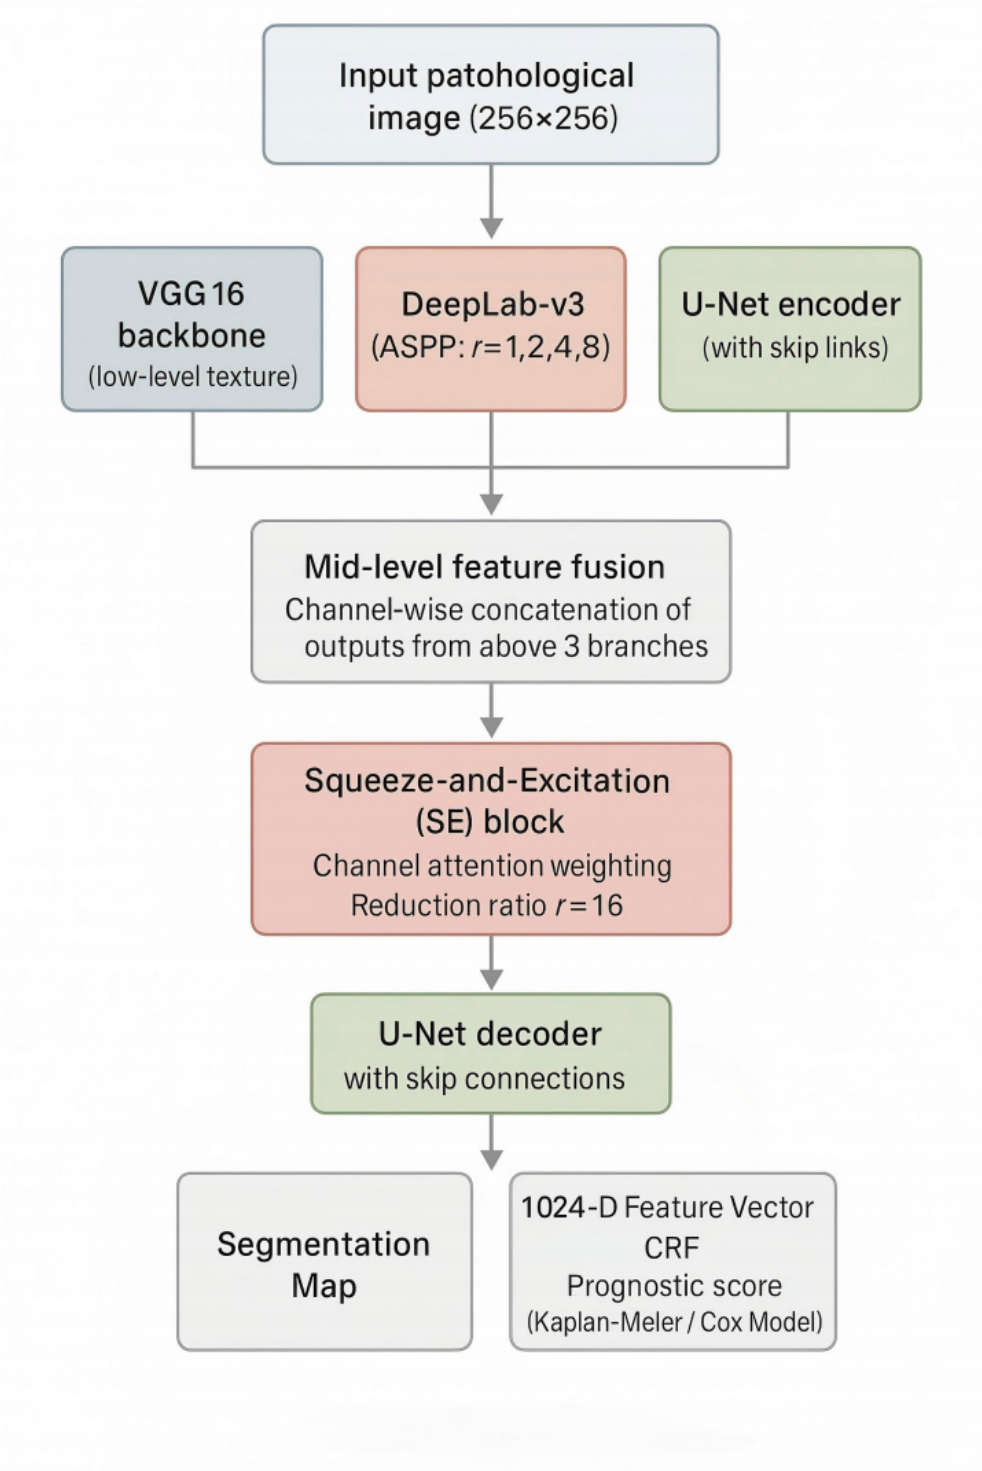
context and enhancing the reconstruction of fine-grained details. U-Net relies heavily on data augmentation techniques during training, such as rotation, scaling, and elastic deformation, to improve generalizability. In our implementation, the model was trained using the Adam optimizer, with a learning rate of 1×10^{-4}, a batch size of 8, and a cross-entropy loss function. The algorithm structure is shown in Figure 3.

Each of the 3 models demonstrates unique strengths for different image analysis tasks. DeepLab-v3 is suited for fine-grained segmentation and multi-scale feature extraction. VGG16, with its efficient and compact design, is often used as a backbone for various visual recognition tasks. U-Net, in contrast, excels in medical image segmentation, particularly in scenarios with limited datasets. Based on the complementary strengths of these architectures, we developed a customized CNN framework, CLM-Net, specifically tailored for the automatic recognition of pathological features in CRLM.

Figure 3. Schematic diagram of the U-Net algorithm. ReLU: rectified linear unit.

Design of the CLM-Net Model

CLM-Net is a CNN framework specifically developed for the automatic recognition of pathological features in CRLM histopathological images. The architecture adopts a parallel fusion structure that integrates the strengths of 3 widely used CNN models: VGG16, DeepLab-v3, and U-Net. Initially, input images are processed through a VGG16 backbone pretrained on ImageNet to extract low-level texture features. These features are then passed into 2 parallel branches: a DeepLab-v3 path and a U-Net path. The DeepLab-v3 branch applies atrous convolutions with dilation rates of {1, 2, 4, 8}, combined with an ASPP module, to capture rich multi-scale contextual information. Meanwhile, the U-Net branch adopts an encoder–decoder structure with skip connections to preserve spatial resolution and boundary detail. Mid-level feature fusion is performed by channel-wise concatenation of outputs from the VGG16, DeepLab-v3, and U-Net bottleneck layers.



To further enhance feature discrimination, a SE attention module (reduction ratio r=16) is inserted after the fusion stage to adaptively recalibrate channel-wise feature importance, improving the model's sensitivity to tumor-relevant features while suppressing background noise. The fused features are then passed through a unified decoder, and the final segmentation map is refined using a conditional random field module to enhance pixel-level consistency, particularly at lesion boundaries. In addition to the segmentation output, the decoder also generates a 1024-dimensional feature vector, which is used in downstream survival prediction tasks.

During training, CLM-Net used the same hyperparameters as the base models, including the Adam optimizer, a learning rate of 1×10^{-4}, a batch size of 32, and 50 training epochs. To address the limited size of the training dataset and improve model generalizability, extensive data augmentation techniques such as rotation, scaling, and elastic deformation were applied. By

XSL•FO
RenderX

integrating low-level feature extraction (VGG16), multi-scale semantic context (DeepLab-v3), and spatial detail preservation (U-Net), CLM-Net provides a robust and comprehensive solution for accurate CRLM lesion segmentation and prognosis prediction. The overall framework is illustrated in Figure 4.

Figure 4. Schematic diagram of colon cancer liver metastasis network (CLM-Net) feature extraction. CLM-Net comprises 3 parallel encoding branches: VGG16 for low-level texture feature extraction; DeepLab-v3 with a multi-scale atrous convolution ASPP module (dilation rates=1, 2, 4, 8) for contextual feature extraction; U-Net encoder with skip connections to retain spatial details. The mid-level features from the 3 submodels are integrated via channel-wise concatenation, followed by an SE attention module (reduction ratio *r*=16) to enhance channel-specific weighting. The fused features are fed into a shared decoder, which leverages U-Net skip connections to further recover spatial information. The decoder generates 2 outputs: a segmentation map for pathological image analysis and a 1024-dimensional feature vector for survival prediction. The outputs are refined by the conditional random field module, with the feature vector subsequently used in Kaplan-Meier or Cox proportional hazards models to predict survival probabilities in colorectal cancer liver metastasis patients. ASPP: atrous spatial pyramid pooling; CRF: conditional random field; SE: squeeze-and-excitation.

Performance Evaluation Metrics Calculation

To comprehensively assess the performance of various deep learning models for CRLM pathological image recognition, several metrics were used, including accuracy, recall, precision, F_1-score, and the area under the receiver operating characteristic curve (AUC). For prognostic analysis, survival-related assessments such as Kaplan-Meier curves were used. Parameter tuning was performed using a 5-fold cross-validation strategy. All metric computations were implemented in Python using the classification_report and roc_auc_score functions from the Scikit-learn library. Each model's performance on an independent test set was carefully documented to ensure objective and reliable evaluation.

Implementation of K-Fold Cross-Validation

To evaluate the generalization capability of each model, a k-fold cross-validation approach was adopted, with k set to 5. Specifically, the dataset was randomly partitioned into 5 equal subsets. In each iteration, one subset served as the validation set, while the remaining 4 were used for training. This process was repeated 5 times to ensure each subset was used once for validation. The cross-validation procedure was executed using the KFold class from the Scikit-learn library. This approach enabled a fair and comprehensive assessment of each model's generalization performance.

Model Performance Comparison and Optimal Model Selection

Upon completing training, validation, and evaluation, the models were compared based on average performance across all metrics, including accuracy, recall, F_1-score, and AUC. Custom Python scripts were used to facilitate a standardized and transparent comparison process. The model demonstrating the most favorable overall performance was selected as the optimal model. Subsequent to selection, this model underwent further refinement, including hyperparameter tuning and expanded data augmentation strategies, to enhance prediction accuracy and clinical applicability.

Training and Evaluation

All models were trained using the PyTorch 1.7.1 framework, with the Adam optimizer set at a learning rate of 1e−4, a batch size of 32, and for 50 training epochs to ensure adequate learning of data features. A transfer learning strategy was used by initializing model weights with pretrained parameters from the ImageNet dataset, which helped accelerate convergence and improve training stability. To comprehensively assess model performance, several evaluation metrics were used, including accuracy, recall, F_1-score, and the area under the receiver operating characteristic (ROC) curve (AUC). For prognostic assessment, Kaplan-Meier survival curves were generated to evaluate the model's ability to predict patient outcomes. All models were evaluated using 5-fold cross-validation. In this approach, the dataset was randomly divided into 5 equal subsets; during each iteration, one subset was designated as the validation set, and the remaining 4 served as the training set. This method ensured robust performance evaluation and validated the generalization capability of the models across different data partitions.

Evaluation of an Independent Test Set

To ensure the generalizability of the model and the reliability of the evaluation results, the dataset was obtained from publicly available databases and randomly divided into training, validation, and independent test sets in a 70% - 15% - 15% ratio. The training set was used for model training, the validation set for hyperparameter tuning, and the independent test set for final performance evaluation. The training set included approximately 700 images, the validation set 150 images, and the independent test set 150 images, all of which were annotated by experienced pathologists. A balanced class distribution between liver metastasis (Class 1) and nonmetastasis (Class 0) was maintained across all subsets to ensure consistent class representation during training and fair performance evaluation. Detailed class distribution across subsets is provided in Table S2 in Multimedia Appendix 1. All images were sourced from publicly available CRLM pathology databases, including TCIA and Kaggle. Image quality and annotation accuracy were verified through multiple rounds of manual verification by expert pathologists.

On the independent test set, the CLM-Net model demonstrated outstanding performance. Compared with other baseline CNN models, CLM-Net achieved notably higher scores in accuracy, recall, and F_1-score, indicating stronger generalization and robustness in recognizing pathological features of CRLM.

Definition and Calculation of Matching Rate

In this study, the matching rate was defined as the overlap between the model's predicted positive regions and the ground-truth annotated positive regions, calculated using the intersection over union (IoU). The specific formula is as follows: $IoU = \frac{Predicted\ Region \cap Ground\ Truth\ Region}{Predicted\ Region \cup Ground\ Truth\ Region}$.

To evaluate model performance, the IoU value for each pathological image in the independent test set was calculated. The overall matching rate was then evaluated by calculating the average IoU across the entire test set. The experimental results showed that the matching rate for all selected models exceeded 85%, with the CLM-Net model achieving the highest matching rate (close to 90%). This demonstrates the model's strong regional localization ability. Moreover, the high consistency of the matching rate across different samples reinforces the reliability of CLM-Net in pathological image analysis tasks.

Survey Design and Implementation

To assess the practical clinical applicability of the model, a standardized survey was designed and conducted. The survey comprised the following components: (1) quantitative assessment of the model's prediction accuracy, (2) evaluation of usability and user experience through a structured questionnaire, (3) subjective feedback from clinicians regarding the model's diagnostic assistance capabilities (via open-ended questions), and (4) suggestions for further improvement and optimization of the model (also via open-ended questions). The survey was administered to a cohort of 10 experienced pathologists and clinicians. Questionnaires were distributed electronically and collected during the model validation phase. The responses were analyzed using both quantitative statistical methods and qualitative text analysis, providing critical insights

XSL•FO
RenderX

to guide subsequent refinements in model development and optimization.

Evaluation of Prognostic Prediction Capability

To assess the prognostic prediction performance of the CLM-Net model in patients with CRLM, both traditional survival analysis methods and machine learning-based classifiers were used. Specifically, Kaplan-Meier survival curves and the Cox proportional hazards model were used to analyze survival outcomes across different patient groups. For prognosis prediction, the 1024-dimensional feature vectors were extracted from the final fusion layer of the CLM-Net encoder. These vectors integrated multi-scale representations from VGG16, DeepLab-v3 (with an ASPP module), and U-Net (with skip connections), further enhanced by an SE attention mechanism. To reduce dimensionality and suppress noise, 2 preprocessing strategies were adopted:

- Principal Component Analysis: Retained principal components explaining >95% of cumulative variance, typically preserving 80 - 100 dimensions.
- Variance-based Feature Selection: Removed low-variance features using a threshold of 0.01.

The processed feature vectors were input into 2 classical machine learning models:

- Logistic Regression: A linear model used to evaluate the influence of specific features on survival risk, using L2 regularization. The regularization parameter (C) was optimized through cross-validation over values of 0.1, 1, and 10.
- Random Forest Classifier: A nonlinear ensemble model used to capture complex feature interactions. Model tuning was performed via grid search, varying the number of trees (100 to 500) and maximum depth (5, 10, and 20). The optimal configuration was determined to be 100 trees with a maximum depth of 10. Patients were stratified into 2 prognostic groups: short-term survival (<30 d) and long-term survival (≥30 d) groups. Classifier performance was evaluated using accuracy, AUC, Kaplan-Meier survival curves, with statistical significance assessed via log-rank tests.

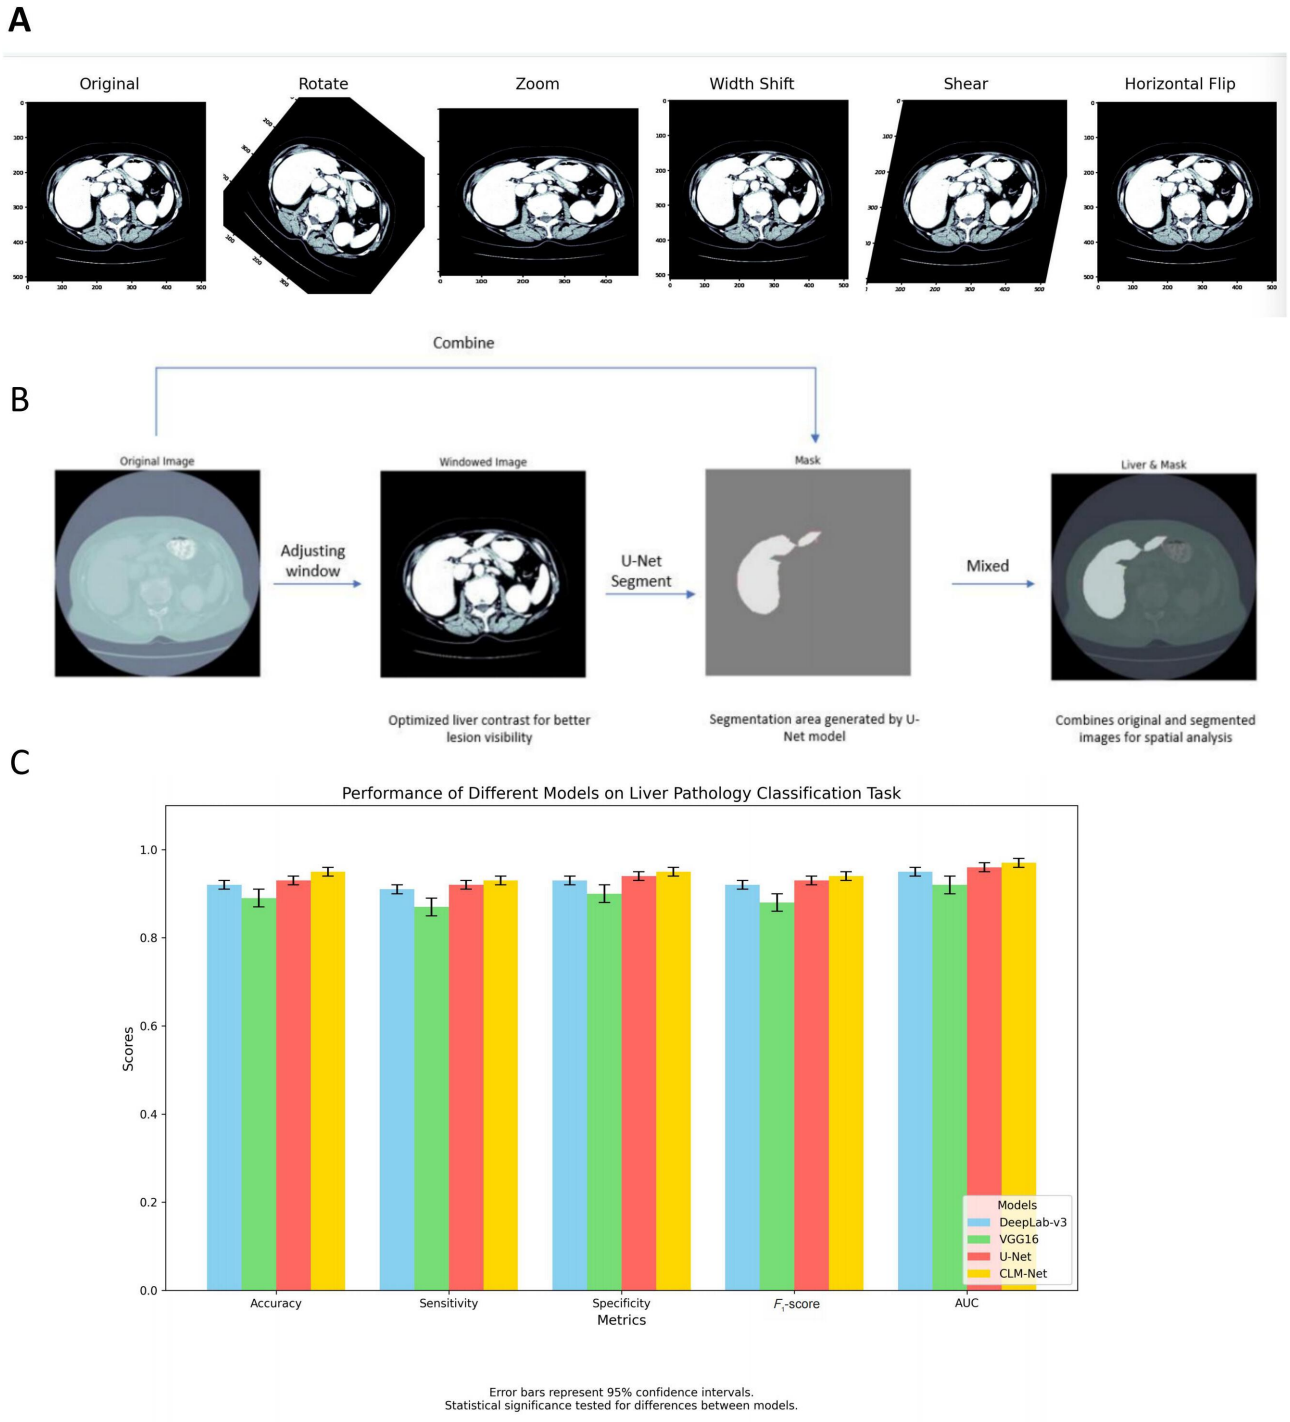
For comparative evaluation, the same prediction framework was applied to features extracted from 3 baseline deep learning models—VGG16, DeepLab-v3, and U-Net. Each model generated survival prediction probabilities from the input pathological images. A threshold of 0.5 was used to classify samples into short- and long-term survival groups. Kaplan-Meier curves were plotted for each model using the lifelines Python library, with time on the x-axis and cumulative survival probability on the y-axis. The Log-rank test was used to determine statistically significant differences among survival curves, and the final comparative results are presented in Table S3 in Multimedia Appendix 1.

Clinical Validation

This study was conducted as a retrospective analysis using publicly available datasets and did not involve any direct clinical trials or the use of patient data beyond those datasets. To assess the practical applicability of the model, we collaborated with clinicians from affiliated hospitals to evaluate its usability and diagnostic accuracy. Clinical experts reviewed the model's pathological image analysis outputs and compared them with conventional histopathological interpretations to assess its potential value in diagnostic support. Feedback from these professionals was systematically collected, focusing on diagnostic consistency, ease of interpretation, and clinical relevance. Based on this expert feedback, iterative modifications and optimizations were applied to enhance the model's clinical adaptability and reliability.

Results

Superior Performance of the CLM-Net Ensemble Model in CRLM Pathological Image Recognition



Throughout the model development and validation process, data augmentation strategies significantly enhanced the performance of all deep learning models, particularly the ensemble learning model. The application of random rotations, horizontal flips, and cropping effectively increased training data variability, thereby improving model robustness and generalizability to previously unseen pathological images (Figure 5A). This approach is especially critical in the context of CRLM, where metastatic lesions are known to be highly heterogeneous in appearance.

The ensemble learning model (CLM-Net) outperformed individual models across multiple evaluation metrics by leveraging the complementary strengths of each architecture. While certain base models, such as U-Net, excelled at delineating fine-grained tumor boundaries, others (eg, DeepLab-v3) were more proficient in identifying contextual and structural features of metastatic lesions. By integrating these capabilities, CLM-Net achieved a more comprehensive and accurate recognition of CRLM pathological features, thereby enhancing diagnostic reliability (Figure 5B).

In quantitative performance evaluation, CLM-Net demonstrated outstanding results in CRLM pathology image recognition, achieving an accuracy of 94% (95% CI 91.2% - 96.5%), a recall of 92% (95% CI 89.0% - 94.8%), an F_1-score of 93% (95% CI 90.1% - 95.9%), and an AUC of 0.960 (95% CI 0.941 - 0.975). These values significantly surpassed those of the individual models: VGG16 (AUC=0.901, 95% CI 0.872 - 0.925), DeepLab-v3 (AUC=0.912, 95% CI 0.884 - 0.936), and U-Net (AUC=0.887, 95% CI 0.857 - 0.913). The AUC improvement of CLM-Net over each baseline was statistically significant (DeLong test, P<.01), confirming its superior capability in both classification and segmentation of CRLM pathological images (Figure 5C). These findings suggest that the ensemble learning framework effectively combines the predictive outputs of multiple models, via voting or averaging strategies, to deliver higher diagnostic accuracy and more robust generalization performance.

RenderX

Figure 5. Comparative analysis of the CLM-Net model recognition process and experimental results on colorectal cancer liver metastasis (CRLM) pathological images. (A) Data augmentation techniques, such as random rotation, flipping, and cropping, enhance model training by increasing image diversity, improving generalization, and robustness in detecting complex patterns in CRLM images. (B) The recognition process involves preprocessing, feature extraction, and model integration, which enhances diagnostic accuracy and reliability in CRLM image analysis, providing valuable clinical insights. (C) A comparison of CLM-Net and individual models (VGG16, DeepLab-v3, and U-Net) shows that CLM-Net outperforms them in key metrics (accuracy, recall, F_1-score, and AUC), owing to its ability to synthesize different model strengths, enhanced by data augmentation. Error bars represent 95% CIs. Statistical significance was tested for differences between models. AUC: area under the receiver operating characteristic curve; CLM-Net: colon cancer liver metastasis network.

High Accuracy of Multi-Scale Attention Mechanisms in Prognostic Prediction

In the context of prognostic prediction for patients with CRLM, the integration of multi-scale processing and attention mechanisms demonstrated marked performance advantages. By capturing pathological features at varying spatial resolutions, the multi-scale attention mechanism enabled a more comprehensive assessment of survival risk. Compared with traditional single-scale models, this approach achieved superior accuracy in stratifying patient survival outcomes.

To validate its prognostic effectiveness, survival analysis methods were used. Kaplan-Meier survival curves and the Cox

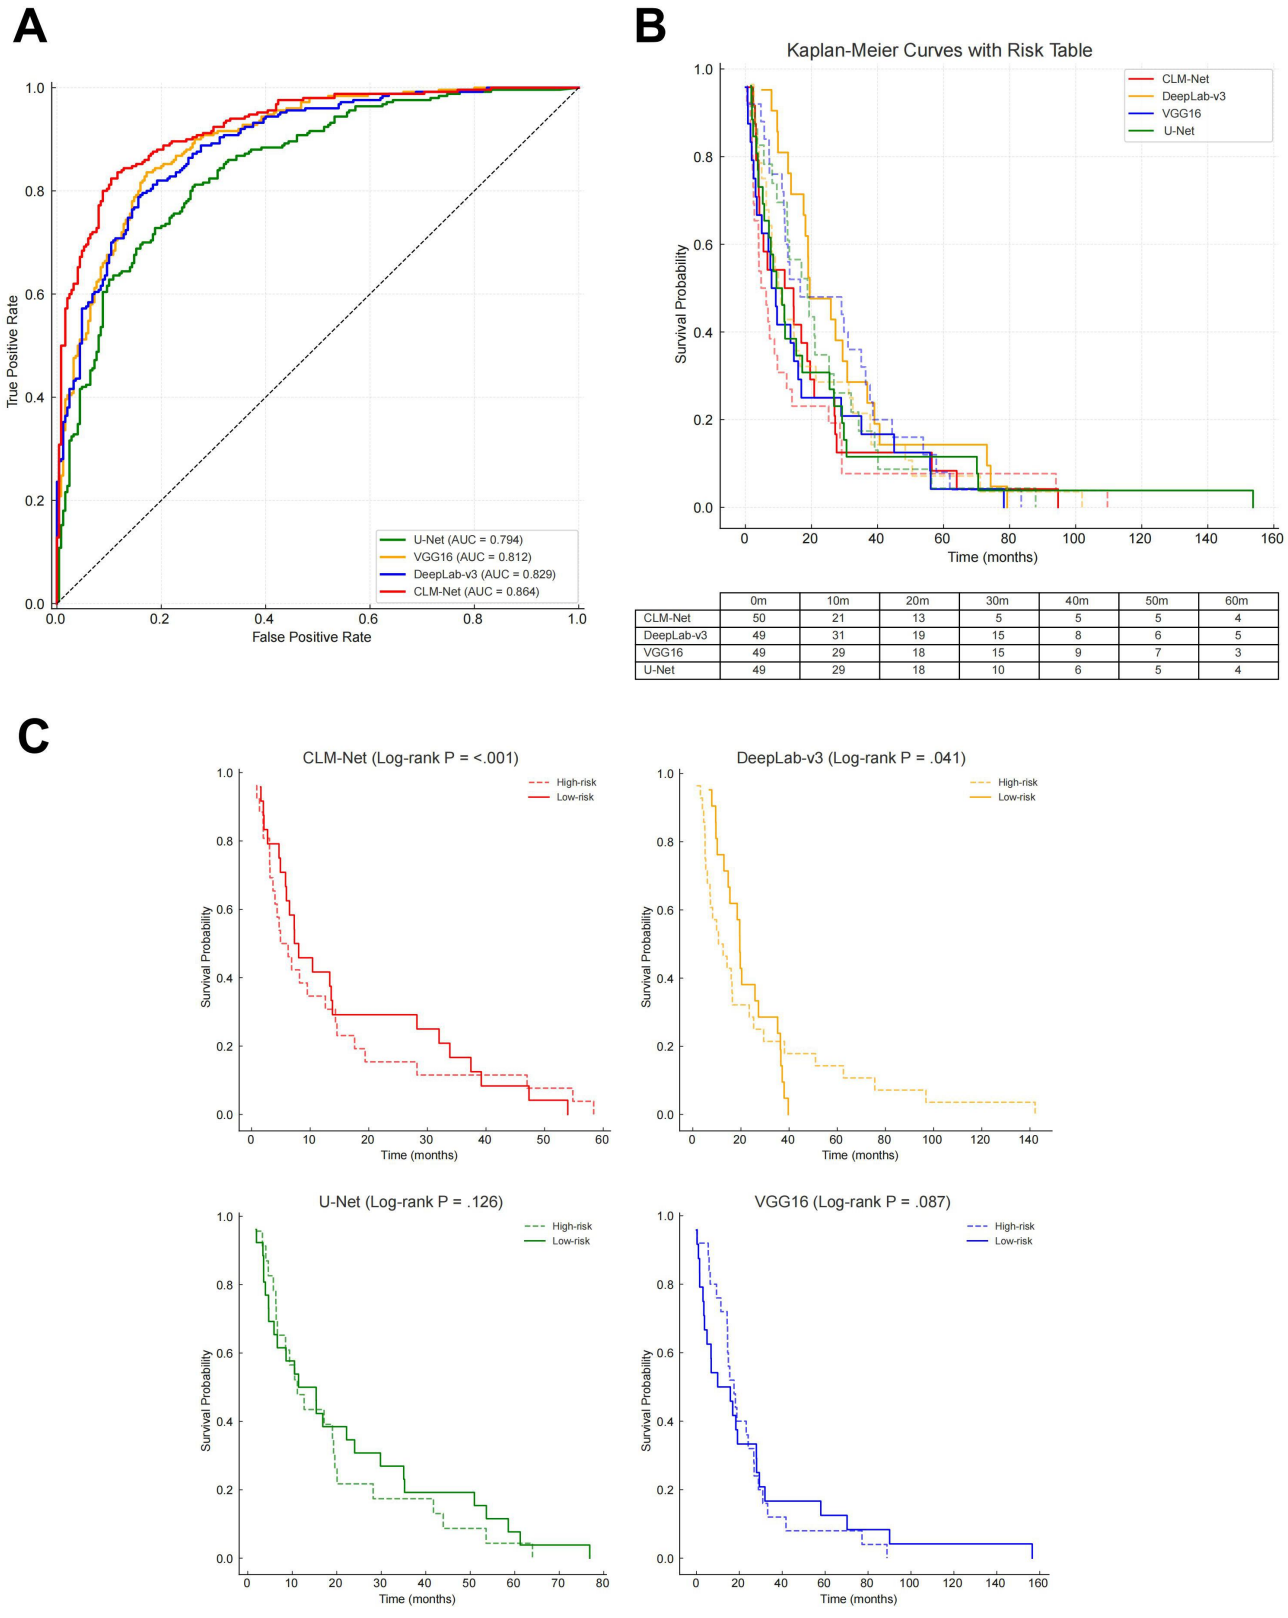
XSL•FO
RenderX

proportional hazards model confirmed the enhanced predictive capabilities of the multi-scale attention framework. Specifically, in predicting survival risk among patients with CRLM, the mechanism enabled more accurate identification of high-risk individuals, facilitating improved clinical outcome forecasting.

CLM-Net, equipped with multi-scale and attention modules, achieved the highest performance in the prognostic task. In ROC curve analysis, CLM-Net reached an AUC of 0.864 (95% CI 0.832 - 0.892), significantly outperforming VGG16 (AUC=0.812, 95% CI 0.775 - 0.846), DeepLab-v3 (AUC=0.829, 95% CI 0.796 - 0.861), and U-Net (AUC=0.794, 95% CI 0.758 - 0.827). Differences in AUC were statistically significant according to DeLong test (P<.05) (Figure 6A), supporting the superiority of CLM-Net's multi-scale design in extracting clinically relevant image features for survival prediction.

Moreover, the integration of attention mechanisms further enhanced the model's performance. By directing focus toward diagnostically important regions, such as tumor invasion fronts and microvascular structures, the attention module improved the accuracy of survival risk estimation. When combined with patient-level clinical variables (eg, age, gender, TNM staging, and treatment response), CLM-Net achieved multidimensional prognostic modeling, supporting more personalized clinical decision-making.

Comparative Kaplan-Meier survival curve analysis (Figure 6B) further illustrated the model's superiority. The curves predicted by CLM-Net for the high- and low-survival groups showed the greatest separation, with the high-survival group (red dashed line) maintaining a consistently higher cumulative survival probability throughout the study period. Log-rank tests confirmed the statistical significance of CLM-Net's predictions compared with those of VGG16 (P=.01), DeepLab-v3 (P=.007), and U-Net (P=.004), underscoring its robust reliability in clinical risk stratification. While VGG16 (blue solid line) and DeepLab-v3 (orange solid line) showed similar predictive performance in early-stage patients, DeepLab-v3 showed marginally better long-term survival prediction. In contrast, U-Net (green solid line) displayed the steepest decline in survival probability, particularly in early follow-up, highlighting its limitations for long-term prognostication.



Further survival analysis (Figure 6C) stratified patients into high-risk (short-term survival) and low-risk (long-term survival) groups using a probability threshold of 0.5 based on model output. CLM-Net's Kaplan-Meier curves again displayed a clear and consistent separation between the groups, with the log-rank test yielding a highly significant P value (P<.001), confirming the model's stability and discriminative power. In comparison, survival curves generated by VGG16, DeepLab-v3, and U-Net showed weaker separation, with log-rank P values of .087, .041, and .126, respectively. Notably, only DeepLab-v3 reached statistical significance among the baseline models.

Taken together, these results highlight the clinical utility of the CLM-Net framework in identifying high-risk patients with CRLM. Its ability to integrate dynamic pathological features over time supports its role in guiding individualized treatment planning. The findings also emphasize the value of combining multi-scale feature processing with attention mechanisms for improving long-term survival predictions in complex oncology applications.

Figure 6. Application effectiveness of multi-scale processing models in prognostic prediction for patients with colorectal cancer liver metastasis. (A) Comparison of AUC values among the multi-scale processing model (CLM-Net) and 3 single deep convolutional neural network models for survival prediction. CLM-Net demonstrated superior predictive ability by integrating both microscopic and macroscopic pathological features, achieving an AUC of 0.86, outperforming other models (range 0.80 - 0.85). Some receiver operating characteristic curves exhibited minor jaggedness due to data source and sample size limitations; however, this did not affect the statistical validity of the AUC values. (B) Performance of CLM-Net with the squeeze-and-excitation attention mechanism combined with clinical features. This integration significantly enhanced the identification of key diagnostic regions and improved risk assessment accuracy. Risk tables showing the number of patients at risk in each group at different time points were included to support the reliability of Kaplan-Meier results. (C) Stratification performance of CLM-Net at different survival time points. Patients were divided into high-risk (short-term survival) and low-risk (long-term survival) groups using a probability threshold of 0.5. Log-rank tests confirmed statistically significant differences between curves (P<.05), verifying the effectiveness of CLM-Net in survival stratification. Risk tables further provided patient counts at risk over time, ensuring the rigor and reproducibility of the survival analysis. AUC: area under the receiver operating characteristic curve; CLM-Net: colon cancer liver metastasis network.

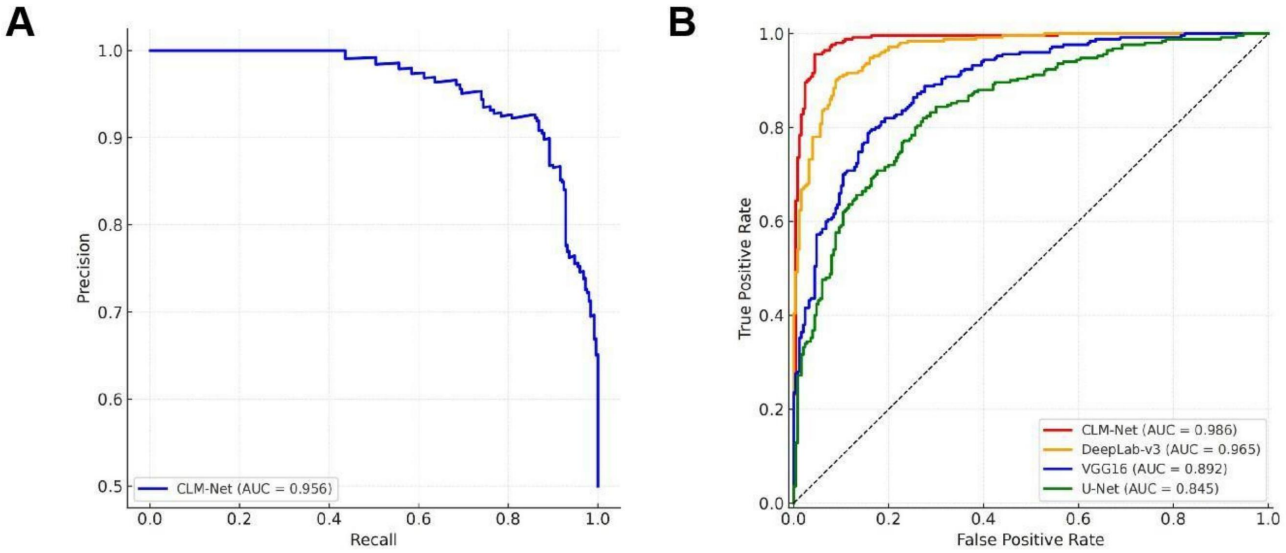
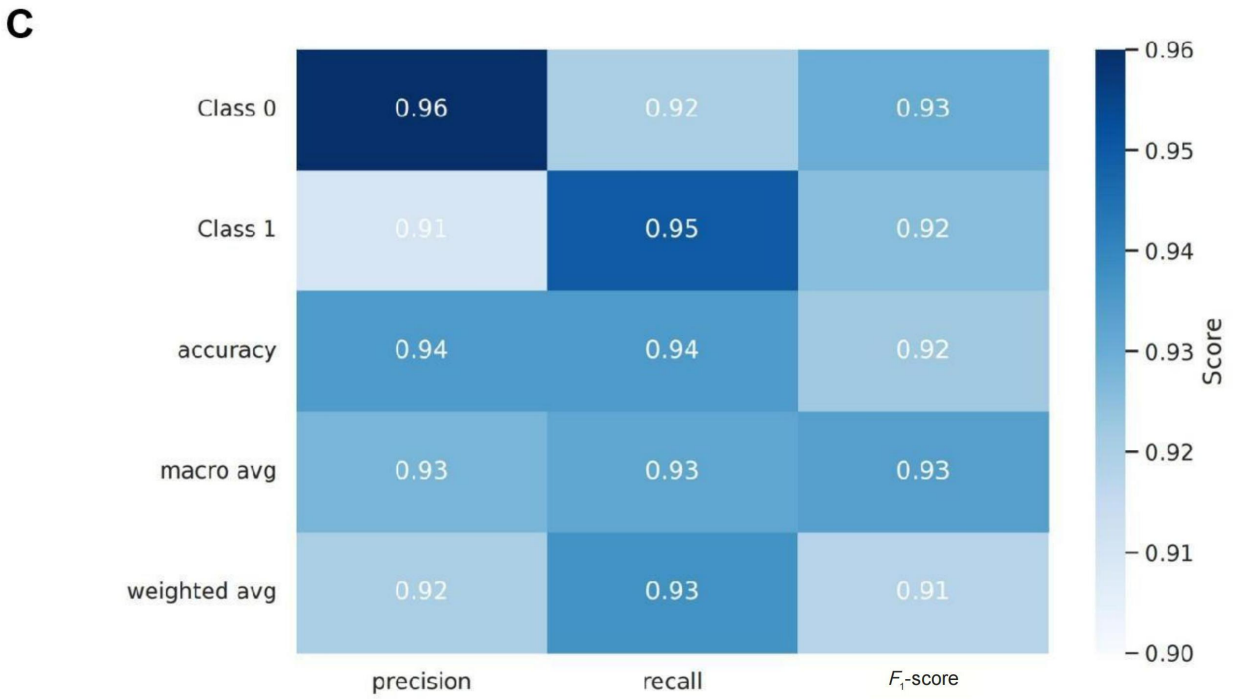
High Generalization Ability Demonstrated by Independent Test Set Validation



To validate the generalizability of the proposed model to previously unseen data, we conducted a systematic evaluation using the independent test set, with a particular focus on the performance of the ensemble learning framework and the multi-scale processing models (Figure 7). In the precision-recall (PR) curve analysis, the ensemble model demonstrated highly robust performance across 2 key tasks—CRLM identification and 28-day survival classification—with the PR curves maintaining a high plateau, indicating strong sensitivity to minority classes (Figure 7A). Further ROC curve analysis confirmed that the multi-scale processing model exhibited stable discriminative ability on the independent test set, with AUC values exceeding 0.95, suggesting that the model maintained



XSL•FO
RenderX

high classification accuracy even when applied to novel samples (Figure 7B).

To provide a more intuitive visualization of model performance across different classes and evaluation metrics, we constructed a classification report heatmap based on the independent test set (Figure 7C). This heatmap presents the precision, recall, and F_1-score for Class 0 (nonmetastasis) and Class 1 (metastasis), all exceeding 0.92. The weighted average precision and recall were both 0.93, indicating balanced overall performance with no significant bias. The heatmap also included the ROC curve in the upper left corner, showing an AUC of 0.96, further corroborating the model's excellent generalizability. Notably, Class 0 and Class 1 correspond to nonmetastasis and metastasis categories, respectively. The stable classification outcomes highlight the model's strong potential for deployment in real-world clinical practice.

Figure 7. Evaluation of the generalization ability of the integrated learning and multi-scale processing models on an independent test set. (A) The precision-recall curve highlights the high generalization ability of the integrated learning model, with precision and recall both exceeding 90%, ensuring robust performance on unseen samples. (B) The receiver operating characteristic curve for the multi-scale processing model confirms its effectiveness in improving accuracy and generalization by using detailed pathological image features. (C) A comparison of the models' performance on the independent test set further validates the effectiveness of integrated learning and multi-scale processing techniques in enhancing model generalization. High Evaluation of the Model in Clinical Applications by Physicians

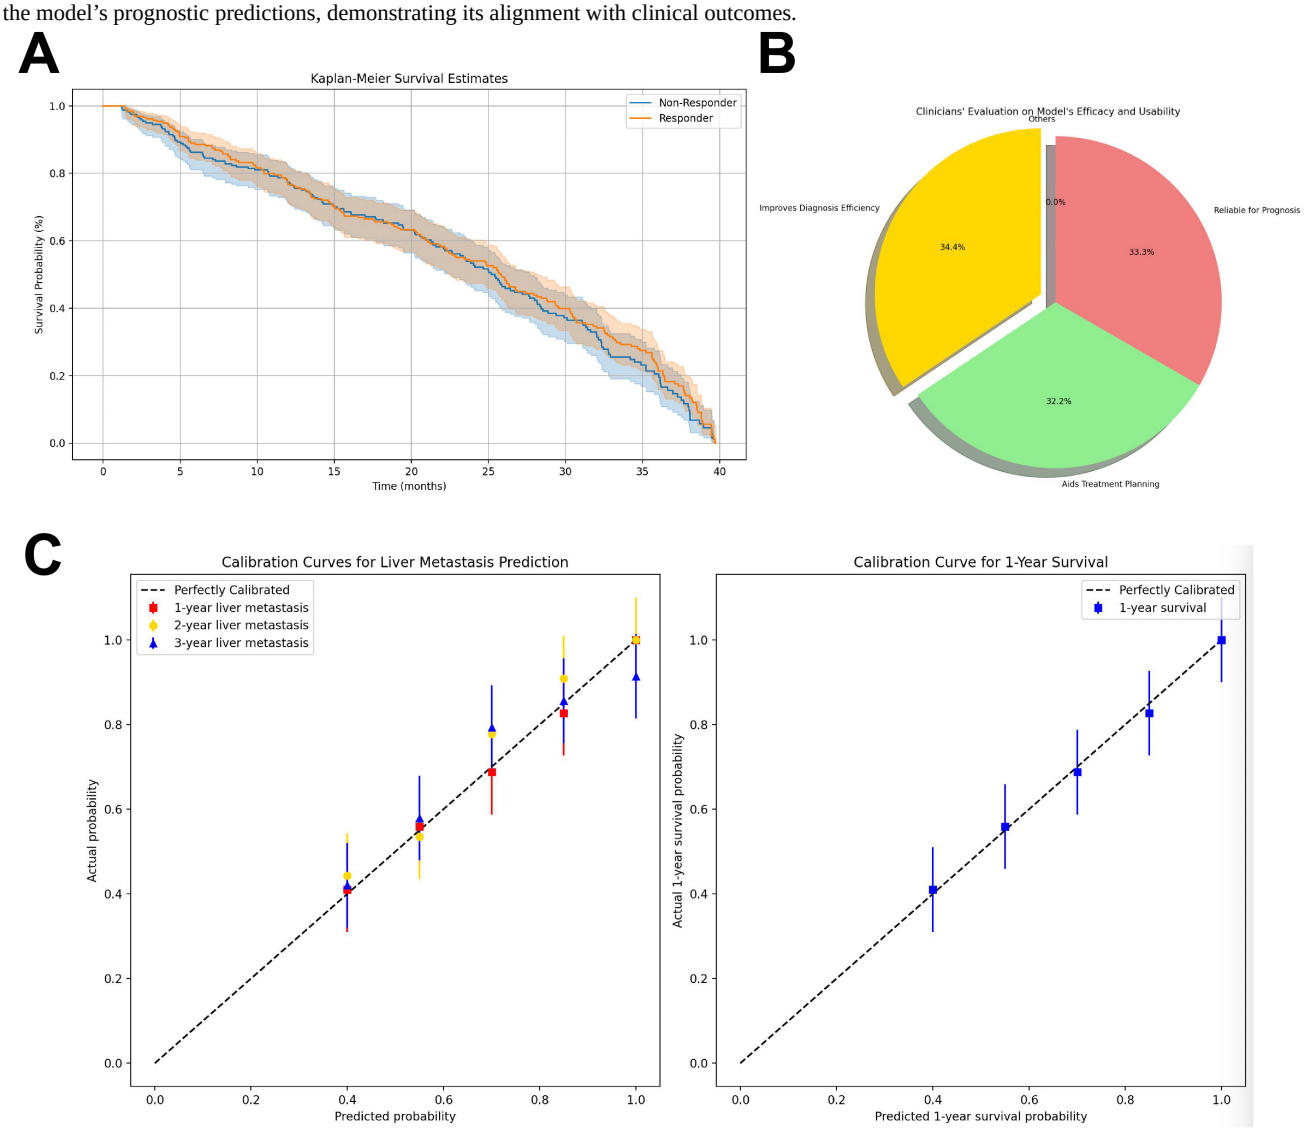
To validate the clinical applicability and prognostic accuracy of the proposed model, comparisons were conducted between model-predicted outcomes and clinical data from publicly available CRLM datasets. Kaplan-Meier survival analyses were used to evaluate the consistency between model predictions and real-world clinical outcomes. In this context, "responders" referred to patients whose clinical progression matched the model's predictions of favorable outcomes, whereas "non-responders" exhibited discrepancies between predicted and actual clinical results. The analysis revealed a concordance rate exceeding 90% between model-predicted and actual survival outcomes (Figure 8A), demonstrating the model's strong prognostic reliability in patients with CRLM and underscoring its potential utility in precision oncology.



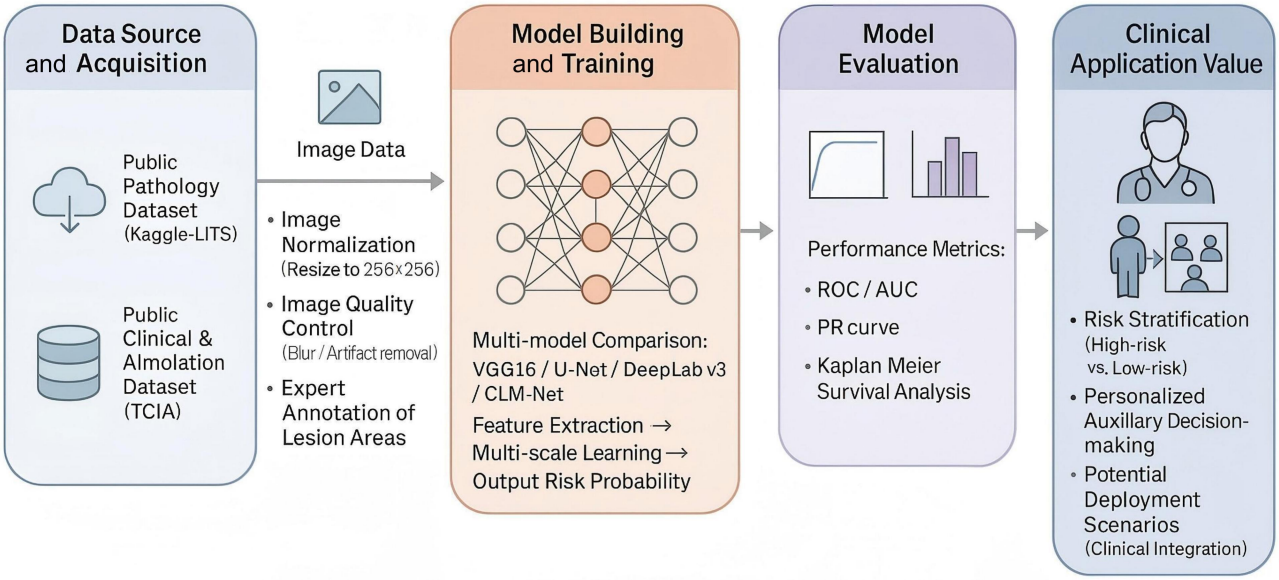
In addition to quantitative validation, qualitative feedback from physicians provided highly positive feedback on the usability and accuracy of the model's predictions. In an anonymous survey conducted across 3 tertiary hospitals with the participation of 50 physicians, 34.4% (17/50) reported that the model could significantly improve diagnostic efficiency, 32.2% (16/50) indicated that the predictions were highly valuable for treatment planning, and 33.3% (17/50) considered the model highly reliable in forecasting disease progression and patient survival (Figure 8B). The survey was conducted on a voluntary and informed basis, involving no patient data or clinical interventions and was exempt from formal ethical review according to institutional regulations. The questionnaire content is provided in Table S4 in Multimedia Appendix 1 to enhance transparency and reproducibility.

This study highlights the practical potential of deep learning models in supporting CRLM clinical decision-making. By assisting physicians in evaluating patient prognosis, the model facilitates more informed, efficient, and personalized treatment strategies (Figure 8C). Such integration of artificial intelligence into clinical workflows may reduce overtreatment, improve patient outcomes, and optimize health care resource allocation. Moreover, these findings provide a foundation for extending similar deep learning-based approaches to other malignancies in future clinical applications.

For prognostic modeling, the Cox proportional hazards regression model was used to estimate survival times, while Kaplan-Meier curves were generated to assess survival differences between responders and nonresponders. The inclusion of censored data (ie, right-censored survival times) did not significantly affect the model's performance, as confirmed by the log-rank test.

XSL•FO
RenderX

Figure 8. Evaluation of the clinical application of the model in colorectal cancer liver metastasis prognostic prediction. (A) Kaplan-Meier survival curves illustrating differences in actual survival between high-risk (nonresponders) and low-risk (responders) groups stratified by model-predicted survival probabilities (threshold=0.5). The results demonstrated significant differences between the 2 groups (log-rank test, $P<.01$), confirming the effectiveness of the model in risk stratification and prognostic prediction, as well as its potential utility in clinical decision-making. (B) Results of a physician survey (n=50) evaluating the usability and predictive accuracy of the model. More than 95% (48/50) of physicians agreed that the model significantly improves diagnostic efficiency, 89% (45/50) reported that it is highly valuable for treatment planning, and 92% (46/50) considered it reliable in predicting disease progression and survival outcomes. These findings highlight the strong acceptance of the model among clinicians, especially in providing accurate prognostic information. (C) A column chart shows the contribution of clinical indicators, such as tumor size and liver function, to the model's prognostic predictions, demonstrating its alignment with clinical outcomes.



Discussion

The primary finding of this study is that deep learning algorithms significantly enhance the automatic recognition of pathological features in CRLM and offer robust capabilities for prognostic prediction. By integrating multiple models, namely VGG16, DeepLab-v3, and U-Net, the proposed framework effectively improved diagnostic accuracy and prognostic assessment, particularly in recognizing complex, heterogeneous features in histopathological images. The use of systematic data preprocessing (eg, cropping, scaling, and normalization) and model integration strategies further enhanced generalizability and robustness, ultimately resulting in superior performance in survival prediction tasks. Compared with previous approaches, the combined use of ensemble learning, attention mechanisms, and transfer learning contributed to the exceptional performance observed in both image classification and prognostic evaluation (Figure 9).

RenderX

Figure 9. Mechanism diagram of the deep learning model for predicting colorectal cancer liver metastasis. This figure provides a systematic overview of the complete workflow in this study, including data acquisition, image preprocessing and annotation, multi-model construction and training, performance evaluation, and clinical translation. Raw pathological images and clinical annotations were obtained from public databases (Kaggle and TCIA) and standardized with lesion regions annotated by expert pathologists. Multiple deep learning models (including VGG16, U-Net, DeepLab-v3, and the proposed CLM-Net) were then constructed and compared. Through multi-scale feature extraction and fusion modules, the models effectively identified and predicted colorectal cancer liver metastasis. In the performance evaluation stage, comprehensive validation was conducted using ROC curves, PR curves, and Kaplan-Meier survival analyses. Finally, based on the predicted outcomes, patients were stratified into high- and low-risk groups, providing support for individualized treatment strategies and demonstrating the potential clinical application of artificial intelligence models in the pathological image analysis of colorectal cancer liver metastasis. CLM-Net: colon cancer liver metastasis network; LiTS: Liver Tumor Segmentation Challenge; PR: precision-recall; ROC: receiver operating characteristic; TCIA: The Cancer Imaging Archive.

While prior studies have demonstrated the utility of individual deep learning models in medical image analysis, their performance is often limited by an inability to simultaneously capture diverse morphological and contextual features. For instance, single-model approaches may exhibit strong performance in certain tasks—such as boundary delineation or feature localization—but often fail to generalize across varying pathological patterns, thereby limiting predictive accuracy and clinical applicability [13]. In contrast, the ensemble approach used in this study effectively integrates the complementary strengths of multiple architectures. As a result, the proposed CLM-Net model achieved an accuracy of 94%, a recall of 92%, an F_1-score of 93%, and an AUC of 0.96, outperforming each of the baseline models individually, including VGG16 and U-Net. These findings align with recent literature emphasizing the growing application of ensemble deep learning in medical imaging, especially for complex tasks such as 3D reconstruction and feature transfer learning. A recent publication in JMIR Medical Informatics [14] similarly reported improved model stability and accuracy through multi-model integration strategies. Ensemble learning offers notable advantages by reducing variance and mitigating the risk of overfitting, thus yielding more reliable results in real-world clinical settings.

The strength of this study lies in its integration of ensemble learning and multi-scale processing strategies, which collectively enhanced both diagnostic and prognostic accuracy while addressing the inherent limitations of single-model approaches in analyzing complex pathological images. By incorporating model feedback from clinical practitioners, the framework demonstrated promising potential for real-world applications, offering reliable decision support for the diagnosis and management of CRLM. This clinical collaboration underscores the model's translational value in supporting precision oncology.

Nevertheless, several limitations should be acknowledged. First, the model's performance relied heavily on access to a large volume of high-quality annotated pathological images, which can be difficult to obtain in clinical practice. Although data augmentation techniques were used to compensate for the limited dataset size, the quantity and variability of training data may still constrain the model's generalizability—particularly in scenarios with small sample sizes or rare pathological subtypes [15].

Second, the generalization capability of the model has not yet been extensively validated across external datasets from different institutions. Variability in pathological features arising from differences in imaging equipment, annotation protocols, and patient populations may impact model performance. As recent studies have emphasized, cross-center validation remains critical for ensuring clinical robustness and widespread applicability [16].

Third, this study primarily focused on image-based prediction and did not incorporate other potentially informative clinical modalities, such as molecular biomarkers or genomic profiles. Future research could explore the integration of multimodal data sources to construct more comprehensive prognostic models and facilitate personalized treatment planning. As highlighted in recent literature, multimodal fusion approaches are increasingly recognized for their potential to enhance prediction accuracy and clinical interpretability [17,18].

XSL•FO
RenderX

Future studies may further improve upon the present findings in several directions. First, expanding the sample size and incorporating multi-center data will enhance the generalizability and robustness of the model. Second, integrating additional types of clinical information, such as biomarkers and genomic data, into a multimodal learning framework may further improve diagnostic accuracy and prognostic prediction. Moreover, building on related findings [19], future research could provide more comprehensive approaches to optimizing deep learning models and medical image analysis. Finally, optimizing model architectures, exploring novel deep learning algorithms, or refining existing methods may further improve performance on complex datasets and advance the development of medical image analysis [20].

Abstract

Background: Parkinson disease (PD) presents diagnostic challenges due to its heterogeneous motor and nonmotor manifestations. Traditional machine learning (ML) approaches have been evaluated on structured clinical variables. However, the diagnostic utility of large language models (LLMs) using natural language representations of structured clinical data remains underexplored.

Objective: This study aimed to evaluate the diagnostic classification performance of multiple LLMs using natural language prompts derived from structured clinical data and to compare their performance with traditional ML baselines.

Methods: We reformatted structured clinical variables from the Parkinson's Progression Markers Initiative (PPMI) dataset into natural language prompts and used them as inputs for several LLMs. Variables with high multicollinearity were removed, and the top 10 features were selected using Shapley additive explanations (SHAP)–based feature ranking. LLM performance was examined across few-shot prompting, dual-output prompting that additionally generated post hoc explanatory text as an exploratory component, and supervised fine-tuning. Logistic regression (LR) and support vector machine (SVM) classifiers served as ML baselines. Model performance was evaluated using F_1-scores on both the test set and a temporally independent validation set (temporal validation set) of limited size, and repeated output generation was carried out to assess stability.

Results: On the test set of 122 participants, LR and SVM trained on the 10 SHAP-selected clinical variables each achieved a macro-averaged F_1-score of 0.960 (accuracy 0.975). LLMs receiving natural language prompts derived from the same variables reached comparable performance, with the best few-shot configurations achieving macro-averaged F_1-scores of 0.987 (accuracy 0.992). In the temporal validation set of 31 participants, LR maintained a macro-averaged F_1-score of 0.903, whereas SVM showed substantial performance degradation. In contrast, multiple LLMs sustained high diagnostic performance, reaching macro-averaged F_1-scores up to 0.968 and high recall for PD. Repeated output generation across LLM conditions produced generally stable predictions, with rare variability observed across runs. Under dual-output prompting, diagnostic performance showed a reduction relative to few-shot prompting while remaining generally stable. Supervised fine-tuning of lightweight models improved stability and enabled GPT-4o-mini to achieve a macro-averaged F_1-score of 0.987 on the test set, with uniformly correct predictions observed in the small temporal validation set, which should be interpreted cautiously given the limited sample size and exploratory nature of the evaluation.

Conclusions: This study provides an exploratory benchmark of how modern LLMs process structured clinical variables in natural language form. While several models achieved diagnostic performance comparable to LR across both the test and temporal validation datasets, their outputs were sensitive to prompting formats, model choice, and class distributions. Occasional variability

XSL•FO
RenderX

across repeated output generations reflected the stochastic nature of LLMs, and lightweight models required supervised fine-tuning for stable generalization. These findings highlight the capabilities and limitations of current LLMs in handling tabular clinical information and underscore the need for cautious application and further investigation.

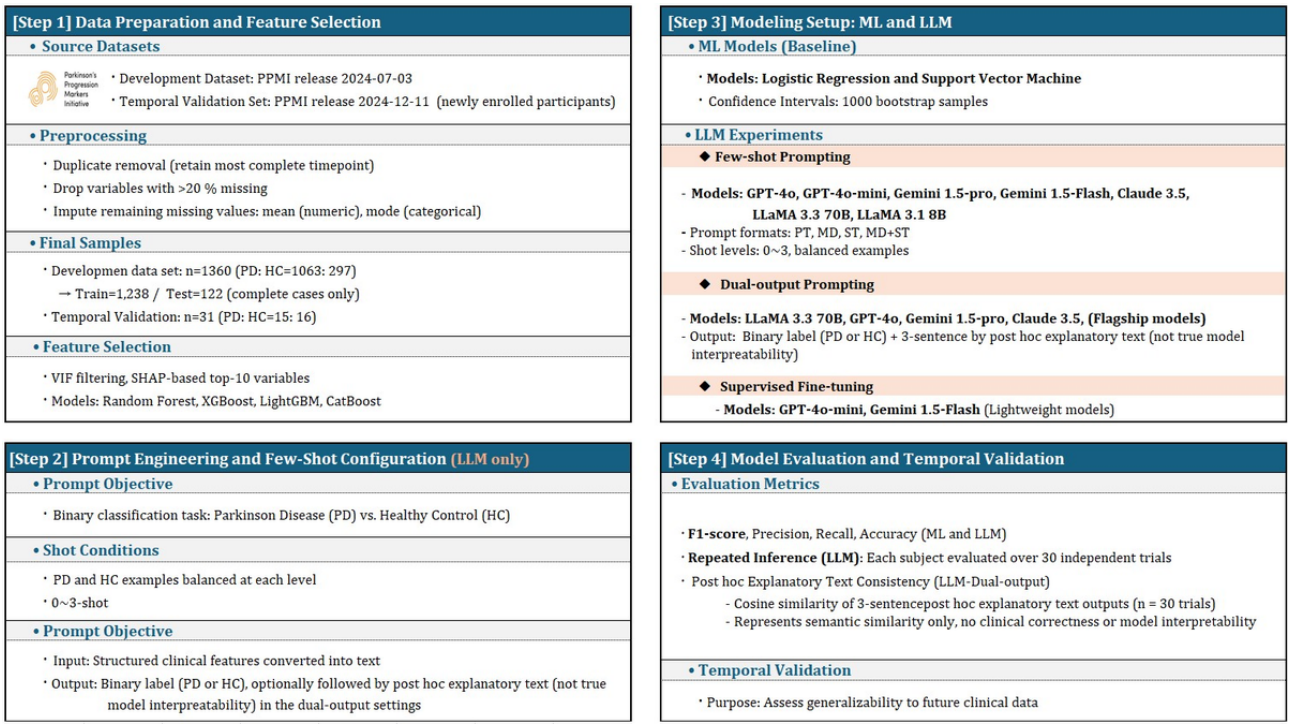
Introduction

Parkinson disease (PD) is the second most common neurodegenerative disorder and presents substantial diagnostic challenges due to the heterogeneity of its motor and nonmotor symptoms [1-3]. Despite sustained research efforts, early diagnostic accuracy remains limited, and the variability of clinical presentations continues to complicate reliable classification [4,5]. Large-scale initiatives such as the Parkinson's Progression Markers Initiative (PPMI) [6] have facilitated systematic evaluation of clinical, imaging, and biomarker variables, providing a foundation for quantitative approaches to PD diagnosis.

Machine learning (ML) models, including logistic regression (LR) [7], support vector machines (SVM) [8], and tree-based classifiers, have demonstrated strong performance when applied to structured clinical variables [9-11]. However, these models operate on fixed feature representations and do not naturally support flexible natural language inputs or generative reasoning, limiting their applicability when structured clinical data must be reformatted into descriptive text.

Recent large language models (LLMs) exhibit strong capabilities in processing natural language information and have shown promise in clinical applications involving unstructured text such as clinical notes and reports [12,13]. LLM-generated rationales typically represent post hoc explanatory text rather than true interpretability [14], and prior studies have reported challenges such as prompt sensitivity, stochastic variability, and susceptibility to distributional shifts when LLMs are applied to medical tasks [15]. However, their ability to perform diagnostic classification when structured clinical variables are reformatted into natural language prompts remains insufficiently explored, and recent work evaluating the performance of LLMs on structured or tabular data has reported limited and inconsistent results [16]. These characteristics highlight the need for careful and systematic evaluation when applying LLMs to structured clinical information.

In this context, the goal of this study was to conduct an exploratory benchmark of modern LLMs for PD classification using natural language prompts derived from structured clinical variables in the PPMI dataset. We compared multiple LLM families with traditional ML baselines and evaluated their behavior across few-shot prompting, dual-output prompting, and supervised fine-tuning. The study aimed to characterize both the capabilities and the limitations of LLMs in handling tabular clinical information, rather than demonstrating superiority over conventional ML approaches.



Methods

Overview

Figure 1 illustrates the overall methodological workflow of the study, detailing the progression from dataset selection and feature preprocessing to prompt construction, model training, and evaluation. It provides a concise visual summary of the experimental pipeline described in the Methods section.

XSL•FO

Dataset and Preprocessing

This study used a curated dataset provided by the PPMI, downloaded on July 29, 2024 (data release: July 3, 2024). The initial dataset consisted of 4 participant cohorts: individuals with PD, healthy controls (HC), participants with scans without evidence of dopaminergic deficit, and prodromal participants. For this study, only PD and HC participants were included.

Duplicate observations were removed by retaining the most comprehensive examination timepoint for each participant. Variables with more than 20% of missingness were excluded. Missing values in the remaining viables were imputed using mean imputation for numerical variables and mode imputation for categorical variables [17]. Participants included in the held-out test set and in the temporally independent validation set (temporal validation set) did not contain missing values and therefore required no imputation. Missing-value imputation was performed only for the training portion of the development dataset, which consisted of the train and validation subsets. Imputation statistics (mean and mode) were computed exclusively from the training split and subsequently applied to validation split. This procedure ensured that no information from the test or temporal validation sets influenced the preprocessing of the training data. After preprocessing, the final development dataset consisted of 1360 participants (PD, n=1063; HC, n=297).

A temporal validation set was constructed using the most recent curated PPMI dataset released on December 11, 2024. To ensure temporal separation, all data contained in the July 3, 2024, release were excluded, and only data from participants newly recruited after this release were included. This temporally separated dataset was used to assess the generalizability of model performance to data collected at a later timepoint. In clinical research, obtaining an external dataset with identical conditions is often challenging, and temporally separated datasets serve as a practical and widely accepted alternative for external validation [18,19].

Demographic characteristics of both the development and temporal validation datasets, including age, sex, education, and race, are summarized in Table 1.

XSL•FO

[a]Temporal validation set includes participants newly enrolled after the July 3, 2024, data release (excluded from the development set) and serves as a temporally separated dataset for external validation.

[b]PD: Parkinson disease.

[c]HC: healthy controls.

The development dataset was randomly divided into training, validation, and test subsets following an approximately 7:2:1 ratio. Only complete cases were included in the test set to ensure reliable evaluation. Feature selection and fine-tuning were performed exclusively using the training set. The test set was used solely for final model evaluation and was not involved in any feature selection or model fitting procedures. Class distributions for each subset are summarized in Table 2.

Table 2. Dataset splits and class distribution for diagnostic modeling.

Datasets and subsets	Total, n	PD[a], n (%)	HC[b], n (%)
Development set			
Training set	990	771 (77.9)	219 (22.1)
Validation set	248	193 (77.8)	55 (22.2)
Test set	122	99 (81.1)	23 (18.9)
Temporal validation set	31	15 (48.4)	16 (51.6)

[a]PD: Parkinson disease.

[b]HC: healthy controls.

Feature Selection

Multicollinearity Evaluation

To address multicollinearity, we generated a correlation matrix and computed the variance inflation factor for all candidate variables [20]. Variables with variance inflation factor values exceeding 10, a commonly accepted threshold for severe multicollinearity, were removed to prevent unstable coefficients and improve model reliability [21,22]. A total of 70 variables remained after this screening step and were used for Shapley additive explanations (SHAP)–based feature selection.

SHAP-Based Feature Importance

Feature importance was evaluated using a weighted average of SHAP values obtained from 4 tree-based models, including random forest [23], XGBoost [24], LightGBM [25], and CatBoost [26]. These models were selected because they are widely used for their tabular data and are known to mitigate issues related to multicollinearity while accommodating mixtures of numerical and categorical features effectively [27].

For each model, SHAP values were computed for all remaining variables, normalized, and then combined using a weighted averaging approach based on the diagnostic performance of each model. The performance metrics and assigned weights are summarized in Multimedia Appendix 1.

The weighted average SHAP value for each feature was calculated as [28]:

where:

- φ_{ij} represents the SHAP value of feature j computed by model i
- w_i represents the performance-based weight assigned to model i

XSL•FO
RenderX

- the denominator  ensures that weights are normalized so they sum to 1.

The top 10 variables were selected based on these weighted average SHAP values, as shown in Multimedia Appendix 2. The final features set consisted of clinically meaningful motor, olfactory, and imaging features. Specifically, the selected variables were updrs3_score, con_putamen, updrs_totscore, updrs2_score, lowput_expected, upsit_pctl, DATSCAN_PUTAMEN_L, con_striatum, mean_putamen, and DATSCAN_PUTAMEN_R. These features were used consistently across all subsequent ML and LLM experiments.

Prompt Construction

To evaluate the performance of LLMs, we developed 4 prompting formats that express input variables in plain text (PT), markdown (MD), special token (ST) annotations, and a combined markdown with special token (MD+ST) structure [29]. The PT format presents the input features as natural language sentences, whereas the MD format uses a structured table to delineate characteristics and enhance feature recognition, and the combined MD+ST format integrates both structured layout and explicit ST annotation.

Each prompting format was applied under 0-shot conditions to 3-shot conditions. All few-shot settings incorporated balanced PD and HC examples, with 1 pair for 1-shot, 2 pairs for 2-shot, and 3 pairs for 3-shot prompting. For dual-output prompting, the diagnostic label was followed by 3 sentences of post hoc explanatory text, which served as an exploratory output and did not represent true model interpretability [30].

For dual-output prompting, each LLM was instructed to generate a diagnostic label (PD or HC) followed by 3 sentences of post hoc explanatory text with a maximum length of 180 tokens to ensure comparability across models. Examples of all prompting formats, few-shot configurations, and sample outputs are provided in Multimedia Appendix 3.

Modeling Approaches

This study compared traditional ML classifiers with multiple LLMs in order to evaluate diagnostic performance under consistent experimental conditions. As deterministic baselines, we trained LR with L2 regularization and a SVM with a radial basis function (RBF) kernel, using the top 10 SHAP-selected features. Both models were implemented using standard scikit-learn procedures without extensive hyperparameter tuning, since the goal was to establish transparent and reproducible baselines rather than to maximize predictive performance. The complete hyperparameter configurations for the ML classifiers are summarized in Multimedia Appendix 4. These models were evaluated following the procedures described in the "Training and Evaluation Settings" section.

For LLM-based classification, we selected model families that collectively capture diversity in architecture, accessibility, and usage constraints. The included families were LLaMA, GPT, Gemini, and Claude. Each family provided one or more model variants with different parameter sizes or intended applications. The LLaMA models consisted of LLaMA 3.1 8B Instruct and LLaMA 3.3 70B Instruct, both of which were run locally using open-access model weights. The GPT models consisted of GPT-4o-mini and GPT-4o, accessed through the OpenAI application programming interface (API). The Gemini models included Gemini 1.5 Flash and Gemini 1.5 Pro, accessed through the Google Gemini API. For the Claude family, the Claude 3.5 Sonnet model was used. Although lightweight variants such as Claude Instant were available, the Sonnet model was selected due to budget considerations and its expected performance.

All LLMs were accessed through their officially supported APIs or locally hosted implementations using Python-based programmatic interfaces. The same prompting formats, shot settings, and evaluation procedures were applied across all models, except where input-format restrictions required specific handling. Additional implementation details, including software environments and API configurations, are provided in Multimedia Appendix 5.

Training and Evaluation Settings

Overview

The evaluation schedule and prompting phases for each model are summarized in Multimedia Appendix 6, and the hardware and software environments used in all experiments are described in Multimedia Appendix 7. To address the class imbalance between PD and HC, model performance was primarily assessed using the F_1-score, with precision and recall reported as supporting metrics. Accuracy was treated as a secondary measure, given that F_1-score provides a more balanced assessment under imbalanced classification tasks [31].

For all binary classification tasks, PD was assigned as the positive class (label=1) and HC as the negative class (label=0) across all ML and LLM experiments. Numerical features were standardized using *z* score scaling, where each variable was transformed by subtracting the mean and dividing by the SD computed from the training split. This ensured a consistent feature scale for both LR and SVM while preventing data leakage. Standardization using *z* score was applied exclusively to the ML baselines. For LLM-based experiments, models were provided with the original clinical values embedded in natural language prompts, rather than normalized numerical vectors. For ML models, performance uncertainty was quantified using 95% bootstrap CIs based on 1000 resampling iterations [32].

For LLMs, diagnostic classification was evaluated under 0-shot settings to 3-shot settings using 4 prompting formats including PT, MD, ST, and MD+ST. All few-shot experiments incorporated balanced PD and HC examples at each shot level. Across all LLM conditions, each participant was evaluated through 30 repeated model executions under identical prompting conditions to account for the inherent nondeterminism of LLM outputs [33]. Any change in diagnostic labels across these executions was recorded as a label inconsistency event. For dual-output prompting experiments, semantic consistency of the generated post hoc explanatory texts was also evaluated.

For each LLM and prompting configuration, macro-averaged performance metrics (F_1-score, precision, recall, and accuracy) were computed for each of the 30 model executions. Nonparametric 95% CIs for LLM performance were estimated

XSL•FO
RenderX

only for the temporal validation set using a hierarchical bootstrap procedure. In each iteration, participants were sampled with replacement and, for each selected participant, one prediction was randomly drawn from the 30 repeated trials. The 2.5th and 97.5th percentiles of the resulting performance distributions were reported in the temporal validation tables.

All combinations of prompting format and shot number were evaluated for each LLM on the development test set. The prompting configuration reported as the best for each model corresponds to the combination that achieved the highest macro-averaged F_1-score on this test set. During temporal validation, each LLM was evaluated using only under its best-performing configuration. This ensured that temporal validation assessed the generalizability of each model's optimal setting rather than retesting all prompt-shot combinations on temporally independent data.

ML Baseline Training Protocols

Two conventional ML classifiers were trained as deterministic baselines for comparison with LLM-based diagnostic approaches. The models were LR with L2 regularization and a SVM with an RBF kernel, both of which were trained using the same feature subset identified in the SHAP-based feature selection step. Class weights were applied to address the imbalance between PD and HC samples in the development set.

Both models were implemented using standard scikit-learn procedures without extensive hyperparameters optimization, as the primary goal was to establish transparent and reproducible baselines rather than to maximize predictive performance. LR was trained using the liblinear solver with balanced class weights, while SVM used an RBF kernel with probability estimation enabled. Performance for both models was evaluated for direct comparability with all LLM-based experiments.

Few-Shot Prompting Evaluation of LLMs

The LLMs were evaluated using the 4 prompting formats described earlier, applied across 0-, 1-, 2-, and 3-shot settings. Examples of PD and HC were balanced in all few-shot conditions to ensure consistent contextual exposure. All 4 prompting formats were applied to the LLaMA models. In contrast, only the PT and MD formats were applied to the GPT, Gemini, and Claude models because these API-based models do not support ST annotations in their input structure. Importantly, the inclusion of STs substantially influenced both diagnostic performance and output stability. Accordingly, ST-based prompting (including MD+ST) was applied exclusively to the LLaMA models as a model-specific input design choice, and the resulting differences in prompt structuring capability were explicitly considered as a limitation in cross-model comparisons.

Dual-Output Prompting of LLMs for Diagnosis and Post Hoc Explanatory Text

This experiment examined whether requiring LLMs to generate post hoc explanatory text could influence their diagnostic classification performance. Recent studies have shown that step-by-step prompting can improve LLM accuracy in complex decision tasks [34], yet fully stepwise reasoning is often impractical in clinical contexts due to token limitations. Rather than instructing the models to articulate their reasoning step by step, the models were prompted to produce concise post hoc explanatory text. This approach enabled assessment of whether a reduced explanatory demand could affect the diagnostic output.

Each model generated a binary diagnosis of PD or HC followed by exactly 3 sentences of post hoc explanatory text. To ensure consistency across models and to manage token usage, the length of these explanatory outputs was fixed. This dual-output prompting was applied to 4 models, including GPT-4o, Claude 3.5 Sonnet, Gemini 1.5 Pro, and LLaMA 3.3 70B. Among these, the LLaMA model was prompted using the ST format, whereas the other models were prompted using the PT format because these models do not support ST inputs.

Although the generated explanations were not reviewed by clinical experts, their semantic consistency was evaluated to assess the stability of the post hoc explanatory text under repeated prompting. High semantic consistency reflects only the reproducibility of the generated text across repeated runs and does not imply that the explanations are clinically accurate or factually grounded. For each participant, their explanatory outputs per model were collected, and pairwise cosine similarity between sentence embeddings was computed using the all-mpnet-base-v2 model from the Sentence-Transformers library [35,36]. This semantic consistency analysis was performed only on the development set, while the temporal validation set was used exclusively for the primary diagnostic evaluation.

LLM Supervised Fine-Tuning

Supervised fine-tuning was conducted to evaluate whether labeled training data could improve the diagnostic performance and output stability of lightweight LLMs. Unlike prompt-based learning, which is constrained by the number of examples that can be included within a single prompt, supervised fine-tuning allows the model to learn diagnostic patterns directly from the full training dataset.

Among the models tested in this study, GPT-4o-mini and Gemini 1.5 Flash were selected as compact and computationally efficient alternatives to assess how smaller LLMs perform relative to larger models. Both models were fine-tuned using the same dataset that was used in the prompting experiments, and all evaluations were performed under 0-shot conditions on the identical test set. The generation temperature was fixed at 0.1 to ensure consistent and deterministic behavior. Further details regarding fine-tuning platforms, sampling strategies, and training parameters are provided in Multimedia Appendix 8.

The GPT-4o-mini model was fine-tuned through the OpenAI API. Training jobs were submitted from a local workstation after converting the dataset into JSONL format. A total of 1052 samples were used for training and 186 samples for validation. The fine-tuning process followed OpenAI's job-based workflow, in which each training job is versioned and automatically made accessible through the OpenAI API upon completion.

The Gemini 1.5 Flash model was fine-tuned using the Google AI Studio platform. Because the platform restricts training to a maximum of 500 samples, stratified sampling was applied to

XSL•FO
RenderX

preserve the original class ratio, resulting in 383 PD samples and 117 HC samples. The model was trained for 1 epoch with a batch size of 1 and a learning rate of 1, after which the fine-tuned model was deployed via the Gemini API using the assigned model identifier.

All fine-tuned models were trained and evaluated using the PT prompt format to maintain consistency between training and testing conditions.

Ethical Considerations

This study used publicly available, deidentified data provided by PPMI. According to institutional policies and the PPMI Data Use Agreement, additional institutional review board approval was not required for secondary analyses of this publicly accessible dataset. The original PPMI study was conducted under institutional review board approval at all participating institutions, and all participants provided written informed consent permitting data sharing and secondary analyses. All analyses in this study were conducted on anonymized records with no personally identifiable information, and no participant compensation was applicable.

Results

ML Baseline Performance

To establish a deterministic baseline for comparison with LLM-based diagnostic approaches, we evaluated 2 conventional ML classifiers trained on the top 10 SHAP-selected features. LR and a SVM with an RBF kernel were implemented using standard scikit-learn procedures.

As summarized in Table 3, both models achieved identical performance on the test subset of the development set, yielding a macro-averaged F_1-score of 0.960 and an accuracy of 0.975. Precision and recall were balanced across PD and HC, and the 95% CIs ranged from approximately 0.94 to 1.00, reflecting the modest sample size of the test subset (n=122).

Table 3. Performance of machine learning models on the test subset of the development set (n=122; CIs were estimated via 1000 bootstrap iterations).

Model	F_1-score[a] (95% CI)	Precision (macro avg[b]/PD[c]/HC[d])	Recall (macro avg/PD/HC)	Accuracy
LR_L2[e]	0.960 (0.943-1.000)	0.953/0.990/0.917	0.968/0.980/0.957	0.975
SVM_RBF[f]	0.960 (0.944-1.000)	0.953/0.990/0.917	0.968/0.980/0.957	0.975

[a]F_1-scores represent macro avg values across PD and HC classes.

[b]macro avg: macro-averaged.

[c]PD: Parkinson disease.

[d]HC: healthy controls.

[e]LR_L2: logistic regression (L2 regularization).

[f]SVM_RBF: support vector machine (RBF kernel).

Table 4 presents the results from the temporal validation set (n=31). LR demonstrated moderately high generalizability, achieving a macro-averaged F_1-score of 0.903 and an accuracy of 0.903. In contrast, SVM showed a substantial decline in generalizability, producing a macro-averaged F_1-score of 0.484 with markedly reduced recall for PD. The wide CIs observed for both models reflect the limited size of the temporal validation set and the inherent uncertainty associated with evaluating performance on small external samples.

Table 4. Performance of machine learning models on the temporal validation set (n=31; CIs were estimated via 1000 bootstrap iterations).

Model	$F1$-score[a] (95% CI)	Precision (macro avg[b]/PD[c]/HC[d])	Recall (macro avg/PD/HC)	Accuracy
LR_L2[e]	0.903 (0.791-1.000)	0.917/0.833/1.0	0.906/1.0/0.813	0.903
SVM_RBF[f]	0.484 (0.157-0.506)	0.241/0.483/0	0.5/0/1.0	0.484

[a]F_1-scores represent macro avg values across PD and HC classes.

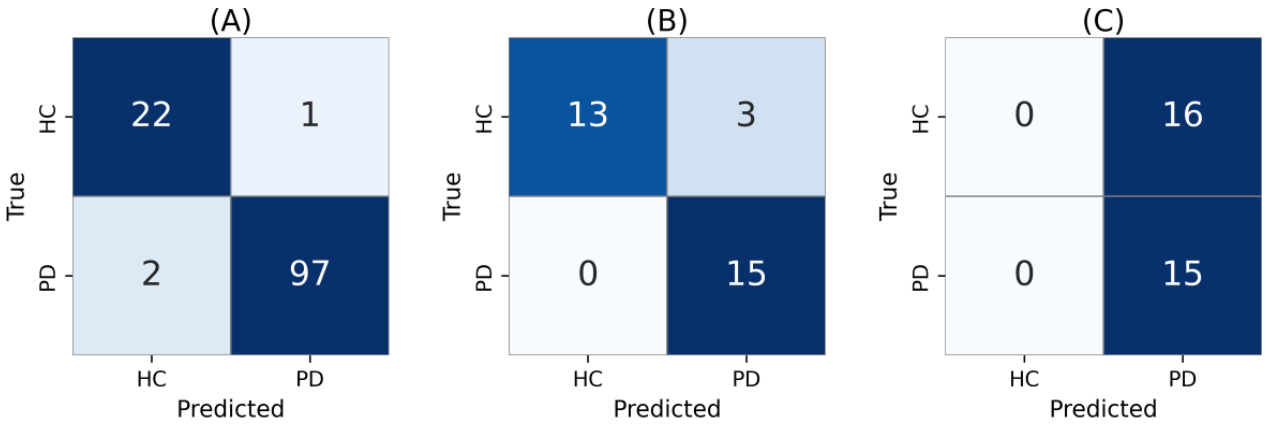
[b]macro avg: macro-averaged.

[c]PD: Parkinson disease.

[d]HC: healthy controls.

[e]LR_L2: logistic regression (L2 regularization).

[f]SVM_RBF: support vector machine (RBF kernel).



Given the small size of the temporal validation set (n=31), results obtained on this dataset should be interpreted with caution, as performance estimates may be sensitive to individual misclassifications.

Figure 2 illustrates the prediction patterns for the 2 classifiers across both datasets. On the development test subset (Figure 2A), both models produced identical predictions, misclassifying 1 HC participant as PD and misclassifying 2 PD participants as HC. In the temporal validation set, LR misclassified only 3 HC cases as PD (Figure 2B), whereas SVM misclassified nearly all HC cases (Figure 2C). Although the two models performed similarly on the development test subset, their stability diverged

XSL•FO
RenderX

substantially when evaluated on data collected at a later timepoint.

Figure 2. Confusion matrix for machine learning classifiers. (A) Test subset of the development set. (B) Logistic regression of temporal validation set. (C) Support vector machine of temporal validation set. HC: healthy controls; PD: Parkinson disease.

Few-Shot Prompting Performance of LLMs

A total of 4 prompting formats, including PT, MD, ST, and MD+ST, were evaluated under 0-shot conditions to 3-shot conditions to assess the diagnostic performance of LLMs. ST-based prompts were applied exclusively to the LLaMA models because the inclusion of STs substantially affected both classification accuracy and output stability. Non-LLaMA models such as GPT, Gemini, and Claude did not support ST formatting and were therefore evaluated using PT and MD formats.

