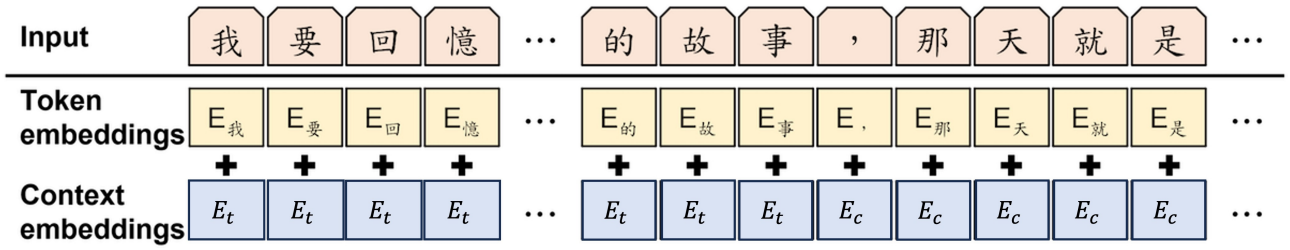
In addition, due to the nature of the AM test, subjects can share stories on unrestricted topics. To facilitate the model to capture more meaningful information from the transcripts, we apply the topic insertion technique proposed by our previous work [11,18]. This technique is to add a sentence with the mentioned topic at the beginning of the transcript, such as “I’m going to share a story of...” The tester specifies the topic during data collection. This step helps ensure that the subsequent transcript is thematic. After the whole preprocessing of linguistic data, from the raw audio xi,km, we finally obtain the transcripts with topics and pauses xi,km,t, along with 9 additional linguistic features xi,km,l, which include mean length of utterance; the number of short, medium, and long pauses; and 5 types of POS tags.

Encoder Module

Acoustic Encoder



During the data preprocessing stage, 1024-dimensional deep learning–based acoustic features, denoted as xi,km,a, were extracted using the wav2vec 2.0 model. These high-level representations were then passed to a lightweight convolutional neural network–based acoustic encoder designed to capture hierarchical temporal-spectral patterns. The encoder consists of three 1D convolutional layers with kernel size 3 and stride 1, each followed by batch normalization, rectified linear unit activation, and max-pooling with a kernel size and stride of 2, progressively reducing the feature resolution by a factor of 8. The convolutional layers use 16, 32, and 64 filters, respectively, to model increasingly abstract local dependencies in the acoustic embedding. The resulting feature maps are flattened and projected through a fully connected layer that maps the representation to a 128-dimensional latent space. This projection enhances computational efficiency, mitigates overfitting, and provides a compact and informative acoustic embedding ai,km for multimodal fusion.

Linguistic Encoder

In the linguistic encoder, the ASR transcript xi,km,t and 9-dimension features xi,km,l generated during data preprocessing are sent to the BERT [20] model and a linear layer, respectively, for initial encoding. During data preprocessing, to ensure that the subjects’ speech has a thematic structure, we add a topic at the beginning of the transcript. In BERT, we borrow the concept of segment embeddings from the original paper [20]. Here, we refer to it as “context embedding” to enhance the model’s understanding of the topic and content. We divide the transcript into 2 parts: topic and context. The topic part is labeled as 0, and the context part as 1. These values are then encoded into context embeddings E_t and E_c through a learning embedding layer. This design helps the model determine whether there is a sufficient correlation between the topic and content. Research in AM tests indicates that episodic memory significantly declines in patients with cognitive impairments [21,22]. Therefore, we can assess the subject’s cognitive state by examining whether the subject’s story contains details related to the topic.

As illustrated in Figure 4, context embeddings are element-wise added to the original BERT token embeddings for further processing. A linear layer is used as a numerical encoder for linguistic features xi,km,l. Finally, the output from BERT and the learned numerical embeddings are concatenated and processed through a projector to obtain the final linguistic embedding ti,km.

Figure 4. Overview of the BERT embedding. Each input token is first mapped to a token embedding, which is combined with additional context embeddings to capture both semantic meaning and conversational context. BERT: bidirectional encoder representation for transformer.

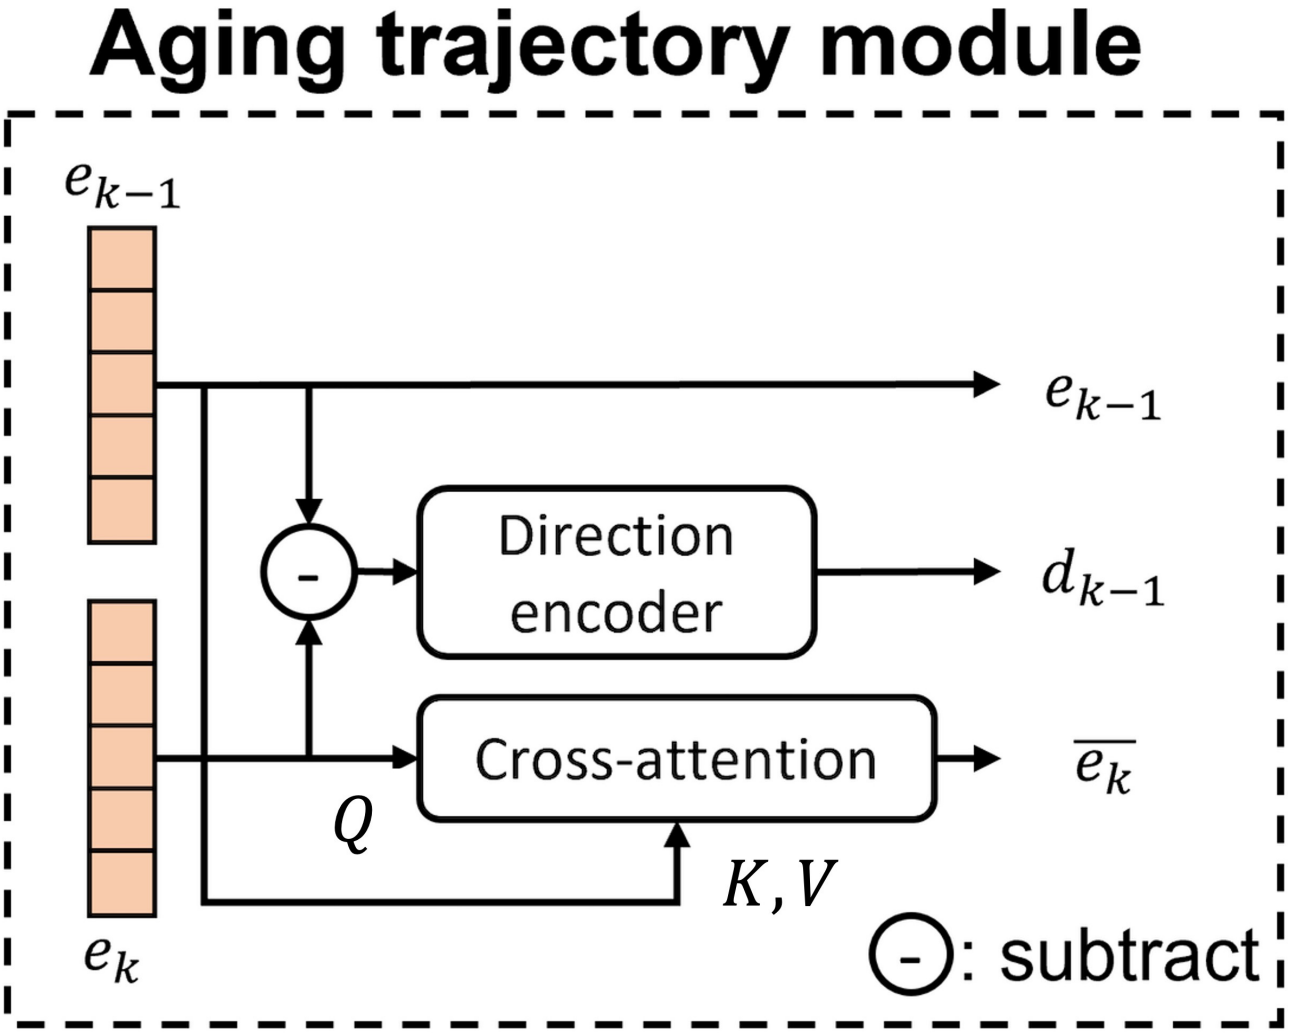
RenderX

Fusion Layer

In this study, we adopt a self-attention fusion method to enable the model to capture information between different modalities more effectively. The concept is illustrated in Figure 5. After obtaining the acoustic embedding ai,km and the linguistic embedding ti,km, these 2 embeddings are added together to form a combined representation, which is then fed into a multihead self-attention layer. Through the calculations of the self-attention layer, we obtain the final integrated embedding ei,km. This design helps the model capture deeper interrelated information between different features.

Figure 5. Overview of the fusion layer. Acoustic and linguistic embeddings are integrated through a multihead attention mechanism, producing a joint embedding that captures cross-modal interactions and complementary cognitive cues.



Aging Trajectory Module

The ATM is a key component of our longitudinal model, designed to capture cognitive changes across multiple visits. The structure is shown in Figure 6. In our study, each subject contributes up to 3 visits. Therefore, the model's initial input is in the form of a triplet, {xi,1m1, xi,2m2,xi,3m3}. After passing them through the encoder model process, this becomes the embedding triplet of the same form, {ei,1m1, ei,2m2,ei,3m3}. In this module stage, the embeddings are fed in pairs, such as {ei,1m1,ei,2m2}or {ei,2m2,ei,3m3}, so that the model focuses on learning the relationship between visits *k* and *k*-1. To model these relationships, we use a cross-attention mechanism, where the embedding from the *k*th visit serves as the query (*Q*), and the embedding from the (*k*-1)th visit serves as the key (*K*) and value (*V*). This mechanism allows us to capture the differences in feature values between 2 visits. The reason for using the *k*th visit embedding as the query and the (*k*-1)th visit embedding as the key and value is that, in practice, we can retrieve information only from the past data and not future data. This approach ensures that the model can access information only from the previous visits, reflecting a realistic scenario where future data are unavailable. By doing so, the model learns to focus on the most relevant past information that can be referenced by the current visit, enabling the tracking of changes and peeking of patterns of cognitive decline over time. This method effectively highlights the differences and similarities between visits, providing a more nuanced understanding of the subject's cognitive progression.

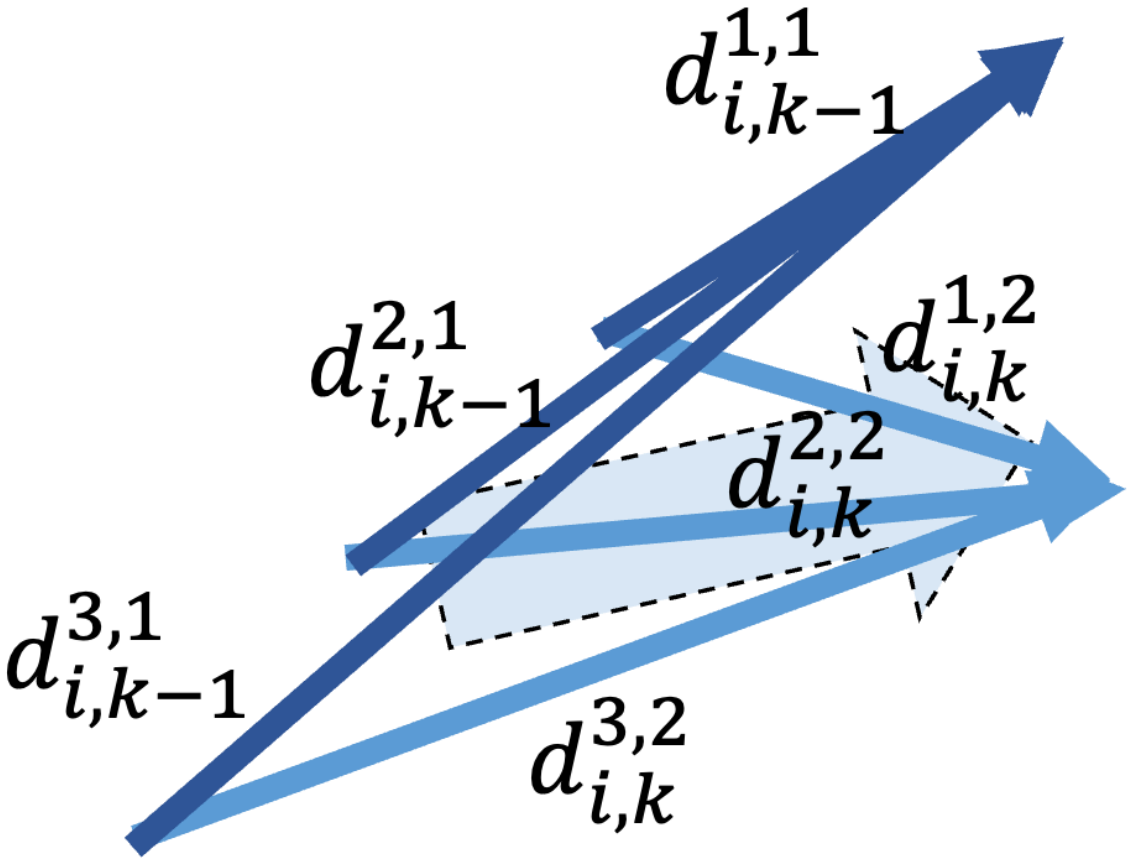
XSL•FO
RenderX

Figure 6. Overview of the aging trajectory module. Consecutive visit embeddings are compared through cross-attention and a direction encoder to capture cognitive differences between visits.

The concept of contrasts is quite straightforward. We aim to explore a deeper understanding of the relationship between the (*k*-1)th and *k*th visits. To achieve this, we use a cross-attention mechanism. In this setup, the embedding from the *k*th visit is used as the query (*Q*), whereas the embedding from the (*k*-1)th visit serves as the key (*K*) and value (*V*). This mechanism allows us to capture the differences in feature values between 2 visits. The reason for using the *k*th visit embedding as the query and the (*k*-1)th visit embedding as the key and value is that, in practice, we can retrieve information only from the past data and not future data. This approach ensures that the model can access information only from the previous visits, reflecting a realistic scenario where future data are unavailable. By doing so, the model learns to focus on the most relevant past information that can be referenced by the current visit, enabling the tracking of changes and peeking of patterns of cognitive decline over time. This method effectively highlights the differences and similarities between visits, providing a more nuanced understanding of the subject's cognitive progression.

To quantify the differences between visits, we introduce a direction encoder f_D, composed of several linear layers. The difference between embeddings is projected into a latent space to represent an aging-oriented change vector *d*, formulated as equation 2, where di,k−1mk−1,mk means the direction from mk-1th story in the (*k*-1)th visit to the mkth story in the *k*th visit. mk=1,2,…,Mi,k, where Mi,k is the total number of stories for subject *i* in the *k*th visit. Similarly, mk-1=1,2,…,Mi,k-1, where Mi,k-1 is the total number of stories for subject *i* in the (*k*-1)th visit.

(2)di,k−1mk−1,mk= fD(ei,kmk−ei,k−1mk−1)



In addition, during the training process, motivated by the research [11,23,24], we introduce 2 types of losses: subject alignment loss and group alignment loss. These alignment losses are designed to align both individual and group targets, helping the direction encoder learn more accurate aging-oriented changes. We expect that by applying these losses, the resulting direction *d* will carry more representative meaning, aiding the longitudinal model in accurately assessing the subject's cognitive condition.

Subject Alignment Loss

In the subject alignment loss L_S, the concept is to ensure that the same subject's internal directions are similar. In our problem setting, the stories of the input triplet are randomly paired in different visits. Therefore, it is expected that the directions from the same subject may vary in the latent space. However, the cognitive decline of a subject should be consistent. Figure 7 shows an illustration of the concept.

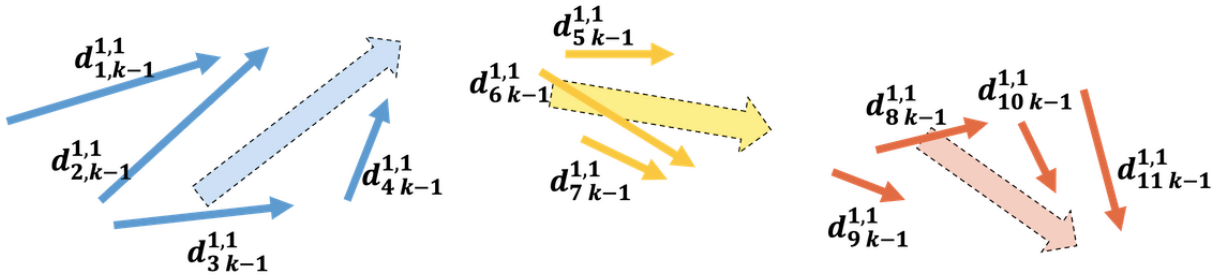
XSL•FO
RenderX

Figure 7. Illustration of the concept for subject alignment loss. It visualizes how the subject alignment loss ensures that the overall trajectory directions of the subject remain consistent, although the internal trajectory of story-level embeddings for the same subject may show slight variations across different visits.

Therefore, subject alignment loss aims to reduce the differences in direction within the same subject. The loss used here is cosine similarity loss. The process of calculating the subject alignment loss is to first calculate the average subject direction for each visit as shown in equation 2. We then compute the subject alignment loss by summing the alignment loss of all subjects as defined in equation 3. The generalized subject alignment loss is defined as equation 3, where di,k−1− represents the average direction of every audio file in the (*k*-1)th visit to *k*th visit from the subject *i* in the latent space, and *N* represents the total number of subjects. $L_{S,i}$ represents the subject alignment loss for subject *i*, and cos θA,B=A.BAB is the cosine similarity function. In our case, since the dataset contains 3 visits, our *V* is 3, and the loss is applied to the pairs (first visit and second visit) and (second visit and third visit).

(3)di,k−1−=1Mi,k−1×Mi,k∑mk=1Mi,k∑mk−1=1Mi,k−1di,k−1mk−1,mk

LS=∑i=1NLS,i



(4) =∑i=1N∑k=2V∑mk=1Mi,k∑mk−1=1Mi,k−11−cosθ(di,k−1−,di,k−1mk−1,mk)

Group Alignment Loss

In the group alignment loss L_G, the concept is to ensure that subjects with the same cognitive label have similar cognitive progression changes as illustrated in Figure 8. Unlike the subject alignment loss, which focuses on the internal alignment of directions within a subject, the group alignment loss emphasizes the external alignment of directions between different subjects. Specifically, we compare the cognitive change directions of subjects with the same label transitions. Here, we use the Supervised Contrastive Loss (SupConLoss) [25] to encourage the directions of subjects with the same label changes to be closer to one another. The label transitions considered are HC to HC, HC to MCI, and MCI to MCI. The process of calculating the group alignment loss is using equations 5 and 6, where *N* represents the total number of subjects, and $L_{G,i}$ represents each group alignment loss for subject *i*. SupConLoss(·, ·) is the SupConLoss function. lk-1,ki is the label transition type of subject *i* from (k − 1)th visit to *k*th visit.

XSL•FO
RenderX

Figure 8. Illustration of the concept for group alignment loss. It visualizes how the group alignment loss enforces consistency in progression directions among subjects sharing the same cognitive label. Blue represents the group from healthy control (HC) to HC, yellow represents the group from HC to mild cognitive impairment (MCI), whereas orange represents the group from MCI to MCI.

(6)LG=∑i=1NLG,i=∑i=1N∑k=2V∑mk=1Mk1Mk−1SupConLoss(ei,mk−1,mk,li)

(6)LG=∑i=1NLG,i=∑i=1N∑k=2V∑mk=1Mk1Mk−1SupConLoss(ei,mk−1,mk,li)

To summarize, group alignment loss L_G aims to minimize the distance between the cognitive progression directions of different subjects with the same cognitive label transitions types. This helps ensure that subjects exhibiting similar cognitive changes have consistent representations, thereby improving the model's ability to generalize across different subjects. By leveraging SupConLoss, we can effectively capture and align these progression patterns, leading to more accurate and robust cognitive state predictions.

Classifier and Overall Loss

After the ATM, we obtain the final outputs {e−i,1m1,e−i,2m2,e−i,3m3,di,1m1,m2, di,2m2,m3}, where e−i,kmk represents the enhanced latent representation after the cross-attention layer. These representations are then concatenated and fed into a classifier. The classifier comprises a batch normalization layer and a fully connected layer to produce the final prediction. Finally, the overall loss function can be formulated by equation 7, where Lclass is the binary classification loss, and α, δ, and γ are the hyperparameters of loss weight for L_E, L_G, and L_S, respectively. The hyperparameters are fine-tuned, and the optimal values are 0.01, 0.001, and 0.001.

(7)L= Lclass+αLE+δLG+γLS

The encoder loss L_E is a contrastive loss designed to enhance the representativeness of the embeddings generated by the encoder and is defined by equation 8, where N is the total number of the subjects, V is the total number of visits, and M_k is the total number of stories in the kth visit. This loss ensures that embeddings with the same cognitive status are closer to one another while pushing apart embeddings with different labels.

(8)LE=∑i=1NLE,i=∑i=1N∑k=2V∑mk=1MkSupConLoss(ei,mk,li)

Dataset

Dataset Collection

Our experiments primarily focus on comparisons using our self-collected National Taiwan University Autobiographical Memory Test (NTU-AM) dataset. Previous studies [6,11,26,27] have confirmed that the AM test effectively tracks changes in cognitive function by evaluating subjects' memory functions. It can be used as a tool for MCI testing. During the test, subjects are asked to recall important life stories from different periods in their past. Compared with formal memory testing methods, this process resembles a general conversation, which helps reduce the stress experienced by subjects.

For the collected data used in this study, professional psychologists conducted one-on-one interviews. During these interviews, a microphone is used to record the conversation between the subject and the interviewer. Furthermore, subjects are asked first to talk about the titles of the important events they want to share (eg, "I want to share the story about when I was admitted to college at the age of 18 and my test result were announced"). The process of describing the events can be divided into two stages, namely, recall and probing.

1. Recall: The subject is first asked to roughly describe the events leisurely and then is encouraged to share as many details of the event as possible.
2. Probing: The interviewer then asks even more detailed questions based on what the subject mentioned in the recall stage. These questions cover various categories, such as "what," "when," "where," emotion or thought, and time integration.

During a single interview, the same subject can share multiple stories as a matter of fact. To sum up, the overall process of the AM interview test can be described as follows: (1) the subject decides the number and content of stories to be shared, (2) shares the recall content of each story, and then (3) the interviewer probes each story with a series of detailed questions.

Moreover, to track the cognitive changes of subjects over a long term, they are invited to take the AM test again after at least 6 months. In our current research, our longitudinal data include up to 3 rounds of AM interview test data, that is, each subject has 1 test data and 2 follow-up data. All data were collected by professional psychologists with institutional review board approval, ensuring high-quality data.

The National Taiwan University Autobiographical Memory Test Cross-Sectional (NTU-AM-CS) dataset was collected under a cross-sectional scenario, with the demographic distribution of participants shown in Table 1. This dataset includes 111 subjects, consisting of 56 HC and 55 MCI participants. Each participant could provide multiple important life stories during a single visit.

XSL•FO
RenderX

Table . The demographic distribution of participants in the National Taiwan University Autobiographical Memory Test Cross-Sectional dataset.

Group	N	Male	Female	Age (years), mean (SD)	Years of education, mean (SD)	MMSE[a], mean (SD)
HC[b] (n=56)	56	18	38	71.3 (5.4)	16.2 (9.8)	28.7 (1.6)
MCI[c] (n=55)	55	17	38	70.7 (6.9)	13.1 (7.1)	27.1 (2.0)
Total (N=111)	111	35	76	71.0 (6.2)	14.6 (8.7)	27.9 (2.0)

[a]MMSE: Mini-Mental State Examination.

[b]HC: healthy control.

[c]MCI: mild cognitive impairment.

The longitudinal scenario dataset, National Taiwan University Autobiography Memory Test Longitudinal (NTU-AM-LG), involves 54 of the original 111 subjects who participated in follow-up studies, including 28 HC and 26 MCI participants. The types of data collected are the same as in the cross-sectional scenario, encompassing both recall and probing audio files. The key difference is that NTU-AM-LG includes story audio files from 3 visits. The demographic distribution for this dataset is also shown in Table 2.

Table . The demographic information of the National Taiwan University Autobiography Memory Test Longitudinal dataset.

Group (N=54)	Male	Female	Age (years), mean (SD)	Years of education, mean (SD)	MMSE[a], mean (SD)
HC[b] (n=28)	12	16	74.0 (5.9)	14.3 (2.7)	28.4 (1.5)
MCI[c] (n=26)	7	19	72.5 (6.4)	14.0 (9.6)	27.5 (1.9)
Total	19	35	73.3 (6.1)	14.1 (7.0)	28.0 (1.8)

[a]MMSE: Mini-Mental State Examination.

[b]HC: healthy control.

[c]MCI: mild cognitive impairment.

Ethical Considerations

The collection of experimental data from human participants was reviewed and approved by the National Taiwan University Hospital Research Ethics Committee B (protocol no. 202105013RINB, approved on June 18, 2021). All participants provided written informed consent prior to data collection. The original consent and institutional review board approval explicitly permitted the secondary analysis of deidentified recordings and transcripts for research purposes, without requiring additional consent. All data were fully deidentified before analysis, and no personal or identifiable information was retained in the research dataset. Participant privacy was protected by storing all files on secure, access-restricted servers, and only aggregated results are reported. Participants received NTD 160 (equivalent to US $5.09) per hour as compensation for their time and contribution. No identifiable participant images are included in this manuscript.

Experiment Dataset

The summary of the collected dataset can be provided. The total number of datasets is shown in Table 3, where the unit of measurement is the number of stories. Since each story includes both recall and probing phases, the quantities are identical for recall and probing data.

Table . Primary dataset statistics.

Dataset	Visit 1		Visit 2		Visit 3		Total	
	HC[a]	MCI[b]	HC	MCI	HC	MCI	HC	MCI
NTU-AM-CS[c]	134	122	N/A[d]	N/A	N/A	N/A	134	122
NTU-AM-LG[e]	44	30	50	40	76	54	170	124

[a]HC: healthy control.

[b]MCI: mild cognitive impairment.

[c]NTU-AM-CS: National Taiwan University Autobiography Memory Test Cross-Sectional.

[d]N/A: not applicable.

[e]NTU-AM-LG: National Taiwan University Autobiography Memory Test Longitudinal.

XSL•FO
RenderX

NTU-AM-CS is a cross-sectional dataset that includes a total of 111 subjects (56 HCs and 55 with MCI). Each subject participated in a single AM interview, during which they could share multiple stories. Therefore, NTU-AM-CS does not include repeated follow-up visits.

NTU-AM-LG is the longitudinal subset derived from NTU-AM-CS. A portion of participants agreed to return for additional follow-up interviews, resulting in up to 3 visits per subject. As shown in Table 3, the number of stories per visit varies because the volume of data depends on how many stories participants chose to share during each session. In some cases, more stories were collected in visit 3 than in earlier visits, which explains the higher data volume observed.

To further clarify disease progression patterns, the number of subjects transitioning across cognitive status categories between visits, including stable (HC→HC, MCI→MCI) and progressive or recovered (HC→MCI, MCI→HC) cases, is shown in Table 4.

Table . Cognitive status transitions between consecutive visits in the National Taiwan University Autobiography Memory Test Longitudinal dataset across visits 1 and 2 and visits 2 and 3.

Transition	Number of cases (subject based), n =108
HC[a] to HC	50
HC to MCI[b]	10
MCI to HC	8
MCI to MCI	40

[a]HC: healthy control.

[b]MCI: mild cognitive impairment.

For additional experiments, we primarily used a semistructured speech dataset. The National Taiwan University Hospital Picture Description Test (NTUH-PIC) and National Taiwan University Hospital Memory Test (NTUH-MEM) datasets, which we collected ourselves, include speech data from picture description and logical memory tests, respectively. Both datasets feature 2 cognitive labels: HC and MCI. In the picture description task, participants are required to describe the scenario depicted in a specific picture as accurately and detailed as possible. In the NTUH-PIC dataset, the well-known "cookie theft" picture [28] is used. For the logical memory test, participants first listen to a story and then must repeat it from memory. The third dataset, ADReSSo [29], was introduced as part of the cognitive challenge at INTERSPEECH 2020. This dataset also involves a picture description test, which also used "cookie theft" [28] but differs from the other datasets in that it includes only 2 cognitive labels: HC and AD. Due to data access limitations, we used only the training set for evaluation in this case. By incorporating these additional datasets, we aim to comprehensively evaluate the robustness and generalizability of our model across various types of speech data and cognitive assessments. The statistics of the additional dataset are shown in Table 5.

Table . Additional dataset statistics.

Dataset	Total	HC[a]	MCI[b]	Language	Test
NTUH-PIC[c]	80	40	40	Chinese	Picture Description Test
NTUH-MEM[d]	104	52	52	Chinese	Logical Memory Test
ADReSSo (Train)	166	79	87	English	Picture Description Test

[a]HC: healthy control.

[b]MCI: mild cognitive impairment.

[c]NTUH-PIC: National Taiwan University Hospital Picture Description Test.

[d]NTUH-MEM: National Taiwan University Hospital Memory Test.

Experiments

We conducted a series of experiments to evaluate our proposed longitudinal multimodal model under different data conditions and to verify the contribution of each model component.

Experiments on NTU-AM-LG

We evaluated the model on the longitudinal NTU-AM-LG dataset using 2 speaking tasks: recall and probing. For each task, we compared four variants of our model:

1. Ours (audio): acoustic branch only, wav2vec 2.0 to acoustic encoder to classifier.
2. Ours (text): linguistic branch only, BERT to linguistic encoder to classifier.
3. Ours (CS): cross-sectional problem setting
4. Ours (LG): full proposed longitudinal multimodal model with direction encoding and alignment losses.

XSL•FO
RenderX

These models were compared against standard baselines (BERT, wav2vec 2.0, and the prior AM-based work [11]), and the corresponding results are reported in the "Results" section.

An ablation study on NTU-AM-LG is made to examine the contribution of the ATM, direction embedding, and the 2 alignment losses, and we performed ablation experiments by removing (1) the direction, (2) the subject alignment loss, (3) the group alignment loss, and (4) both alignment losses.

Experiments on NTU-AM-CS

To demonstrate that the proposed encoders and fusion strategy also work without longitudinal information, we trained the same acoustic and linguistic encoders in the cross-sectional problem setting (Our [CS]) and compared them with BERT, wav2vec 2.0, and the prior AM method [11]. An ablation study is also conducted to highlight the importance of linguistic features and context embeddings.

Experiments on Additional Datasets

We further tested whether our proposed model transfers to other cognitive-speech datasets (NTUH-PIC and NTUH-MEM). We compared our method with that of Lin et al [18].

Finally, to enable comparison with existing AD or MCI speech work on a public dataset, we evaluated our model on the ADReSSo corpus.

Experimental Setup

In the subsequent experiments, due to the limitations of the dataset size, we will present the averaged performance of 10-fold cross-validation. To avoid data leakage, we will split the training set and validation set by subject for the NTU-AM-CS and NTU-AM-LG datasets. It ensures that audio files from different visits of the same subject will not appear in the training set and validation set simultaneously.

For the NTUH-PIC, NTUH-MEM, and ADReSSo datasets, since each subject provides only 1 audio file, there is no need to split the data by subject. We will perform down-sampling on the majority class in the training set during the experimental process to stabilize the model's learning capability. All experiments are conducted on an NVIDIA RTX 4090 GPU.

Evaluation Metrics

In the experimental section, we will use 6 different evaluation metrics to measure the performance of the model: accuracy, F_1-score, precision, sensitivity (recall), specificity, and AUROC. These are common indicators used to assess the predictive ability of a model. Each metric provides a different perspective on the effectiveness of the model.

In the NTU-AM dataset, since the dataset is split by subject, each evaluation set from every fold may have a similar number of subjects, but the number of audio files provided by each subject can vary. This can result in label imbalance in the final soft-voting results. Therefore, the most critical metrics in the subsequent experiments will be F_1-score and AUROC. These 2 metrics provide a fairer assessment in situations with label imbalance. As for other experiments, the primary metrics of interest will be accuracy and F_1-score.

Baseline

In the subsequent experiments in the NTU-AM dataset, we will use a fine-tuned BERT model and the wav2vec 2.0 model as baselines. Since these 2 models are the backbones of our proposed model, in the NTU-AM-LG dataset, the baseline model will be composed of these 2 main models as encoders. The embeddings generated from the 3 visits will be concatenated and passed through the same classifier. For the NTU-AM-CS dataset, the backbone model will serve as the encoder, followed by a classifier. However, these models will not have additional loss functions to assist training during the training process, relying only on the basic binary cross-entropy loss.

Implementation Details

The probing data are interview data, which include both the interviewer's and the subject's voices. Since our study aims to determine whether the subject has a tendency for MCI based on their audio data, the interviewer's speech is considered noise during training. To remove the interviewer's portion, we use the tool kit "pyannote" to split the audio into different speaker segments. This process results in audio files without the interviewer's voice. These cleaned files are then used to generate the linguistic features during the data preprocessing stage.

We used the "openai/whisper-large-v2" version from Hugging Face for the ASR tool. For data preprocessing, the pretrained Wav2vec 2.0 model used for the English dataset is "facebook/wav2vec2-base-960h," while for the Chinese dataset, we used "jonatasgrosman/wav2vec2-large-xlsr-53-chinese-zh-cn," which are also from HuggingFace. We used a 15-second clip segmentation with a 5-second overlap. Considering the limitations of the Wav2vec model, we resampled the audio files to 16,000 Hz and standardized them to mono-channel.

For the linguistic model, the BERT model used for the English dataset is "google-bert/bert-base-uncased," and for the Chinese dataset, it is "hfl/chinese-bert-wwm-ext," which is also the version used for the BERT baseline. In the Wav2vec baseline model, we used "jonatasgrosman/wav2vec2-large-xlsr-53-chinese-zh-cn." The hyperparameters used for implementing the proposed model are shown in Table 6.

Early stop	10
α for encoder loss	0.01
δ for group alignment loss	0.001
γ for subject alignment loss	0.001

[a]BERT: bidirectional encoder representation for transformer.

Results

Results of NTU-AM-LG

We experiment with the model's effectiveness on both recall and probing data. Given the limited research on longitudinal speech, we primarily compare our model against baselines such as BERT, Wav2vec 2.0, and the unimodal model within our longitudinal framework. In addition, we present an ablation study to demonstrate the necessity of each component in our model. We discuss the results for recall data and probing data separately. It is important to note that both the cross-sectional (CS) and longitudinal (LG) models are trained on the same NTU-AM-LG dataset, sharing identical subjects and feature representations. The difference lies only in the problem formulation: the CS model performs single-visit classification, while the LG model performs a prognostic task that leverages prior visit embeddings to predict the final cognitive state. Thus, the performance difference reflects the use of incorporating longitudinal context rather than architectural or data disparities.

Table 7 shows the performance of our proposed model and the baselines for the recall data. First, when the input consists only of audio data, our proposed model "Ours (audio)" outperforms the previous work [11] on most metrics. Notably, there are improvements of 5% and 6% in F_1-score and AUROC, respectively.

[b]Highest value for each metric.

[c]BERT: bidirectional encoder representation for transformer.

[d]CS: cross-sectional.

[e]LG: longitudinal.

As for the model using only linguistic data as input, our proposed linguistic longitudinal model, denoted as "Ours (text)," outperforms BERT, demonstrating that including extra-linguistic features and context embedding helps improve the model's performance with 7% increase in the F_1-score.

Finally, our model, which is denoted as "Ours (LG)" in Table 7, significantly outperforms other models across most metrics for the dual-modal longitudinal model that combines both data types. Specifically, there is up to a 16% improvement in accuracy, a 14% improvement in F_1-score, and a 22% improvement in AUROC. Since the previous work used only unimodal data, examining AM data from different perspectives benefits MCI detection. We also compare the cross-sectional setting results of NTU-AM-LG, denoted as "Ours (CS)" in Table 7, with the longitudinal settings, confirming that long-term tracking of subjects' cognitive trajectories in NTU-AM-LG helps improve the model's prediction accuracy. Specifically, there are improvements of 10% in accuracy, 6% in F_1-score, and 19% in AUROC.