Table 5 presents the best-performing results for each model on the test dataset (n=122). The best-performing configuration for each model corresponds to the prompt type and shot number that achieved the highest macro-averaged F_1-score on the development test set.

LLaMA 3.3 70B and Gemini 1.5 Pro achieved the highest macro-averaged F_1-score of 0.987 with an accuracy of 0.992 and stable predictions across 30 repeated trials. LLaMA 3.1 8B reached the same F_1-score using the MD+ST prompt at the 3-shot setting but showed one instance of prediction inconsistency. Claude 3.5 Sonnet demonstrated strong performance with an F_1-score of 0.972 and an accuracy of 0.984 under 1-shot MD setting, maintaining complete consistency across repeated runs. GPT-4o and GPT-4o-mini achieved slightly lower but stable performance, with macro-averaged F_1-scores of 0.961 and 0.910, respectively. Gemini 1.5 Flash produced the lowest F_1-score (0.894) despite consistent predictions, reflecting reduced sensitivity for HC cases. Detailed per-participant consistency analyses across 30 trials are provided in Multimedia Appendix 9.

Figure 3 displays the confusion matrices for the best-performing configuration of each model. Most classification errors occurred in HC samples, indicating high sensitivity for PD across the LLMs.

Figure 3. Confusion matrices of large language models under the best-performing configurations on the test dataset (n=122). HC: healthy controls; PD: Parkinson disease.

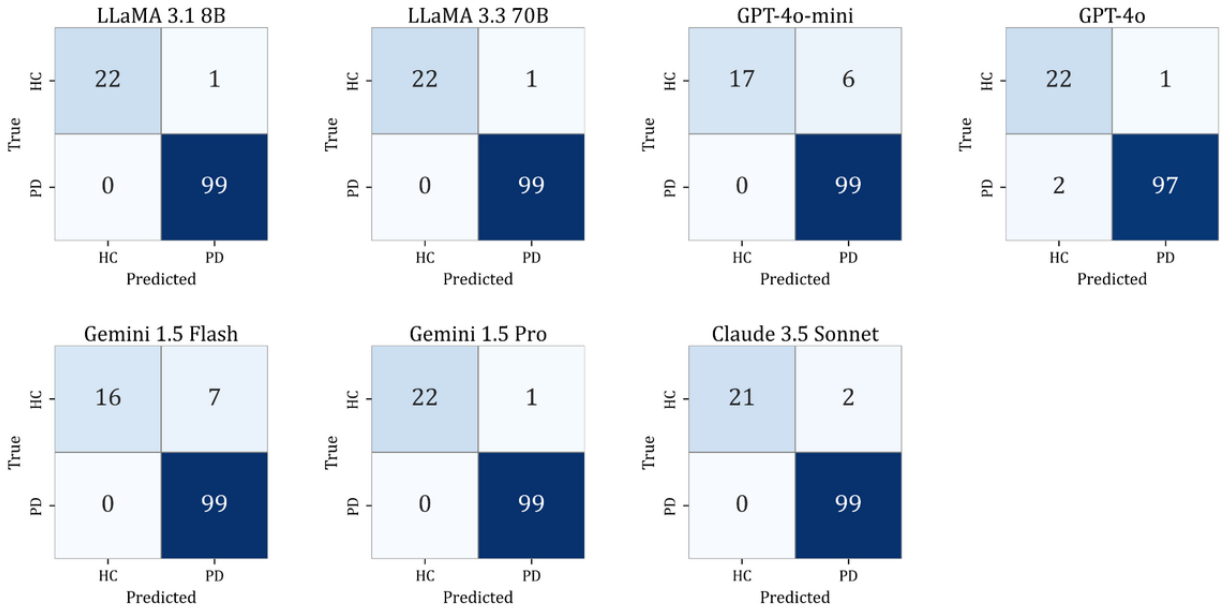

Table 6 and Figure 4 summarize the best-performing configuration of each LLM on the temporal validation set (n=31). LLaMA 3.3 70B achieved the highest macro-averaged F_1-score of 0.968 using the ST format at the 2-shot setting, with recall of 1.00 and consistent predictions across all participants. LLaMA 3.1 8B, Gemini 1.5 Pro, and Claude 3.5 Sonnet showed

XSL•FO
RenderX

comparable performance, each achieving a macro-averaged F_1-score of 0.936 with stable predictions. GPT-4o and Gemini 1.5 Flash achieved moderately high performance (F_1-score=0.903), with consistent predictions across all participants. In contrast, GPT-4o-mini achieved the lowest F_1-score (0.836), driven primarily by reduced recall for HC cases. Across all models, recall for PD remained consistently high (recall≥0.938), demonstrating strong sensitivity even when evaluated on data collected at a later timepoint. Figure 4 shows the confusion matrices for each model under the prompt and shot condition listed in Table 6.

These findings indicate that LLMs generally maintained high diagnostic accuracy and prediction stability under temporally separated data, supporting their potential generalizability beyond the development dataset.

Diagnostic Performance Under Dual-Output Prompting

Dual-output prompting was used to evaluate whether requiring LLMs to generate post hoc explanatory text influenced their diagnostic reliability. This experimental setting included 4 representative models, namely LLaMA 3.3 70B, GPT-4o, Gemini 1.5 Pro, and Claude 3.5 Sonnet. Unlike diagnostic-only prompting, this setup instructed each model to output a binary diagnostic label followed by 3 sentences of post hoc explanatory text. Because the LLaMA models are highly sensitive to input formatting, dual-output prompts for LLaMA 3.3 70B were constructed using the ST format. GPT-4o, Gemini 1.5 Pro, and Claude 3.5 Sonnet do not support ST inputs, and therefore PT prompts were used for these models to maintain compatibility.

As summarized in Table 7, all models achieved high diagnostic performance under dual-output prompting, although overall F_1-scores were slightly lower than those obtained under few-shot prompting. LLaMA 3.3 70B and Claude 3.5 Sonnet each achieved a macro-averaged F_1-score of 0.972 and correctly identified all PD cases. GPT-4o and Gemini 1.5 Pro showed similar results and achieved F_1-scores of 0.958 with an accuracy of 0.975. Most prediction errors occurred in HC cases, whereas all PD samples were correctly classified. Instances of inconsistency across 30 repeated trials were rare, typically affecting no more than 2 participants for each model. The full repeated-trial results are presented in Multimedia Appendix 10.

Figure 5 displays the confusion matrices corresponding to each model's best-performing dual-output configuration.

Figure 5. Confusion matrices of large language models under best-performing dual-output prompting conditions on the test subset of the development set (n=122). HC: healthy controls; PD: Parkinson disease.

Generalizability was further assessed using the temporal validation set (n=31). As shown in Table 8, all models maintained strong diagnostic sensitivity, and recall for PD remained equal to 1 across all participants. GPT-4o achieved the highest macro-averaged F_1-score of 0.968 with an accuracy of 0.968. LLaMA 3.3 70B followed with a macro-averaged F_1-score of 0.935. Gemini 1.5 Pro and Claude 3.5 Sonnet showed modest decreases in performance with F_1-scores of 0.903 and 0.869, respectively, primarily due to HC misclassifications.

Figure 6 presents the confusion matrices for the temporal validation set under the best-performing configuration for each model.

Figure 6. Confusion matrices of large language models under best-performing dual-output prompting conditions on the temporal validation set (n=31). HC: healthy controls; PD: Parkinson disease.

Following the diagnostic classification results presented in Table 7, the semantic consistency of the post hoc explanatory texts was evaluated to assess the stability of generated explanations under dual-output prompting. Pairwise cosine similarity was computed among 30 post hoc explanatory texts generated for each participant, and the resulting mean and SD were averaged across all 122 test participants. As shown in Table 9, all models maintained high semantic consistency, with mean cosine similarity values exceeding 0.95. LLaMA 3.3 70B achieved the highest value under 0-shot prompting (0.997 ± 0.005), and the variation across models and shot settings was small (≤ 0.03). This evaluation was limited to the development set, and additional exploratory metrics for the temporal validation set are provided in Multimedia Appendix 11.

Fine-Tuned Prompting Performance of LLMs

Supervised fine-tuning substantially improved the diagnostic performance of lightweight LLMs and resulted in more consistent classification across the evaluated datasets. Table 10 summarizes the results of GPT-4o-mini and Gemini 1.5 Flash on the development test set (n=122).

Table 10. Fine-tuning performance of lightweight large language models on the development test set (n=122).

Model	Prompt	F_1-score[a]	Precision (macro avg[b]/PD[c]/HC[d])	Recall (macro avg/PD/HC)	Accuracy	Inconsistency[e]	Inconsistent cases[f]
GPT-4o-mini	PT[g]	0.987	0.995 / 0.990 / 1	0.978 / 1 / 0.957	0.992	0	—[h]
Gemini 1.5 Flash	PT	0.973	0.990 / 0.980 / 1	0.957 / 1 / 0.913	0.984	1	HC #23 (9:21)

[a]F_1-scores represent macro avg values across PD and HC classes.

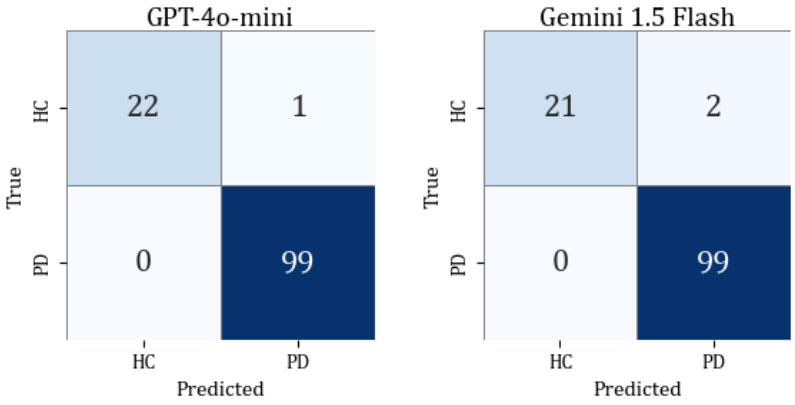
[b]macro avg: macro-averaged.

[c]PD: Parkinson disease.

[d]HC: healthy controls.

[e]Number of participants (out of 122) whose predictions were inconsistent at least once across 30 repeated trials.

[f]Example of inconsistent participants showing the final label (eg, HC #23) and the number of predicted labels across 30 runs (eg, 9:21 indicates 9 HC and 21 PD predictions).



[g]PT: plain text.

[h]Not applicable.

The fine-tuned GPT-4o-mini achieved the highest macro-averaged F_1-score of 0.987, with recall of 1.00 and stable predictions across 30 repeated trials. Gemini 1.5 Flash followed closely with an F_1-score of 0.973, maintaining an accuracy of 0.984 and showing only 1 inconsistent prediction (participant HC #23). Both models were trained and evaluated using PT prompts. The corresponding confusion matrices are shown in Figure 7. Figure 7 displays the confusion matrices of the fine-tuned LLMs on the development test set, showing that nearly all misclassifications occurred among HC participants, whereas both models correctly identified all PD cases in the sample.

XSL•FO
RenderX

Figure 7. Confusion matrices of lightweight large language models after fine-tuning on the development test set (n=122). HC: healthy controls; PD: Parkinson disease.

To further assess model generalizability, both fine-tuned LLMs were evaluated on the temporal validation set (n=31). As summarized in Table 11, GPT-4o-mini achieved F_1-score, precision, recall, and accuracy of 1.000 on the temporal validation set, correctly classifying all participants in this sample. In contrast, Gemini 1.5 Flash demonstrated slightly lower but still strong performance with an F_1-score of 0.903 and an accuracy of 0.903. All PD participants were correctly identified, and the few errors were limited to HC participants. Figure 8 presents the confusion matrices under the same fine-tuned PT prompting configuration. These findings confirm that fine-tuning notably improved classification stability while preserving sensitivity to PD in temporally independent data.

Table 11. Fine-tuning performance of lightweight large language models on the temporal validation set (n=31).

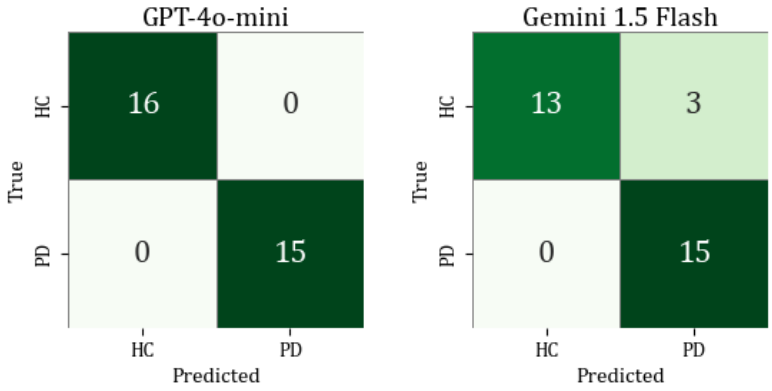
Model	Prompt	F_1-score[a] (95% CI)	Precision (macro avg[b]/PD[c]/HC[d])	Recall (macro avg/PD/HC)	Accuracy	Inconsistency[e]	Inconsistent cases[f]
GPT-4o-mini	PT[g]	1 (1.000-1.000)	1/1/1	1/1/1	1	0	—[h]
Gemini 1.5 Flash	PT	0.903 (0.770-1.000)	0.917/0.833/1	0.906/1/0.813	0.903	1	HC #21 (25:5)

[a]F_1-scores represent macro avg values across PD and HC classes.

[b]macro avg: macro-averaged.

[c]PD: Parkinson disease.

[d]HC: healthy controls.



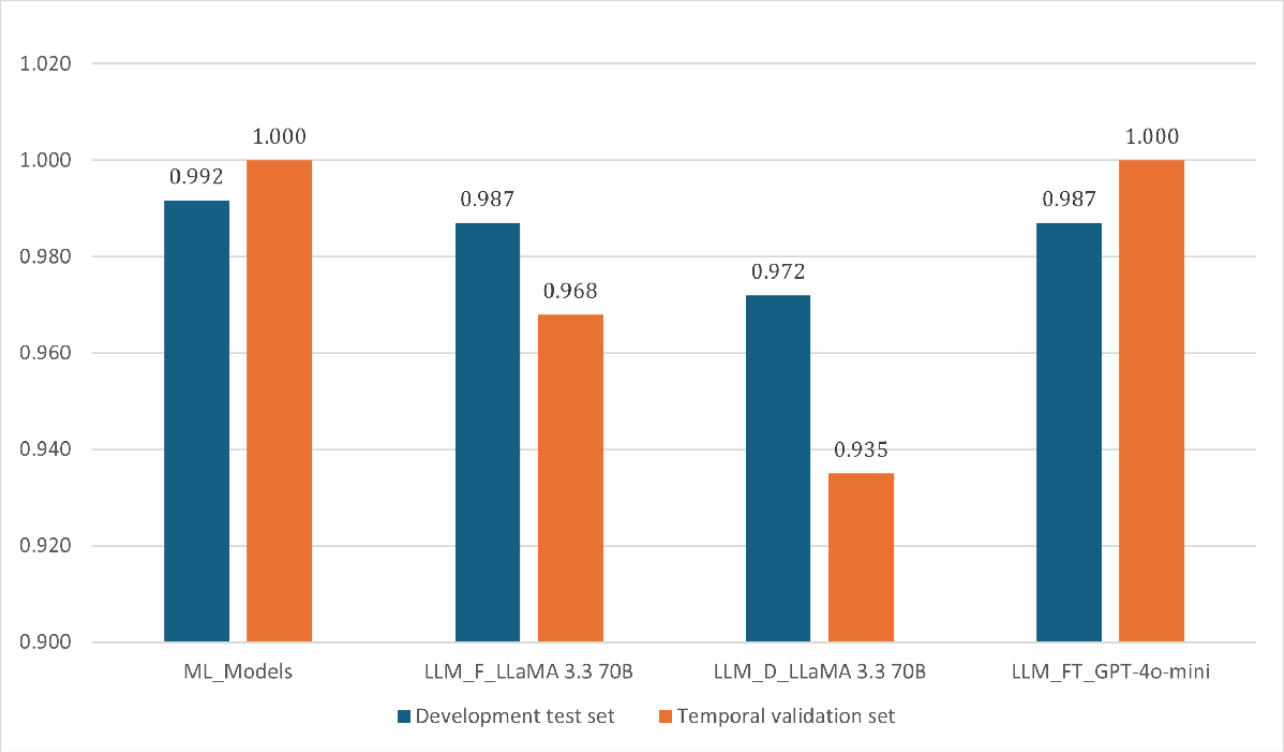
[e]Number of participants (out of 31) whose predictions were inconsistent at least once across 30 runs.

[f]Example of inconsistent participants showing the final label (eg, HC #21) and the number of predicted labels across 30 runs (eg, 25:5 indicates 25 HC and 5 PD predictions).

[g]PT: plain text.

[h]Not applicable.

Figure 8. Confusion matrices of lightweight large language models after fine-tuning on the temporal validation set (n=31). HC: healthy controls; PD: Parkinson disease.



These results confirm that with sufficient training data and consistent prompting formats, even small-scale LLMs can achieve classification accuracy comparable to larger models while maintaining stable performance.

XSL•FO
RenderX

Figure 9 provides an integrated comparison of the best-performing models across all experimental settings, including traditional ML baselines, few-shot prompting with LLM (LLM_F), dual-output prompting with LLM (LLM-D), and fine-tuned prompting with LLM (LLM_FT). Across the development dataset, multiple LLM configurations achieved macro-averaged F_1-scores comparable to LR, and fine-tuned lightweight models reached the highest overall performance.

Figure 9. Comparison of the best macro-averaged F1-scores from the top-performing models in machine learning (ML) and large language model experiments across few-shot, dual-output, and fine-tuned prompting on the development and temporal validation sets.

On the temporal validation dataset, LR maintained moderate generalizability, whereas SVM showed substantial degradation when applied to temporally separated data. In contrast, several LLM configurations preserved high recall for PD and sustained overall performance, particularly under fine-tuned and few-shot prompting conditions. These results demonstrate that while ML baselines provide deterministic reference points, LLMs exhibit greater flexibility across prompting strategies and maintain stable sensitivity to PD in both datasets.

Discussion

Overview

This study examined how modern LLMs process structured clinical variables when these variables are reformatted into natural language prompts for the diagnostic classification of PD. Using SHAP-selected features derived from the PPMI dataset, we compared multiple LLM families and prompting strategies with conventional ML baselines. Three main findings emerged. First, several LLMs achieved diagnostic performance comparable to LR while maintaining high sensitivity for PD across both the development test set and the temporal validation set. Second, the diagnostic behavior of LLMs varied depending on prompt format, model family, and shot configuration, whereas the ML baselines produced deterministic and highly stable predictions. Third, supervised fine-tuning markedly improved both accuracy and output stability in lightweight LLMs, allowing a compact model such as GPT-4o-mini to correctly classify all participants in the temporal validation set. In addition, because the ML baselines in this study were minimally tuned, part of any performance gap between ML models and LLMs may reflect limited optimization of the ML baselines rather than true methodological differences. Accordingly, the present comparisons should be interpreted as exploratory rather than definitive.

The performance of the LLaMA family was strongly influenced by input formatting. In particular, the inclusion or removal of STs resulted in notable differences in accuracy and sensitivity, although their classification results varied more widely across different shot settings [29]. Dual-output prompting, which required models to generate diagnostic labels along with post hoc explanatory text, resulted in slightly lower F_1-scores compared with diagnostic-only prompting but did not substantially destabilize predictions. The generated text exhibited high semantic consistency across repeated trials. These explanations should be regarded as post hoc natural language outputs rather than indicators of true model interpretability, since they are produced after the model's primary diagnostic prediction step [14].

To evaluate whether inconsistent predictions reflected clinically ambiguous participants rather than model-level variability, we conducted a qualitative review of cases that exhibited the highest numbers of label inconsistencies. A total of 2 HC participants and 2 PD participants were selected for detailed examination. All 10 SHAP-selected variables, including Unified Parkinson

XSL•FO
RenderX

Disease Rating Scale (UPDRS) motor scores, University of Pennsylvania Smell Identification Test (UPSIT) percentiles, and dopamine transporter single-photon emission computed tomography putaminal uptake metrics, were compared with the overall distributions of the PD and HC groups. None of the reviewed cases demonstrated borderline or contradictory clinical profiles. The HC cases showed preserved dopaminergic uptake and normal motor assessments, with only mild olfactory reductions typical of healthy older adults. The PD cases exhibited reduced dopaminergic activity, clear asymmetry, and motor impairment consistent with established PD patterns. These observations suggest that label inconsistencies are unlikely to arise from underlying clinical ambiguity. Instead, they appear to reflect model stochasticity and prompt-dependent variability [33].

Supervised fine-tuning clarified the role of training data in stabilizing LLM predictions. When provided with labeled examples, both GPT-4o-mini and Gemini 1.5 Flash demonstrated substantial improvements in diagnostic accuracy and showed consistently high sensitivity to PD on the temporal validation set. GPT-4o-mini classified all 31 participants correctly after fine-tuning. This result suggests that compact models can approximate or exceed the performance of larger models when trained on appropriately structured datasets. It also indicates that fine-tuning can reduce susceptibility to prompt-level variability and may support more reliable behavior in clinical decision-support environments. However, this comparison should be interpreted with caution. Although architectural differences may also contribute to the observed performance gap, GPT-4o-mini was fine-tuned on more than twice as many labeled samples as Gemini 1.5 Flash (1052 vs 500) due to platform constraints. Part of GPT-4o-mini's superior performance may therefore reflect the larger amount of training data rather than inherent model advantages, which limits how directly the two models can be compared.

Overall, this study illustrates both the potential and the limitations of modern LLMs for processing structured clinical variables that are presented in natural language form. While several models achieved strong diagnostic performance and generalized well to temporally separated data, their outputs remained sensitive to prompt structures, model architectures, and few-shot configurations. Occasional inconsistencies across repeated runs further highlight the stochastic nature of LLM output generation [33]. These characteristics reinforce the importance of careful interpretation and the need for rigorous evaluation frameworks before LLMs can be integrated safely into real-world diagnostic workflows.

Limitations

Several limitations should be considered when interpreting these findings. First, although temporal validation provided an important assessment of model generalizability, the temporal validation set was relatively small (n=31), which resulted in wide CIs for the reported performance metrics. In addition, models were trained on datasets that included imputed values, whereas evaluation was conducted on datasets restricted to complete cases without missing data, including both the development test set and the temporal validation set. This mismatch may introduce a distributional shift and result in performance estimates that reflect a best-case evaluation scenario rather than real-world clinical conditions where missing data are common.

Second, the 10 features used for model input were selected using SHAP values from tree-based models. Feature sets obtained using alternative selection strategies may differ, so the current feature subset may not fully represent model-agnostic feature selection. Furthermore, the explanatory text generated by LLMs under the dual-output prompting framework was not reviewed by clinical experts. Accordingly, the semantic consistency metric reflects internal textual stability rather than clinically accurate or factually grounded post hoc explanatory text, and the clinical validity of the generated explanations remains unverified.

Finally, several methodological constraints limit direct model-to-model comparisons. Prompt format and shot configuration were selected based on performance observed on the development test dataset, rather than using a separate validation set for configuration selection. This design choice reflects the study's aim to broadly compare model behaviors rather than to establish definitive optimal configurations. In addition, platform-specific constraints limited the extent of fine-tuning that could be performed across LLMs. While GPT-4o-mini was fine-tuned using 1052 training samples with an additional held-out validation set of 186 samples, the Gemini 1.5 Flash fine-tuning interface restricts supervised training to a maximum of 500 samples, and the machine learning baselines were trained on 990 samples. As a result, the observed performance differences across models may reflect differences in training data availability rather than inherent architectural superiority and should be interpreted as exploratory.

Prompt structuring flexibility also differed across platforms, as the ST format was applied only to the LLaMA models due to platform-specific input constraints, further limiting the degree to which direct model-to-model comparisons can be made in this study.

Future Work

Future research should expand these results in several directions. Larger temporal or external datasets, including real-world clinical settings, are needed to strengthen generalizability assessments. Additional work is warranted to examine optimization strategies for prompt design, temperature settings, and calibration methods that may reduce stochastic variability. Expert-based evaluation of generated post hoc explanatory text may clarify how these outputs can be used to support clinical decision-making. Further exploration of supervised fine-tuning for additional lightweight LLMs could help identify resource-efficient models suitable for deployment in constrained clinical environments. Finally, integrating imaging, sensor-derived digital biomarkers, and longitudinal clinical trajectories may clarify how LLMs can combine multimodal biomedical data for diagnostic tasks.

Conclusions

This study provides an exploratory benchmark of how LLMs process structured clinical variables when presented in natural language form. Multiple LLMs achieved diagnostic performance

XSL•FO
RenderX

comparable to conventional ML baselines and maintained high sensitivity for PD under temporal validation. However, their predictions were influenced by prompt format, shot configuration, and model architecture, and occasional inconsistencies reflected inherent stochasticity rather than clinical ambiguity. Supervised fine-tuning substantially improved reliability in lightweight models, demonstrating that compact architectures can achieve stable and high-performing classification when trained on sufficient labeled examples. These findings highlight both the opportunities and the challenges associated with applying LLMs to structured clinical data and emphasize the need for rigorous evaluation before clinical implementation.

Acknowledgments

The authors would like to thank Editage for English language editing. We also acknowledge the use of generative artificial intelligence (AI) tools (ChatGPT by OpenAI and Grok by xAI) under author supervision for language editing and phrasing refinement during manuscript preparation. All analyses, experimental designs, and interpretations related to LLM diagnostics were fully conceived, conducted, and verified solely by the authors.

Funding

This work was supported by 2 funding sources. First, the Regional Innovation System & Education (RISE) program through the Institute of Regional Innovation System & Education in Busan Metropolitan City, funded by the Ministry of Education (MOE) and the Busan Metropolitan City, Republic of Korea (2025-RISE-02-003). Second, the Global-Learning & Academic research institution for Master's·PhD students, and Postdocs (G-LAMP) Program of the National Research Foundation of Korea (NRF), grant funded by the Ministry of Education (RS-2025-2540216). The funders had no role in the study design, data collection, analysis, interpretation of results, manuscript writing, or the decision to submit the work for publication.

Data Availability

The datasets analyzed during this study are available from the Parkinson's Progression Markers Initiative (PPMI) repository, subject to PPMI data access policies. Selected code and processed data supporting the findings of this study are included in Multimedia Appendix 12. Additional materials can be shared upon reasonable request.

Authors' Contributions

HJS was responsible for the conceptualization, methodology, data curation, formal analysis, investigation, visualization, and writing–original draft. DYK, as the corresponding author, provided overall supervision, project administration, funding acquisition, and contributed to conceptualization and writing–review and editing. YJJ and SMJ contributed to validation and provided clinical insights and feedback during manuscript reviews. All authors read and approved the final version of the manuscript.

Abstract

Background: Considering sex and gender improves research quality, innovation, and social equity, while ignoring them leads to inaccuracies and inefficiency in study results. Despite increasing attention on sex- and gender-sensitive medicine, challenges remain with accurately representing gender due to its dynamic and context-specific nature.

Objective: This work aims to contribute to the implementation of a standard for collecting and assessing gender-specific data in German university hospitals and associated research facilities.

Methods: We carried out a review to identify and categorize state-of-the-art gender scores. We systematically assessed 22 publications regarding the applicability and practicability of their proposed gender scores. Specifically, we evaluated the use of these gender scores on German research data from routine clinical practice, using the Medical Informatics Initiative core dataset (MII CDS).

Results: Different methods for assessing gender have been proposed, but no standardized and validated gender score is available for health research. Most gender scores target epidemiological or public health research where questions about social aspects and life habits are already part of the questionnaires. However, it is challenging to apply concepts for gender scoring on clinical data. The MII CDS, for example, lacks all variables currently being recorded in gender scores. Although some of the required variables are indeed present in routine clinical data, they need to become part of the MII CDS.

Conclusions: To enable gender-specific retrospective analysis of routine clinical data, we recommend updating and expanding the MII CDS by including more gender-relevant information. For this purpose, we provide concrete action steps on how gender-related variables can be captured in routine clinical practice and represented in a machine-readable way.

Introduction

Background

Taking sex and gender (see Textbox 1 and Textbox 2) into account improves the quality of research and care, and it supports social equity [1]. Considering sex and gender from the outset can lead to new discovery and foster innovation. Ignoring sex and gender, however, leads to inaccuracies, inefficiencies, and difficulties generalizing results. This is, for example, highlighted by a recent study showing that men with low femininity reported a significant decrease in anxiety during the COVID-19 pandemic, meanwhile women with low femininity reported a significant increase [2].

XSL•FO
RenderX

Textbox 1. Definition of biological sex [3,4].

Biological sex is defined through biological attributes, such as:

- Genetics (ie, chromosomes, gene expression)
- Hormone levels
- Anatomy (ie, internal and external sex organs/reproductive organs)

Deviations regarding the hormonal or chromosomal attributes are possible, where the external appearance can be intersex and it is not possible to decide.

Textbox 2. Definition of (social) gender [3,4].

Gender refers to socially constructed roles, behaviors, expectations, and norms associated with being a woman, man, girl, or boy. It is formed through biological and psychosexual factors and an individual's social biography, and it is shaped by one's role in society. Gender influences how people perceive themselves and others and how they act and interact.

Many health care decisions are influenced by the patients' sex and gender, through social norms and experiences. Sex- and gender-sensitive medicine is receiving increasing attention in international research [5]. However, several publications have shown that women are still not considered equally to men and are poorly represented due to biased study designs [6-8]. It is well known today that this practice leads to an increase in inequality in medical treatment due to inappropriate therapies. Moreover, sex- and gender-specific reporting is often deficient, which leads to a lack of reproducibility and reduced effectiveness of research studies [1].

Even though the situation has improved, it can still be challenging to represent psychosocial gender aspects, as gender is a context-specific construct that is dynamic and multidimensional and can differ across time, geographical regions, and societies [9].

Gender scores are developed and used to assess gender roles and gender identity. They can be created and applied retrospectively to extract frequently missing gender information from already existing data. For this purpose, gender-sensitive variables in the existing data are determined by expert knowledge or statistical algorithms. Gender scores can then be calculated to predict social gender roles. For example, Lacasse et al [10] and Nauman et al [11] each developed a retrospective gender score and applied it to specific datasets from population studies. Examples for the corresponding gender-sensitive variables are specific *professions*, like in health care or construction, and typical *personality trait*s, like agreeableness or neuroticism; *loneliness* or *stress* was considered. In general, retrospective scores cannot capture participants' current gender identity (see Textbox 3).

Textbox 3. Definition of gender identity [3,4].

Gender identity is determined through individual self-perception and the sexual identity of a person, which may differ from someone's physical appearance or biological sex.

Prospective assessments can enhance the collection of gender-specific data from the outset of a study by incorporating further social data or information regarding the identity. Fraser et al [12] and Lagos and Compton [13], for example, evaluated a prospective 2-step gender identity measure on data from huge studies. The 2-step measure differentiates between a person's current gender identity and birth-assigned sex (see Textbox 3 and Textbox 4). The given examples show that gender scores are mostly used in surveys and studies and hardly used on routine clinical data.

Textbox 4. Definition of birth-assigned sex (BAS) [3,4].

BAS refers to the information that can be found on official documents, like a birth certificate, and is assigned based on the child's external anatomy or sex organs. BAS is often measured by a binary choice of response (ie, male or female). Biological sex is not a dichotomy, nor is BAS, where diversity is given.

All 38 university hospitals in Germany are part of the Medical Informatics Initiative [14] (MII), which serves to close the gap between research and routine care. A core dataset (CDS) is being developed by the MII consortia and the participating university hospitals to foster interoperability and allow a shared use of routine clinical data across Germany. Data Integration Centers collect and process routine clinical data and make them accessible to researchers for secondary use. If and how this established dataset considers gender and gender score applications are open questions.

It is important to note that the discussion about the applicability and state of gender scores does not only affect Germany. Critical assessments of sex and gender scores reveal that the problem affects different western cultures [15-18]. Ignoring gender differences in clinical research is a widespread global issue that undermines the validity and applicability of scientific findings across diverse populations [16]. A study conducted in Australia using the Bem Sex Role Inventory (BSRI) [19] found that the majority of participants received different gender scores in at least 1 of the 3 consecutive years, highlighting the complexity and fluid nature of gender identity [18]. This is particularly

XSL•FO
RenderX

concerning because the BSRI yielded inconsistent results even among a relatively stable population of patients older than 75 years — where minimal shifts in habits or identity would be expected over time. Despite being based on outdated social stereotypes, the BSRI is one of the most used gender scores, and other scores are partly based on it, as we later describe.

In this context, where classic gender scores are struggling, new tools are being considered to annotate medical data according to the gender of patients, thanks to the rise of machine learning methods [20]. The results of such methods can then be systematically used to mitigate biases in research, as done by Neufang et al [21], who developed an artificial intelligence model to improve the fairness of attention deficit hyperactivity disorder diagnosis with respect to gender. It is important to understand whether these algorithms are also applicable to general clinical data datasets, such as the MII CDS, to allow large-scale integration of gender debiasing in future research.

The issues outlined in the previous paragraphs indicate that more work needs to be done to update gender scores, taking into account the changes in commonly defined social rules that have occurred in the last century. In practice, outdated scores, such as the BSRI, are often used without considering proper validation and potential biases [22]. Moreover, a gold standard is still missing for how sex and gender should be considered in research with clinical research data. A practicable score should be balanced, comprehensive, and easily applicable. Interestingly, no gender score has so far been established as an international standard.

We therefore conducted a systematic evaluation of gender scores regarding their applicability in health research using German efforts on Data Integration in Medicine as a benchmark. As the world's third-largest economy and one of the World Health Organization's top two donors, we expected the German MII CDS to be a good candidate for our evaluation. In this article, the term gender score refers to the assessment of gender in general (social gender and gender identity), and the term gender identity measure refers exclusively to gender identity.

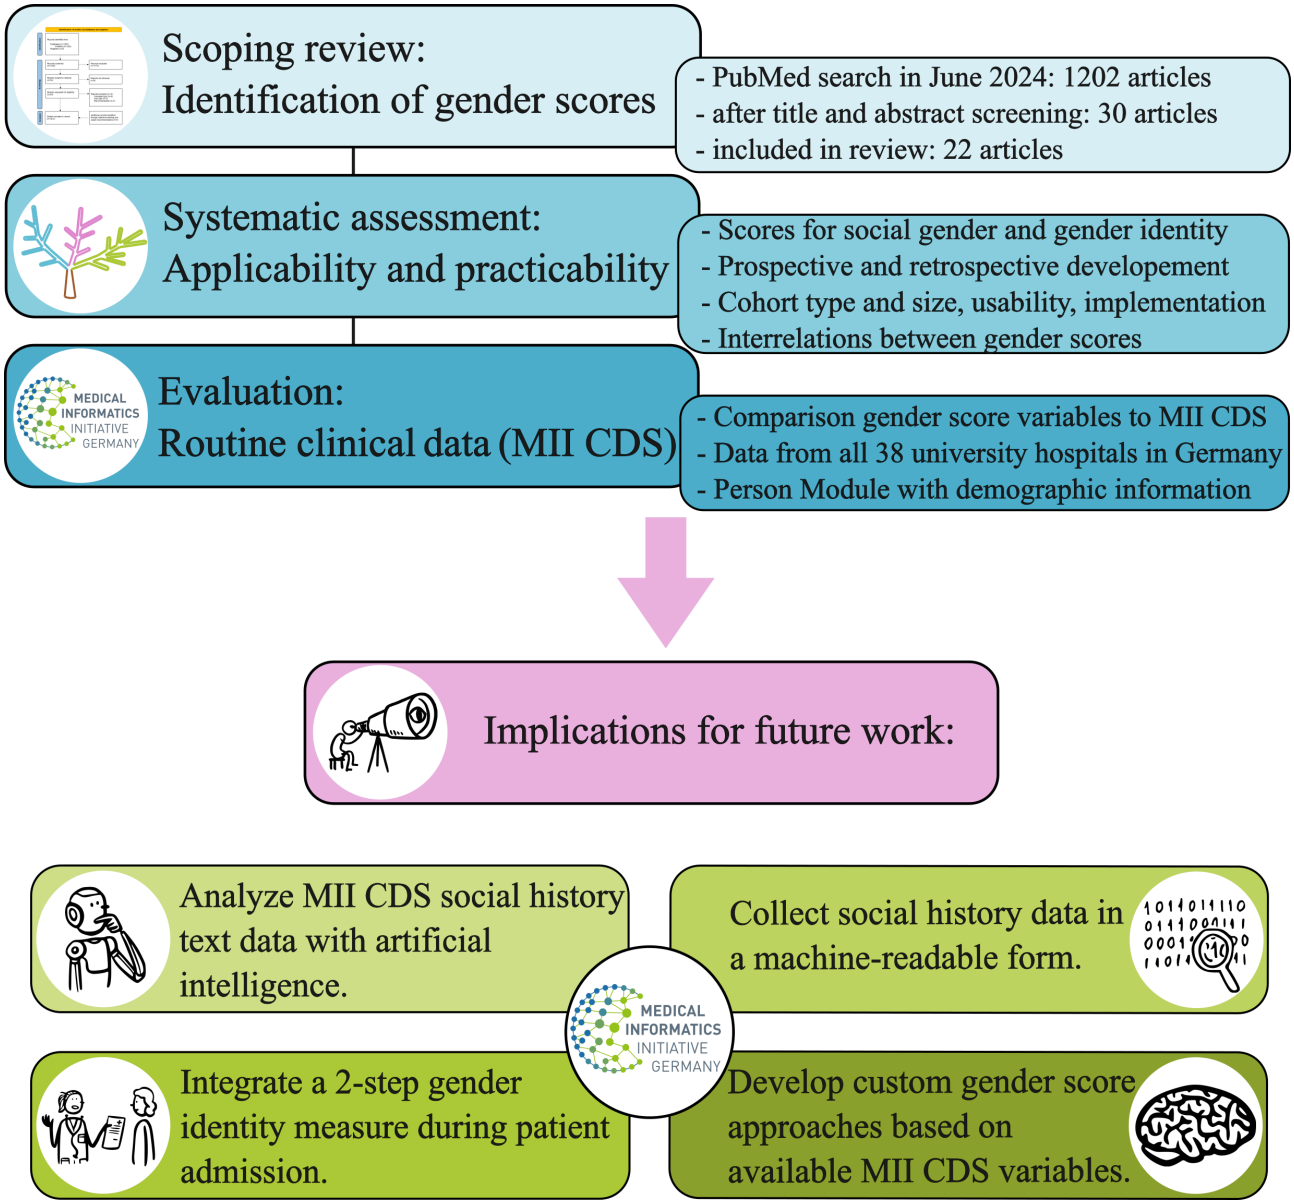
Related Work

The focus of our scoping review protocol published in JMIR Review Protocols [23] was the applicability and practicability of gender scores in health research. Related to the work described in this paper, Horstmann et al [24] published a review on recently used instruments for the operationalization of sex and gender in health research, and the work by Miani et al [25] summarizes epidemiological aspects in gender scores. The reviews included publications until 2020 and 2021, respectively. For this work, we identified the latest scores and therefore deliberately limited our search to publications between 2019 and 2024. Of the 18 articles from our primary result set, 13 were published after 2020.

In parallel to our work on the systematic review of recent gender scores, another systematic review about the operationalization of gender via composite gender scores in epidemiological studies was published in 2024 by Ballering et al [26]. The authors searched 3 databases (PubMed, Web of Science, and CINAHL) and identified 24 articles with a total of 26 gender scores developed in Europe or North America. They aggregated information on gender scores regarding author, year of publication, methodology, cohort information, and the included variables of the respective gender score and found that many variables overlapped across multiple studies.

Ballering et al [26] criticized theory-driven approaches — developed solely based on expert knowledge — as experts are not free from bias, potentially enhancing sexism or other biases. The authors further claim that data-driven approaches — using statistical models to develop gender scores — only predict female or male sex through identified psychosocial variables and do not consider gender itself. Psychosocial variables that do not associate with sex are excluded, and the quality of the gender scores is strongly dependent on the quality of the dataset. Overall, Ballering et al [26] concluded that data-driven approaches might be good to personalize health care, as gendered variables point out differences between women and men that could lead to improved treatment decisions and patient care.

The work by Ballering et al [26] is a great foundation for our work, and we are able to contribute further insights on the applicability of gender scores on routine clinical data. We had an overlap of 13 articles on both sides, with 13 of 22 articles in our review and 13 of 24 articles in the review by Ballering et al [26] (ie, there was an overlap of more than 50%: 59% ours and 54% theirs). We found further articles regarding gender identity that can be applied from the outset of a study or data collection, which could be of great use to implement gender information in routine clinical practice.



Aim of This Work

In the scope of this work, we identified and categorized state-of-the-art gender scores, systematically assessed their applicability and practicability, and evaluated their applicability on German research data from routine clinical practice (see the Applicability of Gender Scores on the MII CDS section).

The process of our work is illustrated in Figure 1. This work aimed to contribute to the necessary implementation of a standard for collecting and assessing gender-specific data in German university hospitals and the respective research facilities; therefore, we formulated 4 action steps for an extension in health research to enable gender-specific analyses (see Figure 1), which are shown at the bottom of the figure and will be described in detail in the Discussion section.

Figure 1. Overview of the implemented methods. MII CDS: Medical Informatics Initiative core dataset.

Methods

Scoping Review

We conducted a scoping review to identify articles that reported on the development and implementation of gender scores in health-related studies (see Figure 1). It resulted in 22 articles, which were identified through a title and abstract screening followed by a full-text evaluation. Moreover, we developed a data charting form to extract information on article type and applicability of the gender score in health research. The review protocol was published in JMIR Research Protocols [23].

Assessment of Applicability and Practicability

To assess the applicability and practicability of gender scores, we followed a systematic approach (see Figure 1). In the scope of this work, we extended the data charting process to fully assess the applicability of gender scores on routine clinical data.

Social Gender and Gender Identity

First, we distinguished between scores for gender identity (see Table 1) versus social gender (see Tables 2 and 3). Gender identity (see Textbox 3) is usually measured in a prospective way because it is a purely subjective perception and it is not possible to extract this information when it was not collected. However, social gender includes norms that are expected in society, stereotypes, and certain behaviors (see Textbox 2), and it can be measured prospectively and retrospectively. Typical behavior (eg, specific hobbies, occupational segregation, doing housework or odd jobs) can be analyzed and interpreted after data collection. A typical female or male lifestyle or behavior will lead to different exposure to risk factors for accidents or disease. Social expectations will also influence the process of recovery.

Table . Prospective gender identity measures [12,13,27,28].

Author(s) (year)	Description	Questions and answer option
Lagos and Compton (2021) [13]	2-step gender identity measure	1. What sex were you assigned at birth? (male, female, intersex) 2. What is your current gender? (woman, man, transgender, a gender not listed here [space for answer])
Fraser et al (2020) [12]	Open-ended gender measure	What is your gender? (open-ended item)
McGuire et al (2019) [27]	Genderqueer Identity Scale	1. I am non binary, genderqueer, or an identity other than male or female. 2. I don't want to be seen in the gender binary (as either male or female) 3. I try to deliberately confuse people about whether I am male or female. 4. I try to do things that are masculine and feminine at the same time. 5. I enjoy it when people are not sure if I am male or female 6. The way I think about my gender has always been the same. 7. My gender comes naturally from within me. 8. My gender is something I have spent a lot of time figuring out. 9. The way I show my gender changes depending on who I am with. 10. The way I think about my gender has been influenced by experiences in my life. 11. The way I think about my gender will probably continue to change further as I age 12. I have done research about gender theory and gender roles. 13. I try to convince others that society should not insist on a gender binary. 14. I try to convince others that society expects people to be too gender conforming. 15. Around me, I make sure people are free to express whatever gender roles they want. 16. The way I show my gender is important because I push society to question traditional gender roles. 17. I encourage others to be more open minded about gender and gender roles. 18. In the future, my gender expression will be traditional. 19. In the future, it will upset me if people misgender me. 20. The way I show my gender will probably be mostly the same from day to day. 21. In the future, I expect that people will rarely question my gender. 22. In the future, I think my gender will be fluid or change over time. 23. I will have a non-traditional gender role (be gender non-conforming).
Lombardi and Banik (2016) [28]	2-step gender identity measure	1. What is your sex or gender? (Check ALL that apply; male, female, other: please specify [space for answer]) 2. What sex were you assigned at birth? (Check one; male, female, unknown or question not asked, decline to state)

[b]Variables that are potentially covered in routine clinical care in Germany.

[c]ICD-10-CA: International Statistical Classification of Diseases and Related Health Problems, Tenth Revision, Canada.

Prospective and Retrospective Scores

Second, we distinguished between prospective (see Tables 1 and 2) and retrospective (see Table 3) scores. It is advisable to include gender variables from the outset of a study; this results in a prospective gender score and is easy to apply to the study dataset. However, the huge amount of existing data drives the development of retrospective gender scores, where gender-specific information can be extracted in hindsight.

Cohort Type and Size

Third, it needs to be considered whether the gender scores themselves are representative. In practice, some gender scores are developed on restricted datasets, for instance, for specific patient groups or other samples that are not representative (eg, older age groups, workers, or specific diagnoses). This is underlined by the finding of Wandschneider et al [9] who showed that gendered practices vary between eastern and western Germany, reflecting a different social development due to the historical political context. As gender norms, stereotypes, or behaviors vary between societies, the relevant gender variables can differ across social groups, countries, and regions or even between different societies within a country.

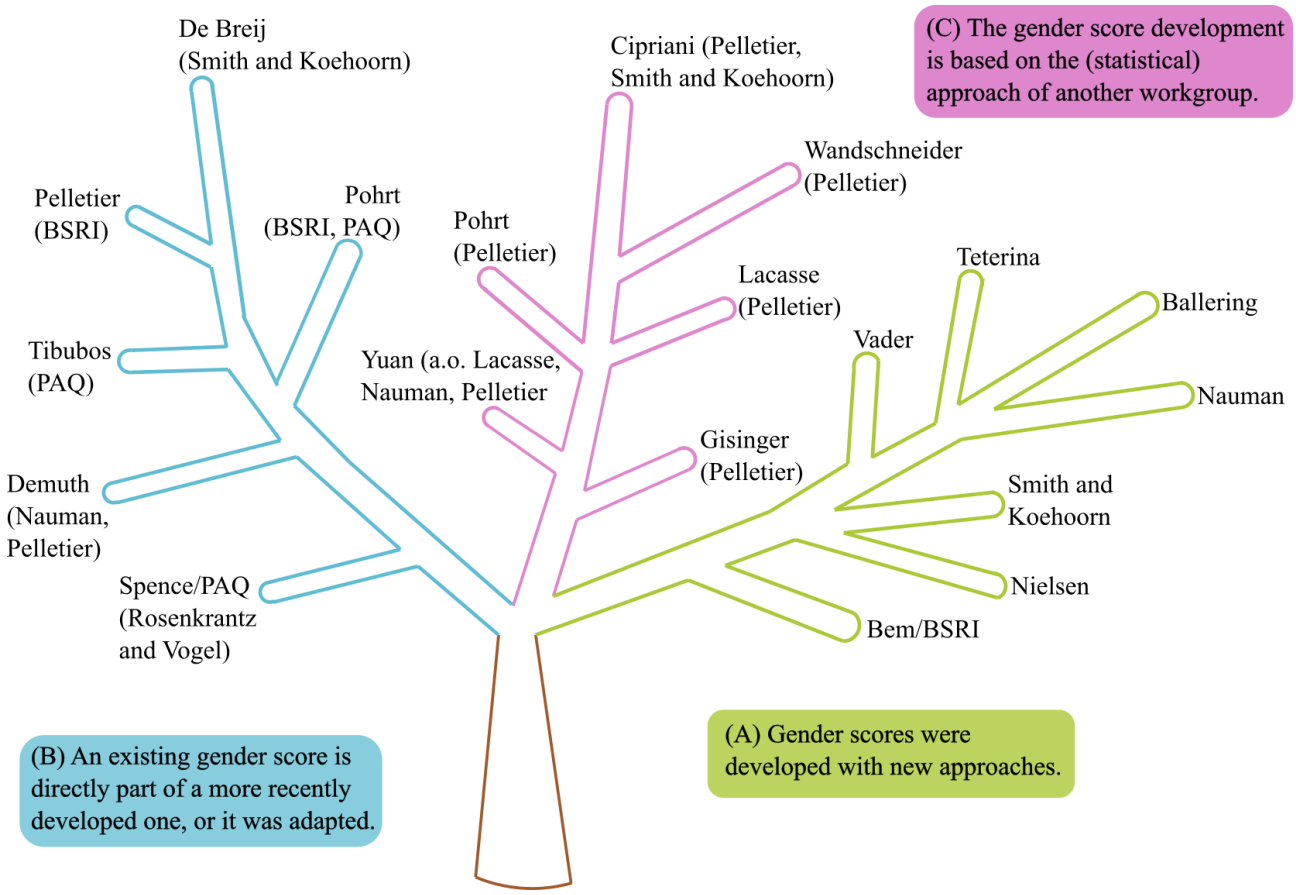
Furthermore, since retrospective scores depend on statistical modeling, we also considered the sample size on which the models were based. Another analysis we performed was to further classify the background under which the score was developed. We took into account whether the research group used patient or population data to categorize which gender score might be more appropriate for the MII CDS. We also considered the continent where the data collection took place, which is important for consistency due to varying gender-sensitive variables depending on the society or geographical location.

Usability

Fourth, we examined the validity, usability, and practicability of the gender scores. Validity is the main issue because it is of high importance that the score is representative regarding gender. Usability refers to how well the score is established. If a new standard is to be introduced, it is of high importance to use an accepted model to ensure that the scores are usable, comparable, and applicable to large-scale studies and assessments. Practicability refers to how difficult a score would be to integrate into health research.

Implementation

The fifth point we included in our assessment was the level of implementation of scores. To apply scores systematically on existing data, a theoretical model was not sufficient. Instead, it was necessary to have the executable code of a model to integrate it directly. Therefore, we further investigated the applicability of gender scores from the technical viewpoint to evaluate whether models can, realistically, be implemented in a clinical setting. We used the following categories to describe this aspect: code published — refers to a gender score for which an executable model was published; data published — refers to a gender score for which the underlying data are available and a score could be reproduced; statistical parameters published — refers to a model for which all statistical parameters were published and the model could be constructed from them; not published — a model for which not all relevant parameters are available. We considered “code published” the gold standard regarding applicability. “Data published” and “parameters published,” on the other hand, might contain sufficient information to construct an executable model. In the scope of this study, we considered code or data available “on request” as unavailable. However, in practice, there might still be limitations if the description of the article is not concise enough to reproduce all steps.



Interrelations

Based on the extracted data, we performed further analysis to better understand the currently available gender scores. We noticed early on that direct dependencies exist between gender scores. Therefore, we extracted and modeled different types of dependencies between gender scores (see Figure 2). This

XSL•FO
RenderX

analysis allowed us to investigate how scores were developed and whether improvements were made to existing gender scores.

Figure 2. Interrelations between gender scores, where the first 1 or 2 author names identify the work and the developed gender score (see Tables 2 and 3) [9-11,17,19,20,29-41]: (A) gender scores developed with completely new approaches and methods are shown in green; (B) the included or adapted gender scores are in parentheses in the blue branch; (C) gender scores developed based on previous methods and statistical approaches, which are shown in parentheses, are shown in pink. BSRI: Bem Sex Role Inventory; PAQ: Personal Attributes Questionnaire.

One relation between gender scores captures cases in which an existing gender score was used directly or adapted in another score (see Figure 2B). For instance, the gender score from Pelletier et al [20] includes the BSRI [19]. de Breij et al [33] adapted the score from Smith and Koehoorn [34] but changed "caring for children" to "informal caregiving" as the data were available in their dataset (see Figure 2B).

Moreover, development relationships (see Figure 2C) reflect when one gender score was developed based on the approach, for instance the statistical model, of another research group. For example, Gisinger et al [35], with their statistical model of principal component analysis and logistic regression analysis, were inspired by the approach of Pelletier et al [20].

Applicability on Clinical Routine Data

To assess whether gender scores are applicable on existing data and whether they can be integrated in clinical routine data, we used the technical specification of the MII Core Data Set - Module "Person" as a representative sample against which to evaluate the gender scores (see Figure 1). The MII CDS [14] (see the Background section) is being collected across all 38 university hospitals in Germany. It contains interoperable, consolidated data items with a high degree of standardization in line with international standards to make collaborative data analysis practicable and efficient.

The CDS [42] consists of basic and extension modules that are subject to iterative refinement. The basic modules are generic, and the extension modules are relevant for specific medical fields and disciplines such as oncology or intensive care. We used the *Person Module*, one of the early basic modules, which contains demographic information such as name, date of birth, address, and administrative gender as stated in official documents. The CDS has a comprehensive description of how the data are structured and how the data can be accessed, which allows us to directly compare it against gender scores. The information is available and can be compared based on a sample dataset [43]. Overall, this makes the CDS a suitable choice for studying how gender scores can be applied in realistic clinical data collection.

Retrospective scores required that we compared the variables contained in the gender scores against the variables available in routine clinical data. To perform this comparison, we systematically analyzed all variables contained in the sample dataset of the MII CDS against the variables included in the statistical models of the gender scores.

Ethical Considerations

We did not collect any personal data, so ethical approval was not needed.

Results

The full results of the review are presented in Multimedia Appendix 1 to maintain brevity in the main text.

Scoping Review

Our review results are categorized into prospective development (Tables 1–2) and retrospective development (Table 3) and between gender scores (Tables 2–3) and gender identity measures (Table 1). Articles that overlapped with the already published review by Ballering et al [26] are marked in the tables.

Assessment of Applicability and Practicability

Social Gender, Gender Identity, and Prospective and Retrospective Scores

We distinguished between articles targeting gender identity and articles targeting social gender. We further classified them into prospective and retrospective development and application.

The 4 identified gender identity measures (see Table 1) are prospectively applicable and could be included in future studies for further data collection regarding gender identity. Participants need to be asked explicitly which gender they belong to; this information cannot be analyzed from existing data.

Moreover, we found 18 gender scores to measure social gender in different ways. Of these, 7 are prospective gender scores (see Table 2) that could provide guidance on how to apply (social) gender to a study from the outset. Of the 18 scores, 11 are retrospective (see Table 3) and could be applied on already existing data.

Cohort Type and Size

The background of the cohorts is of importance for the practicability. A score contains different variables, depending on whether it was developed on data from population studies or on patient data. The majority of datasets are based on population studies and thus on specific information that is typically collected in these studies. For a complete comparison of cohorts, see our results in Multimedia Appendix 1.

Only 2 gender scores were developed exclusively based on patient data. Teterina et al [37] focused on patients who entered the emergency department with traumatic brain injuries and published an innovative approach to distinguishing gender by diagnostic codes. These diagnostic codes also describe the background of the accident or incident, enabling conclusions to be drawn about gender. Cipriani et al [36] focused on the effects of gender on emergency patients with psychological crisis. Therefore, they used variables assessing childhood trauma, education, sleep quality, and living situation.

Moreover, the article by McGuire et al [27] assessed gender identity during transition through the collection of patient and population data.

However, all of these studies were restricted by the specific patient cohort group and focused on specific conditions. This hampers their applicability on the general public and their usefulness as broadly applied gender scores for routine clinical data.

In addition, the used population cohorts were neither comprehensive nor inclusive. Many studies used a cohort with a specific age group [11,20,29,31,38,39] or with a specific background like being retired [29] or being a worker [10,33]. This is a major weakness for generalizing results, as a gender score based on a limited cohort is not representative of society as a whole and therefore lacks comprehensiveness.

Furthermore, the majority of cohorts used for developing gender scores are based in the same geographic region, primarily Europe and North America. Only one gender identity measure was used on a cohort in Oceania [12]. We could not find a single gender score publication with a cohort from Asia, South America, or Africa. As a result, the developed scores are not representative for every cohort group and are not universally applicable.

With respect to the size of the cohorts, which forms the basis for the statistical development of retrospective gender scores and influences the reliability of statistical models, we noted that some works used huge cohorts or datasets with n>100,000 [35,37,40] and the outstanding cohort size of approximately 700,000 individuals in the study by Smith and Koehoorn [34]. Other gender scores worked with smaller cohort sizes of n<1000 [19,32,33].

Usability

We examined the validity of scores, meaning how representative the work is regarding gender. Gender can be different in each society, so it is a major task to implement a gold standard. Some research groups used sex as the dependent variable and, therefore, gender as a predictor for sex (eg, [9-11,20]). This approach can be problematic since gender should be considered beyond biological sex.

Statistical regression approaches can be systematically validated by using a control set to test the generalization of the regression model (eg, by systematic evaluation on a dedicated validation set [20,36,37,40]). Researchers who developed a number of scores using the approach by Pelletier et al [20] did not specify whether they performed a systematic validation of their developed scores [9,29,35]. Nauman et al [11] did not use a validation, and Yuan et al [39] reported a performance value without describing the validation setting they used.

3120,2922

Exclusively theory-driven gender scores, where variable scaling is determined by human experts, were not evaluated since there is no gold standard for gender [33,34,38]. Looking at usability, referring to how well established a score already is, some authors did not mention any practical application of their scores [31], whereas other scores were often cited, adapted, and reapplied [19,20,32,34]. Although highly cited scores seem to be widely accepted and used, they might still not be well suited to represent gender. The most cited score was the BSRI, which is also part of other gender scores (eg, [20,29]; see Figure 2), and was often criticized and considered outdated [22].

Regarding practicability, we considered the scope and complexity of questionnaires and how universally applicable variables are on existing data. Some variables were very specific

XSL•FO
RenderX

for the used cohort, whereas others frequently appeared in similar studies. Most gender identity measures are well-suited for clinical data collection, being concise and easy to understand, except for the score from McGuire et al [27], which involves 23 questions and focuses on gender transition, making it less suitable. BSRI [19] and PAQ [32] are lengthy prospective gender scores, same as other gender scores containing them. Tibubos et al [30] developed a shorter form of the PAQ with only 8 variables. We also listed different forms of data collection, from self-reporting questionnaires (eg, [20,34]) to interviews (eg, [13,33,42]). The length of forms could be especially relevant if participants complete a self-reporting questionnaire. Interviews tend to be more time-consuming for the staff conducting them.

Regarding retrospective scores, the length does not have such a big impact, but some scores are much shorter than the majority [34,39]. A minimalistic score can be a trade-off between prediction quality and the number of necessary variables. This was, for instance, investigated by Ballering et al [40], who compared the performance between gender scores including 9 and 85 predictive variables.

Implementation

Only 3 research groups made their analysis code publicly available (*code published*) and provided reproducible gender scores [9,17,40].

Two studies published their data [17] or used publicly available data [39] (*data published*), which are necessary to evaluate their conclusion. All other works did not publish data, which might be justified by data protection regulations. However, anonymized data could still be helpful for recreating a study.

Statistical parameters were published in most retrieved papers (*statistical parameters published*), some more complete than others. However, in the majority of cases, our assessment showed that reconstructing a gender score from the provided parameters would be challenging.

We identified one paper that did not publish the gender score (*not published*) [31]. They adapted the scores from Nauman et al [11] and Pelletier et al [20] to form a new gender score, but they did not provide any specific information regarding their methodology.

Overall, repeatability was made difficult by many of the research groups, and the use of existing scores was made complicated. A systematic overview of the reproducibility of each study is given by our results in Multimedia Appendix 1.

Interrelations

We registered different dependencies and relationships between gender scores and visualized them (see Figure 2). Of the retrieved articles, 7 were developed with totally new approaches or methods (see Figure 2A).

Other scores adapted or included content-related parts of already existing scores (see Figure 2B). For example, Pelletier et al [20] included the BSRI masculinity and femininity scores [19]. Spence et al [32] were inspired by Rosenkrantz et al [41] for the development of the PAQ in 1975, and thereupon, Tibubos et al [30] developed a short form of the PAQ in 2022. It is notable that the BSRI [19] and PAQ [32] each form the basis of 2 other scores.

Sometimes research groups implemented the statistical or methodological approach of another team (see Figure 2C). For instance, the statistical approach of Pelletier et al [20] was frequently used as the basis for current gender scores, for example, by Wandschneider et al [9], Lacasse et al [10], Gisinger et al [35], Pohrt et al [29], Cipriani et al [36], and Yuan et al [39].

Applicability on Clinical Routine Data

Evaluation Overview

We tested all retrieved scores and their published variables for whether they are available in the MII CDS. Initially, we planned to only test retrospective scores developed on clinical data. However, we found that this would limit the number of possible scores too much.

The evaluation of the applicability on clinical routine data required a careful and considerate approach, as variable names are often ambiguous and it is usually not possible to match them directly. This can, for instance, be seen in variables related to care work, which include “responsibility for caring for other people in the household” [29], “dinner is always prepared by someone else” [40], “caregiver strain” [17], “taking care of sick people” [38], “informal caregiving” [33], and “responsibility for caring for children” [34]. Even though some gender scores might be well described and could be used for other datasets, transferring the variables appropriately to a different dataset proved to be complex.

Applicability of Gender Scores on the MII CDS

In the comparison between the variables contained in gender scores and within the MII CDS, we used a two-step approach: We first tried to match the exact gender score variables against the MII CDS, and in case this remained unsuccessful, we extended the search to similar or generic terms.

We found that no variables of any gender score are covered in the MII CDS. This finding is surprising since a high number of variables covered in gender scores, such as occupation, level of education, civil status, children, household composition and size, and social support, are part of social history, which is routine clinical information.

Our principle finding regarding this question was that no gender score can be applied upon the MII CDS. One exception is the score from Teterina et al [37], which includes diagnostic codes and disease-specific data, which could be matched against the MII CDS. This score, however, is highly specific and not usable as a generalized approach. Currently, the MII CDS only encodes the administrative gender as male, female, undifferentiated, or diverse [43]. Administrative gender refers to the gender that is recorded or recognized in official documents (eg, the ID card). It may differ from the birth-assigned sex.

Overall, most scores were applied on population studies or included in studies from the outset. These gender scores frequently include personality traits and psychological

XSL•FO
RenderX

assessments (eg, stress, loneliness scales), which are not part of routine clinical practice and, therefore, also not part of the MII CDS.

To summarize, there are no fitting variables for the MII CDS, and it is impossible to apply an existing gender score to the dataset in order to include gender-specific analysis on clinical routine data.

Discussion

Principal Findings

This work identified and reviewed state-of-the-art gender scores and gender identity measures. These were systematically assessed regarding their applicability and practicability in health research. Last, we tested their applicability on routine clinical data using the MII CDS as a reference dataset.

We found that no gender score is applicable on the MII CDS, because the variables required for the gender scores are not part of the CDS. However, many variables that are commonly included in gender scores are also assessed during a patient's clinical stay. For instance, variables regarding personal background (eg, living with your partner or children, professional field, or self-employment) are often asked during a clinic stay to verify if specific therapies or treatments are feasible. Physicians need to know if patients have responsibilities at home, if they have support, and if they have a stable social environment. A person's background is gender-dependent and influences not only clinical routine but also research data and therapy guidelines (eg, risk factors dependant on lifestyle). This is underlined by the information in Multimedia Appendix 2, which presents examples of current social history documentation practices in a German hospital compared against typical variables used in gender scores. Several variables related to gender scores can be directly inferred from these documentations; however, they are currently not included in the MII CDS. We therefore argue that the current lack of applicability of gender scores on clinical routine data results from missing structured data collection in or extraction methods from clinical information systems. Since the MII CDS is an ongoing effort to standardize research data from routine clinical practice, we recommend that the Person Module of the MII CDS should be updated and expanded to create a sufficient knowledge base for gender health research. Specifically, we formulated 4 action steps that will enable gender-specific analyses (see Figure 1): analyze social history data, collect social history data in a machine-readable form, integrate a 2-step gender identity measure during patient admission, and develop custom gender score approaches for clinical data.

Recommended Action Steps

Analyze Social History Data

Social history is part of routine clinical data collected for many patients. However, the captured information is oftentimes not structured. It can be found in the doctor's notes or additional study data if patients are included in clinical trials. As a first step toward evaluating what information is currently available, we suggest analyzing the full-text information in the patient records using natural language processing and large language models for data extraction. It will be interesting to learn what conclusions and predictions one could draw from the available information and how this information corresponds to the described gender scores. Typical social anamnesis texts are given in Multimedia Appendix 2, showcasing the low information content. A structured analysis of social history data is still ongoing, but the preliminary check of the information content already indicates that the practice of documentation must be significantly improved.

Collect Social History Data in a Machine-Readable Form

We recommend that key components of patients' social histories — such as occupation, education, civil status, number of children, household composition and size, social support — be collected in a structured, machine-readable format. Instead of recording social history solely as narrative text in physician reports, clinical information systems should provide individual fields for each variable, allowing clinicians to select or enter information directly. This approach would reduce the effort required for data processing and aggregation, enable semantic annotation, and facilitate automated export and comparison across datasets.

Several national-level initiatives already exemplify such practices. Scandinavian countries, for instance, collect structured social and demographic data that can be integrated with health care data [44,45]. Similarly, the Canadian Institute for Health Information promotes the standardized collection of social and behavioral data across health care settings, including variables such as family composition, living arrangements, social support, and socioeconomic status. Existing research has also demonstrated how such information can be effectively captured using discrete, machine-readable fields rather than free-text formats [46].

A widely recognized standard that could be further adapted for this purpose is HL7 FHIR [47], which provides a structured framework for encoding social history elements in clinical IT systems. Future work should build on these existing resources — as well as our overview for gender scores — to develop a system that supports the structured capture of variables necessary for calculating gender scores. Although it is important to build future work upon existing standards, ideally, the analysis of clinical data items determining gender should be conducted before designing structured data capture forms for patient social history.

Integrate a 2-Step Gender Identity Measure During Patient Admission

Moreover, to include as many gender dimensions as possible, it would be beneficial to collect more gender-specific data. A promising approach would be to implement the 2-step gender identity measure [13] with open-ended answers during patient admission. Implementing a prospective approach, with minimal effort, would provide valuable insights into gender identity in everyday clinical practice. Although the DIVERGesTOOL [48] was originally developed as an extension of the 2-step approach for the German research context, it may also be well suited for use in patient admission settings. It adds a third question

XSL•FO
RenderX

regarding whether differences in sex development have ever been medically diagnosed.

However, collecting such data must be approached with care, because asking gender-related questions at patient admission can involve sensitive issues and carries potential risks. For transgender, nonbinary, or gender-nonconforming individuals, disclosing gender identity may raise concerns about discrimination or biased treatment. Patients frequently withhold this information due to previous negative experiences and a lack of trust in health care providers [49,50]. Inadequate staff training and poorly designed forms can lead to misgendering or exclusion. To ensure respectful and safe care, it is essential to provide staff with proper training, use inclusive language, and implement supportive documentation systems.

Develop Custom Gender Score Approaches for Clinical Data

Researchers should think beyond the common gender score approaches and develop a gender score that is suitable to clinical data and not only population studies.

An innovative approach was carried out by Teterina et al [37], who used diagnostic codes of patients with traumatic brain injuries in Canadian emergency departments. Researchers should try similar approaches on general — nondisease-specific — clinical data with diagnostic or medication variables. Furthermore, developing a minimalistic retrospective score could prove advantageous in balancing prediction quality with the number of required variables, making the scores applicable even when limited information is available (eg, [40]).

Even though gender is gaining importance in health research, it is still far from being implemented. Our investigation shows that a gold standard is missing that accounts for variations across social groups (eg, including geographical regions, age, time). Due to the lack of a gold standard, some research groups use gender as a predictor for sex when developing gender scores, which contradicts the purpose of introducing gender in research — to move beyond biological sex and gather more detailed information. Solely theory-driven approaches, where experts determine the used variables and their scaling, cannot be validated.

Last, repeatability is a major challenge when aiming at implementing existing gender scores. Due to inconsistent research group practices, existing gender scores are often described only theoretically without providing detailed variables, questions, or complete information on variable weighting. We therefore urge authors to provide complete documentation and executable models when developing gender scores.

To achieve the necessary progress, every inclusion of gender into health research is beneficial, even if it might not be comprehensive or sufficient to cover all aspects.

Limitations

Our collection of gender scores is based on a scoping review conducted to provide a broad overview of the topic. One limitation of this approach is that only one reviewer conducted the full-text screening and the categorization of the retrieved articles. However, during data extraction, more than 30% (7/22, 32%) of the publications were initially double-checked by a second domain expert [23]. The reviewers were in full agreement on all reviewed articles; thus, a single reviewer continued the data extraction. Moreover, our review does not claim to provide a complete list of all existing gender scores but does provide general statements on the current state of gender scores and their applicability in health research.

Moreover, the MII CDS might not be fully representative to test against population-based gender scores. Most gender scores were developed on population or specific patient data, while the MII CDS contains routine clinical data. However, it is important to include gender not only in population research but also in clinical research. This is why we selected the MII CDS as a target dataset for routine clinical data to test the practicability in this setting. As a result, we were able to show that gender scores are not yet a feasible instrument for routine clinical data and are able to make recommendations on how to update and extend the MII CDS in the future.

Comparison With Prior Work

Ballering et al [26] highlighted that gender scores should be the minimum effort in epidemiological studies, but the community should go further than that because the retrospective application of a gender score implies a lack of gender consideration from the outset of the study (eg, the study design). Our findings found several shortcomings with currently available retrospective gender scores. Therefore, our results suggest that self-reported gender assessments are more precise and better suited to assess gender, confirming the theory of Ballering et al [26].

Moreover, we can confirm the findings of Ballering et al [26], specifically that the most common variables in gender scores are related to occupation, income, education, civil status, caregiving and household responsibilities, and ways of spending (leisure) time. Furthermore, our results showed that, even though several of these variables are collected in everyday clinic work, they are not processed and stored in a machine-readable way.

Conclusions

Considering sex and gender enhances equity and research quality. Despite the high importance of the topic, it remains challenging to include gender into health research for several reasons. Ethical implications such as properly defining the concept of “gender” as opposed to “sex,” identifying appropriate ways of asking about a patient’s gender, and raising awareness of the importance with nurses and doctors are nontechnical reasons why the health gender gap remains. Technical implementation is hampered by the absence of a generally applicable clinical gender score. Structured, computer-processable data and metadata about gender-specific aspects in a patient’s social history is also lacking.

In this work, we identified, categorized, and systematically assessed state-of-the-art gender scores from epidemiology and clinical studies. We evaluated their applicability and practicability on a German national research dataset for routine clinical practice, the MII CDS. We found that gender cannot be predicted based on the MII CDS, even though several of the frequently used variables are part of routine clinical practice in Germany.

XSL•FO
RenderX

However, we see an urgent need to include gender-relevant information to the MII CDS in order to narrow the gap between routinely collected clinical data and available research data (see Multimedia Appendix 2). Therefore, further work is necessary to enable gender-specific analysis and to routinely collect more gender-specific data in clinics, for example, during patient admission.

Despite different approaches for assessing gender, no standardized and validated gender score that could be used retrospectively in clinical research exists.

Our study is limited to the German clinical landscape, and our evaluation of possible scores is based on a scoping review. Future investigations into the literature and common practices at clinics inside and outside Germany might give further insights and add to the action items suggested in this work.

Funding

This work was funded by the German Federal Ministry of Education andResearch as part of the project “Inclusive Excellence in Medicine” (01FP23G10A,01FP23G10B) and the “Network University Medicine” (01KXX2121).

Abstract

This research letter summarizes early lessons from 4 enterprise implementations of artificial intelligence–enabled customer relationship management platforms in health care and describes governance practices associated with improvements in affordability, adherence, and access at program level.

(JMIR Med Inform 2026;14:e83564) doi:10.2196/83564

KEYWORDS

artificial intelligence; health care customer relationship management; salesforce; patient affordability; patient adherence; patient access; digital transformation; governance

Introduction

Health systems continue to face pressure to improve patient outcomes while safeguarding affordability and equitable access [1-4]. Electronic health records support clinical workflows but are not designed for proactive patient outreach or service coordination [5]. Artificial intelligence (AI)-enabled customer relationship management (CRM) platforms support automated eligibility checks, outreach, and risk alerts [6-8]. This research letter summarizes early descriptive insights from enterprise implementations of AI-enabled CRM platforms.

Methods

Program Selection and Sampling Frame

A case-informed thematic analysis was conducted across 4 large health care programs. These were the largest CRM-based patient service deployments accessible to the author during this period. Programs were included if they had live AI-enabled CRM workflows for affordability, adherence, or access for at least 12 months. Each program operated independently with different teams, geographies, and product lines. Data reflect operations recorded between January 2019 and March 2024 across the 4 programs. All outcomes reflect a descriptive analysis of the operational dashboards and do not infer causal relationships.

Data Sources and Definitions

The following three data sources were used, each aggregated at program level.

1. Governance documents summarizing decision logs, compliance checkpoints, and escalation patterns.
2. Stakeholder feedback was gathered through routine program review meetings and documented in standard internal templates.
3. Internal dashboards tracking key operational indicators. These dashboards were deidentified, contained no patient level data, and were part of routine program monitoring.

Program level outcome metrics were defined as follows.

1. Adoption: proportion of active CRM users among provisioned patient service staff within a measurement window.
2. Affordability efficiency: average time for co-pay or financial assistance verification.

XSL•FO
RenderX

3. Therapy initiation time: average days between benefit verification and therapy start.
4. Discontinuation rate: proportion of enrolled patients who stopped therapy during a defined period.

Baseline values came from preimplementation operations, and follow-up reflected the first stable post launch period. Findings are observational.

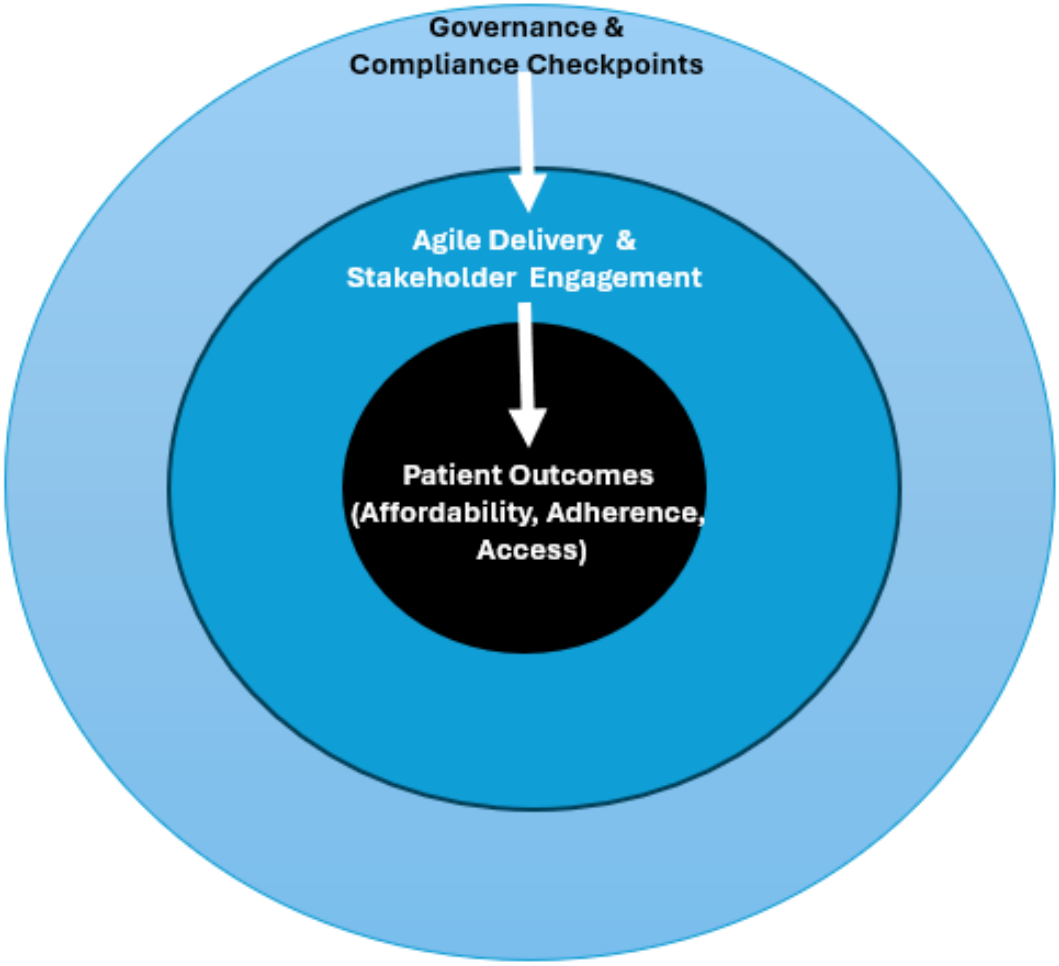
Ethical Considerations

This work used only aggregated, deidentified operational dashboards and program documents. No patient-level identifiable data or human subject interaction occurred. Institutional review board approval was not required.

Results

Theme 1: Patient Outcome Alignment and Sponsorship

Programs that centered goals on patient experience and outcomes such as therapy initiation time or affordability enrollment sustained stronger executive sponsorship. Programs framed as IT upgrades struggled to maintain alignment.



Theme 2: Continuous Engagement and Adoption

High adoption correlated with structured engagement of patient service teams and compliance officers. Regular feedback cycles supported adoption above 85% vs below 60% in minimally engaged programs [2].

Theme 3: Hybrid Governance Improved Delivery Efficiency

All 4 programs used a hybrid model that combined Agile sprints with scheduled compliance reviews. This approach reduced backlog resolution time by about 30%. Figure 1 summarizes the governance structure.

Figure 1. Hybrid governance framework for artificial intelligence–enabled customer relationship management. The framework illustrates three concentric layers: (1) patient outcomes (affordability, adherence, access) at the core, (2) agile delivery and stakeholder engagement in the middle layer, and (3) governance and compliance checkpoints in the outer layer. Arrows depict how governance structures enable engagement, which in turn drives improved patient outcomes.

XSL•FO
RenderX

Theme 4: Program-Level Improvements in Affordability, Adherence, and Access

Changes reflect aggregated dashboards and are not causal. Examples include a reduction in co-pay verification time from 4 days to 3 days (25% faster), a 12% reduction in therapy discontinuation rates, and a shortening of therapy initiation time from 20 days to 17 days (15% faster) (Table 1).

Table 1. Program level customer relationship management–enabled improvements.

Patient service	Artificial intelligence functionality	Outcome	Example (anonymized)
Affordability	Automated co-pay verification	Reduced processing time (4 days to 3 days, a 25% improvement)	Fortune 10 rollout (USA)
Adherence	Predictive risk alerts	12% reduction in therapy discontinuation	Consulting-led program
Access	Automated prior authorization	Therapy initiation shortened (20 days to 17 days, a 15% improvement)	Enterprise-wide program

Discussion

Summary of Findings

Across 4 large-scale implementations, AI-enabled CRM platforms supported improvements in affordability, adherence, and access through workflow automation, risk identification, and coordinated service tasks. The most consistent predictors of success were early alignment with patient-centered outcomes, continuous stakeholder engagement, and hybrid governance structures.

Interpretation and Limitations

Results reflect aggregated, unaudited operational dashboards and cannot establish causality [9,10]. Findings describe program-level improvements observed post implementation and may not generalize to organizations with different scales, regulatory environments, or infrastructure maturity.

Future Directions

Future studies should incorporate multi-site comparative designs, validated outcomes, and integration with digital therapeutics and device streams to strengthen evidence for CRM-enabled patient service transformation.

Conflicts of Interest

None declared.

Abstract

Background: Artificial intelligence–based medical devices (AIMDs) have emerged as transformative technologies in modern health care. However, comprehensive analysis of recent approval trends and characteristics of AIMDs in China remains limited.

Objective: This study aimed to provide an up-to-date overview of AIMDs approved in China up to June 2025.

Methods: We conducted a search of the Drugdataexpy database to identify AIMDs approved up to June 30, 2025, using artificial intelligence–related keywords in the "structural composition" and "intended use" fields. After manual verification and exclusion of non-AIMDs, we collected key characteristics, including name, manufacturer, approval date, risk class, clinical evaluation pathway, medical specialty, data source, review pathway, and algorithm type. Statistical analysis encompassed descriptive statistics and trend analysis. We used the Fisher exact test and Pearson chi-square test to assess the associations between risk class and categorical variables.

Results: A total of 154 AIMDs were identified since the first approval in 2020, with annual approvals increasing from 9 in 2020 to 45 in 2024 (a 49.53% compound annual growth rate), although the 20 approvals in the first half of 2025 suggest a potential moderation in pace. Most AIMDs (123/154, 79.9%) were categorized as class III, and the risk class was significantly associated with approval year (P=.03), manufacturer location (P=.03), and medical specialty (P=.004). Of the 123 class III devices, 19 (15.4%) were approved through innovation review, and 2 (1.6%) each were approved through priority and emergency approval. Deep learning was the dominant algorithm (143/154, 92.9%). Radiology dominated the field (106/154, 68.8%), with computed tomography serving as the primary data source (96/154, 62.3%), particularly for applications in pulmonary nodule detection and cardiovascular assessment. Clinical trials were the primary evaluation pathway for 76.6% (118/154) of all AIMDs. This approach was predominant for class III devices (116/123, 94.3%), whereas most class II devices (21/31, 67.7%) used a clinical exemption pathway. Market concentration was evident, with the top 4 manufacturers accounting for 38.3% (59/154) of all approvals and geographically clustered in major innovation hubs such as Beijing, Shanghai, Shenzhen, and Hangzhou.

Conclusions: China's AIMD ecosystem is experiencing growth, heavily focused on radiology and computed tomography–based solutions within a risk-proportionate regulatory framework. The market is characterized by significant manufacturer and geographic concentration.

Introduction

Artificial intelligence (AI) has emerged as a transformative force in modern health care, offering unprecedented capabilities in data analysis, pattern recognition, and clinical decision support [1,2]. Among its many applications, AI-based medical devices (AIMDs) have gained substantial traction, particularly in medical imaging, diagnostics, and predictive analytics [3]. These technologies promise to enhance diagnostic accuracy; reduce physician workload; and, ultimately, improve patient outcomes [4].

Worldwide, regulatory authorities have responded to the rapid development of AIMDs by establishing frameworks to ensure their safety, efficacy, and clinical utility [5-8]. In the United States, the Food and Drug Administration approved 691 AI- and machine learning (ML)–based medical devices by October 2023, with most cleared through the 510(k) pathway and concentrated in radiology and cardiology [9,10]. Similarly,

XSL•FO
RenderX

Europe has witnessed a substantial increase in CE-marked AIMDs, with approval numbers growing significantly since 2015 [11].

China, as a major player in both AI innovation and health care digitalization, has also made significant strides in this domain [12,13]. The National Medical Products Administration (NMPA) approved its first AIMD in 2020. Since then, the number of approvals has grown steadily, reaching 59 by mid-2023, all categorized as class III [14]. In China, medical devices are categorized into 3 classes based on increasing risk: class I (low risk), class II (medium risk), and class III (high risk). This classification dictates the regulatory pathway for market approval. Class III devices, deemed to pose the highest risk, require centralized registration approval from the NMPA itself and are subject to the most stringent review of clinical evidence. Class II devices may receive approval from provincial-level medical product administrations. AIMDs in China are typically categorized as class II or class III. The classification is determined by the algorithm's maturity and its role in clinical decision-making. Specifically, AIMDs with lower algorithm maturity are managed as class III devices if they are intended for auxiliary decision-making. Conversely, if they are intended for non–decision support tasks, they are managed as class II devices. In China, the clinical evaluation pathway for medical devices consists of 3 types: clinical trials, clinical comparison with similar products, and exemption from clinical evaluation. The clinical exemption pathway relies on the *Catalogue of Medical Devices Exempt From Clinical Evaluation* issued by the NMPA [15].

In recent years, the NMPA has actively refined and optimized its review processes for AIMDs. Key efforts include issuing evaluation guidelines, clarifying regulatory classifications, developing clinical evaluation guidance for specific product types, and introducing comprehensive support measures spanning the entire product life cycle [16-19]. These advancements have spurred a new wave of submissions and approvals, fostering a more structured and efficient ecosystem for AIMD market entry. Despite this progress, the literature to date primarily documents AIMD approvals in China up to 2023. There remains a lack of comprehensive analyses covering the most recent developments, particularly those in 2024 and 2025—a period likely marked by regulatory maturation and increased approvals. This study adopted innovation diffusion theory [20] as its primary analytical lens. This theory posits that the adoption rate and pattern of an innovation are influenced by its perceived attributes, including relative advantage, compatibility, complexity, trialability, and observability, within a specific social system.

Therefore, this study aimed to provide an up-to-date analysis of AIMDs approved in China as of June 2025. By examining trends in approval numbers, device characteristics, and regulatory pathways, it may offer insights into the evolving AIMD landscape in China and its implications for future health care innovation.

Methods

Data Source and Search Strategy

To identify AIMDs approved up to June 30, 2025, we searched the Drugdataexpy database [21]. As this is a Chinese-language database, the keyword search was performed using the Chinese equivalents of the following English-language terms in the database fields for "structural composition" and "indications" or "intended use": "deep learning," "machine learning," "neural network," "artificial intelligence," or "algorithm." The NMPA's official website, while providing free access to regulatory announcements, lacks keyword-based filtering capabilities in its search function, thereby limiting efficient retrieval of AIMDs.