Table 8 shows the results of the probing data. For the audio data, our proposed model outperforms wav2vec 2.0 in most metrics, with improvements of 9%, 18%, and 10% in accuracy, F_1-score, and AUROC, respectively. This indicates that instead of directly using wav2vec 2.0's output representation for classification, extracting features using wav2vec 2.0 followed by a convolutional neural network–based acoustic encoder structure can better capture the hidden cognitive patterns in audio data.

Ours (LG[d])	0.89[e]	0.83[e]	0.90[e]	0.82[e]	0.95[e]	0.89[e]

[a]AUROC: area under the receiver operating characteristic curve.

[b]BERT: bidirectional encoder representation for transformer.

[c]CS: cross-sectional.

[d]LG: longitudinal.

[e]Values in boldface are the highest values for each metric.

For the linguistic data results, our model performs comparably with BERT, with improvements of 8%, 3%, and 10% in F_1-score, precision, and sensitivity, respectively. This suggests that the inclusion of linguistic features and the context embedding layer can also aid in MCI detection on probing data.

Finally, in the dual-modal data tests, the proposed longitudinal model achieved the best performance, excelling in every metric. Specifically, it showed improvements of up to 13%, 30%, and 19% in accuracy, F_1-score, and AUROC, respectively. Comparing the longitudinal model with the cross-sectional model, it is evident that the longitudinal model continues to perform better. This indicates that incorporating input from multiple time points and considering the concept of aging direction can enhance the model's predictions, resulting in performance increases of 12%, 16%, and 21% in accuracy, F_1-score, and AUROC, respectively.

Ablation Study

In the longitudinal setting, the most crucial idea is the alignment loss we proposed. Therefore, this section examines the contribution of alignment loss by removing each loss individually. The results are shown in Table 9. In the table, "Without direction" refers to not including direction embedding as the classifier input; namely, the input would be ei,1m1, ei,2m2, ei,3m3 treating each time point's data as independent.

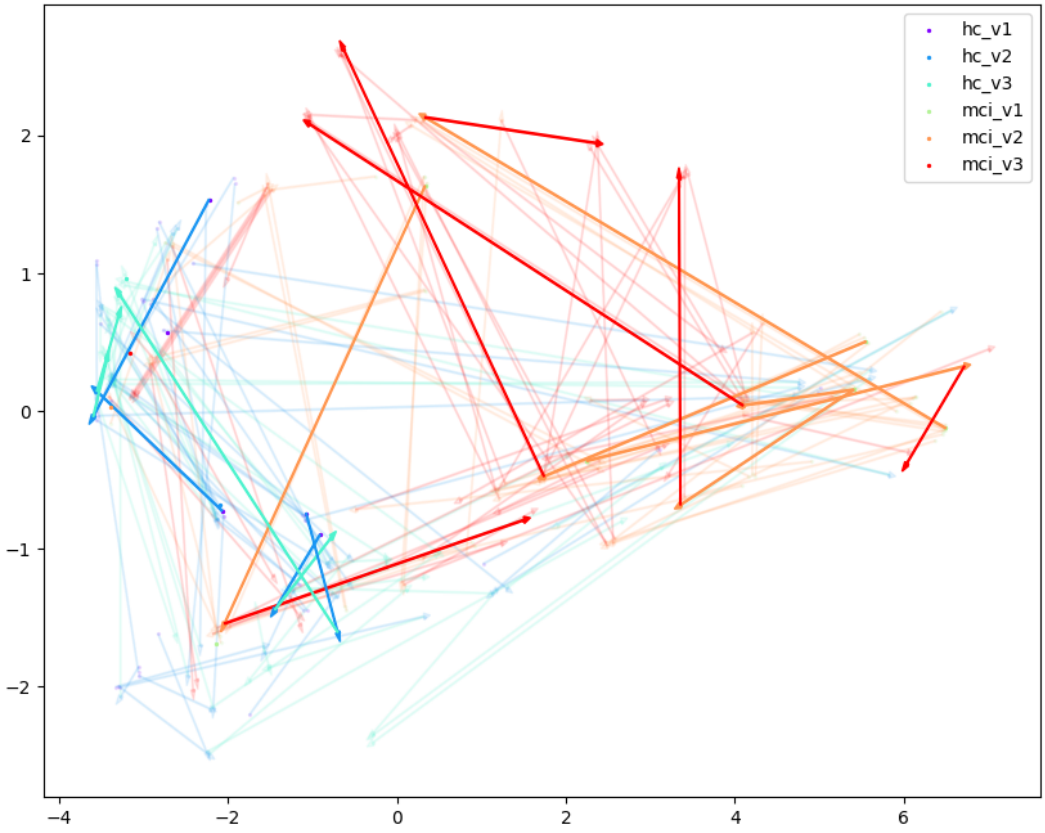
[a]AUROC: area under the receiver operating characteristic curve.

[b]LG: longitudinal.

[c]Highest value for each metric in recall data and probing data, respectively.

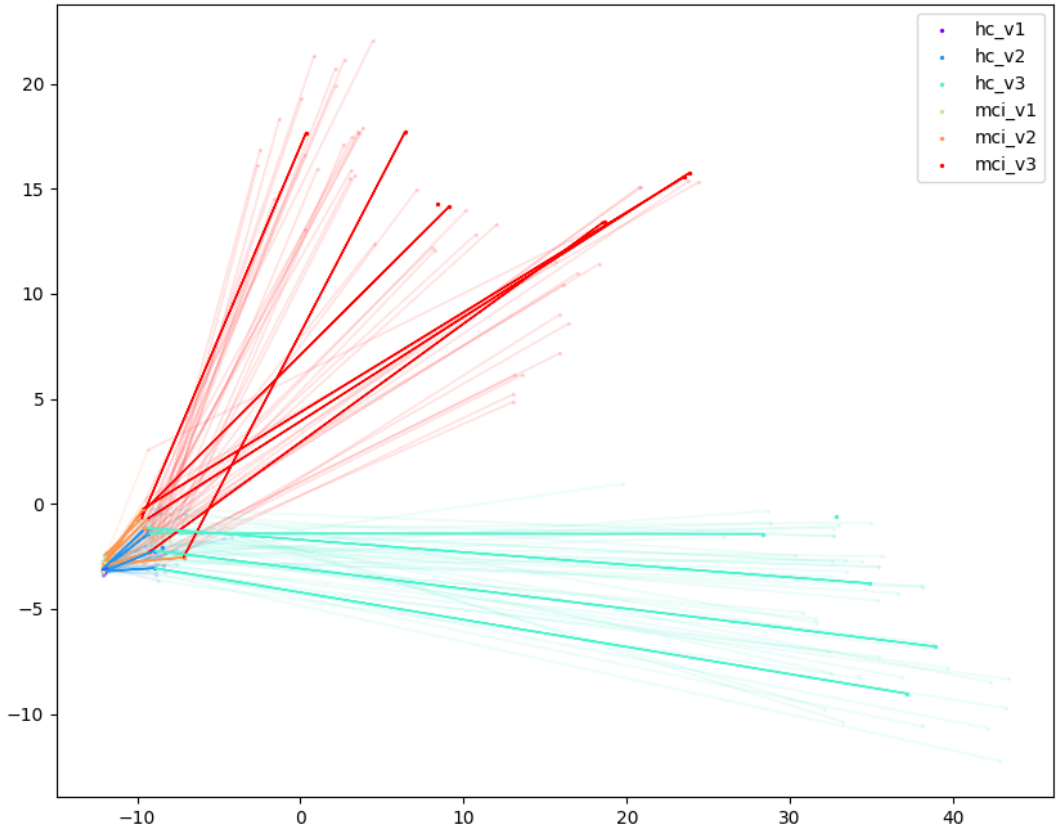
The results show that incorporating alignment losses with direction embedding improves performance across both recall and probing data. For instance, on recall data, our full model improves AUROC by 10% (0.85 vs 0.75) and F_1-score by 4% compared with "Without direction." On probing data, the gains are even larger, with AUROC improved by 12% (0.89 vs 0.77) and F_1-score improved by 13% (0.83 vs 0.70). Importantly, removing the group alignment loss results in the sharpest performance drop, with AUROC decreasing by 17% (0.68 vs 0.85) and 21% (0.68 vs 0.89) for recall and probing data, respectively. Similarly, removing both alignment losses further reduces AUROC to 0.63 (recall) and 0.70 (probing), confirming their necessity.



Overall, these results highlight the complementary importance of both alignment losses that rely on the strong supervisory signal of ground-truth label transitions to capture temporal progression patterns in longitudinal settings. Removing either the subject alignment loss or the group alignment loss results in significant performance degradation, and removing both leads to the sharpest decline. This indicates that while the subject alignment loss stabilizes intrasubject trajectory consistency, the group alignment loss aligns intersubject cognitive progression trends across similar diagnostic groups.

Visualization

We visualize the latent space distribution of subjects across different visits to better interpret the role of the alignment loss. After passing through all modules, we extracted the final embeddings, applied principal component analysis for dimensionality reduction, and projected the results into a 2D space. The arrows in Figures 9 and 10 represent the trajectory of each subject's embeddings across consecutive visits, thereby illustrating how cognitive states evolve over time.



XSL•FO
RenderX

Figure 9. Principal component analysis projection of subject embeddings without alignment loss. The x- and y-axes represent the first 2 principal components. Colors denote diagnostic group and visit (blue tones = healthy control visits 1 - 3; red tones = mild cognitive impairment visits 1 - 3). Arrows illustrate the trajectory of each subject's embeddings. The scattered trajectories reflect high variability and weak temporal consistency without alignment loss.

XSL•FO
RenderX

Figure 10. Principal component analysis projection of subject embeddings with alignment loss. The x- and y-axes show the first 2 principal components. Colors indicate diagnostic group and visit (blue tones = healthy control visits 1 - 3; red tones = mild cognitive impairment visits 1 - 3). Arrows illustrate the trajectory of each subject's embeddings. With alignment loss, trajectories become far more coherent and directionally consistent, indicating improved temporal stability and clearer separation between healthy control and mild cognitive impairment progression patterns.

As shown in Figure 9 (without alignment loss), the trajectories are scattered and inconsistent, with large variability both within and across groups. This makes it difficult to distinguish between HC and MCI or to capture stable temporal patterns. In contrast, Figure 10 (with alignment loss) reveals more coherent trajectories: subjects within the same group (HC or MCI) show consistent progression directions across visits, while the separation between HC and MCI becomes clearer. Importantly, this indicates that the alignment loss encourages the model to capture cognitive progression trends rather than random variability in story content, reflecting interpretable patterns of decline (for MCI) and stability (for HC).

These results demonstrate that the alignment loss not only improves metrics but also enhances interpretability by aligning temporal trajectories in a way that reflects clinically meaningful differences in cognitive change. Feature-level analyses could provide even more intuitive examples of how the ATM aligns specific cognitive markers in speech. Future feature-level analyses could further enhance this by providing more intuitive illustrations of how the ATM captures and aligns specific cognitive markers in speech.

Results of NTU-AM-CS

In addition to the main longitudinal experiment, we conducted further evaluations in a cross-sectional setting to assess the performance of our proposed model. Here, the primary comparison is with our previous work [11], which also used audio and text data. However, a key difference is that the prior work relied on manual transcripts, which are less scalable and require special preprocessing for the transcripts. The results are shown in Tables 10 and 11.

Our proposed method performs better or comparably on critical metrics such as F_1-score and AUROC in the results of recall data. Specifically, there is an 11% improvement in F_1-score. However, the precision is not as good as in the study by Chang et al [11]; our sensitivity metric performs better. For probing data, our method also yields better results in F_1-score and AUROC. However, the overall performance of the NTU-AM-CS dataset is not as promising as that of the NTU-AM-LG dataset. Detecting MCI features in AM data is challenging and reinforces the idea that long-term data relationships aid in model prediction.

Ablation Study

We investigated the contributions of linguistic features and context embedding in the encoder module for the prediction ability. The results are shown in Table 12. It demonstrates the impact of removing individual components on the model's predictions. For example, when linguistic features are removed, there is a noticeable decrease in specificity and a 6% drop in F_1-score. The most significant impact is seen when context embedding is removed, resulting in a 9% decrease in F_1-score and substantial declines in most other metrics. Only the sensitivity metric performs better, but overall, the original configuration still performs best in terms of F_1-score, which balances sensitivity and precision.

[c]Highest values of each evaluation metric.

These results indicated that linguistic features provide auxiliary information that aids the model's decision-making, particularly in identifying negative samples. Context embedding supports the model's understanding of the story by distinguishing between the story topic and content through embeddings.

Result of Additional Dataset

In the experiment with an additional dataset, our main goal was to confirm whether the method our model uses to encode data is also applicable to other datasets related to cognitive tests. This means whether the way we encoded each data contributes to MCI detection. In Table 13, we present several results related to the detection of MCI. Our primary comparison targets in the NTUH-PIC and NTUH-MEM datasets are as per the study by Lin et al [18], which use textual information, including pauses, for MCI prediction. From the NTUH-PIC experimental results, there was an improvement of 11% in accuracy and 18% in F_1-score.

Table . Results of the National Taiwan University Hospital dataset.

Dataset	Method	Accuracy	F_1-score	Precision	Sensitivity	Specificity	AUROC[a]
NTUH-PIC[b]	Lin et al [18]	0.68	0.63	0.81[c]	0.58	0.78[c]	N/A[e]

[d]CS: cross-sectional.

[e]N/A: not applicable.

[f]NTUH-MEM: National Taiwan University Hospital Memory Test.

Similarly, in the NTUH-MEM dataset, a 10% improvement was observed in both accuracy and F_1-score compared with the study by Lin et al [18], indicating overall better performance. This experiment demonstrates that our data-encoding method effectively extracts latent representations suitable for MCI detection. Viewing data from multiple modalities provides consistent benefits for MCI detection. In addition, the performance differences observed in the NTU-AM-CS experiment indicate that using AM data for MCI detection is relatively challenging.

Due to the nature of the self-collected dataset, making comparisons with other works is challenging. Therefore, we present results on an open dataset in the final experiment. However, the ADReSSo dataset provides only HC and AD data. Table 14 shows our results alongside those of other state-of-the-art methods. Overall, our approach yields the best results, with a 4% improvement in both accuracy and F_1-score. In addition, our precision achieves the best performance. Once again, it confirms that our data-encoding method contributes to predictive outcomes in AD and MCI detection.

Discussion

Principal Results

In this study, we proposed a longitudinal framework for MCI detection using AM test speech data. The key innovation is the ATM, which leverages direction embeddings with subject and group alignment losses to model cognitive changes across multiple visits.

Our experiments demonstrate that the longitudinal framework substantially outperforms cross-sectional approaches. Compared with single-visit models, the longitudinal model achieved notable improvements, with AUROC gains of up to 21%, F_1-score increases of 16%, and accuracy improvements of 12%. These results confirm that incorporating multi–time point information provides a clearer picture of subtle cognitive trajectories that cannot be fully captured using only cross-sectional data.

The ablation studies further highlight the effectiveness of the alignment mechanisms. Removing the alignment losses led to considerable performance degradation, particularly a 17% - 21% drop in AUROC when the group alignment loss was excluded. This underscores the critical role of alignment in ensuring temporal consistency and improving the robustness of the framework.

In addition to evaluations on our self-collected dataset, we validated the framework on the publicly available ADReSSo dataset, which uses English picture description speech. Despite differences in language and task, our model achieved more than 88% accuracy, suggesting that the approach generalizes well across languages and cognitive assessment protocols.

In our analysis, the distribution of false positives and false negatives provides additional context for interpreting the model's sensitivity and specificity. False positives, which reduce specificity, were often linked to healthy subjects who displayed atypical speech characteristics such as disfluencies, pauses, or reduced lexical richness that mimicked early cognitive decline. On the other hand, false negatives, which lower sensitivity, were frequently observed in MCI subjects who retained strong narrative skills or enriched their responses with contextual details, thereby masking subtle impairments. These observations illustrate how individual variability in speech patterns can differentially impact sensitivity and specificity, underscoring both the strengths and the boundary conditions of the framework. While the alignment-based approach improves overall robustness, further refinement of feature representations and the inclusion of personalized modeling strategies may help balance sensitivity and specificity more effectively.

Taken together, these results highlight both the methodological and clinical significance of the proposed approach. Improvements in AUROC of 10% - 15% can translate into earlier identification of at-risk individuals and a reduction in false negatives in real-world screening. This demonstrates the potential of longitudinal, dual-modal speech analysis as a noninvasive, scalable tool for long-term cognitive monitoring, with the flexibility to be integrated into routine memory clinic assessments or used as a low-cost prescreening solution to complement standardized neuropsychological testing.

Limitations

Although the proposed framework shows promising performance for early MCI detection, several limitations remain. One major limitation of this study lies in the relatively small sample size of the NTU-AM-LG dataset, which includes only 54 subjects. Although each subject contributes multiple audio recordings across different visits, the limited number of unique participants poses inherent challenges for deep learning models, including a higher risk of overfitting, model instability, and low statistical power. As a result, while the proposed model demonstrates promising performance trends, its robustness and generalizability should be interpreted with caution. To mitigate these risks, we adopted strict subject-independent data splits and cross-validation to avoid data leakage and improve reliability. Nevertheless, future studies with larger and more diverse longitudinal datasets are essential to confirm the model's generalization capability and to further validate its clinical applicability. Furthermore, we also validate our approach on the publicly available ADReSSo dataset, although it is limited to a cross-sectional study. Cross-lingual robustness also presents a challenge, as our dataset is in Chinese while ADReSSo is in English. Linguistic and cultural factors such as narrative structure, emotional expression, and lexical choices may influence AM speech patterns and, in turn, affect model generalizability. Nevertheless, our results demonstrate encouraging cross-lingual generalizability. We highlight this as an open challenge and a direction for future work, where

XSL•FO
RenderX

cross-lingual adaptation and multilingual modeling will be crucial to improving robustness across diverse populations.

Moreover, the current longitudinal dataset includes 3 visits per participant, which restricts the ability to capture long-term trajectories of cognitive change. Collecting data across additional time points would allow the development of models better suited to characterizing the progression of cognitive decline.

This study also acknowledges potential confounding factors arising from the use of automatic speech processing tools. The *whisper-timestamped* model and *pyannote* diarization tool kit were used for transcription and speaker segmentation, respectively; however, the resulting ASR and diarization errors were not formally measured. Such errors, especially the higher ASR error rates likely to occur in participants with MCI due to disfluency or reduced articulation, and diarization inaccuracies that may introduce noise, could impact the extracted linguistic and acoustic features. These unaddressed confounders represent an inherent limitation of this study.

Further Studies

Based on the current findings, several directions can be explored in future work. First, extending the framework to multilingual settings will be essential for improving cross-lingual generalizability, as language and cultural factors strongly influence AM narratives. Second, adapting the model for low-resource scenarios will enhance its applicability in real-world clinical practice, where large-scale longitudinal datasets are often unavailable. Techniques such as transfer learning, data augmentation, and self-supervised pretraining could make the system more robust under such constraints.

Third, integrating AM speech analysis with other noninvasive modalities, such as wearable sensor data, offers the potential to capture complementary behavioral and physiological signals (eg, activity levels, sleep patterns, and heart rate variability). Such multimodal fusion could provide a more holistic view of cognitive health and improve early detection of decline. Finally, future studies should focus on personalized modeling of cognitive trajectories, acknowledging that the pace and pattern of decline vary across individuals. Personalized approaches may increase the clinical relevance of the framework and support tailored interventions.

Conclusions

We developed a dual-modal longitudinal analysis system to enhance the accuracy of diagnosing MCI. The system consists of an encoder and an ATM. We used a pretrained Wav2vec 2.0 model for speech data and BERT for text data to generate latent representations. Our proposed ATM generates significantly improved performance for MCI prediction, with F_1-scores of 0.78 and 0.83 on the recall and probing datasets, respectively. Combining data from both modalities improved understanding of the AM test data, with up to 19% and 12% improvements in F_1-score compared with unimodal models. In addition, ablation experiments verified the necessity of context embedding and linguistic features in the linguistic encoder. Our model's effectiveness was consistently superior across different datasets.

Abstract

Background: General anesthesia comprises 3 essential components—hypnosis, analgesia, and immobility. Among these, maintaining an appropriate hypnotic state, or anesthetic depth, is crucial for patient safety. Excessively deep anesthesia may lead to hemodynamic instability and postoperative cognitive dysfunction, whereas inadequate anesthesia increases the risk of intraoperative awareness. Electroencephalography (EEG)-based monitoring has therefore become a cornerstone for evaluating anesthetic depth. However, processed electroencephalography (pEEG) indices remain vulnerable to various sources of interference, including electromyographic activity, interindividual variability, and anesthetic drug effects, which can yield inaccurate numerical outputs.

Objective: With recent advances in machine learning, particularly unsupervised learning, data-driven methods that classify signals according to inherent patterns offer new possibilities for anesthetic depth analysis. This study aimed to establish a methodology for automatically identifying anesthesia depth using an unsupervised, machine learning–based clustering approach applied to pEEG data.

Methods: Standard frontal EEG data from participants undergoing elective lumbar spine surgery were retrospectively analyzed, yielding more than 16,000 data points. The signals were filtered with a fourth-order Butterworth bandpass filter and transformed using the fast Fourier transform to estimate power spectral density. Normalized band power ratios for delta, high-theta, alpha, and beta frequencies were extracted as input features. Fuzzy C-Means (FCM) clustering (c=3, m=2) was applied to categorize anesthetic depth into slight, proper, and deep clusters.

Results: FCM clustering successfully identified 3 physiologically interpretable clusters consistent with EEG dynamics during progressive anesthesia. As anesthesia deepened, frontal alpha oscillations became more prominent within a delta-dominant background, while beta activity decreased with loss of consciousness. The fuzzy membership values quantified transitional states and captured the continuum of anesthetic depth. Visualization confirmed strong correspondence among cluster transitions, Patient State Index trends, and spectral density patterns.

Conclusions: This study demonstrates the feasibility of using unsupervised machine learning to enhance anesthetic depth assessment. By applying FCM clustering to pEEG data, this approach improves the understanding of anesthesia depth and integrates effectively with existing monitoring modalities. The proposed FCM-based method complements current EEG indices and may assist anesthesia practitioners and even nonanesthesia professionals in assessing anesthetic depth to enhance patient safety.

Introduction

General anesthesia induces temporary loss of consciousness characterized by unconsciousness, immobility, and autonomic regulation of pain [1,2]. Maintaining an appropriate depth of anesthesia is essential for patient safety. Insufficient anesthesia may lead to intraoperative awareness, autonomic hyperactivity, and significant psychological distress [3]. Conversely, excessive anesthesia has been associated with neuroinflammation [4], neuronal injury, and postoperative cognitive dysfunction or delirium [5,6]. Therefore, continuous monitoring of anesthetic depth during surgery is of critical importance. Electroencephalography (EEG)-based monitoring serves as a valuable tool for this purpose. Real-time EEG analysis provides insight into anesthetic states, as oscillatory patterns vary with the anesthetic dose, type, and patient characteristics [7,8]. The Perioperative Quality Initiative 6 Workgroup, led by Chan, details the available EEG monitors [9]. Understanding perioperative neural activity enables anesthesiologists to optimize anesthesia delivery and enhance patient outcomes.

Artificial intelligence is revolutionizing anesthesiology, with techniques such as anesthesia depth monitoring [10]. Unsupervised machine learning operates without predefined hypotheses and identifies patterns and structures within datasets to classify patients, medications, and groups [11]. Unlike supervised machine learning, which correlates the input data with known outcomes, unsupervised machine learning categorizes instances based on inherent patterns. In EEG analyses, unsupervised machine learning methods such as fuzzy clustering have been used to analyze sleep stages [12], detect epileptic spikes [13], and identify significant elements in multichannel recordings [14].

Anesthesia management fundamentally involves 3 key components: hypnosis, analgesia, and muscle relaxation. During induction and maintenance, a reproducible spectral shift occurs in the EEG, wherein frontal alpha oscillations become prominent within a delta-dominant background, delta power progressively increases with deepening anesthesia, and beta activity decreases as consciousness is lost [8,15-17]. Power spectral metrics—including relative alpha, beta, and delta power, power ratios, and spectral entropy—have been shown to reliably distinguish between conscious and anesthetized states [18-20]. Inhalational agents such as sevoflurane and desflurane consistently produce dose-dependent increases in frontal alpha and delta power [17,21-23], providing a physiologic basis for categorizing anesthesia into light, proper, and deep stages. However, current perioperative EEG-based indices, such as the Bispectral Index (BIS) [24,25] and Patient State Index (PSi) [26,27], primarily reflect the hypnotic component but can be influenced by various factors, potentially leading to misleading processed numerical outputs. Therefore, this study aimed to enhance anesthetic depth assessment by focusing on the hypnosis dimension and applying unsupervised machine learning methods, specifically Fuzzy C-Means (FCM) clustering, to processed electroencephalography (pEEG) data.

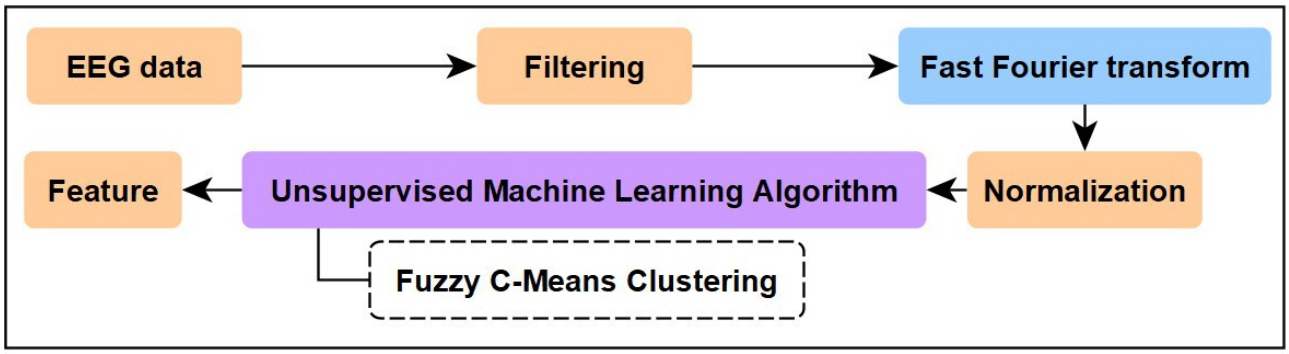
The primary objective of this study was to establish a methodology for automatically identifying anesthesia depth through a visualized presentation, leveraging machine learning–based clustering techniques. By applying unsupervised learning to pEEG data, this approach aims to enhance the classification and understanding of anesthesia depth and facilitate patient-specific anesthesia management.

Methods

Recruitment

Data were collected at the Veterans General Hospital, Taipei, with the approval of the Institutional Review Board (number 2021-09-008BC). More than 16,000 data points were collected from 10 participants (Participants 1 - 10) who underwent elective lumbar spinal surgery in the prone position. The ages of the participants ranged from 44 to 78 years, with the American Society of Anesthesiologists' physical status classifications ranging from class I to class III. Participants with conditions such as pregnancy, neurological disorders, ongoing infections, a history of central nervous system medication use, respiratory failure, heart failure, or renal failure were excluded.

Masimo SedLine [28] brain function monitoring was performed with the participant in the supine position. Induction included fentanyl at 1 - 3 mcg/kg as an adjunct for intubation, followed by propofol at 1 - 3 mg/kg as an induction bolus. Rocuronium was administered at an intubation dose of 0.6 - 1 mg/kg for muscle relaxation. The participant was then intubated.



During maintenance, the inhalational agent sevoflurane was administered, with dosage adjustments titrated based on the PSi levels and pEEG density spectral array (DSA) patterns. The participant was then placed in a prone position for lumbar spinal surgery. After the completion of the surgery, the participant was returned to the supine position, and the inhalation agent was gradually titrated off. Rocuronium administration was reversed using sugammadex. Subsequently, the participants were extubated and transferred to the postanesthetic care unit for further monitoring and recovery.

Data Collection and Processing

Figure 1 outlines the preprocessing steps for the EEG data in our study.

XSL•FO

Figure 1. Signal processing flow diagram. Flow diagram illustrating preprocessing and feature-extraction steps applied to processed electroencephalography data obtained from participants who underwent elective lumbar spine surgery at Taipei Veterans General Hospital. Raw frontal electroencephalography signals were filtered with a fourth-order Butterworth bandpass filter, and power spectral density was estimated using the Welch method with a 30-second window and 2-second overlap. Normalized delta, high-theta, alpha, and beta band power ratios were extracted as input features for unsupervised clustering using the Fuzzy C-Means (FCM) algorithm (*c=3*, *m=2*). EEG: electroencephalography.

Signal Processing and Feature Extraction

EEG tracings from the 4 Masimo SedLine channels were averaged into 1-dimensional signals and synchronized for consistency. Each participant's EEG data were recorded at a sampling frequency of 178 Hz, with a data collection period ranging from 3 to 5 hours, depending on the duration of anesthesia. A fourth-order Butterworth bandpass filter (0.5 - 30 Hz) was applied to minimize the ripple and achieve a maximally flat response. Power spectral density was estimated using the Welch method implemented in Python (SciPy library), using a 30-second window with a 2-second sliding overlap to ensure both temporal continuity and frequency resolution. Additional preprocessing specifications are available in Multimedia Appendix 1. The Welch method and the fast Fourier transform were used to estimate the power spectral density, facilitating the extraction of alpha (8 - 12 Hz), beta (13 - 30 Hz), delta (0.5 - 4 Hz), and high-theta (6 - 8 Hz) band powers. Normalization was performed by calculating the ratio of each band's power to the sum of the power of these 4 specific bands (delta+high-theta+alpha+beta), ensuring that the sum of the feature vector elements equals 1. The 4 - 6 Hz and 12 - 13 Hz bands were excluded based on their limited variation across states. Removing these transitional zones established a "spectral buffer" to reduce noise, allowing the algorithm to prioritize the more discriminative delta and alpha and high-theta features. Manual artifact rejection was conducted by board-certified anesthesiologists and engineers to identify and exclude segments exhibiting abnormal, noisy epochs indicative of artifacts.

FCM Clustering Algorithm

FCM clustering categorizes data points into clusters with membership values between 0 and 1, accommodating the uncertainty in the cluster assignment. It was performed with 3 clusters (c=3), a fuzziness parameter (m) of 2, random initialization of cluster centers, and a convergence threshold of 0.005. The model iteratively updates the centroids and membership values until convergence, guided by a fuzziness parameter (m) that regulates cluster ambiguity. A global FCM model was established to generate fixed global cluster centroids. These fixed centroids were then applied to all participants to calculate membership values. Further implementation details are provided in Multimedia Appendix 1. This method extracts delta, alpha, high-theta, and beta band power ratios from pEEG signals to partition the data into 3 statistically distinct clusters. These clusters were subsequently labeled as "slight," "proper," and "deep" based on their physiological spectral characteristics. The capability of FCM to manage data ambiguity makes it suitable for nuanced depth assessments under general anesthesia.

Ethical Considerations

This study was conducted in accordance with the ethical principles outlined in the Declaration of Helsinki and was approved by the Institutional Review Board of Taipei Veterans General Hospital, Taiwan (number: 2021-09-008BC). Written informed consent was obtained from all participants prior to enrollment. The data used in this study were deidentified before analysis to ensure participant confidentiality and privacy. No identifiable personal information or images were included in the manuscript or supplementary materials. Participants did not receive any financial compensation for their participation in the study.

Results

Overview

In this study, an unsupervised learning method, FCM, was used to analyze the pEEG data from participants with complete datasets. Table 1 summarizes the demographic information and baseline characteristics of the participants. The analysis focused on a feature set comprising the delta-band power ratio and the sum of the alpha and high-theta band power ratios. The results revealed 3 distinct clusters. Based on the centroids' spectral features, we assigned post hoc clinical labels to these clusters representing different anesthesia depths: slight (green), proper (blue), and deep (red). This clustering approach was validated using visual representation to confirm the effectiveness of the feature set in differentiating anesthesia depths. Subsequently, the same method was applied to individual participant data, categorizing each participant's pEEG into 1 of the 3 clusters, thus providing a detailed estimation of the anesthesia depth for each individual.

FCM Clustering Analysis of pEEG Features

FCM clustering was applied to all participants, using alpha, beta, delta, and high-theta band power as the selected features for clustering. Figure 2 illustrates the FCM clustering results for all participants, with the delta band power ratio plotted on the *x*-axis and the sum of the alpha and high-theta band power ratios on the *y*-axis. Each data point represents a single time point of a participant's pEEG signal and is clustered into 3 distinct groups: slight anesthesia depth (green), proper anesthesia depth (blue), and deep anesthesia depth (red). The contribution of the beta band power ratio can be inferred as the sum of the delta, alpha, high-theta, and beta band power ratios equals 1, although not explicitly displayed. This visual depiction offers insights into the distribution of a participant's single time points within each anesthesia depth cluster.

After establishing the efficacy of the selected features and parameters through a collective analysis of the participants, our investigation shifted focus to the individual application of this methodology. The fixed global cluster centroids were then applied to the data of Participants 1 - 10 to calculate membership values and simplified estimation results. Following the methodology outlined, where all time indices share a common time scale, the pEEG data were combined with PSi data retrieved from the Masimo SedLine brain function monitoring system, and the time-frequency images were compared within the same figure, with each participant outputting a distinct figure. Within these figures, Participants 4 and 6 are described in the article. By incorporating this comprehensive approach, our study verified the applicability of the selected features and enhanced confidence in the adaptability of our methodology to diverse clinical scenarios and datasets, strengthening the reliability of our conclusions and paving the way for further exploration and validation within the anesthesia depth assessment domain.

XSL•FO
RenderX

Figure 2. Fuzzy C-Means clustering results for all participants. Two-dimensional clustering distribution of processed electroencephalography features from participants undergoing elective lumbar spine surgery. The *x*-axis represents the delta-power ratio and the *y*-axis the combined alpha and high-theta power ratios. Fuzzy C-Means clustering (*c=3*, *m=2*) identified 3 physiologically interpretable clusters corresponding to anesthesia-depth levels: slight (green), proper (blue), and deep (red). Each point denotes a 30-second windowed segment of electroencephalography data, demonstrating the continuum of anesthetic states observed across the study population.

Participant 4 and Participant 6: FCM Clustering Analysis

Participant 4 underwent the same data retrieval and processing procedures as the other participants, with raw EEG data obtained from the Masimo SedLine brain function monitoring system. These data were subjected to filtering, fast Fourier transformation, normalization, and subsequent FCM clustering. The culmination of these processes is depicted in Figure 3, which comprises multiple panels, sharing a synchronized timescale on the *x*-axis.

Figure 3A shows the PSi of Participant 4 obtained from the Masimo SedLine brain function monitoring system. The *x*-axis represents the time scale, whereas the *y*-axis displays the PSi values, reflecting the PSi over time.

Figure 3B shows the results of FCM clustering for Participant 4. The *y*-axis illustrates the estimated membership values and denotes the degree of belongingness of each cluster. This belongingness quantifies the "fuzziness" of the FCM clustering, indicating the confidence level of each assignment of the data point to a particular cluster. It effectively quantifies the "color shading" shown in Figure 2, where darker shades represent higher confidence levels in cluster assignments. For example, a membership value of 1 signifies full belongingness to the cluster, and a value of 0.8 indicates 80% confidence in the assignment. This "soft" labeling approach allows for a more nuanced understanding of the clustering results, providing insights into the uncertainty associated with each classification of the data point.