This study included AIMDs regulated under the Guidelines for Registration Review of Artificial Intelligence Medical Devices [16], encompassing stand-alone software as a medical device and software in a medical device (SiMD) where AI is a core component. After manual review of full-text descriptions, we excluded records that did not meet the AIMD definition. We also removed entries corresponding solely to routine administrative renewals without changes to the device's core AI software or intended use. Substantive approvals for major changes or modifications to existing devices (eg, the addition of new AI functionality) were retained. Details of the search strategy and process are provided in Multimedia Appendix 1. To minimize omissions, we reran the search for each retained product name to capture devices manufactured by other companies. Our results were cross-validated against the AIMDs approved before July 2023 as listed in the study by Liu et al [14]. Ambiguous entries were checked against the corresponding NMPA evaluation reports or the manufacturers' websites.

Data Extraction

For each eligible AIMD, we extracted the approval number, device name, manufacturer, approval date, structural composition, intended use, risk class, clinical evaluation pathway (clinical trials, clinical comparison with similar products, or exemption from clinical evaluation), and review pathway (innovative, priority, or emergency special review vs standard). From these fields, we derived the city of the manufacturer, medical specialty, body area, and data source of the AIMD. The medical specialty for each AIMD was assigned based on the device's registered intended use and its core function. For devices with applications relevant to multiple specialties, the specialty was determined by the primary clinical context and decision support role stated in the indications for use. The body area for each device was functionally classified into nonoverlapping categories based on the primary anatomical structure and type of clinical analysis specified in the device's intended use: "heart" referred to devices targeting cardiac muscle, chambers, or electrophysiology (eg, electrocardiogram analysis); "cardiovascular" referred to devices focused on the vascular system (eg, computed tomography [CT] or magnetic resonance angiography); "lung" referred to devices analyzing lung parenchyma (eg, nodule detection); and "thorax" referred to devices assessing nonparenchymal structures within the thoracic cavity (eg, rib fracture detection). Algorithm type was determined through a tiered review: it was first identified from

XSL•FO
RenderX

the "structural composition" and "intended use" fields. If not specified there, the full registration dossier was consulted for explicit technical descriptions.

To facilitate downstream data processing, minor lexical variants in device names referring to the same product—such as "medical image" vs "imaging"—were standardized to a single, consistent terminology. For the analysis of market concentration, "manufacturer" referred to the ultimate parent corporate entity. AIMDs approved under the legal names of subsidiaries belonging to the same corporate group were aggregated under the parent company's name. A customized extraction form was piloted on 10 AIMDs and then applied independently by 2 reviewers (LZ and JY). Any disagreements were resolved through discussion until consensus was reached.

Statistical Analysis

Descriptive statistics were used to summarize the extracted variables and assess temporal trends. We calculated the compound annual growth rate for annual approvals from 2020 to 2024 and applied the Mann-Kendall trend test to assess the significance of the growth trend. For AIMDs that used multiple data sources, each modality was counted separately in the subsequent analysis of data source distribution. Associations between categorical variables (approval year, medical specialty, and manufacturer's city) and AIMD risk class were evaluated. The Fisher exact test was used for analyses involving variables with low expected cell counts (approval year and medical specialty), whereas the Pearson chi-square test was used for other comparisons. All tests were 2 sided, with $P<.05$ indicating statistical significance. Analyses were conducted using SPSS Statistics for Windows (version 27.0; IBM Corp).

Ethical Considerations

This study was a secondary analysis of publicly available regulatory records retrieved from a database. No data from human participants or identifiable personal information were used, and no primary data collection was conducted. The data are anonymized and publicly accessible. In accordance with the institutional policy of China Pharmaceutical University, ethics board approval was not required for this study. This study complies with China's Data Security Law [22] and Personal Information Protection Law [23].

Results

Overview of AIMD Approvals in China

As of June 30, 2025, a total of 154 AIMDs had been approved in China since the initial authorization in 2020. Figure 1 shows the inclusion flowchart for AIMDs approved in China. All devices were intended for use by health care professionals, with none designed for direct patient use. The annual approval numbers exhibited a clear upward trend from 2020 to 2024: 9 in 2020, a total of 16 in 2021, a total of 26 in 2022, a total of 38 in 2023, and 45 in 2024. From 2020 to 2024, the compound annual growth rate was 49.53%, and the trend test confirmed a statistically significant increasing trend in annual approvals ($P<.001$). Data for the first half of 2025 show 20 approvals, indicating that the trend may be entering a phase of moderation or plateau (Figure 2). Detailed information on these AIMDs sorted by approval date is provided in Multimedia Appendix 2.

Among the 154 AIMD approvals, 15 device types had at least 3 approvals (Table 1). Pulmonary nodule CT image auxiliary detection software ranked first with 14 (9.1%) approvals. It was followed by coronary artery CT angiography image vessel stenosis auxiliary assessment software with 8 (5.2%) approvals. Coronary artery CT fractional flow reserve calculation software and intracranial hemorrhage CT image auxiliary triage software tied for third, each with 7 (4.5%) approvals. Diabetic retinopathy fundus image auxiliary diagnosis software and pneumonia CT image auxiliary triage and assessment software each had 6 (3.9%) approvals. Pediatric hand x-ray image auxiliary bone age assessment software had 4 (2.6%) approvals. A total of 8 additional products each obtained 3 (1.9%) approvals, spanning various applications from CT image processing and electrocardiogram analysis to specialized endoscopic, angiographic, and x-ray–based diagnostic tools.

Data Source of AIMDs

As shown in Table 2, CT was the predominant data source for these AIMDs, identified in 62.3% (96/154) of approvals. This markedly exceeded other data sources, including x-ray (18/154, 11.7%), magnetic resonance imaging (12/154, 7.8%), endoscopy (9/154, 5.8%), electrocardiography (9/154, 5.8%), and fundus photography (9/154, 5.8%).

Table . Data sources used in approved artificial intelligence–based medical devices in China (2020 - 2025). Devices using multiple data sources were counted under each relevant modality. Therefore, the sum of counts exceeds the total number of devices (n=154).

Data source	Devices, n (%)
CT[a]	96 (62.3)
X-ray	18 (11.7)
MRI[b]	12 (7.8)
Electrocardiogram	9 (5.8)
Endoscopy	9 (5.8)
Fundus photography	9 (5.8)
Microscopic images	6 (3.9)
Ultrasound	3 (1.9)
Polysomnography	1 (0.6)

[b]MRI: magnetic resonance imaging.

Risk Class and Correlation Analysis

The vast majority of AIMDs (123/154, 79.9%) were categorized as class III, with 20.1% (31/154) categorized as class II (Figure 3). Significant associations were found between risk class and 3 key variables: the year of approval (P=.03), the manufacturer's city (P=.03), and the medical specialty (P=.004). In 2020 and 2021, only class III AIMDs were approved. After 2022, the share of class II AIMDs rose each year, from 11.5% (3/26) in 2022 to 35% (7/20) in 2025. The proportion of class III AIMDs was markedly higher in Hangzhou (16/16, 100%) and Beijing (47/54, 87%) than in other cities. The distribution of risk classes varied substantially across medical specialties. Ophthalmology and cardiology exhibited a 100% (16/16) class III rate, whereas 21.7% (23/106) of AIMDs in radiology were class II.

Figure 3. Sankey diagram of approved artificial intelligence–based medical devices in China (2020-2025).

Review Pathway and Algorithm

Of the 154 AIMDs, 23 (14.9%) gained market access through national-level special review pathways, which were exclusively for class III devices. Specifically, of the 123 class III devices, 19 (15.4%) were approved via innovation review, 2 (1.6%) were approved via priority review, and 2 (1.6%) were approved via emergency approval, constituting a combined 18.7% (23/123) of all class III approvals. The remaining 85.1% (131/154) of the devices followed the standard review process. Of the 154 AIMDs, 143 (92.9%) used deep learning architectures; 3 (1.9%) used classic ML methods; and for the remaining 8 (5.2%) devices, the algorithmic approach was not disclosed in the available registration materials.

Clinical Evaluation Pathways

Analysis of the clinical evaluation pathways for the 154 AIMDs (Table 3) showed that most (n=118, 76.6%) submitted clinical trial reports as their primary evidence. The remaining devices were approved either through an exemption from clinical evaluation (n=23, 14.9%) or via a clinical comparison with similar products already available on the market (n=13, 8.4%).

Of the 123 class III devices, 116 (94.3%) used clinical trials, whereas clinical comparison with similar products and clinical exemption were less common (n=5, 4.1% and n=2, 1.6% of devices, respectively). In contrast, among the 31 class II devices, clinical exemption was the most frequent pathway (n=21, 67.7%), followed by clinical comparison with similar products (n=8, 25.8%) and clinical trials (n=2, 6.5%).

XSL•FO
RenderX

Table . Clinical evaluation pathways for approved artificial intelligence–based medical devices in China (2020 - 2025; n=154).

	Total, n (%)	Class III devices (n=123), n (%)	Class II devices (n=31), n (%)
Clinical trial	118 (76.6)	116 (94.3)	2 (6.5)
Exemption from clinical evaluation	23 (14.9)	2 (1.6)	21 (67.7)
Clinical comparison with similar products	13 (8.4)	5 (4.1)	8 (25.8)

Medical Specialty and Body Area

The 154 AIMDs spanned 14 medical specialties. Radiology dominated with 68.8% (n=106) of approvals, followed by cardiology (n=16, 10.4%), ophthalmology (n=9, 5.8%), and gastroenterology (n=9, 5.8%). The remaining AIMDs covered pediatrics, pathology, cytogenetics, sleep medicine, orthopedics, neurosurgery, hematology, gynecology, urology, and dentistry (Table 4).

The most common body areas for these AIMDs were the lung (27/154, 17.5%), the cardiovascular system (24/154, 15.6%), and the head (22/154, 14.3%), with the heart accounting for 7.1% (11/154). Additionally, 10.4% (16/154) of the AIMDs were used across multiple body areas (Table 5).

Table . Distribution of artificial intelligence–based medical devices by medical specialty in China (2020 - 2025; n=154).

Medical specialty	Devices, n (%)
Radiology	106 (68.8)
Cardiology	16 (10.4)
Ophthalmology	9 (5.8)
Gastroenterology	9 (5.8)
Pediatrics	4 (2.6)
Others	10 (6.5)

Table . Distribution of artificial intelligence–based medical devices by target body area in China (2020 - 2025; n=154).

Body area	Devices, n (%)
Lung	27 (17.5)
Cardiovascular system	24 (15.6)
Head	22 (14.3)
Multiple	16 (10.4)
Heart	11 (7.1)
Eyes	9 (5.8)
Thorax	8 (5.2)
Bone	6 (3.9)
Liver	5 (3.2)
Colon	5 (3.2)
Neck	4 (2.6)
Hand	4 (2.6)
Breast	4 (2.6)
Others	9 (5.8)

Manufacturer and Geographic Distribution

We identified 67 manufacturers in total, with a high degree of market concentration. The top 4 companies alone produced 38.3% (59/154) of the AIMDs: Yukun and United Imaging led with 11% (17/154) of the devices each, followed by Infervision with 9.1% (14/154) and Deepwise with 7.1% (11/154). In contrast, 48 manufacturers had only 1 or 2 products each. Manufacturers with more than 2 approved AIMDs are shown in Table 6.

Geographically, of the 154 approved AIMDs, 54 (35.1%) were from manufacturers headquartered in Beijing, 32 (20.8%) were from Shanghai, 18 (11.7%) were from Shenzhen, and 16 (10.4%) were from Hangzhou (Table 7). Thus, these 4 cities accounted for 77.9% (n=120) of all the approved AIMDs. Beijing was home to Yukun and Infervision, Shanghai was home to United

XSL•FO
RenderX

Imaging, and Hangzhou was home to Deepwise, which were precisely the top 4 companies listed above. Shenzhen hosted a broader ecosystem, including Carewell, Tencent Smart Healthcare, RuiXin, and Edan Instruments, but none brought more than 10 AIMDs to market.

Table . Manufacturers with ≥2 approved artificial intelligence–based medical devices in China (2020‐2025; n=154).

Manufacturer	Devices, n (%)
Yukun	17 (11.0)
United Imaging	17 (11.0)
Infervision	14 (9.1)
Deepwise	11 (7.1)
Yizhun	5 (3.2)
SenseTime	4 (2.6)
Carewell	4 (2.6)
Tongxin	3 (1.9)

Hefei	1 (0.6)
Guiyang	1 (0.6)

Discussion

Principal Findings

This study provided an overview of AIMDs in China up to June 2025. A total of 154 AIMDs were approved, and annual approvals showed an upward trend. Most of these AIMDs (123/154, 79.9%) were class III and relied on deep learning. They were concentrated in radiology, particularly CT-based; produced by a small number of manufacturers; and located in a few cities.

China did not approve its first AIMD until 2020, later than both the United States and Europe, where approvals for AIMDs occurred as early as 2015 [10] despite variations in the definitions of AIMDs. The number of AIMD approvals in China remains lower than that in the United States and Europe. However, we have observed a rapid increase in AIMD approvals in China, reflecting technological advancements and a supportive regulatory environment.

Our analysis, extending the timeline to mid-2025, built on and updated the foundational work of Liu et al [14]. While confirming the continued dominance of radiology and class III devices previously reported, our data revealed new dynamics. Specifically, we observed a marked increase in the absolute number of approvals and a significant shift with the emergence of class II AIMDs after 2022—a trend that was not fully evident in the earlier data. Furthermore, the sustained market concentration among top manufacturers and in key geographic hubs suggests that these early structural characteristics consolidated rather than dispersed as the market grew. These comparisons highlight the rapid evolution of this field and underscore the value of longitudinal tracking to inform regulatory and market strategies. It should be noted that our counts for 2021 to 2022 were slightly higher than those reported by Liu et al [14]. We identified additional AIMDs, including image processing software and CT fractional flow reserve calculation software. A primary reason for this discrepancy is a fundamental difference in data scope. Our dataset encompassed both centrally approved class III devices and provincially approved class II devices, whereas Liu et al [14] primarily focused on class III approvals granted by the NMPA. Additionally, differences can be attributed to distinct search strategies: our approach incorporated AI-related keywords—such as “deep learning” and “algorithm”—within the “structural composition” and “intended use” fields, whereas their search relied on device-naming conventions, using terms such as “computer-assisted detection” and “computer-assisted triage.”

A prime example of an AIMD category with significant clinical penetration in China is pulmonary nodule CT image auxiliary detection software. This category had 14 approved variants from multiple manufacturers, making it the most widespread AIMD type. According to manufacturer data, United Imaging has deployed its solution in over 2000 hospitals nationwide. Their

XSL•FO
RenderX

clinical evaluations indicate that the software can increase the detection rate of pulmonary nodules by approximately 32% and improve radiologists' reading efficiency by approximately 26% compared with conventional methods [24].

Regarding risk classification, most Chinese AIMDs are designated as class III, whereas all US AIMDs are cleared as class II [25] and Europe has only approximately 1% of AIMDs in class III [11]. The large share of class III in China suggests that many AIMDs were treated as high risk and required the strictest review. From 2020 to 2021, only class III AIMDs were observed; from 2022 onward, this pattern shifted, with a steady influx of class II products. The observed change can be attributed to the *Principles for the Classification Defining of AI-Based Medical Software Products* issued by the NMPA in 2021 [26], which applies to both software as a medical device and SiMD. For SiMD, the assigned risk class applies to the product as a whole, reflecting a holistic regulatory assessment of the AI functionality's clinical role within the device. This guideline allowed AIMDs with mature algorithms that provided only non–real-time assistance—such as measurement, marking, or workflow optimization—to be placed in class II. Previously, any software bearing AI technology had been categorized as class III. The significant association between risk classification and the manufacturer's city likely reflects regional policy support and the clustering of expertise in cities such as Beijing and Hangzhou, where high-risk AIMD development appears concentrated.

Our analysis further revealed that the vast majority of approved AIMDs were supported by premarket clinical evidence through clinical trials or clinical comparison with similar products. Exemption from clinical evaluation was granted for only 23 AIMDs, 21 (91.3%) of which were class II and predominantly consisted of image processing software. This pattern reflects the practical implementation of a risk-based regulatory framework: higher-risk AIMDs generally necessitate more robust premarket clinical validation, while pathways such as exemption or comparison are more frequently applied to lower-risk AIMDs to facilitate efficient market access. Nevertheless, reliance on exemptions and comparative assessments for lower-risk approvals raises concerns about the sufficiency and transparency of premarket evidence. To strengthen the regulatory framework, we recommend clarifying exemption eligibility criteria and tightening the evidentiary standards for demonstrating equivalence.

We did not identify any safety-related recalls among the 154 AIMDs approved as of June 2025. A recent study of Food and Drug Administration–authorized AI and ML devices found that 5.2% were linked to adverse events and 5.8% were recalled, primarily due to software issues [27]. The lack of similar public reports in China may stem from its later market start and differences in data transparency. Accordingly, establishing a robust postmarket surveillance system is essential to detect risks arising from algorithm or workflow changes, and it requires commitments from regulators and manufacturers to ensure the ongoing safety of AIMDs.

Radiology dominated China's AIMD landscape, with an emphasis on CT-based applications, reflecting alignment with the nation's health care needs and its existing technological infrastructure. This focus is evident in the concentration of devices targeting pulmonary nodules and cardiovascular conditions, both representing substantial disease burden. Pulmonary nodules are clinically significant as early indicators of lung cancer, which remains the most common cancer type and the leading cause of cancer death in China [28]. Similarly, cardiovascular diseases rank as the leading cause of overall mortality, accounting for approximately 2 out of every 5 deaths [29].

The high proportion of radiology-related AIMDs approved in China aligns with the trend observed in the United States [25]. Medical imaging modalities such as CT, magnetic resonance imaging, and x-ray generate structured, digital data well suited for AI applications. Among these modalities, CT images have formed the basis for most AIMDs developed in China. The widespread availability of CT scanners in Chinese health care facilities, together with relatively uniform imaging protocols, has accelerated the growth of AI diagnostic software based on CT.

Market concentration emerged as another notable finding, with a limited number of manufacturers accounting for a large share of approved AIMDs. Notably, these dominant manufacturers were primarily headquartered in major cities such as Beijing, Shanghai, and Hangzhou. This market dominance appears to stem from the convergence of several reinforcing factors. These include the concentration of technical and regulatory expertise, preferential access to high-quality medical data through partnerships with leading hospitals, and the availability of substantial venture capital in these regions [30,31].

The observed characteristics of China's AIMD market, specifically its pronounced concentration in clinical specialties and geographic regions, were interpreted through the lens of innovation diffusion theory. First, radiology dominated the field, especially CT-based applications, illustrating innovations with high compatibility through seamless integration into digital imaging workflows and a clear relative advantage in improving efficiency during high-volume screenings, which promotes rapid early adoption. Second, the geographic concentration of approvals in Beijing, Shanghai, Shenzhen, and Hangzhou reflects the social system effect. These megacities concentrate critical resources for diffusion, such as policy incentives, venture capital, and technical talent, forming powerful hubs that accelerate local development and initial market penetration of AIMDs.

The observed approval trends could not be fully understood without considering China's evolving regulatory framework. Our data showed sustained growth consistent with the aims of recent NMPA reforms. Notably, the 2025 measures to optimize full life cycle supervision and support the innovative development of advanced medical devices explicitly aimed to accelerate reviews of advanced devices, optimize premarket processes, and strengthen postmarket surveillance. This policy shift provided essential context for interpreting market dynamics and indicated a regulatory environment oriented toward facilitating efficient innovation while ensuring safety throughout a product's life cycle. Furthermore, the emphasis on fostering

XSL•FO
RenderX

high-level industrial clusters offered a lens to interpret the pronounced geographic concentration of approvals observed in this study. The synergy between concentrated innovation resources in hubs such as Beijing and Shanghai and proactive regulatory support appears to be a defining feature of China's AIMD ecosystem.

Limitations

This study has several limitations. First, the identification of an AIMD depended on the explicit mention of AI techniques in its functional components or intended use. Devices that did not explicitly state the use of AI might have been missed despite cross-checking ambiguous cases with review reports and websites. Second, classifying medical specialties was challenging because many devices spanned multiple clinical domains. We assigned a single primary specialty, which may underrepresent secondary applications. Third, although we standardized device names by merging minor variations that referred to the same product, some inconsistencies may persist, underscoring the need for unified naming conventions.

Conclusions

This analysis indicated that AIMDs in China are experiencing rapid growth. The regulatory landscape is dominated by radiology applications, with CT-based solutions for pulmonary nodules and cardiovascular conditions especially prominent. There is also a high degree of market concentration among leading manufacturers.

Abstract

Background: Medical discharge letters are critical for continuity of care but often lack clarity and personalization, making it difficult for health care providers to retrieve essential information. While large language models (LLMs) offer potential for automating summary generation, their effectiveness depends heavily on the quality and contextual relevance of the prompts used.

Objective: The objective of this study was to develop and describe a human-centered, replicable framework for creating individualized prompts that guide LLMs in generating summaries tailored to the specific needs of health care providers.

Methods: A multidisciplinary workshop was conducted at Ghent University Hospital with 26 health care providers from 5 institutions, including hospitals and general practitioner networks. Participants brainstormed ideal summary formats, generating 170 ideas categorized into themes such as "structure," "medical history," "medication," and "follow-up." These insights informed the development of a 110-item structured questionnaire distributed to 33 participants. Responses were used to generate personalized and generic prompts, refined using the context, objective, style, tone, audience, and response (CO-STAR) framework.

Results: "Structure and layout" (40/170, 23.5%) and "follow-up" (27/170, 15.9%) were the most emphasized categories in the workshop. The questionnaire confirmed the importance of the "follow-up" and "medical history" sections. Prompts were generated per participant and by health care type, incorporating frequently selected responses. The CO-STAR framework was applied to improve prompt clarity and alignment with clinical expectations. Communication emerged as a new category during the workshop and was universally valued in the questionnaire.

Conclusions: This study presents a novel, systematic approach to prompt engineering in clinical artificial intelligence applications. By translating qualitative input into structured, individualized prompts, the framework is designed to improve the usability and relevance of artificial intelligence–generated summaries. It proposes a scalable approach for integrating human-centered design into LLM deployment in health care, with the aim of supporting more accurate, context-aware clinical documentation. However, these outcomes remain to be empirically validated; this study is limited to the design and implementation of a human-centered prompt construction pipeline in a specific multicenter setting.

KEYWORDS

large language models; clinical artificial intelligence integration; clinical AI integration; prompt engineering; discharge summaries; human-centered design; artificial intelligence; AI

Introduction

Background

Medical discharge letters are essential communication tools, yet their length, complexity, and variability often hinder efficient information retrieval by health care professionals, who frequently encounter difficulties in identifying key elements such as medication changes, follow-up recommendations, and significant diagnostic findings. Moreover, the informational needs of a general practitioner, a surgeon, an intensivist, and other health care providers could differ substantially.

This complexity not only hinders continuity of care but also introduces risk. In recent years, large language models (LLMs) have shown promise in helping extract, summarize, or restructure clinical documents such as medical discharge letters [1]. However, evaluating the quality and safety of such applications remains a human-centered task requiring careful planning and expert validation.

XSL•FO
RenderX

Numerous studies have evaluated the use of LLMs for generating medical discharge letters [2-4]. Despite the growing sophistication of these models, human evaluation remains indispensable for assessing the clinical accuracy, completeness, and safety of the generated outputs. Physicians, in particular, play a critical role in validating whether artificial intelligence (AI)–generated summaries address the nuanced informational needs of health care providers [2,3]. As Tam et al [5] emphasize, a structured planning phase is essential before initiating human evaluation. This phase begins with clearly defining the evaluation objectives and the specific tasks to be assessed. However, while the final evaluation is typically conducted by clinicians, the development of the prompts that guide LLMs is often carried out by engineers or a single physician. This disconnect may result in prompts that do not fully reflect the diverse and context-specific requirements of end users [2-4,6,7].

Effective medical prompt engineering is emerging as a critical skill for health care professionals navigating the integration of AI into clinical practice. As Meskó [8] emphasizes, the rise of LLMs such as ChatGPT represents a paradigm shift in health care, offering unprecedented opportunities for enhancing clinical workflows, patient communication, and decision-making. However, realizing these benefits depends heavily on the clinician's ability to craft precise, context-aware prompts that guide AI systems toward generating accurate and relevant outputs. Patil et al [9] further highlight that well-designed prompts—grounded in medical knowledge and aligned with evidence-based guidelines—are essential for eliciting clinically meaningful responses from AI tools. They argue that prompt engineering should be recognized as a core competency in medical education, enabling physicians to harness AI effectively while maintaining ethical standards and minimizing bias. These perspectives underscore that prompt engineering is not solely a technical task. However, at present, it is neither a skill that all health care professionals possess nor one that they have time to develop in depth. Moreover, as generative AI continues to evolve, its evaluation should be approached as an ongoing process, recognizing that performance, reliability, and clinical relevance may shift over time and require continuous monitoring and adaptation. Furthermore, due to the variability in ChatGPT's responses, evaluating its performance in health care requires repeated testing to ensure reliability. Without incorporating repetition, research findings may be biased and lack credibility [10].

In our project, Framework & Implementation of AI Tools (FRAIT), we aim to develop AI-driven solutions that are tailored to the specific needs of health care providers. The first phase of the project adopts a design thinking approach to design a prompt that accurately reflects the unique requirements and expectations of individual health care professionals. This involves close collaboration to understand their workflows and information needs and the specific clinical contexts in which they operate. Once this tailored prompt is established, the second phase will involve evaluating its effectiveness by applying it to Dutch medical discharge letters, assessing how well it extracts or summarizes relevant information. In this paper, we concentrate on the initial phase: constructing a prompt that is both meaningful and practical for the health care provider, ensuring that it aligns with their clinical and administrative objectives.

Objectives

The aim of this study was to develop a comprehensive process that starts by identifying the needs of health care providers regarding the ideal format for medical discharge letter summaries and results in creating an individualized prompt to generate such summaries effectively.

Methods

Part 1: Workshop

Overview

Health care providers, primarily physicians, were recruited from 5 different institutions: 3 hospitals (Ghent University Hospital, AZ Oudenaarde, and AZ Sint-Lucas Ghent) and 2 general practitioner circles (Huisartsenvereniging Ghent and Huisartsenkring Schelde Leie). The target recruitment range was 20 to 30 health care providers.

The workshop took place on Wednesday, October 16, 2024, at Ghent University Hospital. The workshop followed a 3-part structure consistent with design thinking principles: an energizer to foster engagement, a brainstorming session to elicit ideas, and a feedback round to collaboratively refine and prioritize outputs.

A set of 7 questions, each with 3 possible responses (blue, yellow, and green; Table S1 in Multimedia Appendix 1) was provided to assess the level of LLM use. Results were presented as numbers and percentages. Data were collected through 2 different persons manually counting the groups and a validation based on pictures (Figure S1 in Multimedia Appendix 1).

Following an introduction to the project, the participants were organized into 6 groups, each encompassing a diverse array of institutions and specializations. We used the digital platform Padlet [11] to conduct this brainstorming session, which allowed us to document all steps in the process. The participants had the option to enter their ideas on an available laptop or through their smartphones, which did not require any log-in credentials or other personal information.

The main question for the brainstorming session was the following:

> *What does my ideal generated summary from a medical discharge letter look like? Eg: use of bullet points, Eg: include history. Take us through your thinking: what should be included? All ideas are welcome – personal preference counts. No consensus required, the groups are for cross-pollination / inspiration.*

The emphasis was placed on both layout and content (eg, "I would like to see the accurate medical history, and I would like it to be highlighted").

All ideas were free text, although they required a label or category. The available labels at the start of the brainstorming session were "history," "current problems," "medication,"

XSL•FO
RenderX

"decision," "follow-up," "structure and layout," and "other" or "I don't know." New categories could be added during the brainstorming session.

A preliminary feedback session was held after 15 minutes to discuss the label "other" in more detail for refinement. Subsequently, an additional 15-minute brainstorming session was scheduled.

Statistics

A word cloud was used to visualize and cluster tokens and words based on their frequency within various ideas. The number of ideas by group and category was reported as frequencies and percentages, means and SDs, and medians and IQRs.

During the workshop, results were presented by category as well as the most common words within each category. The full text of the ideas for these specific words was provided to facilitate further discussion within the group if any clarification was required.

Part 2: Questionnaire

The ideas generated from the brainstorming session were systematically categorized. Two independent researchers (MD and HR) conducted data cleaning to eliminate duplicates and segment the ideas into smaller, manageable components. A structured table was developed (Table S2 in Multimedia Appendix 1) where each row represented a primary idea and subsequent columns contained subquestions. Each idea was assigned to a predefined category. For multiple-choice questions, the possible answers were maintained in a separate table (Table S3 in Multimedia Appendix 1). Using this structured table, a complete list of questions was generated. Additionally, we developed a prompt for each potential response in this questionnaire in Dutch, as well as an automated English translation. The questionnaire was designed using Microsoft Forms, with the embedded Microsoft Copilot used to streamline the automation process.

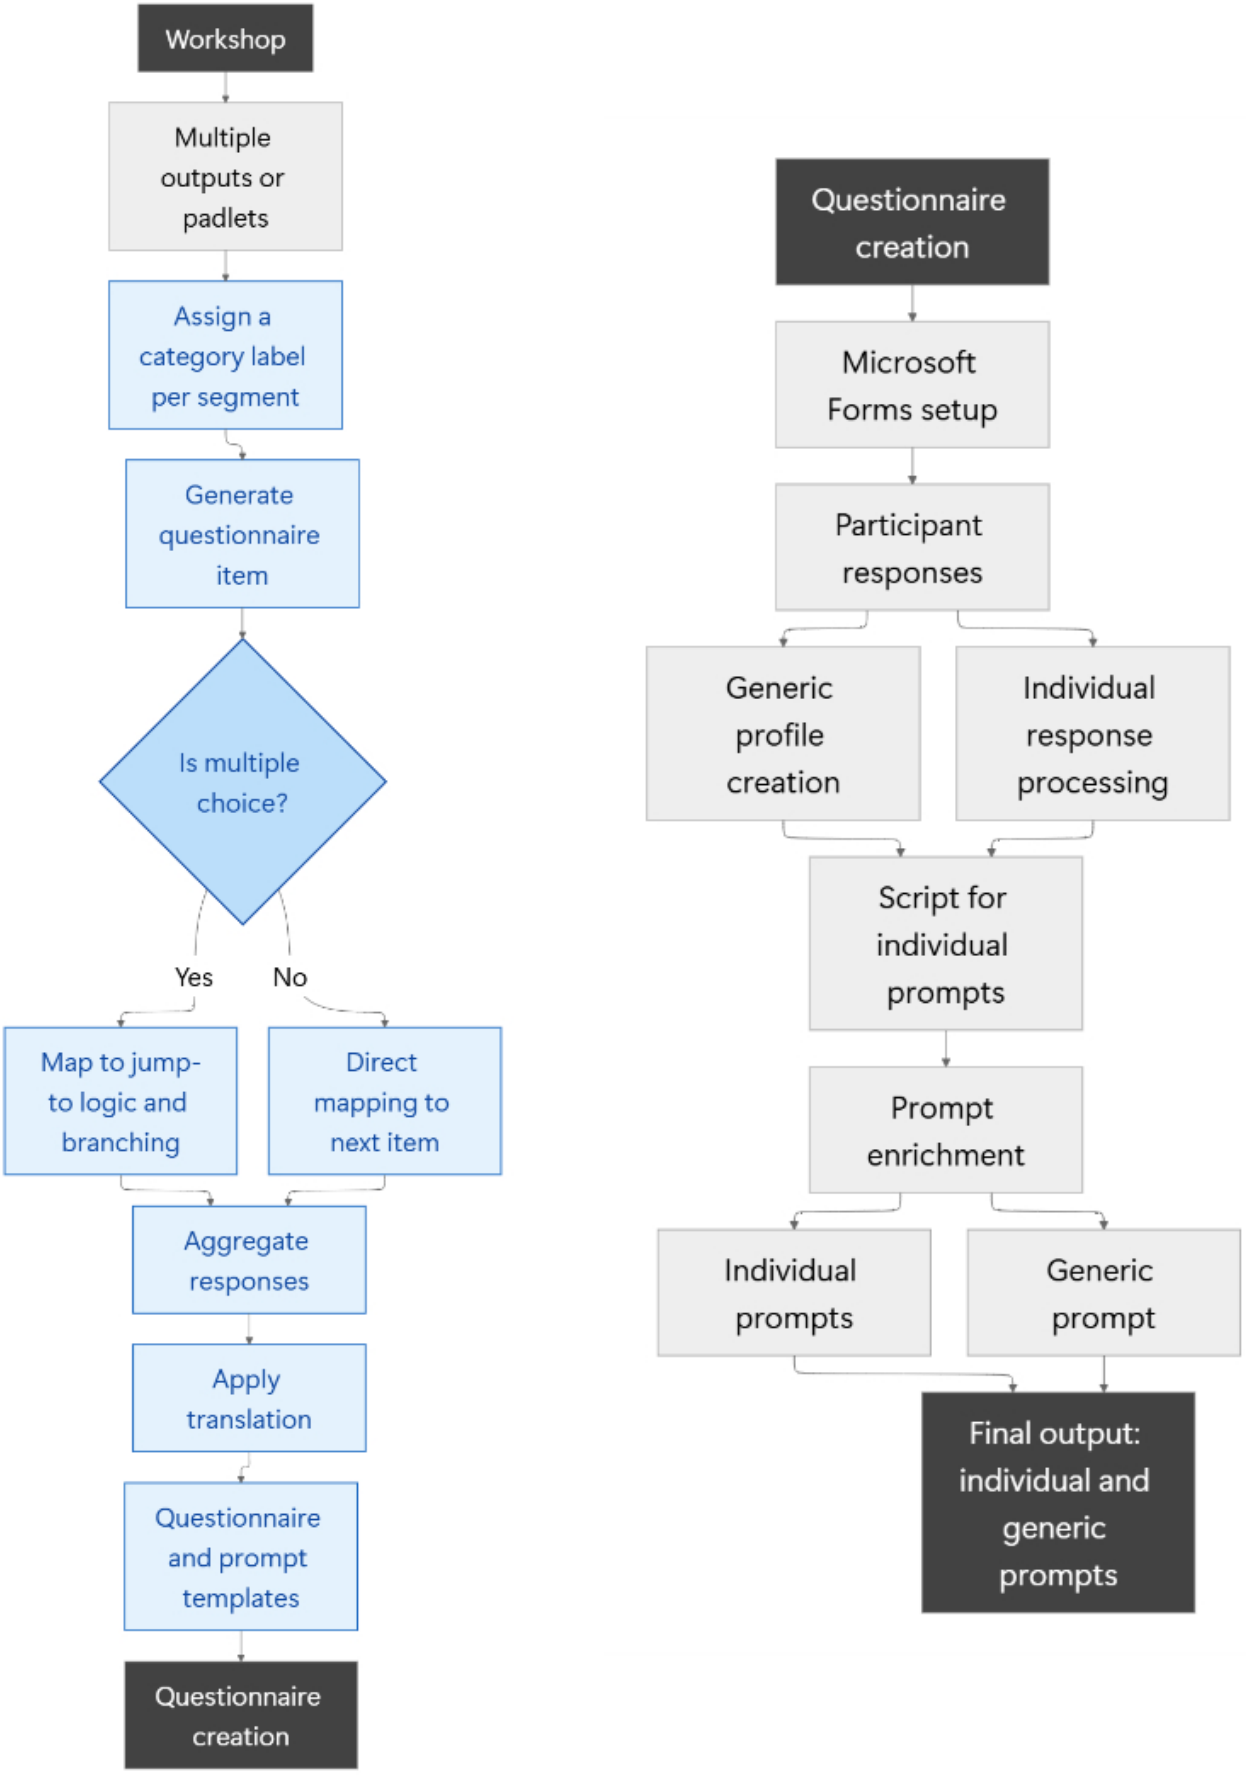
Initially, some general questions were added regarding the type of health care provider and the number of years in practice. An open-ended question for suggestions was included at the end. This questionnaire was distributed to all participants of the workshop and an additional group of general practitioners who will be involved in the ongoing process of the FRAIT project.

The results of the questionnaire were combined with the predetermined prompt for each answer, resulting in a unique prompt for each participant. Additionally, a generic prompt was created overall and by type of health care provider. This generic prompt selected the most frequently chosen answer for each question. For multiple-choice questions, an option must be present in at least one-third of the answers.

To transform the workshop ideas into a structured questionnaire and prompt templates, we applied a systematic multistep process. Each free-text idea was carefully reviewed and split into the smallest meaningful units, with each segment representing a single, actionable suggestion. For example, a statement such as "I want the summary to highlight medication changes and provide a clear follow-up plan" was divided into 2 distinct ideas: highlighting medication changes and providing a clear follow-up plan. Segmentation was guided by the principle that each unit should be assignable to a single category and actionable in prompt design.

Segments were then assigned to predefined categories, such as "medical history," "medication," "follow-up," and "structure and layout." If a segment fit multiple categories, it was assigned to all relevant categories (multilabel coding). New categories were created when multiple participants raised themes not covered by existing categories.

The coding process was iterative and collaborative. Two researchers independently segmented and categorized all ideas. Rather than aiming for consensus or exclusion of divergent ideas, we used a structured framework (Tables S2 and S3 and Figure S2 in Multimedia Appendix 1) to ensure that all contributions from the workshop were systematically included. MD constructed the initial framework by segmenting and categorizing all ideas, whereas HR independently reviewed the results for completeness and accuracy. Any ambiguities or uncertainties were discussed, but the primary objective was the comprehensive inclusion of all perspectives, not convergence on a single interpretation. This approach maximizes methodological transparency and reproducibility, as every idea generated during the workshop is traceable through the coding and questionnaire development pipeline.



Two Python scripts (Python Software Foundation) were created to automate data processing and prompt generation. The first script constructs a dynamic questionnaire by normalizing text, analyzing response frequencies, and reshaping data for optimal mapping between questions and answers. The second script translates completed responses into individualized and generic AI prompts using index-based mapping and neural machine translation for Dutch-to-English conversion. Both scripts aggregate and profile responses to ensure that generated prompts reflect the most common preferences among health care providers, supporting transparent and reproducible prompt engineering.

Finally, we enhanced all prompts by incorporating segments before and after the original prompts, adhering to the context, objective, style, tone, audience, and response (CO-STAR) framework [12-14]. To operationalize the CO-STAR framework, we incorporated both participant input and established clinical communication standards during the prompt enrichment phase. Workshop and questionnaire participants were asked to articulate their preferences regarding the presentation of discharge summaries, including aspects such as clarity, formality, and professional perspective. These responses informed the initial drafting of prompts. Figure 1 illustrates the complete process.

We compared responses in the questionnaire for each category of health care provider, ensuring that there were at least 5 responses per type. Our primary emphasis was on content questions, not layout questions. Because our sample size was limited, we restricted our analysis to descriptive statistics only.

Ethical Considerations

All approvals were granted by the ethical committee of Ghent University Hospital (ONZ-2024 - 0304). The ethical committees of AZ Sint-Lucas Ghent and AZ Oudenaarde were informed of the study. Each participating organization, both hospitals and general practitioner circles, handled recruitment themselves, using their own internal communication channels and procedures to invite participants. The recruitment letter was included with our submission to the ethical committee. Informed consent was obtained from all participants before the start of the workshop (Figure S3 in Multimedia Appendix 1).

To ensure participant anonymity and data privacy, all responses collected during the workshop and questionnaire phases were anonymized before analysis. No personally identifiable information was linked to the responses, and participants were given the option to contribute via digital platforms without requiring log-in or personal credentials. Data were stored securely and accessed only by authorized research team members. These measures were implemented in accordance with institutional guidelines and approved by the relevant ethical committees.

Participants received compensation for the time they spent contributing to the project. This compensation acknowledged the substantial effort required to evaluate the summaries and attendance to the workshop, to ensure that clinicians were remunerated for their professional expertise and time commitment. No additional financial or material incentives were provided beyond this time-based compensation.

Results

Part 1: Workshop

A total of 26 health care providers were recruited for this workshop (Tables S4 and S5 in Multimedia Appendix 1). However, 7.7% (2/26) of the individuals were not present during the first half hour and did not respond to the initial questions. Overall, 5 groups were formed: 4 groups consisting of 5 participants each and 1 group consisting of 6 participants.

Table S1 in Multimedia Appendix 1 lists the questions at the start of the workshop and outlines the profiles of the participants. Figure S4 in Multimedia Appendix 1 presents the outcomes of tokenizing all ideas, which are visualized using a word cloud. Figure S5 in Multimedia Appendix 1 also contains an example of the initial concepts as presented to the participants from one of the groups.

Following a 15-minute feedback session and a plenary discussion on topics categorized as “other,” a new “communication” category was established based on requests from 2 separate groups, demonstrating responsiveness to participant input. Through an iterative process of coding and review, all ideas, including those applicable to multiple categories, were systematically preserved.

At the conclusion of the workshop, a comprehensive compilation of 170 ideas generated by all groups was assembled. The complete list, along with corresponding group names, can be found in Table S6 in Multimedia Appendix 1. The “structure and layout” category contained the greatest number of ideas (40/170, 23.5%), whereas only 6.5% (11/170) of the ideas were left unlabeled by participants. “Communication,” introduced during the second round, constituted the smallest category (Table 1).

The finalized coded table served as the foundation for developing a 110-item questionnaire using branching logic for multiple-choice questions. This systematic approach facilitated the creation of both individualized and generic prompt templates.

Table . Distribution of workshop-generated ideas by category, illustrating the thematic focus and relative emphasis placed by health care providers on different aspects of discharge summary design.

Category	Participant group	Ideas (N=170), n (%)	Ideas (n), mean (SD)	Ideas (n), median (IQR)
Communication	4	8 (4.7)	2 (1.2)	2 (1-3)
Current problems	5	20 (11.8)	4 (2)	5 (3-5)
Decision	5	19 (11.1)	3.8 (1.9)	3 (3-4)
Follow-up	5	27 (15.9)	5.4 (1.1)	5 (5-6)
Medical history	5	24 (14.1)	4.8 (3.8)	4 (3-5)
Medication	5	21 (12.4)	4.2 (3.3)	3 (2-6)
Other or “I don’t know”	4	11 (6.5)	2.8 (1.5)	2 (2-3)
Structure and layout	5	40 (23.5)	8 (2.5)	8 (7-8)

Part 2: Questionnaire

After refining the ideas, a structured table was created as the foundation for the questionnaire. These 2 files, along with their interpretations (available only in Dutch), are included in Tables S2 and S3 and Figure S2 in Multimedia Appendix 1. We provide a Python script that can be used to generate a list of questions and the appropriate “jump-to” points where necessary starting from these files. The resulting 110 questions were uploaded to Microsoft Forms, ready to be answered by the participants. The complete list of questions is available in Table S7 in Multimedia Appendix 1, and a (translated) snippet of these questions can be found in Figure 2. In the same script, when creating questions with multiple possible answers, the corresponding prompt for each answer was also added.

XSL•FO
RenderX

Figure 2. Snippet from the resulting questionnaire list translated into English demonstrating the mapping of provider needs to specific questions and corresponding artificial intelligence prompt template.

39	What medication do you want to see?	Medication	['None', 'All Medication', 'Medication on Admission', 'Medication on	[40, 40, 40, 40, 40, 40, 40]	['Show the none', 'Show the all medication', 'Show the medication upon admission', 'Show the medication upon dismissal', 'Show the changed	item

Table S8 in Multimedia Appendix 1 shows the number of questions for each section. “Medical history” and “admission history” constituted the largest parts of the questionnaire.

Most health care providers (30/33, 90.9%) were physicians, with over 81.8% (27/33) having more than 5 years of experience (Figure S6 in Multimedia Appendix 1). The “follow-up” section was highly valued by all participants, whereas the “examination” section received the least interest (Figure S7 in Multimedia Appendix 1).

An example of the resulting individualized and final generic prompt can be found in Figure S8 in Multimedia Appendix 1.

The implementation of the CO-STAR framework produced prompts that effectively reflected both health care provider preferences and established professional standards. The “style” component was defined as “written from the perspective of a medical professional,” and the “tone” element specified the use of formal language. These parameters were selected based on aggregated participant feedback, which underscored the importance of professionalism and clarity in clinical communication. Consequently, the final prompts incorporated user-driven insights alongside best practices, ensuring that AI-generated summaries were both contextually relevant and professionally suitable. A comprehensive overview of the adjustments made to the CO-STAR framework is provided in Figure 3. The prompt structure was enhanced with an introductory segment and a concluding section, whereas the central portion, labeled “<Individual preference>,” reflects findings from the questionnaire.

Table 2 shows the differences in the 10 most common preferences regarding discharge summaries between general practitioners and specialists. General practitioners tend to seek additional details regarding medication and follow-up, whereas specialists more frequently request information pertaining to admission history and examinations.

Figure 3. Illustration of the context, objective, style, tone, audience, and response framework application in prompt engineering: integrating health care provider preferences and clinical standards to optimize artificial intelligence–generated discharge summary prompts.

Color code: C=context - O=objective - S=style - T=tone - A=audience - R=response

"This text is a medical discharge letter (the report of a hospital admission). I would like a summary in Dutch. The intention is that I, as a healthcare provider, can use this letter to properly follow up the patient. The summary must be a maximum of one page long and clearly structured. Use formal language based on the expertise of a physician. Start with the patient's name, date of birth and the name of the hospital. All dates must be in the format day/month/year. If a requested part is not in the letter, bundle the missing parts at the bottom per section in one sentence and use 'Not mentioned' as an indication. “

<Individual preferences>

“We would like to provide some additional explanation: The name of the sections should be translated like: General = Algemeen, Medical History = Voorgeschiedenis, Medication = Medicatie, Examinations = Onderzoeken, Admission history = Opnameverloop, Follow-up = Follow-up, Decision = Besluit. If new diagnoses are requested in the history, this means that you add the new diagnoses that were made during admission to the history. By interventions we mean operations. The admission process describes the path that the patient takes during the admission, the evolution of the condition and the steps that are taken during the admission in chronological order. Here we also expect to report the administration of blood transfusions, radiotherapy or chemotherapy, the performance of diagnostic examinations such as biopsies, endoscopies, the placement of feeding tubes, etc. In Medical imaging / Technical examinations we mean by the protocol all actions that are performed during this examination and all findings that are made in this. If changes in medication are requested, we mean changes in dose, frequency and form and whether medication has been stopped completely or new medication has been started. To do this, make a comparison between the medication on admission on the one hand and the medication on discharge and the medication at the therapy proposal on the other. Medication that has remained the same is not mentioned in the case of changed medication. If the question is about the risk of clotting, mention blood clots/thrombosis and embolisms and the use of blood-thinning medication. Also mention here if you find anything about cerebral infarction/CVA or heart attack/AMIAMI. Clotting disorders should also be mentioned here. Communication is about discussing the condition and the further policy with the patient and his family. If a section should not be mentioned, leave it out of the summary completely. The information in the summary should come from the original letter. An exception to this is if ICD codes or ICPC codes are mentioned. When asking for ICD codes, the ICD-10 code should be mentioned next to the diagnosis, as can be found at https://icd10be.health.belgium.be/. When asking for ICPC codes, you can find them at https://browser.icpc-3.info/. If a patient has come from another hospital, mention this under general.”

RenderX

Table . Comparison of discharge summary preferences between general practitioners (GPs) and specialists, highlighting the top 20 content areas with the greatest differences in selection rates. Options with negative percentages were favored by specialists, whereas those with positive percentages were preferred by GPs.

Section	Preference	Difference between GPs and specialists (%)
Admission history	Showing acquisition of the interventions performed	−25.3
Admission history	Showing consultations	−14.0
Examinations	Showing the protocol	−13.3
Medical history	Showing life-threatening allergies	−13.3
Examinations	Showing laboratory test results	−12.6
Admission history	Showing main diagnosis	−11.6
Medical history	Showing reaction to allergy	−11.6
Admission history	Showing new diagnoses	−9.8
Examinations	Showing clinical investigation	−8.6
Examinations	Showing medical imaging or technical investigations	−8.6
Follow-up	Showing inclusion in specific care processes	26.8
Follow-up	Showing message for GP	18.7
General	Showing whether the patient is palliative	16.6
Follow-up	Showing the institutions involved	16.6
Medication	Showing changed medication (dose, frequency, and shape)	15.1
Medication	Showing new medication	14.4
Follow-up	Showing in section “follow-up” the communication	13.2
Follow-up	Showing multidisciplinary follow-up (social and home help)	13.2
Medication	Showing stopped medication	12.5
Medication	Showing duration of medication use	12.3

Discussion

Principal Findings

From a single workshop with motivated health care providers, it was possible to generate an automated, individualized prompt tailored to their respective needs, enabling the creation of an ideal medical discharge summary. The process began with the identification of key areas that required attention, such as medical history, medication details, and follow-up procedures. Participants provided input on what specific information should be included in each section, ensuring that the final generated summary would be comprehensive and tailored to the needs of health care professionals. To the best of our knowledge, this is the first study to begin with a multidisciplinary workshop involving physicians from diverse specialties and translate their input into tailored AI prompts.

The collaboration between specialists and general practitioners resulted in an exchange of ideas, leading to a broader perspective from both groups. This synergy allowed for a more holistic approach to the creation of the summary, taking into account both the specialized and general aspects of patient information. At the same time, it became clear that reflecting on one’s ideal summary is not always easy—despite it being a personal matter. Sparring with others did not necessarily lead to adopting their viewpoints but proved valuable in helping participants critically reassess and refine their own preferences.

Dividing the scope into layout and content made the resulting ideas more concrete. By separating these 2 elements, participants were able to focus more effectively on each aspect, leading to clearer and more actionable suggestions. This also leads to a clearer prompt for further evaluation possibilities (in future work), providing a solid foundation for future improvements and refinements based on feedback from health care professionals.

Within the workshop, numerous ideas were generated. The open question at the end—“Do you have any additional comments or suggestions regarding this questionnaire? Are there aspects that you think are missing or not sufficiently addressed? Please note them below.”—received responses primarily on practical issues from only a few participants.

During the workshop, it was observed that all groups contributed an equal number of ideas. Most ideas were related to the

XSL•FO
RenderX

structure of the generated summary, primarily due to the existence of a single category for the broader theme. The "follow-up" category encompassed the highest number of ideas, although there was significant overlap with other categories. The "communication" category, introduced during the workshop, predominantly contained ideas that pertained to the "follow-up" category. This trend was also evident in the questionnaire, where the "communication" section was the only one indicated as desirable by all participants.

The "medical history" and "admission history" sections often included diverse content, resulting in numerous questions from participants. The "medication" and "follow-up" sections also encompassed a wide range of topics, which necessitated their inclusion as multiple-choice questions. This strategy allowed for a targeted approach, meaning that only 1 detailed question on content was asked for each selected topic (eg, "What information do you want to see for the medication? 'Start date,' 'Duration,' 'Dose,' 'Time of intake,' 'Frequency,' 'Form e.g. oral,' 'Show drug substance name,' 'Clinical effect,' 'Criteria for stopping/changing specific medication,' 'Reason for starting, stopping, changing'").

Such a detailed and structured approach ensures that all relevant aspects are thoroughly explored and addressed, providing a comprehensive framework for summarizing medical discharge letters efficiently and effectively.

Comparison With Prior Work

The most significant refinement aligned with the CO-STAR prompt engineering framework was introduced in the "response" section, with a particular emphasis on clarifying the definitions of key terminology embedded within the prompt. This adjustment is crucial for enhancing the model's interpretability and ensuring consistent semantic alignment between the prompt and the generated summary. As demonstrated in the work on SARA [13], a generative AI for legal summarization, precise control over terminology and density within prompts directly influences the coherence and legal validity of the summaries produced. Similarly, the Institute of Electrical and Electronics Engineers Computer Society's International Conference on Computers, Software, and Applications 2024 study [12] on automatic smart contract generation underscores the importance of terminological precision in the response phase to mitigate ambiguity and improve automation reliability. Furthermore, the insights from Teo [14] from the GPT-4 prompt engineering competition highlight how nuanced refinements in prompt structure—especially in the response section—can significantly elevate performance in competitive and real-world applications.

Our findings align with broader trends in health informatics that emphasize the centrality of user needs and adaptive information delivery. For instance, psychoeducational mobile health interventions for parents of small-for-gestational-age fetuses have shown how adaptive, user-centered systems can enhance engagement and outcomes [15]. The ADEPT framework further illustrates how optimizing data flow in dynamic, real-world environments supports effective, personalized care [16]. By translating qualitative input from health care providers into structured, individualized prompts, our framework extends these principles to the domain of clinical AI, ensuring that LLM-generated discharge summaries are not only technically robust but also contextually relevant and responsive to end user needs.

Limitations

An important aspect of this framework's broader impact is its adaptability beyond its original Dutch-speaking setting. Future efforts should focus on translation and cultural adjustment of all materials, questionnaires, and prompts used in workshops. This will require close collaboration with language specialists and domain specialists to ensure accurate terminology, workflows, and compliance. Owing to its modular design, the framework allows for easy alignment of categories and prompts with various health care systems' specific summarization needs. This methodology is applicable across medical specialties by engaging domain experts during assessment and prompt development, ensuring that specialty-specific information needs are addressed. By taking these steps, the framework will become more valuable and help develop AI tools that are effective, equitable, and well-suited to diverse clinical contexts.

Despite aiming for comprehensiveness, the balance between breadth and depth sometimes required trade-offs, prioritizing clarity and efficiency over detailed customization. For instance, preferences were gauged using a multiple-choice question such as "What do you want to see..." followed by only a single question about layout preferences for each item.

This initial prompt is a first step in the improvement in the quality and relevance of AI-generated summaries. It is evident that further refinement is necessary. This ongoing fine-tuning will involve a meticulous evaluation of the generated summaries, taking into account detailed feedback from health care professionals. Such iterative adjustments aim to enhance the precision and contextual accuracy of the summaries, ensuring that they meet the nuanced needs of diverse medical specializations.

Future Steps

The subsequent phase will involve evaluating the generic and individual prompts, with the assessment being developed collaboratively with the health care providers. The prompt will be broken down into smaller components, generating binary questions regarding layout and more specific inquiries related to content accuracy (eg, if an outcome is incorrect, does it constitute a hallucination?). A collection of representative medical discharge letters will be made available for this purpose. Upon completion of the evaluation, it will likely be necessary to review the prompt to identify opportunities for further optimization and integrate additional content informed by the evaluation findings.

Conclusions

This study presents a novel, systematic framework for developing individualized prompts to summarize medical discharge letters grounded in the real-world needs of health care providers. A key strength of this approach lies in the deliberate separation between layout and content preferences, which proved highly effective in capturing both structural and informational expectations.

XSL•FO
RenderX

By translating qualitative input into structured, personalized prompts, this framework aims to improve the relevance and usability of AI-generated summaries and serve as a replicable model for diverse clinical and research settings, although empirical validation remains necessary. The framework supports applications in data collection, data analysis, and personalized feedback generation. This study is limited to the design and implementation of a human-centered prompt construction pipeline in a specific multicenter setting; direct evaluation of AI-generated outputs and broader scalability will be addressed in future work.

Acknowledgments

The authors would like to express their sincere gratitude to the entire team at the Data Science Institute of Ghent University Hospital, as well as to the management, program participants, and coordinators representing the participating organizations. Artificial intelligence was used within the project to enhance efficiency: Figure 1 was created with assistance from Claude (Anthropic). The questionnaire was created in Microsoft Forms using Microsoft Copilot under the Microsoft Office license of Ghent University Hospital.

Funding

The Framework & Implementation of AI Tools project was funded by the Belgian government through the Data Innovation project.

Data Availability

All data generated or analyzed during this study are included in this published article and its supplementary information files (Multimedia Appendix 1). The supporting Python scripts are available in a public GitHub repository [17]. The script frait_part1_questions.py generates a dynamic questionnaire for the Framework & Implementation of AI Tools system. Its primary output is an organized set of questions designed to assist health care providers in selecting relevant sections and details for inclusion in a medical summary. The script frait_part1_prompt.py translates completed questionnaire responses into artificial intelligence prompts, which are used for medical document summarization.

Evaluating GPT-4 Responses on Scars or Keloids for Patient Education: Large Language Model Evaluation Study

Mingjun Rao, MD; Tang Xiujun, MSc; Wang Haoyu, BA

Department of Plastic Surgery, Guizhou Provincial People's Hospital, 83 Zhongshan East Road, Nanming District, Guiyang, China

Corresponding Author:
Tang Xiujun, MSc
Department of Plastic Surgery, Guizhou Provincial People's Hospital, 83 Zhongshan East Road, Nanming District, Guiyang, China

Abstract

Background: Scars and keloids impose significant physical and psychological burdens on patients, often leading to functional limitations, cosmetic concerns, and mental health issues such as anxiety or depression. Patients increasingly turn to online platforms for information; however, existing web-based resources on scars and keloids are frequently unreliable, fragmented, or difficult to understand. Large language models such as GPT-4 show promise for delivering medical information, but their accuracy, readability, and potential to generate hallucinated content require validation for patient education applications.

Objective: This study aimed to systematically evaluate GPT-4's performance in providing patient education on scars and keloids, focusing on its accuracy, reliability, readability, and reference quality.

Methods: This study involved collecting 354 questions from Reddit communities (r/Keloids, r/SCAR, and r/PlasticSurgery), covering topics including treatment options, pre- and postoperative care, and psychological impacts. Each question was input into GPT-4 in independent sessions to mimic real-world patient interactions. Responses were evaluated using multiple tools: the Patient Education Materials Assessment Tool-Artificial Intelligence for understandability and actionability, DISCERN-AI for treatment information quality, the Global Quality Scale for overall information quality, and standard readability metrics (Flesch Reading Ease score, and Gunning Fog Index). Three plastic surgeons used the Natural Language Assessment Tool for Artificial Intelligence to rate the accuracy, safety, and clinical appropriateness, while the Reference Evaluation for Artificial Intelligence tool validated references for reference hallucination, relevance, and source quality. We conducted the same analysis to assess the quality of GPT-4–generated content in response to questions from 3 medical websites.

Results: GPT-4 demonstrated high accuracy and reliability. The Patient Education Materials Assessment Tool-Artificial Intelligence showed 75.5% understandability, DISCERN-AI rated responses as "good" (26.3/35), and the Global Quality Scale score was 4.28 of 5. Surgeons' evaluations averaged 3.94 to 4.43 out of 5 across dimensions (accuracy 3.9, SD 0.7; safety 4.3, SD 0.8; clinical appropriateness 4.4, SD 0.5; actionability 4.1, SD 0.8; and effectiveness 4.1, SD 0.8). Readability analyses indicated moderate complexity (Flesch Reading Ease Score: 50.13; Gunning Fog Index: 12.68), corresponding to a 12th-grade reading level. Reference Evaluation for Artificial Intelligence identified 11.8% (383/3250) hallucinated references, while 88.2% (2867/3250) of references were real, with 95.1% (2724/2867) from authoritative sources (eg, government guidelines and the literature). The overall results about questions from medical websites were consistent with the answers to Reddit questions.

Conclusions: GPT-4 has serious potential as a patient education tool for scars and keloids, offering reliable and accurate information. However, improvements in readability (to align with sixth to eighth grade standards) and reduction of reference hallucinations are essential to enhance accessibility and trustworthiness. Future large language model optimizations should prioritize simplifying medical language and strengthening reference validation mechanisms to maximize clinical utility.

(JMIR Med Inform 2026;14:e78838) doi:10.2196/78838

KEYWORDS

scar; keloid; GPT-4; patient education; generative AI; generative artificial intelligence; readability; large language model

Introduction

Scars and keloids are common skin healing outcomes [1], often causing discomfort during the proliferative phase [2]. When located on visible areas such as the face, they can severely impact a patient's appearance, leading to psychological distress such as low self-esteem, anxiety, and depression, which may further hinder social interactions and career development [3]. Scars near joints may cause functional limitations, while perineal scars can result in long-term complications such as dyspareunia and dysmenorrhea [4,5]. Many patients urgently seek to improve both the aesthetic and functional aspects of scars or keloids. However, treatments often require multimodal approaches over weeks to months, making high patient adherence crucial.

XSL•FO
RenderX

Consequently, access to accurate, timely, and comprehensive management information is critical for patients to better understand treatment expectations, options, prognosis, and potential complications [6-9].

Currently, patients increasingly rely on internet-based health information [10]. This trend faces multifaceted challenges, including information overload, variability in source credibility and content accuracy, and the health literacy required to understand the contents [11,12]. Notably, many online resources on scars or keloids are often unreliable, fragmented, or difficult to understand, failing to tackle the fundamental needs of patients with scars or keloids [13].

In recent years, artificial intelligence (AI) tools powered by large language models (LLMs), such as GPT-4 (used by ChatGPT), have demonstrated significant potential in delivering medical information [14]. GPT-4's capacity to generate natural language responses through interactive conversions could aid users in understanding intricate medical concepts, treatment, and management strategies, positioning it as a potentially valuable alternative to traditional search engines for accessing knowledge associated with scars or keloids [15-17].

It is reported that 52% of US adults have used LLMs, and GPT-4, as a leading LLM, receives over 5 billion monthly visits. In total, 39% of LLM users have used LLMs for health care queries [18]. Despite the increasing use of LLMs in health care [19-21], there remains a research gap, and it is currently unclear whether GPT-4 can generate high-quality patient education content related to scars and keloids. Thus, we conducted this study to comprehensively assess the use of GPT-4 in keloid and scar patient education by performing a multidimensional evaluation (encompassing accuracy, reliability, readability, and reference quality) of GPT-4 responses.

Methods

Study Objective

This study aimed to investigate the potential of GPT-4 to provide reliable, accurate, readable, and actual medical information for patients with scars or keloids. To achieve this, we used GPT-4 (OpenAI) to evaluate its accuracy, reliability, readability, and hallucinations in answering questions related to treatments of scars or keloids.

Question Collection

The research questions were manually collected by the authors from Reddit. First, the authors analyzed all posts on the "Hot" page (the most popular and recently active posts) of the r/Keloids subreddit, all posts on the r/SCAR subreddit, and all posts on the r/PlasticSurgery subreddit as of April 6, 2025. We extracted the main text of each post that included the keywords "Scar" or "Keloid" and organized the data using Microsoft Excel. Second, one author (MR) excluded the posts that contained no questions, were duplicates, or had repeated questions. In addition, the same author (MR) performed the initial classification of the questions. To ensure reliability and minimize bias, another author (WH) independently reviewed the process. Consistency between the two authors' classifications was confirmed through discussion. This data collection approach has been adopted in previous Reddit-based research [22]. Furthermore, we adopted 49 questions about keloids or scars from 3 medical websites.

Ethical Considerations

The institutional review board of the People's Hospital of Guizhou Province, affiliated with Guizhou University, deemed this study exempt from ethics approval.

Quality Assessment

Overview

Each question was input individually into GPT-4. Following previous research protocols, a new chat session was initiated for each question to avoid context contamination and to simulate real-world patient interactions [23]. Consistent with real-world activities using GPT-4, no specialized prompt instructions were appended to the question inputs. The contents generated by ChatGPT-4 were evaluated using a modified version of existing health information quality assessment tools.

Patient Education Materials Assessment Tool-AI Tool

The Patient Education Materials Assessment Tool (PEMAT) was used to assess the understandability and actionability of ChatGPT-generated content. The original PEMAT includes 17 items for understandability and 7 for actionability. Since all contents generated by ChatGPT are pure text, the PEMAT was simplified to 8 items for understandability and 3 items for actionability (Multimedia Appendix 1). Each item received 1 point if it met the standard, and scores were reported as percentages. A score of 70% or greater was recorded as a "pass" per PEMAT guidelines [24].

DISCERN-AI Tool

The DISCERN standard, a previously validated tool to help health care consumers and professionals evaluate the quality of treatment information, was adapted for ChatGPT-generated content. Since all contents generated by ChatGPT are pure text, 7 items (questions 3 - 9 from the 15-item DISCERN tool) were selected and scored on a 1 to 5 scale (Multimedia Appendix 2). Each output was rated as follows: very poor (7 - 12 points), poor (13 - 17 points), fair (18 - 23 points), good (24 - 28 points), and excellent (29 - 35 points) [24,25].

Global Quality Scale

The Global Quality Scale (GQS) is a 5-point Likert scale used to evaluate information quality and the flow and ease of use of information. The scores range from 1 (low quality) to 5 (high quality), while scores of 4 or 5 indicated high-quality outputs, a score of 3 was considered moderate quality and scores of 1 or 2 were categorized as low quality.

Readability Assessment

The readability of the ChatGPT-generated content was evaluated using several established readability formulas, including Flesch Reading Ease score, Gunning Fog Index, Flesch-Kincaid Grade Level, Coleman-Liau Index, and Simple Measure of Gobbledygook (SMOG). Each output was copied into Microsoft Word and analyzed via the Readable website [26]. The Flesch Reading Ease score ranges from 0 to 100, and higher scores

XSL•FO
RenderX

indicate greater readability. A score between 60 and 70 corresponds to reading levels of grades 8 and 9 and is generally understandable by the average adult. The Gunning Fog Index and Flesch-Kincaid Grade Level are used to estimate sentence complexity; the scores represent the years of formal education required to understand the contents. For example, a score of 12 implies the output is suitable for readers at the 12th-grade level. The Coleman-Liau Index is similar to the Gunning Fog Index and Flesch-Kincaid Grade Level but uses character counts instead of syllables, making it more suitable for languages where syllable counts may not accurately reflect complexity. The SMOG Index measures syllable density, often used to assess health information materials. A score of 12 indicates that the material is suitable for readers at the 12th-grade level or higher.

Natural Language Assessment Tool for Artificial Intelligence

Three experienced plastic surgeons independently reviewed each GPT-4–generated content using a specially developed Natural Language Assessment Tool for Artificial Intelligence (NLAT-AI) [24]. Using this tool, we assessed accuracy, safety, appropriateness, actionability, and effectiveness. Each output was rated using a 5-point Likert scale (1=strongly disagree, 5=strongly agree; Multimedia Appendix 3). All results were summarized using descriptive statistics.

Reference Evaluation for AI

Given known issues of LLM hallucination (ie, generating plausible but nonexistent references), a brief evaluation tool, Reference Evaluation for AI, was developed to analyze references provided in ChatGPT-generated content [27]. Each reference was verified through direct links or a Google search. The tool assessed (1) reference hallucination (whether references were real or fabricated), (2) relevance and consistency between references and AI output, and (3) source quality (based on the authority of the issuing institution or organization, such as government guidelines, health care organizations, or scientific research; Multimedia Appendix 4).

Results

Question Collection and Classification

A total of 507 posts were identified and analyzed (posts from the r/Keloids subreddit: n=193, 38.1%; posts from the r/Keloids subreddit: n=211, 41.6%; and posts from the r/Scar subreddit: n=103, 20.3%). After removing posts that merely shared information or were duplicates, 354 unique questions were obtained. The questions were categorized into 16 groups based on their contents (Table 1). Furthermore, we obtained 49 questions from 3 medical websites that included 38 unique questions (Table S1 in Multimedia Appendix 5).

Table . Questions on scars or keloids from Reddit (N=354).

Question group	Questions, n (%)
Questions on other respects	28 (7.9)
Questions on other treatments for scars or keloids	4 (1.1)
Questions on common treatments for scars or keloids	46 (13)
Questions on trauma-related scars or keloids	16 (4.5)
Questions on psychological issues caused by scars or keloids	9 (2.5)
Questions on at-home scar or keloid care	3 (0.8)
Questions on preoperative scar or keloid consultation	37 (10.5)
Questions on postoperative scar or keloid consultation	55 (15.5)
Questions on selection of treatments for scars or keloids	80 (22.6)
Questions on impact of scars or keloids on daily life	2 (0.6)
Questions on scar or keloid symptoms	7 (2)
Questions on scar camouflage	6 (1.7)
Questions on the impact of nutrition on scars or keloids	3 (0.8)
Questions on choosing physicians for scar or keloid treatment or related costs	32 (9)
Questions on old scars	14 (4)
Questions on scar or keloid prevention	12 (3.4)

Evaluation of GPT-4–Generated Content

GPT-4 generated content that provided a wide range of medically accurate information. Using the PEMAT-AI, DISCERN-AI, and GQS patient education material evaluation tools, the output of GPT-4 was assessed, with all tools indicating high scores. The overall understandability score using PEMAT-AI easily surpassed the 70% threshold for acceptability (mean 75.5%, SD 12.2%). The DISCERN-AI tool resulted in an overall rating of “good” quality (mean 26.3, SD 3.4), with all 16 groups of questions rated as “good.” The GQS score averaged 4.3 out of 5 (SD 0.8), categorizing the outputs as high quality. More details are shown in Table S1 in Multimedia Appendix 6. Intraclass correlation coefficient (ICC) for

XSL•FO
RenderX

PEMAT-AI, DISCERN-AI, and GQS were 0.73, 0.69, and 0.78, respectively (Table S2 in Multimedia Appendix 5). The results of the ICC demonstrated high reliability of the evaluation tools.

Plastic Surgeons' Evaluation via the NLAT-AI Tool

Using the NLAT-AI tool, 3 independent plastic surgeons evaluated the GPT-4–generated content. All dimensions of the contents received scores above the neutral midpoint of 3 on a 5-point Likert scale. The overall average scores for each dimension were as follows: accuracy 3.9 (SD 0.7), safety 4.3 (SD 0.8), appropriateness 4.4 (SD 0.5), actionability 4.1 (SD 0.8), and effectiveness 4.1 (SD 0.8). More detailed descriptive statistics for each question are presented in Table S2 in Multimedia Appendix 6. Internal validity tests showed an ICC of 0.76 (Table S2 in Multimedia Appendix 5), indicating high reliability.

Readability Assessment

The results of the readability assessments indicated that the GPT-4–generated content was "difficult to read." The average Flesch Reading Ease score was 50.1 (SD 8.1), which is considered moderately difficult. The Gunning Fog Index averaged 12.7 (SD 3.3), and the Flesch-Kincaid Grade Level was 12.4 (SD 2.5), indicating that the text was at a high school level (approximately suitable for individuals aged 16 - 17 years). The Coleman-Liau Index averaged 12.8 (SD 2.6), and the SMOG Index averaged 11.3 (SD 3.16). More detailed evaluation results are shown in Table S3 in Multimedia Appendix 6.

Reference Evaluation for AI Assessment

Most of the references provided in GPT-4's output effectively supported the content. A total of 88.2% (2867/3250) of the references were from actual sources (actual websites or academic papers), while 383 hallucinated references were identified. Among these 2867 real references, 2746 (95.8%) references effectively supported the content. In addition, a total of 95.1% (2724/2867) of the real references were from authoritative sources (government guidelines, health care organizations, or scientific research). More detailed evaluation results are shown in Table S4 in Multimedia Appendix 6.

The Assessment of Questions From Websites

The evaluation results of GPT-4 responses to website-sourced questions were broadly consistent with those from Reddit-derived questions across all assessments (Tables S3-S6 in Multimedia Appendix 1).

Discussion

Principal Findings

This is the first study to assess the overall quality of ChatGPT responses to real-world questions from Reddit about keloids or scars. The results revealed that the content generated by GPT-4 was generally comprehensive and aligned with current medical guidelines and the literature. Using several assessment tools, as well as plastic surgeons' evaluations, the scores were robust, and the plastic surgeons' evaluations were largely positive. The overall results indicate that GPT-4–generated content is reliable, accurate, safe, and actionable, despite there being room for improvement in terms of readability and hallucination.

Over 80% of dermatology outpatients obtain medical information through social media or the internet, with 47% considering it an important source of information [28]. Although patients have access to a wealth of information, studies evaluating the quality of online health information have identified significant deficiencies [29]. As for scars and keloids, the information available to patients contains a lot of low-quality content. A previous study assessing 88 websites related to "burn scars" showed that most of the commercial websites provided information of moderate to poor quality [13]. In contrast, LLMs provide a broad range of fundamentally accurate information and real-time dynamic interactions compared to traditional webpages [30,31]. As a leading LLM, GPT-4 exhibits certain advantages over other LLMs and has demonstrated top-tier performance across diverse evaluations in health care. In answering questions from the American Board of Surgery In-Training Examination, GPT-4 achieved an accuracy rate comparable to that of Copilot, while significantly outperforming Gemini [32]. In other fields of clinical medicine, GPT-4 also attained superior performance relative to other LLMs [33,34]. However, in a substantial number of evaluative scenarios, the performance of GPT-4 did not yield statistically significant differences when compared with Copilot or Gemini. Collectively, the performance of GPT-4 currently represents the best capability of LLMs.

In our study, experienced plastic surgeons evaluated the outputs of GPT-4, confirming that the contents were reliable and accurate. The accuracy of GPT-4 in patient education has also been studied in other clinical contexts (eg, rhinoplasty, sleep apnea, and prostate cancer) where it demonstrated high accuracy and strong reliability [24,35,36]. Such high accuracy and reliability suggest that LLMs such as GPT-4 can effectively address clinical questions from patients with scars or keloids, serving as a valuable auxiliary tool in clinical medicine.

Despite GPT-4's significant potential in responding to keloid or scar patient queries, its outputs commonly had high reading difficulty. Our study revealed that the average reading level of GPT-4–generated content was at a high school level. The results suggest that ChatGPT does not always meet the comprehension needs of all patients. The relatively low readability of GPT-4 can hinder accessibility for certain socioeconomic populations with limited health literacy [37]. Among the latest generation of young adults in the United States, up to 13% have not graduated from high school. This rate reaches 20% among people of color (including African Americans and Native Americans) [38], who are also identified as high-risk groups for developing malignant scars [39]. Due to poor readability, GPT-4 has apparent barriers in its application among these populations [40,41]. To enhance the utility of LLMs for populations with lower educational attainment, it is recommended that developers consider training specialized LLMs based on datasets with good readability [42]. Biomedical text can be simplified through hyperparameter substitution techniques, improving patient understanding [43]. In addition, structured prompting can also contribute to enhancing readability [44].

XSL•FO
RenderX

Moreover, our study also revealed the existence of hallucination, where GPT-4 cited nonexistent references or websites. Fabricated references not only mislead readers and distort their understanding of keloid or scar but also—given the presence of numerous seemingly authoritative yet false information sources—may lead patients to overtrust the content generated by GPT-4 [45,46]. Given the presence of hallucinations, specific clinical diagnosis and treatment must rely on clinicians; LLMs can only serve as auxiliary tools. To address the hallucination issue in LLMs, it is recommended that developers effectively apply retrieval-augmented generation to retrieve documents from an external corpus (such as academic library systems), as this can significantly reduce the hallucinations [47-49]. Integrating external, structured knowledge sources (such as knowledge graphs, databases, or other domain-specific resources) into LLMs can also help ensure that LLMs produce responses with fewer hallucinations [50]. Furthermore, prompt engineering can mitigate hallucination by improving the reasoning capabilities [51].

GPT-4 can provide comprehensive and generally accurate information, which can further assist patients with keloids or scars in accessing timely and precise information. However, current LLMs exhibit limitations, such as hallucinations and relatively low readability; therefore, they are not recommended as the sole source of information for patients. Limited by the lack of clinical background in current LLMs; the insufficient ability to process audio, image, and video information; limited ability to access academic libraries; and the noninterpretability of black box algorithms, current LLMs still require further development to be adapted for applications in health care [52]. The AI agent, as a promising approach, can extend the capabilities of LLMs by enabling them to use external tools, plan and execute multistep tasks, as well as interact dynamically [53]. Multimodal LLM is promising to process text (eg, clinical notes and user-input questions), medical images (eg, photos and computed tomography scans), and videos (eg, treatment procedures) provided by patients, which will more effectively assist patients and health care providers in clinical practice about keloid and scar management [54].

Limitations

Most of the questions collected from Reddit were posts from patients who had not yet sought medical care. Consequently, the questions posed may be biased toward pretreatment information needs, as fewer questions were reported during the treatment phase. This may compromise the generalizability of GPT-4's evaluation across different patient care stages. In addition, Reddit users are concentrated in the age group of 18 to 49 years, with an average age of 23 years, and the majority are aged under 30 years. Thus, the data collected from Reddit clearly fails to represent the middle-aged and older population [55]. Relying solely on Reddit posts for data collection introduces demographic selection bias.

In terms of assessment tools, the qualitative assessment conducted by experienced plastic surgeons was inherently at risk of bias, given the surgeons' attitudes toward the use of GPT-4. Nevertheless, they provided valuable insights owing to their in-depth understanding of scar and keloid education materials. Furthermore, exploratory assessment tools (DISCERN-AI, PEMAT-AI, and NLAT-AI) were used in this study, while their validity requires further testing. LLMs differ from traditional printed educational materials in that their responses to repeated queries of the same question are generated instantaneously and may vary. Currently, existing assessment tools lack the ability to detect such variability in LLM outputs when the same question is posed multiple times [56]. Furthermore, content generated by LLMs is often conveyed with excessive certainty, as these models lack the ability to accurately express information involving uncertainties. Providing definitive answers to such uncertain content may mislead patients, yet current assessment scales fail to evaluate this critical limitation [57,58]. Further research is needed to develop specific tools to enable more robust evaluation of LLM output quality.

Conclusions

Our analysis found that GPT-4 provided high-quality responses to real-world questions related to scars and keloids, suggesting its potential as a useful patient education tool in scar and keloid treatment. The GPT-4 outputs were generally reliable and accurate but need improvement, primarily in readability and hallucinations.

Abstract

Background: Large language models (LLMs) have emerged as promising tools for enhancing public access to medical information, particularly for chronic diseases such as atherosclerotic cardiovascular disease (ASCVD). However, their effectiveness in patient-centered health communication remains underexplored, especially in multilingual contexts.

Objective: Our study aimed to conduct a comparative evaluation of 3 advanced LLMs—DeepSeek R1, ChatGPT-4o, and Gemini—in generating responses to ASCVD-related patient queries in both English and Chinese, assessing their performance across the domains of accuracy, completeness, and comprehensibility.

Methods: We conducted a cross-sectional evaluation based on 25 clinically validated ASCVD questions spanning 5 domains—definitions, diagnosis, treatment, prevention, and lifestyle. Each question was submitted 5 times to each of the 3 LLMs in both English and Chinese, yielding 750 responses in total, all generated under default settings to approximate real-world conditions. Three board-certified cardiologists blinded to model identity independently scored the responses using standardized Likert scales with predefined anchors. The assessment followed a rigorous multistage process that incorporated randomization, washout periods, and final consensus scoring.

Results: DeepSeek R1 achieved the highest "good response" rates (24/25, 96% in both English and Chinese), substantially outperforming ChatGPT-4o (21/25, 84%) and Gemini (12/25, 48% in English and 17/25, 68% in Chinese). DeepSeek R1 demonstrated superior median accuracy scores (6, IQR 6-6 in both languages) and completeness scores (3, IQR 2-3 in both languages) compared to the other models (P<.001). All models had a median comprehensibility score of 3; however, in English, DeepSeek R1 and ChatGPT-4o were rated significantly clearer than Gemini (P=.006 and P=.03, respectively), whereas no significant between-model differences were observed in Chinese (P=.08). Interrater reliability was moderate (Kendall W: accuracy=0.578; completeness=0.565; comprehensibility=0.486). Performance was consistently stronger for definitional and diagnostic questions than for treatment and prevention topics across all models. Specifically, none of the models consistently provided responses aligned with the latest clinical guidelines for the following key guideline-facing question "What is the standard treatment regimen for ASCVD?"

Conclusions: DeepSeek R1 exhibited promising and consistent performance in generating high-quality, patient-facing ASCVD information across both English and Chinese, highlighting the potential of open-source LLMs in promoting digital health literacy

XSL•FO
RenderX

and equitable access to chronic disease information. However, a clinically critical weakness was observed in guideline-sensitive treatment: the models did not reliably provide guideline-concordant standard treatment regimens, suggesting that LLM use should be limited to lower-risk informational subqueries (eg, definitions, diagnosis, and lifestyle education) unless augmented by expert oversight and safety controls.

KEYWORDS

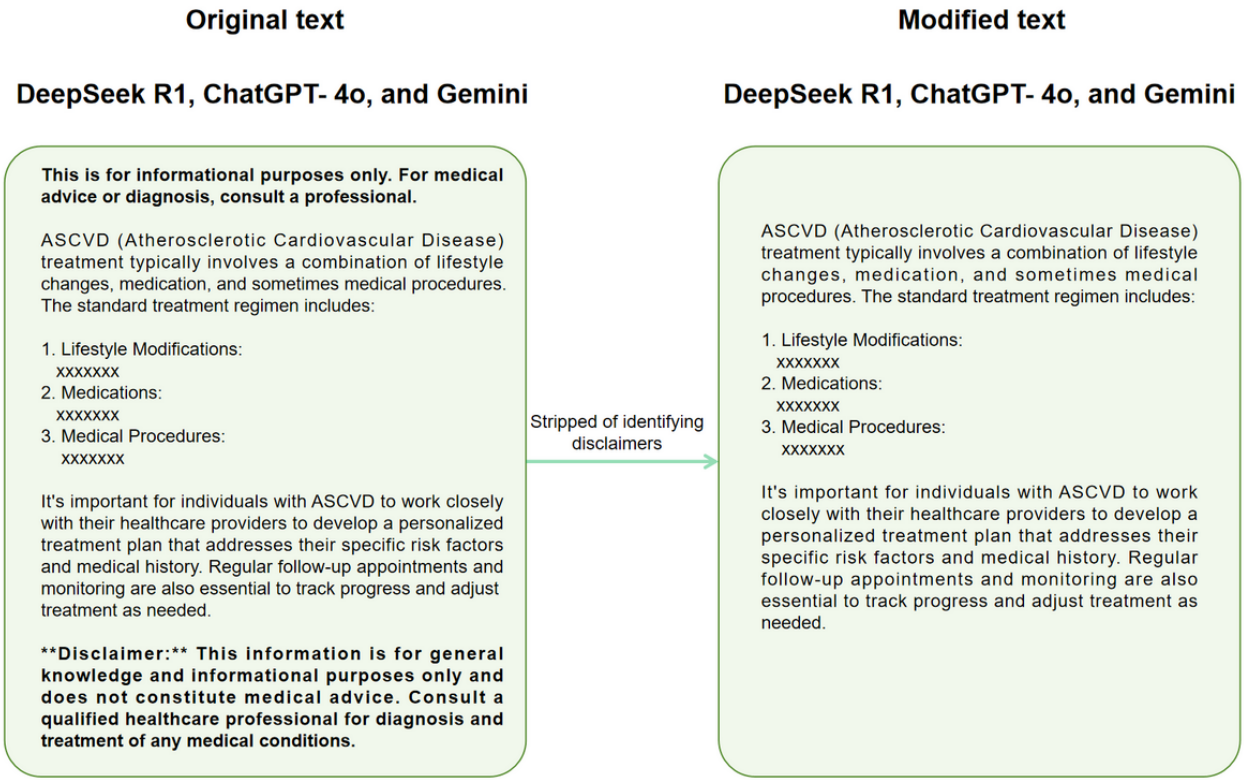
atherosclerotic cardiovascular disease; large language models; DeepSeek R1; ChatGPT-4o; Gemini; artificial intelligence; AI

Introduction

Atherosclerotic cardiovascular disease (ASCVD) is a major public health concern worldwide, significantly affecting morbidity and mortality rates and contributing to the global burden of disease [1]. Effective management and prevention strategies are paramount in reducing its impact on human health and longevity. In recent years, the development of advanced natural language processing technologies, particularly large language models (LLMs), has introduced a novel paradigm in health care communication [2]. LLMs are deep learning models trained on massive corpora of text data, enabling them to generate humanlike responses, summarize complex information, and interact with users in natural language. Models such as ChatGPT exemplify this technological advancement, offering scalable tools for disseminating medical information and supporting patient education, with the potential to enhance chronic disease prevention and self-management [3,4].

Despite their promise, the application of LLMs in health care—especially in clinical decision-making—remains constrained by several limitations [5,6]. First, LLMs do not inherently possess medical reasoning capabilities; their outputs are generated based on learned language patterns rather than grounded clinical judgment [7]. This introduces risks of producing plausible-sounding but clinically inappropriate advice. Second, the variability in training data sources and lack of domain-specific fine-tuning may result in inconsistent or outdated information [8]. Finally, while individual models may excel in certain tasks, performance can vary widely across different LLMs, especially in medical settings where accuracy and contextual appropriateness are vital [9]. Therefore, rigorous comparative evaluations are needed to identify the models that are most reliable, transparent, and suitable for patient-centered communication within health care and public health contexts.

To our knowledge, there have been no studies specifically focused on the performance of LLMs in providing information about ASCVD. Therefore, this study aimed to assess the performance of various advanced LLMs (ChatGPT-4o [OpenAI], Gemini [Google], and DeepSeek R1) in delivering accurate, comprehensive, and comprehensible information related to ASCVD. Using open-ended questions and simulated patient scenarios, we evaluated the quality and reliability of responses from a patient-centered perspective.