Figure 3C represents a modified rendition of Figure 3B, specifically tailored to illustrate the anesthesia depth classification for Participant 4. Along the *y*-axis, this plot delineates the categorization into slight, proper, or deep anesthesia groups at individual time points. Figure 3B provides a detailed depiction of the continuous membership values, reflecting the degree of belonging to each cluster: slight, proper, and deep. However, this comprehensive display introduces the challenge of intuitively discerning the predominant cluster at a single point. While this approach offers a more complete dataset, it complicates the task of determining the cluster affiliations for each data point. Hence, the modified version in Figure 3C simplifies this interpretation by highlighting the cluster with the "higher value." This adaptation facilitates a more straightforward assessment of the anesthesia depth classification by presenting a clearer distinction. This clarity enhances the utility of visualization in aiding clinician decision-making during patient monitoring and management.

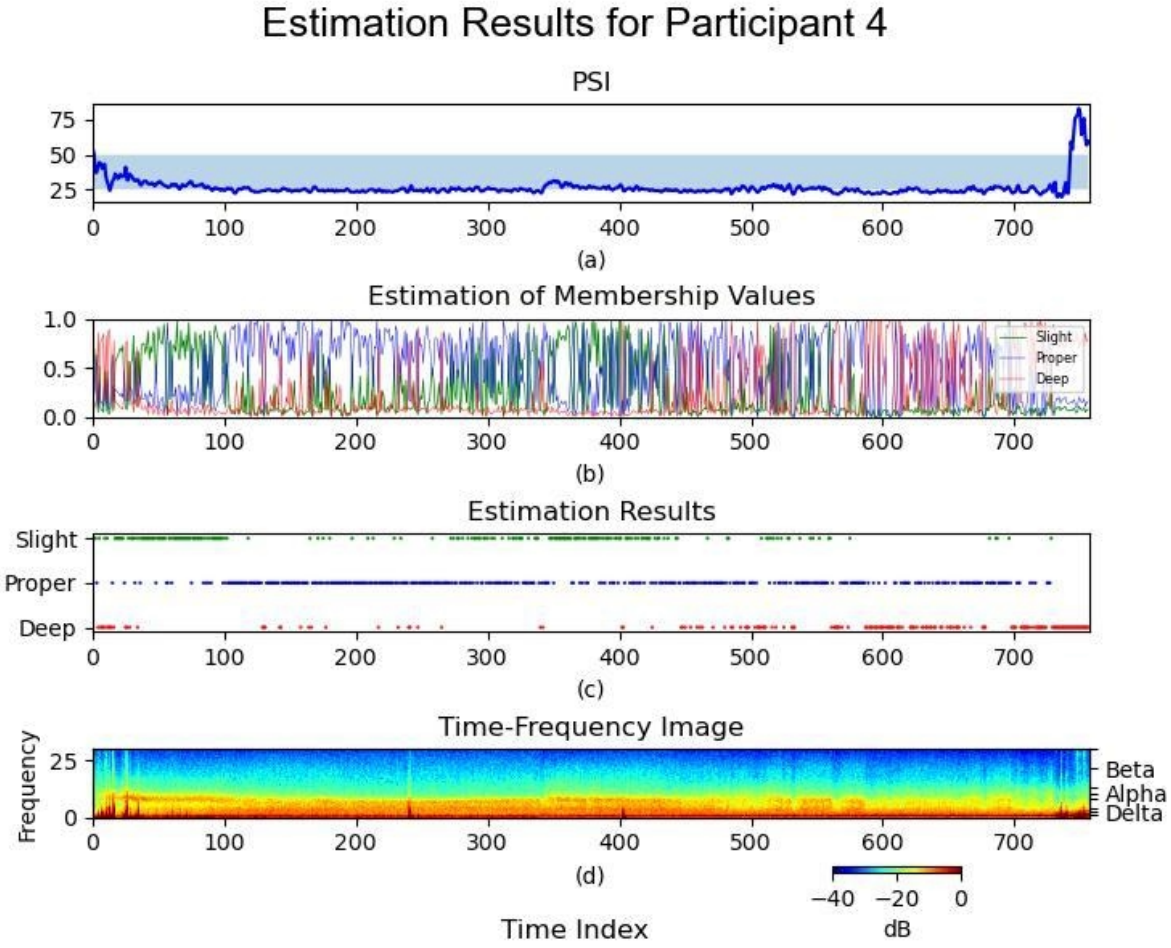

Figure 3D presents a time-frequency image derived from the raw EEG signal without processing, providing insights into the frequency components of the EEG signal over time. Overall, Figure 3 provides a comprehensive analysis of the EEG signals and anesthesia depth classification for Participant 4, contributing

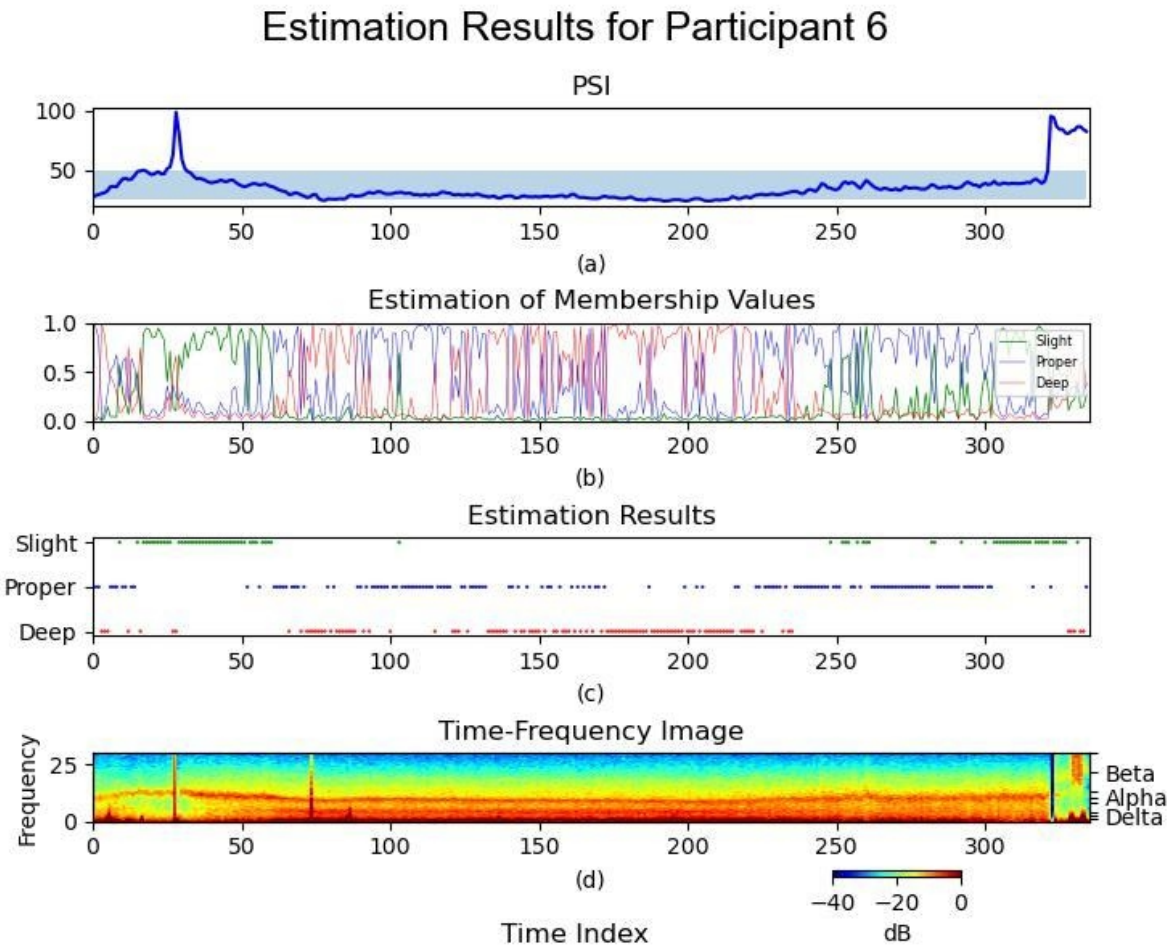
XSL•FO
RenderX

to the understanding of brain function monitoring and anesthesia management.



Participant 6 then underwent identical signal processing and analysis procedures, resulting in Figure 4. This comprehensive Figures 4A-D underwent the same rigorous process as shown in Figures 3A-D.

Figure 3. Fuzzy C-Means clustering analysis of Participant 4. Representative analysis of Participant 4 (male, 75 years, American Society of Anesthesiologists class II) who underwent lumbar spine surgery at Taipei Veterans General Hospital. (**A**) shows the Patient State Index trend over time; (**B**) displays Fuzzy C-Means membership values representing the degree of belongingness to each cluster; (**C**) illustrates the simplified classification into slight, proper, and deep anesthesia levels; (**D**) presents the corresponding electroencephalography time-frequency spectrogram. These plots depict temporal transitions in anesthetic depth.

Figure 4. Fuzzy C-Means clustering analysis of Participant 6. Representative analysis of Participant 6 (male, 45 years, American Society of Anesthesiologists class I) who underwent elective lumbar spine surgery at Taipei Veterans General Hospital. (**A**) shows the Patient State Index trend over time. (**B**) displays Fuzzy C-Means membership values representing the degree of belongingness to each cluster. (**C**) illustrates the simplified classification into slight, proper, and deep anesthesia levels. (**D**) presents the corresponding electroencephalography time-frequency spectrogram. These plots depict temporal transitions in anesthetic depth. PSi: Patient State Index.

Discussion

Principal Findings

This study explored the feasibility of improving anesthetic depth assessment by applying unsupervised machine learning to pEEG data. EEG patterns vary with the depth of anesthesia [10]. PEEG-derived indices, such as the BIS and PSi, are susceptible to various influences, presenting limitations in their interpretation [24]. Purdon et al [8] characterized the EEG signatures of intravenous and inhaled anesthetics, providing additional insights into the depth of anesthesia. In Figure 2, the delta ratio quantifies cortical suppression, as delta oscillations reflect deep anesthesia and thalamocortical inhibition. The theta and alpha ratios were selected for their modulation by anesthetics in the frontal cortex. Alpha oscillations indicate stable unconsciousness under propofol and sevoflurane, correlating with GABAergic inhibition, while theta oscillations become prominent at higher anesthetic concentrations, particularly with sevoflurane, signaling transitions between moderate and deep anesthesia. Figures 3 and 4 depict Participants 4 and 6, respectively, demonstrating the combination of PSi values, anesthesia depth clustering values, simplified clustering results, and processed time-frequency images. These visual presentations illustrate patient-specific anesthesia depth, facilitating the automatic identification of anesthesia depth.

Postoperative delirium and neurocognitive complications after spinal surgery remain significant concerns [29], and perioperative EEG monitoring may contribute to their management [30]. In this study, one participant (Participant 4) had a history of cognitive dysfunction due to dementia. All participants underwent lumbar spinal surgery in the prone position with sevoflurane as the maintenance agent. The operation time ranged from 170 to 405 minutes. Most participants were discharged within 1 week, and no other cognitive impairments were documented.

Limitations

This study was constrained by a small sample size. While the extensive dataset of over 16,000 EEG epochs ensures high within-subject data density and supports the internal stability of the model for the analyzed participants, we acknowledge that the limited number of independent participants restricts the external generalizability of the findings. Previous studies have indicated that a sampling frequency of 100 Hz is sufficient for EEG-based analysis [31]. While a larger sample size could

XSL•FO
RenderX

further refine the FCM clustering results presented in Figure 1, the primary determinants of clustering effectiveness in single-subject EEG analysis are the duration and density of the data. With 3 to 5 hours of continuous EEG recordings per participant, our study provided sufficient granularity for meaningful intrasubject clustering, as demonstrated in Figures 3 and 4. Our primary objective was to explore the feasibility and establish the methodological framework for applying unsupervised machine learning to processed EEG data.

García et al [32] explored EEG activity and delineated an analgesia-related axis alongside hypnosis during general anesthesia, revealing distinct changes in EEG patterns. We acknowledge the limitation of a single-dimensional index in capturing the full spectrum of neural activity during anesthesia. However, our primary goal is to demonstrate the feasibility of unsupervised clustering within a clinical framework, focusing on the hypnosis axis—one of anesthesia's 3 key components. This study used frontal EEG signals, as used in processed systems such as BIS and SedLine. Frontal EEG monitoring inherently limits spatial coverage but remains the clinical standard due to its accessibility and reliability. The frontal cortex exhibits predictable EEG dynamics—α-spindle emergence and δ-wave dominance—with increasing anesthetic depth, correlating with loss of consciousness and hypnotic adequacy [33-35].

While this study does not include external validation or direct quantitative comparisons, this reflects the broader challenge in anesthetic depth classification, which lacks a universal standard. Although no intraoperative recall was observed, determining the optimal depth of anesthesia remains complex. Conventional monitors, such as BIS and SedLine, along with DSA visualization, aid clinical judgment but do not serve as definitive references. The study introduces a complementary tool to enhance anesthetic depth assessment. This is reflected in Figures 3 and 4, where multiple monitoring modalities are integrated to provide additional insights.

Finally, the frame-by-frame analysis maximizes temporal sensitivity but may result in rapid state transitions, or "flickering," as observed in Figure 3C. For clinical application, future iterations would likely require temporal smoothing algorithms to stabilize the output and minimize alarm fatigue. Despite strong visual correspondence with PSi trends, standardized quantitative metrics were not calculated due to methodological constraints. Specifically, the significant time delay inherent in the PSi algorithm [36] limits direct linear correlation with the frame-by-frame FCM method, and imposing rigid thresholds for concordance rates contradicts the continuous, fuzzy nature of anesthetic depth.

Comparison With Prior Work

Unsupervised learning involves algorithms that identify patterns or structures within a dataset, facilitating the discovery of novel classification methods [10]. Systematic reviews have highlighted the effectiveness of unsupervised clustering methods in various medical applications. Clustering analysis has revealed pivotal features underlying the progression from early stage to advanced Alzheimer disease [37]. Unsupervised learning models applied in cardiac resynchronization therapy can accurately discern patient clusters and are valuable for phenotyping and predicting treatment responses [38]. In amyotrophic lateral sclerosis research, the k-means score, a hierarchical clustering method, has emerged as the most widely used method for stratification and progression prediction [39]. We predefined 3 practical categories—slight, proper, and deep anesthesia—to emulate the structured reasoning process that governs intraoperative anesthetic management. Clinicians continuously evaluate anesthetic depth and determine whether to increase, maintain, or decrease anesthetic delivery. Each titration is typically incremental and followed by a brief observation period to allow pharmacokinetic redistribution and physiological stabilization before reevaluation. Although the equilibration interval varies among individuals, such judgments integrate both the instantaneous anesthetic state and its temporal evolution [36]. FCM clustering offers distinct advantages for modeling this continuum. It enables classification into clinically interpretable states while concurrently generating fuzzy membership values that quantify the degree to which a given epoch inclines toward a "lighter" or "deeper" level of anesthesia. This property captures the continuous and overlapping nature of anesthetic depth and mirrors the gradual, feedback-driven adjustments that characterize intraoperative anesthesia management.

In our continuous monitoring data, transitions between anesthetic states occurred gradually, consistent with the physiological continuum of anesthesia depth. Abrupt shifts from "light" directly to "deep" anesthesia were uncommon and, when observed, were generally attributable to identifiable physiological perturbations—such as bolus drug administration, intense noxious stimulation, or sudden hemodynamic changes—rather than modeling artifacts. Processed EEG indices may also be transiently affected by electromyographic [40], electrocardiographic [41], or mechanical vibration artifacts, particularly during spine surgery. These interferences are usually recognizable in the raw EEG tracing and can be excluded from analysis.

Near-equal memberships across clusters (≈33% each) are uncommon and typically occur when a feature vector lies between centroids or during transient noise, reflecting a transitional or indeterminate phase rather than a distinct anesthetic state. Interpretation of anesthetic depth is inherently pattern-based, as clinicians assess temporal trends and spectral features in the DSA—for instance, alpha dominance suggests adequate hypnosis, whereas delta and theta predominance or burst suppression indicate a deeper anesthetic level [42]. Therefore, a single epoch with near-equal memberships would not influence clinical judgment, which relies on the overall evolution of EEG patterns rather than isolated points.

Prior research has focused on developing and enhancing automated system controls, including closed-loop anesthesia. Components such as measurement devices, controllers, and actuators are central to these advancements [43]. pEEG-derived indices, such as the BIS [43,44] and PSi [45], frequently serve as key targets. This study introduced unsupervised learning clustering as a potential new approach for assessing anesthesia depth, offering additional avenues for improving automated anesthesia control systems.

RenderX

The novel clustering approach provides an alternative method for assessing anesthesia depth, particularly focusing on the "hypnosis" axis, as depicted in Figure 3B and C. These figures illustrate the EEG density spectral array data from Participant 4, suggesting segmentation into slight, proper, and excessively deep anesthesia depths. Unlike traditional PSi values, which provide singular metrics, the representation of Figure 3B with fuzziness on the *y*-axis shows nuanced membership toward anesthesia depth clusters. The graphical depiction in Figure 3C highlights the peak values, indicating the period of deep anesthesia. This approach offers a novel tool for assisting clinical judgment in anesthesia depth assessment.

Among conventional unsupervised clustering paradigms, FCM, Gaussian Mixture Models (GMMs), and density-based algorithms such as Density-Based Spatial Clustering of Applications with Noise (DBSCAN) exhibit fundamentally distinct analytical mechanisms. FCM minimizes a distance-weighted objective function while permitting graded memberships across clusters—an essential property for anesthesia-related data in which EEG and physiological variables vary continuously and overlap across anesthetic states. In contrast, GMM represents data as a superposition of Gaussian components and assumes that each cluster conforms to an elliptical, symmetric distribution. However, anesthetic EEG features often display non-Gaussian characteristics, including skewness and heavy tails arising from nonlinear pharmacodynamic effects and interindividual variability, rendering GMM less robust and prone to boundary instability. Density-based algorithms such as DBSCAN, although effective in identifying discrete or spatially separated clusters, depend on fixed density thresholds and therefore perform poorly with continuous-depth data, where transitions between anesthetic states are gradual and density gradients evolve smoothly. Considering these properties, FCM provides a mathematically rigorous and physiologically consistent framework for delineating the smooth, overlapping transitions that define anesthetic depth.

Building upon these theoretical considerations, we initially explored k-means clustering but found it less flexible in classifying anesthetic depth. When visualizing frequency band proportions, k-means struggled to capture transition zones effectively, reinforcing our decision to use FCM for a more adaptable classification. The FCM algorithm stands out in unsupervised machine learning because of its adaptability and effectiveness in increasing data volumes. It iteratively adjusts centroids and clusters, creating personalized representations tailored to individuals, analogous to bespoke garments [46]. This adaptability ensures an accurate assessment of anesthesia depth dynamics, which is crucial for personalized healthcare.

Conclusions

In conclusion, this study established a machine learning–based methodology for anesthesia depth assessment, demonstrating its feasibility and providing preliminary insights into classification, visualization, and patient-specific management. By applying FCM clustering to processed EEG data, this novel approach enhances the understanding of anesthesia depth patterns and integrates with existing monitoring modalities, including PSi values and time-frequency image visualization for a more comprehensive assessment. Although preliminary, these findings lay the foundation for future research and refinement.

Multimedia Appendix 1

Detailed data preprocessing workflow and Fuzzy C-Means (FCM) parameter settings. Electromyography signals were processed via the Welch method (*30-s windows, 2-s overlap*). Normalized delta, high-theta, alpha, and beta band-power ratios were extracted as input features. The FCM algorithm ($c = 3$, $m = 2$) was applied with random initialization of cluster centers to identify three anesthesia depth clusters. Measures of dispersion for the delta band within each cluster are summarized in Table S1. Figures S1 and S2 show additional two-dimensional clustering distributions, demonstrating consistent three-cluster separation across different frequency-band pairings.

Abstract

Background: Upper and lower extremity lymphedema is a chronic, progressive condition that significantly impairs the quality of life of affected patients. Despite the recently established effectiveness of physical therapy and supermicrosurgical interventions, current guidelines frequently lag behind emerging evidence and commonly do not offer stage-specific treatment algorithms. This gap in evidence-based guidance may prompt clinicians with limited experience to seek support from large language models such as ChatGPT.

Objective: Given the potential of artificial intelligence to rapidly integrate emerging research, this study evaluated how clinicians from different professional backgrounds rate the quality and reliability of personalized lymphedema management recommendations generated by ChatGPT.

Methods: In this exploratory cross-sectional study, ChatGPT generated treatment recommendations for 6 standardized lymphedema case scenarios. An international panel of 67 participants (resident doctors, board-certified specialists, physiotherapists, and advanced practice nurses) from 34 institutions across 11 countries assessed the recommendations using a modified DISCERN questionnaire with a 9-point agreement scale ranging from 1 (completely disagree) to 9 (completely agree). Ratings were summarized as pooled means with variability measures and compared across clinician groups (residents vs board-certified physicians vs physiotherapists or advanced practice nurses) using group comparison testing.

Results: ChatGPT was rated most favorably for diagnostic accuracy and treatment relevance, with higher ratings among residents than board-certified physicians. Residents assigned significantly lower scores for source indication, source currency, and communication of uncertainty. Between-group differences were observed across multiple DISCERN items, consistent with systematically more critical appraisal by experienced specialists. Participants reported moderate to high trust and willingness to consider ChatGPT as a supplementary resource, with more favorable perceptions among younger respondents.

Conclusions: Clinicians perceived ChatGPT as potentially useful for preliminary orientation and educational support in lymphedema management, especially for less experienced users. Despite not being blinded, lower ratings in evidence transparency and uncertainty communication, particularly among experienced specialists, suggest that current artificial intelligence outputs should not be used as stand-alone guidance. Future work should test clinically integrated, citation-grounded workflows in prospective settings and evaluate whether they improve decision quality and efficiency.

Introduction

Lymphedema is a chronic condition characterized by the accumulation of interstitial fluid, typically resulting from damage or disruption of lymphatic pathways [1]. In the Western world, lymphedema is commonly caused by oncologic surgery or radiotherapy and significantly reduces quality of life due to extremity swelling, limited mobility, and psychosocial distress [1-5].

Lymphedema treatment is highly individualized, influenced by age, preexisting comorbidities, and prior interventions [1]. Conservative treatment includes complex decongestive therapy; however, recent literature has demonstrated promising long-term outcomes after supermicrosurgical interventions, such as lymphovenous anastomosis (LVA) and vascularized lymph node transfer (VLNT) [6-9]. Due to the personalized nature of lymphedema treatment, following the current guidelines of the AWMF (Arbeitsgemeinschaft der Wissenschaftlichen Medizinischen Fachgesellschaften, S2k) or the International Society of Lymphology (ISL) may result in difficulties providing universally applicable, stage-specific recommendations [10,11]. Furthermore, the guidelines may include outdated information, primarily due to the time-intensive nature of expert consensus and validation processes [10,11]. Given the rapid advancements in lymphatic surgery, the incorporation of novel treatment approaches into official guidelines may take years, as this process requires a predefined and structured consensus. Consequently, there is a possibility that patients may receive care that is no longer up to date in a clinical context.

Large language models (LLMs) such as ChatGPT (OpenAI) represent a new approach to the processing of knowledge, which also applies to medical information [12,13]. These technologies have the potential to reshape medical decision-making by accelerating the integration of novel research into clinical routines [14-17]. Thus, unlike traditional guidelines, artificial intelligence (AI) is hypothesized to accelerate the transition of new findings into personalized treatment recommendations. However, whether this potential is truly realized in practice strongly depends on data implementation and prompting [18].

Therefore, the goal of this study was to assess ChatGPT's ability to define and generate treatment recommendations for lymphedema by evaluating the quality, accuracy, and perceived utility of its recommendations across an interdisciplinary panel of relevant medical specialties. Additionally, the differences in acceptance were compared between resident doctors in training and board-certified plastic surgeons with experience in either lymphatic surgery or lymphedema management.

Methods

Study Design

The study was designed as a multidisciplinary assessment of ChatGPT-generated treatment recommendations of 6 cases of chronic lymphedema, ranging from ISL stage I to ISL stage 3 of the upper and lower limb (Multimedia Appendix 1). To ensure consistency, all cases were submitted to GPT-4o (GPT-4 Omni) on December 18, 2024, at noon Central European Time by the first authors (AF and CEE). Each case was entered into a distinct, separate chat session to limit session history bias. Only the initial response was considered, and the option to regenerate the response was not used. The responses obtained from GPT-4o were compiled into a PDF and were subsequently evaluated by a panel of resident doctors (considered inexperienced), board-certified doctors (considered experienced), and physiotherapists or advanced practice nurses (APNs) using a 9-point agreement scale [19].

Clinical Vignettes and Treatment Recommendations

The clinical vignettes were designed with the intention of incorporating the underlying etiology of lymphedema through past medical history, current patient symptoms, and findings from clinical examination. Cases were prepared to be as realistic as possible and to reflect real clinical scenarios. Patients were clearly categorized into the 3 ISL stages, with corresponding indocyanine green studies illustrating the lymphatic patterns consistent with the stage described in each clinical vignette [10]. Furthermore, the cases were illustrated with images adapted from Principles and Practice of Lymphedema Surgery by Cheng et al [20]. A standardized prompt was used for each case and is provided in Multimedia Appendix 1.

Evaluation

The evaluators had access to the original prompts, all 6 clinical cases, and the corresponding treatment recommendations generated by ChatGPT (Multimedia Appendix 1). The web-based questionnaire for subsequent evaluation was developed and distributed using the Research Electronic Data Capture (REDCap; Vanderbilt University) platform [21]. The DISCERN tool, a validated questionnaire for assessing the quality of written treatment information, was adapted to a 9-point agreement scale and then used for the quantitative evaluation of each generated response [19].

In accordance with the instructions provided in the DISCERN handbook [19], questions 1 and 2 ("Are the aims clear?" and "Does it achieve its aims?") were excluded from the evaluation as they were found to be irrelevant to the defined research question of this study. Two additional questions were included in the evaluation of each case: one concerning correct staging (question 1) and the other regarding overall final agreement with the treatment option recommended by ChatGPT (question 16). In summary, each response was evaluated using 16 questions rated on a 9-point agreement scale, where 1 represents complete disagreement and 9 represents complete agreement. Finally, 3 concluding questions were added to evaluate the overall agreement regarding the treatment recommendation by ChatGPT and the attitude regarding AI use as a clinical decision tool (Multimedia Appendix 2). In addition, each participant was given the option to offer feedback. These open-text comments were reviewed descriptively by the first authors to provide contextual insight alongside the quantitative results. No formal

XSL•FO
RenderX

qualitative analysis or coding approach was applied. All available comments were read in full, and relevant observations are summarized in Multimedia Appendix 3.

Survey Distribution

The survey was conducted from January 7 to March 18, 2025. Resident doctors without prior experience in lymphedema management were recruited internationally through the same broader professional networks as the expert panel, primarily via participating centers in the LYMPH trial, as well as international resident and student networks. Experienced, board-certified doctors specializing in lymphedema treatment were identified and contacted, most of whom had previously participated in the international lymphedema consortium through existing collaborations [22]. A total of 64 board-certified doctors were invited via email to take part in the study, receiving a survey link along with a comprehensive explanation of its objectives and requirements (response rate 24/64, 37.5%). Additionally, 30 physiotherapists and lymphedema APNs specializing in lymphedema treatment were invited (response rate 10/30, 33.3%) through the same consortium and a contact list provided by the Lymphödem Vereinigung Schweiz (a Swiss patient organization) [22,23]. As resident recruitment was conducted via mass email and a preexisting student group, the response rate of invited resident doctors could not be calculated.

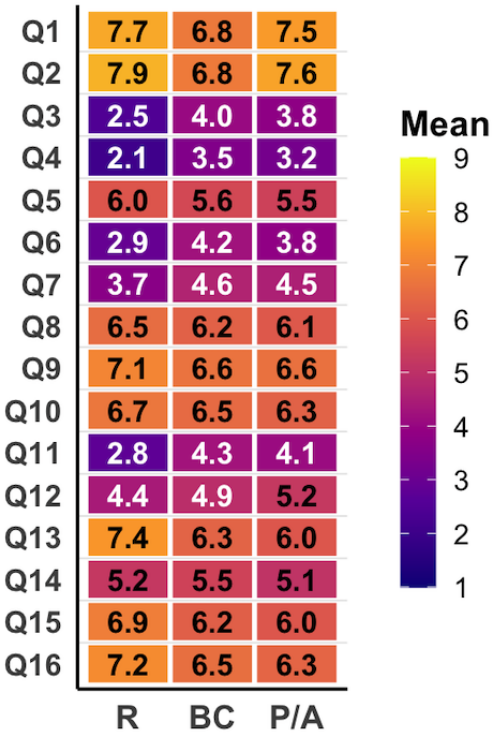
Statistical Analysis

Statistical analysis was conducted using R software (version 4.4.3; R Foundation for Statistical Computing) [24]. The primary end point was the scoring of agreement and reliability of ChatGPT-generated treatment recommendations stratified by experience groups. Consequently, participants were categorized into 3 groups: resident doctors, board-certified doctors, and physiotherapists or APNs. For each question, group-wise means and SDs were calculated. The Levene test was used to confirm homogeneity of variances prior to conducting 1-way ANOVA. Depending on the result of the Levene test, either standard ANOVA (for equal variances) or Welch ANOVA (for unequal variances) was used to test for differences between groups. Where applicable, an “overall” group comprising all participants was included for descriptive purposes only and was excluded from inferential statistical testing. A 2-sided P value of ≤.05 was considered statistically significant.

Ethical Considerations

This study was conducted in accordance with the Declaration of Helsinki. On the basis of the fictional nature of the cases and the absence of human subject data, the local ethics committee (Ethikkommission Nordwest- und Zentralschweiz) deemed that no formal ethics approval was required. Participation in the web-based survey was voluntary. All participants were informed about the purpose of the study, and informed consent was implied through completion of the survey. Participants had the option to discontinue the survey at any time without any consequences. All data were collected anonymously. Data protection and confidentiality were ensured in accordance with applicable regulations. No compensation was provided. No identifiable individuals are shown in any figures or supplementary materials.

Results



A total of 67 participants from 34 different institutions across 11 countries completed the survey, including 33 (49.3%) resident doctors, 24 (35.8%) board-certified doctors, and 10 (14.9%) lymphedema physiotherapists or APNs. The mean age was 35.6 (SD 14.1) years, with resident doctors averaging 28.0 (SD 6.0) years, board-certified doctors 45.0 (SD 14.0) years, and physiotherapists or APNs 42.0 (SD 19.9) years.

Diagnostic Accuracy and Relevance (Q1 and Q2)

Staging and diagnostic accuracy (question 1; Q1) were generally rated high (mean 7.3, SD 1.5), with board-certified doctors assigning significantly lower scores than resident doctors (P<.001; Table 1). Similarly, the relevance of the recommendations (Q2) was rated highly (mean 7.5, SD 1.4), with board-certified doctors rating significantly lower compared to resident doctors or physiotherapists or APNs (P<.001; Figure 1; Table 1). A detailed overview of scoring per case is provided in Multimedia Appendix 4.

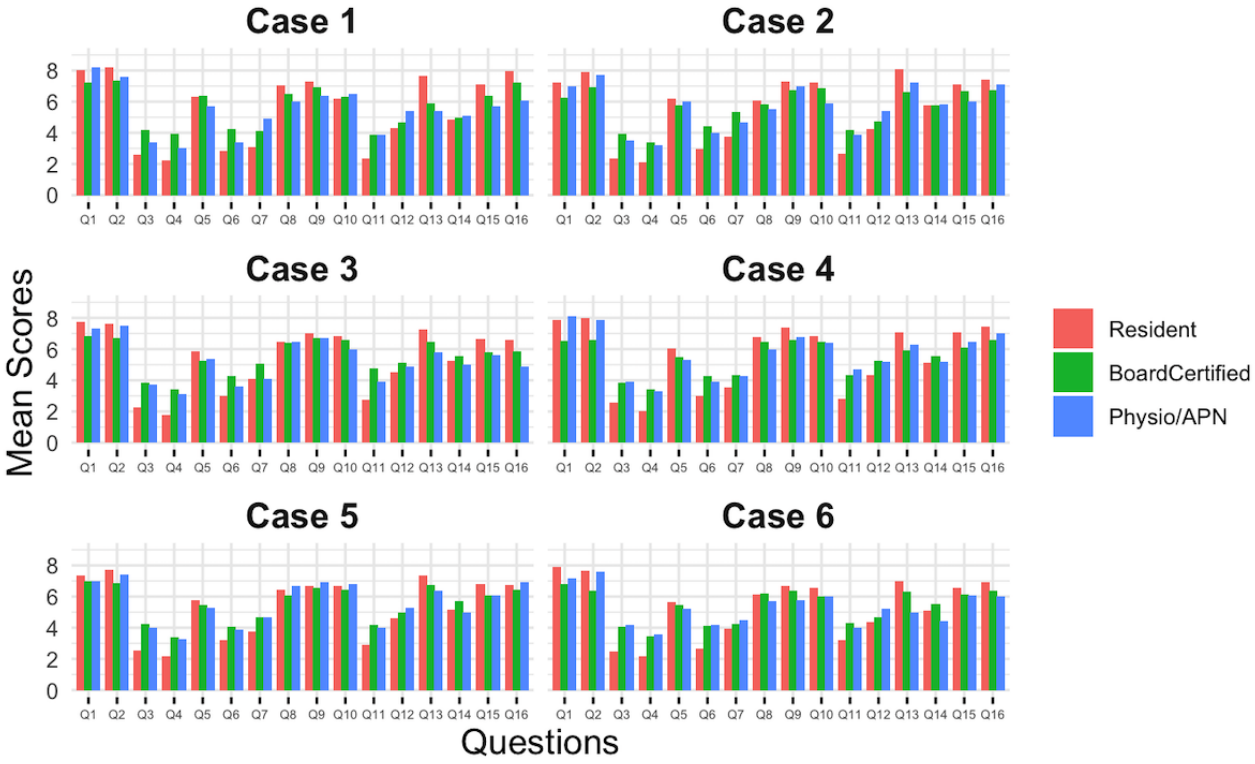
Question[b]	Overall (n=67), mean (SD)	Resident doctors (n=33), mean (SD)	Board-certified physicians (n=24), mean (SD)	Physiotherapist or APN[c] (n=10), mean (SD)	*P* value
Q1—diagnostic accuracy	7.3 (1.5)	7.7 (1.2)	6.8 (1.6)	7.5 (1.9)	*<.001*[d]
Q2—relevance	7.5 (1.4)	7.9 (1.0)	6.8 (1.6)	7.6 (1.1)	*<.001*
Q3—indication of sources used	3.2 (2.5)	2.5 (2.1)	4.0 (2.4)	3.8 (2.9)	*<.001*
Q4—currency of sources used	2.7 (2.1)	2.1 (1.6)	3.5 (2.1)	3.2 (2.9)	*<.001*
Q5—balanced and unbiased information	5.8 (1.8)	6.0 (1.7)	5.6 (1.6)	5.5 (2.2)	.07
Q6—additional supporting information	3.5 (2.3)	2.9 (2.1)	4.2 (2.0)	3.8 (2.7)	*<.001*
Q7—communication of areas of uncertainty	4.1 (2.1)	3.7 (2.0)	4.6 (1.8)	4.5 (2.5)	*<.001*
Q8—explanation of how the treatment works	6.3 (1.8)	6.5 (2.0)	6.2 (1.5)	6.1 (2.0)	.23
Q9—benefits of treatment	6.8 (1.6)	7.1 (1.8)	6.6 (1.3)	6.6 (1.7)	*.04*
Q10—risks of treatment	6.6 (1.9)	6.7 (2.0)	6.5 (1.5)	6.3 (2.0)	.22
Q11—consequences of treatment refusal	3.5 (2.2)	2.8 (2.0)	4.3 (1.9)	4.1 (2.7)	*<.001*
Q12—impact on quality of life	4.7 (2.4)	4.4 (2.3)	4.9 (2.1)	5.2 (2.8)	*.03*
Q13—availability of multiple treatment options	6.8 (1.9)	7.4 (1.7)	6.3 (1.8)	6.0 (2.2)	*<.001*
Q14—support for shared decision-making	5.3 (2.3)	5.2 (2.4)	5.5 (2.1)	5.1 (2.3)	.37
Q15—overall quality of the recommendation	6.5 (1.6)	6.9 (1.4)	6.2 (1.8)	6.0 (1.8)	*<.001*
Q16—overall agreement	6.8 (1.8)	7.2 (1.6)	6.5 (1.9)	6.3 (2.3)	*<.001*

[a]Values represent the pooled mean (SD) across the 6 standardized lymphedema case scenarios from an exploratory cross-sectional survey of 67 clinicians (resident doctors, board-certified physicians, and physiotherapists or advanced practice nurses) from 34 institutions in 11 countries (January-March 2025).