Methods

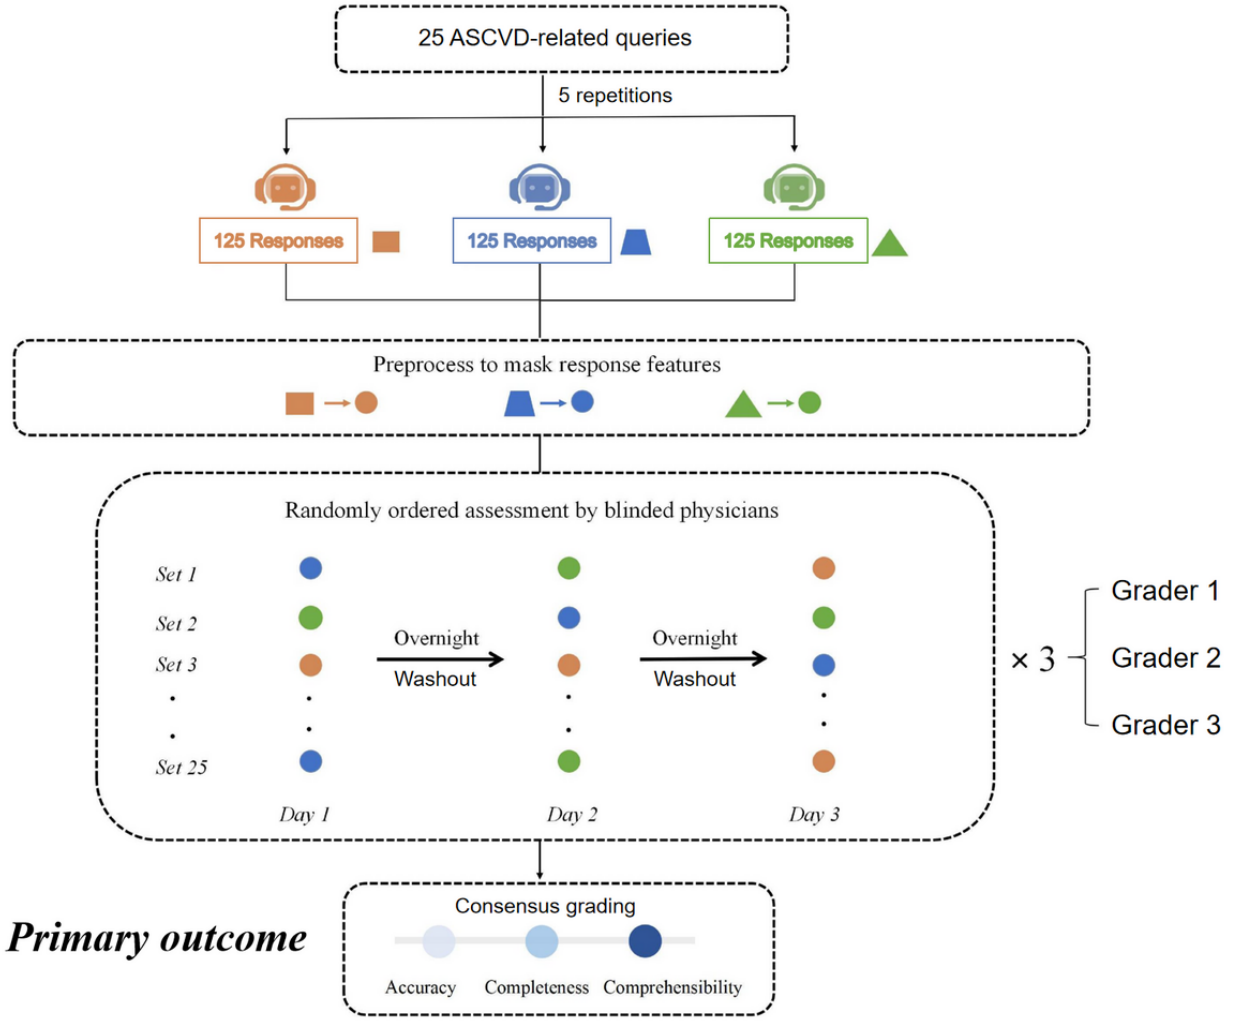
Question Design and Acquisition of Responses

Our study was conducted from May 15 to 30, 2025. Three qualified physicians (PL, YX, and YW) devised 25 comprehensive questions based on common concerns of patients regarding ASCVD, focusing on patient-centered care and disease management. These queries covered definitions, diagnosis, treatment, prevention, and lifestyle. To mitigate language bias and evaluate multilingual performance, each question was posed in both English and Chinese. To reduce randomness and assess response consistency, each question was submitted 5 separate times to 3 state-of-the-art LLMs—DeepSeek R1, ChatGPT-4o, and Gemini—in both languages, generating a total of 750 responses (25 questions × 3 models × 2 languages × 5 repetitions). To simulate real-world use scenarios, all models were assessed using their default, publicly available versions without any parameter adjustments (eg, temperature, maximum tokens, or top-p nucleus sampling). Crucially, the web-browsing or retrieval-augmented generation capabilities enabled by default in these public interfaces were allowed to function. This ensured that our findings reflected the typical performance accessible to end users who rely on these tools for real-time information retrieval. Each chat was conducted using the “new chat” function to avoid bias from correlation interference and ensure that each session was unaffected by previous prompts. All generated responses were exported as plain text. For DeepSeek R1, the reasoning content and blocks were programmatically removed before human review. Subsequently, all responses were stripped of identifying disclaimers (Figure 1). The complete set of 750 generated responses has been made publicly available in Multimedia Appendix 1 to ensure full transparency and facilitate further research.

XSL•FO
RenderX

Figure 1. Deidentification and preprocessing of model outputs before blinded scoring: raw large language model responses were exported as plain text and stripped of disclaimers and model-identifying metadata, yielding anonymized text for review by 3 cardiologists.

Assessment Methodology



An evaluation panel of 3 board-certified cardiologists assessed the model outputs through a rigorous multistage process. For each of the 25 questions in both languages, 5 independent responses were generated per model. To avoid model selection bias, responses were randomly shuffled within their respective question sets, ensuring that the reviewers remained unaware of the specific language model that generated each response.

To minimize memory bias, 3 cardiologists independently assessed the responses in 3 separate rounds, each conducted on a distinct day with an overnight washout period. Assessments were benchmarked primarily to the 2021 European Society of Cardiology guidelines for cardiovascular disease prevention and the 2024 guidelines for managing chronic coronary syndromes, with cross-checks against the 2025 ACC/AHA/ACEP/NAEMSP/SCAI Guideline for the Management of Patients With Acute Coronary Syndromes [10-12]. We verified that no major guideline updates relevant to our end points were released during the evaluation window (May 15-30, 2025). Using predefined anchors detailed in Table S1 in Multimedia Appendix 2, each reviewer rated every response on 3 dimensions: accuracy (6-point Likert scale: 1="completely incorrect"; 6="completely correct"), completeness (3-point Likert scale: 1="incomplete"; 3="complete"), and comprehensibility (3-point Likert scale: 1="difficult to understand"; 3="easy to understand") [13]. The scoring protocol comprised 3 steps. First, for each question, each model generated 5 responses; the 3 reviewers independently rated every response on the 3 dimensions. Second, the reviewers convened to finalize one consensus score per response per dimension: identical ratings were carried forward, whereas discrepancies were resolved through discussion until unanimity was reached—or, if needed, with brief input from a senior cardiologist. Third, for each question, the arithmetic mean of the 5 consensus scores served as the final per-question score; because per-question scores were nonnormally distributed, between-platform comparisons used the median of the 25 per-question scores. Detailed scoring procedures for the blinded assessment are provided in Tables S2 to S4 in Multimedia Appendix 2.

The overall study design and process are illustrated in Figure 2. We established the following quality thresholds based on the arithmetic mean of the 5 repeated responses per question: an accuracy score of at least 4 was considered acceptable, whereas a score of at least 2 was required for both comprehensibility and completeness. Within the acceptable performance levels, we introduced a new concept called "good response" to facilitate the comparison of the LLMs' excellent responses. A "good response" was defined as having a mean accuracy score of ≥4, mean comprehensibility and completeness scores of ≥2, and a mean total score (sum of accuracy, completeness, and comprehensibility) score of ≥10. The total score threshold (10) was intentionally set higher than the sum of the minimum component scores (8) to ensure that a "good response" exceeded the baseline requirements in at least one dimension (eg, higher accuracy or completeness) rather than merely meeting the minimum acceptable standard in all categories.

XSL•FO
RenderX

Figure 2. Study design and data flow for the blinded comparison of large language models on atherosclerotic cardiovascular disease (ASCVD) questions. Outputs were generated under default settings; all model-identifying markers and disclaimers were removed; and responses were randomized and presented model blind to cardiologists for independent rating, consensus finalization, per-question aggregation, and cross-model comparison.

Data Analysis

All data analyses were performed using Prism (version 9.5.1; GraphPad Software) and SPSS (version 26.0; IBM Corp). Continuous variables were described using measures of central tendency and dispersion expressed as median and range. Graphical representations were used to enhance the clarity and interpretability of the data. When the data deviated from a normal distribution, differences between 2 groups were assessed using the Mann-Whitney *U* test, whereas differences among the 3 LLMs were evaluated using the Kruskal-Wallis rank sum test followed by the Dunn multiple-comparison test. The Fisher exact test was used for categorical variables. Interrater reliability was assessed using the Kendall *W* coefficient of concordance, with levels of agreement interpreted as follows: poor (0-0.2), fair (0.21-0.4), moderate (0.41-0.6), good (0.61-0.8), and excellent (0.81-1) [14]. A 2-sided *P* value of <.05 was considered statistically significant.

Ethical Considerations

The data analyzed in our study consisted of deidentified, synthetic outputs generated by LLMs in response to 25 guideline-informed ASCVD questions curated from publicly accessible sources; no patients or personal data were involved. Accordingly, participant recruitment and written informed consent were not applicable, and—per institutional policy—this work did not constitute human participant research and did not require ethics committee review.

Results

Performance

Overview

The "good response" rates for the 3 LLMs were as follows (Table 1): DeepSeek R1 achieved a "good response" rate of 96% (24/25) in both English and Chinese, outperforming ChatGPT-4o (21/25, 84%) and Gemini (12/25, 48% in English and 17/25, 68% in Chinese). Figure 3 illustrates the comparative distribution of scores across the 3 dimensions. In terms of accuracy, DeepSeek R1 maintained a dominant profile with high consistency, whereas Gemini exhibited the widest score variance. Regarding completeness, DeepSeek R1 frequently achieved maximum scores, whereas ChatGPT-4o often provided partially complete responses. Comprehensibility remained high for all models, with DeepSeek R1 and ChatGPT-4o showing slightly more stability than Gemini. Performance analysis revealed a critical pattern: model performance was consistently

XSL•FO
RenderX

and substantially weaker in the treatment domain than in all others, with "good response" rates of 80% (8/10) for DeepSeek R1, a total of 60% (6/10) for ChatGPT-4o, and 30% (3/10) for Gemini (Multimedia Appendix 3). For instance, none of the models consistently provided answers that aligned with the latest clinical guidelines in response to the question "What is the standard treatment regimen for ASCVD?" Similarly, the responses varied significantly in accuracy and detail for the question "How common is coronary artery bypass grafting (CABG) in ASCVD patients?" The following sections provide a detailed analysis of each model's performance across the domains of accuracy, completeness, and comprehensibility.

XSL•FO
RenderX

Table 1. Performance of the 3 large language models on atherosclerotic cardiovascular disease (ASCVD) questions in a blinded, bilingual evaluation. Questions spanned 5 domains (definitions, diagnosis, treatment, prevention, and lifestyle) and were scored by 3 board-certified cardiologists using predefined anchors. A "good response" was defined as an arithmetic mean score across the 5 repetitions of ≥4 for accuracy, ≥2 for completeness, and ≥2 for comprehensibility, with a mean total score (sum of accuracy, completeness, and comprehensibility) of ≥10 after consensus.

Figure 3. Distribution of accuracy, completeness, and comprehensibility ratings for large language model (LLM) responses to atherosclerotic cardiovascular disease–related questions. (A) Shows the distribution of accuracy scores across LLMs. (B) Shows the distribution of completeness scores across LLMs. (C) Shows the distribution of comprehensibility scores across LLMs.

Accuracy

Regarding accuracy, 97% (146/150) of the questions met the acceptable standard, with English-language responses reaching 99% (74/75) accuracy and Chinese-language responses reaching 96% (72/75) accuracy. For both English- and Chinese-language questions, the median accuracy score for DeepSeek R1 was consistently 6 (IQR 6-6 for both languages), whereas for ChatGPT-4o and Gemini, it was 5 (ChatGPT: IQR 5-6 for both languages; Gemini: IQR 4-5 for English and 5-6 for Chinese; Table 2). As detailed in Table 3, for all English-language queries, the mean accuracy score of DeepSeek R1 responses was 5.88 (SD 0.33), whereas the mean scores for ChatGPT-4o and Gemini were 5.40 (SD 0.64) and 4.84 (SD 0.68), respectively. For all Chinese-language queries, the mean

XSL•FO
RenderX

accuracy score for DeepSeek R1 responses was 5.80 (SD 0.40), whereas the mean ChatGPT-4o and Gemini scores were 5.20 (SD 0.76) and 5.00 (SD 0.86), respectively.

Table 2. Median scores for responses from the 3 large language models.

Assessment metric	DeepSeek R1, median (IQR)		ChatGPT-4o, median (IQR)		Gemini, median (IQR)	
	English	Chinese	English	Chinese	English	Chinese
Accuracy (1-6)	6 (6-6)	6 (6-6)	5 (5-6)	5 (5-6)	5 (4-5)	5 (5-6)
Completeness (1-3)	3 (2-3)	3 (2-3)	2 (2-2)	2 (2-2)	2 (2-2)	2 (2-3)
Comprehensibility (1-3)	3 (3-3)	3 (3-3)	3 (3-3)	3 (3-3)	3 (2-3)	3 (3-3)

Table 3. Mean scores for responses from the 3 large language models.

Assessment metric	DeepSeek R1, mean (SD)		ChatGPT-4o, mean (SD)		Gemini, mean (SD)	
	English	Chinese	English	Chinese	English	Chinese
Accuracy (1-6)	5.88 (0.33)	5.80 (0.40)	5.40 (0.64)	5.20 (0.76)	4.84 (0.68)	5.00 (0.86)
Completeness (1-3)	2.72 (0.45)	2.76 (0.43)	2.24 (0.43)	2.12 (0.43)	2.00 (0.57)	2.36 (0.63)
Comprehensibility (1-3)	2.96 (0.20)	2.92 (0.27)	2.88 (0.33)	2.84 (0.37)	2.64 (0.48)	2.92 (0.27)

Completeness

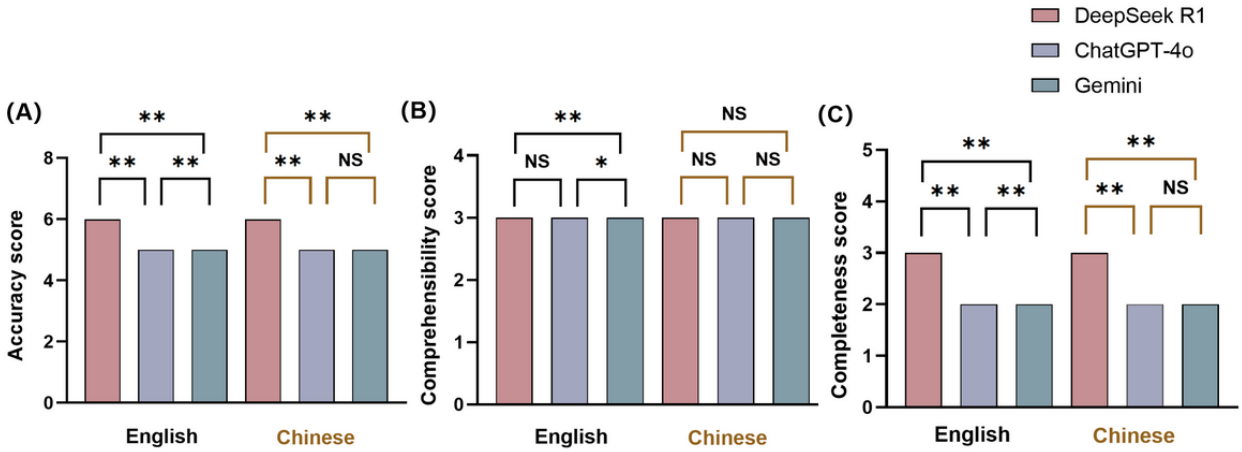
In terms of completeness, 95% (142/150) of responses were acceptable, including 95% (71/75) in both English and Chinese. Regardless of the language of the questions, the median completeness score for DeepSeek R1 was consistently 3 (IQR 2-3 for both languages), with ChatGPT-4o and Gemini both achieving median scores of 2 (ChatGPT: IQR 2-2 for both languages; Gemini: IQR 2-2 for English and 2-3 for Chinese; Table 2). For all English-language questions, the mean completeness score for DeepSeek R1's responses was 2.72 (SD 0.45), with ChatGPT-4o and Gemini achieving mean scores of 2.24 (SD 0.43) and 2.00 (SD 0.57), respectively. For all Chinese-language questions, the mean completeness score for responses from DeepSeek R1 was 2.76 (SD 0.43), with ChatGPT-4o and Gemini scoring a mean of 2.12 (SD 0.43) and 2.36 (SD 0.63; Table 3), respectively.

Comprehensibility

Regarding comprehensibility, all responses were at an acceptable level. Regardless of the language of the questions or the model used, the median comprehensibility score for all questions was consistently 3 (DeepSeek R1 and ChatGPT: IQR 3-3 for both languages; Gemini: IQR 2-3 for English and 3-3 for Chinese; Table 2). As shown in Table 3, for all English-language questions, the mean comprehensibility score for DeepSeek R1's responses was 2.96 (SD 0.20), whereas ChatGPT-4o and Gemini scored a mean of 2.88 (SD 0.33) and 2.64 (SD 0.48), respectively. For all Chinese-language questions, the mean comprehensibility score for DeepSeek R1 responses was 2.92 (SD 0.27), with ChatGPT-4o and Gemini scoring a mean of 2.84 (SD 0.37) and 2.92 (SD 0.27), respectively.

Interrater Reliability

For accuracy scores, the Kendall *W* coefficient of concordance ranged from 0.434 to 0.732, with a mean of 0.578 (SD 0.15). In terms of completeness scores, the coefficient varied from 0.360 to 0.782, averaging 0.565 (SD 0.21). For comprehensibility scores, the range was between 0.386 and 0.581, with a mean value of 0.486 (SD 0.10). This indicates that the scores for accuracy, completeness, and comprehensibility were at a moderate level of agreement.



Model Comparison

In the overall comparison of English- and Chinese-language questions, DeepSeek R1 consistently outperformed the other models in terms of accuracy and completeness. For English-language questions, DeepSeek R1 achieved the highest median accuracy score of 6, significantly surpassing both ChatGPT-4o and Gemini (P<.001 for each pairwise comparison), whereas ChatGPT-4o also outperformed Gemini (P=.008). All 3 models received a median comprehensibility score of 3; the difference between DeepSeek R1 and ChatGPT-4o was not significant (P=.07), although DeepSeek R1 was significantly clearer than Gemini (P=.006), and ChatGPT-4o was moderately clearer than Gemini (P=.03; reflecting significant differences in mean ranks per the Mann-Whitney U test despite identical medians). Regarding completeness, DeepSeek R1 again led the models, scoring significantly higher than both ChatGPT-4o and Gemini (P=.009), with ChatGPT-4o also providing more complete responses than Gemini (P=.007). For Chinese-language questions, DeepSeek R1 maintained a significant lead in accuracy over ChatGPT-4o and Gemini (P<.001 in both cases), whereas the difference between ChatGPT-4o and Gemini was not statistically significant (P=.07). All 3 models achieved the same median comprehensibility score of 3, with no significant differences (P=.08). In terms of completeness, DeepSeek R1 again outperformed both ChatGPT-4o and Gemini (P<.001), whereas no significant difference was observed between ChatGPT-4o and Gemini (P=.06). Overall, DeepSeek R1 demonstrated consistently superior performance in both accuracy and completeness across languages. Differences in comprehensibility were minor, with Gemini showing slightly lower clarity in English. These findings affirm DeepSeek R1's leading capabilities and highlight subtle language-specific variations in the outputs of the other models (Figure 4). Specific

XSL•FO
RenderX

examples of LLM failures contrasted with superior responses are detailed in Table S5 in Multimedia Appendix 2.

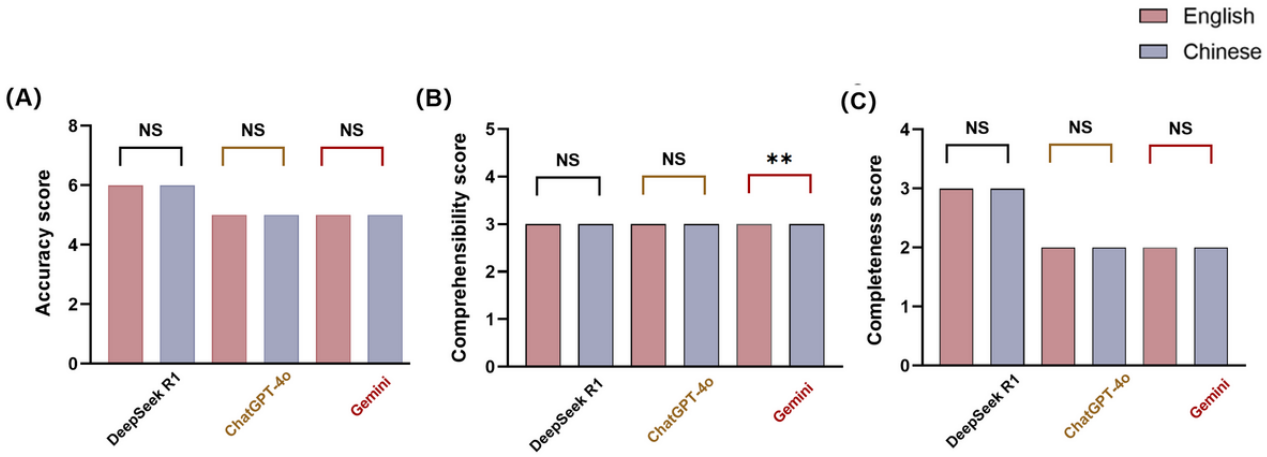


Figure 4. Comparison of large language model performance on atherosclerotic cardiovascular disease–related questions within languages. Scores are shown for accuracy, completeness, and comprehensibility. *P<.05; **P<.01; NS: not significant.

Language-Based Response Comparison

For DeepSeek R1, there were no significant differences between English and Chinese in terms of accuracy, completeness, and comprehensibility scores. Similarly, for ChatGPT-4o, there were no significant differences between English and Chinese across the same metrics, indicating a comparable performance in both languages. For Gemini, the accuracy and completeness scores showed no significant differences between English and Chinese. However, there was a significant difference in comprehensibility scores (P<.001) as the median comprehensibility score for English was 3 (IQR 2-3), whereas for Chinese, it was 3 (IQR 3-3). This indicated that the comprehensibility scores were more consistent in Chinese compared to having more variability in English (Figure 5).

Figure 5. Comparison of large language model performance on atherosclerotic cardiovascular disease–related questions across languages within models. For each model, scores for accuracy, completeness, and comprehensibility are shown for English and Chinese. **P<.01; NS: not significant.

Discussion

Principal Findings

Our study evaluated the performance of 3 advanced LLMs—DeepSeek R1, ChatGPT-4o, and Gemini—in providing accurate, comprehensive, and comprehensible information on ASCVD in both English and Chinese. This evaluation was conducted using a rigorous, blinded study design that incorporated randomization, washout periods, and consensus-based physician assessments. While the widespread emergence of LLMs has significantly expanded public access to medical information—particularly for underserved or non–English-speaking populations [15,16]—concerns about their reliability persist [17,18]. By systematically evaluating multiple LLMs across languages and using patient-centered ASCVD scenarios, our study offers a more holistic perspective on their capabilities and limitations. From a public health standpoint, this approach not only highlights the potential of LLMs to enhance digital health literacy and self-management of chronic diseases but also underscores the need for ongoing oversight and model validation to prevent the spread of misinformation [19,20].

The results demonstrated that DeepSeek R1 generally outperformed the other models in terms of accuracy and completeness and also achieved a slightly higher average score for understandability. Several factors may contribute to this superior performance. DeepSeek R1 is reported to rely heavily on reinforcement learning, which may contribute to improved

XSL•FO
RenderX

logical coherence and multistep reasoning. Additionally, the model is open source under the Massachusetts Institute of Technology license and may offer lower operating costs compared to proprietary models. This open-source nature confers several advantages—including reduced dependency on commercial application programming interfaces (APIs), lower implementation costs, and the potential for institution-specific fine-tuning—making it particularly attractive for health care systems with limited technical resources [21]. Critically, this open-source architecture offers a decisive advantage for clinical implementation: data sovereignty. Unlike proprietary cloud-based models (eg, ChatGPT-4o and Gemini) that necessitate the transmission of sensitive patient data to external commercial servers—raising significant compliance challenges with regulations such as HIPAA (Health Insurance Portability and Accountability Act; United States) and the General Data Protection Regulation (Europe)—DeepSeek R1 allows for local, on-premise deployment [22,23]. Health care systems can host the model within their secure firewalls, ensuring that patient data never leave the institution's control. This capability not only resolves privacy concerns but also creates a secure environment for the aforementioned fine-tuning on proprietary medical records. Furthermore, it is important to clarify that the high comprehensibility scores in this study were achieved without the reasoning chains being visible to the raters. This indicates that DeepSeek R1's internal chain-of-thought process effectively structures the final response for clarity independent of the visible reasoning trace [24]. Taken together, these characteristics suggest that DeepSeek R1 may be a promising candidate for disseminating reliable, cost-effective, and customizable medical information in both clinical and public health contexts.

Language-based comparisons revealed no significant performance differences between English and Chinese for both DeepSeek R1 and ChatGPT-4o. Although Gemini exhibited slightly higher scores in Chinese—particularly in comprehensibility—this difference was not statistically significant, indicating that the variation likely reflects incidental model behavior rather than a systematic language-based advantage. Achieving consistent performance across languages is essential for the global applicability of LLMs in health care communication. Our evaluation indicates a consistent and clinically relevant pattern: across all 3 LLMs, recommendations in the treatment and prevention domain were less reliable than responses to definitional and diagnostic queries. This observation is consistent with external reports that therapeutic, guideline-facing tasks show variable concordance and that performance can be highly sensitive to task framing and evaluation metrics beyond headline accuracy [25-27]. Recent benchmarks likewise describe mixed adherence across clinical scenarios, underscoring the difficulty of encoding and operationalizing rapidly evolving therapeutic knowledge within free-text generation [26-28]. Taken together, these findings suggest that, without explicit retrieval and provenance controls, current general-purpose architectures may not consistently reflect the most up-to-date evidence at inference time, which in turn can pose risks in high-stakes areas such as medication dosing and care timing [25-27]. They also help explain why standard offline evaluations may overestimate real-world reliability ("evaluation illusion") and why even low omission or error rates can have high clinical salience in treatment contexts [9,29].

In practical terms, our findings offer concrete guidance for implementing LLMs in clinical ASCVD care. The encouraging performance of models such as DeepSeek R1 supports adjunctive, nonautonomous use in patient-facing education platforms and, with clinician oversight, selective clinical decision support. For instance, models excelling in comprehensibility are best suited for generating patient education materials, whereas those with superior accuracy on guideline-specific content may better support the drafting of clinical summaries for specialist review. Successful integration will require attention to electronic health record interoperability; comprehensive staff training programs that cover the capabilities, limitations, and appropriate use of these artificial intelligence (AI) tools; and governance (privacy, auditability, and provenance). From a real-world clinical relevance standpoint, cost and deployment considerations (eg, licensing, API use, computing capacity and infrastructure, and local IT constraints) should inform model selection and scaling within existing health care workflows. In particular, open-source options (eg, DeepSeek R1) can lower licensing costs, enable local or hybrid deployment under strict data governance controls, and permit institution-specific tuning with auditable provenance—benefits that may improve feasibility in resource-constrained settings [30]. Given the observed fragility in guideline-sensitive domains, we recommend a clinician-in-the-loop workflow with tiered risk classification, automated guideline-concordance audits, and retrieval-augmented generation to anchor outputs in current evidence, with explicit human sign-off before the information enters care pathways [31,32]. Furthermore, transparent processes for obtaining patient consent for the use of AI-generated content in their care are essential. In addition, institutions should address regulatory and ethical implications (data protection, provenance, and accountability) and establish postdeployment monitoring and incident reporting processes to detect and mitigate potentially harmful responses [33].

Comparison to Prior Work

Unlike prior studies that have primarily examined single models within narrow clinical contexts [34,35], our investigation extends earlier designs by conducting a head-to-head, bilingual comparison of 3 advanced LLMs—DeepSeek R1, ChatGPT-4o, and Gemini—under a rigorous, blinded methodology incorporating randomization, washout, and consensus-based physician scoring. This design enabled more systematic cross-model comparisons than evaluations focused on 1 system or 1 language. The need for such rigor is underscored by reports from multidisciplinary areas such as cardio-oncology, where ChatGPT has answered only 68% of guideline-based queries correctly [36], highlighting the challenges that general-purpose models face when integrating complex clinical knowledge.

Focusing on ASCVD-related patient education and chronic disease self-management, we found that DeepSeek R1 achieved higher scores for accuracy and completeness and acceptable comprehensibility in both English and Chinese in our dataset,

XSL•FO
RenderX

suggesting suitability for patient-facing communication when used nonautonomously. These findings are concordant with recent *Nature Medicine* benchmarks showing that open-source systems can approach the performance of proprietary models in selected tasks [25,37]. Moreover, the open-source nature of DeepSeek R1 may enable privacy regulation–compliant local deployment and institution-specific fine-tuning—features that can support data-governed health systems—whereas its stable bilingual performance in our study aligns with goals of equitable information access [38]. At the same time, our domain-level analysis echoes and extends prior observations by showing that guideline-sensitive content remains comparatively fragile, reinforcing the need for clinician oversight and regular guideline concordance checks [39].

Limitations

Our study has several methodological limitations that should be considered when interpreting the findings. First, composite constraints in study design, item construction, and the evaluation perspective were present. The question set was clinician led, which may introduce selection bias; it used a fixed, evenly distributed, 5-domain preset (ie, definitions, diagnosis, treatment, prevention, and lifestyle) without direct patient involvement for external validation; model comparison was limited to 3 mainstream LLMs; and assessment relied entirely on expert review without patient-side measures such as comprehension or patient-reported outcomes. Collectively, these factors may affect clinical representativeness, diversity, and ecological validity [40].

Second, we acknowledge a moderate level of interrater agreement among the expert cardiologists as measured using the Kendall *W* (accuracy=0.578; completeness=0.565; comprehensibility=0.486). While such moderate reliability is not uncommon when evaluating nuanced, open-ended medical text where a degree of clinical subjectivity is inherent, it must be noted as a key limitation. To mitigate the impact of this disagreement, we used standardized anchors and a consensus adjudication step, and our statistical analysis (using medians and IQRs with nonparametric tests) was specifically chosen to limit the influence of rater heterogeneity. Nevertheless, this variability introduces uncertainty into the statistical significance of the differences found between models and suggests that expert opinions on AI-generated text quality can vary nontrivially. This is particularly relevant for clinical applications, where the use of such AI-generated content, especially for medical pathways or decision support, demands an even higher degree of caution. Consequently, the findings warrant a cautious interpretation. To enhance reliability in future work, we recommend developing more detailed scoring criteria with concrete examples and implementing a formal rater training and calibration process, including a pilot evaluation to establish baseline agreement.

Third, sample size and statistical power were not determined a priori. As an exploratory benchmarking study in a nascent area lacking established effect sizes, we did not perform an a priori power analysis. We used a coverage and stability-oriented design (25 items across 5 domains and 5 independent generations per model per language; 750 responses in total) to balance breadth and response stability. Although primary between-model contrasts reached statistical significance ($P<.001$)—suggesting adequate sensitivity post hoc—the absence of prespecified power planning limits generalizability; future confirmatory studies should use effect sizes and variance estimates from this work for formal power and sample size planning.

In addition, language and cultural generalizability are limited. Performance was evaluated only in English and Chinese. Differences in health beliefs, communication norms, and linguistic nuance across other languages and cultures may affect acceptability and applicability; broader multilingual, multicultural validation is needed.

Finally, geographic variation and reliance on the chosen reference guidelines (“benchmark binding”) may influence concordance judgments across health systems. While we benchmarked against specific international guidelines, ASCVD management varies by region and health system (eg, drug availability, targets, pathways, and reimbursement). Consequently, judgments of being concordant or nonconcordant are bound to the chosen reference standards, and local calibration is advisable for cross-region application.

Future Directions

First, longitudinal performance tracking should be prioritized. Standardized benchmarking with regular retesting across model updates, languages, and domains should be established to quantify performance drift, with early warning triggers for degradation; preregistered, multicenter confirmatory studies should be favored.

In addition, direct head-to-head comparisons with human materials should be conducted. LLM outputs should be benchmarked against human-authored patient education materials, assessing quantitative metrics (eg, accuracy and readability) and qualitative outcomes (eg, patient preference and trust) within a composite evaluation framework.

Moreover, pragmatic integration with clinical systems should be pursued. Low-coupling approaches to clinical systems under data minimization and privacy constraints (eg, standardized APIs, compliance and audit trails, and provenance and version management) should be explored to improve deployability.

Furthermore, communication should be tailored to patient literacy, language, culture, and context. Adaptive presentation methods based on health literacy, cultural background, preferred language, and clinical context should be developed and validated, maintaining clinical correctness while improving accessibility and understanding [41]. To ensure that these tailored communication strategies are effective, future work must include patient-centered validation, assessing the correlation between expert ratings and actual patient understanding and incorporating patient-reported outcome measures.

Finally, safety governance should be strengthened with structured risk management and monitoring. Future work should refine scoring anchors and operational definitions, broaden and diversify rater panels with structured calibration, conduct sensitivity and robustness analyses, implement routine guideline

XSL•FO
RenderX

concordance audits and a risk stratification framework (eg, dosing errors, contraindications, and care delay advice) [27], and establish continuous monitoring and incident reporting mechanisms to detect and mitigate potentially harmful or misleading outputs [26].

Conclusions

Our study evaluated the performance of several advanced LLMs in delivering information related to ASCVD, a major chronic disease burden in public health. In a blinded, bilingual comparison of DeepSeek R1, ChatGPT-4o, and Gemini, DeepSeek R1 demonstrated the highest accuracy and completeness, whereas all models showed comparable comprehensibility. Performance was consistently stronger for definitional and diagnostic queries than for treatment and prevention queries, indicating lower alignment with current therapeutic guidance in those domains. Notably, for the core question regarding the standard treatment regimen for ASCVD, none of the models consistently provided answers aligned with the latest clinical guidelines, representing a safety-relevant limitation of current general-purpose LLMs. These results delineate the present capability profile of LLMs for patient information on ASCVD and establish an empirical baseline for subsequent validation.

Acknowledgments

This work was supported by the National Science and Technology Major Project (2023ZD0503900 and 2023ZD0503902). The authors also wish to acknowledge the developers of the large language models evaluated in this study, whose groundbreaking work made this research possible. While drafting this manuscript, the authors used DeepSeek with the sole purpose of checking the grammar of the text.

Abstract

Background: Emergency triage accuracy is critical but varies with clinician experience, cognitive load, and case complexity. Mis-triage can delay care for high-risk patients and exacerbate crowding through unnecessary prioritization. Large language models (LLMs) show promise as triage decision-support tools but are vulnerable to hallucinations. Retrieval-augmented generation (RAG) may improve reliability by grounding LLM reasoning in authoritative guidelines and real clinical cases.

Objective: This study aimed to evaluate whether a dual-source RAG system that integrates guideline- and case-based evidence improves emergency triage performance versus a baseline LLM and to assess how closely its urgency assignments align with expert consensus and outcome-defined clinical severity.

Methods: We developed a dual-source RAG system—Multi-Evidence Clinical Reasoning RAG (MECR-RAG)—that retrieves sections from the Hong Kong Accident and Emergency Triage Guidelines (HKAETG) and cases from a database of 3000 emergency department triage encounters. In a retrospective single-center evaluation, MECR-RAG and a prompt-only baseline LLM (both DeepSeek-V3) were tested on 236 routine triage encounters to predict 5-level triage categories. Expert consensus reference labels were assigned by blinded senior triage nurses. Primary outcomes were quadratic weighted kappa (QWK) and accuracy versus consensus labels. Secondary analyses examined performance within 3 operationally and clinically relevant triage bands—immediate (categories 1 and 2), urgent (category 3), and nonurgent (categories 4 and 5). In 226 encounters with follow-up, we also assigned outcome-based severity tiers (R1-R3) using a published 3-level urgency reference standard and defined a disposition-safety composite.

Results: MECR-RAG achieved a mean QWK of 0.902 (SD 0.0021; 95% CI 0.901-0.904) and accuracy of 0.802 (SD 0.0082; 95% CI 0.795-0.808), outperforming the baseline LLM (QWK 0.801, SD 0.004; accuracy 0.542, SD 0.0073; both $P<.001$) and demonstrating expert-comparable agreement with triage nurses (interrater QWK 0.887). In 3-group analysis, MECR-RAG reduced overtriage from 68/236 (28.8%) with the baseline LLM to 30/236 (12.7%) and maintained low undertriage from 4/236 (1.7%) to 3/236 (1.3%), with the largest gains in the diagnostically ambiguous yet operationally important categories 3 and 4. In a secondary outcome-based analysis defining high-severity courses as R1+R2, MECR-RAG detected high-risk patients more sensitively than initial nurse triage (124/130, 95.4% vs 117/130, 90.0%; $P=.02$) while maintaining nurse-level specificity. MECR-RAG yielded the lowest weighted harm index (13.7, 19.5, and 20.3 per 100 patients for MECR-RAG, nurses, and the baseline LLM, respectively).

Conclusions: A dual-source RAG triage system that combines guideline-based rules with case-based reasoning achieved expert-comparable agreement, reduced overtriage, and better aligned urgency assignments than a prompt-only baseline LLM. Secondary outcome–based analyses in this cohort suggested more favorable triage patterns than initial nurse triage, supporting MECR-RAG as a concurrent decision-support layer that flags discordant or high-risk assignments; prospective multicenter implementation studies are needed to determine effects on emergency department crowding, delays, and patient outcomes.

Introduction

Emergency triage is a critical step in emergency department (ED) operations, determining which patients are seen first when demand exceeds capacity. However, triage accuracy varies with clinicians' experience, cognitive load, and the complexity of presenting symptoms, and even trained nurses may misclassify a substantial minority of encounters [1,2]. Undertriage risks delayed recognition of life-threatening illness and preventable morbidity or mortality, whereas overtriage diverts scarce resources toward lower-acuity patients and can exacerbate ED crowding and boarding, both of which are associated with worse outcomes [2]. These challenges are particularly pronounced in mid-acuity categories, which represent most ED visits and where small changes in urgency assignment can translate into large differences in waiting time, crowding pressure, and exposure to harm.

Large language models (LLMs) have emerged as potential tools for clinical decision support because they can interpret free-text notes, integrate medical knowledge, and generate structured recommendations. In emergency care, LLMs have been tested for triage on simulated vignettes and curated cases, but reported performance has been highly variable, with agreement with human raters (Cohen κ) ranging from 0.125 to 0.899 across models, datasets, and evaluation frameworks [3-8]. A fundamental limitation of current "prompt-only" LLMs is their tendency to hallucinate, generating outputs that appear plausible but are factually incorrect or unsupported [9]. In emergency triage, such hallucinations may lead to urgency levels being assigned based on fabricated reasoning, outdated rules, or misinterpretation of presenting complaints, posing potential risks to patient safety and consistency.

Retrieval-augmented generation (RAG) has been proposed as a way to mitigate hallucinations by grounding LLM outputs in external, task-specific knowledge sources such as clinical guidelines, textbooks, electronic health records, and biomedical literature [10-12]. By retrieving relevant evidence at inference time and conditioning generation on that material, RAG can improve access to current, domain-specific knowledge and make model reasoning more transparent. Early work in emergency care has shown that adding retrieval can improve triage or referral accuracy compared with nonretrieval models. Yazaki et al [13] integrated RAG with a triage guideline database and tested GPT-3.5 on 100 structured, simulated scenarios derived from the Japanese National Examination for Emergency Medical Technicians, finding that the RAG-enhanced model achieved 70/100 (70%) accuracy and outperformed both emergency medical technicians and physicians. Gaber et al [14] used a curated dataset of 2000 real-world ED cases from the MIMIC-IV (Medical Information Mart for Intensive Care IV) database and retrieved evidence from a corpus of 30,000 PubMed abstracts, demonstrating superior triage-level prediction and exact-match accuracy compared with nonretrieval workflows.

Despite these advances, existing applications of RAG to emergency triage and referral have important gaps. One study relied largely on textbook-style, simulated examination cases [13], whereas another used routine labels from structured research datasets without clinician-adjudicated ground truth [14]. In both studies, RAG was applied to a single knowledge source—either structured triage guidelines or biomedical literature—rather than explicitly combining protocol-based rules with experiential knowledge from prior cases.

To our knowledge, no prior work has evaluated a dual-source RAG system that jointly retrieves local triage guidelines and real-world past triage cases, or directly compared such a system with a prompt-only LLM using raw, unstructured triage documentation paired with a blinded expert consensus reference standard and outcome-based validity checks. This design better captures the complexity and variability of real-world practice and strengthens the translational relevance of performance estimates.

There is also growing recognition that agreement with human labels alone is an incomplete measure of triage quality. Large cohort studies of systems such as the Emergency Severity Index (ESI) and the Manchester Triage System (MTS) have shown that nurse-assigned categories can underestimate or overestimate "true" acuity when judged against downstream outcomes such as hospitalization, intensive care unit (ICU) transfer, revisits, and short-term mortality [15-17]. In parallel, a *Journal of the American Medical Association* (*JAMA*) editorial on artificial intelligence (AI) in medicine has argued that evaluations of AI tools should prioritize clinically meaningful outcomes, patient-centered care, quality, and equity rather than focusing solely on narrow technical accuracy metrics [18]. Accordingly, evaluations of LLM-enabled triage should explicitly examine how assigned urgency levels align with downstream clinical severity and sentinel safety events, rather than treating concordance with nurse labels as sufficient.

In this context, we developed a dual-source RAG system—Multi-Evidence Clinical Reasoning RAG (MECR-RAG)—that retrieves both structured local triage guidelines (Hong Kong Accident and Emergency Triage Guidelines [HKAETG]) and analogous past triage cases and applies a structured Multi-Evidence Clinical Reasoning (MECR) framework to assign 5-level urgency categories. We retrospectively evaluated MECR-RAG on real ED triage notes, benchmarking it against a prompt-only baseline LLM and against expert nurse consensus labels. Our primary aim was to determine whether a dual-source RAG triage system (MECR-RAG) improves 5-level triage accuracy and agreement (quadratic weighted κ and accuracy) with expert nurse consensus compared with a prompt-only baseline LLM and to benchmark its performance against expert triage nurses. We hypothesized that MECR-RAG would achieve higher agreement than the baseline LLM and noninferior agreement relative to expert nurses. As a secondary aim, in a subset with follow-up data, we

XSL•FO
RenderX

assessed outcome-informed validity by examining how MECR-RAG, the baseline LLM, and initial nurse triage aligned with downstream clinical severity tiers and a composite of sentinel safety outcomes. This early-phase, single-center evaluation, reported in accordance with TRIPOD-LLM (Transparent Reporting of a multivariable prediction model for Individual Prognosis Or Diagnosis - Large Language Models) [19], is intended to provide a methodologically rigorous foundation for future prospective and implementation studies of RAG-enhanced triage decision-support systems designed to augment, rather than replace, nurse-led triage.

Methods

Study Design and Setting

This study was a retrospective, proof-of-concept evaluation of a RAG-enhanced LLM for ED triage classification. The primary objective was to compare the performance of an RAG-based LLM that referenced both historical case data and the HKAETG against a prompt-only baseline LLM in assigning triage urgency levels.

The HKAETG is a 5-level triage system implemented across all 18 government-funded public EDs in Hong Kong. Its structure is conceptually aligned with other internationally recognized systems such as the MTS and ESI. Under the HKAETG, patients are assigned to 1 of 5 categories based on clinical urgency and time-to-treatment targets: category 1 (critical, 0 minutes), category 2 (emergency, 10 minutes), category 3 (urgent, 30 minutes), category 4 (semiurgent, 120 minutes), and category 5 (nonurgent, 180 minutes).

All study data were sourced from a single center, Princess Margaret Hospital (PMH), a major acute public hospital in Hong Kong and one of the city's largest tertiary care facilities. PMH operates a 24-hour ED and manages a high volume of complex and time-sensitive cases. In 2023 and 2024, the ED recorded 113,974 and 110,812 visits, respectively, highlighting its central role in emergency care delivery.

Pilot Study, Sample Size Calculation, and Model Selection

Before the main evaluation, we conducted a pilot study to inform model selection, prompting strategy, and sample size estimation. We randomly sampled 1000 ED triage cases from December 2024; 200 cases were used for pilot testing, and the remaining 800 cases were reserved to simulate a retrieval database. All pilot cases were excluded from the final study.

Three commercially available LLMs (DeepSeek-V3, GPT-4o, and Claude 3.7 Sonnet) were compared in both prompt-only and RAG configurations, with performance assessed against clinician-assigned triage labels using quadratic weighted kappa (QWK) and accuracy. Across models, performance was statistically similar in this pilot. DeepSeek-V3 was therefore selected as the backbone model for the main study primarily on the basis of its inference cost, application programming interface (API) accessibility, and comparable pilot performance.

In the pilot setting, the MECR-RAG configuration achieved an approximate QWK of 0.75 compared with 0.50 for the prompt-only baseline. Using the formula for comparing 2 kappa coefficients described by Fleiss, with α=.05 and power=.80 [20], the minimum required sample size to detect this difference was 48 cases. We nevertheless included 236 consensus-labeled triage cases in the final study to improve the precision of performance estimates and enhance generalizability.

Data Sources and Participants

The test set comprised ED triage cases collected at PMH between January 1 and December 31, 2023. All ED visits during this period were eligible regardless of age, sex, or presenting problem. To ensure temporal representativeness and reflect real-world variation in case mix, we used a stratified sampling strategy in which 1 calendar day was randomly selected from each month and 20 cases were sampled from that day. Within each sampled day, triage categories were sampled to approximate overall category distributions while modestly oversampling rare categories to improve precision for high-acuity strata. Four cases were excluded because case-number identification errors prevented data retrieval, yielding a final test set of 236 triage cases.

Reference labels were assigned using a blinded, multirater consensus process. Two advanced practice nurses with more than 10 years of emergency experience independently reviewed each case. Raters were blinded to the original nurse-assigned triage category and saw only information available at the time of triage: presenting complaint, condition on arrival, vital signs, and relevant past medical history when documented. Downstream data, including investigations, diagnoses, treatments, and ward progress, were withheld so that labels reflected only the initial triage decision context and matched the information provided to the LLMs. Disagreements were adjudicated by a third senior triage nurse to obtain a final consensus category for each encounter.

For retrieval, we constructed a separate database of 3000 anonymized ED visits to PMH between January 1 and December 31, 2024. All encounters in 2024 were eligible, with no clinical exclusion criteria, to preserve the natural diversity of documentation and presentations. Days were randomly sampled from each month, and cases were then drawn from those days to achieve broad temporal coverage; modest oversampling of rare triage categories (categories 1, 2, and 5) ensured sufficient representation while maintaining the real-world skew toward categories 3 and 4. The final database contained 94/3000 (3.1%) category 1, 120/3000 (4.0%) category 2, 1705/3000 (57.0%) category 3, 1035/3000 (34.5%) category 4, and 46/3000 (1.5%) category 5 encounters, with detailed monthly and category-specific sampling shown in Table S1 in Multimedia Appendix 1. To stress-test temporal robustness and reduce bias from contemporaneous documentation habits, 2023 test cases were evaluated against a 2024 retrieval database using the same triage guideline version; the full rationale is provided in Textbox S1 in Multimedia Appendix 1.

Preprocessing

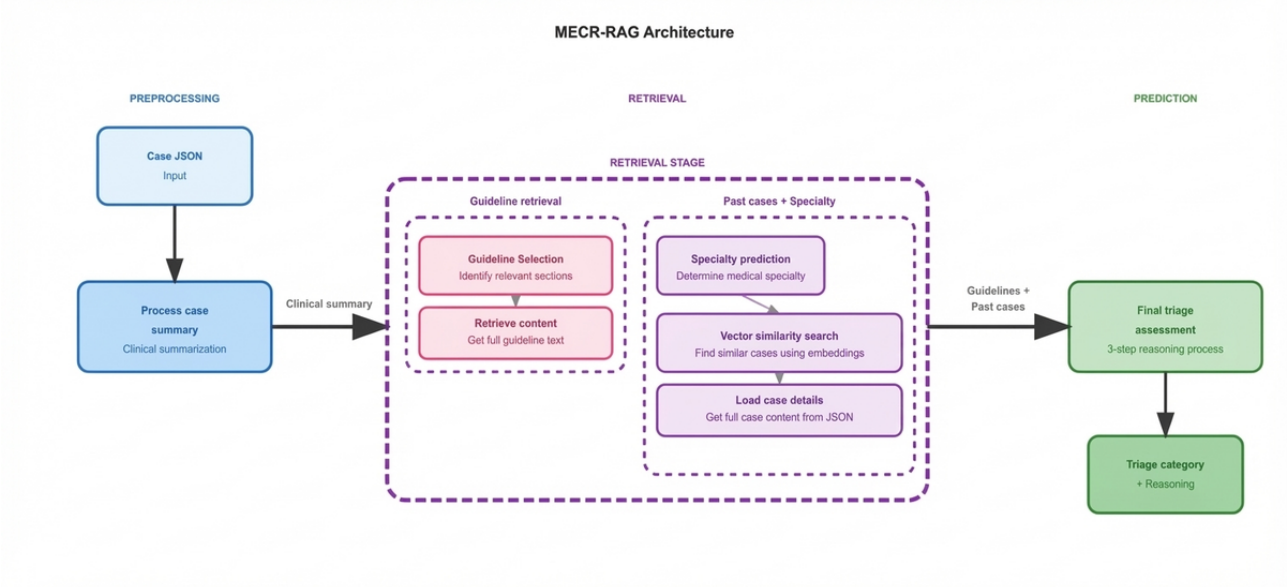
Raw, unstructured triage documentation for both test cases and retrieval-database cases was exported from the electronic medical record, deidentified, and converted into a structured,

XSL•FO
RenderX

machine-readable text format. We retained only nurse-entered information available at the time of triage (eg, demographics, presenting complaint, condition on arrival, vital signs, and relevant past medical history) and excluded any downstream assessments, investigations, treatments, and outcomes. The latest version of the HKAETG (version 6, revised 2022) was similarly digitized and segmented into retrievable guideline sections. Both triage notes and guideline sections were then processed for semantic retrieval; further preprocessing and summarization details are provided in Textbox S2 in Multimedia Appendix 1.

LLM and RAG System Description

For all primary analyses, we used DeepSeek-V3 as the base LLM, accessed via a commercial API without any additional fine-tuning or architectural modification. In what follows, we refer to the DeepSeek-V3 model without retrieval as the "baseline LLM" and the dual-source retrieval-augmented configuration as MECR-RAG. Within each experimental configuration, the same LLM instance handled all stages of the pipeline (preprocessing, retrieval, and generation) with deterministic generation (temperature=0) to minimize stochastic variability. A separate embedding model was used to generate vector representations for semantic retrieval, and the same embedding configuration was applied during database construction and at query time to ensure consistency.



The pipeline was implemented in Python and executed on a standard desktop workstation without graphics processing unit acceleration. End-to-end processing time for the full MECR-RAG configuration was approximately 1 minute per case, including preprocessing, retrieval, and triage prediction, suggesting that near-real-time decision support would be technically feasible. Detailed model versions, libraries, and runtime benchmarks are provided in Section A1 in Multimedia Appendix 1.

MECR-RAG System Architecture

The MECR-RAG system follows a 5-stage pipeline designed to mirror how expert triage nurses combine protocol knowledge with experiential reasoning. First, the raw triage note is summarized into a concise, structured representation optimized for retrieval. Second, the model selects the most relevant sections of the HKAETG using an agentic reasoning step that prioritizes life-threatening conditions and documented physiologic abnormalities. Third, the system predicts the most likely attending specialty (eg, medicine, surgery, and orthopedics) to constrain subsequent case retrieval. Fourth, a hybrid retrieval module identifies similar past triage cases by combining metadata filters (age group and predicted specialty) with vector similarity search. Finally, the model applies a structured, MECR prompt that integrates guideline excerpts, retrieved cases, and the index presentation to assign a 5-level urgency category and provide a textual rationale.

The overall architecture is orchestrated using a modular, node-based workflow that preserves intermediate states, supports full audit trails, and enables systematic component ablation. A schematic overview of the MECR-RAG pipeline is shown in Figure 1, and additional implementation details are provided in Section A2 in Multimedia Appendix 1.

Figure 1. Overview of the Multi-Evidence Clinical Reasoning retrieval-augmented generation system architecture. MECR-RAG: Multi-Evidence Clinical Reasoning retrieval-augmented generation.

The MECR-RAG pipeline consists of 5 sequential processing stages: clinical case summarization, agentic guideline section selection, specialty prediction for metadata filtering, hybrid past-case retrieval combining metadata and vector similarity search, and multievidence reasoning for the final triage assessment. LangGraph nodes manage state transitions and data flow throughout the pipeline.

Indexing and Database Construction

To support efficient retrieval, both historical triage cases and guideline content were converted into structured, machine-readable representations and indexed in a vector database. Historical cases were transformed into standardized triage-time summaries that captured presenting complaints, key vital signs, and brief clinical context, while preserving links to

XSL•FO
RenderX

metadata such as age group, triage category, and attending specialty. The same summarization template was applied to both database cases and incoming test cases to ensure that queries and indexed documents occupied a comparable embedding space.

The HKAETG document was similarly segmented into discrete sections and summarized to highlight the spectrum of presentations covered by each rule set. Each guideline section was stored with a short synopsis and structural metadata (eg, system, chief complaint, and red-flag criteria) to facilitate targeted retrieval during triage. The combined indexing strategy was designed to balance retrieval quality, computational efficiency, and scalability to larger case repositories. Details of prompt templates, sectioning rules, and indexing parameters are described in Section A3 in Multimedia Appendix 1.

Retrieval System Design

The retrieval layer implements a dual-source strategy that distinguishes authoritative protocol knowledge from experiential case patterns. Guideline retrieval is performed via an agentic selection step: given the summarized index case and a list of guideline section titles and synopses, the LLM selects up to 2 sections it deems most relevant, explicitly favoring conditions associated with high short-term risk or abnormal vital signs. This approach avoids purely lexical matching and aligns guideline selection more closely with clinical reasoning.

Past-case retrieval uses a multistage, hybrid approach. The model first predicts 1 or 2 likely specialties using triage-available information only, then filters the case database by age group and specialty to construct a clinically plausible candidate pool. Within this subset, vector similarity search identifies the closest matches based on the summarized clinical text. A small number of top-ranked cases are returned, along with similarity scores and metadata, for use in the final reasoning step. Similarity thresholds, top-k values, and fallback strategies were chosen empirically and are reported in Section A4 in Multimedia Appendix 1.

Generation and Prompting Strategy

The generation stage uses an MECR prompt that extends conventional chain-of-thought reasoning for the specific demands of triage. Rather than a single undifferentiated reasoning path, the prompt enforces a 3-tier structure: (1) a clinical risk assessment aligned with formal triage category definitions, (2) integration of condition-specific recommendations from the retrieved HKAETG sections, and (3) comparison with retrieved past cases to identify contextual factors that may support escalation or de-escalation (eg, frailty, social circumstances, and borderline physiology). Each evidence source produces an independent provisional triage recommendation.

The model is then instructed to reconcile these recommendations into a single final category, explicitly justifying the choice and indicating which sources carried the most weight. Outputs include the predicted triage category, a structured explanation, and a coarse confidence label (high, medium, or low), enabling clinicians to audit the reasoning process and gauge when additional scrutiny is warranted. The complete MECR prompt details are provided in Section A5 in Multimedia Appendix 1.

Ablation Configurations

To isolate the contribution of individual retrieval components, we implemented 3 reduced configurations alongside the full MECR-RAG system. The baseline configuration used the same triage definition table and reasoning structure but removed all retrieval, relying only on the index case description. The guideline-only configuration added agentic guideline selection but did not use past-case retrieval, whereas the case-only configuration retrieved similar past cases without guideline sections. In all ablation variants, preprocessing steps, LLM model, and evaluation procedures were held constant to ensure that performance differences could be attributed to the presence or absence of specific retrieval sources rather than to implementation artifacts. The details are provided in Section A6 in Multimedia Appendix 1.

Outcome Definition and Label-Based Evaluation

The primary outcome was the 5-level triage category (categories 1-5) predicted by each LLM configuration, compared with consensus labels assigned by expert triage nurses. Two configurations were evaluated: the MECR-RAG system, which incorporated both the HKAETG and retrieval of past triage cases, and a prompt-only baseline model with no retrieval component. Model outputs were assessed against the final adjudicated triage category for each case.

The primary performance metric was QWK, chosen because it accounts for the ordinal nature of triage categories and penalizes larger discrepancies more heavily, in line with their greater clinical consequence. Overall accuracy was reported as a complementary measure summarizing the proportion of exact matches between model predictions and consensus labels.

To provide a more clinically grounded view of performance, we also calculated precision, recall, and F_1-score for each triage category and for a post hoc grouping of triage levels into 3 urgency bands: immediate (categories 1 and 2), urgent (category 3), and nonurgent (categories 4 and 5). This mapping reflects local operational workflows, in which small changes in urgency assignment can translate into large differences in waiting time and risk exposure. These group-level metrics were used to characterize overtriage and undertriage patterns beyond aggregate QWK and accuracy estimates.

Because LLM outputs are probabilistic, all primary comparisons between MECR-RAG and the baseline LLM were repeated across 5 independent runs using identical test cases, prompts, retrieval databases, and API settings. For these analyses, we summarized performance as mean values with 95% CIs calculated across runs. For analyses based on a single representative run—for example, evaluations using the median-performing prediction set or post hoc subgroup comparisons—95% CIs were obtained via nonparametric case-level bootstrapping (1000 resamples). The specific CI method used is reported alongside each result, and full resampling details are provided in Textbox S3 in Multimedia Appendix 1.

XSL•FO
RenderX

Secondary Outcome-Based Validity Analysis

Because there is no universally accepted gold standard for "true" acuity at ED presentation, triage tools are typically judged against surrogate outcomes such as hospitalization, ICU admission, revisits, and short-term mortality [15,16]. Large observational studies have shown that nurse-assigned categories can substantially underestimate or overestimate severity, with mis-triage affecting up to one-third of patients in some cohorts [17,21]. To complement our consensus label-based evaluation, we therefore derived outcome-based severity tiers and a disposition-safety composite (DSC) and re-examined how MECR-RAG, the baseline LLM, and initial nurse triage aligned with downstream clinical courses.

For all encounters with sufficient follow-up, we assigned an ordinal outcome-based severity tier (R1-R3) adapted from the multilevel reference standard used in MTS validation work, in which a multidisciplinary expert panel defined 3 urgency levels [15]. R1 represented high-acuity courses analogous to the "immediate or very urgent" reference category and was defined by the presence of any marker of life-threatening illness, such as markedly abnormal vital signs with modified early warning score ≥5 or depressed consciousness, emergency surgery or other high-intensity interventions shortly after ED arrival, or death in the ED, ICU, or during the index admission. R2 corresponded to an "urgent" course and included patients who did not meet R1 criteria but required substantial acute treatment (eg, intravenous medication, fluids, and nebulizers) or hospitalization. R3 comprised lower-acuity courses in which none of the R1 or R2 markers were present. Patients who left without being seen (LWBS) were coded separately and excluded from outcome-based binary analyses. Full operational definitions and mapping of specific outcome elements to R1-R3 are provided in Table S2 in Multimedia Appendix 1.

To capture sentinel deterioration events that may reflect underrecognition of severity at triage, we additionally defined a DSC based on components commonly used as ED quality and safety indicators. DSC was coded as positive if any of the following occurred after the index ED visit: (1) unplanned ICU transfer within 72 hours of ward admission, (2) ED revisit within 72 hours resulting in unplanned hospital admission (including ICU admission when present), or (3) all-cause death within 7 days [22-24]. A binary variable, DSC_any, was set to 1 if at least one component was present. Outcome adjudication for R1-R3 and DSC_any was performed using routinely collected outcome data and was fully blinded to the index triage category and all model outputs.

Using these constructs, we prespecified 4 binary analytic "lenses" for sensitivity analyses. A classic lens defined outcome+ as R1 only and outcome– as R2 or R3, with test+ as triage categories 1-2 versus 3-5, mirroring conventional MTS validation [15]. An operational lens defined outcome+ as R1 or R2 versus R3 and test+ as categories 1-3 versus 4-5, reflecting the separation between patients who should not wait in the lowest-priority stream and those who can safely do so. Two augmented lenses incorporated DSC_any: an augmented classic lens (outcome+=R1 or DSC_any; test+=categories 1 and 2) and an augmented operational lens (outcome+=R1 or R2 or DSC_any; test+=categories 1-3). These lenses were intended to test robustness across different, clinically motivated definitions of high severity and to align with prior recommendations on composite triage outcomes. Full definitions are provided in Textbox S4 in Multimedia Appendix 1.

For each lens and each triage method (nurse triage, baseline LLM, and MECR-RAG), we constructed 2×2 tables of test+ versus outcome+ and calculated sensitivity, specificity, and 95% CIs, along with positive and negative likelihood ratios (LR+ and LR–) and diagnostic odds ratios (DORs). To compare models on the same patients, we used paired McNemar tests to assess differences in sensitivity (within outcome+ cases) and specificity (within outcome– cases). As additional clinically interpretable summaries, we examined (1) the proportion of R1 cases assigned to immediate (categories 1 and 2), (2) the proportion of R2 cases assigned to nonurgent (categories 4 and 5), and (3) a weighted harm index per 100 patients that assigns higher penalties to more dangerous errors (R1 or R2 assigned to nonurgent) than to overtriage of R3 cases. Case-level harm scores were compared between models using paired signed tests. Detailed formulas for likelihood ratios, DORs, CIs, and harm index computation are provided in Textbox S5 in Multimedia Appendix 1.

Statistical Analysis

All analyses were conducted using R (version 4.5.0; R Core Team). Interrater agreement and kappa statistics were calculated using standard packages for reliability analysis. Classification metrics were obtained using established machine learning libraries, and nonparametric CIs were estimated using bootstrap resampling. Between-model comparisons used tests appropriate to the data structure, including Friedman tests with Nemenyi post hoc procedures for repeated-run summary metrics and Cochran Q and McNemar tests for paired binary outcomes. Exploratory subgroup, scaling, and cross-model generalizability analyses were treated as descriptive and were not formally powered for hypothesis testing. Full details of the statistical workflow, including package names, resampling schemes, handling of multiple runs, and exploratory analyses, are provided in Textbox S6 in Multimedia Appendix 1.

Ethical Considerations

This study was approved by the Hospital Authority Central Institutional Review Board (reference number CIRB-2024-561-4). Because this was a retrospective analysis of anonymized patient records with no impact on clinical care, the Central Institutional Review Board granted a waiver of informed consent. All data used in this study were fully anonymized prior to analysis, and no identifiable patient information was retained or accessible to the study team. No compensation was provided, as no participants were recruited or contacted for this study.

Results

Participants

The final test set comprised 236 ED triage encounters from 2023. After expert consensus adjudication, the distribution of triage categories was 23/236 (9.7%) category 1, 23/236 (9.7%)

XSL•FO
RenderX

category 2, 82/236 (34.7%) category 3, 98/236 (41.5%) category 4, and 10/236 (4.2%) category 5. The mean patient age was 55.1 (SD 26.2; range 0.3-98.0) years. Overall, 131/236 (55.5%) patients were male and 105/236 (44.5%) were female. The most common clinical specialties were medicine (115/236, 48.7%), orthopedics (36/236, 15.3%), surgery (33/236, 14.0%), and pediatrics (13/236, 5.5%), with the remaining 39/236 (16.5%) classified as other specialties.

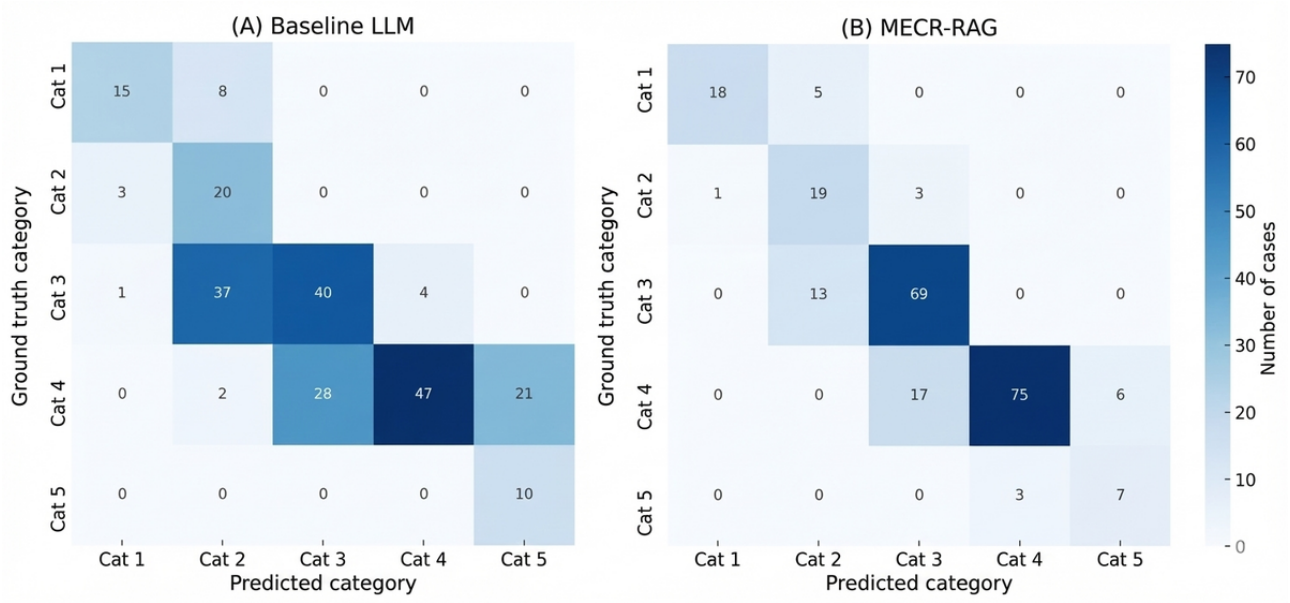
The retrieval database used by the MECR-RAG system consisted of 3000 anonymized ED encounters from 2024. The triage category distribution was constructed to reflect real-world attendance patterns, which are typically skewed toward lower-acuity presentations, with modest upsampling of categories 1, 2, and 5 to ensure adequate representation of rare but clinically important groups. The mean age in the retrieval database was 56.7 (SD 25.6; range 0.2-104.0) years, with an equal sex distribution (1500/3000, 50.0% male and 1500/3000, 50.0% female). The specialty mix was similar to the test set, with medicine accounting for 1395/3000 (46.5%) encounters, followed by orthopedics (441/3000, 14.7%), surgery (435/3000, 14.5%), pediatrics (210/3000, 7.0%), and other specialties (519/3000, 17.3%). Baseline characteristics of both datasets are summarized in Table 1, and characteristics of the 1000- and 2000-case retrieval subsets used in the scaling analysis are provided in Table S3 in Multimedia Appendix 1.

Table 1. The demographic and triage category distribution of the test set and 3000-case retrieval-augmented generation database.

Characteristic	Test set (N=236)	3000-case database (N=3000)
Age (years), mean (SD; range)	55.1 (26.2; 0.3-98.0)	56.7 (25.6; 0.2-104.0)
Sex, n (%)		
Male	131 (55.5)	1500 (50.0)
Female	105 (44.5)	1500 (50.0)
Triage categories, n (%)		
Category 1	23 (9.7)	94 (3.1)
Category 2	23 (9.7)	120 (4.0)
Category 3	82 (34.7)	1705 (57.0)
Category 4	98 (41.5)	1035 (34.5)
Category 5	10 (4.2)	46 (1.5)
Specialty, n (%)		
Medicine	115 (48.7)	1395 (46.5)
Orthopedics	36 (15.3)	441 (14.7)
Surgery	33 (14.0)	435 (14.5)
Pediatrics	13 (5.5)	210 (7.0)
Others	39 (16.5)	519 (17.3)

Age is presented as mean (SD). Triage category and specialty values are reported as percentages of total cases within each dataset. Other specialties include dentistry; dermatology; ear, nose, and throat; neurosurgery; obstetrics and gynecology; oncology; ophthalmology; and psychiatry. Both datasets were constructed to reflect real-world triage distributions, with modest oversampling of rare categories (eg, categories 1, 2, and 5) to ensure sufficient representation for model evaluation. Full sampling rationale is provided in the “Methods” section. The test set and retrieval database exhibited broadly comparable distributions in age, sex, and specialty.

Comparative Performance of MECR-RAG and the Baseline LLM, Benchmarked Against Expert Rater Agreement



The MECR-RAG system showed substantially higher agreement with consensus triage labels than the baseline LLM. Across 5 independent runs, MECR-RAG achieved a mean QWK of 0.902 (SD 0.0021; 95% CI 0.901-0.904), compared with 0.801 (SD 0.004; 95% CI 0.798-0.804) for the baseline model (mean paired difference 0.101, SD 0.0058; 95% CI 0.097-0.106; P<.001). Classification accuracy followed the same pattern, with a mean accuracy of 0.802 (SD 0.0082; 95% CI 0.795-0.808) for MECR-RAG versus 0.542 (SD 0.0073; 95% CI 0.536-0.548) for the baseline LLM (mean paired difference 0.264, SD 0.0150; 95% CI 0.251-0.278; P<.001). Similar effect sizes were observed when analyses were repeated using single median-run prediction sets, indicating that MECR-RAG’s advantage was robust to run-to-run variability.

To benchmark model performance against human experts, we evaluated interrater reliability between the 2 professional triage nurses who generated the reference labels; their QWK was 0.887. By comparison, MECR-RAG achieved a mean QWK of 0.902 (SD 0.0021; 95% CI 0.901-0.904). Using a prespecified noninferiority margin of −0.05, MECR-RAG met criteria for noninferiority to expert agreement, and this conclusion was unchanged in sensitivity analyses restricted to single median-performing runs. Taken together, these findings suggest that MECR-RAG attains expert-comparable consistency in 5-level triage classification while clearly outperforming a

XSL•FO
RenderX

prompt-only LLM. Confusion matrices comparing triage classification performance between the baseline LLM and MECR-RAG are shown in Figure 2. Results are shown for the median-performing run across 5 stochastic trials in this figure.

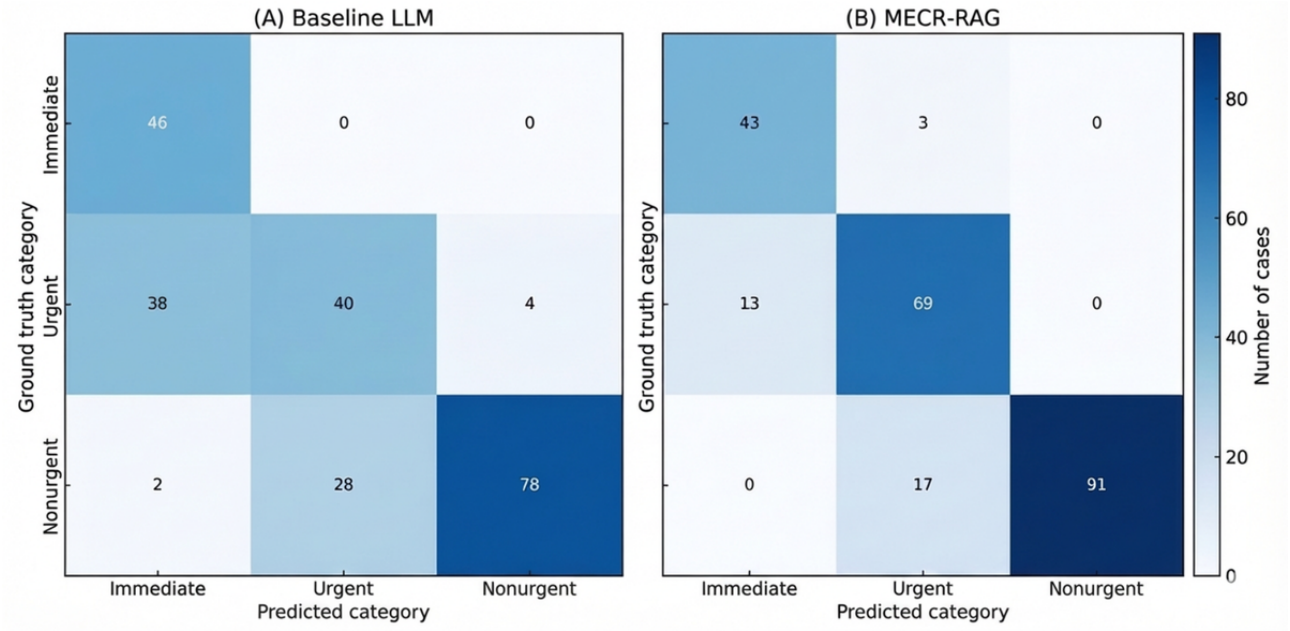


Figure 2. Confusion matrices comparing 5-level triage classification performance between the baseline prompt-only large language model (panel A) and the Multi-Evidence Clinical Reasoning retrieval-augmented generation system (panel B) on 236 emergency department triage encounters in the test set. LLM: large language model; MERC-RAG: Multi-Evidence Clinical Reasoning retrieval-augmented generation.

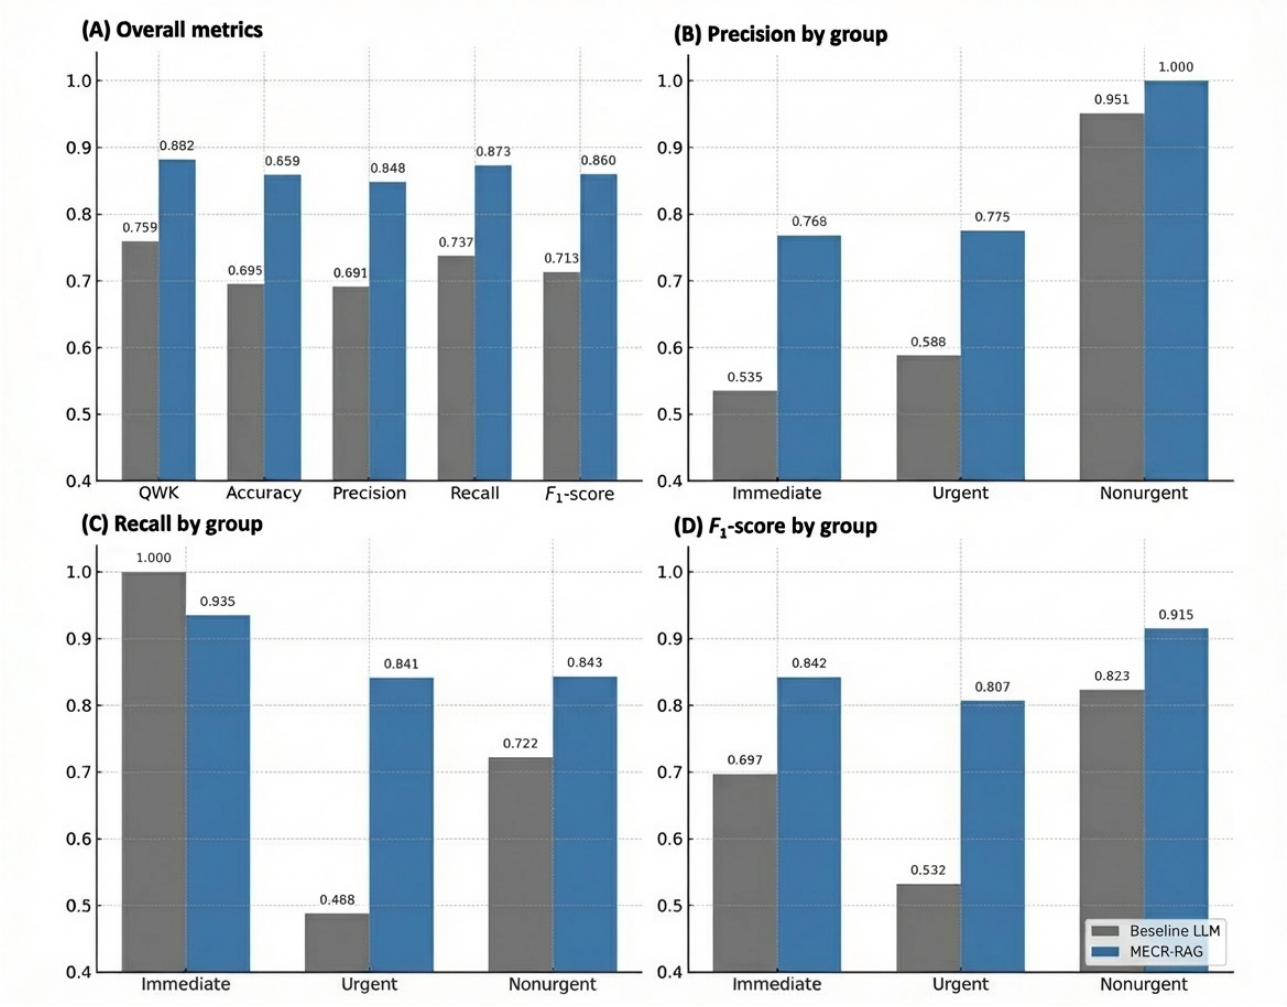
Performance Using Clinically Grouped Triage Categories

To reflect operational priorities in the ED, we conducted a post hoc analysis collapsing the 5 triage categories into 3 clinically meaningful groups: immediate (categories 1 and 2), urgent (category 3), and nonurgent (categories 4 and 5). This schema mirrors local workflows, in which immediate cases are seen without delay, urgent cases typically wait approximately 32 minutes, whereas nonurgent cases typically wait approximately 240 minutes based on 2024 institutional data. All metrics in this analysis were derived from the median-performing model run to approximate single-run deployment. Confusion matrices for grouped predictions are shown in Figure 3. Results reflect the median-performing run across 5 stochastic trials in this figure.

Figure 3. Confusion matrices comparing triage group classification performance between the baseline prompt-only large language model (panel A) and the Multi-Evidence Clinical Reasoning retrieval-augmented generation system (panel B) under a 3-group schema. LLM: large language model; MERC-RAG: Multi-Evidence Clinical Reasoning retrieval-augmented generation.

Under this 3-group schema, MECR-RAG maintained high overall performance, achieving a QWK of 0.882 (95% CI 0.840-0.920) compared with 0.759 (95% CI 0.700-0.813) for the baseline LLM (paired difference 0.125, 95% CI 0.077-0.174; P<.001). Accuracy similarly favored MECR-RAG (0.859 vs 0.695; paired difference 0.164, 95% CI 0.110-0.225; P<.001).



XSL•FO
RenderX

Macrolevel precision, recall, and F_1-score were also higher for MECR-RAG (precision 0.848 vs 0.691; recall 0.873 vs 0.737; F_1-score 0.860 vs 0.713).

Error-pattern analysis showed that MECR-RAG slightly reduced undertriage compared with the baseline LLM (3/236, 1.3% vs 4/236, 1.7%; McNemar P=.69), while substantially reducing overtriage. Overtriage decreased from 68/236 (28.8%) with the baseline LLM to 30/236 (12.7%) with MECR-RAG (McNemar P<.001). Thus, the model reduced unnecessary escalation without compromising detection of higher-acuity cases.

Performance advantages for MECR-RAG were consistent across triage groups. For immediate cases, MECR-RAG had slightly lower recall than the baseline LLM (0.935 vs 1.000) but substantially higher precision (0.768 vs 0.535), yielding a higher F_1-score (0.842 vs 0.697). Overall correctness did not differ significantly (McNemar P=.25), suggesting comparable sensitivity with fewer false positives. In the urgent group, MECR-RAG markedly outperformed the baseline model (recall 0.841 vs 0.488; precision 0.775 vs 0.588; F_1-score 0.807 vs 0.532; McNemar P<.001), indicating improved discrimination in this diagnostically challenging and operationally dominant band. For nonurgent cases, MECR-RAG again showed higher recall (0.843 vs 0.722) and F_1-score (0.915 vs 0.823), with perfect precision (1.000 vs 0.951; McNemar P=.01). These patterns, summarized in Figure 4, suggest that MECR-RAG delivers a more favorable balance between safety and operational efficiency, particularly in the mid- and low-acuity groups that account for most ED visits and drive waiting-time differentials.

Figure 4. Comparative model performance across overall and triage group-specific metrics. LLM: large language model; MERC-RAG: Multi-Evidence Clinical Reasoning retrieval-augmented generation. QWK: quadratic weighted kappa.

Comparative model performance across overall and triage group-specific metrics. Performance is evaluated using a clinically relevant 3-level grouping: immediate (categories 1 and 2), urgent (category 3), and nonurgent (categories 4 and 5), corresponding to local time-to-physician targets and resource prioritization. Panel A summarizes overall performance across QWK, accuracy, precision, recall, and F_1-score for the baseline prompt-only LLM and the MECR-RAG system; MECR-RAG achieved higher QWK (0.882) and accuracy (0.859) than the baseline LLM (QWK 0.759; accuracy 0.695; both P<.001). Panels B-D show precision, recall, and F_1-score, respectively, by triage group, with MECR-RAG consistently outperforming the baseline LLM across all groups and particularly in the urgent group (F_1-score 0.807 vs 0.532). All results are based on the median-performing model run.

XSL•FO
RenderX

Outcome-Informed Validity Relative to Clinical Severity

Among the 236 triage encounters, 226 (95.8%) had sufficient follow-up information to assign an outcome-based severity tier (R1-R3); the remaining 10 (4.2%) patients were LWBS and were excluded from all outcome-based analyses but retained in label-based performance summaries. Within the 226 encounters with outcome labels, 13/226 (5.8%) met R1 criteria, 117/226 (51.8%) met R2 criteria, and 96/226 (42.5%) were classified as R3. When high-severity outcomes were defined as R1+R2 (n=130) and triage "positive" as categories 1-3 versus 4-5, MECR-RAG achieved the highest sensitivity for high-risk courses at 124/130 (95.4%), compared with 117/130 (90.0%) for initial nurse triage and 122/130 (93.8%) for the baseline LLM. The gain versus nurses was statistically significant (McNemar χ^2_1 =5.14; *P*=.02), whereas sensitivity did not differ from the baseline LLM (χ^2_1 =0.17; *P*=.68). Specificity for low-risk (R3) cases was 77/96 (80%) for MECR-RAG, 78/96 (81%) for nurses, and 66/96 (69%) for the baseline LLM. Thus, MECR-RAG maintained nurse-level specificity (χ^2_1 =0.00; *P*=1.00) while significantly improving specificity over the baseline LLM (χ^2_1 =5.26; *P*=.02). All 3 systems correctly avoided assigning nonurgent (categories 4 and 5) to any R1 cases (0/13 each). The DOR for distinguishing R1+R2 from R3 was 83.8 (95% CI 32.0-218.9) for MECR-RAG, 39.0 (95% CI 18.1-84.1) for nurses, and 33.6 (95% CI 14.6-77.4) for the baseline LLM, consistent with a more favorable overall trade-off between undertriage and overtriage for MECR-RAG, although CIs overlapped because of limited event counts.

To examine clinically important undertriage, we focused on R2 patients assigned to nonurgent triage (categories 4 and 5). Among 117 R2 encounters, 13/117 (11.1%) were initially labeled nonurgent by nurses, compared with 8/117 (6.8%) by the baseline LLM and 6/117 (5.1%) by MECR-RAG. In paired analysis, MECR-RAG approximately halved R2 nonurgent misclassification relative to nurses (13 to 6 cases; McNemar χ^2_1 =5.14; *P*=.02), with a smaller, nonsignificant reduction compared with the baseline LLM (8 to 6 cases; χ^2_1 =0.17; *P*=.68). Considering the entire triage distribution, MECR-RAG also produced the safest nonurgent queue in terms of hidden high-risk patients: among patients predicted as nonurgent, the proportion with R1+R2 outcomes was 6/83 (7%) for MECR-RAG, compared with 13/91 (14%) for nurses and 8/74 (11%) for the baseline LLM. immediate groups were correspondingly enriched for high-severity outcomes, with 47/47 (100%) R1+R2 for nurses, 56/56 (100%) for MECR-RAG, and 82/86 (95%) for the baseline LLM. These patterns suggest that MECR-RAG reduces undertriage of R2 patients into the lowest-priority stream while preserving a clear outcome-based risk gradient across immediate, urgent, and nonurgent groups.