[b]Q: question.

[c]APN: advanced practice nurse.



[d]Values in italic demonstrate statistical significance ($P<.05$).

Source Transparency and Objectivity (Q3-Q5)

The clarity of source citation (Q3) and the dating of sources (Q4) were rated very low across all groups, with mean scores of 3.2 (SD 2.5) and 2.7 (SD 2.1), respectively (Figure 2). Interestingly, resident doctors gave both questions significantly lower ratings than the other groups ($P<.001$). Interestingly, Q5 (objectivity or neutrality of ChatGPT) received an average score of 5.8 (SD 1.8), with no significant differences between groups.

XSL•FO
RenderX

Figure 2. Mean scores by professional group for all cases. Overview of mean scores across 6 lymphedema case scenarios by professional group. Bars represent mean scores. APN: advanced practice nurse; Q: question. Exact values can be found in Multimedia Appendix 4.

Supportive Information and Areas of Uncertainty (Q6 and Q7)

The quality of additional resources (Q6) was rated badly, with a mean score of 3.5 (SD 2.3) across all cohorts. Similarly, the communication of uncertainty (Q7) received moderate scores of 4.1 (SD 2.1), with residents giving the lowest scores across both questions (P<.001).

Treatment Explanation and Options, Risk Communication, and Quality of Life Considerations (Q8-Q13)

ChatGPT's performance in communicating treatment options and possible risks was generally rated positively, with Q8 (how the treatment would work), Q9 (benefits of treatment), and Q10 (potential risks) all receiving favorable scores (mean 6.3, SD 1.8; mean 6.8, SD 1.6; and mean 6.6, SD 1.9, respectively). In contrast, Q11 (consequence of no treatment) consistently scored low (mean 3.5, SD 2.2). Q12 assessed whether the provided information addressed the impact of the treatment on patients' quality of life. Ratings were moderate (mean 4.7, SD 2.4), with residents rating the responses significantly lower than other groups. Q13 (ChatGPT mentioning that there may be more than one treatment choice) was generally rated positively (mean 6.8, SD 1.9).

Shared Decision-Making and Overall Quality (Q14-Q16)

Support for shared decision-making (Q14) was rated moderately (mean 5.3, SD 2.3). The overall impression of the quality of responses (Q15) and overall agreement with treatment recommendations (Q16) both received high ratings (mean 6.5, SD 1.6 and mean 6.8, SD 1.8, respectively), with physiotherapists or APNs rating the answers the lowest (P<.001).

Concluding Questions—Trust and Future Use

Concluding question (CQ) 1 assessed trust in ChatGPT's responses, CQ2 assessed willingness to use ChatGPT in future clinical work, and CQ3 assessed whether participants would recommend it for clinical decision-making. Resident doctors rated all 3 concluding questions (CQ1-CQ3) significantly higher than board-certified doctors and physiotherapists or APNs. CQ2 showed a similar pattern, with resident doctors at a mean of 6.5 (SD 1.4), board-certified doctors at 5.3 (SD 2.2), and physiotherapists or APNs at 5.3 (SD 2.3). Finally, for CQ3, which assessed whether participants would recommend AI as a clinical decision-making tool, residents again scored highest, followed by board-certified doctors and physiotherapists or APNs (Figure 3; Table 2). All survey comments are listed in Multimedia Appendix 3.

Discussion

In this exploratory, cross-sectional study, a total of 67 participants, comprising 33 resident doctors still in training, 24 board-certified doctors, and 10 lymphedema physiotherapists or APNs, from 34 different institutions across 11 countries evaluated ChatGPT-generated treatment recommendations for 6 fictional lymphedema cases. This is the first study to evaluate ChatGPT-generated treatment recommendations for lymphedema.

Notably Higher Acceptance of ChatGPT Among Younger Doctors

The overall high level of agreement with the ChatGPT-generated treatment recommendations (Q16) indicates broad acceptance across all cases and groups (Table 1). Resident doctors expressed a more positive opinion toward ChatGPT, a tendency that is presumably attributable to their lesser clinical experience and greater openness to digital technologies in medical practice, indicating that the evaluation of ChatGPT may also be influenced by generational factors (Figure 3) [25,26]. Importantly, however, this favorable perception was not uncritical. Residents assigned significantly lower scores than board-certified physicians for source transparency (Q3-Q4;

XSL•FO
RenderX

Figure 1). The lower ratings may reflect stricter expectations regarding explicit source citation, differences in grading thresholds, or a reduced ability to recognize implicit sources that experienced clinicians may infer based on prior knowledge [27]. As the study design does not allow discrimination between these explanations, no conclusions can be drawn regarding the underlying cause of this difference. Nevertheless, several resident doctors reported that ChatGPT already serves them as a useful orientation tool, particularly in situations with limited prior familiarity with a condition or treatment options. This underscores the tool's potential as a rapid decision support or educational aid, as it only uses a few seconds to generate an extensive response [18]. It also highlights the need to integrate the critical use of AI tools into medical education. As residents showed greater willingness to use ChatGPT, targeted training could help prevent misconceptions and ensure these tools complement, rather than replace, clinical reasoning.

However, board-certified doctors demonstrated a lower level of agreement with treatment recommendations provided by ChatGPT, possibly due to their greater clinical experience and higher expectations regarding therapeutic nuances. This may, in part, stem from the perception that AI systems are not yet capable of providing fully personalized treatment algorithms. This viewpoint was supported in the open comments section (Multimedia Appendix 3), where experienced clinicians repeatedly pointed out that well-established surgical interventions, such as LVA and VLNT, were insufficiently addressed. In this study, LVA and VLNT were only briefly mentioned in cases 2, 3, 4, and 6 and only as potential options if compression therapy and liposuction were deemed insufficient. Reconstructive procedures such as LVA and VLNT are mentioned in both the German AWMF (S2k) guidelines and the ISL consensus document [10,11]. While the AWMF (S2k) guidelines suggest considering surgical options only after 6 months of conservative treatment without any lasting beneficial effect, the ISL guidelines refer to microsurgical interventions without specifying any time frame regarding previous complex decongestive therapy [10,11]. However, recent literature suggests that these procedures may also be used earlier or even as a preventative measure, thus challenging the traditional time threshold [28,29]. Given that key papers and guideline discussions on LVA and VLNT were already available well before October 2023, their limited presence in the responses is unlikely to be explained by the model's knowledge cutoff alone [30]. A more plausible explanation is that ChatGPT defaults to what it has seen most often: conservative management pathways that are widely taught and described, and a generally "play it safe" tendency when asked broad clinical questions [31]. In other words, the model may not be unaware of surgery; rather, it may just not surface it unless the prompt explicitly asks for surgical options or provides more detail about operative candidacy [12]. Nevertheless, newer ideas such as prophylactic LVA may still be underrepresented due to the recency of the evidence. Future work should test whether prompting specifically for surgical options changes the balance and completeness of the recommendations. These findings also emphasize the necessity of incorporating temporal limitations when using AI tools in clinical decision-making processes [7,8,20,28-30,32,33]. Furthermore, the strong emphasis on lymphedema management using conservative treatment options may result from the broader and more established evidence base in this area, which has developed over decades and is therefore more prominently represented in ChatGPT's training data.

Physiotherapists or APNs expressed greater skepticism regarding ChatGPT's treatment recommendations, as highlighted in the open comments section. The recommendations were regarded as being too generalized and lacking personalization. It was emphasized that effective lymphedema care necessitates ongoing, individualized assessment, a component that the AI recommendations did not adequately address.

Prompt Quality and Lack of Sources Limit ChatGPT's Clinical Reliability

One of the key characteristics of ChatGPT is its reliance on user input—responses are generated solely based on the prompt it receives [12]. As a result, the specificity and clarity of the input significantly affect the quality, depth, and relevance of the output [12]. Shorter prompts tend to produce shorter, less detailed responses. Citations were completely absent in ChatGPT's responses and consistently rated poorly by participants (Q3; Table 1), demonstrating that the absence of sources significantly limited the reliability of AI-generated treatment recommendation and, consequently, did not earn the physicians' trust. Furthermore, the absence of information regarding additional sources (Q6), the lack of mention of areas of uncertainty (Q7), and the omission of potential consequences of forgoing treatment (Q11) were also rated negatively (Table 1).

As an LLM, ChatGPT does not inherently verify the information it provides, but instead generates content based on linguistic patterns, which may influence the accuracy of treatment recommendations [12]. Notably, previous studies emphasized the need to explicitly ask for citations, as the model may otherwise omit references or produce so-called "hallucinations," meaning fabricated or incorrect references [34,35]. As our prompt did not explicitly request sources, thus reflecting the expected real-world use of ChatGPT, the absence of citations was expected. However, this highlights 2 key limitations. First, when users lack the background knowledge to formulate precise prompts, the model's effectiveness is significantly reduced. Second, users currently have no possibilities to verify the origin or quality of the information provided. Previous studies have shown that such uncritical reliance on unverifiable information has the potential to result in inefficient or inappropriate treatment decisions and, consequently, potentially harm the patient [36]. It is also important to emphasize that ChatGPT does not *collect* information but rather generates responses based on statistical patterns in its training data, which further limit its interpretive reliability.

ChatGPT may also pose security risks [12]. Of particular concern is the use of false or deliberately misleading prompts, the aim of which is to manipulate the model into generating inaccurate responses [12]. To ensure patient safety, any clinical implementation would require strict regulatory oversight. A more realistic, and potentially safer, alternative could involve embedding ChatGPT within a clinical decision support system using prevalidated clinical data [37]. In this scenario, ChatGPT would function as a predictive model, assisting in

XSL•FO
RenderX

decision-making within a strictly regulated and supervised data environment.

Study Strengths and Limitations

This is the first exploratory, cross-sectional study evaluating the agreement, reliability, and decision-making value of AI using LLMs in generating treatment recommendations for lymphedema management in a global, multidisciplinary, and interprofessional panel. Strengths of this study include the sizeable expert panel of 67 doctors and lymphedema therapists from 34 different institutions across 11 countries. A potential limitation of this study is that evaluators were aware that responses were generated by ChatGPT, which may have introduced either positive bias (novelty or expectation effect) or negative bias (preexisting skepticism toward AI). The results should therefore be interpreted as clinicians' perceptions of AI-generated recommendations rather than a purely objective measure of model performance. The lack of human-generated reference standard represents an important limitation, as it prevents the interpretation of absolute DISCERN scores; these should instead be understood in a relative context across professional groups. Although the 6 vignettes were deliberately designed to reflect common clinical presentations across the ISL stage spectrum across both extremities, they cannot capture the full heterogeneity of lymphedema. Consequently, generalizability to all clinical contexts is limited, and future studies should evaluate a larger and more diverse set of cases. Another limitation of this study is the use of an adapted assessment tool based on the DISCERN criteria. Although the underlying framework is validated, modifications to the item set and scoring scale may have altered the original psychometric properties of the instrument. As resident recruitment was conducted via large email and international student group, the response rate of invited resident doctors could not be calculated. Moreover, all analyses were based on a single, time-stamped response per case and were not controlled for random seed values or multirun variability, as this would have substantially increased survey burden. Furthermore, because the study was conducted using the standard ChatGPT web interface rather than the application programming interface, we were unable to access or control key inference parameters such as temperature, top-p, or system prompts. As a result, these factors were not reported. Finally, the study did not assess how variations in prompt design might affect the consistency or accuracy of the generated recommendations. Additionally, participants did not generate the prompts themselves, which may limit user satisfaction to the generated responses.

Conclusions

ChatGPT has the capacity to provide relevant basic knowledge for lymphedema management and may be particularly useful for less experienced clinicians. However, it has not yet succeeded in replacing expert consultation and offers only limited personalization. Additionally, its constraints regarding source transparency and prompt dependency highlight the need for cautious and context-aware integration into clinical practice.

Acknowledgments

During the revision of this manuscript, the authors used GPT-5.2 to improve readability. The authors subsequently reviewed and edited the content as needed and take full responsibility for the final version of the publication.

Funding

This study was funded by the Freiwillige Akademische Gesellschaft Basel, the Swiss Cancer Research Foundation, Rising Tide Foundation, the Swiss National Science Foundation, and the Theodor und Ida Herzog-Egli Stiftung.

Data Availability

The datasets generated and analyzed during this study are stored on the secure Research Electronic Data Capture platform hosted by the Department of Clinical Research at the University of Basel and can be provided by the corresponding author upon reasonable request.

Authors' Contributions

All authors contributed to the study conception and design. Clinical vignettes were prepared by AF, CEE, and EAK. Data collection was conducted by AF, CEE, and EAK. Statistical analysis and figure preparation were performed by AF and SRW. Data interpretation and drafting of the manuscript were carried out by AF and CEE. The study was supervised by EAK. All authors reviewed and approved the final manuscript.

Abstract

Background: Autosomal dominant polycystic kidney disease (ADPKD), characterized by progressive cyst growth and renal decline, is the leading genetic cause of end‐stage renal disease.

Objective: This study aims to develop and validate machine learning (ML) models for predicting the risk of progression to dialysis in patients with ADPKD using a nationwide administrative database. Early identification of high-risk patients is critical for timely monitoring.

Methods: This retrospective cohort study used data from Taiwan's National Health Insurance Research Database (2007‐2018) to identify newly diagnosed patients with ADPKD. Six ML algorithms, including logistic regression, random forest, and extreme gradient boosting (XGBoost), were employed to predict progression to dialysis. Models were developed using 10-fold cross-validation, with the Synthetic Minority Oversampling Technique applied within training folds to address class imbalance. An ensemble-based feature selection strategy was implemented to identify the most robust predictors and optimize final model performance. Model evaluation was conducted using a strict temporal split.

Results: The study included 1856 patients with ADPKD, of whom 302 (16.27%) progressed to dialysis. Multivariable Cox regression identified several significant risk factors, including age 66 years and older (hazard ratio [HR] 4.63, 95% CI 2.71‐7.92; P<.001), anemia (HR 4.33, 95% CI 3.25‐5.78; P<.001), congestive heart failure (HR 1.81, 95% CI 1.29‐2.54; P<.001), and acute kidney injury (HR 1.69, 95% CI 1.19‐2.41; P=.003). Among the ML models, the XGBoost model, using an optimized set of 27 features, demonstrated the highest predictive performance on the held-out temporal test set (accuracy 98.3%; area under the curve 0.955; F_1-score 0.800; Brier score 0.022). The top predictors in the XGBoost model largely aligned with age, comorbidity burden, anemia, and cardiovascular disease markers. Medication use (eg, anticoagulants, loop diuretics, febuxostat) was also among the most influential predictors; however, medication-related predictors should be interpreted as proxies for disease complexity rather than direct risk modulators.

Conclusions: ML models can predict dialysis risk in patients with ADPKD using administrative data with temporal validation. This approach may support risk stratification by helping identify individuals at higher predicted risk who may warrant closer monitoring and further specialist evaluation.

Introduction

Background

Polycystic kidney disease (PKD) is the leading genetic cause of end-stage renal disease (ESRD). The most common mutations in PKD occur in the *PKD1* or *PKD2* gene, which encode the proteins polycystin-1 and polycystin-2, respectively. These mutations result in abnormal cell proliferation, fluid secretion, and differentiation, leading to the formation and growth of cysts [1]. The progressive nature of renal cysts may cause structural and functional changes in the kidney. According to the latest guidelines, the estimated prevalence of PKD varies widely, ranging from approximately 2 to 14 per 10,000 individuals, depending on the study methodology and population characteristics [2].

Contemporary management of autosomal dominant polycystic kidney disease (ADPKD) has evolved to include both the management of associated complications and direct interventions aimed at the disease mechanism. A cornerstone of care remains the control of hypertension, a common and impactful complication. Angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin II receptor blockers (ARBs) are widely recommended for their established efficacy in blood pressure control and proteinuria mitigation [3,4]. In addition, lifestyle interventions, such as dietary sodium restriction and weight management, play a crucial role in preserving renal function [5,6]. In parallel, disease-modifying therapies, such as the vasopressin V2 receptor antagonist tolvaptan, have been developed to slow cyst growth in select patients with rapidly progressing disease, who are often identified using prognostic markers such as genetic status or total kidney volume (TKV) [7]. Furthermore, other medications, such as statins and metformin, are frequently prescribed to manage concurrent conditions in this population, though their role as primary treatment options for ADPKD itself remains under investigation [8,9].

Study Objective

While risk stratification using advanced tools is crucial for guiding specialized treatments, a significant need remains for risk assessment methods based on accessible, routinely collected data. Currently, the gold-standard models for prognostication in ADPKD include the Mayo Imaging Classification, which utilizes height-adjusted TKV and patient age to predict the rate of estimated glomerular filtration rate (eGFR) decline, and the PROPKD score, which integrates genetic information (*PKD1* vs *PKD2* mutation type) with early clinical manifestations [2,10,11]. Although these models are invaluable, their broad implementation is often hindered by their dependence on specialized and resource-intensive evaluations. For instance, the Mayo Classification requires magnetic resonance imaging (MRI) or computed tomography to measure TKV, while the PROPKD score necessitates comprehensive genetic sequencing. These resources can be costly and are not universally available in all clinical settings, creating a gap for more scalable screening tools.