As a complementary summary of mis-triage burden, we constructed a weighted harm index that assigns higher cost to more dangerous errors: R1 assigned to nonurgent (categories 4 and 5) was weighted as 5, R2 assigned to nonurgent as 2, and R3 assigned to immediate or urgent (categories 1-3) as 1. Across the 226 cases with outcome labels, initial nurse triage accumulated a weighted error sum of 44 (harm index 19.47 per 100 patients), the baseline LLM 46 (20.35 per 100 patients), and MECR-RAG 31 (13.72 per 100 patients). At the individual case level, the baseline LLM incurred higher harm scores than MECR-RAG in 19 discordant cases and lower scores in 6, with 201 ties (2-sided sign test *P*=.02), indicating a statistically significant net reduction in weighted harm with MECR-RAG. Compared with nurses, harm scores were lower for MECR-RAG in 14 cases and higher in 8 (204 ties; *P*=.29), suggesting a numerically favorable but underpowered difference. Overall, these outcome-based analyses indicate that MECR-RAG not only improves high-severity sensitivity and reduces R2 undertriage but also yields the lowest aggregate mis-triage burden when accounting for both the direction and severity of errors.

To test robustness to alternative definitions of clinical severity, we repeated binary analyses under classic and augmented outcome "lenses" that defined outcome+ using R1 alone, R1 combined with the DSC, and R1 or R2 combined with the composite (see Methods). Across all lenses, MECR-RAG consistently showed the most favorable trade-off between sensitivity and specificity, with the highest DORs and positive likelihood ratios compared with nurses and the baseline LLM. In a classic Manchester-style lens (outcome+=R1 only; test+=categories 1-2 vs 3-5), all 3 systems achieved perfect sensitivity for R1 cases, but MECR-RAG improved specificity relative to the baseline LLM and approached nurse performance. When the DSC (unplanned ICU transfer within 72 hours, 72-hour revisit with admission, or death within 7 days) was incorporated into augmented lenses, MECR-RAG again maintained the highest discrimination despite wide and overlapping confidence intervals reflecting the small number of sentinel events. Full 2×2 tables, effect estimates, CIs and details for each lens are provided in Tables S4-S7 and Section B in Multimedia Appendix 1. Complementary exploratory analyses, including subgroup performance stratified by age and sex and model behavior on adjudicated disagreement cases, are reported in Sections C and D in Multimedia Appendix 1.

Component-Wise Ablation of Retrieval Mechanisms

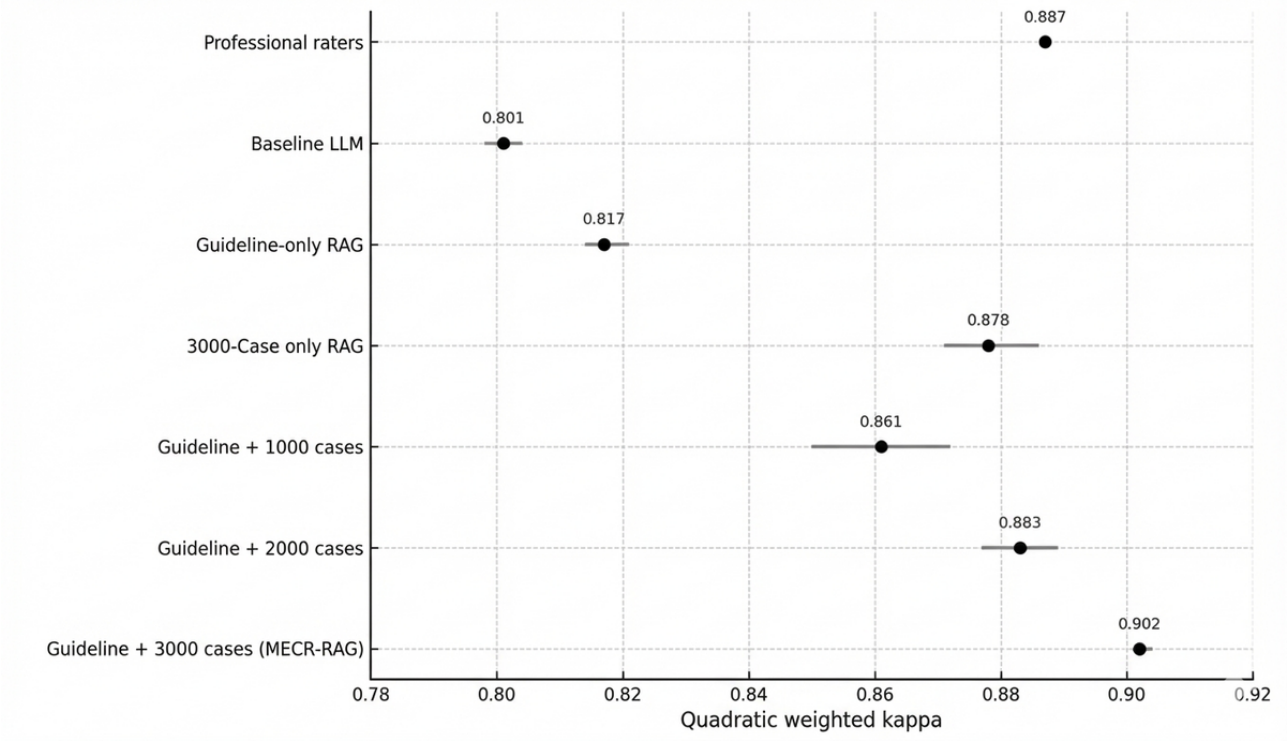
To assess the contribution of individual retrieval components, we conducted a component-wise ablation across four configurations: (1) a prompt-only baseline LLM without retrieval, (2) a guideline-only RAG model retrieving sections from the HKAETG, (3) a case-only RAG model retrieving similar past triage cases, and (4) the full MECR-RAG system combining both guideline and case retrieval. Each configuration used an identical preprocessing and generation pipeline and was evaluated over 5 independent runs. QWK was the primary outcome, with overall accuracy, macrolevel precision, and macrolevel recall as secondary metrics.

Across configurations, MECR-RAG achieved the highest agreement with expert consensus (mean QWK 0.902, SD 0.0021; 95% CI 0.901-0.904; accuracy 0.802, SD 0.0082), followed by the case-only model, then the guideline-only model, and finally the baseline LLM. Both guideline-based and case-based retrieval improved performance relative to the baseline, but their combined use in MECR-RAG produced the largest and most consistent gains. Friedman tests on QWK and accuracy across the 4 models were statistically significant, and

XSL•FO
RenderX

post hoc Nemenyi comparisons identified MECR-RAG as the only configuration with a statistically superior rank to the baseline LLM under conservative multiple-comparison control. Full numerical results are shown in Figure 5 (QWK) and Figure 6 (accuracy) and are detailed in Table S8 in Multimedia Appendix 1.

Figure 5. Quadratic weighted kappa performance of model variants and professional raters. LLM: large language model; MERC-RAG: Multi-Evidence Clinical Reasoning retrieval-augmented generation; RAG: retrieval-augmented generation.



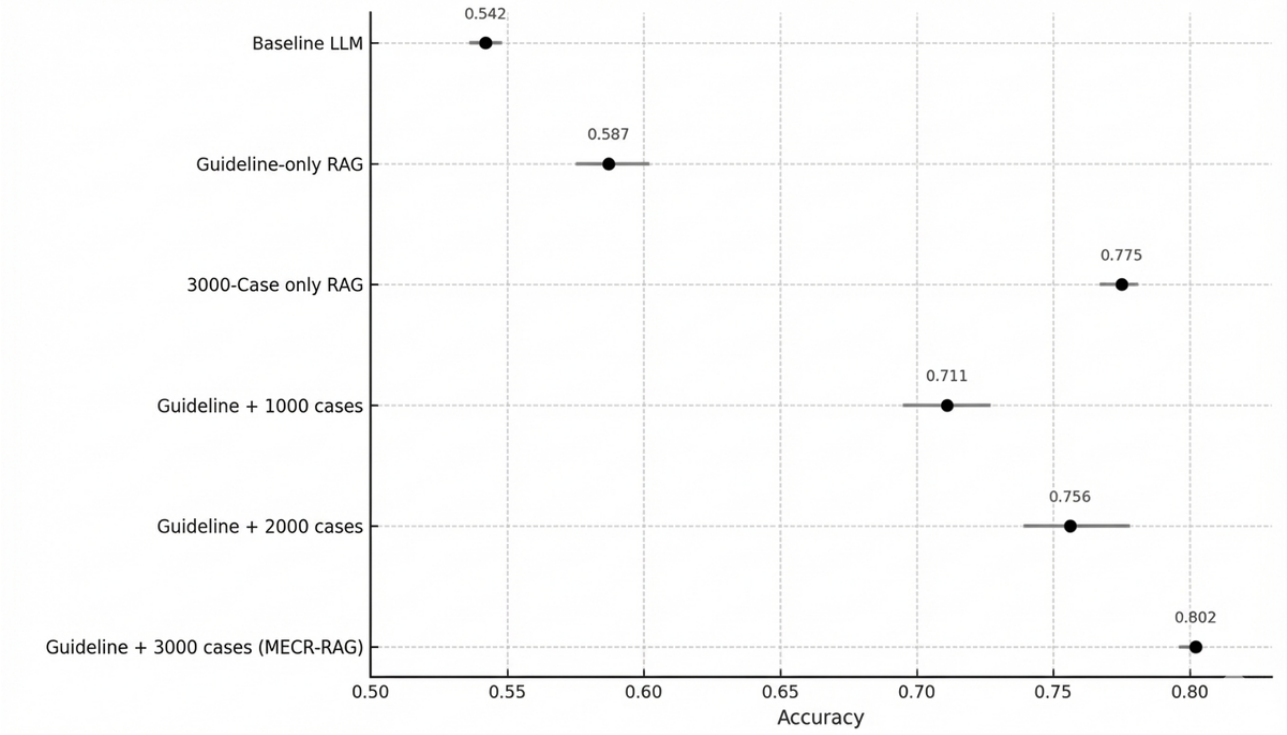


Figure 6. Accuracy performance across model variants. LLM: large language model; MERC-RAG: Multi-Evidence Clinical Reasoning retrieval-augmented generation; RAG: retrieval-augmented generation.

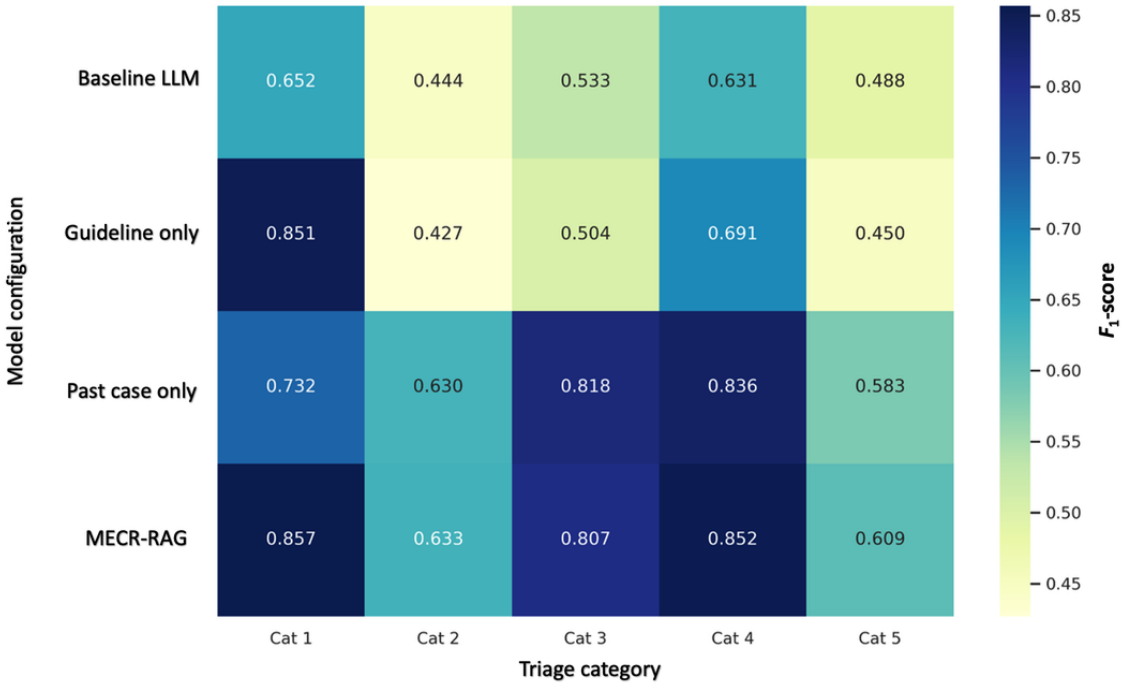


To understand how retrieval affected different acuity levels, we examined per-category accuracy and F_1-scores for triage categories 1-5. Guideline retrieval contributed most strongly to category 1 (critical) performance, where the guideline-only model achieved the highest accuracy and F_1-score, consistent with the value of structured, rule-based protocols for recognizing

XSL•FO
RenderX

life-threatening presentations. In contrast, case retrieval had the largest impact on categories 3 and 4, where the case-only and MECR-RAG models substantially outperformed both the baseline and guideline-only configurations, reflecting the importance of experiential pattern recognition in diagnostically ambiguous, midacuity presentations. For categories 2 and 5, model differences were smaller and not statistically robust, although MECR-RAG generally retained the highest F_1-scores. Overall, MECR-RAG delivered the best balance of precision and recall across all categories, supporting the complementary value of combining guideline-based and case-based retrieval (Figure 7; detailed estimates in Table S9 in Multimedia Appendix 1).

Figure 7. Component-wise ablation analysis of model performance across triage categories. LLM: large language model; MERC-RAG: Multi-Evidence Clinical Reasoning retrieval-augmented generation.

As an exploratory scaling analysis, we also varied the size of the past-case retrieval database from 1000 to 3000 cases and observed monotonic gains in QWK and accuracy with reduced between-run variability at larger retrieval pools (Tables S3 and S10 in Multimedia Appendix 1).

In Figure 5, the mean QWK values with 95% CIs are shown for the baseline and retrieval-augmented model variants. Points represent mean QWK across 5 stochastic runs, and horizontal error bars indicate 95% CIs across these runs. The professional benchmark (QWK 0.887) reflects interrater agreement between 2 expert triage nurses. The figure includes both ablation variants—a guideline-only RAG model and a 3000-case-only RAG model—and scaling variants that combine guideline and past case retrieval with databases containing 1000, 2000, and 3000 past triage cases. The MECR-RAG model (guideline plus 3000 past cases) achieved the highest mean QWK and was statistically superior to the baseline prompt-only large language model (LLM; mean paired difference 0.101, SD 0.0058; 95% CI 0.097-0.106; P<.001), while demonstrating noninferior agreement compared with professional raters.

In Figure 6, the mean accuracy values with 95% CIs are shown for the baseline prompt-only LLM, RAG variants, and combined retrieval configurations. The x-axis shows accuracy, with points representing mean values across 5 stochastic runs and horizontal error bars indicating 95% CIs. The figure includes ablation variants (guideline-only and 3000-case-only RAG) and scaling variants that combine guideline retrieval with 1000, 2000, or 3000 past cases. The MECR-RAG configuration (guideline plus 3000 past cases) achieved the highest accuracy and demonstrated a statistically significant improvement compared with the baseline LLM.

F_1-scores for each triage category (categories 1-5) across 4 model configurations. Rows represent the baseline prompt-only LLM, a guideline-only RAG model, a 3000-case-only RAG model, and the MECR-RAG system, and columns represent triage categories. Values reflect outputs from the median-performing evaluation run. Guideline retrieval contributed most prominently to performance in category 1, while case retrieval improved performance in categories 3 and 4, where patient presentations are more heterogeneous and require contextual interpretation. The MECR-RAG system generally achieved the highest or near-highest F_1-scores across triage categories, illustrating the additive value of combining structured guideline knowledge with experiential case-based retrieval.

XSL•FO
RenderX

Generalizability Across LLM Architectures

The primary model used for all prior evaluations was DeepSeek-V3. To evaluate whether the MECR-RAG framework generalizes beyond this development model, we conducted exploratory assessments using 2 additional foundation models: Claude 3.7 and GPT-4o. Each model was tested on the same 236-case triage dataset with the same 3000-case retrieval database under 2 configurations: the MECR-RAG system and a baseline, prompt-only LLM without retrieval augmentation.

In these single-run evaluations, MECR-RAG consistently outperformed the corresponding baseline configuration. For Claude 3.7, QWK improved from 0.840 under the baseline to 0.890 with MECR-RAG. Similarly, GPT-4o achieved a QWK of 0.890 with MECR-RAG, compared with 0.778 without retrieval. Although these results are based on single inference runs and are not statistically powered for formal comparison, they provide preliminary evidence that the dual-source retrieval framework may confer similar relative gains across distinct LLM back ends. A detailed breakdown of model predictions versus consensus triage labels for Claude 3.7 and GPT-4o, under both MECR-RAG and baseline conditions, is provided in Figures S1 and S2 in Multimedia Appendix 1, respectively.

Taken together, these preliminary findings suggest that the benefits of dual-source retrieval generalize beyond DeepSeek-V3 and may confer cross-model robustness of MECR-RAG across LLMs from different developers, supporting its broader applicability in diverse clinical settings. Further benchmarking across a wider range of model families, input formats, and deployment environments is warranted to validate robustness and assess trade-offs in latency, interpretability, and resource efficiency for real-world clinical deployment.

Discussion

Principal Findings

This retrospective evaluation suggests that a dual-source, retrieval-augmented LLM can achieve expert-comparable agreement with consensus nurse triage labels while substantially outperforming a prompt-only baseline model. MECR-RAG improved QWK and accuracy over the baseline LLM under both the 5-level and 3-group schemas and met prespecified noninferiority criteria compared with professional triage nurses. The largest gains occurred in Categories 3 and 4 and in the urgent versus nonurgent grouping, which together accounted for most ED visits and are operationally dominant, with large differences in waiting times. Ablation analyses indicated that both guideline retrieval and case retrieval contributed to performance, with the full dual-source MECR-RAG configuration consistently outperforming guideline-only and case-only variants. Performance also improved as the retrieval database increased from 1000 to 3000 cases, suggesting that retrieval quality benefits from a richer case pool. Exploratory cross-model experiments with Claude 3.7 Sonnet and GPT-4o further suggested that these benefits generalize across different LLM back ends.

Ground Truth Validity and Construct Interpretation

In this study, the primary reference standard was expert nurse consensus at the time of presentation, which reflects routine clinical decision-making but is an imperfect proxy for underlying acuity. Large US data on ESI version 4 report mis-triage in 32.2% of encounters (3.3% undertriage and 28.9% overtriage), underscoring that nurse-level labels are imperfect proxies for “true” acuity [17]. Even with trained emergency staff, approximately 17% of triage assignments may be inaccurate [21]. To address these limitations, we complemented consensus labels with outcome-informed constructs, ordinal severity tiers (R1-R3) and a DSC, adapted from MTS validation work and recommendations on triage outcome selection [15,22,24].

Within these outcome-based frameworks, MECR-RAG showed higher sensitivity for R1+R2 courses than initial nurse triage at comparable specificity, reduced misclassification of R2 patients into the nonurgent stream, and yielded the lowest weighted harm index, suggesting closer alignment between assigned urgency and downstream clinical course. At the same time, event counts for the most severe outcomes were modest, and both nurse consensus and the composite outcomes remain pragmatic proxies rather than definitive measures of “true” severity. We therefore interpret these findings as supportive evidence that MECR-RAG performs well against clinically grounded, outcome-informed constructs of acuity, rather than as proof that it fully captures an underlying severity state.

Comparison With Prior Work

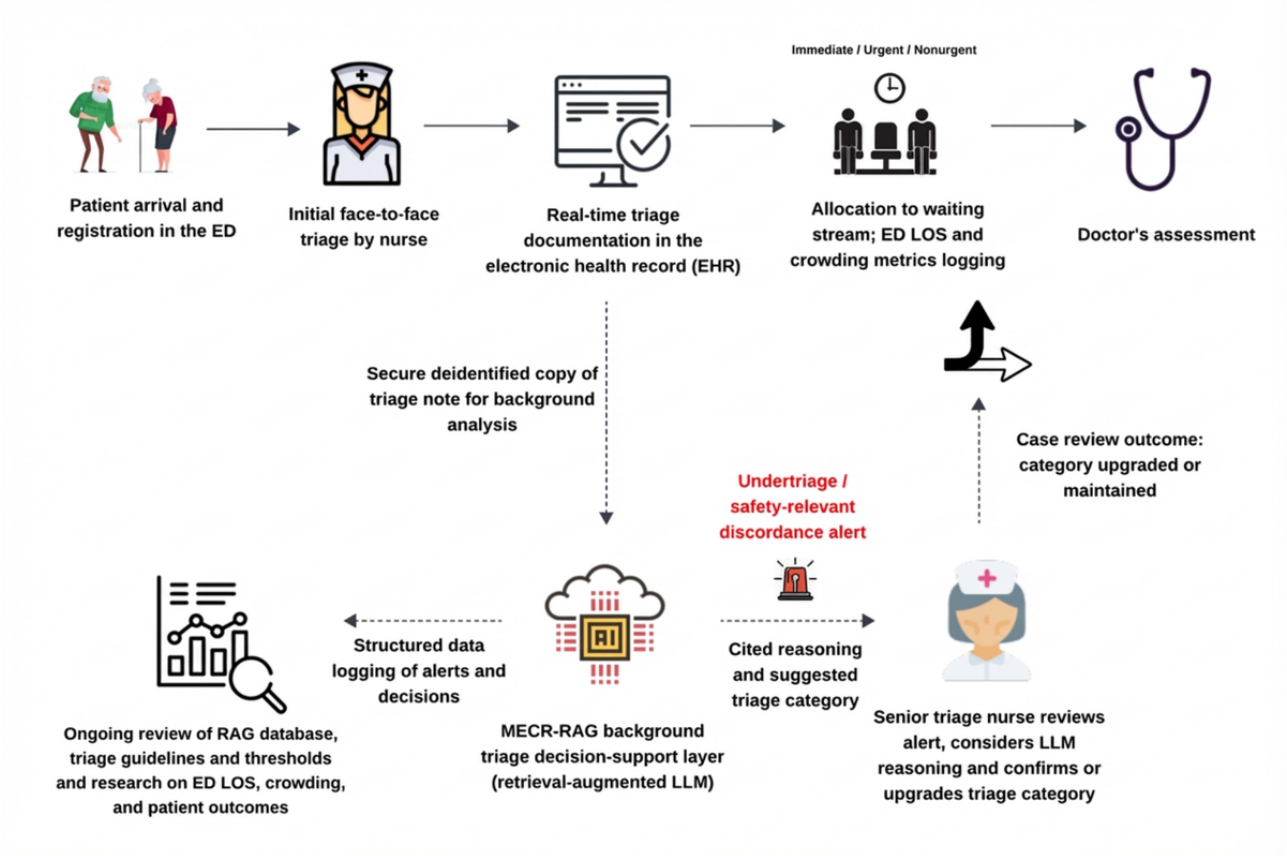
To our knowledge, this is the first study to evaluate a dual-source, RAG-enhanced LLM for emergency triage using raw triage documentation paired with expert-consensus reference labels and complementary outcome-informed severity constructs. Prior RAG studies in emergency care have shown that retrieval can improve triage or referral performance on simulated exam-style cases or curated ED datasets but have relied on structured scenarios or routine triage labels without independent adjudication [13,14]. Our design addresses the broader evidence gap noted in a recent systematic review, in which only 5% of 519 published evaluations of health care LLMs used real patient care data for testing [25]. This provides a more realistic and stringent test of RAG-enhanced triage than has been reported previously.

Masanneck et al [4] established an early benchmark by evaluating LLM triage performance against expert assessments, but their dataset consisted of physician-curated vignettes from a single day, with selected patient attributes adjusted according to predefined standard operating procedures. In contrast, our study applies dual-source RAG to a year-long sample of anonymized triage notes without manual editing or reinterpretation, preserving the fidelity of frontline documentation and temporal variation. Zaboli et al [3] and Paslı et al [7] have likewise emphasized the importance of handling unstructured narratives and integrating local triage frameworks; our dual-retrieval design directly addresses these needs by combining structured guideline content with real-world case patterns.

XSL•FO
RenderX

Our findings also align with broader work on nurse triage systems, showing that midacuity presentations are both the most common and the most difficult to classify. In a large cohort of over 5.3 million adult ED encounters using ESI version 4, Sax et al [17] found that approximately 29% of visits were overtriaged and that the sensitivity of ESI version 4 for identifying low-acuity, low-resource patients (correctly assigning ESI 4-5 among patients using <2 resources and with no critical interventions) was only 50%. A majority of encounters were assigned to the midlevel category ESI 3, highlighting poor differentiation between lower- and higher-acuity patients. Validation of the HKAETG has similarly shown the lowest interrater agreement for categories 3 and 4, reflecting the intrinsic difficulty of distinguishing "urgent" from "semiurgent" presentations [26]. In our cohort, categories 3 and 4 comprised about three-quarters of all cases, and the prompt-only LLM reproduced the overtriage patterns documented in both human and LLM triage studies. In contrast, MECR-RAG substantially reduced overtriage and improved precision and recall specifically in these mid- and low-acuity strata, suggesting that dual-source retrieval may help address a long-standing bottleneck in emergency triage performance.

Clinical and Operational Implications



Although we did not directly measure ED length of stay (LOS), boarding, or mortality, several findings suggest how MECR-RAG could plausibly influence safety and flow if implemented as decision support. Under a 3-group schema (immediate, urgent, and nonurgent), MECR-RAG achieved higher agreement and accuracy than the prompt-only LLM, with markedly less overtriage and similarly low undertriage. Gains were concentrated in the urgent and nonurgent tiers, which dominate the case mix and are associated with substantially longer waits for lower-priority patients at our center. In outcome-based analyses, MECR-RAG showed higher sensitivity for R1+R2 courses than initial nurse triage at nurse-level specificity, reduced misclassification of R2 patients into the nonurgent stream, and yielded the lowest severity-weighted harm index. Together, these patterns indicate fewer high-risk patients "hidden" in the longest-wait queue and fewer low-risk patients unnecessarily occupying high-acuity resources, aligning urgency assignments more closely with downstream clinical course.

These redistributions of risk are clinically relevant because prolonged ED LOS, crowding, and boarding have been repeatedly linked to delayed treatment, longer inpatient stays, and higher short-term mortality. More efficient separation between urgent and nonurgent queues could, in principle, help decompress monitored areas, reduce avoidable time in high-acuity spaces for low-risk patients, and support more timely care for those with high-severity courses. However, our evaluation was retrospective and did not include LOS, crowding, or mortality as prespecified end points. Any potential contribution of MECR-RAG therefore remains hypothesis-generating and must be tested in prospective, outcome-focused studies.

As illustrated in the proposed human-in-the-loop workflow (Figure 8), MECR-RAG is intended to function as a background triage decision-support layer: triage nurses retain primary responsibility for assigning categories, while a secure, deidentified copy of the triage note is analyzed in parallel, with the system remaining silent for most encounters and surfacing alerts only for predefined safety-relevant discordances (eg, potential undertriage of urgent or immediate cases). Alerts and explanations can then be reviewed by a senior nurse, who may confirm or upgrade the triage category, while all alerts, decisions, and associated operational metrics are logged to support ongoing quality assurance and research on ED LOS, crowding, and downstream outcomes. A staged implementation strategy, beginning with shadow-mode deployment and progressing to focused pilots of discordance alerts with monitoring for automation bias, alert fatigue, throughput, and equity, will be essential before wider rollout.

XSL•FO
RenderX

Figure 8. Conceptual human-in-the-loop workflow for Multi-Evidence Clinical Reasoning retrieval-augmented generation as a background triage decision-support layer in the emergency department. ED: emergency department; LLM: large language model; LOS: length of stay; MECR-RAG: Multi-Evidence Clinical Reasoning retrieval-augmented generation; RAG: retrieval-augmented generation.

Patients follow the routine care pathway shown in the top row: arrival and registration in the ED, initial face-to-face triage by a nurse, real-time triage documentation in the electronic health record, allocation to an urgency-based waiting stream (immediate, urgent, or nonurgent) with logging of ED LOS and crowding metrics, and subsequent doctor's assessment. In parallel, a secure deidentified copy of the triage note is sent to the MECR-RAG system, which operates as a background triage decision-support layer. MECR-RAG generates its own triage recommendation with cited reasoning and remains silent for most encounters, but triggers an undertriage or other safety-relevant discordance alert when its recommendation conflicts with the nurse-assigned category. Alerts and explanations are routed to a senior triage nurse, who may confirm or upgrade the triage category; all alerts, decisions, and outcomes are logged to support ongoing quality assurance and research on ED LOS, crowding, and patient-centered outcomes.

Limitations and Future Directions

This study has several important limitations. First, within the staged evaluation pathway outlined by DECIDE-AI (Developmental and Exploratory Clinical Investigations of Decision support systems driven by Artificial Intelligence), this retrospective, offline prediction study represents preclinical (in silico) validation and should not be interpreted as evidence of real-world clinical effectiveness or safety [27]. Moreover, strong offline discrimination does not reliably translate into clinical benefit after implementation; prior early warning and sepsis tools (including the Rothman Index and the Epic Sepsis Model) have shown materially weaker performance and limited impact in independent, postdeployment evaluations, partly due to differences in data quality, missingness, case mix, alert logic, and workflow across sites [28-32]. Retrospective deep learning models are also vulnerable to dataset shift, class imbalance, and missing data, further limiting transportability across settings and time [33]. Randomized evaluations of AI-enabled interventions similarly suggest that even high-performing models may fail to improve primary clinical end points without careful workflow integration and attention to system constraints [34,35]. Accordingly, our retrospective, single-center results for MECR-RAG should be viewed as predeployment evidence and require prospective, multicenter evaluation before inferring equivalent real-time performance or improved patient outcomes.

Second**,** the evaluation was conducted in a single ED using the HKAETG; performance may differ under other triage frameworks (eg, MTS and ESI), languages, documentation practices, workflows, and patient case mix. Although the retrieval-augmented design is modular and could, in principle, be adapted by reindexing local guidelines and locally representative triage notes without retraining the underlying LLM, portability remains an empirical question and requires external validation and prospective multicenter evaluation.

Third, the retrieval database and text summaries were constructed automatically from routine triage notes without manual adjudication, and prompts were generated without clinician editing. This reflects realistic deployment conditions and improves scalability, but some retrieved exemplars may be

XSL•FO
RenderX

mislabeled or incomplete, and clinically relevant nuances may be lost during summarization. In addition, we did not directly evaluate usability, interpretability, automation bias, or workflow impact, which are increasingly recognized as critical determinants of the safety and effectiveness of AI-enabled clinical decision-support systems [32,36].

These limitations point to clear priorities for future work. Prospective, multicenter studies across institutions using different triage frameworks (HKAETG, MTS, and ESI) are needed to assess generalizability and to determine how MECR-RAG performs in real-time workflows. Consistent with DECIDE-AI and recent guidance from major journals and professional societies, future evaluations should move beyond agreement metrics to prespecify patient-centered and operational end points, including ED and hospital LOS, crowding and boarding times, unexpected ICU transfer, time-critical treatment delays, and short-term mortality [18,37-39]. Implementation-focused studies should also examine how MECR-RAG is integrated into practice (eg, as a second reader or discordance alert), its effects on clinician behavior, workload, and equity, and unintended consequences such as alert fatigue or overreliance on model outputs, ideally using pragmatic randomized or quasi-experimental designs where feasible [34,35]. Framing this work as an early-phase evaluation and explicitly outlining the need for prospective, outcome-focused trials in line with current AI evaluation guidance positions MECR-RAG as a promising candidate for further study rather than a tool ready for immediate widespread deployment.

Conclusions

In summary, this retrospective, single-center study provides one of the first evaluations of a dual-source, retrieval-augmented LLM for emergency triage on real triage notes with expert consensus labels, extending prior work beyond simulated scenarios and routine labels. MECR-RAG achieved agreement comparable to expert nurses and clearly outperformed a prompt-only LLM, particularly in the high-volume category 3-4 bands, while approximately halving overtriage and keeping undertriage very low. In exploratory outcome-based analyses within this cohort, MECR-RAG also showed higher sensitivity for high-severity courses, a safer nonurgent queue, and the lowest severity-weighted harm index compared with initial nurse triage. These findings support the potential of retrieval-augmented LLMs as clinically coherent decision-support tools that function as background second readers—surfacing guidelines and analogous cases, flagging discordant or high-risk assignments for senior review—and thereby potentially improving allocation of high-acuity resources in ways that could, if replicated prospectively, help reduce ED crowding, LOS, and related adverse outcomes. However, this remains an early-phase, retrospective, single-center evaluation based on proxy outcomes, and rigorous prospective multicenter studies across different triage frameworks, with prespecified patient-centered and operational end points and careful attention to workflow, usability, and equity, are essential before such systems can be recommended for routine clinical deployment.

Acknowledgments

We would like to thank KH Leung for organizing and facilitating the consensus triage labeling process. We are also grateful to the emergency department nursing staff at Princess Margaret Hospital for their triage assessments, which formed the basis of the clinical documentation used in this study.

Funding

No external financial support or grants were received from any public, commercial, or not-for-profit entities for the research, authorship, or publication of this article.

Data Availability

The datasets generated or analyzed during this study are not publicly available due to institutional and regulatory restrictions imposed by the Hospital Authority of Hong Kong, but are available from the corresponding author on reasonable request. The underlying code supporting the findings of this study is available at MECR-RAG-Clinical-Research [40].

Authors' Contributions

HS conceptualized the study design, developed the methodology, collected and curated the data, performed the analysis, created the figures, and drafted the initial manuscript. TK developed the computational architecture, configured the model framework, implemented and executed the MECR-RAG system.

Conflicts of Interest

None declared.

Abstract

Background: Venous thromboembolism (VTE) is a common and severe complication in intensive care unit (ICU) patients with sepsis. Conventional risk stratification tools lack sepsis-specific features and may inadequately capture complex, nonlinear interactions among clinical variables.

Objective: This study aimed to develop and validate an interpretable machine learning (ML) model for the early prediction of VTE in ICU patients with sepsis.

Methods: This multicenter retrospective study used data from the Medical Information Mart for Intensive Care IV database for model development and internal validation, and an independent cohort from Changshu Hospital for external validation. Candidate predictors were selected through univariate analysis, followed by least absolute shrinkage and selection operator regression. Retained variables were used in multivariable logistic regression to identify independent predictors, which were then used to develop 9 ML models, including categorical boosting, decision tree, k-nearest neighbor, light gradient boosting machine, logistic regression, multilayer perceptron, naive Bayes, random forest, and support vector machine. Performance was evaluated by discrimination (area under the curve [AUC]), calibration, and clinical use (decision curve analysis). A subgroup analysis stratified by the Sequential Organ Failure Assessment score was conducted in the external cohort to assess model stability across sepsis severity levels. Model interpretability was assessed using Shapley Additive Explanations (SHAP) to quantify the contribution of features to the predicted risk.

Results: A total of 25,197 patients from the Medical Information Mart for Intensive Care IV cohort and 328 patients from the external cohort were included, with VTE incidences of 844 out of 25,197 (3.4%) and 30 out of 328 (9.2%), respectively. The light gradient boosting machine model performed best, achieving an AUC of 0.956 in internal validation. Despite the higher VTE incidence and clinical severity in the external validation, the model maintained robust generalization with an AUC of 0.786. Notably, the model achieved enhanced discriminative ability in the severe sepsis subgroup (Sequential Organ Failure Assessment score >6) with an AUC of 0.816, compared with 0.769 in the mild to moderate sepsis subgroup. Calibration curves indicated strong agreement between predicted and observed outcomes, and decision curve analysis showed superior net benefit across clinically relevant thresholds. SHAP analysis identified central venous catheterization, serum chloride and bicarbonate levels, arterial catheterization, and prolonged partial thromboplastin time as the most influential predictors. Partial dependence plots revealed both linear and nonlinear associations between these variables and VTE risk. Individual-level force plots further enhanced interpretability by visualizing personalized risk profiles.

Conclusions: We developed a high-performing and interpretable ML model for predicting VTE in ICU patients with sepsis. The model demonstrated robustness across cohorts and enhanced performance in the severe sepsis population. By integrating

XSL•FO
RenderX

diverse clinical data and leveraging SHAP for transparent explanations, this tool may support personalized prophylaxis and early diagnostic strategies.

venous thromboembolism; sepsis; machine learning; SHAP; MIMIC-IV

Introduction

Sepsis is a life-threatening condition characterized by acute organ dysfunction resulting from a dysregulated host response to infection and remains a leading cause of mortality in the intensive care unit (ICU) [1]. According to the Global Burden of Disease Study, approximately 48.9 million cases of sepsis occur annually worldwide, resulting in an estimated 11.0 million deaths, which accounts for 19.7% of all global deaths [2]. Venous thromboembolism (VTE), comprising deep vein thrombosis and pulmonary embolism (PE), is a common and severe complication of sepsis that significantly worsens patient outcomes. Despite adherence to guideline-recommended thromboprophylaxis, the incidence of VTE in patients with sepsis remains high at 37.2%, up to 10-fold greater than in ICU populations with no sepsis [3]. Previous studies have shown that the presence of VTE is associated with a 28-day mortality rate of 28.6% among patients with sepsis, and the occurrence of PE nearly doubles the risk of in-hospital death (odds ratio [OR] 1.94) [4,5]. These findings underscore the urgent need for early and accurate VTE risk stratification in sepsis to guide timely clinical interventions and reduce morbidity and mortality in this high-risk population.

Current clinical methods for predicting VTE in patients with sepsis have notable limitations. Traditional biomarkers such as D-dimer, although widely used, lack specificity in the context of sepsis, as the condition itself activates coagulation pathways and elevates fibrin degradation products [6,7]. Furthermore, commonly used scoring systems such as the Wells and Autar scores were primarily developed and validated in trauma or postoperative populations. These tools do not account for sepsis-specific indicators, such as the Sequential Organ Failure Assessment (SOFA) score or lactate levels, thereby limiting their predictive use in patients with sepsis [8-10]. Although multivariable logistic regression (LR) models that incorporate clinical and laboratory variables have shown promise, with reported area under the curve (AUC) values reaching up to 0.87, these models are inherently linear and may fail to capture the complex and nonlinear interactions among sepsis-related risk factors [11,12].

Machine learning (ML) techniques have emerged as powerful tools for handling high-dimensional data, uncovering nonlinear associations, and automating feature selection. In recent years, ML models have demonstrated superior performance in predicting complications such as septic shock and acute kidney injury (AKI) in ICU patients, with reported AUC values reaching up to 0.90 [13-15]. However, earlier generations of ML models often functioned as “black boxes,” which limited their adoption in clinical settings due to the lack of interpretability. Explainable ML approaches, such as Shapley Additive Explanations (SHAP), have been developed to address this challenge. By quantifying the contribution of each feature, SHAP enhances model transparency and facilitates clinical understanding [16]. For instance, Liu et al [17] developed an interpretable ML model for septic shock prediction, whose explanatory outputs aligned closely with hemodynamic mechanisms described in the Sepsis-3 guidelines, thereby reinforcing its clinical relevance [18].

Therefore, this study aimed to develop an interpretable ML model that integrates clinical features and laboratory indicators to predict the risk of VTE in ICU patients with sepsis. By applying SHAP to interpret model outputs and identify key predictors, we sought to create a decision support tool that combines high predictive accuracy with strong clinical interpretability, ultimately facilitating personalized prevention strategies.

Methods

Data Sources

The training and internal validation datasets were extracted from the Medical Information Mart for Intensive Care IV version 3.0 (MIMIC-IV v3.0) database, which contains comprehensive and high-quality data from 65,366 patients admitted to the ICU at Beth Israel Deaconess Medical Center between 2008 and 2022. One of the authors (YZ) completed the Collaborative Institutional Training Initiative examination (record ID: 60227322) and was granted access to the database for research purposes.

Ethical Considerations

Ethical approval for the use of MIMIC-IV data was granted by the institutional review boards of Beth Israel Deaconess Medical Center and the Massachusetts Institute of Technology, with a waiver of informed consent due to the use of deidentified data. The data were handled in accordance with the Health Insurance Portability and Accountability Act standards to ensure patient privacy and confidentiality. In addition, ICU patients admitted to Changshu Hospital affiliated to Soochow University between January 2019 and August 2024 were included as an external validation cohort. Ethical approval for this component of the study was obtained from the ethics review committee of Changshu Hospital (number L2024055). As the study was observational in nature and used routinely collected clinical data, the requirement for written informed consent was waived. All electronic data were anonymized before analysis, and access to the dataset was restricted to the primary research team to maintain strict confidentiality. All procedures conformed to the ethical standards set forth in the Declaration of Helsinki. No compensation was provided to any participants involved in this study.

Study Population

This study included adult ICU patients (aged 18 years and older) with sepsis. For patients with multiple ICU admissions, only the first admission was analyzed. Sepsis was defined according to the Third International Consensus Definitions for Sepsis and Septic Shock (Sepsis-3), which require a suspected or confirmed infection accompanied by an increase in the SOFA score of 2 points or more [18]. VTE was defined as an acute episode of deep vein thrombosis (either upper or lower extremities), superficial vein thrombosis (either upper or lower extremities), or PE. VTE diagnoses were identified based on either the *ICD-9* (*International Classification of Diseases, Ninth Revision*; codes 45119, 4512, 45181, 45182, 45183, 45184, 45189, 4519, 4532, 4538, 45381, 45382, 45383, 45384, 45385, 45386, 45387, 45389, 4539, 4150, 41511, 41512, 41513, 41519, 45340, 45341, 45342, 4510, 452, 4530, 4531, and 4533) or the *ICD-10* (*International Statistical Classification of Diseases, Tenth Revision*; codes I808, I809, I8290, I82890, I2699, I2692, I2690, I2602, I2609, I8000, I8001, I8002, I81, I820, and I821) in the MIMIC-IV database, or through diagnostic imaging reports from Changshu Hospital, including duplex venous ultrasonography and contrast-enhanced computed tomography. In the Changshu Hospital cohort, the ICU implemented a routine lower limb venous ultrasound screening protocol for all patients with sepsis meeting high-risk criteria. Patients were excluded meeting any of the following criteria: (1) ICU stay of less than 24 hours, (2) a documented VTE diagnosis prior to sepsis onset, and (3) VTE events occurring within 24 hours following the sepsis diagnosis.

Patients from the MIMIC-IV cohort were randomly split into a training set and an internal validation set in a 7:3 ratio. The training set was used for variable selection and model development, while the internal and external validation sets were used to assess model performance. The overall study workflow is illustrated in Figure 1.

Figure 1. Flowchart of patient enrollment and cohort selection. CatBoost: categorical boosting; DT: decision tree; ICU: intensive care unit; KNN: k-nearest neighbor; LGBM: light gradient boosting machine; LR: logistic regression; MIMIC: Medical Information Mart for Intensive Care Unit; MLP: multilayer perceptron; NB: naive Bayes; RF: random forest; SHAP: SHapley Additive exPlanations; SVM: support vector machine; VTE: venous thromboembolism.

Data Extraction and Processing

Data from the MIMIC-IV database were extracted using Structured Query Language via pgAdmin 4 (version 6.21; pgAdmin Development Team). All clinical and laboratory variables were collected within the first 24 hours of ICU admission, with only the initial measurement included for variables with multiple readings. A set of variables was extracted for each patient, encompassing (1) demographics: age (years), sex, race (Asian, Black, White, Hispanic, and other), height (cm), weight (kg), BMI (kg/m^2), and insurance (Medicare or other); (2) vital signs: heart rate (HR, times per minute), respiratory rate (RR, times per minute), systolic blood pressure (mm Hg), diastolic blood pressure (mm Hg), temperature (°C), and oxygen saturation (SpO_2, %); (3) severity scores: Glasgow Coma Scale, SOFA score, and simplified acute physiology score II (SAPS II); (4) laboratory data: white blood cell count (K/μL), hemoglobin (g/dL), platelet (PLT, K/μL), C-reactive protein (mg/dL), alanine aminotransferase (U/L), aspartate aminotransferase (U/L), albumin (g/dL), creatinine (mg/dL), sodium (mEq/L), potassium (mEq/L), chloride (mEq/L), calcium (mg/dL), blood urea nitrogen (mg/dL), hematocrit (%), glucose (mg/dL), international normalized ratio, prothrombin time (PT, seconds), partial thromboplastin time (PTT, seconds), pH, partial pressure of oxygen (PaO_2, mm Hg), partial pressure of carbon dioxide ($PaCO_2$, mm Hg), base excess (mEq/L), lactic acid (mEq/L), and bicarbonate (HCO_3^-, mEq/L); (5) ventilation parameters: positive end-expiratory pressure (PEEP, cmH_2O), fraction of inspired oxygen (FiO_2, %), and PEEP/FiO_2 ratio; (6) comorbidities: hypertension, diabetes, myocardial infarction (MI), chronic obstructive pulmonary disease (COPD), asthma, pancreatitis, acute respiratory failure (ARF), AKI, acute respiratory distress syndrome (ARDS), and malignant cancer; and (7) therapeutic interventions: arterial catheterization, central venous catheterization, cardiopulmonary bypass, continuous renal replacement therapy (CRRT), ventilation, heparin, aspirin, and vasopressors use. The same set of variables was extracted from the external validation cohort at Changshu Hospital affiliated with Soochow University, ensuring consistency between the datasets.

For missing data, variables with less than 5% missingness were imputed using mean substitution. For those with 5%-30% missing values, multiple imputation methods were used. Variables with more than 30% missing data were excluded from analysis to minimize bias and preserve model robustness. Outliers were identified and treated as missing values and subsequently handled using the same imputation strategies.

Statistical Analysis

All statistical analyses were performed using Stata software (version 16.0; StataCorp LLC), R software (version 4.1.2; R Foundation for Statistical Computing), DecisionLinnc (version 1.0; DecisionLinnc Corp), and Python (version 3.9.12; Python Software Foundation). The Kolmogorov-Smirnov test was used to assess the normality of continuous variables. Variables with a normal distribution were expressed as means and SDs, and group comparisons were conducted using the 2-tailed independent samples *t* test. Non–normally distributed variables were presented as median and IQR and analyzed using the Mann-Whitney *U* test. Categorical variables were summarized as counts (percentages) and compared using the chi-square test. Two-sided *P* values of <.05 were considered statistically significant.

Variable Selection and Model Development

Variables that showed statistically significant differences in the univariate analysis were considered candidate predictors. These variables were further refined using the least absolute shrinkage and selection operator regression to minimize overfitting and reduce multicollinearity. Predictors with nonzero coefficients were subsequently entered into a multivariate LR model. Independent predictors identified through this process were incorporated into the ML models.

Following variable selection, the Synthetic Minority Oversampling Technique (SMOTE) preprocessing algorithm was applied to address class imbalance between VTE and non-VTE cases in the training cohort. In the training cohort, VTE cases (576/17,637, 3.27%) were highly unbalanced compared with non-VTE cases (17,061/17,637, 96.73%). After SMOTE application, the VTE class was balanced to match the non-VTE class, resulting in a 50:50 distribution with a total of 34,122 samples used for model training. This oversampling method helped ensure that the models were trained on a balanced dataset, thereby improving their ability to detect minority class events. A total of 9 ML algorithms were trained on the development cohort, including categorical boosting (CatBoost), decision tree, k-nearest neighbor, light gradient boosting machine (LGBM), LR, multilayer perceptron, naive Bayes, random forest (RF), and support vector machine. For all ML models, we used a 5-fold cross-validation strategy, combined with Grid Search, for hyperparameter optimization and model selection. Notably, SMOTE was applied exclusively to the training folds of the cross-validation process to prevent data leakage into the validation folds or the internal validation set.

Model Evaluation and Interpretation

Model performance was assessed using the internal and external validation datasets. Discrimination was evaluated by plotting receiver operating characteristic curves and calculating the AUC. Calibration curves were used to compare predicted probabilities with observed outcomes. Clinical use was assessed using decision curve analysis, which estimated the net benefit across a range of probability thresholds. In addition, several evaluation metrics were computed, including accuracy, sensitivity, specificity, and the Youden index, to offer a comprehensive assessment of model performance.

The best performing model was selected based on comprehensive evaluation of these metrics. To assess the model's stability and performance in different risk populations, a stratified analysis was conducted on the external validation cohort based on the SOFA score. Patients were divided into 2 subgroups: mild to moderate sepsis (SOFA score ≤6) and severe sepsis (SOFA score >6). To enhance model interpretability, SHAP analysis was conducted. SHAP values were computed to quantify the contribution of individual features to the model's predictions and to explore feature interactions. Visualization

XSL•FO
RenderX

tools from the SHAP package in Python, including feature importance plots, bee swarm plots, force plots, and partial dependence plots (PDPs), were used to provide an intuitive understanding of the model's decision-making process.

Results

Baseline Characteristics

A total of 25,197 patients from the MIMIC-IV cohort and 328 patients from the external validation cohort were included in the study. Among them, 844 out of 25,197 (3.4%) patients in the MIMIC-IV cohort and 30 out of 328 (9.2%) patients in the external cohort developed VTE. The baseline characteristics of all patients are summarized in Table 1. In the MIMIC-IV cohort, patients who developed VTE were younger and exhibited significantly higher HRs and RRs than those with no VTE (all $P<.001$). Laboratory parameters revealed higher PLT counts, serum chloride levels, and PTT in the VTE group (all $P<.05$). In addition, patients with VTE had higher illness severity scores, as indicated by elevated SOFA and SAPS II scores (both $P<.05$). Comorbidities such as ARF, AKI, and ARDS were significantly more common in the VTE group (all $P<.001$). Furthermore, these patients were more likely to have undergone invasive procedures, including arterial and central venous catheterization (both $P<.001$). In the external validation cohort, similar patterns were observed. Patients with VTE demonstrated higher rates of ARDS and more frequent use of mechanical ventilation than patients with no VTE (both $P<.001$). These findings highlight significant differences in demographics, clinical severity, comorbidities, and therapeutic interventions between patients with and with no VTE across both cohorts, emphasizing the relevance of these factors in VTE risk stratification.

[ff]CRRT: continuous renal replacement therapy.

Selection of Predictors

Patients in the training set were divided into VTE and non-VTE groups. Univariate analysis identified several variables significantly associated with VTE, including admission age, insurance, HR, RR, SAPS II, alanine aminotransferase, potassium, chloride, glucose, PTT, PaO_2, $PaCO_2$, PEEP, and comorbidities such as diabetes, MI, COPD, pancreatitis, ARF, AKI, and ARDS (all *P*<.05). In addition, therapeutic interventions including arterial catheterization, central venous catheterization, cardiopulmonary bypass, CRRT, heparin use, and aspirin use were significantly associated with VTE (all *P*<.05; Table 2). Least absolute shrinkage and selection operator regression identified 18 variables with nonzero coefficients at the optimal lambda value of 0.0029. These included age, insurance, HR, potassium, chloride, PTT, diabetes, MI, COPD, pancreatitis, ARF, AKI, ARDS, arterial catheterization, central venous catheterization, CRRT, heparin use, and aspirin use (Figures 2A and 2B). These variables were subsequently entered into a multivariate LR model, which revealed that potassium (OR 0.8711, 95% CI 0.7541-0.9756; *P*=.02), chloride (OR 1.0206, 95% CI 1.0081-1.0326; *P*=.001), PTT (OR 1.0086, 95% CI 1.0054-1.0115; *P*<.001), MI (OR 0.2851, 95% CI 0.1101-0.5999; *P*=.003), AKI (OR 1.5274, 95% CI 1.2166-1.9369; *P*<.001), arterial catheterization (OR 1.8985, 95% CI 1.4102-2.5648; *P*<.001), central venous catheterization (OR 2.0805, 95% CI 1.5213-2.8382; *P*<.001), and heparin use (OR 1.5509, 95% CI 1.1203-2.0851; *P*=.01) were independently associated with VTE risk (Table 3). We noted instances of complete separation in the training set for comorbidities such as diabetes and COPD, where the VTE subgroup contained zero cases, leading to extreme ORs in the multivariable LR.

Development and Validation of Models

All selected variables were incorporated into the development of 9 ML models to predict the risk of VTE in ICU patients with sepsis. The 9 ML models exhibited varying degrees of predictive performance in the training set (Figure 3A). Internal validation based on receiver operating characteristic curve analysis demonstrated that the LGBM model achieved the highest predictive performance (AUC=0.956), followed by CatBoost (AUC=0.924), RF (AUC=0.794), decision tree (AUC=0.704), k-nearest neighbors (AUC=0.673), multilayer perceptron (AUC=0.660), support vector machine (AUC=0.621), LR (AUC=0.621), and naïve Bayes (AUC=0.588; Figure 3B). Detailed performance metrics, including sensitivity, specificity, accuracy, precision, F_1-score, and AUC for each model, are shown in Table 4. Notably, the LGBM model exhibited the highest specificity (0.942), accuracy (0.910), precision (0.956), and F_1-score (0.921), consistently outperforming the other algorithms across these key evaluation indicators.

Calibration analysis revealed that the LGBM model demonstrated strong alignment between predicted probabilities and observed outcomes, reflecting robust reliability (Figure 4A). In the decision curve analysis, the LGBM model consistently provided the highest net benefit across a broad range of clinically relevant threshold probabilities, further supporting its clinical applicability in decision-making scenarios (Figure 4B).

Figure 4. Calibration curve of the LGBM model in the internal validation set (A). Decision curve analysis of the LGBM model in the internal validation set (B). CatBoost: categorical boosting; DT: decision tree; KNN: k-nearest neighbor; LGBM: light gradient boosting machine; LR: logistic regression; MLP: multilayer perceptron; NB: naive Bayes; RF: random forest; SVM: support vector machine.

External validation using an independent test cohort further confirmed the robustness and generalizability of the LGBM model, which achieved an AUC of 0.786, outperforming all other ML models in this cohort (Figure 3C). The consistent performance observed across both internal and external validation cohorts underscores the strong generalizability and clinical potential of the LGBM model for predicting VTE in ICU patients with sepsis.

Following stratification based on SOFA score, the LGBM model demonstrated enhanced discriminative ability in the high-risk group. The AUC for the severe sepsis group was 0.816, which was higher than the AUC of 0.769 observed in the mild to moderate sepsis group. The detailed performance metrics are shown in Table 5.

Explanation of the Model

Figure 5 displays the top 15 predictive features for VTE incidence as identified by the LGBM model using SHAP analysis. The feature importance plot, ranked by the mean absolute SHAP values, highlights the variables with the greatest overall impact on model predictions (Figure 5A). The 5 most influential features were central venous catheterization, chloride, bicarbonate, arterial catheterization, and PTT. The corresponding SHAP beeswarm plot (Figure 5B) illustrates each feature's influence on individual predictions, where SHAP values to the right of zero reflect increased predicted risk. It revealed that the presence of central venous or arterial catheters, elevated chloride and bicarbonate levels, and prolonged PTT consistently contributed to a higher VTE risk.

RenderX

Figure 5. SHAP summary plot for clinical variables contributing to the light gradient boosting machine (LGBM) model. (A) Feature importance ranking plot based on the LGBM model. (B) Scatter plot of variables for SHAP analysis based on the LGBM model. AKI: acute kidney injury; HCO3-: bicarbonate; HR: heart rate; pH: potential of hydrogen; PLT: platelet; PTT: partial thromboplastin time; SHAP: SHapley Additive exPlanations.

To further examine the marginal effects of key predictors on model output, PDPs were generated for the top-ranked features (Figures 6A-6F). These plots depict how the predicted risk of VTE changes on average with varying values of a single feature, while holding others constant. For dichotomous variables such as central venous (Figure 6A) and arterial (Figure 6D) catheterization, the plots showed a marked increase in the average predicted risk when catheters were present compared with their absence. Continuous variables including serum chloride (Figure 6B), bicarbonate (Figure 6C), and HR (Figure 6F) exhibited monotonic relationships, with risk increasing steadily as the values rose. In contrast, PTT (Figure 6E) exhibited a distinct threshold effect. The predicted risk remained low and stable within the normal range and then increased sharply for values beyond approximately 45 seconds before plateauing at highly prolonged levels, confirming its nonlinear risk association identified by SHAP.

Interpretation of Individual Prediction

To enhance case-level interpretability, SHAP force plots were used to visualize the contribution of individual features to specific predictions (Figure 7). In these plots, each feature was represented as a colored bar that moves the predicted value away from a baseline, which corresponds to the average prediction across the dataset. Features that increase the predicted risk are shown in red, while those that reduce the risk are shown in blue. The length of each bar reflects the extent of the feature's influence. A longer bar indicates a stronger impact on the final predicted probability.

Figure 7. SHapley Additive exPlanations (SHAP) force plots for explaining of individual's prediction results according to the light gradient boosting machine model. (A) SHAP force plot of a high-risk example. (B) SHAP force plot of a low-risk example. AKI: acute kidney injury; HCO3-: bicarbonate; HR: heart rate; PT: prothrombin time; PTT: partial thromboplastin time; SAPS: simplified acute physiology score II; SBP: systolic blood pressure.

For example, in Figure 7A, the predicted VTE probability for a specific patient was 0.11, which was higher than the baseline value. This elevated risk was primarily attributed to the presence of a central venous catheter, a markedly prolonged PTT of 81.9 seconds, and a high HR of 141 min^{-1}. In contrast, Figure 7B showed a patient with a predicted probability of 0.02, which was lower than the baseline. In this case, protective features including the absence of a central venous catheter, absence of AKI, and a low SAPS II score collectively outweighed the influence of risk factors such as elevated BMI and bicarbonate level. These examples demonstrated that the model was capable of producing clear and clinically relevant explanations for individual predictions.

Discussion

Principal Findings

In this multicenter retrospective study, we developed and validated several ML models to predict the risk of VTE in critically ill patients with sepsis. Among the models tested, the LGBM algorithm demonstrated the highest predictive accuracy with an AUC of 0.956 in the internal validation set and maintained strong generalizability with an AUC of 0.786 in an external cohort. The observed VTE incidence in our external validation cohort (30/328, 9.15%) was substantially higher than the 3.35% (844/25,197) incidence recorded in the MIMIC-IV development cohort. While this difference contributed to the drop in the AUC during external validation, this discrepancy is likely a consequence of multiple factors, including divergent diagnostic practices, disparities in clinical risk profiles, and racial composition differences between the 2 cohorts.

First, variations in VTE surveillance and diagnostic criteria likely served as a primary driver. The MIMIC-IV cohort relied on retrospective identification via *ICD* (*International Classification of Diseases*) codes, a method known to carry a risk of misclassification bias and potential underascertainment, particularly of asymptomatic events. Conversely, the external validation cohort used explicit diagnostic imaging reports and implemented a routine lower limb venous ultrasound screening program for high-risk patients with sepsis. This systematic, active surveillance methodology inherently tends to yield a higher VTE capture rate compared with passive, coding-based case ascertainment. Second, the external validation group exhibited a substantially higher baseline severity and utilization of aggressive life support interventions. Patients with VTE in this cohort showed markedly higher rates of established risk factors such as mechanical ventilation (83.33% vs 49.29% in MIMIC-IV VTE group), ARDS (53.33% vs 30.81%), and CRRT (33.33% vs 11.37%) [19-21]. This heightened clinical severity and iatrogenic risk profile provide a sound clinical explanation for the elevated VTE incidence. Third, the inherent demographic differences between the cohorts represent a major challenge to model generalizability. The MIMIC-IV cohort is composed of a racially diverse population, while the external validation cohort is predominantly Asian, representing a geographically and ethnically distinct cohort. Given that VTE risk is known to vary significantly across different racial groups, this change in demographic distribution may be a contributing factor to the observed performance decrease [22].

Despite these significant differences in cohort characteristics and VTE incidence, the LGBM model maintained the highest predictive performance in both internal and external validation, underscoring its inherent robustness and generalization capacity. These performance advantages align with recent findings that gradient boosting methods often outperform logistic models in predictive accuracy when applied to large clinical datasets [23,24]. Crucially, we applied SHAP to interpret the model's predictions. This analysis identified a set of key risk factors driving VTE predictions, including the presence of central and arterial catheters, serum chloride and bicarbonate levels, and the PTT. By quantifying each feature's contribution to individual risk scores, SHAP facilitated insight into why certain patients

XSL•FO
RenderX

were classified as high-risk. This combination of robust performance and interpretability suggests that our model may assist clinicians in identifying ICU patients with sepsis at an increased risk of VTE, thereby supporting timely prophylaxis or diagnostic evaluation. Conventional instruments such as the Caprini, Padua, or Wells scores were primarily developed for general medical or surgical populations and relied on a linear, additive combination of risk factors [10,25]. These tools lack the specificity required to capture the distinct pathophysiology of sepsis which involves a complex interplay among inflammation, endothelial dysfunction, and coagulopathy collectively referred to as sepsis-induced coagulopathy [26,27]. The pathophysiology of sepsis-induced VTE is inherently nonlinear. Complex interactions among organ failure, systemic inflammation, and iatrogenic factors such as the use of catheters and vasopressors jointly modulate VTE risk in a manner that traditional linear models cannot fully capture [28,29]. In contrast, our LGBM model is consistent with previous ML applications in critical care and automatically captures complex relationships and interactions among predictors while integrating heterogeneous ICU data to generate a more accurate and nuanced risk estimate [30]. Our study found that the LGBM model significantly outperformed the LR model, achieving an AUC value of 0.956 compared with 0.621, which underscores the advantage of advanced ML algorithms in modeling the complex relationships among multiple risk factors. We recognize that prior studies have used advanced ML models for VTE prediction in critically ill patients. For instance, Jin et al [31] developed an RF model for VTE prediction in ICU patients that achieved an AUC of 0.788 in their validation dataset. Our model demonstrates equivalent predictive power in a challenging, sepsis-specific cohort. This robust performance likely stems from 2 key strengths of our approach: first, the inherent efficiency and predictive power of the LGBM algorithm compared with other boosting techniques; second, and more critically, our model's unique inclusion of metabolic and acid-base markers, such as serum chloride and bicarbonate, may offer a more nuanced reflection of the prothrombotic state induced by sepsis-associated organ dysfunction, thereby enhancing predictive accuracy.

The comparative analysis between the LR findings and the SHAP feature ranking reveals the core limitation of traditional statistical approaches in septic VTE prediction. The discrepancy observed for bicarbonate is illustrative. While bicarbonate was not retained in the final LR model, suggesting that its linear signal lacked statistical significance for VTE risk, the LGBM model ranked it as the third most influential predictor overall. This strongly suggests that bicarbonate's predictive power does not stem from a simple linear effect but from its complex nonlinear relationship or crucial interaction with other factors, reflecting the severity of systemic acid-base disturbances. Similarly, MI appeared as a protective factor in the final multivariable regression (OR 0.2851), but its marginal contribution was deemed less vital by SHAP than core metabolic and iatrogenic factors. This protective association in the linear model was likely influenced by confounding or collinearity among chronic conditions, potentially because patients with a history of MI often receive stricter chronic anticoagulation management, which may suppress their VTE risk and mask the true underlying risk in the linear model. The issue of complete separation for variables such as diabetes and COPD further highlights the inherent defect of LR when processing sparse data, as it led to unreliable, extreme coefficients. These findings collectively validate the choice of the nonlinear LGBM model and underscore the necessity of relying on its transparent SHAP feature analysis to evaluate the true, complex VTE risk drivers that are often obscured by the restrictive linearity of traditional statistical methods. Furthermore, the finding that the LGBM model achieved a higher AUC (0.816 vs 0.769) in the severe sepsis subgroup is significant. This enhanced discriminative power in the highest risk population confirms the model's clinical use, suggesting that it is particularly effective for targeted VTE prophylaxis and early intervention in patients with multiorgan dysfunction.

The interpretability enabled by SHAP analysis is essential for clinical translation and offers valuable pathophysiological insights. The top predictors identified by our SHAP analysis are closely related to the pathophysiology of sepsis-associated VTE and reinforce the model's clinical plausibility. The paramount importance of central venous catheterization aligns with Virchow's triad as the catheter can directly cause endothelial injury and lead to local blood flow stasis, both of which are potent triggers for thrombosis [32]. This finding is consistent with numerous studies highlighting indwelling catheters as a major iatrogenic risk factor for VTE in ICU patients [33,34]. The contribution of arterial catheterization, although less pronounced, further underscores the role of endothelial disruption from invasive devices.

Beyond these established risk factors, the model identified the predictive value of metabolic parameters such as serum chloride and bicarbonate. Elevated serum chloride is frequently associated with metabolic acidosis, which commonly develops in severe sepsis and shock [35]. Acidosis has been shown to enhance PLT aggregation and impair fibrinolysis, thereby promoting a prothrombotic state [36]. The association with bicarbonate likely reflects the severity of systemic acid-base disturbances commonly observed in septic shock. These findings suggest that fluid resuscitation strategies and acid-base management may represent modifiable components of VTE risk. The role of PTT is particularly noteworthy. Although a prolonged PTT is traditionally associated with bleeding risk, in sepsis it may paradoxically indicate consumptive coagulopathy in which widespread microthrombosis rapidly consumes clotting factors and leads to their depletion, a hallmark of disseminated intravascular coagulation [37]. The PDP revealed a nonlinear risk profile, where VTE risk increased markedly once PTT exceeded approximately 45 seconds. This nonlinear relationship would likely be overlooked in traditional linear analyses and highlights the model's capacity to identify clinically meaningful physiological thresholds. The contribution of HR appears more direct as its PDP showed a monotonic increase in predicted VTE risk with rising HR. Tachycardia is a cardinal manifestation of the systemic inflammatory response and catecholamine surge in sepsis, reflecting physiological stress and a hyperdynamic state that may promote endothelial dysfunction and a prothrombotic environment [38,39].

Strengths and Limitations

A major strength of our study lies in the integration of rigorous model development with interpretability, which enhances its potential clinical applicability. The model was developed using the large, high-quality public MIMIC-IV database and externally validated it in a geographically and ethnically distinct cohort from our own center. This 2-tiered validation strategy is essential for evaluating model generalizability, which remains a common limitation in single-center ML studies [40]. The decline in AUC from 0.956 to 0.786 during external validation, while still maintaining the best performance among all models, underscores the model's robust generalizability. This performance gap likely reflects intrinsic differences between the 2 cohorts, such as patient genetics, local clinical practices, VTE screening protocols, and data-recording standards. These findings underscore the critical need for local calibration or model retraining before deploying any predictive model in a new clinical setting. In addition, our use of SHAP enhances model transparency and interpretability rather than producing a purely opaque prediction tool. By generating individualized explanations through force plots, our model provides clinicians with transparent and actionable insights that support clinical decision-making and facilitate integration into routine workflows. Such interpretability is essential for translating ML tools from research settings to real-world clinical practice.

Despite these strengths, our study has several limitations. First, its retrospective design allows for the identification of associations but not the establishment of causality. The reliance on *ICD* codes for VTE diagnosis in the MIMIC-IV database may lead to some misclassification, as coding practices can vary and may not capture all clinically recognized events [41]. Second, we included data from only the first 24 hours of ICU admission. While this time frame is critical for early risk stratification, VTE is a dynamic process, and models incorporating time series data may provide greater predictive accuracy [42]. Third, despite comprehensive data extraction, some potential confounders, such as the specific type and dosage of thromboprophylaxis, patient mobility status, or the specific subtypes of malignancy, were not available. This includes the lack of detailed or consistently documented data on heparin dosage, such as prophylactic versus therapeutic, or duration, which forced us to treat heparin use as a binary variable. Finally, although the use of imputation for missing data is standard practice, it may still introduce a small degree of bias.

Future research should aim to prospectively validate our LGBM model in multicenter interventional trials to confirm its clinical use and impact on patient outcomes. Further refinement of the model may involve incorporating dynamic variables throughout the ICU stay and integrating emerging biomarkers related to coagulopathy and endothelial dysfunction. In addition, exploring federated learning approaches could enable the development of more robust and generalizable models across institutions while preserving patient data privacy [43].

Conclusions

This study presents a high-performing and interpretable LGBM model for predicting VTE in ICU patients with sepsis by effectively integrating a broad spectrum of clinical and laboratory data. By leveraging SHAP to enhance transparency, the model extends beyond a simple predictive tool to function as a decision support system capable of elucidating complex risk profiles and enabling clinicians to implement more personalized and effective VTE prevention strategies. This work lays the foundation for the adoption of sophisticated yet interpretable artificial intelligence–driven tools aimed at reducing the burden of VTE in this high-risk patient population.

Abstract

Background: Artificial intelligence tools, particularly large language models (LLMs), have shown considerable potential across various domains. However, their performance in the diagnosis and treatment of breast cancer remains unknown.

Objective: This study aimed to evaluate the performance of LLMs in supporting radiologists within multidisciplinary breast cancer teams, with a focus on their roles in facilitating informed clinical decisions and enhancing patient care.

Methods: A set of 50 questions covering radiological and breast cancer guidelines was developed to assess breast cancer. These questions were posed to 9 popular LLMs and clinical physicians, with the expectation of receiving direct "Yes" or "No" answers along with supporting analysis. The performances of the 9 models, including ChatGPT-4.0, ChatGPT-4o, ChatGPT-4o mini, Claude 3 Opus, Claude 3.5 Sonnet, Gemini 1.5 Pro, Tongyi Qianwen 2.5, ChatGLM, and Ernie Bot 3.5, were evaluated against that of radiologists with varying experience levels (resident physicians, fellow physicians, and attending physicians). Responses were assessed for accuracy, confidence, and consistency based on alignment with the 2024 National Comprehensive Cancer Network Breast Cancer Guidelines and the 2013 American College of Radiology Breast Imaging-Reporting and Data System recommendations.

Results: Claude 3 Opus and ChatGPT-4 achieved the highest confidence scores of 2.78 and 2.74, respectively, while ChatGPT-4o led in accuracy with a score of 2.92. In terms of response consistency, Claude 3 Opus and Claude 3.5 Sonnet led the pack with scores of 3.0, closely followed by ChatGPT-4o, Gemini 1.5 Pro, and ChatGPT-4o mini, all recording impressive scores exceeding 2.9. ChatGPT-4o mini excelled in clinical diagnostics with a top score of 3.0 among all LLMs, and this score was also higher than all physician groups; however, no statistically significant differences were observed between it and any physician group (all $P>.05$). ChatGPT-4 also had a higher score than the physician groups but showed comparable statistical performance to them ($P>.05$). Across radiological diagnostics, clinical diagnosis, and overall performance, ChatGPT-4o mini and the Claude models achieved higher mean scores than all physician groups. However, these differences were statistically significant only when compared to fellow physicians ($P<.05$). However, ChatGLM and Ernie Bot 3.5 underperformed across diagnostic areas, with lower scores than all physician groups but no statistically significant differences (all $P>.05$). Among physician groups, attending

XSL•FO
RenderX

physicians and resident physicians exhibited comparable high scores in radiological diagnostic performance, whereas fellow physicians scored somewhat lower, though the difference was not statistically significant (P>.05).

Conclusions: LLMs such as ChatGPT-4o and Claude 3 Opus showed potential in supporting multidisciplinary teams for breast cancer diagnostics and therapy. However, they cannot fully replicate the intricate decision-making processes honed through clinical experience, particularly in complex cases. This highlights the need for ongoing artificial intelligence refinement to ensure robust clinical applicability.

KEYWORDS

breast cancer; large language models; LLMs; radiology assistance; clinical decision-making; ACR BI-RADS; NCCN guidelines; radiologist; National Comprehensive Cancer Network; American College of Radiology Breast Imaging-Reporting and Data System

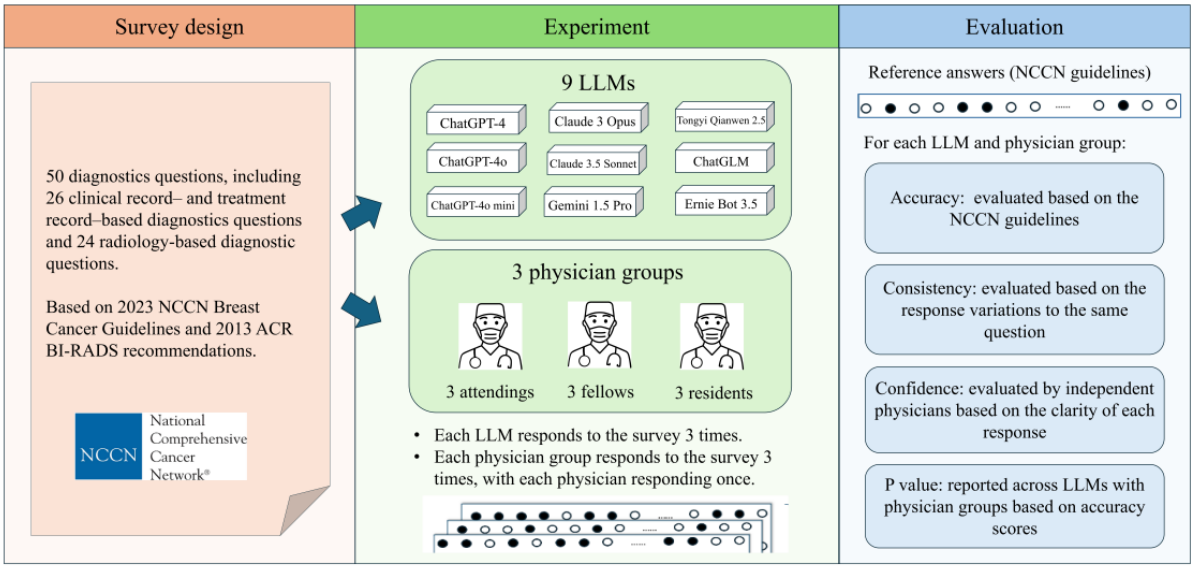
Introduction

Breast cancer is one of the most common malignancies in women worldwide, with over 2 million diagnoses each year, and it remains the leading cause of cancer-related deaths in women [1,2]. According to a World Health Organization departmental news report in 2021, breast cancer mortality and incidence rates are higher in low- and middle-income countries than in high-income nations, largely due to disparities in early detection and treatment. However, the biological characteristics of breast cancer vary significantly, including imaging features, pathological traits, and lymph node assessment, making early screening and personalized treatment challenging yet crucial.

A mature early screening system relies on well-established professional teams and standardized, specialized guidelines. Although there have been recent advancements, developing countries still face significant challenges in breast cancer care in terms of multidisciplinary coordination among specialist teams (surgeons, oncologists, pathologists, and radiologists), well-balanced medical resources, and adequately trained physicians [3,4]. Furthermore, many physicians rely on empiricism and practice medicine rather than evidence-based guidelines [5,6]. Therefore, there is an urgent need for effective artificial intelligence (AI) tools to support health care professionals in resource-limited settings, improve diagnostic accuracy, and enhance patient outcomes [7,8].

In recent years, several prominent large language models (LLMs) have emerged, including ChatGPT (OpenAI), Gemini Advanced (Google LLC), Claude (Anthropic), Tongyi Qianwen (Alibaba Corporation), ChatGLM (Zhipu AI), and Ernie Bot (Baidu). These models, trained on extensive datasets, offer significant potential in health care by generating complex text through deep learning. ChatGPT, for instance, gained rapid popularity, attracting over 1 million users within days of its release. (knowledge base updated as of October 2023). Studies have shown its potential in medicine, performing well on the United States Medical Licensing Examination and the Board of Radiology-style examination [9,10]. ChatGPT can help radiologists simplify cumbersome diagnostic imaging descriptions [11,12]. Notably, the recommendations provided by ChatGPT for the clinical management of early-diagnosed breast cancer closely align with decisions made by multidisciplinary teams (MDTs) [13]. ChatGPT has indicated a level of congruence with the National Comprehensive Cancer Network (NCCN) guidelines in identifying a wide range of therapeutic agents for the treatment of advanced metastases or advanced primary tumors [14]. However, recent studies highlighted significant limitations in ChatGPT-4.0, revealing a “curse reversal,” where a model trained on “A is B” may struggle to infer “B is A” [15].

The rapid advancement of AI has ushered in a new era of innovation, with the emergence and continuous refinement of various LLMs profoundly transforming the health care sector. This study evaluates the performance of various LLMs in addressing breast cancer guideline-related questions, comparing them with radiologists of varying expertise levels to assess their potential in enhancing radiologists’ diagnostic capabilities.



Methods

Study Design

The study aimed to evaluate the performance of 9 LLMs in breast cancer imaging diagnosis and to compare their performance with that of breast imaging specialists. We developed a set of 50 questions focused on breast cancer diagnosis and treatment based on the 2013 version of the American College of Radiology Breast Imaging-Reporting and Data System (ACR BI-RADS) classification and the 2024 NCCN Breast Cancer Guidelines. The first 24 questions focused on radiological diagnostics, while the remaining 26 questions pertained to clinical diagnosis and treatment. Questions were then presented to breast radiologists and the 9 LLMs for diagnostic responses. The accuracy, confidence, and consistency of each model in responding to the diagnostic queries were assessed. Furthermore, we conducted a comparative analysis of each model’s performance against radiologists possessing varying levels of clinical experience. The study design is provided in Figure 1.

RenderX

Figure 1. Graph in the full-text abstract: the study design, including question categorization, experiment, and evaluation workflow. ACR BI-RADS: American College of Radiology Breast Imaging-Reporting and Data System; LLM: Large Language Model; NCCN: National Comprehensive Cancer Network.

Participants and Models

The 9 LLMs included ChatGPT-4.0, ChatGPT-4o, ChatGPT-4o mini, Claude 3 Opus, Claude 3.5 Sonnet, Gemini 1.5 Pro, Tongyi Qianwen 2.5, ChatGLM, and Ernie Bot 3.5. In addition, the study recruited a total of nine board-certified radiologists, stratified into three distinct experience levels: (1) resident physicians (n=3; 1-5 years of postlicensure experience), undergoing subspecialty training to develop foundational clinical expertise; (2) fellow physicians (n=3; 5-10 years of experience), having completed residency and pursuing advanced fellowship training (1-3 years) to specialize in breast imaging diagnostics; and (3) attending physicians (n=3; >10 years of experience), senior specialists with independent diagnostic authority, responsible for clinical decision-making and trainee supervision. This hierarchical cohort enabled comparative benchmarking of LLM performance against progressive stages of radiologist expertise. Each physician received the same set of 50 questions.

Questions Design

The set of 50 questions was developed based on guidelines extracted from the 2024 NCCN Breast Cancer Guidelines and the 2013 ACR BI-RADS diagnostic criteria, which are widely regarded as the gold standards in clinical breast cancer diagnosis. These criteria are commonly adhered to by physicians in clinical breast cancer diagnosis. In this study, we used these same standards to evaluate the responses provided by the LLMs and physicians to ensure validity and fair comparison. The questions covered a range of common clinical diagnostic decision-making scenarios, providing radiological evidence, such as mammography, ultrasound, and magnetic resonance imaging, as well as clinical information indicators such as medical history, physical examination findings, and laboratory test results, across preoperative, intraoperative, and postoperative stages.

Procedure

Nine physicians were divided into 3 groups based on their experience levels, with each physician answering all 50 questions once. They were prohibited from consulting guidelines or reference materials and were required to complete the questions within 30 minutes. Each physician independently completed the assessment to minimize recall bias. The study aimed to simulate real-world conditions by controlling time and eliminating external aids.

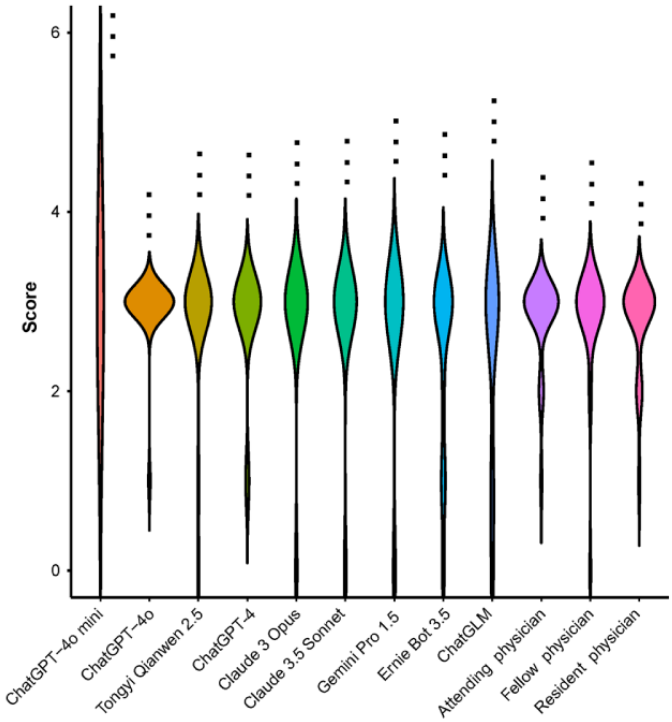
All LLMs were queried via the Google application programming interface on a single date (August 21, 2024) without any additional context (such as task background or medical knowledge priming) and generated responses accordingly. Each LLM independently answered every question 3 times. Standard responses were defined as “yes” or “no.” A response was classified as “yes” if it demonstrated a strong affirmative inclination, supported by compelling theoretical evidence and logical reasoning. Conversely, a response was classified as “no” if it showed a clear negative inclination, backed by equally robust theoretical evidence and sound logic. If an LLM produced an ambiguous response, lacked sufficient evidence, or contained flawed reasoning, it was prompted to reanswer. If the reanswered response remained unsatisfactory, 2 senior physicians with over 10 years of experience were recruited to classify the response based on their professional judgment, thereby evaluating the AI model’s accuracy. In cases of disagreement, the evaluators reevaluated the response based on the 2024 NCCN Guidelines and the 2013 ACR BI-RADS criteria to reach a consensus through discussion.

All LLM-generated responses were anonymized, randomized, and then assessed by evaluators who were blinded to the source (LLM identity) of each response. The accuracy of each response was assessed against the diagnostic NCCN guidelines.

XSL•FO
RenderX

Responses consistent with the guidelines were assigned a score of 1, while inconsistent responses received a score of 0. The accuracy score for each question was calculated by summing the scores of the 3 responses. The overall accuracy performance of both the LLMs and physician groups was determined by averaging the accuracy scores across the 50 questions, resulting in a score ranging from 0 to 3. Subsequently, the accuracy performance of the LLMs was compared to that of the physician groups through rigorous statistical analysis.

Confidence and Consistency



Confidence refers to the clarity of responses, categorized as either "confident" or "nonconfident." A confident answer provides an explicit "yes" or "no" to questions, while a nonconfident answer lacks a direct "yes or no" statement, despite potentially containing detailed explanations, requiring additional prompting to elicit a definitive response. Confident answers received are scored 1, while nonconfident answers are scored 0. The confidence score for each question is calculated by summing the scores from 3 independent response attempts. Each LLM's overall confidence performance is assessed by averaging these scores across 50 questions, resulting in a score ranging from 0 to 3. The confidence ratio represents each LLM's average confidence score divided by the maximum possible score (ie, 3).

Consistency evaluates whether an LLM provides uniform responses across 3 independent attempts to answer the same question. If all 3 answers are identical, the responses are considered consistent, regardless of their alignment with guideline criteria. For consistency assessment, an LLM receives 3 points if all 3 answers to a question are identical, and 2 points if one answer differs from the others. Each LLM's consistency performance is evaluated by averaging these scores across 50 questions, with possible scores ranging from 2 to 3. The consistency ratio is defined as each LLM's average consistency score divided by the maximum possible score (ie, 3).

Statistical Analysis

R software (version 4.4.2; R Foundation for Statistical Computing) was used for data management and statistical analysis. Continuous variables were described using means, and specific group instances were expressed as absolute values. The Wilcoxon rank-sum test was used for score comparisons between 2 different groups. We opted not to perform a Kruskal-Wallis test (for overall multigroup comparison) before pairwise analyses because our research focus was on hypothesis-driven, targeted comparisons between 2 specific groups: each LLM vs each physician subgroup (attendings, fellows, and residents). This design directly aligned with our aim—to evaluate whether single LLMs differ in performance from radiologists at distinct experience levels—rather than testing for overall differences across all groups. Differences between groups were considered significant at $P<.05$. P value correction for multiple comparisons was applied using the Benjamini-Hochberg method. Adjusted P values are provided in Multimedia Appendix 1, Tables 2-4, and corresponding Figures 2-4 to present direct pairwise comparison results; raw P values for multiple comparisons are provided exclusively in Multimedia Appendix 2.

Figure 2. Accuracy scores of large language models (LLMs) compared to physicians in clinical diagnosis and treatment questions of breast cancer. 3-star or dot symbols on each violin from top to bottom represent P values compared to each LLM to attending, fellow, and resident physicians, using the Wilcoxon rank-sum test. Symbols are as follows: "***" represents $P<.001$, "**" represents $.001\leq P<.01$, "*" represents $.01\leq P<.05$, and "black dots" represents $P\geq.05$.

Results

Representative Examples

Textbox 1 provides a representative selection of question-answer examples from the 9 LLMs, while a more comprehensive collection of cases is provided in the Multimedia Appendix 3.

Textbox 1. Representative examples of questions and answers from the 9 large language models (LLMs).

Sample question:

- Can an oval, hypoechoic lesion, growing nonparallel or vertically, with a heterogeneous echo pattern and obscured margins on breast ultrasound, be classified as Breast Imaging Reporting and Data System (BI-RADS 4b)?

ChatGPT-4 response:

- Yes, an oval, hypoechoic lesion growing nonparallel (vertically) with a heterogeneous echo pattern and obscured margins observed on breast ultrasound could be classified as BI-RADS 4b. This classification indicates a moderate suspicion of malignancy, meaning the lesion exhibits characteristics that are more suspicious than those typically found in BI-RADS 4a but not as definitively malignant as those in BI-RADS 4c.
- The characteristics you described—nonparallel orientation (often termed “taller than wide”), heterogeneous echo pattern, and obscured margins—suggest a higher level of concern. These features are often associated with a greater likelihood of malignancy:
  - Nonparallel or vertical orientation: this orientation is more typical of malignant lesions, as benign masses often grow in parallel with the skin.
  - Heterogeneous echo pattern: this can indicate variability within the lesion, which is more common in malignant tumors than in benign growths.
  - Obscured margins: this suggests that the lesion’s borders are not clearly defined, which can be an indication of invasive growth, a characteristic more typical of malignant processes.
- Conclusion: a lesion under 5 mm without a lipid core showing a washout pattern on magnetic resonance imaging should be approached with a high degree of suspicion for malignancy. This situation requires proactive management, including possible biopsy and close imaging follow-up, to ensure timely diagnosis and treatment.

ChatGPT-4o response:

- Yes, an oval, hypoechoic lesion that is growing nonparallel (vertically oriented), with a heterogeneous echo pattern and obscured margins on breast ultrasound can be classified as BI-RADS 4b. BI-RADS 4b is used to describe lesions with a moderate suspicion of malignancy.
- Key features of BI-RADS 4b:
  - Oval shape: while an oval shape can suggest a benign lesion, other features, such as orientation, margin appearance, and internal echo pattern, significantly influence the level of suspicion.
  - Nonparallel growth (vertically oriented): a lesion that grows nonparallel, or “taller than wide,” raises concern for malignancy. This orientation is often associated with invasive tumors because malignant lesions tend to invade tissue in a vertical direction.
  - Heterogeneous echo pattern: a heterogeneous echo pattern, where the lesion appears uneven or varied in echogenicity, is suspicious because it can indicate the presence of both solid and cystic components, or areas of differing cellular density, which is common in malignant tumors.
  - Obscured margins: obscured or indistinct margins are another red flag for malignancy. Clear, well-defined margins are typically seen in benign lesions, while indistinct margins suggest invasion into surrounding tissues.
- In conclusion, the combination of nonparallel growth, heterogeneous echo pattern, and obscured margins justifies a BI-RADS 4b classification, meaning the lesion has a moderate risk of malignancy and requires biopsy for a definitive diagnosis.

ChatGPT-4o mini response:

- Yes, an oval, hypoechoic lesion with a nonparallel (vertically oriented) growth pattern, heterogeneous echo pattern, and obscured margins on breast ultrasound can be classified as BI-RADS 4b.
- Here’s why this classification might be appropriate:
  - Oval shape: while typically less suspicious than irregular shapes, an oval shape alone does not rule out malignancy.
  - Hypoechoic: a darker appearance on ultrasound is often associated with both benign and malignant lesions.
  - Nonparallel growth pattern: a vertical or irregular growth pattern can be more concerning, as it may suggest infiltration into surrounding tissues.
  - Heterogeneous echo pattern: variability in echo patterns within a lesion can be indicative of more complex internal structures, which may be suggestive of malignancy.
  - Obscured margins: margins that are not well-defined or are irregularly shaped can be a sign of malignancy.
- BI-RADS 4b indicates a moderate suspicion of malignancy, with a likelihood of 10%-50%. This classification suggests that while there is a notable suspicion of cancer, the probability is not as high as in BI-RADS 4c. A biopsy is recommended to obtain a definitive diagnosis.

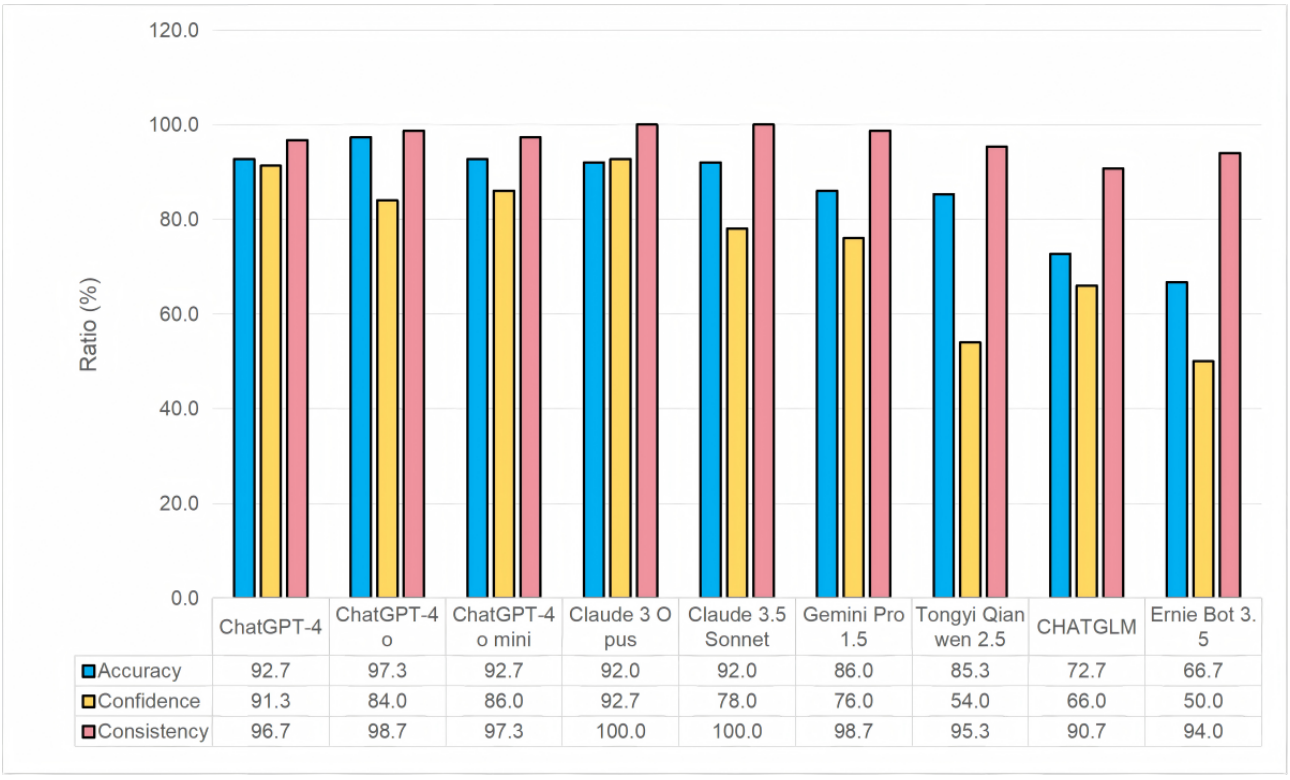
RenderX



Confidence Level

Claude 3 Opus achieved the highest average score of 2.78, followed by ChatGPT-4 with a score of 2.74. The remaining models scored as follows: ChatGPT-4o 2.52, ChatGPT-4o mini 2.58, Claude 3.5, Sonnet 2.34, Gemini 1.5 Pro 2.28, Tongyi Qianwen 2.5 1.62, ChatGLM 1.98, and Ernie Bot 3.5 1.50. Claude 3 Opus and ChatGPT-4 demonstrated significantly higher confidence compared to the other models (Table 1 and Figure 5).

Table 1. Confidence and consistency levels of the large language models (LLMs).

Methods	Confidence level	Consistency level
ChatGPT-4	2.74	2.90
ChatGPT-4o	2.52	2.96
ChatGPT-4o mini	2.58	2.92
Claude 3 Opus	2.78	3.00
Claude 3.5 Sonnet	2.34	3.00
Gemini 1.5 Pro	2.28	2.96
Tongyi Qianwen 2.5	1.62	2.86
ChatGLM	1.98	2.72
Ernie Bot 3.5	1.50	2.82

Figure 5. Percentage of accuracy, confidence, and consistency levels of large language models (LLMs) across all 50 questions.

Consistency

Claude 3 Opus and Claude 3.5 Sonnet achieved the highest score of 3.0, demonstrating their superiority. The remaining models achieved the following consistency scores: ChatGPT-4o: 2.96, Gemini 1.5 Pro: 2.96, ChatGPT-4o mini: 2.92, ChatGPT4: 2.90, Tongyi Qianwen 2.5: 2.86, Ernie Bot 3.5: 2.82, and ChatGLM: 2.71 (Table 1 and Figure 5).

Performances on Clinical Diagnostics and Treatment Questions

In the comparison of clinical diagnostic problems, the mean accuracy scores are 3 (SD 0), 2.92 (SD 0.39), 2.81 (SD 0.69), 2.81 (0.49), 2.81 (SD 0.63), 2.77 (SD 0.65), 2.77 (SD 0.82), 2.77 (SD 0.82), 2.65 (SD 0.98), 2.38 (SD 1.02), and 2.35 (SD 1.13) for ChatGPT-4o mini, ChatGPT-4o, Tongyi Qianwen 2.5, attending physicians, fellow physicians, ChatGPT-4, Claude 3 Opus, Claude 3.5 Sonnet, Gemini 1.5 Pro, Ernie Bot 3.5, and ChatGLM, respectively. No significant differences were observed between any language modeling group and the various

XSL•FO
RenderX

physician groups. Regarding comparisons among physician groups, no significant differences were detected between different physician subgroups (Table 2, Figure 2, and Multimedia Appendices 1 and 4).

Table 2. Accuracy score comparisons of large language models (LLMs) with physician groups for clinical diagnostic and treatment questions.

Methods	Value, mean (SD)	FDR[a]-adjusted *P* value		
		Attending physician	Fellow physician	Resident physician
ChatGPT-4	2.77 (0.65)	.84	.97	.66
ChatGPT-4o	2.92 (0.39)	.44	.81	.49
ChatGPT-4o mini	3 (0)	.37	.42	.23
Claude 3 Opus	2.77 (0.82)	.62	.90	.49
Claude 3.5 Sonnet	2.77 (0.82)	.62	.90	.49
Gemini 1.5 Pro	2.65 (0.98)	.84	.97	.66
Tongyi Qianwen 2.5	2.81 (0.69)	.62	.90	.49
ChatGLM	2.35 (1.13)	.44	.44	.49
Ernie Bot 3.5	2.38 (1.02)	.44	.42	.49
Attending physician	2.81 (0.49)	—[b]	.90	.74
Fellow physician	2.81 (0.63)	—	—	.66
Resident physician	2.77 (0.51)	—	—	—

[a]FDR: false discovery rate.

[b]Not applicable.

In Figure 2, 3-star or dot symbols on each violin from top to bottom represent *P* values compared to each LLM to attending, fellow, and resident physicians, using the Wilcoxon rank-sum test. Symbols are as follows: "***" represents $P<.001$, "**" represents $.001\leq P<.01$, "*" represents $.01\leq P<.05$, and "." represents $P\geq.05$.

Performances on Radiological Diagnostics Problems

In the comparison of radiological diagnostic problems, the scores were as follows: ChatGPT-4 2.79, ChatGPT-4o 2.92, ChatGPT-4o mini 2.54, Claude 3 Opus 2.75, Claude 3.5 Sonnet 2.75, Gemini 1.5 Pro 2.5, Tongyi Qianwen 2.29, ChatGLM 2.0, and Ernie Bot 3.5 1.58. The attending physicians scored 2.46, the fellow physicians scored 2.04, and the resident physicians scored 2.5. The differences between ChatGPT-4, ChatGPT-4o, ChatGPT-4o mini, Claude 3 Opus, Claude 3.5 Sonnet, and Gemini 1.5 Pro and the fellow physicians were statistically significant ($P<.05$). There were statistically significant differences between ChatGPT-4o and the resident physicians ($P=.04$). In contrast, the differences between Tongyi Qianwen 2.5, ChatGLM, and the physician groups were not statistically significant ($P>.05$). In comparisons among physician groups, the differences were not statistically significant ($P>.05$; Table 3, Multimedia Appendices 1 and 4, and Figure 5).

Discussion

Principal Findings

With the global population aging, the rising incidence of cancer, and the increasing complexity of treatment options, there is a growing demand for MDT discussions. However, implementing high-level MDTs in underdeveloped countries remains a significant challenge [16], largely because of the knowledge barriers between specialist doctors. An important question is how specialist doctors in less developed regions can achieve the same medical standards as those in developed regions, easily access authoritative and professional medical knowledge, and overcome barriers between specialties. The recently developed chatbot can theoretically provide instant, evidence-based responses, demonstrating significant potential as an ideal tool for enhancing high-quality health care in underserved regions. In our comparison of 9 LLMs, Claude 3 Opus demonstrated the highest confidence score at 2.78, followed by ChatGPT-4 (2.74) and ChatGPT-4o mini (2.58). These scores suggest that these models exhibit a higher degree of certainty when managing complex medical issues. In contrast, Ernie Bot 3.5's confidence score of 1.50 was significantly lower, indicating a reduced ability to comprehend and process medical problems. These findings underscore the varying levels of proficiency among language models in accurately addressing the same problem. Interestingly, unlike human practitioners, not all chatbots confidently respond to closed-ended questions with a definitive "yes" or "no," suggesting that training data diversity and model architecture significantly impact diagnostic accuracy. This uncertainty may lead to reduced consistency and accuracy of their outputs, thus limiting their independent use in practical clinical applications, making them inseparable from close collaboration with physicians during decision-making.

In addition, in the consistency assessment, Claude 3 Opus and Claude 3.5 Sonnet achieved the highest scores of 3, followed by ChatGPT-4o and Gemini 1.5 Pro, both scoring 2.96, with ChatGPT-4o mini at 2.92. In contrast, ChatGLM and Ernie Bot 3.5 exhibited lower consistency scores of 2.72 and 2.82, respectively. These results highlight the differences in response stability across the LLMs, a factor that is especially critical for clinical decision support. In clinical applications, particularly in dynamic and complex environments, models lacking sufficient consistency may undermine confidence in their outputs. Although Claude 3 Opus and Claude 3.5 Sonnet surpassed the ChatGPT models in response consistency (scoring 3), the ChatGPT models demonstrated superior performance in diagnostic accuracy. However, none of the models provided correct answers to all question sets. Therefore, while AI introduces new possibilities in fields such as medicine, it also presents challenges that require careful expert scrutiny to avoid imposing additional burdens on patients and health care professionals [17,18].

By comparing the nine LLMs with the responses of nine radiologists on the overall 50 guideline questions, ChatGPT-4o achieved the highest score of 2.92, significantly outperforming all physician groups. The difference between ChatGPT-4o and all physician groups (*P*<.05) was statistically significant. ChatGPT-4, ChatGPT-4o mini, Claude 3 Opus, and Claude 3.5 Sonnet all scored higher on average than the physician groups. However, the difference was statistically significant only for the comparison with fellow physicians (*P*<.05). In contrast, Gemini 1.5 Pro and Tongyi Qianwen 2.5 had lower scores, with no statistically significant differences compared to each group

XSL•FO
RenderX

of doctors (P>.05). ChatGLM and Ernie Bot 3.5 showed lower scores than all physician groups, but the differences were not statistically significant. No statistically significant differences (P>.05) were found in the comparisons between each group of doctors, suggesting that attending physicians, fellow physicians, and resident physicians performed comparably in answering the entire question set. Attending physicians and resident physicians both scored 2.64, which may reflect a more consistent ability to answer certain routine questions across all years of experience. Fellow physicians, on the other hand, scored slightly lower, but the difference was not significant, suggesting that their performance in overall diagnostic and therapeutic tasks remains competitive.

In the evaluation of radiological diagnostic performance, ChatGPT-4o scored 2.92. A significant difference was observed between ChatGPT-4o and resident physicians (P=.04), and a significant difference was also detected between ChatGPT-4o and fellow physicians (P<.05). ChatGPT-4 achieved a score of 2.79, surpassing all physician groups on average. However, this difference reached statistical significance solely in the comparison with fellow physicians (P<.05). The difference between ChatGPT-4o mini and the fellow physicians was statistically significant (P=.01). Claude 3 Opus and Claude 3.5 Sonnet both scored 2.75, higher than all physician groups; in particular, the difference between these LLMs and fellow physicians was statistically significant (P<.05), suggesting superior performance in radiological diagnostics. Gemini 1.5 Pro scored 2.50, showing small differences compared with attending physicians and resident physicians but significantly higher than fellow physicians (P=.01). Tongyi Qianwen 2.5 and ChatGLM scored lower, with no statistically significant differences compared to physician groups (P>.05). Ernie Bot 3.5 had the lowest score (1.58) among all LLMs, with no statistical significance compared to any physician group, indicating relatively poorer performance. We conclude that the ChatGPT and Claude series outperform junior medical doctors in addressing complex medical issues, highlighting their potential clinical utility. However, ChatGLM and Ernie Bot 3.5 may require further optimization to improve their performance in medical diagnostics. In the diagnostic radiology domain, the average performance of attending physicians and resident physicians was comparable, whereas the small group of fellow physicians scored lower on average. It is noteworthy that resident physicians, who have recently completed standardized residency training, may be more familiar with the specific guidelines on which the questions were based. Attending physicians, benefiting from extensive clinical experience, would be expected to exhibit an advantage in diagnosing complex imaging findings. The performance variation across the small physician subgroups underscores the preliminary nature of these comparisons.

In the assessment of clinical diagnosis and treatment performance, ChatGPT-4o mini achieved the highest score of 3 among all LLMs, although no statistically significant differences were found when compared with any physician group. ChatGPT-4o scored 2.92 and showed no significant difference compared with physician groups (P>.05); however, it outperformed all physician groups on average. Other LLMs, including ChatGPT-4, Claude 3 Opus, and Claude 3.5 Sonnet, exhibited similar performance to physician groups. ChatGLM and Ernie Bot 3.5 showed weaker performance. Overall, the ChatGPT and Claude series of LLMs outperformed some physician groups with lower seniority in complex health care challenges, indicating potential for clinical applications. Further optimization may be necessary for ChatGLM and Ernie Bot 3.5 to enhance their diagnostic performance. Scores between attending physicians and fellow physicians were identical, while resident physicians scored slightly lower; however, these differences did not reach statistical significance. Radiologists of varying experience levels may possess adequate knowledge of clinical guidelines in diagnosis and treatment, particularly when dealing with standardized procedures or common diseases, resulting in minimal differences. Despite differences in experience, attending physicians and fellow physicians demonstrated similar proficiency in applying clinical guidelines.

It is noteworthy that Tongyi Qianwen 2.5 was the only model unable to generate a response to a specific question, instead providing the feedback, “I’m very sorry, but I don’t think I fully understand what you mean. Let’s change the subject first, shall we?” This issue may be attributable to the complexity and specialized nature of the question, or potential biases and gaps in the model’s training data, leading to insufficient knowledge in specific domains. Our data indicate that when Tongyi Qianwen 2.5 fails to respond, the model’s accuracy may be overstated, and its actual performance is significantly below expectations.

Comparison With Previous Work

In our analysis of the 9 language models, Ernie Bot 3.5, Tongyi Qianwen 2.5, and ChatGLM were more likely to recommend referring the questions to medical experts when faced with specialized imaging terminology and clinical scenarios, rather than providing a definitive answer. In contrast, Claude 3 Opus and the ChatGPT series provided more detailed diagnostic imaging feedback, including recommendations for additional biopsies to support diagnosis and an emphasis on multidisciplinary collaboration. Regarding clinical considerations for surgery, the ChatGPT series excelled by offering surgical recommendations for breast cancer patients, while also demonstrating conventional surgical approaches and discussing recent therapeutic advancements. Furthermore, the ChatGPT family outperformed other language models in breast cancer diagnosis and treatment, with each model excelling in its respective area of expertise. This finding highlights the critical need to select the most appropriate language model based on task-specific performance, thereby enhancing problem-solving across various scenarios. These interactive language models provided feedback significantly faster than breast cancer radiologists, reducing time costs and increasing productivity. With continued iteration and improvement, ChatGPT has demonstrated considerable potential in radiology, including concise report generation, support for medical education, clinical decision aids, patient communication optimization, and data analysis [19,20]. Analyzing the reasons for comparable performance between leading language models reveals several key advantages: (1) large-scale, high-quality training data: both the developers of Claude 3 Opus and Chat

XSL•FO
RenderX

GPT have invested substantial resources in acquiring and curating authoritative medical literature, textbooks, and specialized professional databases; (2) comparable model scale and architecture: as state-of-the-art LLMs, both likely use similar parameter scales and analogous underlying architectural designs; (3) equivalent alignment methodologies: both organizations have likely implemented similar reinforcement learning from human feedback techniques, using extensive human evaluator input to enhance the accuracy of model outputs; (4) competition-driven enhancement: market competition has compelled both companies to continuously improve model performance, particularly in high-value vertical domains such as health care. This competitive environment has resulted in both products demonstrating enhanced logical reasoning capabilities; (5) domain-specific knowledge processing: both models have likely incorporated specialized training methodologies for processing technical terminology and complex semantic relationships within specialized conceptual frameworks; (6) parallel safety control mechanisms: in high-risk domains such as medicine, both models have presumably implemented stringent output controls and prudence measures to ensure responsible performance. Given the continuous evolution of LLMs, their capabilities in complex domains, particularly medicine, are rapidly advancing. Future research should further investigate the potential of these models to maximize their value in clinical diagnosis and treatment [21].

However, LLMs were not specifically trained for the medical field and rely on large datasets collected from public sources, such as web pages, books, and websites. Chinese LLMs have reported average accuracy in general medical question-answering of around 82%; yet, performance drops significantly in complex clinical reasoning tasks, such as breast cancer diagnosis (below 50%) [22]. Advanced models, such as ChatGPT-3.5, ChatGPT-4.0, and Claude-2, achieve slightly higher performance (approximately 60%) in breast cancer clinical assessments, though this still highlights critical limitations in high-stakes medical applications [23]. Despite the vast amount of training data, these models lack comprehensive common sense, which limits their reasoning ability. The literature suggests that LLM performance can be significantly enhanced by guiding reasoning steps incrementally, particularly in tasks involving longer reasoning chains [24,25]. In our study, however, the 9 LLMs were unable to accurately diagnose all rigorous and logical medical problems, and a "curse of reversal" phenomenon was observed. Furthermore, unlike real-time search engines such as Google and Bing, LLMs can only generate responses based on their training data and do not have real-time access to current information [26,27]. In addition, LLMs cannot reliably differentiate between factual and fictional statements, posing a potential risk as sources of misinformation in certain cases [28-30]. Moreover, the training data for these models are not publicly available, and the sources of their information are not disclosed, making it difficult to verify the accuracy of their outputs [31]. Therefore, radiologists must continue to rely on traditional evidence-based education and approach LLMs critically, cross-referencing their outputs with credible medical sources [32].

Limitations

This study has several limitations. First, our findings are subject to the inherent limitations of the author-crafted, closed-ended question format. Although designed for objective assessment, this format may not fully capture the reasoning capabilities of LLMs and could potentially underestimate their performance in real-world, open-ended clinical scenarios. Second, the binary definition of a "confident" response as a direct "yes" or "no" may not adequately reflect clinical decision-making, where acknowledging uncertainty is a sign of expertise. This could have introduced bias by favoring LLMs that generate definitive answers over physicians who appropriately consider diagnostic nuances. Third, the physician sample size, while sufficient for initial comparisons, remains relatively small and may not be fully representative of the broader population of radiologists, which could affect the generalizability of our pairwise comparisons. Fourth, the study's generalizability is constrained by its specific design: the assessment is limited to 50 selected questions that do not encompass all aspects of the guidelines, and the performance of the LLMs was evaluated on a single, specific task (answering structured concordance questions). Consequently, the results may not be directly extrapolated to other clinical datasets or different natural language processing tasks. Fifth, the study conditions, including a strict 30-minute time limit and a "no-consultation" rule for the participating physicians, may not reflect real-world clinical practice, where complex cases often benefit from more time and collaborative discussion. These methodological choices, while necessary for standardization, may have disadvantaged the physicians and thus the conclusions of this study must be heavily qualified by this context. In addition, it has been reported that LLMs may generate different responses to identical prompts at different times, due to model updates [31,33]. Future studies should use larger and more diverse physician cohorts, incorporate more nuanced assessments of confidence, explore the impact of different time constraints and collaborative settings, and use a broader range of question types and clinical tasks to validate and extend our findings.

Future Directions

In medical AI applications, LLMs participating in clinical decision-making face critical responsibility challenges, including decision output liability, misinformation risks, and privacy breach accountability [30]. Typically, LLMs do not independently generate decision outputs but function as tools for physicians. Clinicians must integrate guidelines, relevant literature, and their clinical expertise to formulate final clinical decisions. When using LLMs, it is essential to conceal patients' identifying information to safeguard privacy.

This necessitates establishing explicit legal frameworks that delineate responsibility boundaries among developers, health care institutions, and physicians, while constructing comprehensive accountability mechanisms [34,35]. Concurrently, LLMs present a risk of generating inaccurate medical information that could potentially mislead diagnostic and therapeutic decisions. To address this concern, model developers must implement rigorous content review protocols

XSL•FO
RenderX

and ensure professional, authoritative verification of training corpora.

Conclusions

In conclusion, within the context of our study, Claude 3 Opus and the ChatGPT series, particularly ChatGPT-4o, excelled in addressing breast cancer–related guideline questions and demonstrated significant potential for clinical application. In contrast, the less consistent performance of other LLMs, especially Ernie Bot 3.5 and ChatGLM, suggests that both confidence and consistency should be carefully considered when selecting and applying LLMs to ensure efficacy and stability in clinical practice. This preliminary evaluation indicates that LLMs can provide radiologists with extensive cross-disciplinary knowledge, potentially enhancing contributions within MDTs. However, they cannot fully replace human expertise, particularly in complex diagnostic scenarios that require nuanced decision-making honed by clinical experience.

Acknowledgments

We also sincerely thank Dr Siping Luo, Dr Xiao Luo, Huimei Lü, Zhichunmei Yuan, and Qiuxinmei Chen for their invaluable suggestions in designing the 50 breast cancer questions.

Data Availability

The datasets generated or analyzed during this study are available from the corresponding author upon reasonable request.

Funding

This research was funded by the Department of Science and Technology of Guangdong Province (grant no 112175605105) and the research project “Preoperative Localization and Navigation of Non-Mass Breast Cancer with DCE-MRI and Ultrasound Fusion Imaging” (grant no 2023yjlcyj019), and the Shenzhen Basic Research Project (Natural Science Foundation; grant no JCYJ20220530150416036). The funding period was 3 years, starting in June 2023, with a total budget of CNY $35,615 (US $5000).

Authors' Contributions

CY was responsible for conceptualization, developing the conceptual framework, and formulating the ideas for this study. HJ and CY prepared the original draft, including substantive translation, and contributed to manuscript creation. HJ, CY, JY, and CY participated in the review and editing of the manuscript, covering both prepublication and postpublication stages. Supervision of the study was provided by HJ, CY, and JY, who oversaw and took leadership responsibility for the planning and execution of research activities. Resource support, including the provision of breast cancer–related guideline materials, was provided by JY, HJ, and CY. Formal analysis was conducted by WZ, who applied statistical techniques to analyze the research data, while data curation, including management of LLM models and essential software code, was performed by WZ and SZ. Investigation, including data collection during the study, was carried out by GR, WW, and MW. Project administration was coordinated by JY, who ensured the smooth planning and execution of research activities. Funding acquisition was secured by HJ and JY.

Abstract

Background: Triage errors in emergency departments (EDs), including undertriage and overtriage, pose significant risks to patient safety and resource allocation. With increasing patient volumes and staffing challenges, artificial intelligence (AI) integration into triage protocols has gained attention as a potential solution.

Objective: This study aims to develop and compare 3 AI models—natural language processing (NLP), large language model (LLM), and Joint Embedding Predictive Architecture (JEPA)—for predicting triage outcomes according to the French Emergency Nurses Classification in Hospital (FRENCH) scale and to assess their performance relative to nurse triage and clinical expert consensus.

Methods: We conducted a retrospective analysis of prospectively collected data from adult patients triaged at Roger Salengro Hospital ED (Lille, France) over 7 months (June-December 2024). Three AI models were developed: TRIAGEMASTER (NLP with Doc2Vec + MLP), URGENTIAPARSE (LLM with FlauBERT + Extreme Gradient Boosting [XGBoost]), and EMERGINET (JEPA with variance-invariance-covariance regularization). Of 73,236 ED visits, 657 (0.90%) had complete audio recordings and structured data. Data were split 80:20 into training and validation sets with stratification. Gold-standard labels were established by senior clinician consensus (minimum 5 years of ED experience). The primary outcome was concordance with the gold-standard FRENCH triage level, assessed using weighted κ, Spearman correlation, F1-score, area under the receiver operating characteristic (AUC-ROC) curve, mean absolute error (MAE), and root mean square error (RMSE). Secondary analyses evaluated Groupes d'Etude Multicentrique des Services d'Accueil (GEMSA) prediction and performance by input data type.

Results: URGENTIAPARSE demonstrated superior performance, with a composite z score of 2.514 compared with EMERGINET (0.438), TRIAGEMASTER (–3.511), and nurse triage (–4.343). URGENTIAPARSE achieved an F1-score of 0.900 (95% CI 0.876-0.924), an AUC-ROC of 0.879 (95% CI 0.851-0.907), a weighted κ of 0.800 (P<.001), a Spearman correlation of 0.802 (P<.001), an MAE of 0.228, and an RMSE of 0.790. Exact agreement was 90.0%, with near-agreement (+1 or –1 level) of 92.8%. However, training showed perfect accuracy (1.0) with poor validation performance (~0.5), indicating overfitting. EMERGINET achieved moderate performance (F1-score=0.731, AUC 0.686), while TRIAGEMASTER and nurse triage performed poorly (F1-score=0.618 and 0.303, respectively). For GEMSA prediction, URGENTIAPARSE maintained superiority (κ=0.863, Spearman=0.864, P<.001). Class 1 (highest acuity) was underrepresented (4/657, 0.61%), limiting undertriage risk assessment.

XSL•FO
RenderX

Conclusions: The LLM-based architecture (URGENTIAPARSE) demonstrated the highest accuracy for ED triage prediction among the tested models, outperforming traditional NLP, JEPA, and current nurse triage practices. However, severe overfitting, extreme selection bias (657/73,236, 0.90%, inclusion), a monocentric design, and sparse high-acuity representation limit clinical applicability. Before deployment, the model requires regularization, external validation across diverse EDs, prospective testing, and comprehensive safety evaluation, particularly for undertriage detection. Integration of AI triage support systems shows promise but demands rigorous validation, bias mitigation, and transparent uncertainty quantification to ensure patient safety.

Introduction

Triage in emergency departments (EDs) is vital for prioritizing patients by severity, directly affecting outcomes, efficiency, and resource use. In busy or understaffed settings, accurate triage is essential to ensure safe and equitable care.

In France, the French Emergency Nurses Classification in Hospital (FRENCH) triage scale has become a standardized reference tool for emergency medical services [1]. This 6-level urgency stratification system (1=immediate life-threatening to 6=nonurgent) was designed to promote consistency and reproducibility. However, in practice, its application often varies [2], shaped by disparities in nurse experience, time pressure, interpretive inconsistencies, and fatigue. These factors lead to 2 key errors: undertriage, in which serious cases are underestimated, risking delays in care and potentially preventable mortality; and overtriage, in which minor cases are overprioritized, leading to crowding and inefficient use of resources [3].

Against this backdrop, artificial intelligence (AI) has emerged as a promising complement to traditional triage [4]. AI systems in emergency medicine can process diverse data, operate continuously, and provide consistent and transparent decisions; however, their success over the past decade has been mixed.

Early AI triage systems relied on natural language processing (NLP) to extract clinical meaning from text, using hand-crafted rules or statistical models [5]. Although these early systems were effective, they lacked the ability to understand context, nuance, or rare cases. Advances emerged with large language models (LLMs) such as Bidirectional Encoder Representations from Transformers (BERT) and its French version, FlauBERT [6]. These transformer-based models provided deep contextual understanding. When combined with boosting algorithms such as Extreme Gradient Boosting (XGBoost), LLMs formed hybrid architectures that balanced high performance with interpretability [7], 2 pillars of clinical deployment. More recently, Joint Embedding Predictive Architectures (JEPA) have introduced a third paradigm. JEPA models do not predict outcomes directly; instead, they embed both inputs and targets (eg, triage categories) into a shared latent space. Using techniques such as energy minimization and variance-invariance-covariance regularization (VICReg) [8,9], these models can uncover subtle cross-modal patterns. However, their complexity poses ongoing challenges for interpretability, an essential requirement in medical contexts.

Few studies have compared AI models under consistent conditions [10,11]. Most focus on narrow tasks, rely on limited or noisy data, and are often developed outside the French health care system, reducing their relevance for users of the FRENCH scale. Furthermore, recent work has highlighted concerns regarding judgment biases in triage [11,12], hallucinations in LLMs [13], and the need for robust calibration and uncertainty quantification in clinical AI systems [14].

This study aims to address this gap. We conducted a retrospective analysis of triage encounters at the Centre Hospitalier Universitaire (CHU) Lille ED, one of France's major academic hospitals [15]. Using rich clinical data and nurse-patient dialogues, 3 AI models—TRIAGEMASTER, URGENTIAPARSE, and EMERGINET—were developed to predict FRENCH triage levels. These models were evaluated against expert consensus to identify the best-performing system and to assess their clinical suitability and limitations.

Methods

Study Design

This study was designed as a retrospective, observational, monocentric analysis conducted in the Adult Emergency Department of the CHU Lille, France. The ED is a high-volume academic tertiary care facility serving a diverse patient population, with approximately 73,000 adult visits annually. The investigation covered a continuous 7-month period from June 1, 2024, to December 31, 2024. This time frame was selected to capture seasonal variations in ED activity and to ensure a sufficiently large and heterogeneous dataset.

Ethical Compliance

The study adhered to strict French and European ethical standards, with approval and registration from the Comité d'Éthique de la Recherche en Santé, Health Data Hub filing (project number 18605502), and Commission Nationale de l'Informatique et des Libertés (CNIL) Méthodologie de Référence-004 compliance [16]. Audio recordings were collected with patient information at triage. Personal data were present before anonymization and underwent rigorous deidentification, including removal of names, dates, identifiers, and geographic information smaller than the department level, with transcript verification performed by 2 independent

XSL•FO
RenderX

reviewers. As this was a retrospective analysis of deidentified data, individual informed consent was waived in accordance with French regulations. The study followed the Transparent Reporting of a multivariable prediction model for Individual Prognosis Or Diagnosis (TRIPOD)-AI guidelines (see Multimedia Appendix 1). Owing to patient confidentiality, the full dataset and code are not publicly available; only the code used to define the gold standard is shared (see Multimedia Appendix 2).

Population and Inclusion Criteria

The study included adult patients (≥18 years) evaluated in the Lille CHU ED with complete structured clinical data and recorded nurse-patient audio interviews. Exclusion criteria were minors (<18 years), legally protected adults, patients who declined data use (n=2), and cases with incomplete recordings, corrupted files, missing structured data, or failed transcription quality checks (n=22).

Data Acquisition and Preprocessing

The study relied on 2 primary data sources. First, structured clinical data were extracted from the ResUrgences ED management software (version 2024.1.148; Berger-Levrault). Variables collected included age, sex, vital signs (systolic and diastolic blood pressure, heart rate, temperature, oxygen saturation, and supplemental oxygen requirement), pain score (visual analog scale 0-10), time of presentation, comorbidities, chief complaint category, the initial FRENCH triage decision, and the Groupes d'Etude Multicentrique des Services d'Accueil (GEMSA) scale (corresponding to patient outcome after diagnostic evaluation and treatment in the ED) [17].

Unstructured data from nurse-patient triage interviews were audio-recorded using standardized digital recorders and manually transcribed by trained personnel, with accuracy verified by 2 independent reviewers. Transcripts were linked using unique patient identifiers and time stamps, anonymized in accordance with CNIL guidelines, and securely stored on Health Data Hub–approved servers for modeling. Recording participation was limited to volunteer nurses (n<10) during their regular shifts, introducing potential selection bias in conversation style and patient characteristics.

Comparison of Included Versus Excluded Cohorts

To assess selection bias, we compared demographic and clinical characteristics between included patients (n=657) and the broader ED population (n=72,579) during the study period. The included cohort had a similar mean age (42.6 vs 43.2 years, *P*=.68), sex distribution (330/657, 50.2%, male, *P*=.67), and vital sign distributions. However, included patients had slightly lower acuity (mean nurse FRENCH 3.4 vs 3.1, *P*=.02) and higher admission rates (15.5% vs 12.3%, *P*=.03), likely reflecting volunteer nurse participation patterns and recording feasibility during less chaotic triage encounters (Table 1).

[b]FRENCH: French Emergency Nurses Classification in Hospital.

[c]GEMSA: Groupes d'Etude Multicentrique des Services d'Accueil.

Gold-Standard Construction

A gold-standard triage label was established through independent review by 3 senior emergency physicians (minimum 5 years of postresidency ED experience, board-certified in emergency medicine) who were strictly blinded to the original nurse triage assignment, all AI model outputs, and patient outcomes (laboratory results, imaging, disposition, and diagnoses established after the index triage encounter). Each adjudicator independently reviewed the complete triage transcript, vital signs, and demographic data, and then assigned a FRENCH level based solely on information available at the time of triage.

Initial interrater agreement was substantial (Fleiss κ=0.72, 95% CI 0.68-0.76). For the cases with disagreement (155/657, 23.6%), adjudicators met for a structured consensus discussion without knowledge of which assignments were discordant. Final consensus was reached in all cases through majority voting after discussion. This gold standard served as the reference for model training and evaluation. To assess potential incorporation bias, we conducted a sensitivity analysis excluding cases in which the gold standard differed from nurse triage by more than 1 level (n=47), and found similar model performance rankings.

Model Architectures and Training Pipelines

Three distinct AI models were developed, each representing a major class of current machine learning techniques. All models were implemented in Python 3.9 (Python Foundation) with PyTorch 1.12 and scikit-learn 1.1, and trained on NVIDIA A100 graphics processing units (40 GB VRAM), with training times of 2-4 hours per model.

Leakage Safeguards and Hyperparameter Tuning

Overview

Critical measures were implemented to prevent data leakage. All preprocessing steps (Doc2Vec fitting, FlauBERT fine-tuning, and feature scaling) were confined strictly to the training folds, with transformations subsequently applied to validation data. Hyperparameter tuning was performed using 5-fold stratified cross-validation nested within the training set only, without accessing validation data. Random seeds were fixed (seed=42) to ensure reproducibility. Early stopping monitored validation loss with a patience of 10 epochs to prevent overfitting.

TRIAGEMASTER (NLP)

This model used paragraph vector embeddings (Doc2Vec, distributed memory model; vector dimension=100, window=5, min_count=2, epochs=40) to represent free-text input [18], concatenated with *z* score–normalized numerical features derived from structured data (age, sex encoded as binary, and all vital signs). The architecture consisted of a 3-layer feedforward neural network (input→128→64→6 output classes) with Rectified Linear Unit activations [19], dropout regularization (P=.32, applied after each hidden layer), batch normalization, and an L2 weight penalty ($\lambda=1\times10^{-5}$). Optimization used the Adam optimizer with an initial learning rate of 0.001, batch size of 32, and learning rate decay (factor=0.5, patience=5 epochs). The maximum sequence length was 512 tokens. Missing data (<2% of vital signs) were imputed using median values from the training set.

Classification probabilities were derived via softmax activation. CIs for the area under the curve (AUC) were calculated using the DeLong method [20]. Model performance was evaluated across the full range of predicted probabilities. Optimal probability thresholds were defined as the predicted probability that maximized the F_1-score [21]. Inference latency averaged 47 ms per patient on production CPU hardware (Intel Xeon Gold 6248R).

URGENTIAPARSE (LLM)

Built on the FlauBERT language model (flaubert-base-cased, 137 million parameters) [6], this architecture fine-tuned contextual embeddings from patient complaints over 5 epochs with a learning rate of 2×10^{-5}, and then extracted the [CLS (classification)] token embedding (768 dimensions). These embeddings were concatenated with normalized structured variables and fed into an XGBoost classifier (n_estimators=200, max_depth=6, learning_rate=0.1, min_child_weight=3, subsample=0.8, colsample_bytree=0.8, reg_alpha=0.1, reg_lambda=1.0, scale_pos_weight adjusted for class imbalance). This hybrid design enabled both interpretability and high-dimensional pattern recognition [22]. Feature importance was derived using Shapley Additive Explanations (SHAP) values [23], providing transparent model behavior traceable to individual tokens and vital signs. The maximum sequence length was 512 tokens with truncation. Class weights were inversely proportional to class frequencies to address imbalance. Inference latency averaged 312 ms per patient.

EMERGINET (JEPA)

This JEPA encoded textual and structured inputs into a shared latent space (dimension=256) through dual encoders (text encoder: FlauBERT base + 2-layer bidirectional Long Short-Term Memory with hidden size 128 [24]; structured encoder: 3-layer MLP with hidden sizes (64, 128, 256)). The loss function minimized contrastive energy between predicted and target class embeddings using cosine similarity, regularized with VICReg (variance weight=1.0, invariance weight=1.0, covariance weight=0.04) to enforce variance >1.0, invariance via mean squared error, and a near-identity covariance matrix [8]. Training used the Adam optimizer (learning rate=1×10^{-4}, batch size=16, 100 epochs). Final classification was performed using nearest-neighbor matching in embedding space with temperature-scaled softmax (temperature=0.07). Inference latency averaged 189 ms per patient.

XSL•FO
RenderX

Training and Validation Procedures

Each model was trained on 80% of the dataset (n=526) and validated on the remaining 20% (n=131), stratified by gold-standard triage level to maintain class balance (class proportions: 1=4/657, 0.61%; 2=86/657, 13.1%; 3B=354/657, 53.9%; 4=118/657, 18.0%; and 5=95/657, 14.5%; classes 3A and 6 had 0 cases). Hyperparameter grids were searched using 5-fold cross-validation on the training data only. All models were trained 3 times with different random initializations to assess stability; reported metrics are means across runs, with SDs <0.03 for all primary metrics. Training and validation loss curves were monitored to detect overfitting.

Evaluation Metrics

Performance Metrics for Ordinal Outcomes

Model performance was assessed using both absolute error measures and classification agreement metrics. Unless otherwise specified, all *P* values were 2-tailed, with a significance threshold of α=.05. Given the ordered nature of the FRENCH scale, metrics that account for ordinality (weighted κ, Spearman correlation, and mean absolute error [MAE]) were prioritized.

MAE

This measures the average deviation between predicted and actual triage levels.

where  is the predicted value, y_i is the true value, and n is the total number of cases.

Root Mean Square Error

This emphasizes larger misclassification errors:

Weighted Cohen κ

This accounts for agreement beyond chance and penalizes larger discrepancies using quadratic weights:

where $fo_{i,j}$ are observed frequencies, $fe_{i,j}$ are expected frequencies under independence, and $w_{i,j}=(i-j)^2/(k-1)^2$ with k classes. Significance was tested via bootstrap (10,000 iterations).

Spearman Correlation Coefficient

This measures the monotonic association between predicted and true ordinal ranks:

$r_s=[\text{cov}(rg_X,rg_Y)]/[\sigma rg_X \sigma rg_Y]$ **(4)**

F1-scores

Macro F_1-score reflects the unweighted average across all triage classes (treating each class equally), whereas micro F_1-score is weighted by class frequency:

F_1-score = (TP)/[TP+1/2(FP+FN)] **(5)**

where TP denotes true positive, FP false positive, and FN false negative. Class-specific F_1-scores were calculated to assess performance in rare high-acuity classes.

Exact Agreement Percentage

This represents the proportion of predictions that exactly match the gold standard.

Near-Agreement Percentage

This represents the proportion of predictions within the +1 or –1 triage level of the gold standard.

Area Under the Receiver Operating Characteristic Curve

This summarizes discrimination across all classification thresholds, calculated using a one-versus-rest strategy for multiclass classification, with 95% CIs estimated via the DeLong method [20].

Composite z Score

This is an integrated performance indicator combining multiple metrics for ranking.

Score = $Z(-\text{MAE}) + Z(-\text{RMSE}) + Z(\kappa_w) + Z(r_s)$ **(6)**

where $Z(X) = (X - \mu_X)/\sigma_X$ standardizes each metric to mean 0 and SD 1 across all models. Negative MAE and RMSE were used, so higher z scores indicate better performance for all components.

Multiclass Brier Score

This is the mean squared difference between predicted probabilities and one-hot encoded outcomes, providing global probabilistic accurac

where  is the predicted probability for class j of case i, y_{ij} is a binary indicator (1 if true class, 0 otherwise), and k is the number of classes.

Asymmetric Error Analysis

Given the clinical importance of undertriage (predicting lower acuity than the true acuity, potentially delaying critical care), we analyzed error asymmetry by calculating the undertriage rate (proportion of predictions <true class) and the overtriage rate (proportion of predictions >true class). For classes 1-2 (highest acuity), we report sensitivity, specificity, positive predictive value, and negative predictive value separately, as undertriage in these categories poses the greatest patient safety risk.

Calibration Analysis

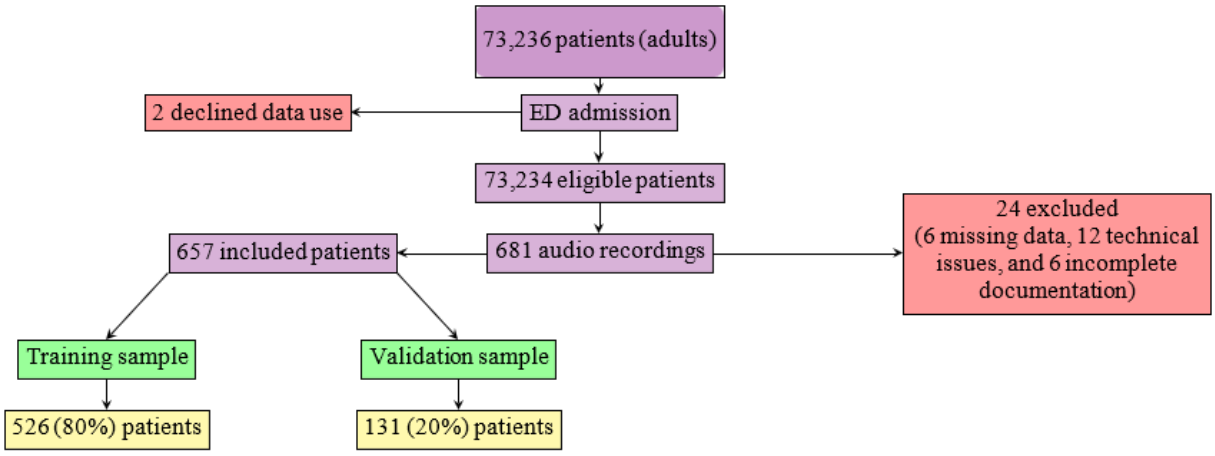
Model calibration was assessed by grouping predicted probabilities into quantile-based bins (10 bins per class) and comparing mean predicted probabilities with observed frequencies. Reliability diagrams plotted mean predicted probability versus observed frequency for each bin, with perfect calibration represented by the diagonal. Expected calibration error and maximum calibration error were computed as measures of calibration quality. Additionally, risk distributions were

XSL•FO
RenderX

visualized using density ridge plots stratified by true triage class and faceted by predicted class.

Secondary Analyses

A secondary analysis compared actual versus AI-predicted GEMSA scores (patient disposition: 2=discharged home, 3=short stay unit, 4=admitted to ward, and 5=intensive care unit [ICU]) using models trained separately on nurse-recorded structured histories and full interview transcripts. Another analysis assessed model performance according to input data type (structured data only vs unstructured transcripts only). Both analyses used evaluation methods consistent with the primary analysis. All statistical analyses were performed in R version 4.2 (R Foundation) and Python 3.9.



Results

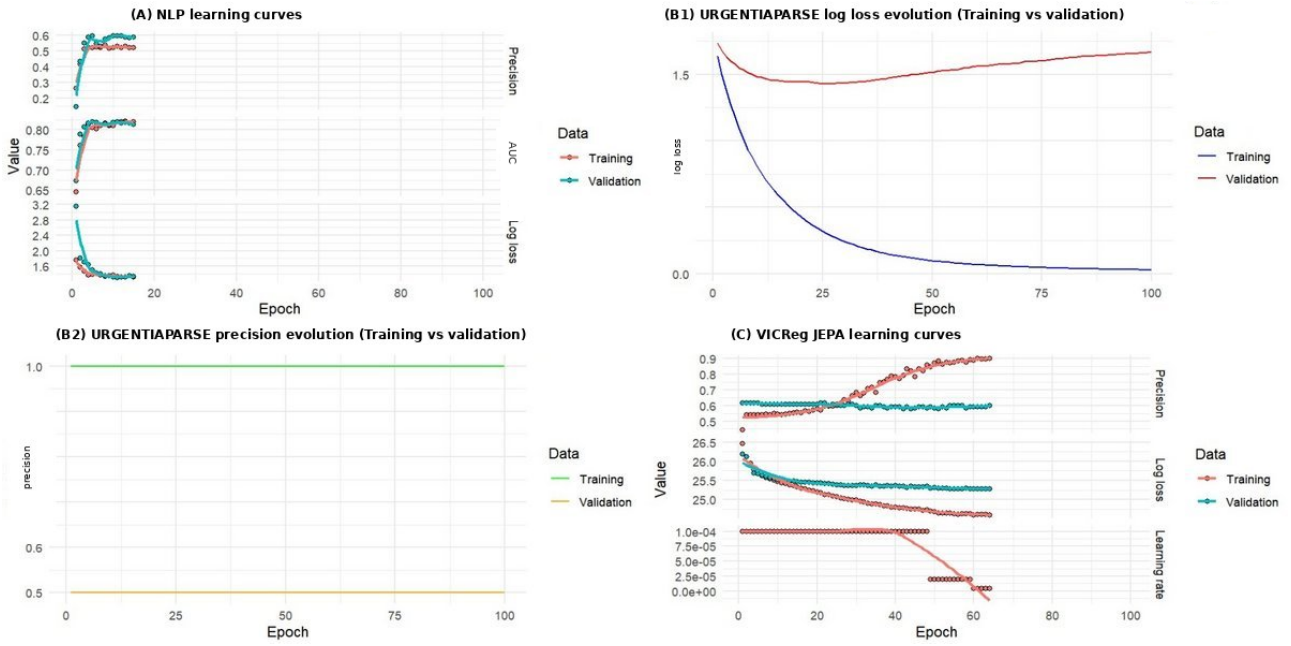
Population Characteristics

During the inclusion period, 73,236 patients visited the ED of Roger Salengro Hospital. Two patients declined data use. Triage nurse interviews were recorded and transcribed for 681 (0.93%) patients. After excluding 24 cases (6 with missing data and 18 with transcription quality issues), 657 (0.90%) patients met the inclusion criteria (Figure 1).

Included patients had a mean age of 42.6 (SD 19.7) years and a median age of 38 years. The sample was gender-balanced (330/657, 50.2%, male). Most admissions occurred during morning hours (241/657, 36.7%, 6 AM-2 PM). The primary chief complaints were trauma (127/657, 19.3%), abdominal (102/657, 15.5%), and cardiovascular (81/657, 13.1%). One-quarter of patients (161/657, 24.5%) had 1 or more comorbidities, predominantly cardiovascular. Most patients were triaged as FRENCH 3B (354/657, 53.9%), with sparse representation in the highest acuity categories (class 1: 4/657, 0.61%).

Figure 1. Patient flow diagram showing inclusion, exclusion, and dataset splitting. ED: emergency department.

Training Performance and Overfitting Assessment



Over 100 training epochs, TRIAGEMASTER achieved a training accuracy plateau of approximately 75%, with validation accuracy similarly stable at 72%, while log loss decreased and stabilized for both sets, indicating reasonable generalization (Figure 2A).

URGENTIAPARSE exhibited severe overfitting, achieving perfect training accuracy (1.0) by epoch 20 but persistently poor validation accuracy (~0.5 throughout training), indicating memorization rather than learning generalizable patterns (Figure 2B.2). Training log loss approached 0, whereas validation loss remained high and flat at approximately 1.5, with an AUC plateau of 0.69 (Figure 2B.1). This discrepancy indicates that, despite strong performance on the training data, the model fails to generalize to unseen cases—a critical limitation for clinical deployment.

EMERGINET reached a training accuracy of 0.85, but validation accuracy remained at 0.60, indicating moderate overfitting (Figure 2C). Training loss declined steadily, whereas validation loss remained higher and stable, reflecting the performance gap.

XSL•FO
RenderX

Figure 2. Learning curves for 3 artificial intelligence models. (A) TRIAGEMASTER shows stable learning with consistent training and validation performance. (B1) URGENTIAPARSE log-loss evolution demonstrates severe overfitting, with training loss approaching 0 while validation loss remains high. (B2) URGENTIAPARSE accuracy evolution confirms perfect training accuracy (1.0) but poor validation accuracy (0.5). (C) EMERGINET VICReg JEPA learning curves show moderate overfitting, with a gap between training and validation performance. JEPA: Joint Embedding Predictive Architecture; NLP: natural language processing; VICReg: variance-invariance-covariance regularization.

Overall Model Performance

URGENTIAPARSE (LLM) achieved the highest composite score (2.514), outperforming EMERGINET (JEPA, 0.438), TRIAGEMASTER (NLP, –3.511), and nurse triage (–4.343; Table 2). URGENTIAPARSE demonstrated strong discrimination, with a micro F_1-score of 0.900 (95% CI 0.876-0.924), macro F_1-score of 0.894 (95% CI 0.869-0.919), and AUC of 0.879 (95% CI 0.851-0.907). Agreement metrics were substantial: weighted κ of 0.800 (P<.001, 95% CI 0.761-0.839) and Spearman correlation of 0.802 (P<.001, 95% CI 0.768-0.832). Error metrics showed an MAE of 0.228 classes (approximately 1 triage level error every 4-5 patients) and an RMSE of 0.790. Exact agreement was 90.0%, with near agreement (+1 or –1 level) of 92.8%.

EMERGINET achieved moderate performance (micro F_1-score=0.731, macro F_1-score=0.747, AUC 0.686, κ=0.560, P<.001), whereas TRIAGEMASTER performed poorly (micro F_1-score=0.618, AUC 0.642, κ=0.370, P<.001; Spearman=0.005, P=.95). Current nurse triage showed the lowest performance (micro F_1-score=0.303, AUC 0.776, κ=0.080, P=.08; exact agreement=30.3%), likely reflecting the difference between real-time clinical judgment under time pressure and the gold standard established by senior physicians following comprehensive information review.

Receiver operating characteristic (ROC) curve analysis (Figure 3) confirmed the superiority of URGENTIAPARSE across most triage classes, with particularly strong performance for classes 2, 4, and 5 (AUC >0.85). However, class 1 performance was perfect (AUC 1.0) because of extreme sparsity (n=4), limiting the reliability of this estimate. Performance for class 3 was lower (AUC 0.748), likely reflecting the combined representation of 3A (invasive procedures) and 3B (noninvasive), with no 3A cases in the dataset.

Table 2. Primary analysis comparing triage prediction performance across artificial intelligence models and nurse triage.

Model	Mean absolute error	Root mean square error	κ[a]	Spearman[b]	Micro F_1-score	Macro F_1-score	Exact	Near[c]	z score[d]	Area under the curve
URGENTIAPARSE	0.228	0.790	0.800	0.802	0.900	0.894	0.900	0.928	2.514	0.879
EMERGINET	0.401	0.979	0.560	0.602	0.731	0.747	0.820	0.860	0.438	0.686
TRIAGEMASTER	0.637	1.180	0.370	0.005	0.618	0.613	0.554	0.696	-3.511	0.642

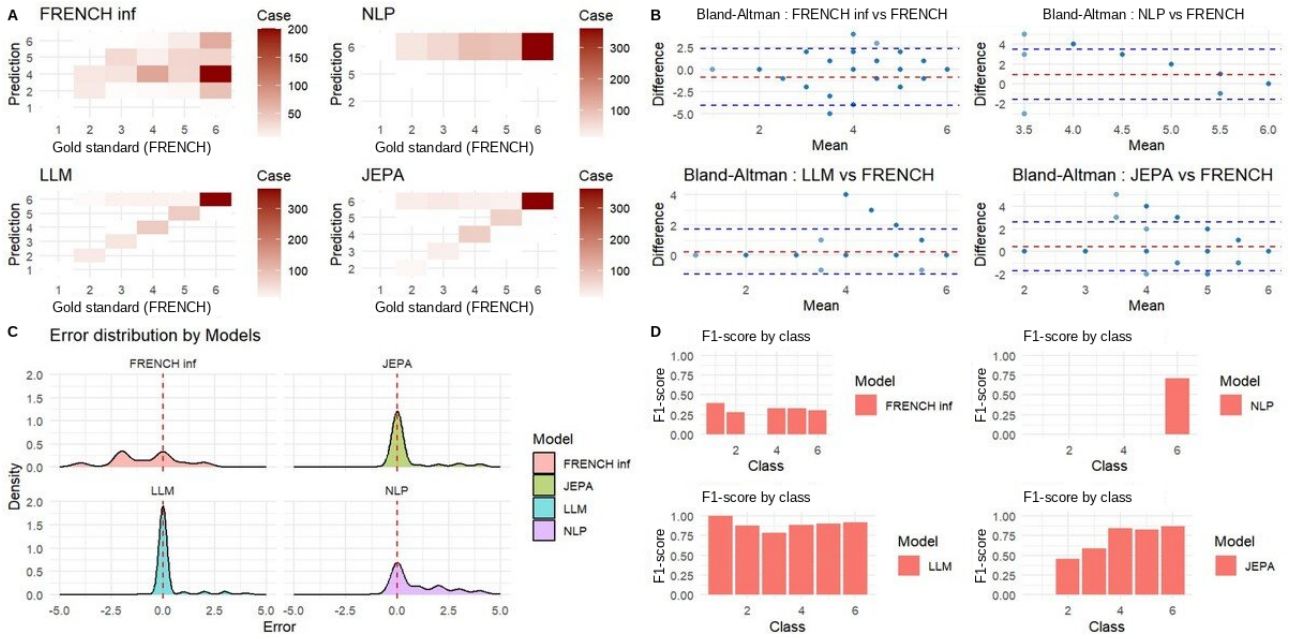
Figure 3. Receiver operating characteristic (ROC) curves for each triage class and the mean curve across all models. URGENTIA-PARSE (large language model) demonstrates superior discrimination for most classes. The results for class 1 (area under the curve [AUC] 1.0 for multiple models) should be interpreted cautiously due to extreme sparsity (n=4). (A) FRENCH inf vs triage — This panel shows ROC curves for a rule-based French triage reference system, where Class 1 achieves near-perfect discrimination (AUC 0.998) but most other classes perform poorly (AUC 0.27–0.63), yielding a modest multiclass AUC of 0.776. (B) TRIAGEMASTER — This panel displays the per-class ROC performance of TRIAGEMASTER, a structured NLP triage model, with moderate overall discrimination (mean AUC 0.641) and relatively homogeneous class-level AUCs ranging from 0.509 to 0.854, suggesting balanced but limited performance across triage levels. (C) URGENTIAPARSE — This panel presents URGENTIAPARSE's ROC curves, the best-performing model overall (multiclass AUC 0.879), with Class 1 achieving perfect separation (AUC 1.0) and strong performance across most classes, reflecting its superior ability to discriminate triage severity levels from free-text clinical notes. (D) EMERGINET — This panel illustrates EMERGINET's ROC curves, showing strong Class 1 discrimination (AUC 0.985) but more heterogeneous performance across the remaining classes (AUC 0.556–0.72), resulting in an intermediate mean AUC of 0.686.

Error Pattern Analysis

Confusion matrices revealed distinct error patterns (Figure 4, top row). URGENTIAPARSE and EMERGINET slightly overestimated acuity for lower triage levels (predicting higher urgency than true), indicating a clinically conservative bias. TRIAGEMASTER systematically underestimated acuity across most classes. Nurse triage showed scattered and inconsistent patterns, with frequent misclassification across nonadjacent categories.



Bland-Altman analysis (Figure 4, middle row) confirmed low, well-centered errors for URGENTIAPARSE (mean difference –0.02, 95% limits of agreement –1.58 to 1.54) and EMERGINET (mean difference 0.08, limits –2.05 to 2.21). TRIAGEMASTER showed larger deviations (limits –3.02 to 2.98), and nurse triage demonstrated extreme disagreement (limits –4.21 to 3.87).

Error distribution analysis (Figure 4, bottom left) showed that URGENTIAPARSE and EMERGINET had narrow, well-centered error distributions (SD <1.0), whereas TRIAGEMASTER and nurse triage exhibited broad, dispersed distributions, indicating less reliable predictions.

Class-specific F_1-scores (Figure 4, bottom right) demonstrated that URGENTIAPARSE maintained consistently high performance across all represented classes (F_1-score >0.75 for classes 2-5), whereas the other approaches showed variable and often poor class-specific performance, particularly for minority classes.

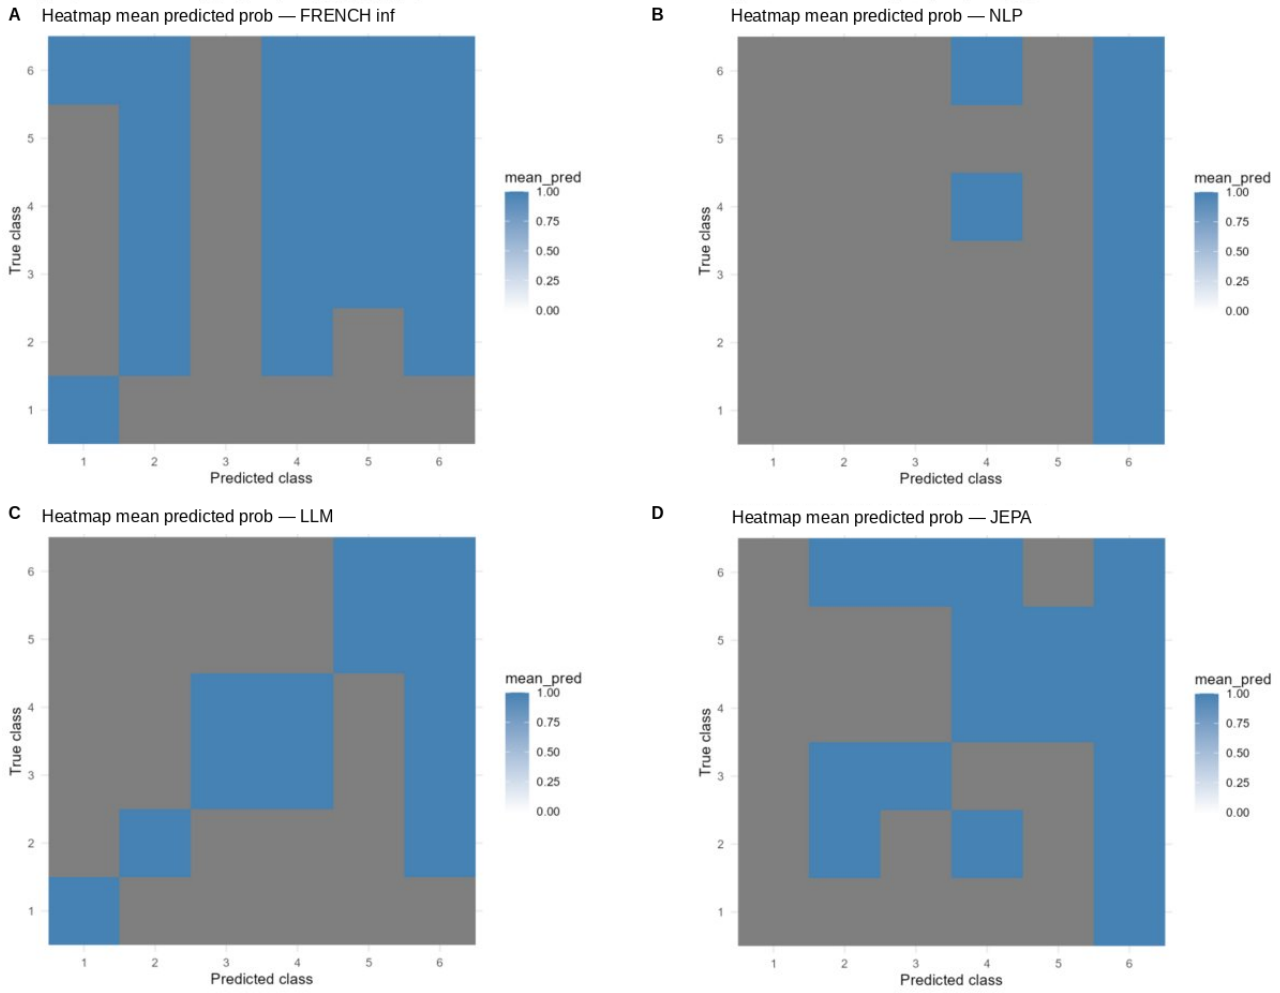
Figure 4. Comprehensive evaluation of four AI-based triage models against the FRENCH gold standard. (A) Confusion matrices comparing predicted versus gold standard triage levels (1–6) for FRENCH inf, NLP, LLM, and JEPA models. (B) Bland-Altman plots assessing systematic bias and limits of agreement between each model and the FRENCH gold standard. (C) Kernel density distributions of prediction errors illustrating the bias and precision of each model. (D) Per-class F1-scores quantifying the discriminative performance of each model across the six triage severity levels.

Asymmetric Error and Undertriage Risk

Given the clinical importance of undertriage, we analyzed error directionality. URGENTIAPARSE had an undertriage rate of 4.6% (predicting lower acuity than true) and an overtriage rate of 5.4% (predicting higher acuity), reflecting a slight conservative bias favoring patient safety. For high-acuity classes (1-2, n=90), URGENTIAPARSE achieved a sensitivity of 87.8% (95% CI 79.2%-93.7%) and a specificity of 95.1% (95% CI 91.3%-97.6%), with a positive predictive value of 86.8% and a negative predictive value of 95.6%. However, the limited representation of class 1 (n=4) constrains the assessment of undertriage risk among the most critical patients. Future deployment would require prospective monitoring, with particular attention to undertriage events and associated patient outcomes.

Calibration and Reliability

Multiclass Brier scores indicated superior probabilistic calibration for URGENTIAPARSE (0.142), compared with EMERGINET (0.385), TRIAGEMASTER (0.524), and nurse triage (0.693). However, detailed calibration analysis revealed heterogeneous reliability across classes (Figure 5).



Class-specific calibration analysis showed the following patterns:

- Class 1: Predictions were overconfident, with limited probability range coverage because of extreme sparsity.
- Class 2: Predictions were dominated by high-probability values (>0.8), indicating limited use of intermediate confidence levels.
- Class 3: Displayed a partially calibrated diagonal trend, but with inconsistencies across probability bins.
- Class 4: Demonstrated the most balanced calibration, with broader probability coverage and closer agreement between predicted and observed frequencies.

These findings highlight substantial class-specific differences and underscore the need for post hoc calibration methods (eg, temperature scaling or isotonic regression) before clinical deployment to ensure reliable probability estimates for risk stratification.

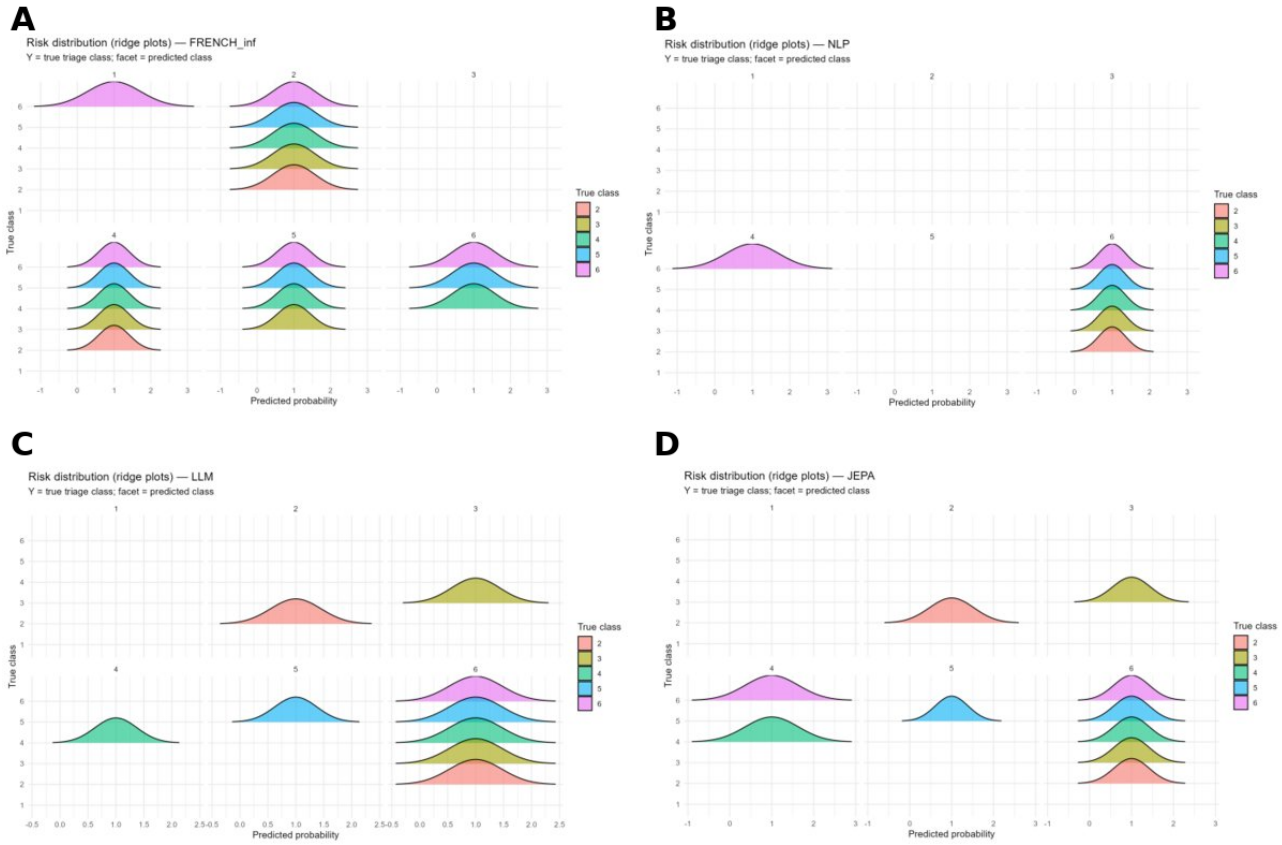
XSL•FO
RenderX

Figure 5. Mean predicted probability heatmaps for the four triage models. Each panel displays, for each true triage class (y-axis, 1–6), the mean predicted probability assigned to each predicted class (x-axis, 1–6), with blue intensity encoding probability magnitude (0–1): (A) FRENCH inf, (B) NLP, (C) LLM, and (D) JEPA — blue blocks concentrated along or near the diagonal indicate well-calibrated class-specific predictions. Perfect calibration would be indicated by high intensity only along the diagonal.

Risk Distribution Analysis

Ridge plot analysis (Figure 6) revealed distinct behavioral patterns across approaches. Nurse triage demonstrated relatively consistent distributional patterns, with moderate overlap between adjacent classes and clear modal peaks, suggesting reasonable discrimination but substantial uncertainty.

TRIAGEMASTER exhibited variable performance, with notable gaps in certain class predictions (particularly panels 1 and 3), indicating an inability to consistently predict across all triage categories. Distributions were concentrated around specific probability values, suggesting either high confidence in limited scenarios or potential overfitting.



URGENTIAPARSE displayed markedly selective characteristics, with substantial gaps in class representation across prediction scenarios. Several triage classes appeared absent in certain combinations, suggesting that the LLM produced more selective predictions. When predictions were generated, distributions were tightly concentrated with distinct modal peaks, indicating high confidence. This sparse prediction pattern may reflect superior discrimination in clear-cut cases but raises concerns regarding coverage across diverse patient presentations. It may also suggest that the model effectively refrains from uncertain predictions—a behavior that requires explicit characterization and validation.

EMERGINET showed heterogeneous patterns, with some classes displaying broad, diffuse distributions and others exhibiting sharp, concentrated peaks, indicating variable predictive confidence across triage categories.

The distinct sparse pattern observed with URGENTIAPARSE warrants careful consideration for clinical implementation. Although it may indicate superior precision in unambiguous cases, the absence of predictions for certain class combinations presents challenges for comprehensive triage coverage. This pattern requires further validation to ensure adequate performance across all patient presentations, including edge cases and ambiguous scenarios.

XSL•FO
RenderX

Figure 6. Risk score distributions by predicted triage class across models (ridge plots). For each model, predicted probability distributions are shown separately per predicted class (facets 1–6, columns) and colored by true triage class (2–6, see legend). (A) FRENCH_inf model (French clinical rule-based inference). (B) NLP model (natural language processing). (C) LLM model (large language model). (D) JEPA model (Joint Embedding Predictive Architecture). The x-axis represents the predicted probability; the y-axis represents the true triage class. Substantial overlap between distributions within a facet indicates high inter-class confusion for that predicted class.

Secondary Analysis: GEMSA Prediction

URGENTIAPARSE substantially outperformed the other models in predicting patient disposition (GEMSA), achieving a composite *z* score of 2.473 versus –2.056 for TRIAGEMASTER and –4.399 for EMERGINET (Table 3). Performance metrics included an MAE of 0.082, RMSE of 0.402, weighted κ of 0.863 (P<.001), Spearman correlation of 0.864 (P<.001), micro F_1-score of 0.957, and macro F_1-score of 0.628. High exact agreement (95.7%) and near agreement (96.0%) further confirmed its accuracy and reliability.

Confusion matrices (Figure 7, top) showed that URGENTIAPARSE produced highly concentrated predictions along the diagonal (accurate), EMERGINET demonstrated moderate accuracy, and TRIAGEMASTER displayed scattered predictions. Bland-Altman analysis (Figure 7, middle) confirmed strong agreement for URGENTIAPARSE (mean difference 0.04, limits –0.83 to 0.91), moderate agreement for EMERGINET (limits –2.12 to 1.96), and large deviations for TRIAGEMASTER (limits –2.51 to 2.25).

Error distributions (Figure 7, bottom left) showed that EMERGINET had small, tightly clustered errors; URGENTIAPARSE exhibited slightly broader but well-centered errors; and TRIAGEMASTER demonstrated wide, poorly centered distributions. Class-specific F_1-scores (Figure 7, bottom right) revealed that URGENTIAPARSE achieved consistently high scores across the represented GEMSA categories, whereas EMERGINET and TRIAGEMASTER showed poorer and more uneven performance.

XSL•FO

Impact of Data Modality: Structured Versus Unstructured Inputs

Analysis of input data type impact (Table 4) revealed that structured data (vital signs, demographics, and chief complaint codes) yielded slightly better performance than unstructured transcripts for URGENTIAPARSE (*z* score 1.806 vs 1.628) and TRIAGEMASTER (–4.790 vs –4.949), whereas EMERGINET showed minimal difference (–1.357 vs –0.993). These findings suggest that (1) vital signs and demographic data contain substantial triage-predictive information; (2) LLMs can extract meaningful patterns from both modalities; and (3) optimal performance likely requires multimodal integration. The relatively small performance gap between modalities for URGENTIAPARSE indicates that the transcript-based LLM captures much of the clinically relevant information, supporting the feasibility of voice-based triage assistance systems.

Discussion

Principal Findings

This retrospective proof-of-concept study developed and compared 3 AI architectures for ED triage prediction using real nurse-patient interaction data and national triage standards. Of 73,236 ED visits over a 7-month period, 657 (0.90%) patients with complete audio recordings and structured data were included in the analysis. The LLM-based model (URGENTIAPARSE) demonstrated superior performance across multiple metrics (composite *z* score=2.514, F_1-score=0.900, AUC 0.879, weighted κ=0.800, $P<.001$) compared with the JEPA-based EMERGINET (*z* score=0.438), the NLP-based TRIAGEMASTER (*z* score=–3.511), and current nurse triage practices (*z* score=–4.343). Secondary analyses confirmed the superiority of URGENTIAPARSE for disposition prediction (GEMSA) and its robustness across structured and unstructured data modalities. However, severe methodological limitations—particularly extreme selection bias, overfitting, sparse representation of high-acuity cases, and the monocentric design—preclude immediate clinical deployment and underscore the need for substantial additional validation.

Comparison With Prior Work

Our findings align with and extend previous research on AI-assisted triage. The URGENTIAPARSE F_1-score (0.900) substantially exceeds that of prior French ED triage models: Clinical BELGPT-2 achieved an F_1-score of 0.62 [12], while external models such as Mistral 7B and Llama 3 8B demonstrated moderate performance, with larger models (Mixtral 8x7B) underperforming [11]. Our results also surpass those reported in the original FRENCH scale validation studies (AUC 0.83-0.86 for hospitalization prediction [1,25]) when applied by nurses, suggesting that AI has the potential to enhance triage accuracy.

However, unlike previous studies, we observed severe overfitting despite the use of regularization techniques. This likely reflects the extremely small effective sample size relative to model complexity (657 cases for the 137-million-parameter FlauBERT base), the high-dimensional input space (768-dimensional embeddings plus structured features), and substantial class imbalance with sparse representation of high-acuity cases. Recent studies on LLM hallucinations [13] and time-series forecasting [26] suggest potential mitigation strategies, including semantic entropy–based uncertainty quantification, prompt engineering, and backbone reprogramming—approaches that warrant investigation in future iterations.

Our calibration analysis revealed class-specific heterogeneity, consistent with recent findings on proper scoring rules for multiclass classification [14]. The observation that URGENTIAPARSE generates sparse, high-confidence predictions rather than well-distributed probability estimates suggests that the model may benefit from postprocessing approaches such as temperature scaling or Platt scaling to improve probability calibration before clinical implementation.

Prior studies have identified biases in triage decisions related to patient sex, nurse experience, and pain reporting [11,12]. Although our study did not explicitly assess these biases, the gold-standard consensus process and AI model evaluation framework established here could facilitate future bias detection studies. For example, systematic perturbation analyses, such as modifying patient sex references in transcripts while holding all other factors constant, could be conducted to evaluate potential model sensitivity to demographic attributes.

Clinical Implications and Deployment Considerations

If validated prospectively across diverse settings, LLM-based triage support could enhance patient safety and operational efficiency through real-time decision support that highlights high-risk cases for immediate review; quality assurance by flagging discrepancies between nurse and AI triage for senior clinician verification; training tools that provide immediate feedback to novice nurses; and workload redistribution during surge periods by prescreening low-acuity cases. However, multiple critical barriers must be addressed before deployment.

The perfect training accuracy (1.0) with poor validation performance (~0.5) observed for URGENTIAPARSE indicates

XSL•FO
RenderX

severe memorization rather than learning generalizable patterns. Potential solutions include substantial data augmentation, such as paraphrasing, synonym replacement, and back-translation for transcripts, combined with controlled perturbations of vital signs. More aggressive regularization strategies, including higher dropout rates, stronger L2 penalties, and techniques such as mixup or cutmix, may also help. Model simplification through adapter layers or low-rank adaptation (LoRA) fine-tuning of FlauBERT, rather than full model fine-tuning, could further reduce overfitting. In addition, ensemble methods that average predictions from multiple diverse architectures, transfer learning from related domains (eg, ambulance call triage or primary care urgency assessment), and active learning to selectively acquire cases with the highest model uncertainty all warrant investigation.

With only 4 (N=657) class 1 cases (0.61%) and 86 (13.1%) class 2 cases, we cannot reliably evaluate model performance for the most critical patients—those for whom undertriage could be fatal. Prospective deployment would therefore require conservative threshold selection that prioritizes overtriage over undertriage; mandatory senior clinician override for any AI-suggested downgrade relative to nurse triage; and real-time monitoring dashboards tracking undertriage events and associated patient outcomes, including ED length of stay, ICU admission, in-hospital mortality, and 72-hour return visits. In addition, automatic model deactivation should be triggered if the undertriage rate exceeds predefined safety thresholds.

Current probability estimates also require post hoc calibration—using methods such as temperature scaling, Platt scaling, or isotonic regression—to ensure reliable confidence estimates. Furthermore, implementing abstention mechanisms, whereby the model declines to issue a prediction when uncertainty exceeds a predefined threshold, may improve safety by deferring ambiguous cases to human judgment. Techniques from conformal prediction could additionally provide statistically rigorous uncertainty quantification with formal coverage guarantees.

Although SHAP values provide token- and feature-level explanations for URGENTIAPARSE predictions, clinicians require intuitive, actionable insights that align with real-world decision-making. Future work should therefore focus on generating natural language explanations—for example: “Triage level 2 suggested due to elevated heart rate (124 bpm), chest pain complaint, and description of respiratory distress.” Contrastive explanations could further enhance interpretability and trust, such as “If the heart rate were within the normal range, the predicted triage level would be 3.” Such counterfactual framing helps clinicians understand which features are most influential and how changes in patient presentation might alter the recommendation.

Real-time deployment requires inference latency under 5 seconds, a requirement met by the current 312-ms latency. However, seamless electronic health record integration without disrupting nurse workflow remains essential. An intuitive user interface that displays AI recommendations with confidence levels and key supporting features, combined with easy override mechanisms requiring mandatory documentation of the rationale, would facilitate adoption. Establishing feedback loops in which clinician corrections are logged for continuous model improvement completes the integration requirements.

AI triage support raises profound liability questions, with unclear responsibility among nurses, AI developers, and hospitals when undertriage occurs. Algorithmic bias is another concern, as model performance may vary by patient demographics, insurance status, or language. Privacy considerations regarding the secure handling of audio recordings and transcripts must be addressed, and equity requires ensuring that all patient subgroups receive accurate predictions. Comprehensive fairness audits, bias mitigation strategies, and clear governance frameworks must precede any deployment.

Limitations

This study has multiple substantial limitations that constrain interpretation and generalizability across several domains.

The severe selection bias represents perhaps the most concerning methodological limitation. Only 657 of 73,236 (0.90%) ED visits had usable recordings, representing <1% of eligible encounters. Recordings were limited to volunteer nurses (fewer than 10) during feasible moments, likely excluding the highest-acuity cases requiring immediate intervention without time for a structured interview; chaotic shifts with multiple simultaneous arrivals; patients with altered mental status, language barriers, or communication difficulties; nurses uncomfortable with recording technology; and specific periods, such as overnight and weekends. The included cohort had slightly lower acuity than the broader ED population (P=.02), introducing systematic bias that limits generalizability to the real-world case mix. Future studies must implement systematic recording protocols that capture consecutive cases across all shifts, nurses, and patient types to obtain representative samples.

The sparse representation of the highest-acuity classes constitutes the most critical limitation for clinical deployment. Out of 657 cases, class 1 included only 4 (0.61%), class 2 included 86 (13.1%), and no class 3A or class 6 cases were observed. This extreme imbalance severely limits model training on high-risk cases, where undertriage has the greatest consequences. Reliable performance estimation for rare but critical categories becomes impossible, as CIs for class 1 metrics are extremely wide. The ability to detect undertriage patterns that could lead to preventable morbidity or mortality therefore remains fundamentally constrained. Generalization to settings with different acuity distributions also cannot be assessed. Class-specific performance metrics, particularly sensitivity for classes 1-2, have limited reliability and require validation in datasets with adequate representation across the full triage spectrum. Techniques such as the synthetic minority oversampling technique or focal loss to address extreme class imbalance should be explored in future work.

The severe overfitting observed for URGENTIAPARSE fundamentally limits real-world applicability. The model achieved perfect training accuracy (1.0), whereas validation accuracy remained approximately 0.5, clearly indicating that the model memorized training examples rather than learning generalizable triage patterns. This overfitting persisted despite

XSL•FO
RenderX

dropout (P=0.3), L2 regularization ($\lambda=1\times10^{-5}$), and early stopping, suggesting that the effective sample size (n=657) is insufficient for the model complexity (137 million parameters in FlauBERT base). Although we report validation set performance rather than training set performance, the marked training-validation discrepancy signals a high risk of catastrophic failure on truly external data with different patient populations, nurse communication styles, or institutional protocols. Prospective external validation across multiple, diverse EDs is therefore essential before any consideration of clinical use. Potential solutions include more aggressive regularization, model simplification through adapter layers or LoRA fine-tuning, ensemble methods, or the collection of substantially larger training datasets, with a target of over 10,000 cases for stable LLM fine-tuning.

The monocentric design severely constrains external validity. Conducted at a single French academic tertiary care hospital, the results may not generalize to community hospitals with different patient demographics, resource levels, and triage processes. Rural or low-volume EDs, with different case mix and staffing patterns, represent an entirely different operational context. Non-French health care systems using alternative triage scales, such as the Emergency Severity Index, Canadian Triage and Acuity Scale, Manchester Triage System, or Australasian Triage Scale, would require complete model retraining and revalidation. Non-French language contexts would likewise necessitate retraining language models on appropriate corpora. EDs serving culturally, linguistically, or socioeconomically distinct patient populations may exhibit fundamentally different triage patterns. Multicenter validation across diverse settings—including academic and community hospitals, urban and rural locations, and multiple countries—is therefore required to assess transportability and identify factors that affect model performance.

The exclusion of repeat ED visits creates an important gap in our understanding of model performance. By including only index visits, we cannot assess model behavior in patients with frequent ED utilization, complex chronic conditions requiring a longitudinal perspective, or evolving clinical presentations across multiple encounters. Repeat visitors often present atypically and may benefit most from AI-assisted triage, yet they were systematically excluded from model development. This exclusion may bias performance estimates upward if repeat visitors are more difficult to triage accurately.

Several concerns regarding gold-standard construction could introduce incorporation bias. Adjudicators reviewed complete transcripts and vital signs with unlimited time for deliberation, in sharp contrast to real-time nurse triage conducted under time pressure and with incomplete information. This fundamental difference in decision-making context may overestimate AI-human agreement, as both the AI and gold-standard adjudicators had access to complete information unavailable to real-time nurses. Although blinded to outcomes, adjudicators were aware that they were establishing a research gold standard rather than making operational decisions with immediate consequences, which may have influenced risk tolerance and the willingness to assign higher acuity levels. The initial interrater agreement (κ=0.72) indicates substantial but not perfect consensus, with a 23.5% disagreement rate suggesting meaningful variability in expert interpretation even with complete information. The gold standard therefore reflects retrospective expert judgment, which may differ from optimal real-time triage, particularly when information available only after initial presentation is considered. A sensitivity analysis excluding cases with nurse-gold-standard discrepancies over 1 level yielded similar results, partially mitigating this concern but not eliminating it.

Limited independent validation of the FRENCH scale itself represents an often overlooked limitation. Although the FRENCH scale serves as the French national standard, independent validation studies remain limited beyond the original 2009 and 2019 publications [1,25]. The original validation reported an AUC of 0.858 for hospitalization prediction and moderate correlations with resource utilization. A 2019 validation study including 29,423 patients reported similar findings, with an AUC of 0.83 and moderate but significant correlations between triage level and resource utilization or testing [25]. Thus, even compared with FRENCH validation studies, the URGENTIAPARSE model demonstrates superior AUC performance relative to nurses who conducted triage in those studies. However, our gold-standard consensus process effectively establishes an “ideal FRENCH application” and does not validate whether FRENCH itself optimally predicts patient outcomes. Future research should therefore evaluate AI predictions against objective clinical end points, such as ICU admission, in-hospital mortality, 72-hour return visits, and length of stay, independent of triage scale assignment, to assess true clinical utility rather than agreement with an imperfect reference standard.

The lack of prospective validation and real-world testing fundamentally limits our ability to make clinical recommendations. This retrospective analysis cannot assess real-time inference performance or the integration challenges that inevitably arise during deployment. The impact on actual triage decisions and nurse acceptance remains unknown and could substantially affect real-world utility. Effects on patient outcomes, ED workflow, and resource utilization also cannot be determined from retrospective data. Model degradation over time, as patient populations, disease patterns, or institutional practices evolve through concept drift, represents a realistic threat that requires prospective monitoring. Rare failure modes and edge cases typically become apparent only during large-scale deployment involving thousands or tens of thousands of predictions. Unintended consequences, such as deskilling of nurses who become overly reliant on AI recommendations, or gaming of the system if performance metrics become targets, could further undermine potential benefits. Prospective stepped-wedge cluster randomized trials comparing AI-assisted versus standard triage across multiple sites, therefore, represent essential next steps before any clinical implementation can be responsibly considered.

The absence of cost-effectiveness and implementation analyses limits informed adoption decisions. We did not evaluate the computational infrastructure costs required for deployment, including graphics processing unit servers, maintenance, and

XSL•FO
RenderX

updates, which may be substantial for resource-constrained hospitals. Training costs for nurses to use the system effectively also remain unknown and could be prohibitive if extensive instruction is required. The impact on triage time and ED throughput could be positive or negative, depending on implementation details. Cost per quality-adjusted life year gained represents the gold standard for health care economic evaluation, but requires long-term outcome data that are currently unavailable. Scalability challenges related to broad dissemination across diverse health care settings also remain unaddressed. Economic evaluation from a health system perspective is therefore essential for adoption decisions in the context of finite health care resources.

The absence of fairness and bias assessment represents a significant ethical limitation. We did not systematically evaluate whether model performance varies by patient demographics—including age, sex, race or ethnicity, insurance status, language, or socioeconomic status—potentially exacerbating health disparities. Prior work has identified sex-based and other biases in human triage decisions [11,12]; AI systems may perpetuate or amplify these biases if they are not explicitly addressed during development. If the model performs worse for already disadvantaged populations, deployment could worsen existing health inequities. Comprehensive fairness audits stratified by protected characteristics are therefore required before deployment, along with bias mitigation strategies if disparities are identified. Partnerships with ethicists, patients, and advocacy groups to define fairness metrics aligned with societal values should precede any clinical implementation.

Technological and data quality constraints affected the study throughout. Audio recording quality varied substantially, leading to transcription errors that may have affected model input quality in unpredictable ways. Equipment loss and technical failures resulted in 24 exclusions (3.5% of recorded cases), suggesting that real-world deployment would encounter similar challenges. Missing data for certain vital signs (<2%) required imputation using training set medians, which may have introduced bias. Real-world deployment would face these and additional challenges, necessitating robust handling of noisy, incomplete, or corrupted inputs with graceful degradation rather than catastrophic failure. The model's behavior when confronted with poor-quality audio, incomplete vital signs, or technical failures remains unknown.

The lack of uncertainty quantification and explicit abstention mechanisms precludes safe clinical deployment. The model currently provides point predictions without well-calibrated CIs or explicit abstention when uncertainty is high. Clinical deployment requires principled uncertainty quantification—using methods such as conformal prediction, Bayesian approaches, or ensemble disagreement—to determine when deferral to human judgment is warranted. Without such mechanisms, the model may generate highly confident yet incorrect predictions in novel situations outside its training distribution. The sparse prediction patterns observed for URGENTIAPARSE may reflect implicit abstention behavior that should be explicitly characterized; however, we have not systematically examined when or why the model declines to issue predictions.

Limited interpretability persists despite SHAP analysis. Although SHAP values provide mathematical attributions indicating which input features most influenced each prediction, they may not align with clinical reasoning patterns or offer actionable insights for clinicians. A nurse or physician may not find numerical feature importance scores intuitive or helpful in understanding why the AI generated a specific recommendation. Natural language explanation generation that translates SHAP values into clinically meaningful statements remains underdeveloped. User studies assessing interpretability from the clinician perspective are therefore needed to determine whether these explanations facilitate, rather than hinder, clinical decision-making.

Regulatory and legal uncertainties cloud the path to clinical implementation. This research prototype has not undergone regulatory review, such as Conformité Européenne (CE) marking in Europe or Food and Drug Administration (FDA) clearance in the United States, which would likely be required for medical device classification of clinical decision support software. The regulatory pathway for AI-based triage support systems remains unclear and continues to evolve. Legal liability frameworks for AI-assisted triage are also poorly defined. When undertriage occurs with AI assistance, responsibility among nurses, AI developers, and hospitals remains ambiguous. These legal and regulatory uncertainties must be resolved before widespread deployment can proceed.

Finally, the absence of a continual learning framework limits long-term sustainability. Static models trained on historical data inevitably degrade as patient populations, diseases, and clinical practices evolve. Deployment would therefore require active monitoring of model performance in production; detection of performance degradation or concept drift; triggered retraining protocols when performance declines; and potentially online learning mechanisms to adapt to changing patterns while maintaining safety. We have not developed or validated any such infrastructure. Without continual learning capabilities, the model would become progressively obsolete, even if initially successful.

Despite these numerous and substantial limitations, this study provides important proof-of-concept evidence that LLM architectures can achieve high accuracy for ED triage prediction when evaluated using carefully collected retrospective data. The study also establishes a rigorous evaluation methodology that incorporates multiple complementary metrics and comprehensive error analysis, upon which future research can build. The limitations outlined above provide a detailed road map for the substantial additional work required before clinical translation can be responsibly considered, including the specific methodological improvements, additional studies, and infrastructure development necessary to support safe and effective deployment.

Future Research Directions

Building on these findings and addressing the identified limitations, future research should prioritize several key areas.

XSL•FO
RenderX

Trials across more than 10 diverse EDs—including academic and community hospitals, urban and rural settings, and varied patient demographics—with systematic consecutive case enrollment targeting more than 10,000 patients would enable assessment of external validity, detection of site-specific effects, and adequately powered subgroup analyses. A stepped-wedge cluster randomized design would allow causal inference regarding the impact on patient outcomes, including mortality, length of stay, ICU admission rate, and 72-hour return visits, while controlling for temporal trends.

Oversampling the highest-acuity encounters in classes 1-2 through deliberate recording protocols during trauma activations, stroke alerts, cardiac arrests, and other critical presentations would enable reliable detection of undertriage and robust safety evaluation. This targeted data collection would address one of the most important current limitations.

Systematic comparison of advanced overfitting mitigation strategies is also warranted. Such evaluation should include parameter-efficient fine-tuning approaches (eg, LoRA, adapters, and prompt tuning); aggressive data augmentation (eg, back-translation, paraphrasing, synonym replacement, and controlled vital sign perturbations); semisupervised learning leveraging unlabeled transcripts; multitask learning jointly predicting triage, disposition, resource utilization, and outcomes; transfer learning from related domains such as ambulance call triage or primary care urgency assessment; and ensemble methods combining diverse architectures with different inductive biases.

Systematic assessment of model behavior under a range of perturbations would strengthen confidence in its robustness. These should include adversarial attacks representing intentional gaming; distribution shifts due to seasonal variation, pandemics, or novel diseases; missing data resulting from incomplete vital signs, silent patients, or technical failures; transcription errors arising from speech recognition failures; and edge cases, such as rare presentations, complex comorbidities, or psychiatric crises. Developing certified robustness guarantees represents an important objective.

Stratified performance evaluation by protected characteristics—including age, sex, race or ethnicity, insurance status, language, and socioeconomic status—combined with detection of disparate impact, root cause analysis of identified biases, and rigorous testing of mitigation strategies (eg, reweighting, fairness constraints, or adversarial debiasing) would address equity concerns. Partnerships with ethicists, patients, and advocacy groups to define fairness metrics aligned with societal values are essential.

Development of natural language explanation generation, contrastive explanations that articulate how predictions would change if specific features differed, visualization tools highlighting salient features, and user interface optimization informed by clinician feedback would enhance interpretability. Human factors studies evaluating how AI recommendations influence decision-making—including risks of automation bias (overreliance) or dismissiveness (underreliance)—would further inform safe implementation.

Rigorous cost-effectiveness analysis from a health system perspective; budget impact modeling; implementation barrier assessment; stakeholder engagement with nurses, physicians, administrators, and patients; workflow redesign; training program development; and sustainment planning would support adoption. Qualitative studies exploring nurse and physician attitudes, concerns, and acceptance would help identify potential obstacles early.

Infrastructure for continual model performance monitoring, concept drift detection, triggered retraining protocols, online learning mechanisms, and transparent reporting to end users and regulators would maintain performance over time. Development of living systematic reviews tracking field performance as deployment expands would build the evidence base.

Exploration of synergies with AI-assisted diagnosis supporting downstream care decisions, predictive models for ED crowding and resource planning, automated documentation reducing nurse burden, and early warning systems for deterioration after initial triage could create an integrated ecosystem. Emerging work on AI transforming health care from acute care to early prevention [27,28] suggests potential for broader impact across the care continuum.

Collaboration with regulatory agencies, including the European Medicines Agency and FDA, to establish appropriate oversight frameworks balancing innovation with patient safety, defining clinical validation requirements, and clarifying liability and postmarket surveillance obligations for AI medical devices would facilitate responsible translation.

Conclusions

This study demonstrates that LLM-based AI (URGENTIAPARSE) can achieve high accuracy for ED triage prediction, outperforming traditional NLP (TRIAGEMASTER), JEPA (EMERGINET), and current nurse triage practices when validated against a senior clinician consensus gold standard. With an F_1-score of 0.900, AUC of 0.879, weighted κ of 0.800, and 90% exact agreement, the LLM model shows promise for enhancing triage consistency and potentially supporting clinical decision-making.

However, severe methodological limitations mandate extreme caution. Critical barriers to clinical deployment include severe overfitting, with perfect training accuracy but poor validation performance indicating an inability to generalize beyond the training data; extreme selection bias, with only a 0.9% (657/73,236) inclusion rate limiting representativeness; sparse high-acuity case representation, with only 4 class 1 cases precluding reliable undertriage risk assessment where stakes are highest; a monocentric design constraining external validity; retrospective analysis without prospective real-world validation; and absent economic, workflow, fairness, and regulatory analyses.

Before any consideration of clinical deployment, this AI triage support system requires large-scale prospective multicenter validation targeting more than 10,000 cases across diverse settings; comprehensive overfitting mitigation and model robustness enhancement; targeted high-acuity case collection

XSL•FO
RenderX

enabling undertriage safety evaluation; fairness audits and bias mitigation strategies; post hoc calibration and uncertainty quantification with abstention mechanisms; interpretability enhancement with natural language explanations; human factors studies and workflow integration testing; economic evaluation and implementation planning; regulatory review and approval; and continuous performance monitoring infrastructure with concept drift detection.

While this proof-of-concept establishes technical feasibility and identifies the most promising architecture among the tested alternatives, the substantial gap between current evidence and safe clinical deployment must be acknowledged transparently. AI-assisted triage holds potential to improve patient safety, enhance consistency, reduce cognitive burden on nurses during surge periods, and support quality assurance—but realizing these benefits responsibly requires rigorous validation, thoughtful implementation, continuous monitoring, and humility about current limitations. This study provides a foundation and road map for that essential future work.

Abstract

Background: In the field of traditional Chinese medicine (TCM), diagnostic work based on tongue images to recognize the physical constitution is a process of collecting clinical information, reasoning, and combining the patient's tongue image features with questioning. It is necessary to simulate the recognition of pathological information of tongue images by TCM practitioners and professional dialogue based on tongue image features, which helps to develop an intelligent interactive system for TCM diagnosis.

Objective: This study aimed to develop and validate a vertical model of the TCM domain with TCM's understanding and reasoning capability for tongue images.

Methods: A TongueVLM multimodal large model is designed, which includes a visual encoder module, a modal fusion module, and a language decoder module. First, the visual encoder based on the CLIP-ViT (Contrastive Language-Image Pre-Training With Vision Transformer) pretrained model is used for image patch, dimensionality reduction, and migration learning, which maps the high-dimensional tongue features into low-dimensional language encoding vectors. Further, a modal fusion module with a residual architecture is applied to map visual features to a natural language word embedding space, realizing the conceptual alignment between visual encoding and TCM terminology. Finally, fine-tuning of visual instructions is performed based on the LLaMA (large language model meta artificial intelligence), and a TCM-domain large language model with 7B parameters is trained.

Results: The constructed multimodal dataset has 3 test datasets, and experiments are conducted using 3000 samples from each test dataset, respectively. Experimental results indicate that the TongueVLM model outperforms general-purpose large models on all 3 tasks. On the multimodal test dataset, the TongueVLM model achieved accuracy rates of 79.8%, 78.6%, and 60.7% in evaluation tasks respectively, it achieves 9.1%, 8.4%, and 1.1% in greater accuracy than LLaVA-OneVision, and is 7.5%, 7%, and 5.9% more accurate than Qwen2.5-VL-7B, with the text generation time being around 24 tokens per second.

Conclusions: The TongueVLM model, which achieves tongue image description generation and physical constitution reasoning in TCM, is suitable for the application of a Chinese medicine intelligent diagnosis system.

KEYWORDS

vision-language model; tongue image description generation; visual constitution reasoning; visual dialogue; intelligent diagnosis of traditional Chinese medicine (TCM)

Introduction

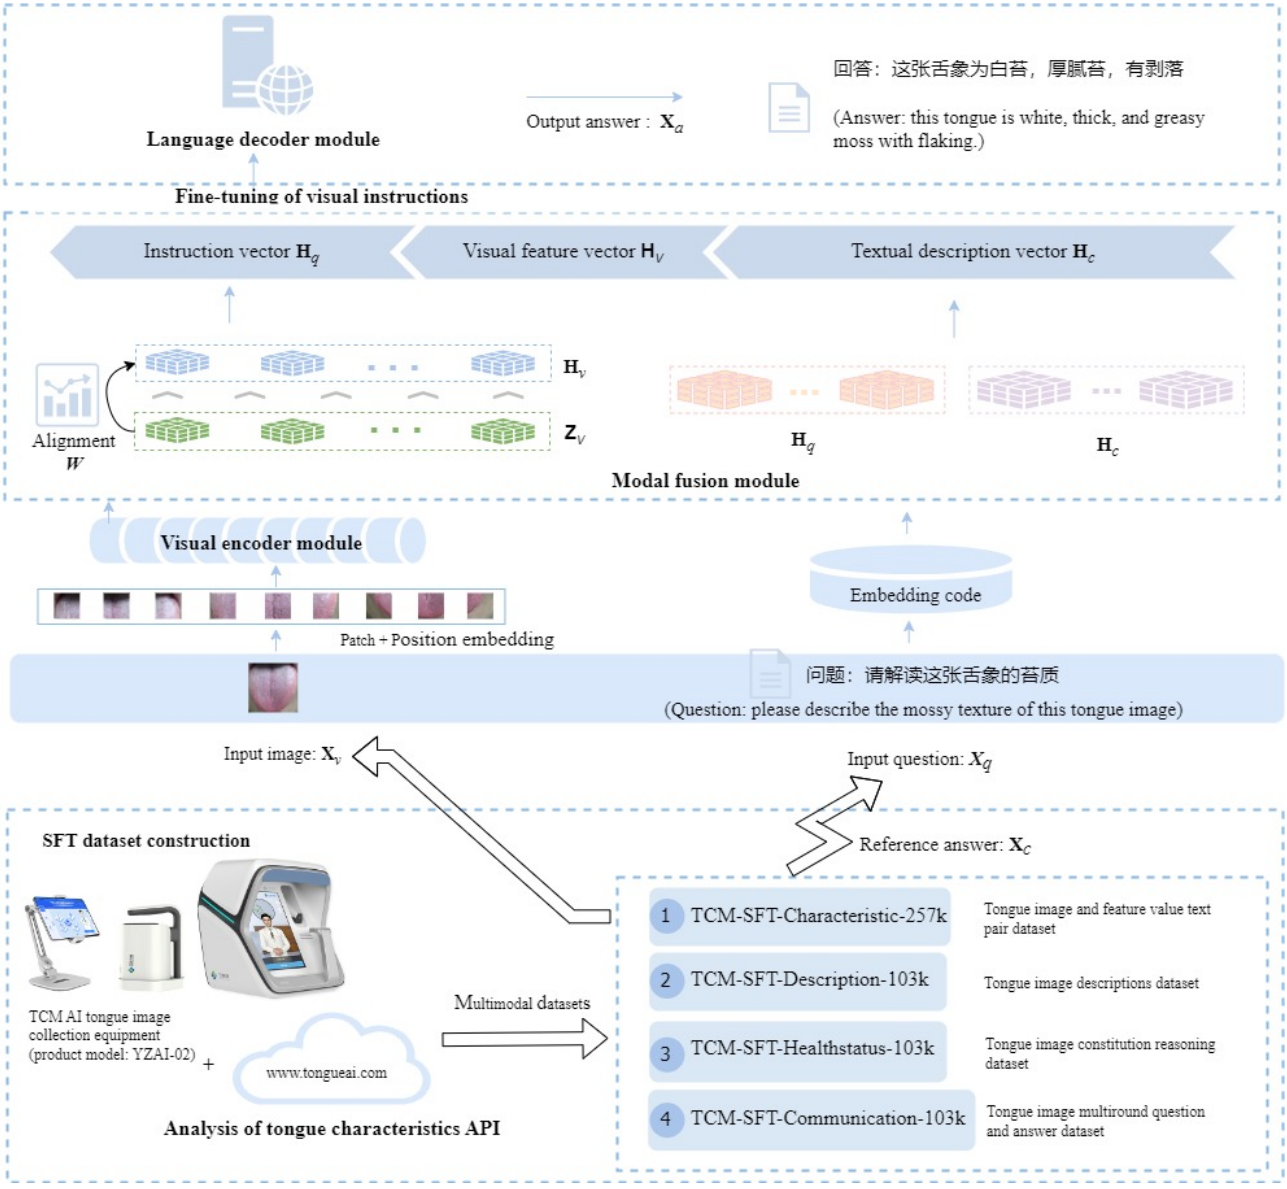
In recent years, the research focus on computer vision has gradually shifted toward innovative transformers and their variant architectures. These studies have made significant progress in the 3 basic tasks of image classification, object detection, and image segmentation, along with in-depth experiments on visual-textual multimodal data validity. The visual transformer model, represented by the vision transformer, approaches or even surpasses the convolutional neural network approach in several benchmark tests [1-14]. The key technique of the vision transformer is to construct image-to-vector transformations and effectively maintain the features of the image, bridging the gap between language and vision. Lava family [15-17], GPT-4v [18], and Gemini 1.5 [19] visual-language multimodal modeling have even ushered artificial intelligence-generated content into a new era of visual applications, and the field of medicine has received increasing attention from researchers [20-26].

In the field of traditional Chinese medicine (TCM), diagnostic work based on tongue images to recognize the physical constitution is a process of collecting clinical information, reasoning, and combining the patient's tongue image features with questioning. It is necessary to simulate the recognition of pathological information of tongue images by TCM practitioners and professional dialogue based on tongue image features, which helps to develop an intelligent interactive system for TCM diagnosis. However, the following limitations still exist in the current investigation: (1) high cost of acquisition equipment and collection of clinical data, mostly relying on publicly available datasets, and prominent data sample noise problems; (2) lack of qualitative or quantitative specialized labeling data; (3) lack of validation and analysis of the visual encoding results at the modal fusion stage; and (4) the evaluation metrics of the trained models focus on technical performance and ignore professional human judgments.

Previous studies have shown that, based on the image recognition model in the field of TCM applications, they fused the traditional image features of the tongue with deep tongue features and combined them with a machine learning model to construct a physical constitution identification, which compensated for the lack of information in a single modality and improved the accuracy of constitution classification [27-29]. In terms of training a vertical model of TCM based on a large language model (LLM), we constructed a pretraining dataset and an instruction fine-tuning dataset oriented to TCM and adopted a 2-phase training method of continuous pretraining and supervised fine-tuning to develop an LLM of TCM [30-35]. This model outperforms the existing models in several evaluation metrics and can play a role in TCM consultation.

Medical applications based on multimodal large models are also favored by researchers. A dataset containing 5.3 million+ image-text pairs was used to train the UniMed-CLIP model, which outperforms the existing health care visual language models (VLM) with 0-shot performance [36]. Multimodal health care models, which introduce evaluation metrics and frameworks and perform well in multimodal Q&A (question and answer) and text-based Q&A tasks [33,37]. BiomedCLIP with LLaMA-3 (large language model meta artificial intelligence) to realize a lightweight and efficient medical visual Q&A model [38]. Med-VQA interpretability by localizing image preference regions [39] enhanced the performance of biomedical VLMs by using instruction fine-tuning and multi-image training, respectively [40,41]. Aligned visual features with medical concepts and Med-VQA, enhanced the generation of large models, and achieved excellent performance on public datasets [42-44].

The primary aim of this study is to develop and validate TongueVLM, a specialized VLM for TCM tongue diagnosis. Specifically, our objectives were to (1) design a novel multimodal architecture that effectively aligns visual features of tongue images with domain-specific TCM textual knowledge; (2) construct a high-quality, multimodal dataset for supervised study, and end-to-end training on the TCM dataset; and (3) evaluate the performance of TongueVLM against established baseline models, and validation multimodal capabilities across 3 tasks of tongue feature description generation, physical constitution reasoning, and multiround dialogue.



Methods

Overall Architecture of TongueVLM

Our TongueVLM model uses a hybrid architecture combining the visual encoder module, modal fusion module, and language decoder module. First, the visual encoder based on the CLIP-ViT (Contrastive Language-Image Pre-Training With Vision Transformer) pretrained model is used for image patch, dimensionality reduction, and migration learning. Further, a multimodal fusion module with a residual architecture is applied to map visual features to the natural language word embedding space, realizing the conceptual alignment between visual encoding and TCM terminology. Finally, a visual-textual instruction dataset is constructed to perform multimodal instruction fine-tuning based on the LLaMA general-purpose LLM. As a result, a vertical model of the TCM domain with TCM understanding and reasoning capability for tongue images is obtained. The realization procedure is shown in Figure 1.

Model Design

Phase 1: Visual Encoder Module

In the first phase, the visual encoder module of the network was designed. Applying tongue images with TCM feature description text pair data in CLIP-ViT pretrained model migration learning. Semantically rich text is used as training labels to project the image feature representations into a kind of encoding that is like the text encoding space, as shown in Figure S1 in Multimedia Appendix 1.

First, we speak of image patch dimensionality reduction preprocessing. Scale the input image $\mathbf{x}_v \in (H,W,C)$ to $\mathbf{x} \in (h,w,C)$ (h is the height, w is the width, and C is the number of channels). Sequence of blocks that transform x into $\mathbf{x}_p \in (N^2,p^2C)$ for image patch operations. The number of blocks is $N^2=(h\times w)/p^2$, and the block dimension is (p^2C); where p is the image patch size. A sequence of blocks is converted into a patch embedding vector $\mathbf{E}_{patch}' \in (N^2,dim)$ by a linear transformation, where dim=1024, p=14, and N= 24. $\boldsymbol{x}_0$ is the zeroth encoding vector taken at the output layer of the transformer encoder, which serves as the visual feature encoding. By adding a learnable embedding vector before the image patch embedding vector E_{patch}, the image block embedding vector becomes $\mathbf{E}_{patch} \in (N^2+1,dim)$. The absolute position encoding algorithm is used to create a learnable position embedding vector $\mathbf{E}_{pos} \in (N^2+1,dim)$ for the block position. The elementwise summation operation on $\mathbf{E}_{patch}$ and $\mathbf{E}_{pos}$ yields an embedding vector $\mathbf{z} \in (N^2+1,\text{dim})$ that incorporates spatial positional encoding and visual representations.

XSL•FO
RenderX

Second, transformer encoder processing. The encoder consists of a stack of **L**=24 encoding layers, and the encoder inputs are image feature embedding vectors $z \in (N^2+1, dim)$. Each encoding layer consists of 2 unitary structures connected: the first unitary structure consists of a multihead self-attention layer and a layer normalization, as well as a residual connectivity module, and the second unitary structure consists of a feedforward fully connected layer multilayer perceptron and a layer normalization, as well as a residual connectivity module.

Phase 2: Modal Fusion Module

The modal fusion module is designed with a multilayer linearly transformed residual architecture, which is a bridging module between the visual model and the language generation model. The tongue visual encoding features are projected into the natural language word embedding vector feature space to solve the conceptual alignment problem of visual encoding with TCM terminology.

The modal fusion module design uses a combination of multiple linear layers and GELU (Gaussian Error Linear Unit) activation functions, as shown in the middle region of Figure S2 in Multimedia Appendix 1. This design allows the modal fusion layers to transform visual features while maintaining essential nonlinear characteristics. In addition, the introduction of the residual structure enables the model to realize efficient feature transformation and projection while fully preserving the integrity of the original visual features.

Splice visual encoding with textual word-embedded encoding to form a sequence of visual-textual instructions. First, the visual encoding feature $\mathbf{Z}_v$ is converted into a visual feature vector $\mathbf{H}_v$, and the textual instruction and textual description are converted into an instruction vector $\mathbf{H}_q$ and a textual description vector $\mathbf{H}_c$ by word embedding encoding, respectively. Thereafter, the vectors are spliced in the order of instruction, visual, and textual description to form the visual-textual fusion instruction sequence data.

Phase 3: Language Decoder Module

The modal fusion module connects the visual encoder and language decoder for end-to-end fine-tuned training on the constructed visual-textual data for a variety of downstream generative output tasks, such as visual quizzing, image description generation, and visual dialogue. The language decoder module chooses LLaMA, a pretrained model with good support for Chinese, which consists of a 32-layer transformer decoder layer, and each decoder layer contains an RMSNorm normalization layer, a grouping attention mechanism, and a multilayer perceptron projection layer. The network architecture is shown on the right side of Figure S2 in Multimedia Appendix 1.

During training, each input image $\mathbf{X}_v$ is associated with a few rounds of dialogue data, where each round of question description  can be defined as follows.

The visual encoder module extracts the visual feature V_x (the feature representation obtained by encoding the input image using a visual encoder) and caches it into the context, and the subsequent t-th round (t>1) of training data only needs to input the new instruction  and answer  . The model automatically fuses the historical dialogue information with the initial visual feature $\mathbf{V}_x$ and builds a spliced sequence of instructions  to realize multiple rounds of dialogue training through cross-round dependency.

The instruction sequence  of multiple rounds and the corresponding output reply text  are temporally spliced into a uniform sequence  , the autoregressive training objective is used for instruction tuning, and the maximum likelihood function optimization model is formulated as follows:

where θ is a trainable parameter (the training process is to adjust to maximize the likelihood function) and $\mathbf{X}_{instruct,<i}$,$\mathbf{X}_{a,<i}$ is the instruction sequence and answer sequence of all rounds before the current prediction x_i, respectively. $p(\mathbf{X}_a|\mathbf{X}_v,\mathbf{X}_{instruct})$ is the probability of predicting $\mathbf{X}_a$ under the current $\mathbf{X}_v$ and $\mathbf{X}_{instruct}$ is based on the premise of guaranteeing the accuracy of the result of $\mathbf{X}_a$under the premise that the prediction results of all rounds before the current round takes the maximum probability value.

In other words, the model uses the information accumulated in the history of the previous *t*-1 rounds of the conversation (especially the context of the textual instructions) to accurately estimate the probability distribution of the generated results in the t-th round. In this way, the model can maintain its understanding of the context over consecutive rounds of interactions and accordingly generate accurate responses associated with the content of the previous rounds.

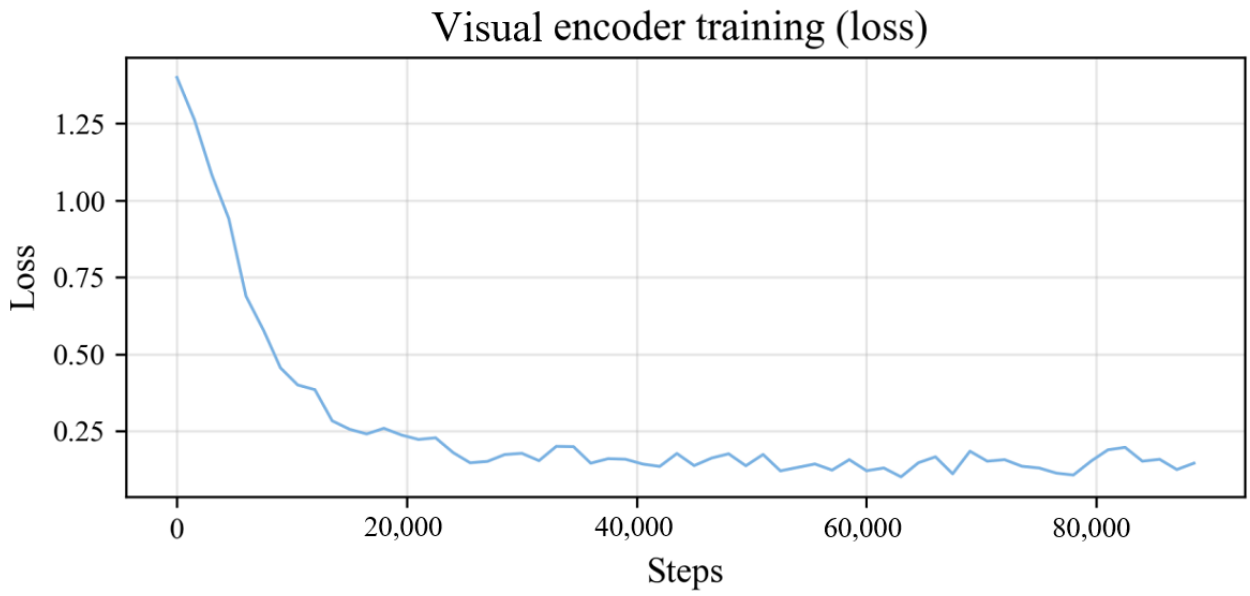
Datasets and Preprocessing

The 90,000 tongue images collected by the TCM artificial intelligence tongue image collection equipment (product model: YZAI-02) jointly developed by Hefei Cloud Diagnostics Information Technology Co and Anhui University of TCM were used, which consists of a standard LED ring light source, a portable collection device, an ultrahigh-definition camera, and a host computer, as well as supporting software. The tongue feature recognition API (application programming interface) was applied to preprocess the collected tongue images with color correction, tongue region segmentation, and tongue moss and tongue texture separation, after which tongue feature analysis was performed on the tongue images to obtain more than 40 types of qualitative or quantitative text containing tongue color, tongue texture, moss color, moss texture, and sublingual collateral data and 10 types of TCM constitution [45].

The TongueVLM training datasets are constructed, including TCM feature description data (traditional Chinese medicine–supervised fine-tuning, TCM-SFT (TCM–supervised fine-tuning)-Characteristic-257k, and TCM-SFT-Description-103k), multiround Q&A data

XSL•FO
RenderX

(TCM-SFT-Healthstatus-103k), and physical constitution reasoning data (TCM-SFT-Communication-103k). The methodology for constructing the dataset is described in Multimedia Appendix 1. The distribution of the tongue image features in the dataset is shown in Figures S3 and S4 in Multimedia Appendix 1.



Model Training Strategy

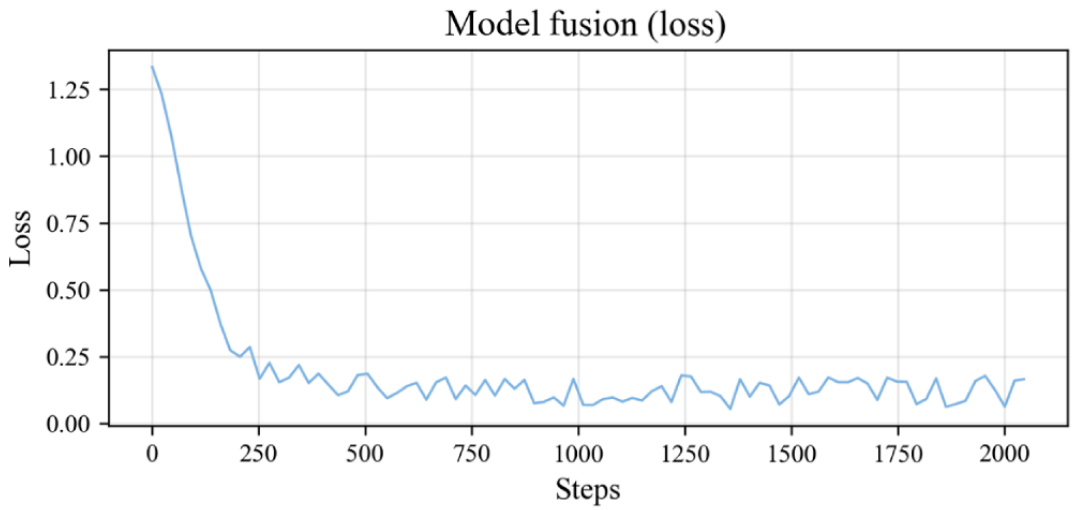
Stage 1: Pretraining of the Visual Encoder

TCM tongue characterization datasets (TCM-SFT-Characteristic-257k) of 257,000 tongue images and characterization texts are constructed, and the zeroth encoding vector used for learning by comparing the similarity between the tongue images and their corresponding tongue manifestation characterization is used for training the fine-tuning of the tongue visual encoder.

The process to obtain the visual encoder model is as follows: first, the training parameters openai/clip-vit-large-patch14-336 (OpenAI Inc, pretrained weights for the clip model on 400 million text-image pairs) were used as the initial weights for the visual encoder and the text transformer encoder. The Adam optimizer was used in the model training, with the smoothing constant betas set to (0.9, 0.999) and the weight decay parameter weight_decay set to 1e-3, the training batch size was set to 8, the learning rate was 5e-5, the number of training epochs was 3, and the maximum sequence length was 77. Second, the loss function uses the cosine similarity $Cos(I_m,T_n),m\in[1\ldots N^2],n\in[1\ldots N^2]$, where I_m is the embedding vector encoded by visual features and T_n is the embedding vector encoded by textual semantics. The optimization objective is to maximize the cosine similarity $Cos(I_j,T_j)$ between correct image-text pair embeddings while minimizing the cosine similarity $Cos(I^j,T^k),j\neq k$ of incorrect image-text pair embeddings. The results show that the loss value stabilizes after 3 epochs of training, and the loss curves are shown in Figure 2.

Figure 2. Visual encoder training loss and dynamic learning rate curves. The loss curve shows that after 3 rounds of training, the training loss of modal fusion has gradually stabilized, indicating that the model is beginning to converge.

Stage 2: Training of the Fusion Modal



TCM tongue description datasets (TCM-SFT-Description-103k) of 103,000 tongue images and description text are constructed, the visual encoder of TongueVLM and the network weights of the LLM are frozen, the visual-textual multimodal instruction data are fed into the LLM, and the modal fusion module is fine-tuned for training.

The process to obtain the modal fusion model is, first, the training method and parameters are as follows: the pretrained visual encoder weight parameters are loaded, the modal fusion layer weight parameters are randomly initialized, and only the modal fusion layer weights are allowed to participate in the gradient update. The Adam optimizer was used in the model training, with the smoothing constant betas set to (0.9, 0.999) and the weight decay parameter weight_decay set to 1e-4, the training batch size on each GPU is 8, the gradient accumulation step is 8, the learning rate is 2e-5, and the total number of iteration rounds is 3. Spend 30 hours to complete all the training on the Ubuntu (version 20.04.6, Canonical Ltd) platform using 2×RTX4090. Second, the loss function adopts the cross-entropy loss , where C is the total number of word lists, L is the length of the prediction sequence, $S_{n,i}$ denotes the probability that the word in the ith position is the nth word in the lexicon based on the previously known sequence, and $y_{n,i}$ denotes the ground-truth labels in the ith position in the prediction sequence (expressed as 1-hot encoding; ie, if the corresponding word in the position is the nth vocabulary word in the lexicon, only the first element of the 1-hot vector is 1 and the rest are 0), the goal is to minimize the loss; when the probability of each word in the prediction sequence is infinitesimally close to the actual vocabulary 1-hot encoding, that is, for any position i in the prediction sequence, $S_{n,i}\approx y_{n,i}$, the loss will be minimized, and

XSL•FO
RenderX

at this time, the model is considered to be in the optimal state. The results show that the loss value stabilizes after 3 epochs of training, and the loss curves are shown in Figure 3.

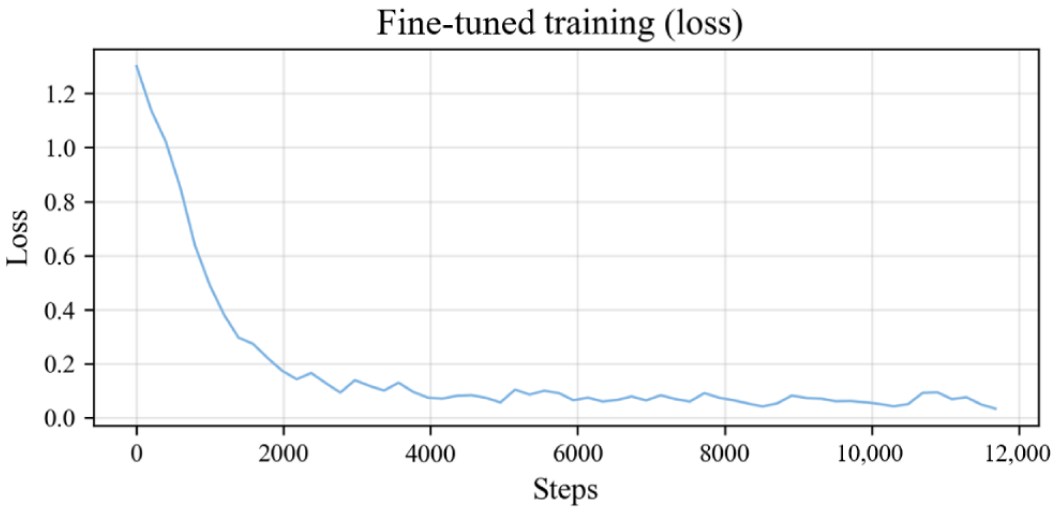


Figure 3. Loss curve of the modal fusion model. It shows that after 3 training epochs, the model enters a stable convergence state, and the loss curve for its modal fusion training stabilizes.

Stage 3: End-to-End Fine-Tuning of TongueVLM

The training data are the TCM multimodal dataset (training set 510,000; validation set 25,000). First, of the training method and parameters, load the pretrained visual encoder weight parameters and modal fusion layer weight parameters, freeze the weight parameters of the visual encoder, and allow only the modal fusion layer and the language decoder weights to participate in the gradient update. The Adam optimizer was used in the model training, with the smoothing constant betas set to (0.9, 0.999) and the weight decay parameter weight_decay set to 1e-4, the training batch size is set to 8 on each GPU, the number of gradient accumulation steps is 8, the learning rate is 2e-5, and the total number of iteration rounds is 3. It takes 135 hours to complete all the training on the Ubuntu (version 20.04.6, Canonical Ltd.) platform using 2×RTX4090. Second, of loss function, the cross-entropy loss function is adopted, and the loss curve is shown in Figure 4. After 4000 iterations, the loss tends to stabilize, and the loss fluctuation is very small when the number of iterations is 8000; currently, the model has converged.

Figure 4. Fine-tuned training loss curve of TongueVLM. It shows that with the increase of training epochs, the fine-tuning training loss of TongueVLM gradually tends to stabilize, indicating the effectiveness of the optimization algorithm and the basic convergence of the model after about 8000 iterations.

Ethical Considerations

This study was conducted in accordance with the ethical standards of the Declaration of Helsinki and was approved by the ethics committee of the Second Clinical Medical School of Anhui University of Chinese Medicine (Anhui Acupuncture and Hospital). The data used in this research were sourced from 2 distinct origins. First, for data from the Yunzhen 365 app, the data consisted of deidentified user-uploaded tongue images and associated text. All users of the app provided informed consent upon registration, agreeing to the use of their anonymized data for research purposes in accordance with the app's terms of

XSL•FO
RenderX

service and privacy policy. Second, for data from hospital records, the clinical data were obtained with approval from the relevant hospital's institutional review board (2022-zjks-25). Patient confidentiality was strictly maintained, and all personal identifiers were removed before analysis.

All procedures involving human data were reviewed and approved by the appropriate ethics committees. No additional identifiable personal information was accessed or used in this study. Participants received no compensation for their involvement in this study.

Results

Overall Performance of TongueVLM on Benchmark Tasks

The performance evaluation of the TongueVLM on the TCM multimodal test dataset is as follows.

To determine whether the answer texts generated by professional TCM practitioners are close in meaning to the standard answer texts in the corresponding test set, the evaluation is divided into 3 results; according to the degree of similarity in meaning, we define a score value Score for it, in descending order: consistent (Score=100), similar (Score=50), and irrelevant (Score=0); the accuracy of TongueVLM on the test set can be expressed as follows:  , where N is the number of test datasets and $Score_i$ is the score of the i-th test dataset.

To directly verify the effectiveness of the improved methods proposed in this study for the field of TCM, we selected visual multimodal models with similar architectures for comparison: LLaVA-1.5 (released in October 2023; Meta Platforms, Inc), LLaVA-1.6 (released in January 2024; Meta Platforms, Inc), and LLaVA-OneVision (released in August 2024; Meta Platforms, Inc). To demonstrate that good results can be achieved in the field of TCM through targeted model design without relying on massive general data, we also compared it with the current open-source multimodal large model benchmark Qwen2.5-VL-7B (released in August 2024; Alibaba Cloud). The accuracy and performance are shown in Table 1. The experimental results show that the TongueVLM model outperforms the general-purpose large model on all 3 tasks; it is 9.1%, 8.4%, and 1.1% more accurate than LLaVA-OneVision and 7.5%, 7%, and 5.9% more accurate than Qwen2.5-VL-7B. The generation time efficiency of each large model is similar, with the generation time of text being 24 tokens per second (approximately 40 words per second, given the word-to-token ratio in our dataset). Due to the optimization of the lexicon in the field of TCM, TongueVLM inference speed is slightly faster than the baseline model.

Table 1. Evaluation indicators for the output of the model. Shows the evaluation metrics of the model output. Experiments are conducted using the test dataset of 3 multimodal datasets, with each test dataset containing 3000 samples with detailed data represented as: number of scores 0, number of scores 50, number of scores 100/total number of test datasets.

Ablation Studies on the 3-Stage Training Strategy

Visual Encoding Feature Layer Comparison Experiment

The visual encoder extracts image features and outputs a total of 24 hidden layers (disregarding the hidden layer feature values before being input into the visual encoder), and it is necessary to select the appropriate layer as the visual feature information input. Therefore, comparison experiments were conducted on 3 datasets, and the last 5 hidden layers (20th to 24th) features were selected as the visual feature information to train the TongueVLM model; the accuracies on the test datasets are shown in Table 2 below. The experimental results show that the model performs best in all tasks when the penultimate layer of features output from the visual encoder, that is, the 23rd layer of features, is selected as the final visual feature information. These findings reveal that the visual features extracted at that depth level have significant advantages for multimodal intelligent analysis related to TCM tongue diagnosis.

XSL•FO
RenderX

Table 2. Accuracy of different hidden layers as a visual encoder in the test dataset. A total of 500 samples were randomly selected from each of the 3 multimodal test datasets for experimentation. It shows the accuracy of different hidden layers as visual encoders in the test dataset, with detailed data represented as: number of scores 0, number of scores 50, number of scores 100/total number of test datasets).

Modal Fusion Module Structure Experiment

To verify the reasonableness of the structure of the modal fusion module, 3 different neural network structures, namely, numbers 1 (Linear + GELU), 2 (Linear + GELU + Linear + GELU + Linear), and 3 (Linear + GELU + Linear + GELU + Linear + Linear + Res), are designed, and initial weights are randomized with the same datasets; the accuracy on the test datasets is shown in Table 3. The results show that the difference in the effect of the 3 structures on the final performance is not significant. However, the use of the fusion structure of group number 3, containing multilayer linear transformation, together with a multilayer nonlinear activation function and the introduction of residual connections, slightly outperforms the performance of the other schemes. Therefore, group number 3 is chosen as the neural network structure for modal fusion learning.

Table 3. Comparative analysis of the modal fusion neural network structure in terms of accuracy on the test datasets. A total of 500 samples were randomly selected from each of the 3 multimodal test datasets for experimentation with detailed data represented as: number of scores 0, number of scores 50, number of scores 100/total number of test datasets.

[a]TCM-SFT: traditional Chinese medicine–supervised fine-tuning.

Modal Fusion Module Pretraining Experiment

The weight parameters of the modal fusion are also fine-tuned for training during the overall training of the TongueVLM model; thus, the pretraining of the modal fusion is compared to that of number 1, the pretraining is fine-tuned individually, and number 2 is randomly initialized in TongueVLM without pretraining. The accuracy of the 3 test datasets is shown in Table 4 below. The results show that the accuracy improvement using the individually fine-tuned pretraining approach is significant, with 2.3%, 5%, and 3.5% improvement for the 3 datasets, respectively. Fine-tuning the modal fusion layer using the Chinese interpretation feature description data allows the model to focus more on constructing and optimizing higher-order correspondences between visual-language features.

Table 4. Evaluation of pretraining methods for modal fusion modules. A total of 500 samples were randomly selected from each of the 3 multimodal test datasets for experimentation with detailed data represented as: number of scores 0, number of scores 50, number of scores 100/total number of test datasets.

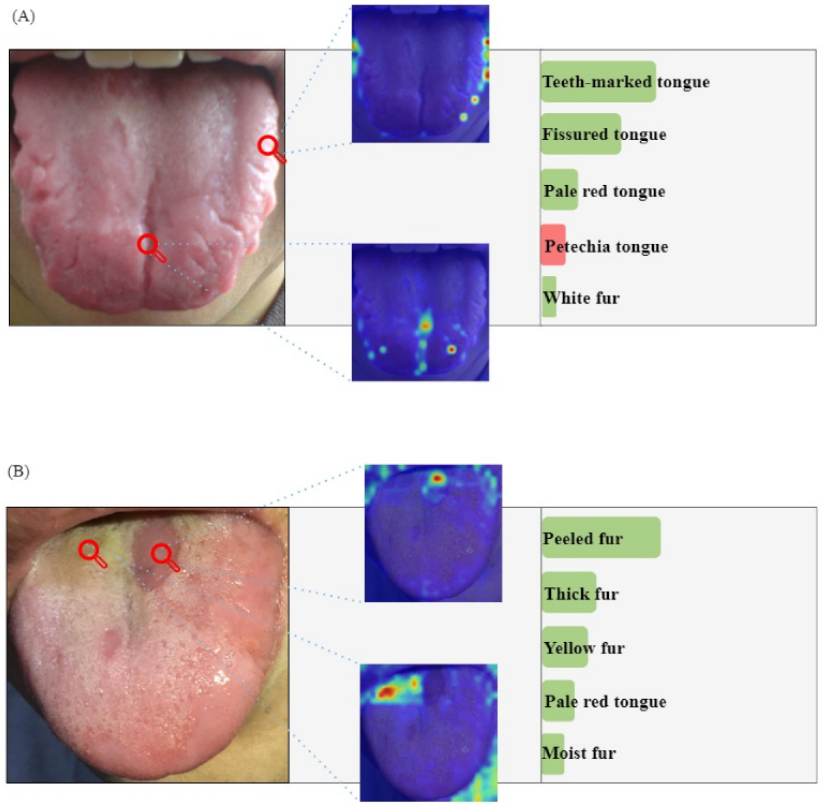
Analysis of Module Effectiveness and Interpretability

In this experiment, the visualization of the projection of the attention weight values of the multihead self-attention layer during the forward computation of the visual encoder to the image is investigated, and pseudo-color maps of the regional thermal response during the visual encoding process for typical texture feature locations on the surface of the tongue image are generated.



XSL•FO
RenderX

The multihead attention weights during the forward propagation of the cached visual encoder are Atten_weights$\in R^{(num_heads,dim,dim)}$, where num_heads$\in$(1,2,…,16) is the number of heads of multihead attention, and *dim*=577 is the length of the encoding sequence. The 0th position of the encoding sequence is the classification head, and the $E_i \in R^{(dim-1,dim-1)}$ vector represents the correlation between the 24 × 24 patches of the image in the ith attention header.

As shown in Figure 5, feature locations were selected in the tongue image; Figure 5A for fissured and teeth-marked tongues, and Figure 5B for peeled fur and yellow moss. The attention weights for the specified location are projected into the pseudo-color map of the original image. The text labels of the top 5 tongue features are obtained as output, with red indicating incorrect prediction and green indicating correct prediction, and the length of the color indicates the magnitude of its probability.

Through the feature attention visualization map, it can be seen that the visual encoder for tongue texture features focuses on localized regional positional responses, while the tongue color feature focuses on the overall area response of the image, so that the visual encoder can learn the effective feature information on the tongue, which provides good support for the subsequent feature fusion.

Figure 5. Visualization of the thermal response of the visual encoder's multihead attention. Presents the top 5 categories and their confidence levels of tongue image features predicted by the model in text form. Green represents correctly predicted labels, red represents incorrectly predicted labels, and the length of the color bars intuitively indicates the probability of the prediction.

Validation of Multimodal Capabilities Across Tasks

Tongue Image Description Generation Capability

In the task of describing the tongue images, we observe that LLaVA-1.6, LLaVA-OneVision, and Qwen2.5-VL-7B all generate output answers according to structured texts. Moreover, the text of LLaVA-1.6's response to the tongue surface image was intermingled with the description of the tongue sublingual veins. This type of response may be a language hallucination of the LLM. The output text of the TongueVLM is relatively short, but in terms of content, it focuses mainly on image color, texture, and morphological information. Representative examples of model outputs are shown in Table S1 in Multimedia Appendix 1. The tongue feature interpretation of the TongueVLM model is closer to the results of visual model recognition, which fully demonstrates that the TongueVLM model, which has been fine-tuned with the tongue multimodal datasets, solves the conceptual alignment between the visual encoding of the images and the TCM terminology.

Physical Constitution Reasoning and Analysis Capability

In the task of physical constitution reasoning about the tongue image, we observe that the output of the LLaVA-1.5 model completely deviates from the TCM context and seems to lack an understanding of the concept of TCM physique, and the LLaVA-1.6 model outputs the reasoning thinking about TCM physique through the tongue image. The LLaVA-OneVision model misjudges the tongue feature as a red tongue, but can reason about the physical constitution in combination with the tongue feature. Of course, the output is also wrong.

XSL•FO
RenderX

QWen2.5-VL-7B still follows some kind of templated output content, which is accurate in understanding the tongue color and color of the tongue fur features, but misclassifies the tongue shape as fat and large and dentate to the extent that the analysis of the physical constitution is not accurate enough.

In contrast, the TongueVLM model shows professional advantages in the TCM field in terms of effectively recognizing the tongue features and then briefly outputs the results through the tongue features, but its language expression level is slightly rough and needs to be further improved. Representative examples of model outputs are shown in Table S2 in Multimedia Appendix 1.

Tongue Image Dialogue Capability

In the multiround dialogue task of TCM with tongue images, we observe that all the models can accurately recognize the teeth-marked tongue feature in the tongue image in the first round of dialogue, and LLaVA-1.6 not only interprets the tongue feature dimension but also associates more scientific knowledge with the physical condition. However, in the second round of dialogue, LLaVA-1.5 and LLaVA-1.6 gave vague answers of "possibly related." Moreover, LLaVA-OneVision and Qwen2.5-VL-7B were able to provide definite answers, but they were not related to the teeth-marked tongue feature in the previous round of dialogue. The TongueVLM model combines the content of the teeth-marked tongue feature and provides the exact answer; thus, the TongueVLM model still outperforms the other models. Representative examples of model outputs are shown in Table S3 in Multimedia Appendix 1.

The experimental results show that the TongueVLM model outperforms the general-purpose large model on all 3 tasks. First, in terms of tongue feature descriptions, the TongueVLM model is closest to the recognition results of the visual model and includes color and morphological features and local positional features, and the parallel computation time of multiple visual models is greater than that of the large model, which fully reflects the image feature retention ability and computational performance of the TongueVLM visual encoder. Second, in terms of physical constitution reasoning, it is obvious that LLaVA-1.5 does not have expertise in TCM. LLaVA-1.6, LLaVA-OneVision, and Qwen2.5-VL-7B are generated by interpreting the text according to the unified paradigm; it cannot distinguish between tongue photos and sublingual photos, and identifying the positive and negative features is difficult. The TongueVLM model, on the other hand, quantitatively analyzes and localizes the positive features of the tongue image and can reason about the physical constitution based on the tongue image features, with an accuracy of 78.6%. The traditional method requires multiple visual models to extract the tongue features and then input the feature data into decision trees, support vector machines, and other classifiers for supervised learning of somatic qualities, which is less efficient to execute. Third, in terms of multiround Q&As, the TongueVLM model's interactive answers are brief, the contextual correlation is stronger, and the language discourse is not as strong as that of LLaVA-1.6, but its overall answers are more precise and concise, and language generation is not an advantage of the visual model.

Discussion

Principal Findings

This study proposes a TongueVLM network architecture design and a 3-stage training framework, achieving state-of-the-art performance on multimodal tongue image diagnosis tasks. Crucially, ablation experiments confirm that the staged training strategy is essential for stable optimization, while visual analysis demonstrates that the model spontaneously focuses on tongue regions relevant to clinical diagnosis.

The TongueVLM multimodal model proposed in this study is characterized by the following key features. First, the visual encoder characterizes the image features with the language encoding of low-dimensional vectors and approximates the feature extraction capability of the visual model by migration learning of TCM images from the CLIP-ViT pretrained model, which is a key step in the visual-to-large language model. Second, the modal fusion module splices visual and textual instruction data, realizes a seamless connection between natural language and image feature information, and unifies the multimodal data format input to the large model. Third, the TongueVLM model is fine-tuned and trained end-to-end on the TCM dataset. The model exhibits high accuracy in all 3 tasks of tongue feature description generation, physical constitution reasoning, and multiround dialogue.

Limitations and Future Work

This study has several limitations. First, the current data modality only includes tongue image and text-based question-answering data, failing to encompass the complete information system of TCM's "observation, auscultation, inquiry, and palpation." Second, the dataset's diversity requires enhancement, with shortcomings in ethnic distribution and standardization of image acquisition environments, which may compromise the model's generalizability. Third, evaluation of generated texts (eg, tongue pattern descriptions) still relies on expert judgments with inherent subjectivity, lacking objective, fine-grained automated assessment criteria. Finally, the model's generalization capability for clinically rare tongue patterns remains to be validated.

Future research may explore the following directions: first, in terms of model architecture, a gating mechanism is introduced to achieve adaptive attention regulation. Meanwhile, it is considered to incorporate modules such as depth-wise separable convolution to compensate for the shortcomings of self-attention mechanisms in capturing local detail features. Second, expand multimodal data sources by systematically integrating comprehensive information from facial diagnosis, pulse diagnosis, olfactory diagnosis, and physical constitution identification to construct a full-disease-course diagnostic model more aligned with TCM's holistic perspective. Third, fuse multidimensional data acquisition technologies such as 400-1000 nm spectral data and thermal infrared imaging data, and 3D tongue morphology to establish a more refined quantitative tongue pattern characterization system. Fourth, explore automated evaluation frameworks based on LLMs to achieve fine-grained quantitative assessments of the professionalism, consistency, and logical coherence of generated content. Fifth,

XSL•FO
RenderX

advance prospective trials in collaboration with clinical institutions to validate the model's auxiliary diagnostic efficacy and clinical applicability in real-world diagnostic settings. Sixth, currently, TongueVLM is built upon a 7B-parameter model, and its deployment still imposes certain computational requirements. We will explore parameter-efficient fine-tuning techniques (eg, low-rank adaptation) and model quantization. Finally, the model will incorporate continuous learning mechanisms to iteratively improve its tongue image recognition accuracy and diagnostic reasoning ability, thereby advancing research on artificial intelligence–assisted TCM tongue diagnosis.

Conclusions

Intelligent diagnosis and treatment technology in the field of TCM is often based on knowledge graphs, deep learning visual models, and machine learning approaches. Traditional supervised learning is limited by the quality and size of the training data, as well as the difficulty of fusion with natural language and its limited generalizability. The findings demonstrate that the TongueVLM model achieves ideal results in terms of understanding tongue images, constitutive reasoning, and dialogue abilities, and provides a foundational framework suitable for future integration into a Chinese medicine intelligent diagnosis system.

Abstract

Background: Medical ambient artificial intelligence (AI) scribes reduce documentation burden, but the current evidence is almost entirely from English systems. In the Arabic-speaking world, physicians converse mainly in Arabic and write clinical notes in English, adding cognitive burden. Due to scarce corpora in the Arabic language, the development of Arabic-enabled AI speech technologies has been challenging. Here, we address this gap by developing and evaluating a bilingual Arabic-English medical AI scribe.

Objective: This study aims to evaluate the feasibility and performance of a bilingual medical Arabic-English ambient AI scribe, Sahl AI, using a full end-to-end methodology from raw audio to clinical note.

Methods: A prospective, single-arm feasibility pilot study was conducted in 2 stages across outpatient clinics, inpatient services, and primary care clinics within Riyadh First Health Cluster: development and implementation. In stage 1 (development), consultation audios were collected and manually annotated to fine-tune the AI pipeline. Version 1 of Sahl AI underwent feasibility evaluation using a modified 9-item Physician Documentation Quality Instrument (PDQI-9) framework based on Likert-scale ratings. Subsequently, in stage 2 (implementation), the AI pipeline was fine-tuned, and version 2 was evaluated as a real-world deployment in family medicine clinics. Independent reviewers evaluated clinical notes. Physician experience was captured using targeted surveys.

Results: During stage 1, the AI pipeline was fine-tuned, producing version 1 of Sahl AI, which was tested in 64 clinical encounters for technical feasibility. This evaluation yielded a mean modified PQDI-9 score of 42.2 (SD 2.98) out of 45, with the model scoring 4.35 (SD 0.82) out of 5 in the accuracy domain. Following further optimization, version 2 of Sahl AI was evaluated during stage 2, using 55 real-world consultations assessed by 2 independent physician evaluators. Sahl AI achieved mean modified PDQI-9 scores of 42.4 (SD 1.84) out of 45 for Arabic and 37.8 (SD 1.10) out of 40 for English. On the Likert scale, for the accuracy domain, the mean score was 4.53 (SD 0.46) out of 5 for Arabic compared with 4.77 (SD 0.37) out of 5 for English (P=.06). Internal consistency (mean 4.94, SD 0.17) and comprehensibility (mean 4.89, SD 0.21) were the top-rated domains. The targeted survey of a larger cohort of 22 family medicine physicians using Sahl AI showed that most responding physicians agreed that notes were comprehensive and perceived potential time savings and reduced burnout.

Conclusions: Sahl AI, a bilingual Arabic-English medical ambient AI scribe, generates accurate and high-quality notes, and in targeted postimplementation surveys, most physicians agreed that it produced comprehensive notes and perceived potential benefits for time savings and stress or burnout. This provides the first empirical basis for rigorous end-to-end ambient AI scribe evaluation in low-resource languages such as Arabic.

Introduction

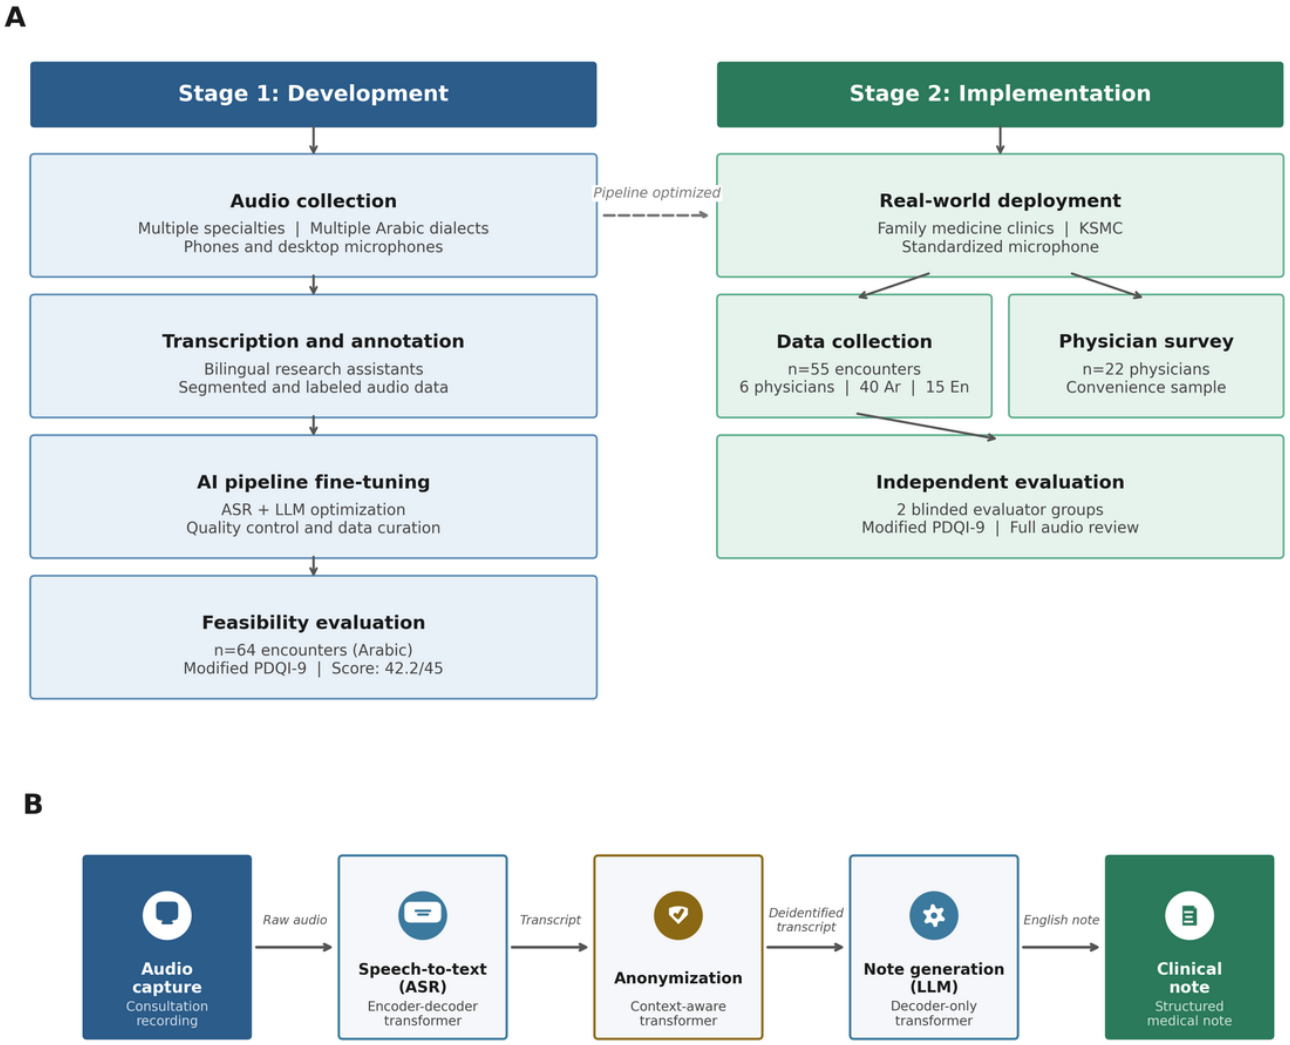
Physicians devote a significant portion of their time to the administrative task of documenting medical encounters with patients [1]. Clinical documentation serves critical functions, including care continuity, quality assurance, and in many jurisdictions, medico-legal protection. It is an essential component for ensuring patient safety and also impacts subsequent tasks, such as submitting insurance claims [2]. The digitization of medical records and the widespread adoption of electronic health record systems have substantially increased the documentation burden on physicians, leading to increased physician burnout [3]. Furthermore, clinical documentation has become a distraction, changing the traditional doctor-patient relationship into a doctor-computer-patient interaction [4].

Clinical documentation is typically completed either during or after patient encounters. Documenting in real time may interrupt the clinical interaction, whereas postvisit documentation may add to physician workload and relies on recall rather than contemporaneous capture. Ambient artificial intelligence (AI) scribes automate clinical note generation and improve the doctor-patient relationship, freeing physicians to focus on personalized care [5,6]. This study evaluates Sahl AI, an AI tool for Arabic and English, using the modified 9-item Physician Documentation Quality Instrument (PDQI-9) tool. This research is unique in its dual-language focus and is particularly relevant in Arabic-speaking countries where clinical encounters are conducted in Arabic, while medical documentation is recorded in English. This supports health care providers who routinely switch between languages during consultations when eliciting patient histories and documenting care.

Arabic is often categorized as a low-resource language in speech technologies due to its complex characteristics. These include its writing system with positional variance and diacritical marks, phonology that features emphatic consonants and vowel length distinctions, and grammar that involves root-based morphology and case-gender agreement. The variability is further compounded by numerous dialects and diglossia, as well as influence from other languages and its significant religious context. This necessitates ongoing translation by the physicians, introducing cognitive strain. Although ambient AI scribes offer a potential solution to mitigate this burden, the effectiveness of bilingual systems in such linguistically complex environments remains insufficiently examined. Therefore, the aim of this study was to develop and assess the feasibility and physician experience of a bilingual Arabic-English medical ambient AI scribe in routine clinical practice.

Methods

Study Design and Objectives



The study was a prospective, single-arm feasibility pilot study evaluating the performance of Sahl AI, a bilingual ambient AI scribe, in routine physician-patient consultations. The primary objectives were to (1) fine-tune an AI pipeline for automated clinical documentation generation and subsequently (2) evaluate the usability of Sahl AI and its impact on the physicians' workflow and the quality of documentation.

Study Setting and Duration

The study was conducted between December 23, 2023, and November 28, 2024, across outpatient clinics, inpatient services, and primary care centers within Riyadh First Health Cluster (Riyadh, Saudi Arabia). The study comprised 2 stages: (1) a development stage, during which data collection and a feasibility evaluation were performed, and (2) an implementation stage, in which the fine-tuned AI pipeline was assessed in a real-world clinical setting (Figure 1A).

XSL•FO
RenderX

Figure 1. (A) Two-stage study design. Stage 1: iterative development including multidialect Arabic audio collection, manual transcription by bilingual research assistants, ASR and LLM fine-tuning, and feasibility evaluation (n=64 encounters; mean 9-item Physician Documentation Quality Instrument [PDQI-9] score: 42.2/45, SD 2.98). Stage 2: real-world implementation at family medicine clinics (King Saud Medical City [KSMC]), with prospective data collection (n=55 encounters; 40 Arabic, 15 English), independent blinded evaluation using the modified PDQI-9, and a parallel physician experience survey (n=22). Dashed arrow indicates pipeline transfer from development to implementation. (B) Artificial intelligence (AI) pipeline architecture: audio capture, encoder-decoder ASR, anonymization via context-aware transformer for personally identifiable information (PII) deidentification, and decoder-only LLM for clinical note generation. ASR: automatic speech recognition; LLM: large language model.

During stage 1, participating specialties included, but were not limited to, general and internal medicine, general surgery, pediatrics, family medicine, obstetrics and gynecology, cardiology, and respiratory medicine. Both new and follow-up patient encounters were included, provided eligibility criteria were met and physicians were able to conveniently record audio conversations during clinical encounters. During stage 2, new patient encounters were sampled during designated family medicine clinic sessions when participating physicians were available. Verbal consent was obtained from patients by the treating physicians and was documented in the clinical notes.

Eligibility Criteria

The inclusion criteria were as follows: patients of all ages and sexes who provided informed consent for the use of Sahl AI during their clinical consultation. For pediatric patients, consent was obtained from a parent or legal guardian.

The exclusion criteria were as follows: patients with cognitive impairment who were unable to provide informed consent.

Collection of Audio Data for Fine-Tuning

During stage 1, audio data were collected to optimize and fine-tune the AI pipeline using Sahl AI's proprietary Data Collection Pipeline. Audio streams from physician-patient conversations were segmented into shorter audio chunks to facilitate accurate labeling. Participating physicians received training on audio recording using various devices and on obtaining informed consent from patients. The recorded audio was securely stored on cloud servers in compliance with the Kingdom of Saudi Arabia's Personal Data Protection Law (PDPL). The audio data were initially retained for 6 months, with the retention period later extended to 1 year following approval of an ethics amendment.

Recordings were collected across multiple clinical specialties during stage 1 using physicians' personal mobile phones as well as desktop microphones, including Anker PowerConf S360 USB Speakerphones and Kaysuda SP300 Bluetooth Speakerphones. A team of bilingual research assistants fluent in Arabic and English reviewed and edited the transcribed audio

XSL•FO
RenderX

segments to ensure high-quality labeled datasets for AI pipeline optimization. The dataset encompassed a wide range of Arabic dialects, including those spoken in Saudi Arabia, Yemen, Egypt, Sudan, the Levant, Kuwait, and North Africa, as well as simplified Arabic spoken by nonnative speakers and diverse English accents. Data scientists subsequently curated the labeled data, excluding poor-quality audio segments identified during review by the research assistants.

The AI pipeline was iteratively tested with internal evaluation metrics before being piloted with physicians during stages 1 and 2 of the study. The pipeline (Figure 1B) comprised multiple components requiring optimization for clinical deployment. In particular, the speech-to-text engine was based on a transformer-based encoder-decoder automatic speech recognition architecture, in which the encoder transforms raw audio signals into high-level semantic representations and the decoder generates the corresponding text transcription. Prior to clinical note generation, transcripts were processed through a deidentification layer that used a context-aware transformer model to detect and redact personally identifiable information. The large language model component was a decoder-only autoregressive transformer trained using causal language modeling.

Fine-tuning focused on improving robustness to spontaneous clinical dialogue, variability in dialects, and background noise commonly encountered in outpatient and inpatient environments. Model training prioritized transcription accuracy for medical conversations. To minimize overfitting and prevent information leakage, training and evaluation datasets were strictly separated.

Feasibility Study

During stage 1, following the fine-tuning and optimization of the AI pipeline, version 1 of Sahl AI was evaluated in a controlled setting to assess feasibility outside of routine clinical practice. This evaluation involved role-plays and mock conversations between physicians, as well as prerecorded simulated physician-patient conversations generated by nonphysicians. These audio recordings were processed by the AI pipeline to generate clinical notes, enabling the assessment of the ambient AI scribe's performance in the Arabic language. Collectively, these activities constituted the feasibility component of the development stage.

Clinical notes were generated in accordance with the documentation requirements of the Central Board for Accreditation of Healthcare Institutions and included standardized headings, such as chief complaint, history of present illness, past medical or surgical history, allergy, medication, social history, family history, physical examination findings, diagnosis, and plan. Participating physicians evaluated the AI-generated clinical notes after completing the role-play scenarios or listening to the prerecorded simulated conversations.

In total, 64 independent assessments were conducted using a modified PDQI-9 (Table 1), a tool that has been previously validated and used in recent evaluations of ambient AI scribes [7,8]. For the purposes of this study, the PDQI-9 tool was adapted to reflect Arabic-language and bilingual audio-to-text workflows. Specifically, the original domains of "up-to-date" and "synthesized" were replaced with "free from hallucination" and "translated accurately to English," respectively. These modified domains have not been formally validated and were used for exploratory assessment only.

XSL•FO
RenderX

Table . Nine-item Physician Documentation Quality Instrument (PDQI-9) tool measuring the quality of the clinical note across 9 dimensions[a].

Domain	Description
Accurate	The note is true. It is free of incorrect information. For example, if the history is about chest pain and the note mentions abdominal pain, then this represents that the note was not accurate.
Thorough	The note is complete and free from omission and documents all of the issues of importance to the patient. For example, if a symptom about visual loss was discussed and was important to the note but not mentioned, then this represents that the note was not thorough.
Useful	The note is extremely relevant, providing valuable information and/or analysis.
Organized	The note is well formed and structured as per CBAHI[b] recommendations in a way that helps the reader understand the patient's clinical course.
Comprehensible	The note is clear, without ambiguity or sections that are difficult to understand.
Succinct	The note is brief, to the point, and without redundancy.
Internally consistent	No part of the note ignores or contradicts any other part. For example, if 1 section of the note mentions that the patient has asthma but another section says no history of asthma, then this is not internally consistent.
Free from hallucination	The note is free of hallucination and only contains information verifiable by the audio conversation. For example, if the note mentions that the patient smokes and drinks alcohol when it was not at all discussed in the note, then this represents hallucination.
Translated accurately to English	The note reflects the Arabic conversation between the physician and the patient accurately in the English language.

[a]Each domain was scored from 1 to 5 (Likert scale), with 1 being "not at all" and 5 being "extremely."

[b]CBAHI: Central Board for Accreditation of Healthcare Institutions.

Real-World Testing

Based on the findings from stage 1, the AI pipeline was further optimized to improve performance prior to real-world deployment. During stage 2, the model was deployed in family medicine clinics for real-world testing involving both new and follow-up patient encounters. From a larger cohort of physicians, 6 physicians who consented to participate received at least 30 minutes of training on the effective use of the software prior to study initiation.

Physician-patient conversations and the corresponding unedited clinical notes generated by Sahl AI were recorded and subsequently evaluated by 2 independent evaluators. Evaluators listened to the complete audio recordings and assessed the associated unedited clinical notes using the modified PDQI-9 tool. To reduce the likelihood of identifying the physician speaker, evaluators were recruited from clinical specialties different from those of the participating physicians; however, complete anonymization could not be guaranteed, as the evaluators were recruited from the same health cluster. Evaluators were blinded to the identities of both patients and physicians. However, as the raw audio was not modified to redact personally identifiable information, complete blinding cannot be assured. Scores from evaluators were averaged prior to calculating the final modified PDQI-9 domain scores.

The evaluation process involved 2 evaluator groups. Evaluator group 1 comprised a single reviewer, while evaluator group 2 consisted of 2 reviewers who divided the assigned clinical notes between them. Each clinical note was reviewed by 2 evaluators—1 from each group. In cases where domain-level scores differed by 2 or more points, both evaluators were asked to rereview the clinical notes and reconcile discrepancies.

To ensure consistency across recordings, a standardized microphone (Kaysuda SP300 Bluetooth Speakerphones) connected to a laptop computer was used for all consultations. Audio recordings were performed by trained research assistants and uploaded directly through the Sahl AI software. Following each consultation, Sahl AI generated a single clinical note immediately using the recorded audio, which was then reviewed in its unedited form by the independent evaluators.

Clinical encounters were categorized as "Arabic" or "English" based on the predominant language of the consultation, as initially determined by research assistants and subsequently confirmed by the evaluators. Code-switched encounters involving substantial use of both languages were classified according to the language comprising the majority (>50%) of clinical content. Regardless of input language, Sahl AI generated all clinical documentation exclusively in English.

Physician Experience

Following real-world deployment in the family medicine department, a targeted physician experience survey was conducted to capture feedback from clinicians with the direct hands-on use of Sahl AI. The survey was completed between 29 July and 28 November 2024 by 22 physicians. Eligibility was limited to physicians who had used the system in at least

XSL•FO
RenderX

3 clinical encounters, ensuring sufficient exposure to evaluate its impact on clinical workflow. Survey items evaluated perceived note comprehensiveness, time savings, ease of use, impact on physician burnout, and impact on clinical workflow using a 5-point Likert scale ranging from strongly agree to strongly disagree. The survey was designed as a descriptive assessment of user experience among active users rather than a population-level evaluation.

Statistical Analysis

During the development stage, individual modified PDQI-9 scores were recorded for each physician's assessment. In contrast, during the implementation stage, the modified PDQI-9 scores were calculated by calculating the mean scores from 2 independent evaluators for each domain and then summing these domain-level means. The overall modified PDQI-9 scores were reported as mean (SD) and were calculated out of a maximum total score of 45 for Arabic conversations and 40 for English conversations, as the "translated accurately to English" domain was not applicable to English consultations. Since the modified PDQI-9 domain scores were ordinal Likert-scale measures and group sizes were unbalanced (40 Arabic vs 15 English consultations), comparisons between Arabic and English groups were conducted using nonparametric Mann-Whitney *U* tests. Differences between evaluator scores were quantified using the mean absolute deviation (MAD), calculated as the average of the absolute differences between paired domain scores. MAD was computed both overall and at the domain level. Descriptive statistics, including means and frequencies, were used to summarize the responses from the physician experience questionnaire.

Ethical Considerations

This study was approved by the institutional review board of King Saud Medical City (protocol H1R1-18-Sep23-01). Verbal informed consent was obtained from all participating patients prior to audio recording and was documented in the medical record. The use of verbal consent was approved by the institutional review board given the minimal-risk nature of the study and the practical limitations of obtaining written consent during routine clinical encounters without disrupting workflow. For pediatric patients, consent was obtained from parents or guardians. All data collection, storage, and analysis procedures were conducted in accordance with confidentiality requirements and complied with the Saudi Data and Artificial Intelligence Authority PDPL [9]. No patient demographic information was collected, and independent evaluators assessed clinical notes without access to any identifying data. Patients did not receive financial compensation for participation, and physicians participated as part of their routine clinical duties.

Results

Feasibility Pilot

During the development stage of the study, feasibility testing was conducted on 64 Arabic-language conversations, with the results summarized in Table 2. The overall mean modified PDQI-9 score across all domains was 42.2 (SD 2.98) out of 45. Clinical notes achieved the highest ratings in the domains of "useful," "organized," and "comprehensible," with mean scores of 4.86 (SD 0.39), 4.87 (SD 0.34), and 4.85 (SD 0.35) out of 5, respectively. The accuracy domain of version 1 of the pipeline was rated 4.35 (SD 0.82) out of 5. Relatively lower scores were observed for the thorough (mean 4.42, SD 0.81) and free from hallucination (mean 4.45, SD 0.85) domains, highlighting areas for further improvement. The identified strengths and limitations informed the subsequent fine-tuning and optimization of the AI pipeline.

Table . Domain-level performance of Sahl AI-generated clinical notes during the development (n=64) and implementation (n=55) stages, assessed using the modified 9-item Physician Documentation Quality Instrument (PDQI-9) tool[a].

Domain	Development stage[b]		Implementation stage[c]	
	Number of cases	Mean (SD)	Number of cases	Mean (SD)
Accurate	64	4.35 (0.82)	55	4.59 (0.45)
Thorough	64	4.42 (0.81)	55	4.55 (0.45)
Useful	64	4.86 (0.39)	55	4.74 (0.33)
Organized	64	4.87 (0.34)	55	4.54 (0.37)
Comprehensible	64	4.85 (0.35)	55	4.89 (0.21)
Succinct	64	4.84 (0.45)	55	4.49 (0.38)
Internally consistent	64	4.73 (0.60)	55	4.94 (0.17)
Free from hallucination	64	4.45 (0.85)	55	4.87 (0.22)
Translated accurately to English	64	4.79 (0.49)	40	4.85 (0.28)

[a]Values represent mean (SD) Likert-scale scores for each documentation quality domain. The overall mean modified PDQI-9 scores are reported separately for Arabic (out of 45) and English-translated (out of 40) conversations.

[b]Average for development stage: 42.2 (SD 2.98) out of 45.

[c]Average for implementation stage: Arabic: 42.4 (SD 1.84) out of 45; English: 37.8 (SD 1.10) out of 40.

Real-World Implementation

During the implementation stage, real-world testing was conducted in family medicine clinics at King Saud Medical City (Riyadh First Health Cluster). Independent evaluators reviewed 55 new-patient consultations using the modified PDQI-9 tool; 40 consultations involved predominantly Arabic physician-patient conversations, and 15 involved English conversations. The mean modified PDQI-9 score was 42.4 (SD 1.84) out of 45 for Arabic consultations and 37.8 (SD 1.10) out of 40 for English consultations (Table 2).

Across all cases, clinical notes achieved the highest scores in the domains of "internally consistent," "comprehensible," and "free from hallucination" with mean scores of 4.94 (SD 0.17), 4.89 (SD 0.21), and 4.87 (SD 0.22) out of 5, respectively. The mean accuracy domain score for version 2 of the fine-tuned and optimized AI pipeline was 4.59 (SD 0.45) out of 5 across both language groups. Mean scores exceeded 4.5 out of 5 across all domains except for "succinct," which scored 4.49 (SD 0.38), suggesting a tendency toward more verbose clinical notes.

Domain-level scores for Arabic and English encounters were analyzed separately and are presented in Figure 2. A statistically significant difference was observed in the "organized" domain, with higher scores for Arabic compared with English conversations (4.60, SD 0.39 vs 4.37, SD 0.23; P=.02). There was a trend to the English conversations having higher accuracy compared with Arabic conversations (4.77, SD 0.37 vs 4.53, SD 0.46; P=.06). No statistically significant differences were observed across the remaining domains.

Figure 2. Comparison of mean Likert-scale scores for clinical notes generated by Sahl AI, as evaluated by independent reviewers, for Arabic and English conversations across each modified 9-item Physician Documentation Quality Instrument (PDQI-9) domain. Error bars indicate ±1 SD. Between-group differences were assessed using the Mann-Whitney *U* test. NA: not applicable.

Interevaluator Agreement

Interevaluator agreement across modified PDQI-9 domains is presented in Table 3. Overall agreement between evaluator group 1 and evaluator group 2 was high, with a mean absolute deviation of MAD=0.36, indicating close concordance in scoring. Across individual domains, MAD values ranged from 0.13 to 0.66 on a 5-point Likert scale, demonstrating that evaluator ratings typically differed by <1 point. Exact agreement of scores ranged from 34.5% to 87.3%, while agreement within ±1 point on the Likert scale was consistently high across domains (96.4% - 100%).

XSL•FO
RenderX

Table . Interevaluator agreement between evaluator group 1 and evaluator group 2 across modified 9-item Physician Documentation Quality Instrument (PDQI-9) domains[a].

Domain	Number of cases	MAD[b]	Exact agreement (%)	Agreement ±1 (%)	ICC[c]	Cohen kappa
Accurate	55	0.42	60	98.2	0.28	0.28
Thorough	55	0.40	60	100	0.35	0.35
Useful	55	0.35	65.6	100	0.13	0.13
Organized	55	0.60	43.6	96.4	0.12	0.12
Comprehensible	55	0.22	78.2	100	−0.07	−0.06
Succinct	55	0.66	34.5	100	−0.05	−0.05
Internally consistent	55	0.13	87.3	100	0.06	−0.05
Free from hallucination	55	0.26	74.5	100	0.00	0
Translated accurately to English	40	0.20	80	100	0.22	0.22

[a]Agreement is summarized using mean absolute difference, exact agreement (%), and agreement within +1 point on the Likert scale (%), intraclass correlation coefficient (2-way mixed effects, absolute agreement), and weighted Cohen kappa (squared weights).

[b]MAD: mean absolute deviation.

[c]ICC: intraclass correlation coefficient.

The highest interevaluator agreement was observed for the internally consistent (MAD=0.13; exact agreement 87.3%) and translated accurately to English domains (MAD=0.20; exact agreement 80%). Greater variability was observed in more subjective stylistic domains, including succinct (MAD=0.66; exact agreement 34.5%) and organized (MAD=0.60; exact agreement 43.6%). Despite lower exact agreement in these domains, agreement within ±1 point remained high (≥96.4%), supporting overall consistency between evaluators. To supplement the MAD analysis, the intraclass correlation coefficient (ICC; 2-way mixed effects, absolute agreement) and weighted Cohen kappa were calculated for each domain and are reported in Table 3. However, domain-level ICC and kappa values were markedly attenuated by ceiling effects, as 99% of the individual ratings were 4 or 5 on the Likert scale. Under such restricted variance, these metrics can yield paradoxically low or negative values despite high observed concordance; for example, the succinct and internally consistent domains each achieved 100% agreement within ±1 point yet produced negative ICC and kappa values. Given these distributional constraints, the MAD and percentage agreement metrics provide a more clinically meaningful assessment of interevaluator concordance in this setting.

Physician Experience

Physician experience with Sahl AI was evaluated to assess its perceived impact on routine clinical practice. A larger pool of physicians who may not have contributed to the development or implementation stage but used Sahl AI in their clinical practice was surveyed. In total, 22 physicians responded; however, as the total number of invited physicians was not systematically recorded, a formal response rate cannot be calculated, and these results should be interpreted as descriptive feedback from a convenience sample of unknown proportion. The results are summarized in Table 4. Most responding physicians strongly agreed or agreed across all domains that Sahl AI produced comprehensive notes, produced more complete notes compared with current practice, had the potential to save time and reduce physician burnout, was faster, while having a positive impact on their clinical workflow.

XSL•FO
RenderX

Table . Summarization of the physicians' responses to various statements related to the use of Sahl AI and impact on their clinical practice.

Question	Strongly agree, n (%)	Agree, n (%)	Neither agree nor disagree, n (%)	Disagree, n (%)	Strongly disagree, n (%)
Sahl AI produces comprehensive clinical summaries of the consultations	19 (86.4)	3 (13.6)	0 (0)	0 (0)	0 (0)
I feel that Sahl AI can produce more complete notes compared to current documentation practices	14 (63.6)	6 (27.3)	2 (9.1)	0 (0)	0 (0)
Sahl AI was faster and thus has the potential to save time in documenting comprehensive clinical summaries compared to the present practice	19 (86.4)	2 (9.1)	1 (4.5)	0 (0)	0 (0)
I feel that the use of the tool can help reduce physician stress/burnout	15 (68.2)	6 (27.3)	1 (4.5)	0 (0)	0 (0)
It was easy to use the Sahl AI tool	19 (86.4)	2 (9.1)	0 (0)	1 (4.5)	0 (0)
Sahl AI has the potential to positively affect my clinical workflow	16 (72.7)	4 (18.2)	2 (9.1)	0 (0)	0 (0)

Discussion

Principal Findings

This study demonstrates the feasibility and effectiveness of a bilingual Arabic-English medical ambient AI scribe in generating accurate, thorough, and clinically useful documentation in a real-world clinical setting. The study lays a foundation and benchmark for the successful deployment of medical AI technologies for low-resource languages, such as Arabic, and in the bilingual setting. The positive feedback from surveyed physicians regarding the tool's ease of use, potential for time savings and reducing burnout, producing more complete notes and impact on clinical workflow provides preliminary, descriptive evidence of its value in clinical practice. The results are especially relevant to health care systems in Arabic-speaking settings, where improving documentation efficiency and quality remains a critical operational priority. Furthermore, to our knowledge, this study represents the first end-to-end evaluation of a medical ambient AI scribe spanning audio capture to finalized clinical note generation for the Arabic language, extending beyond prior work that has primarily focused on transcript-to-note pipelines.

Comparison to Prior Work

There is a growing body of research evaluating the performance of ambient AI scribes in the English language, but their performance has not been rigorously assessed in other languages, particularly Arabic, which has multiple dialects and is considered a low-resource language in natural language processing due to a dearth of available datasets. This lack of evaluation poses a significant challenge, as the linguistic and cultural nuances of Arabic necessitate tailored solutions for the successful deployment of medical AI technologies in Arabic-speaking regions. Additionally, challenges in recording medical data, such as ensuring data privacy of health data and compliance with laws, such as PDPL, have contributed to this limitation. This study provides a crucial methodology for the collection of data and the training of ambient AI scribes in any language, especially low-resource languages, such as Arabic, which can help address these gaps and pave the way for the successful deployment of these technologies in diverse linguistic and cultural contexts.

Medical ambient AI scribes have been widely adopted in English-speaking health care settings and are generally reported to generate accurate and comprehensive clinical notes. For example, Tierney et al [7] reported a high documentation quality score of 48 out of 50 using a modified PDQI-9 when evaluating English physician-patient transcripts. In contrast, substantially lower scores have been reported in studies evaluating large language models, such as GPT-4, with PDQI-9 scores of 29.7 out of 45 in 1 study and 25 out of 35 using a modified PDQI-9 in another [10,11]. Kernberg et al [11] further noted that the AI-generated notes frequently omitted clinically important information, introduced hallucinated content, or contained factual inaccuracies and that note generation was not consistently reproducible. More recently, an English-language medical ambient AI scribe incorporating audio input in addition to transcripts was evaluated using a modified PDQI-9 tool, achieving a mean score of 41.9 out of 50 [12].

XSL•FO
RenderX

As a reference benchmark, the original PDQI-9 validation study categorized scores of 26.2 out of 45 as "terrible or bad," compared with scores of 36.6 out of 45 as "good or excellent" [8]. Evidence in non-English and low-resource language settings remains limited. A recent study by Lee et al [13] reported a score of 50.2 out of 65 using a modified PDQI-9 tool for synthetic Arabic transcript-to-note generation. Additional efforts have been reported in other non-English contexts, including Spanish-language AI scribe implementations in surgical outpatient settings [14].

In this study, the total mean score was 42.4 (SD 1.84) out of 45 for Arabic conversations and 37.8 (SD 1.10) out of 40 for English conversations. As in prior studies, the assessment instrument was modified to suit the study context. As these modified domains have not been formally validated, the aggregate scores should be interpreted with caution and are not directly comparable to benchmarks established using the original PDQI-9 instrument. However, unlike previous research that primarily assessed note quality based on written transcripts, this study introduces a novel approach by evaluating notes generated directly from original audio recordings of physician-patient consultations. These audio-derived notes were subsequently reviewed by independent evaluators, offering a more authentic and context-rich basis for assessing note quality. This methodology improves existing studies by considering errors from speech-to-text engines, performing an end-to-end evaluation to better reflect real-world situations rather than considering transcripts as ground truth. By evaluating the entire process from audio input to textual output, the approach ensures that the findings are applicable to everyday use cases, enhancing the robustness and reliability of the results. Although the summary of prior work focuses on PDQI-9 and its derivatives for easier comparison, other studies have utilized Recall-Oriented Understudy for Gisting Evaluation (ROUGE), Bidirectional Encoder Representations from Transformers (BERTScore), Crosslingual Optimized Metric for Evaluation of Translation (COMET), and Sheffield Assessment Instrument for Letters (SAIL), among others, which have not been discussed here.

Surveyed physicians perceived that the tool improved note accuracy and quality compared to the clinical practice of typing notes, resulting in more comprehensive and complete documentation compared to current practice. Most responding physicians perceived that the use of Sahl AI can reduce cognitive overload and save time, resulting in a positive overall impact on their clinical workflow. Such findings have been confirmed by other studies, especially showing that the use of ambient AI scribes leads to time saved and reductions in cognitive burden for physicians [10,15-21]. However, a recent report by the Peterson Health Technology Institute concluded that while AI scribes may reduce clinician burnout, it is unclear whether it actually saves time and leads to financial gains [22]. The report concluded that differences in outcomes were likely due to organization-specific metrics, which had variation in how they were defined and measured. Nevertheless, the result of this study is in line with the growing consensus that AI scribes can enhance physician efficiency by alleviating the cognitive burden associated with comprehensive documentation.

Limitations

This study used a single-arm design without a comparator, as comparative evaluation was outside the scope of this work. The absence of baseline comparisons in Arabic or bilingual settings with physician-authored documentation or generic large language models, both in the literature and in this study, limits the ability to draw conclusions regarding comparative effectiveness. Future studies incorporating head-to-head comparisons are required to establish relative performance.

The sample size was limited due to the practical challenges of collecting real-world audio data, which may affect the interpretability and generalizability of the findings. In addition, physicians used Sahl AI as a stand-alone web app that was not integrated into the electronic medical record. Electronic medical record integration is an important factor in simplifying clinical workflows and has been associated with the improved adoption of ambient AI scribes [21]. Real-world testing was conducted exclusively within the family medicine specialty; therefore, the findings may not generalize to other clinical specialties, and further evaluation across diverse clinical domains is warranted. Furthermore, the independent evaluation was conducted by physicians from the same health cluster; although evaluators were blinded to physician and patient identities, full blinding could not be ensured and may have introduced bias, especially as the raw audio was not modified to redact personal identifiable information.

The study did not include a systematic assessment of medical complexity between Arabic and English encounters, which may influence the interpretation of between-group comparisons. Future studies should capture encounter-level characteristics, such as number of medical entities spoken and number of diagnoses, to assess whether any observed language–based differences may be confounded by case complexity. Additionally, encounters were classified as Arabic or English based on the predominant language, without quantifying the degree of code-switching within individual consultations. This may limit the understanding of the model's performance in heavily code-switched versus predominantly monolingual encounters. Separately, a formal safety audit evaluating the potential clinical impact of documentation inaccuracies was not performed. Incorporating such assessments in future work may further strengthen the evidence base. While the training data included multiple Arabic dialects, performance was not systematically evaluated across specific dialect groups, limiting conclusions regarding dialect-level generalizability.

The physician experience survey was based on a convenience sample of clinicians who had used Sahl AI in at least 3 clinical encounters, which may introduce selection bias toward more engaged users. As the survey was distributed through direct outreach during deployment and the total number of physicians invited was not systematically recorded, a formal response rate could not be calculated. Consequently, the survey findings should be interpreted as descriptive user feedback rather than generalizable estimates of physician satisfaction or adoption. As such, the specific percentages reported from the survey should not be interpreted as representative of the broader physician population.

XSL•FO
RenderX

Since the completion of this study, subsequent iterations of the Sahl AI models have been released with improvements in accuracy and processing speed. Further research is needed to evaluate the clinical impact of Arabic medical ambient AI scribes, including objective measures of time savings, documentation quality compared with standard practice, effects on physician-patient interaction, and downstream operational and revenue-cycle outcomes.

Conclusions

This study highlights the potential of medical ambient AI scribe technology to enhance clinical documentation in both Arabic and English clinical environments. Sahl AI demonstrated the ability to generate high-quality clinical notes, with potential benefits including improved documentation quality, time savings, and reduced cognitive burden for physicians. To support broader adoption, future research should address the limitations identified in this study, including evaluation across diverse clinical settings and patient populations, as well as integration with electronic medical record systems. Importantly, this work provides a foundational framework for the development and training of medical ambient AI scribes in low-resource languages, such as Arabic, while also introducing a robust methodology for assessing the quality of AI-generated clinical documentation.

Acknowledgments

We would like to thank all the research assistants involved in labeling the audio data. Generative AI software (ChatGPT [OpenAI; GPT-5.2]) was used to improve the grammar of the text.

Funding

This study received in-kind support from Riyadh First Health Cluster, which funded the research activity of research assistants involved in data collection and labeling of data.

Data Availability

Aggregated modified 9-item Physician Documentation Quality Instrument scores, interevaluator agreement data, and physician survey responses are available upon request from the corresponding author. However, the raw audio recordings were permanently deleted 1 year after collection in accordance with ethics approval requirements and are no longer available.

Abstract

Background: Ambient artificial intelligence scribes are increasingly used to reduce clinician burnout and cognitive load, although their impact on documentation time remains inconsistent across studies. Most existing real-world impact studies have been conducted in the United States and rely on electronic health record time stamps, which may not accurately reflect actual documentation time.

Objective: This study aimed to quantify the impact of ambient scribe technology on clinician efficiency and patient engagement in an outpatient setting using direct observational methods and patient surveys.

Methods: We conducted a prospective, within-clinician quality improvement study at a large academic medical center in Singapore from December 2024 to May 2025. Nine clinicians participated in matched observation sessions with and without an in-house ambient scribe tool. Five trained observers used standardized time-motion methodology to capture documentation time, proportion of eye contact, and consultation duration across 169 consultations. Patient surveys were administered following consultations using the ambient scribe. Linear mixed-effects models were used to account for clustering within clinicians.

Results: Ambient scribe use was associated with a 15.0% reduction in documentation time per consultation (mean 5.3, SD 2.7 minutes to 4.5, SD 2.4 minutes; *P*=.04); a 10.6% increase in proportion of eye contact time (mean 69.6%, SD 18.6% to 77.1%, SD 17.7%; *P*=.009); and no significant change in consultation duration (mean 11.5, SD 6.9 minutes vs 10.9, SD 5.6 minutes; *P*=.42) or total cycle time per patient (mean 13.7, SD 7.7 minutes vs 13.2, SD 6.3 minutes; *P*=.57), where total cycle time includes preclerking, consultation, and postconsultation documentation. Effects were consistent across new and follow-up patients. Patient acceptance was favorable: of 39 surveyed patients, 27 (69.2%) agreed that their physician focused on them more during the consultation, and none expressed discomfort with the technology.

Conclusions: This evaluation of ambient scribe use in an Asian health care setting demonstrates that experienced users achieved reduced documentation time and improved patient engagement without affecting consultation duration or total time per patient. The technology was also well accepted by patients. Taken together, these findings suggest that ambient scribes reallocate clinician effort toward patient interaction rather than enabling faster patient turnover, supporting their implementation across diverse health care settings.

KEYWORDS

ambient intelligence; generative artificial intelligence; clinical documentation; physician-patient interaction; time-motion study; eye contact; ambient scribe; artificial intelligence; AI

Introduction

Ambient scribes use artificial intelligence (AI) to convert verbal clinician-patient interactions into structured clinical documentation. This is one of the fastest-adopted uses of generative AI in health systems worldwide [1].

Recent real-world studies across health systems in the United States demonstrate consistent improvements in clinician well-being and patient interactions with the use of ambient scribes, with studies reporting significant reductions in cognitive load, task burden, and burnout scores alongside enhanced patient experience during consultations [2-7]. However, reported time savings vary considerably between organizations. While some implementations report substantial reductions in documentation time and after-hours charting, others show minimal productivity gains [8,9].

To our knowledge, no comprehensive real-world impact studies have been conducted outside of the United States, leaving questions about the technology's effectiveness in other health care contexts unanswered. Documentation burdens and clinical workflows may differ between countries, potentially affecting the magnitude of time savings and productivity gains achievable through the use of clinical ambient scribes. Additionally, no published studies have evaluated clinical ambient scribe outcomes in multilingual clinical environments despite the prevalence of such settings in many health care systems worldwide. Shah et al [7] have previously highlighted limited functionality with non–English-speaking patients as a specific barrier to ambient scribe adoption. As digital health tools increasingly permeate global health care systems, understanding their implementation in linguistically diverse environments is important for ensuring equitable and effective deployment.

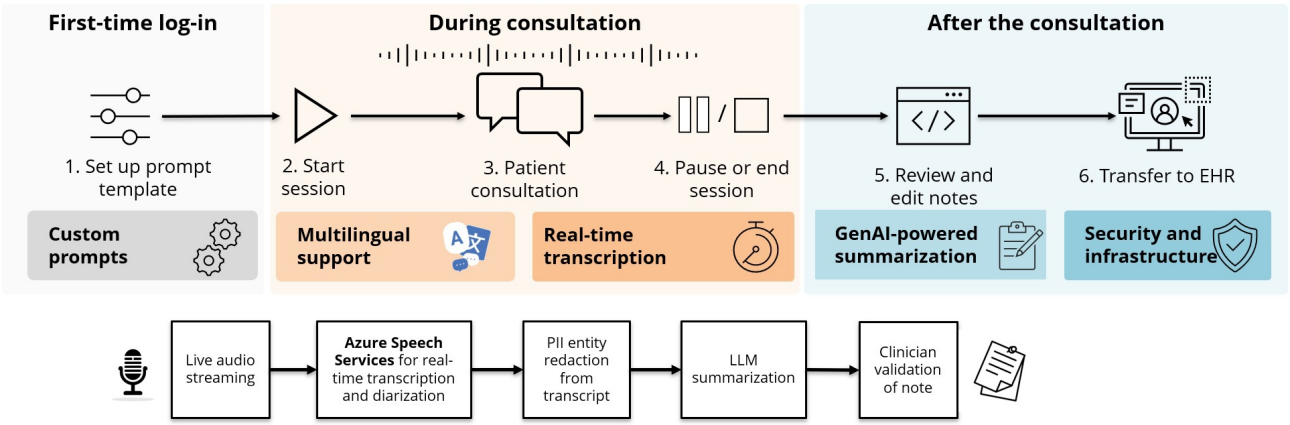
From a methodological perspective, existing studies have relied primarily on electronic health record (EHR) time stamp analysis to measure documentation time and productivity outcomes [4-6,10]. While convenient for large-scale analysis, EHR-based metrics provide only proxy measures that may not accurately reflect the actual time spent on documentation tasks. These metrics often rely on time stamps that capture when a note window is open, which may overestimate documentation time if clinicians multitask or leave notes open [11]. Direct time-motion observation, though more resource intensive, offers superior accuracy in distinguishing active documentation from passive or multitasking periods [12].

To address these evidence gaps, we aimed to determine the effectiveness and acceptability of ambient scribe technology when compared to the standard of care in a multilingual health care setting using direct observational methods.

Methods

Study Design

We conducted a prospective within-clinician observational study to evaluate the real-world clinical impact of an in-house ambient AI scribe in outpatient clinics of Singapore General Hospital, a quaternary referral center with more than 1700 beds that is the largest academic medical center in Singapore [13]. This study was conducted over 5 months between December 27, 2024, and May 30, 2025. It builds on a previous pilot study at the same institution that demonstrated the ambient scribe tool's ability to generate high-quality clinical notes comparable to those written by clinicians [14].



Ambient Scribe Technology

Note Buddy, the ambient scribe tool used in this study, was developed in-house using automatic speech recognition and large language model technology. This tool supports transcription in 5 languages commonly used in Singapore: English, Mandarin, Malay, Tamil, and Cantonese. However, during the study period, only English, Mandarin, and Malay consultations were observed.

Note Buddy can process conversations of up to approximately 96,000 words (based on token limits), identifying speakers and languages at the word level. It leverages GPT-4o's (OpenAI) native multilingual capabilities to process mixed-language transcripts without pretranslation or model fine-tuning. Note Buddy then reformats and summarizes transcripts into clinical consultation notes. On the basis of routine system use, note generation (from end of consultation to completed draft) typically requires 10 to 30 seconds, with duration varying by consultation length and prompt complexity. The system processes audio in real time without storing recordings (Figure 1).

XSL•FO
RenderX

Figure 1. Workflow of Note Buddy use in clinical practice. Users configure prompt templates that specify the structure and formatting of the generated notes. During consultations, the system transcribes clinician-patient interactions in the supported languages. After each consultation, the ambient scribe processes the transcript using the predefined prompt to generate a draft note, which clinicians review, edit if needed, and manually transfer into the electronic health record (EHR). GenAI: generative artificial intelligence; LLM: large language model; PII: personally identifiable information.

Users can customize the generated notes by creating prompt templates specifying note structure and clinical terminology, providing example notes for guidance, or selecting from preconfigured prompts in the prompt library. As the tool was not integrated into the EHR during the study period, clinicians had to manually transfer the AI-generated notes from the ambient scribe into the EHR.

Participants and Setting

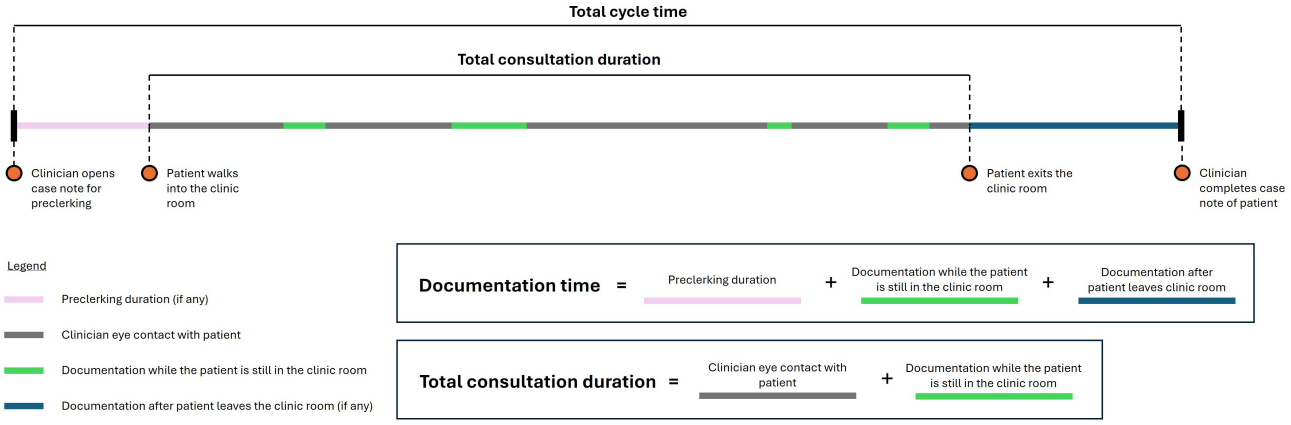
This study was conducted in an outpatient clinic setting where consultations naturally occur in multiple languages according to patient preferences. We recruited clinicians who had generated at least 30 notes using the ambient scribe tool in the 3 months prior to study commencement.

Clinicians unable to participate in 2 consecutive clinic sessions were excluded. Due to the time-intensive nature of direct observation, we intentionally focused on experienced clinician users who had achieved proficiency with the system and were most likely to demonstrate its optimal impact. From 27 eligible clinicians, 9 (33.3%) were selected through convenience sampling based on scheduling feasibility and observer availability.

Each clinician selected 2 clinic sessions for observation: one session using the ambient scribe tool and one using standard documentation methods. Clinicians were asked to select sessions with a similar patient case mix and clinic characteristics. Standard documentation methods consisted of manual typing, with some clinicians potentially using built-in EHR features such as smart phrases. The use of such features was not systematically recorded. Each clinician decided whether to use the ambient scribe tool in the first or second observed session; this was not randomized.

The interval between the 2 clinic sessions was kept within 2 weeks to minimize changes in practice patterns over time. Scheduled appointments remained unchanged to reflect the natural distribution of new and follow-up patients in the real-world setting. The total number of patients per clinic session ranged from 8 to 15.

Data Collection: Observation Methodology



Five observers carried out the observations, with each observer consistently assigned to the same clinician across both clinic sessions. All observations were conducted in person, with the observer present in the consultation room during scribe and nonscribe sessions.

All 5 observers participated in a joint training session to minimize interobserver variability. This included instruction on using a macro-enabled Microsoft Excel worksheet for time-motion data collection. The session concluded with group practice on mock consultations until a consensus was reached on measurement definitions and recording techniques.

Using the standardized macro-enabled Microsoft Excel worksheet, observers recorded real-time data on 3 key metrics and 1 derived metric. Consultation duration was calculated as the time between patient entry and exit from the consultation room. Proportion of eye contact was defined as the percentage of the consultation duration for which the clinician was looking directly at the patient. Documentation time was measured as the total time that the clinician interacted with the computer across all phases of the patient encounter: preclerking (if any), during the consultation, and immediately after the consultation, as illustrated in Figure 2.

XSL•FO
RenderX

Figure 2. Schematic representation of time components measured in the observational time-motion study. Documentation time is the time taken for documentation performed before, during, or immediately after the consultation, defined as the total time the clinician interacted with the computer. Consultation duration is the time between patient entry and exit from the consultation room. Total cycle time is derived from the start of preclerking (if any) to completion of documentation. All time points were recorded in real time by trained observers using a standardized macro-enabled Microsoft Excel worksheet.

Total cycle time was calculated as a derived metric from preclerking start (if any) to documentation completion, as illustrated in Figure 2. This represents the complete time investment per patient encounter and directly reflects potential impact on clinic throughput.

As this ambient scribe was designed for real-time documentation, observers recorded documentation completed within the observation window, which required clinicians to finish notes during or immediately after consultations rather than deferring to later periods. In the sessions with ambient scribe use, documentation time included the time spent reviewing, editing, and manually transferring AI-generated notes into the EHR, as well as the time taken for the ambient scribe to generate the note. Observers did not separately track the time spent on each component.

Data Collection: Sample Size Explanation

Due to the resource-intensive nature of direct observation and the pragmatic evaluation design, we determined the sample size based on clinician availability and feasibility constraints rather than formal power calculations. A post hoc approximation using 2-tailed paired *t* test assumptions (effect size=0.5; α=.05; power=0.95) indicated a minimum of 54 consultations per group (total 108 consultations). This simplified calculation does not account for the clustering of consultations within clinicians, which is addressed by our mixed-effects models. It serves as a conservative proxy given the complexity of power calculations for such models. Our final sample of 169 consultations exceeded this threshold.

Patient Surveys

Patient surveys were conducted to evaluate patient perspectives on ambient scribe use. Four of the 9 participating clinicians were selected through convenience sampling for patient surveys based on surveyor availability and clinician consent. Surveys were conducted across selected clinic sessions, resulting in partial overlap with time-motion observations, although the 2 data collection activities were conducted independently. Surveys were administered verbally by independent surveyors from the Office of Patient Experience immediately following consultations in which the ambient scribe tool was used. The survey assessed 4 domains: perceived quality of the clinical encounter, clinician's attentiveness and engagement, comfort level with AI-assisted documentation, and likelihood of recommending the technology for other clinical encounters. Patients were excluded from surveys if they declined participation or were deemed clinically unsuitable by their physician, for example, due to having just received a poor prognosis.

Statistical Analysis

We used descriptive statistics to summarize the characteristics of participating clinicians and consultation sessions. We applied the Pearson chi-square test to assess whether the distribution of new vs follow-up patients differed between consultations conducted with and without the ambient scribe tool. Linear mixed-effects models were used to account for clustering of consultations within individual clinicians and unequal numbers of observations per clinician. These models included random intercepts for individual clinicians to control for baseline differences in practice patterns and fixed effects for ambient scribe use and patient type (new vs follow-up consultation). Statistical significance was set at P<.05, and all analyses were conducted using SPSS Statistics (version 26.0; IBM Corp).

This manuscript was prepared using the SQUIRE (Standards for Quality Improvement Reporting Excellence) reporting guidelines.

Ethical Considerations

This study evaluated process metrics of an existing ambient scribe tool without collecting identifiable patient data or implementing clinical interventions. In accordance with institutional governance policies, the study was determined to constitute a quality improvement initiative and, therefore, did not require formal institutional review board approval (SingHealth Policy for Governance on Data Use [Non-Research]; document no. SHS-DDS-DAG-1002 [internal policy document]). For routine clinical use of the ambient scribe, explicit patient consent was not required based on institutional guidance as the system functions solely as a documentation support tool and does not store audio recordings. No audio recordings, transcripts, or personally identifiable information

XSL•FO
RenderX

were retained for evaluation purposes, and analyses were limited to deidentified workflow and time-motion metrics. Verbal consent was obtained from patients participating in anonymous satisfaction surveys. Participation was voluntary, and no financial or material compensation was provided to clinicians or patients.

Results

Sample Characteristics

Nine clinicians participated in this study, representing 7 different specialties (Table 1). They had a mean of 20.8 (SD 7.8) years in practice. Each clinician completed matched observation sessions with and without ambient scribe use. Of the 9 clinicians, 4 completed their first observed session using the ambient scribe, and 5 completed their first session without it, resulting in an approximately even distribution of session order. In this study, all clinicians used their own preconfigured prompts and did not make any further modifications to the prompts.

Table . Characteristics of participating clinicians in the observational study of ambient scribe use (n=9).

Characteristics	Values
Duration in practice (y), mean (SD)	20.8 (7.8)
Observed consultations per clinician, mean (SD)	18.8 (6.5)
Clinicians per specialty, n	
Respiratory medicine	2
Endocrinology	2
Gastroenterology	1
Neurology	1
Rehabilitation medicine	1
Neonatology	1
General surgery	1

As shown in Table 2, a total of 169 consultations were observed across the study period: 78 (46.2%) conducted with the ambient scribe and 91 (53.8%) conducted without it. The unequal distribution reflected natural variation in scheduled appointments and patient attendance across the matched clinic sessions. Of these 169 consultations, 54 (32.0%) involved new patients, and 115 (68.0%) were follow-up appointments. Of the 78 consultations with ambient scribe use, 63 (80.8%) were in English, 14 (17.9%) were in Mandarin, and 1 (1.3%) was in Malay.

Table . Distribution of patient types (new vs follow-up) among consultations conducted with and without the artificial intelligence (AI) scribe. The proportions of patient types were similar across groups, with no statistically significant difference in distribution.

Patient type	Overall (n=169), n (%)	Without AI scribe use (n=91), n (%)	With AI scribe use (n=78), n (%)	*P* value[a]
New patients	54 (32.0)	28 (30.8)	26 (33.3)	.72
Follow-up patients	115 (68.0)	63 (69.2)	52 (66.7)	.72

[a]Chi-square test comparing distribution between groups.

Given the potential for variation in individual clinician response, we examined unadjusted clinician-level changes comparing sessions with and without ambient scribe use (Figure 3). Substantial heterogeneity was observed: 7 of 9 clinicians demonstrated reductions in documentation time (7.9% - 34.6%), 6 of 9 had shorter consultation durations (4.3% - 42.2%), and 8 of 9 showed increased eye contact (4.2% - 35.8%).

XSL•FO
RenderX

Figure 3. Unadjusted clinician-level outcome changes with artificial intelligence (AI) scribe use. Each dot represents the percentage change for an individual clinician comparing sessions with and without AI scribe use. The dashed line indicates no change (0%).

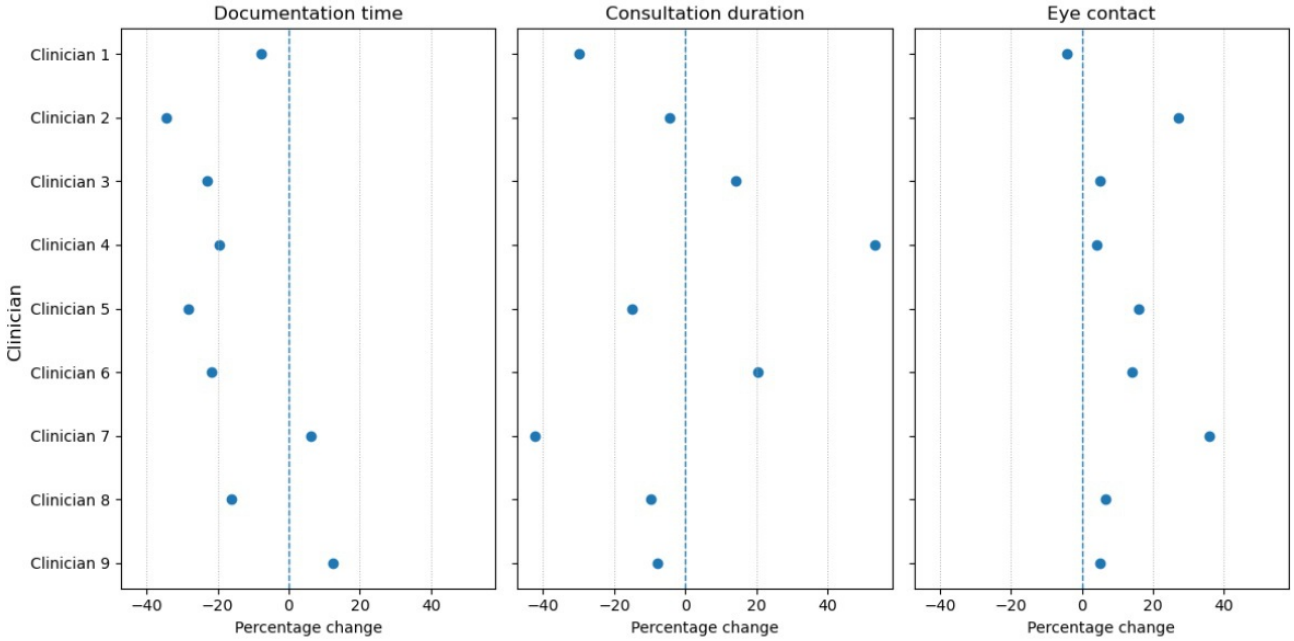


Table 3 summarizes the outcomes associated with the use of ambient scribes. Use of the tool was associated with 15.0% less time spent on documentation (from mean 5.3, SD 2.7 minutes to mean 4.5, SD 2.4 minutes per consultation; *P*=.04). The proportion of eye contact was 10.6% higher with ambient scribe use compared with standard documentation (from mean 69.6%, SD 18.6% to mean 77.1%, SD 17.7% of consultation duration; *P*=.009). Consultation duration was similar between conditions (mean 11.5, SD 6.9 minutes vs mean 10.9, SD 5.6 minutes; *P*=.42), and total cycle time per patient also did not differ significantly (mean 13.7, SD 7.7 minutes vs mean 13.2, SD 6.3 minutes; *P*=.57). The ambient scribe effects were consistent across new and follow-up patients for both documentation time and eye contact (interaction *P* values of .79 and .35, respectively), indicating uniform benefits across different consultation types.

Table . Comparison of outcomes between consultations conducted with and without artificial intelligence (AI) scribe use. Adjusted differences were calculated using linear mixed-effects models accounting for clinician-level clustering.

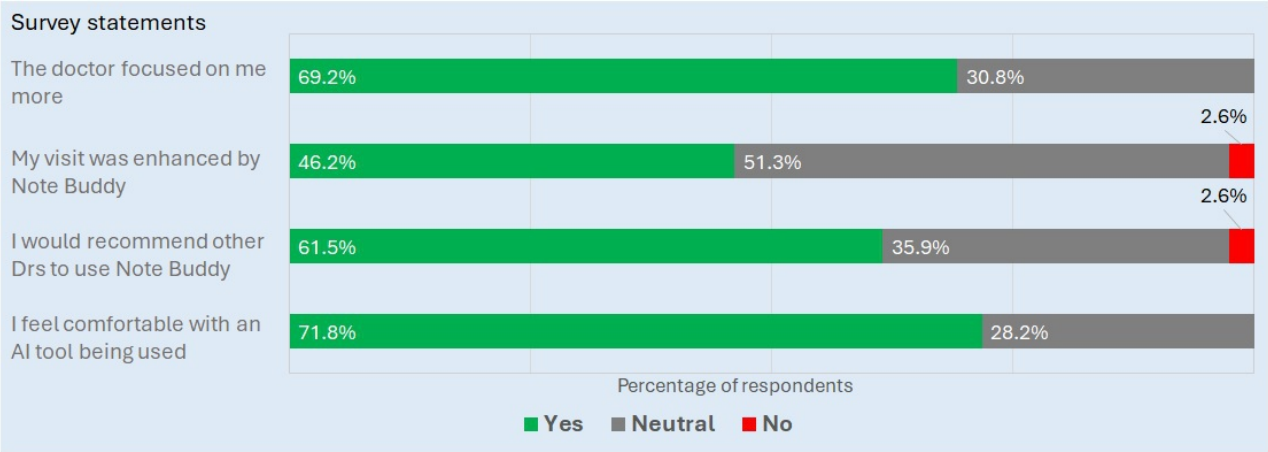
Outcome	Without AI scribe use (unadjusted), mean (SD)	With AI scribe use (unadjusted), mean (SD)	Adjusted difference (95% CI)	Change (%)	*P* value
Documentation time per consultation (min)	5.3 (2.7)	4.5 (2.4)	−0.8 (−1.5 to –0.05)	−15.0	.04
Proportion of eye contact time (%)	69.6 (18.6)	77.1 (17.7)	+7.4 (1.9 to 13.0)	10.6	.009
Consultation duration (min)	11.5 (6.9)	10.9 (5.6)	−0.7 (−2.6 to 1.1)	−6.1	.42
Total cycle time (min)	13.7 (7.7)	13.2 (6.3)	−0.6 (−2.6 to 1.4)	−4.4	.57

Crude independent-sample *t* tests treating all consultations as independent observations yielded similar effect sizes for eye contact (+7.5%; *P*=.008) and consultation duration (–0.67 minutes; *P*=.50). However, the reduction in documentation time reached statistical significance only in the adjusted mixed-effects analysis (crude: −0.74 minutes and *P*=.07; adjusted: –0.8 minutes and *P*=.04). This highlights the importance of accounting for clinician-level clustering.

Secondary Outcomes: Patient Experience

Patient surveys were conducted across 4 clinic sessions involving 4 of the 9 participating clinicians. Of 45 eligible patients in these sessions, 39 (86.7%) completed the surveys; 6 (13.3%) declined participation or were deemed unsuitable by their physician. Of the 39 surveyed patients, 18 (46.2%) were also included in the time-motion observations.

Age demographics are shown in Table 4, with 41.0% (16/39) of the patients aged 65 years and above. Survey language preferences were English (31/39, 79.5%), Mandarin and Chinese dialects (7/39, 17.9%), and Malay (1/39, 2.6%). Survey responses were collapsed into 3 analytic categories (“yes,” “neutral,” and “no”) based on evaluative meaning. Positive responses were coded as “yes,” neutral or indeterminate responses were coded as “neutral,” and negative responses were coded as “no.” The complete survey instrument is detailed in Multimedia Appendix 1.



XSL•FO
RenderX

Table . Age distribution of patients who completed surveys about ambient scribe use during consultations.

Age group (y)	Patients (n=39), n (%)
0 - 19	1 (2.6)
20 - 29	3 (7.7)
30 - 39	7 (17.9)
40 - 49	5 (12.8)
50 - 64	7 (17.9)
≥65	16 (41.0)

Overall, patient acceptance of the AI tool was favorable (Figure 4), with 69.2% (27/39) agreeing that their physician focused on them more during the consultation and 61.5% (24/39) expressing willingness to recommend the technology for use by other physicians. While some patients (20/39, 51.3%) gave neutral responses and 2.6% (1/39) reported that the ambient scribe did not enhance their visit, none expressed discomfort with its use.

Figure 4. Patient perceptions of ambient artificial intelligence (AI) scribe use (Note Buddy). Postconsultation patient surveys assessed perceived clinician attentiveness, consultation experience, comfort with AI-assisted documentation, and willingness to recommend the technology. Responses were collapsed into "yes," "neutral," and "no" categories for presentation.

Analysis of the overlapping subset of patients who were both surveyed and included in time-motion observations (18/39, 46.2%) showed internal consistency between objective measurements and patient perceptions: 61.1% (11/18) of these patients reported that their physician focused on them more during the consultation, whereas measured eye contact was 15.2% higher compared to the same clinicians' sessions without the ambient scribe (mean 72.7%, SD 15.9% vs mean 63.1%, SD 16.9%; *P*=.07). This directional alignment between objective and subjective measures supports the validity of both metrics.

To assess potential selection bias in the patient survey data, we examined whether the effect of the ambient scribe differed between clinicians whose patients were surveyed and those whose patients were not. After adjusting for patient type (new vs follow-up), there was no evidence of a differential effect for either documentation time (interaction *P*=.71) or proportion of eye contact (interaction *P*=.62). These findings suggest that the patient survey results are representative of the broader clinician cohort.

Discussion

Principal Findings

To our knowledge, this is the first study of the real-world impact of an ambient scribe conducted in Asia. Use of an in-house ambient scribe tool was associated with reduced documentation time and increased eye contact, whereas consultation duration remained unchanged. This suggests that clinicians redirected time from clerical tasks toward patient engagement rather than shortening consultations. The overlap between surveyed patients and time-motion observations (18/39, 46.2% of patients) provides supportive internal consistency, with patients who experienced objectively measured increases in eye contact also reporting improved clinician attentiveness.

Allowing clinicians to choose in which clinic session to use the ambient scribe instead of randomizing may have introduced selection bias. However, patient mix and volume were comparable between the scribe and nonscribe sessions (ratio of new to follow-up patients: *P*=.72; patient volume per session: mean 9.0, SD 3.4 with scribe use vs mean 9.8, SD 4.1 without scribe use; *P*=.44), suggesting that any such bias was minimal.

Our findings align with those of recent US studies showing that time savings tend to be modest. Documentation time was estimated to have been reduced by 0.8 minutes (95% CI −1.5 to −0.05; *P*=.04) in the intervention group. Although the upper confidence limit approached zero, indicating potential sensitivity to individual outliers, our observed reduction of 0.8 minutes per consultation is consistent with that observed in prior observational studies. These include findings from Sutter Health

XSL•FO
RenderX

(drop from 6.2 to 5.3 minutes) [6], The Permanente Medical Group (0.4-minute reduction) [15], and Stanford Health Care (0.57-minute reduction) [10], as well as recent randomized controlled trials reporting similar results [4,16]. Additionally, our study uniquely demonstrates improved patient engagement through increased eye contact, which we were able to quantify because we used direct observation rather than EHR-based metrics.

Unsurprisingly, this real-world evaluation demonstrated heterogeneity in individual-level effects between clinicians. However, our mixed-effects model was specifically designed to account for this individual variation while estimating the overall treatment effect, which remained statistically significant despite the heterogeneity. This within-clinician comparison design controlled for individual clinician variability and practice patterns that could confound results. Although our linear mixed-effects model relied on only 9 clinician clusters, which can affect the reliability of variance estimates and increase the risk of type 1 errors in mixed-model analyses, this design allowed us to isolate the specific effects of ambient scribe implementation while accounting for the natural variation in consultation styles and documentation practices across specialists.

Our findings also demonstrate that benefits observed in Western health care systems can be realized in a different cultural and linguistic context. Of the 78 consultations that used the ambient scribe, 63 (80.8%) were conducted in English, 14 (17.9%) were conducted in Mandarin, and 1 (1.3%) was conducted in Malay, highlighting the tool's utility in multilingual environments. The favorable patient responses observed, particularly among older adults, who comprised 41% (16/39) of survey respondents, provide reassuring evidence of acceptance across age groups.

The reproducibility of modest time savings across studies—including our observed 0.8-minute reduction—raises important questions about clinical meaningfulness at the individual clinician and health system levels. Notably, our finding that consultation duration remained unchanged despite reduced documentation time indicates that the time savings did not result in shorter patient encounters. Furthermore, our finding that total cycle time also remained unchanged demonstrates that ambient scribes should not be expected to increase clinic throughput or patient volume at the system level. Recent randomized controlled studies suggest that the primary value of this technology lies in reducing clinician burnout [4,16]. Our results complement this by demonstrating measurable improvements in patient engagement through increased eye contact and positive patient survey responses. Taken together, these findings suggest that ambient scribes should be viewed primarily as quality-of-care interventions that shift clinician attention from clerical tasks to patient interaction rather than as productivity tools [15,17].

Limitations

This study has several limitations. First, the sample was limited to 9 clinicians in specialist outpatient clinics due to the resource-intensive nature of direct observation, which restricts generalizability to other specialties and primary care settings. We focused on experienced ambient scribe users to reflect real-world use patterns as prior research shows that regular users account for 89% of system activations [18]. This means that our findings reflect optimal rather than average implementation outcomes and cannot predict outcomes during initial adoption or among infrequent users. Because our clinicians were both experienced scribe users and relatively senior (mean 20.8, SD 7.8 years of practice), we cannot determine whether the observed benefits reflect scribe proficiency or preexisting EHR documentation efficiency. If our senior clinicians had already optimized their workflows through customized EHR templates and shortcuts, the observed time savings may underestimate the potential benefits for less efficient documenters. Conversely, new users may experience a learning curve that could temporarily reduce initial gains.

Second, the ambient scribe tool required manual transfer of notes into the EHR, which likely underestimates potential time savings compared to fully integrated systems and limits direct comparability with studies of integrated solutions.

Third, several potential biases may have influenced our findings. Clinicians self-selected the sessions in which they used the ambient scribe, introducing the possibility of selection bias. Observer expectancy and Hawthorne effects [19] may have influenced clinician behavior or the measurement of eye contact as observers and clinicians could not be blinded. Interrater reliability could not be assessed because multiple observers in the consultation room would have been intrusive; however, each clinician was consistently observed by the same individual across both conditions to minimize observer-related variability. Patient survey responses may have also been subject to social desirability bias as patients may have been reluctant to express negative views about the technology when surveyed immediately following their consultation within the clinical facility despite the use of independent surveyors. As the ambient scribe tool was developed in-house, some degree of institutional bias is possible, although objective measurement methods were used to minimize this risk.

Finally, this study did not specifically assess whether note accuracy was preserved in the context of the observed reductions in documentation time; nonetheless, the tool's clinical fidelity had been reported in a previous study [14]. The predominance of English-language consultations (63/78, 80.8%) limits conclusions about multilingual performance. Clinicians used different prompts, including customized ones, and we did not systematically analyze variation in prompt length or complexity. Such prompt variability may have influenced the time taken for the ambient scribe to generate a note and represents a potential confounder.

Future Directions

The observed heterogeneity in individual-level effect sizes in this real-world study highlights that the potential benefits of ambient scribe adoption may not be uniform even in experienced users. Future studies should evaluate the impact of ambient scribe technology across a broader range of clinicians and practice environments to identify which user profiles benefit the most and which may require additional support. Qualitative research into factors affecting adoption and sustained use will be important for ensuring long-term effectiveness and

XSL•FO
RenderX

scalability. Future work should systematically evaluate how prompt design—including specialty-specific or individualized prompts—affects the quality of AI-generated documentation and the time required for clinician review and editing. While our study suggested effectiveness in a multilingual patient population, most consultations (63/78, 80.8%) were conducted in English. Further work is needed to assess whether the same benefits are observed in non–English-language consultations as language may influence both scribe performance and outcomes.

Conclusions

This quality improvement study found that ambient scribe use among experienced users was associated with modest reductions in documentation time and improved patient engagement, with high patient acceptance. These findings quantify the impact of ambient scribes in a real-world outpatient setting using direct observational methods. Our findings demonstrate that these benefits can be achieved through in-house–developed solutions, offering health care systems an alternative to commercial products in cases in which data privacy, cost, or localization are key concerns.

Acknowledgments

The authors gratefully acknowledge the contributions of Singapore General Hospital's Office of Patient Experience for survey administration, the SingHealth Office of Insights and Analytics for developing the Note Buddy software, the Singapore General Hospital Specialist Outpatient Clinics for equipment setup, SingHealth's National Neuroscience Institute for time-motion study support, and Joshua Ohde from the Mayo Clinic for manuscript guidance and proofreading. Abstract

Background: This Is My Story (TIMS) was started by Chaplain Elizabeth Tracey to promote a humanistic approach to medicine. Patients in the TIMS program are the subject of a guided conversation in which a chaplain interviews either the patient or their loved one. They are asked four questions to elicit clinically actionable information that has been shown to improve communication between patients and medical providers, strengthening medical providers’ empathy. The original recorded conversation is edited into a condensed audio file approximately 1 minute and 15 seconds in length and placed in the electronic health record where it is easily accessible by all providers caring for the patient.

Objective: TIMS is active at the Johns Hopkins Hospital and has shown value in assisting with provider empathy and communication. It is unique in using audio recordings to accomplish this purpose. As the program expands, there exists a barrier to adoption due to limited time and resources needed to manually edit audio conversations. To address this, we propose an automated solution using a large language model to create meaningful and concise audio summaries.

Methods: We analyzed 24 TIMS audio interviews and created three edited versions of each: (1) expert-edited, (2) artificial intelligence (AI)–edited using a fully automated large language model pipeline, and (3) novice-edited by two medical students trained by the expert. A second expert, blinded to the editor, rated the audio interviews in a randomized order. This expert scored both the audio quality and content quality of each interview on 5-point Likert scales. We quantified transcript similarity to the expert-edited reference using lexical and semantic similarity metrics and identified omitted content relative to that same expert interview.

Results: Audio quality (flow, pacing, clarity) and content quality (coherence, relevance, nuance) were each rated on 5-point Likert scales. Expert-edited interviews received the highest mean ratings for both audio quality (4.84) and content quality (4.83). Novice-edited scored moderately (3.84 audio, 3.63 content), while AI-edited scored slightly lower (3.49 audio, 3.20 content). Novice and AI edits were rated significantly lower than the expert edits (P<.001), but not significantly different from each other. AI and novice-edited interview transcripts had comparable overlap with the expert reference transcript, while qualitative review found frequent omissions of patient identity, actionable insights, and overall context in both the AI and novice-edited interviews. AI editing was fully automated and significantly reduced the editing time compared to both human editors.

Conclusions: An AI-based editing pipeline can generate TIMS audio summaries with comparable content and audio quality to novice human editors with one hour of training. AI significantly reduces editing time and removes the need for manual training; with further validation, it could offer a solution to scale TIMS to a large range of health care settings.

Introduction

Recent statistics show that health worker burnout is a widespread issue [1]. A 2022 Centers for Disease Control and Prevention report found that 46% of health workers "often" or "very often" felt burned out, increasing from 32% in 2018. Physicians in the United States also report similarly high burnout rates (56% in 2021, 53% in 2022, and 48% in 2023), with an all-time high physician burnout rate of 63% during the pandemic [2,3]. Some reasons for this burnout include excessive work hours, administrative burdens (such as electronic health record documentation), insufficient support staff, and limited organizational and leadership support [4-8]. These chronic stresses impact both patients and clinicians. For example, Andhavarapu et al [9] mentioned that symptoms of depression, anxiety, and posttraumatic stress disorder were reported in 34% of the health care workers surveyed (while 14% reported severe posttraumatic stress disorder), with the highest prevalence among nursing staff (42.8%) and physicians (25.2%). Similarly, the National Academies' 2019 report found that between 35% and 54% of US nurses and physicians and 45% to 60% of medical students and residents experience substantial burnout symptoms throughout their careers [10].

Empathy can serve as a solution, reducing widespread symptoms of burnout while promoting professional fulfillment and strengthening connection with patients [11-14]. Already, health care organizations have recognized the value of empathy and designed personal and patient-centered interventions within their clinical workflows [15]. For example, the This Is My Story (TIMS) program was developed by Chaplain Elizabeth Tracey at the Johns Hopkins Hospital to bring a more patient-centered and empathetic approach to medicine [16]. Patients who participate in the TIMS program take part in a conversation with a chaplain; if the patient is noncommunicative, a chaplain has a conversation with the patient's loved ones. These conversations are guided by four questions: How do you prefer to be addressed? What brings you joy? What does your medical team need to know to care for you best? What brings you peace?

In the words of Dr Charles Cumming, Director Emeritus of Otolaryngology at Johns Hopkins, *"TIMS is about helping us get back to the proper essence of medicine...it's essential to get to know the patient if we're going to be able to help that patient as best we can"* [17]. TIMS conversations have demonstrated clear benefits for clinical communication and empathy, providing an opportunity for meaningful connection with patients to directly target the emotional aspects of burnout [16,18-20]. Past studies by Tracey et al [21] support the positive outcomes the program has had on patients, their families, and the care team. For example, one previous study reported a 74% increase in staff empathy for patients and a 99% improvement in interactions by patients' loved ones with the medical team. Although it has also been shown to be useful in improving staff empathy and reducing distress by 69%, the process of recording and editing conversations can be labor-intensive [21]. By automating the conversation summarization process, these benefits can be made accessible to a wider range of patients and medical institutions.

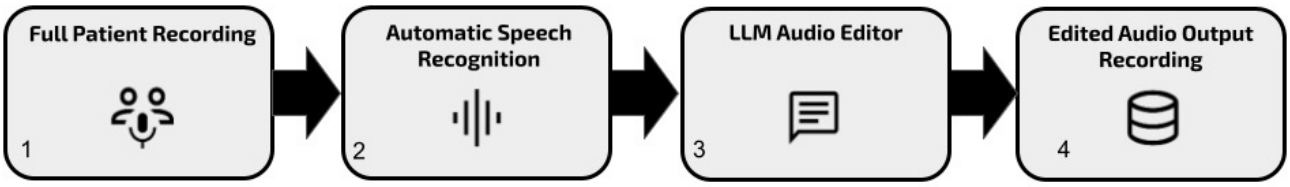
In this study, we propose an automated editing pipeline for TIMS interviews using a large language model (LLM) and evaluate whether artificial intelligence (AI)–edited interviews are a viable alternative to manual editing. Because medical students were frequently trained to edit TIMS interviews during the pandemic, they are a reasonable baseline for comparing performance. We designed our analysis around two key hypotheses: (1) that AI-edited interviews maintain similar quality to expert-edited interviews in both audio and content metrics, and (2) that AI-edited interviews can be produced more quickly than interviews produced by expert or novice editors.

Methods

Study Design

We used a within - subjects, single - group design in which our reviewer evaluated interviews across three independent editing conditions (expert, AI, novice). Editors were eligible if they had professional experience interpreting patient–clinician audio interviews. Two chaplains from the Johns Hopkins Hospital took part in the study. The novice editors were two medical students who joined the study team from the Johns Hopkins School of Medicine, each having completed an hour-long training session on audio - editing with an expert editor (Chaplain Elizabeth Tracey). The two novice editors edited 12 randomly assigned audio interviews, mirroring the normal workflow for the TIMS initiative without the AI tool.

Patient Audio Dataset



We used a retrospective dataset of audio recordings from 24 patients admitted to the Johns Hopkins Neurosciences Critical Care Unit, a tertiary intensive care unit for patients with diseases of the central or peripheral nervous systems, admitted from departments such as neurosurgery, neurology, and others.

AI Editing Pipeline

Audio recordings were first transcribed using Nvidia's Parakeet-TDT 0.6B v2 automatic speech recognition (ASR) model (Figure 1) [22-24]. ChatGPT-4o [25] processed the transcript using a custom prompt. This prompt asked the model to extract only patient statements that provided essential information about their condition, experiences, feelings, or personal identity. It was also directed to exclude any filler or repetitive content and keep humorous or insightful remarks to preserve patient identity and humanity.

XSL•FO
RenderX

Figure 1. Overview of artificial intelligence–automated workflow for summarizing This Is My Story audio interviews. LLM: large language model.

The model was instructed to include the interviewer's four core questions for the TIMS program while excluding interjections or examples provided by the interviewer. Instructions were given to return a processed transcript that the model estimated would take 1.5 minutes during a TIMS interview. The full model prompt is available in Multimedia Appendix 1. The relevant timestamps identified were then used to splice together the final audio file. Examples of cases in which ASR output might have impacted the LLM output are presented in Table S2 in Multimedia Appendix 2. This process was entirely automated and was run on an NVIDIA GeForce RTX 4090 with 24 GB of RAM.

Survey Design

To evaluate both audio quality and content quality for each edited TIMS interview, we created an online questionnaire for our reviewer to complete using a 5-point Likert scale (1=poor, 5=excellent) for each question. The survey included questions grouped into audio (natural flow, pausing/spacing, transitions, pacing, overall listenability of the interview) and content (conversation flow, speaker/topic tracking, patient representation, understanding of patient characteristics, preparation for interaction for patient providers/care team, nuance of the patient's life, relevance of details) quality domains with all details shown in Textbox 1 below. This same survey was used independently for each edited interview for consistent comparison.

Textbox 1. Summary of domain and survey questions following survey administration and data collection.

Audio quality

1. How natural is the conversation flow?
2. How effective are the pauses and spaces between answers?
3. How smooth are the transitions between questions and answers?
4. How does the pacing of the audio feel overall?
5. Overall, how easy is the interview to listen to?
6. Can you understand the flow of the conversation?

Content quality

7. Can you keep track of the speaker and the topic?
8. Is the patient well represented in this conversation?
9. Do you understand the patient's likes/dislikes (proclivities, idiosyncrasies, etc)?
10. Do you feel prepared to interact with the patient in a meaningful way?
11. How well does the conversation capture the depth and nuance of the patient's experience?
12. Does the conversation convey the patient's emotions effectively?
13. How relevant are the details shared during the conversation for understanding the patient's story?
14. How engaging is the conversation in terms of sustaining your interest in the patient's story?

The survey was created and administered using Google Forms. Content experts (ET, JW, CG) provided qualitative feedback on an initial draft of the questions. This feedback focused on improving the clarity and relevance of each item. The questions were then refined based on this input to better capture the intended domains of audio and content quality. It is important to note that because the survey instrument is novel, its reliability and validity have not yet been formally established. The survey asked questions 1, 5, 10, and 11 to gauge general sentiment for the conversation being rated, and more pointed questions to understand where the audios may differ in terms of score (Textbox 1). Since assessing the flow of conversation relies on both audio and content quality, a question about it was used for both parts of the survey. The individual survey responses are available in Figure S1 in Multimedia Appendix 3.

Before rating each edited version, the reviewer listened to the corresponding raw interview as a baseline reference to better understand the context of the interview. Before rating each interview, the reviewer was asked to first listen to two calibration audios—one edited poorly that should score low across all questions, and an expert-edited interview that would score highly. This allowed us to set audio quality expectations for each extreme on the survey. The survey was completed independently for each condition, with the order of the audio

XSL•FO
RenderX

files randomized by condition for each patient to reduce potential order effects.

Editing durations were recorded automatically for the AI pipeline and self‐reported by each novice editor. Expert editing times were not collected due to the limitations of the retrospective dataset.

Content Analysis

For each edited interview, we generated text transcriptions to study the differences in content among the three types of edited interviews. Text transcriptions were created using the Parakeet transcription model. The novice- and AI-edited interviews were compared to the expert edits, and three members of the study team analyzed differences. Types of errors were identified for both AI- and novice-edited conditions across all samples. The most common types of errors were then formalized and described in the results (Table 1). Content similarity between each condition and expert edits was quantitatively measured using ROUGE-L, ROUGE-1, ROUGE-2, bidirectional encoder representations from transformers (BERT), and METEOR on interview transcripts following studies of medical document summarization [26,27]. All metrics measure the similarity of words between summaries and assign a score from 0 to 1, with the ROUGE scores measuring lexical overlap and other scores [28]. METEOR and the BERT scores were used to assess the semantic overlap. Both factor in semantic similarity between words rather than the exact word choice. METEOR also assigns a penalty for differences in phrasing.

Table . Common omissions and inaccurate portrayals by artificial intelligence and novice editors.

Type of error	Artificial intelligence errors	Novice errors
Omission of actionable patient insights	Failure to include specific interests or hobbies of the patient [talking about favorite musical artists bringing her joy]: “She likes Anita Baker, Regina Belle, and Gladys Knight.”	Failure to include information about the patient’s comfort [informing about her medical condition to better care for the patient]: “She has had eczema since she was about three or four, so her skin has to stay moisturized.”
Omission of patient identity and empathy	Failure to include details relevant to understanding the patient’s background [explaining his occupation and hobbies] : “On the church side, he loves to teach. He is a pastor.”	Failure to mention important characteristics about the patient [claiming that her time at Hopkins has made her more independent and resilient]: “She [patient] worked at Johns Hopkins for over 30 years.”
Omission of emotional background	Failure to include framing details relevant for a patient’s background [talking about what brings the patient joy]: “Me [patient’s husband] … We’ve been married 20 years.”	Failure to include details relevant for a patient’s emotional state and anxiety [explaining how he mainly only trusts his partner for everything]: “[He has] a little bit of a trust issue with the medical field.”
Poor narrative fluency	Prompting questions fail to be edited out of the interview: “Introduce yourself and tell me how you’re related to the patient.”	Filler words before prompting questions fail to be edited out of the interview: “That’s great! So, what brings the patient peace?”

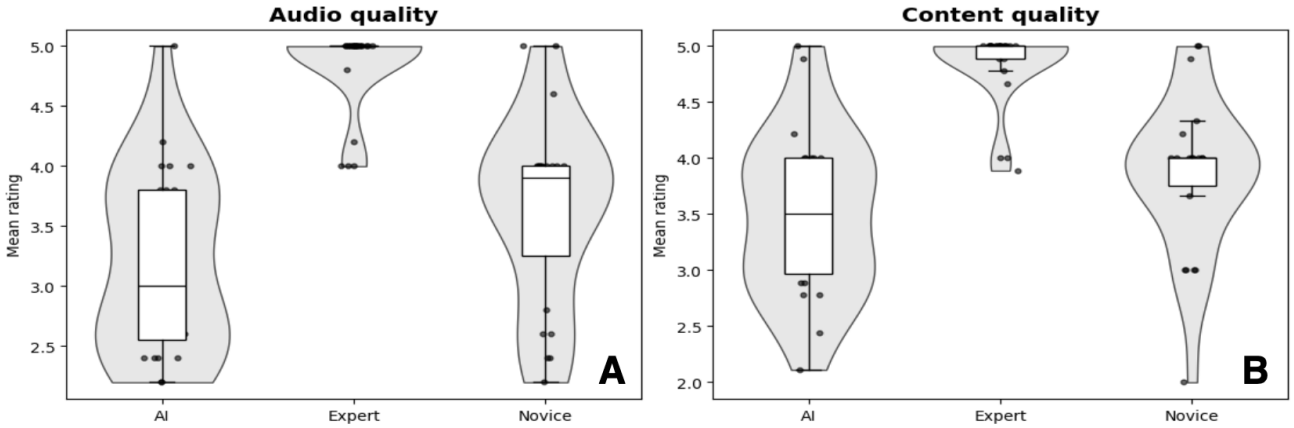
Relationships between audio length and content quality were also explored through simple linear regression of each ROUGE metric on the duration of the original interview (in minutes).

Statistical Analysis

We conducted a Friedman test to compare audio‐quality and content‐quality ratings across conditions, with Bonferroni‐corrected Wilcoxon signed-rank post hoc tests to adjust for multiple comparisons. Editing times were analyzed with an independent‐samples *t* test to test significant differences between the two novice editors. We also examined the relationship between the raw interview length and lexical and semantic score overlap for each editor type using Pearson correlation, testing if each slope differed from zero. We then performed an analysis of covariance with transcript length, editor type, and their interaction term to determine if the slope of the length-overlap relationship differed between AI and novice editors.

Ethical Considerations

Ethical approval was not required for this study as it involved a secondary analysis of anonymized data. The original data collection was conducted under Johns Hopkins institutional review board review and approval of the studies with informed consent obtained from all subjects; the consent allowed for future data use and any participants who declined this future use were not included in this secondary analysis. This study was conducted in accordance with all local, institutional, national, and international regulations on human subject research.



Results

Quantitative Comparison of Editing Quality

Across the three types of editors, the mean audio quality ratings were 3.49 (AI-edited), 3.84 (novice-edited), and 4.84 (expert-edited). Similarly, the mean content quality ratings were 3.20 (AI-edited), 3.63 (novice-edited), and 4.83 (expert-edited). The AI-edited interviews demonstrated a higher variability in the rated content quality compared to the novice-edited interviews (SD 0.73 and SD 0.68, respectively). Both interview types were similarly varied in their audio quality ratings (SD 0.77 and 0.78, respectively). Figure 2 highlights the distributions of content and audio quality ratings across each type of edited interview.

XSL•FO
RenderX

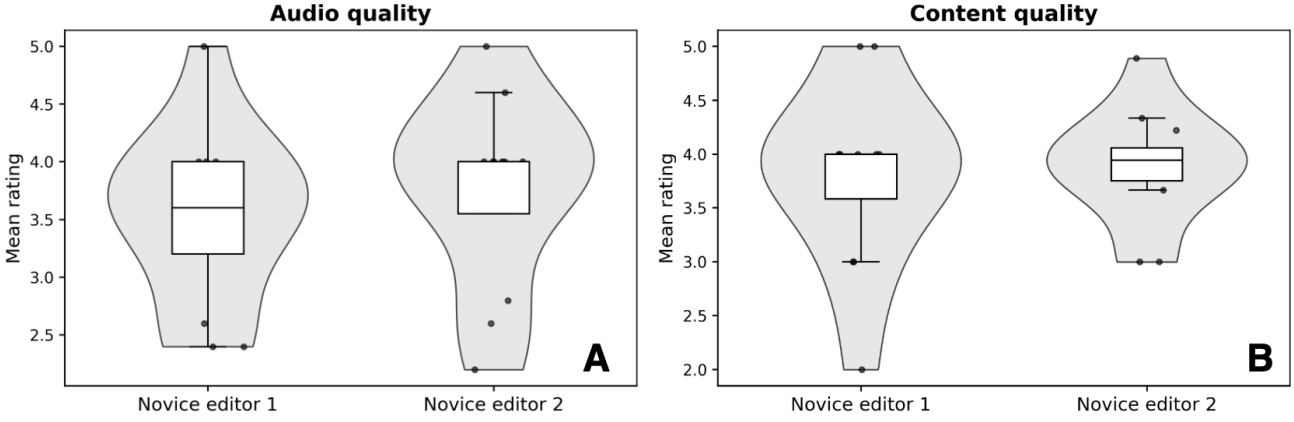


Figure 2. (**A**) A comparison of mean audio quality ratings across the three types of editors aggregated across all 24 audio interviews. (**B**) All editors follow similar trends for the content quality ratings. AI: artificial intelligence.

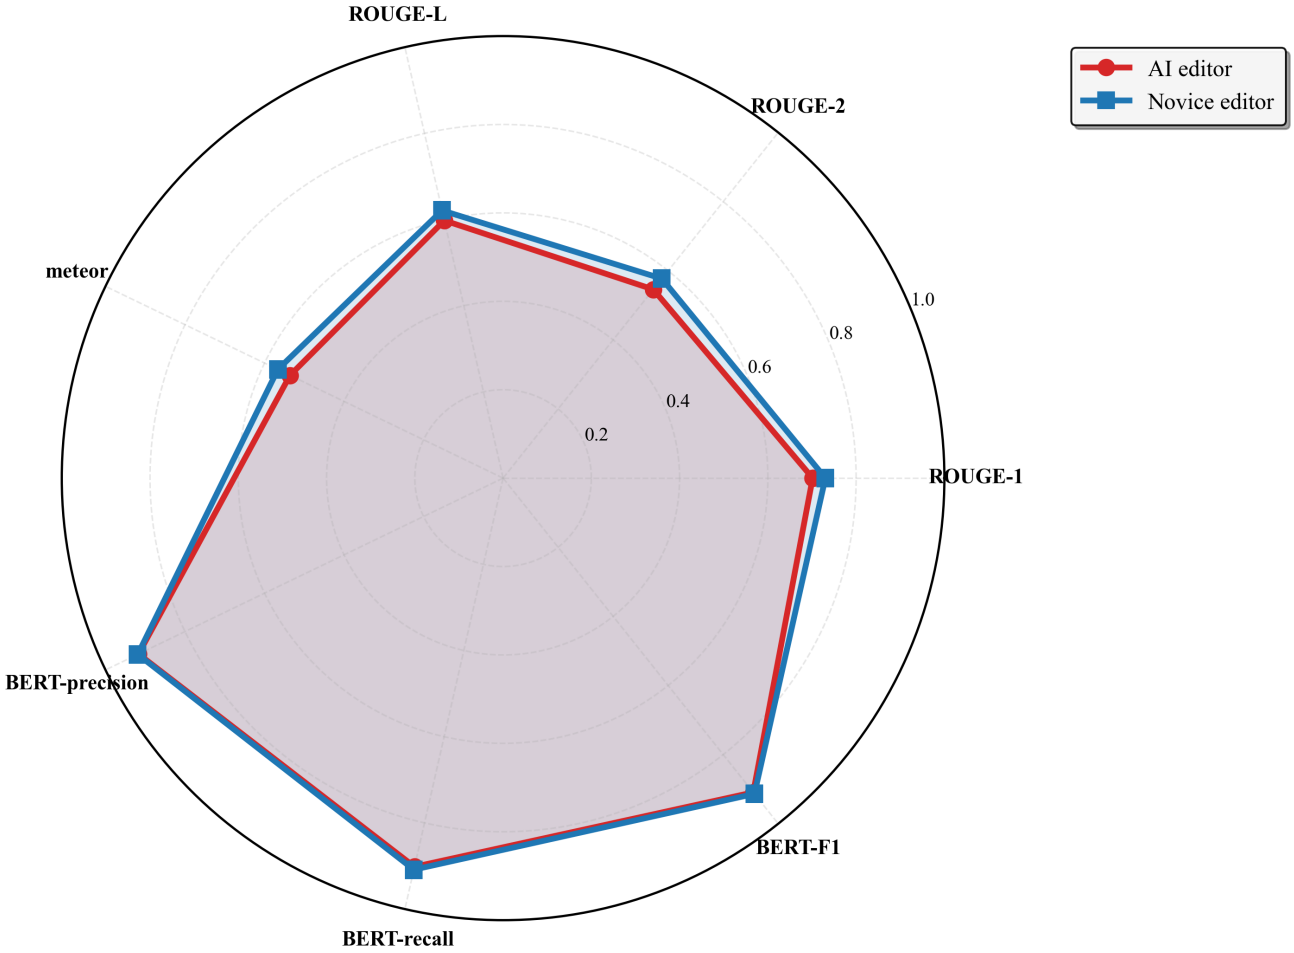
We observed significant differences in audio and content quality between the novice- and expert-edited interviews (P<.001) as well as between the AI- and expert-edited interviews (P<.001). No significant differences were noted between the AI- and novice-edited interviews for either content quality (P=.31) or audio quality (P=.33). A detailed breakdown of the ratings for each individual survey question across all patient interviews can be found in Figure S1 in Multimedia Appendix 3.



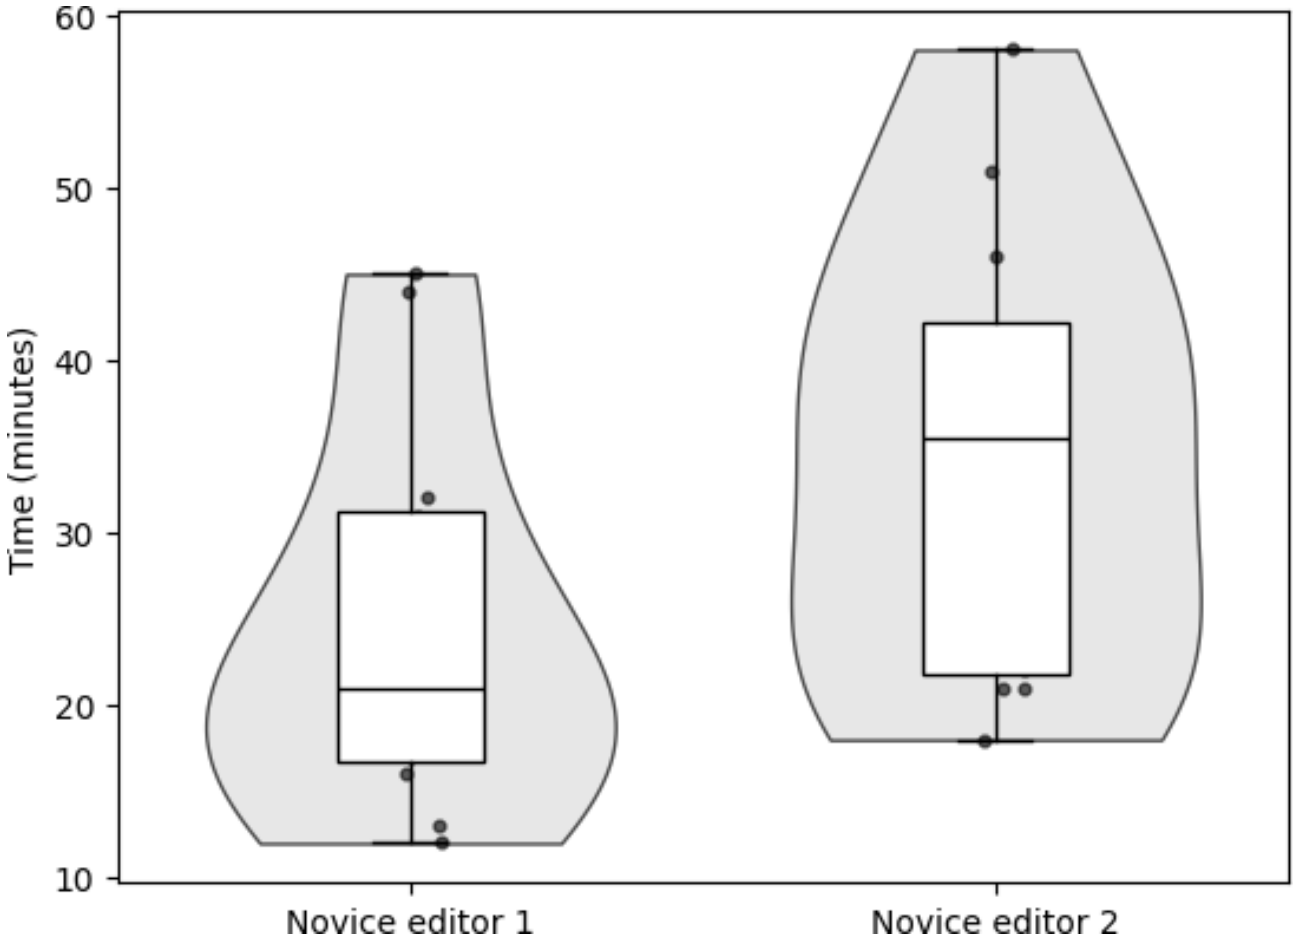
To understand the variability between the novice editors, we broke down the differences in rated audio and content quality in Figure 3. Between the two novice editors, we found that novice editor 1 demonstrated a mean content quality score of 3.81 (SD 0.83) and a mean audio quality score of 3.52 (SD 0.76). The second editor's mean content quality score was measured to be 3.88 (SD 0.52), with a mean audio quality score of 3.75 (SD 0.81). However, neither intragroup difference was significant for both content quality (P>.99) and audio quality (P=.51). Figure 4 shows the mean statistical scores across all audio interviews for both the AI and novice editors.

Figure 3. (**A**) A comparison of mean audio quality ratings between the two novice editors, each of whom edited 12 randomly assigned audio interviews. (**B**) Both editors achieved comparable content quality ratings, but the second novice editor exhibited significantly lower variability. All statistical scores of content similarity highlighted the similarities between the artificial intelligence and novice editors, and we report no statistically significant differences between any metric across both types of editors (P>.05). Detailed scores across each metric are contained in Table S1 in Multimedia Appendix 2.

XSL•FO
RenderX

Figure 4. Mean statistical scores across all 24 audio interviews for both the artificial intelligence and novice editors. AI: artificial intelligence. BERT: bidirectional encoder representations from transformers.

Qualitative Error Analysis



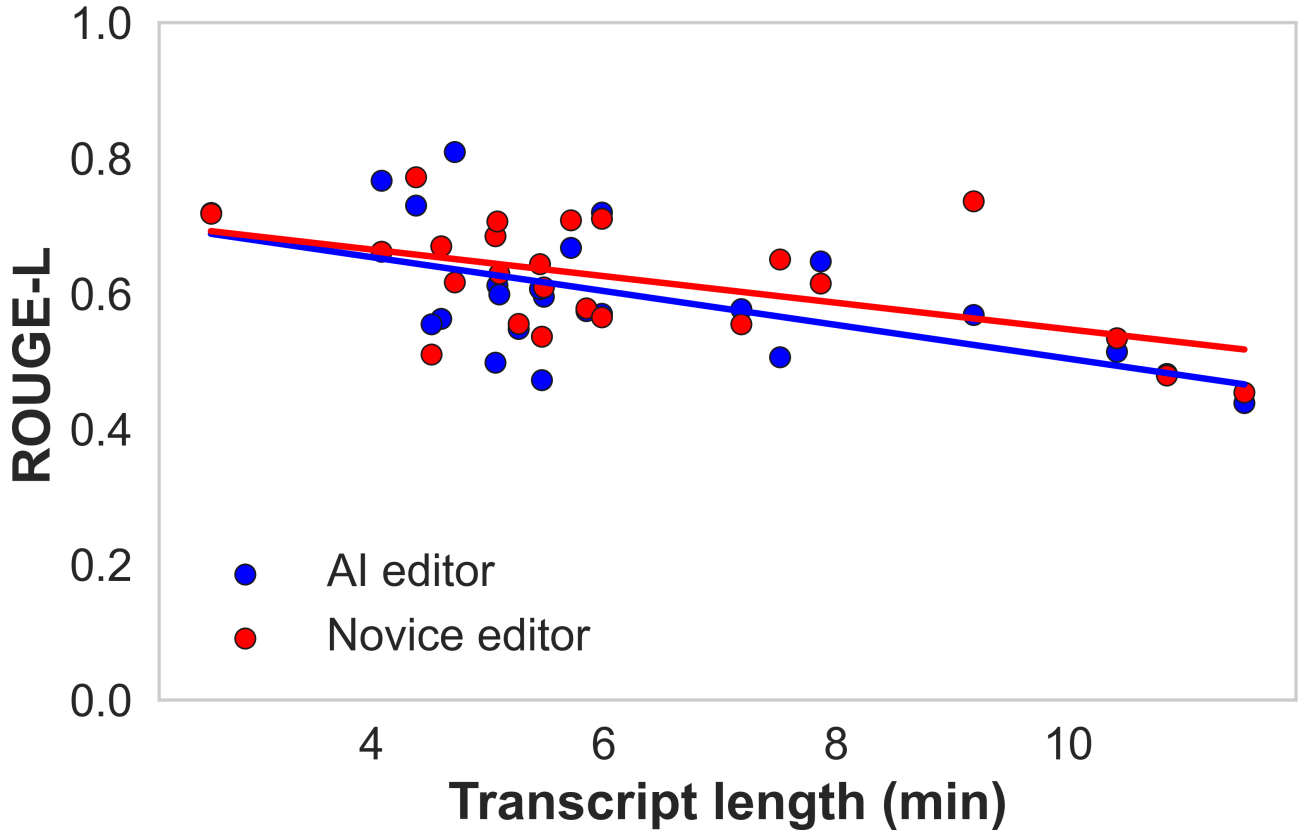
We qualitatively compared the AI- and novice-edited interviews to the expert-edited interviews and found five types of errors repeated across many of the interviews, which are described in Table 1. Many of the errors were similar across the AI- and novice-edited interviews.

Editing Efficiency

On average, each novice editor took 29.54 minutes to edit each interview (SD 12.69 min). However, we report a difference (P=.06) in the time each novice editor takes, with the first editor taking 24.50 minutes (SD 11.18 min) and the second taking 34.58 minutes (SD 13.08 min) to edit each interview. Figure 5 highlights the variability in the time to edit interviews between novice editors. Mean editing times for the expert editor are unavailable as they were not recorded. Based on anecdotal evidence from the expert editor, each audio interview required around 5 to 10 minutes to edit. In contrast to both the expert and novice editors, our automated AI-editing pipeline took less than 10 seconds from ingestion of the raw audio interview to the saving of the edited interview.

XSL•FO
RenderX

Figure 5. Time to edit each interview between each novice editor.



Impact of Interview Length on Editing Quality

We investigated if longer raw audio interviews were associated with changes in the lexical and semantic overlap with the expert reference, as measured by ROUGE-L. For AI-edited interviews, there was a significant negative correlation between transcript length and ROUGE-L scores (r=−0.58, R^2=0.34; Figure 6). This same trend was seen for novice-edited interviews, with a negative correlation (r=−0.52, R^2=0.27). Both slopes were significantly different from zero (P<.05), suggesting longer interviews were associated with lower transcript overlap to expert editor reference for both conditions. Regression plots for ROUGE-1, ROUGE-2, METEOR, and BERT scores showed comparable patterns and are provided in Figure S2 in Multimedia Appendix 3.

XSL•FO
RenderX

Figure 6. Linear regression of the raw transcript length versus ROUGE-L, reflecting the change in lexical similarity to the expert reference with longer interview times.

Discussion

Principal Results

Our study compares the listening experience of patient conversations summarized by an expert editor, a novice editor, and ChatGPT-4o. There was no significant difference in content and audio quality between the AI and novice editors, and both showed varying performance across the samples. Further analysis of the edited transcripts revealed that both of these groups omitted key details. The expert editor had a significantly higher audio and content quality rating than both experimental groups and less variability across samples. Exclusion of natural pauses between phrases and auditory cues to break up conversation led to lower audio quality scores.

Comparison to Prior Work

As burnout remains high among health care workers, TIMS provides an opportunity for meaningful connections with patients to target the emotional aspect of burnout. However, the manpower needed to edit audio is a limiting factor for this program's widespread adoption. Although the audio-editing pipeline introduced was originally developed to expand the TIMS program, these results are also broadly relevant to the use of AI in clinical practice and examine a previously unexplored application of LLMs, specifically editing audio content for a medical context. Previous studies have investigated ChatGPT as a clinical decision-making tool, for taking notes, and analyzing literature [26,28-35]. There have also been studies that demonstrate ChatGPT's capability to elicit empathetic feelings in an emergency setting can even exceed that of clinicians [36-38]. However, the combination of a summarization task to build empathy in a third-party listener has not been investigated. In this study, we aim to evaluate whether an LLM is able to extract emotionally relevant details from a conversation. Additionally, we provide a replicable framework for integrating LLMs in the analysis of patient audio for a broad variety of applications within health care settings. We found that our pipeline faced similar issues raised in previous studies examining ChatGPT's ability to summarize in a medical context. Kernberg et al [39] reported that 58% of structured medical notes from patient-physician interactions omitted important information. A manual analysis of the transcripts revealed that details considered important to a patient's story were also often omitted, highlighting a key disadvantage of LLMs in the literature. ChatGPT also tends to vary widely in the quality of responses across the samples. Although this was a shortcoming observed in the novice editors' performance on audio and content quality (SD 0.68 and SD 0.78), the expert editor's performance was consistent.

In addition to the survey, ROUGE scores (ROUGE-1, ROUGE-2, ROUGE-L) for the novice and AI editors indicated a high level of word overlap with the expert-edited transcript, with no significant differences between the two groups. High (~0.9) BERT scores (BERT-recall, BERT-precision, BERT-F_1) were also reported, indicating a high degree of semantic overlap that was not necessarily reflected in the ROUGE score. As the length of the audios increased, there was a statistically significant negative correlation between interview length and the ROUGE-L score for both AI and novice editors (P<.05), indicating longer interviews tended to have less lexical overlap

XSL•FO
RenderX

with the expert reference. This implies that there might be a length of audio that may not be as suitable for AI editing that will become more apparent as longer audios are recorded. These results from an established tool align with the insights from the survey, suggesting some level of construct validity for the survey questions.

Limitations

There are key limitations beyond the strengths of this study. First, there is no standardized or validated survey instrument available, so the introduction of a novel survey to assess the impact of each audio on a listener was necessary. However, abstract questions concerning "patient representation" or "nuance" are susceptible to subjective interpretation, a weakness that is amplified by our use of a single blinded reviewer. We attempted to standardize these ratings with calibration audios that were developed, but we cannot exclude the possibility that these subjective quality scores were influenced by rater bias. Despite this concern, the consistently high scores awarded to the expert-edited interviews provide some evidence of the survey's validity, as the rater reliably scored the gold-standard interviews. This survey could be adopted in the future by studies to measure the efficacy of interventions to increase empathy in medicine.

Second, the sample size of the study was also relatively limited, with only 24 samples and 1 recruited rater who was surveyed, which makes the results prone to bias. To build on this work, a larger sample size of patient audio interviews and experienced interview raters should be recruited. Previous volunteers of the program were able to receive iterative feedback on their work over long periods, but the novice editors had approximately 1 hour of training in comparison, so their skills were not as developed. Lastly, we were unable to obtain granular editing time measurements from the expert editor as these were retrospectively edited. However, the AI pipeline's completion time of under 10 seconds represents a multiple-orders-of-magnitude improvement in efficiency against any manual editing process.

Future Directions

We have presented the groundwork for an audio transcription and editing pipeline for humanistic patient conversations. Future work should test newer models as they improve, and others that are currently available besides ChatGPT-4o, with the same pipeline. Other strategies to improve performance include fine-tuning the LLM model, using AI agents to summarize the transcript, testing other ASR models, introducing patient-specific contextual metadata, and further prompt engineering to optimize the output. Error propagation was not formally tracked through the entire editing pipeline, but we have hypothesized an association between ASR errors and the final output quality. Future work should investigate these errors.

Conclusions

We conclude that ChatGPT-4o can create summarized audio files with similar audio and content quality to a novice editor in just a fraction of the time. However, the expert editor outperforms the AI editing pipeline and the novice editors on all metrics. After further validation, this tool could be implemented in the TIMS program to reduce workload and overcome adoption barriers.

Acknowledgments

This research has been generously supported with grants from the John Conley Foundation for Ethics and Philosophy in Medicine. We additionally acknowledge support from the Catalyst Award and the Diversity Innovation Grant from Johns Hopkins University. Lastly, we thank the Johns Hopkins Technology Innovation Center for providing access to a protected health information–compliant version of ChatGPT-4o.

Data Availability

The original interview recordings are not publicly available for privacy protection considerations but are available from the corresponding author on reasonable request. The relevant code is provided here [40]. This code corresponds to the automated audio-editing pipeline that processes raw audio, uses ChatGPT-4o to extract key segments, and stitches those selected segments into an AI-edited audio.

Authors' Contributions

All authors contributed to the conceptualization and study design. SR, BB, and ER curated the data and conducted the analysis. ET and JW managed and supervised the project. All authors reviewed and edited the manuscript.