In parallel with these clinical tools, artificial intelligence (AI) has been increasingly used in ADPKD management. AI models have been developed to predict glomerular filtration rate decline, aiding in the early identification of high-risk patients and facilitating proactive management [12]. In imaging-based classifications, deep learning algorithms have been applied to automate ADPKD severity assessment, enhancing objectivity and reducing interobserver variability [13]. AI has also been instrumental in TKV quantification, a crucial prognostic marker in ADPKD. Deep learning-based segmentation models have demonstrated high accuracy in automated kidney segmentation from MRI and computed tomography images, significantly reducing manual workload [14,15]. While these advancements improve disease monitoring, they often still rely on the availability of imaging or detailed clinical data, leaving a gap for predictive models that can leverage more widely accessible administrative data to forecast hard clinical end points.

Therefore, this study aimed to develop and validate an AI-assisted model to identify significant predictors of progression to dialysis in patients with ADPKD using a nationwide administrative database. We evaluated multiple machine learning (ML) algorithms using a prespecified temporal split for model development and evaluation and summarized predictors to enhance interpretability and clinical usability. Our goal was to create a complementary tool for risk stratification, potentially aiding clinicians in monitoring patients and identifying those who may warrant more specialized evaluation.

Methods

Data Sources

This retrospective cohort study was based on the National Health Insurance Research Database (NHIRD), which is derived from Taiwan's universal compulsory health insurance system covering nearly 99% of the 23 million individuals in Taiwan since 1998 [16]. The database includes patients' hospitalization and outpatient visit records, and each individual was continuously followed. Disease diagnoses were coded according to the International Classification of Diseases, Ninth Revision, Clinical Modification (*ICD-9*-CM). The NHI Administration fully adopted *ICD-10*-CM for clinical records in 2016.

Ethical Considerations

This study was conducted in accordance with the principles of the Declaration of Helsinki and was reviewed and approved by the Ethics Review Board of Shin-Kong Wu Ho-Su Memorial Hospital (approval number 20211008R). The requirement for informed consent was waived by the review board because this study involved a secondary analysis of routinely collected administrative data, and no direct contact with individual participants occurred. The original data collection procedures and this secondary analysis were approved without the need for additional consent.

All data obtained from the NHIRD were fully deidentified prior to analysis. Personal identifiers were removed by the data holder, and the authors had no access to information that could be used to identify individual patients. Data access and analysis were conducted in compliance with relevant data protection regulations.

XSL•FO
RenderX

No financial or other compensation was provided to participants, as this study did not involve direct recruitment or interaction with human subjects.

The manuscript and all supplementary materials did not include any images or information that could lead to the identification of individual participants.

Study Design and Population

We identified new-onset ADPKD cases from the Catastrophic Illness Patient Registry between 2007 and 2018. To minimize potential misclassification bias from ICD coding, we implemented stringent validation criteria for both the primary diagnosis and comorbidities. The identification of patients with ADPKD followed a 2-step process: subjects were first identified using ICD diagnostic codes, and their diagnosis was then validated against Taiwan's Catastrophic Illness Patient Registry. A catastrophic illness certificate requires formal review and approval by physicians, ensuring a high degree of diagnostic accuracy for our study cohort [17-19].

The index date was defined as the first date on which a patient met the ADPKD case definition and had validation in the Catastrophic Illness Patient Registry. Baseline predictors were ascertained during the 365-day lookback period preceding the index date.

To construct a clean incident cohort and reduce reverse causation, we excluded individuals aged below 19 years or above 85 years, those with missing core administrative information (eg, sex, age, or index date), and those with evidence of ADPKD during the 2005 to 2006 washout period. We also excluded patients with any evidence of dialysis (hemodialysis or peritoneal dialysis) before the index date and those with kidney transplantation before the index date. Patients were followed from the index date until initiation of dialysis, death, or December 31, 2019, whichever occurred first.

Baseline Variables

The dataset includes a variety of demographic, clinical, and medication-related variables for individuals with ADPKD. The key demographic variables include sex and age. Clinical variables encompass a variety of diseases grouped as cerebrovascular (intracranial aneurysms, ischemic stroke, and hemorrhagic stroke), cardiovascular (hypertension, atrial fibrillation, congestive heart failure [CHF], peripheral vascular disease, arrhythmia, and ischemic heart disease), gastrointestinal (liver cirrhosis, peptic ulcer, diverticulosis, cholangitis, and acute pancreatitis), renal and urological (urinary tract infection [UTI] and acute kidney injury [AKI]), pulmonary (chronic obstructive pulmonary disease [COPD], pneumonia, and asthma), metabolic (dyslipidemia, diabetes mellitus, and gout), mental (dementia, anxiety, and depression), and other (glaucoma and anemia). Each comorbidity was confirmed if the corresponding diagnosis code appeared in at least 1 hospitalization record or at least 3 outpatient visit records within the 365-day lookback period preceding the index date.

Medication variables cover a broad spectrum, including antihypertensives (beta-blockers, alpha-blockers, ACEIs/ARBs, calcium channel blockers [CCBs], methyldopa, hydralazine, minoxidil, clonidine, potassium-sparing diuretics, thiazide diuretics, and loop diuretics), antidiabetic drugs (metformin, sulfonylureas, dipeptidyl peptidase-4 inhibitors, thiazolidinediones, other oral hypoglycemic agents, rapid-acting insulins, and long-acting insulins), antimetabolic agents (statins, fenofibrate, and other lipid-lowering agents), urate-lowering agents (benzbromarone, allopurinol, febuxostat), and other medications (nonsteroidal anti-inflammatory drugs [NSAIDs], sedative hypnotics, tranexamic acid, mammalian target of rapamycin inhibitors, sodium bicarbonate, anticoagulants, antiplatelet agents, and vitamin K). As with the definition of comorbidities, we adopted a widely used and validated approach to enhance specificity. Medication variables were quantified as the cumulative number of prescription days during the 365-day lookback period preceding the index date. This approach was used to capture exposure intensity beyond a binary indicator. The specific codes used to define all comorbidities and medications are detailed in Tables S1 and S2 in Multimedia Appendix 1, respectively.

Outcome Definition and Follow-Up

The primary end point was ESRD, defined as initiation of dialysis or receipt of kidney transplantation without prior dialysis. Patients were followed from the index date until ESRD, death, or December 31, 2019, whichever occurred first. For the ML classification models, the binary outcome was ESRD by the end of follow-up (event=1). In the ML analysis, the label reflects whether ESRD was observed by December 31, 2019, and does not represent a fixed-horizon risk. Patients without ESRD were labeled as nonevents (event=0), including those who died before reaching ESRD.

Data Preprocessing and Handling of Missing Data

Our strategy for handling missing data involved 2 stages. First, case-wise deletion was performed to exclude any patient records with missing core administrative data (eg, sex, age, or date of diagnosis), as indicated in the study flowchart. For the final cohort, predictor variables were constructed such that no missing values remained. The absence of a record for a specific variable was treated as meaningful data rather than as a missing value. For instance, if a patient had no prescriptions for a given medication, the cumulative exposure days were coded as 0. Similarly, if a patient did not meet the predefined criteria for a comorbidity, the variable was coded as 0, indicating absence.

Statistical Analysis

Categorical variables were presented as frequencies with percentages and compared using the chi-square test. Continuous variables were expressed as means with SDs and compared using the *t* test. Multivariable Cox proportional hazards regression models were used to estimate adjusted hazard ratios (HRs) and 95% CIs for the risk of dialysis initiation. A 2-tailed *P* value of <.05 was considered statistically significant. All statistical analyses were performed using SAS version 9.4 (SAS Institute Inc).

ML Model Development and Feature Selection

Given the extended accrual period, we used a temporal split to preserve chronological separation between model development and evaluation. Records from 2007 to 2016 (80%) were used

XSL•FO
RenderX

for model training, and records from 2017 to 2018 (20%) were reserved as an independent held-out test set for performance assessment.

Within the training set, we performed 10-fold cross-validation to improve robustness and reduce overfitting. To address class imbalance, Synthetic Minority Over-sampling Technique (SMOTE) was applied only within the training folds of each cross-validation iteration to avoid information leakage into the validation folds. Model performance was evaluated on the held-out test set using accuracy, Cohen κ, sensitivity, specificity, area under the curve (AUC), F_1 score, and Brier score, recognizing that multiple complementary metrics are needed under imbalanced outcome distributions.

The 6 ML algorithms were chosen to encompass a broad spectrum of modeling techniques, ranging from interpretable linear models to complex, high-performance ensembles. Logistic regression was selected as a conventional statistical method widely used in clinical research, serving as a robust and interpretable baseline for comparison. To capture complex nonlinear relationships, we included 2 distinct models: classification and regression trees, a foundational decision tree algorithm, and multivariate adaptive regression splines, a flexible model adept at identifying interactions between predictors. Finally, to leverage the superior predictive power of ensemble learning, 3 state-of-the-art algorithms were selected [20]. Random forest represents the bagging method, which builds independent trees to reduce variance, whereas CatBoost and eXtreme Gradient Boosting (XGBoost) are representatives of boosting methods that construct models sequentially to correct the errors of their predecessors and often yield high accuracy. This comprehensive selection allowed for a thorough evaluation of predictive performance across different algorithmic families, and these methods have been successfully applied in similar medical informatics contexts [21-23] (see Supplementary Methods in Multimedia Appendix 1 for detailed model descriptions). Hyperparameters for each model were optimized using random search within the training set under 10-fold cross-validation. The held-out temporal test set was used only for final performance evaluation. The specific hyperparameters for all models are detailed in Table S3 in Multimedia Appendix 1. All model construction was conducted using Python (version 3.9; Python Software Foundation).

We employed a 2-pronged feature selection approach to identify the most significant predictors. In the first approach, each model performed feature selection based on its own internal mechanism, and its performance was evaluated using this algorithm-specific feature set. In the second approach, we constructed an overall consensus ranking of predictors using rank aggregation across the 6 algorithms. We prespecified that the best-performing algorithm would be selected based on performance on the held-out temporal test set, considering discrimination, class-imbalance–sensitive metrics, and calibration. For the selected best-performing model, we additionally evaluated parsimony by sequentially adding predictors according to the consensus ordering and selecting the feature count that maximized test-set performance.

Results

Characteristics of the Study Population

From the NHIRD, 2677 incident ADPKD cases were identified between 2007 and 2018. After applying exclusion criteria (n=821), 1856 patients were included in the final cohort (Figure 1).

XSL•FO
RenderX

Figure 1. Study flowchart of patient selection and machine learning model development. The diagram shows the patient selection process from the NHIRD for the period 2007 - 2018 and the subsequent workflow for model development. Patients were split temporally into a training set (2007 - 2016) and a held-out test set (2017 - 2018). ESRD was ascertained through December 31, 2019. ADPKD: autosomal dominant polycystic kidney disease; CART: classification and regression trees; ESRD: end-stage renal disease; eXGB: extreme gradient boosting; LGR: logistic regression; MARS: multivariate adaptive regression splines; ML: machine learning; RF: random forest.

XSL•FO
RenderX

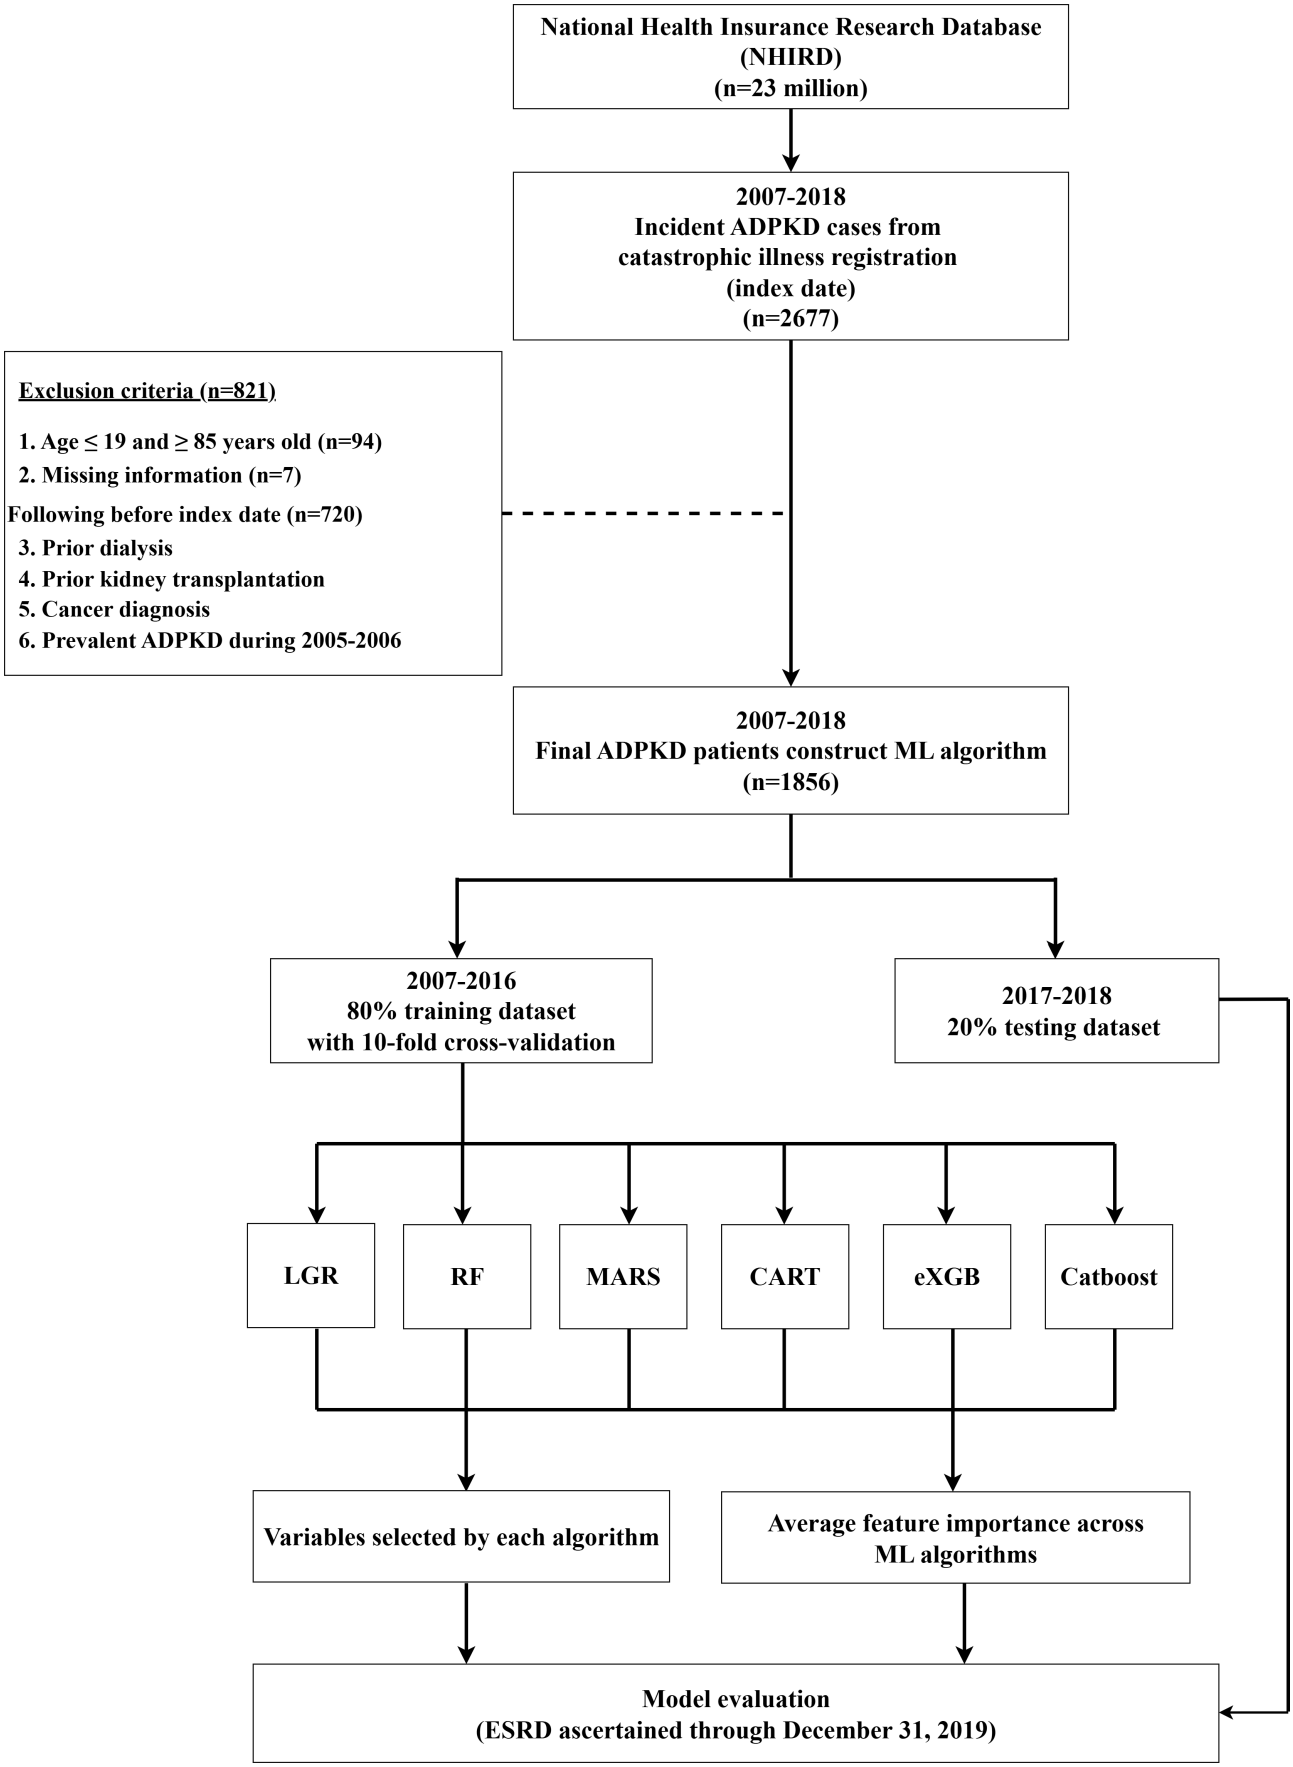

Table 1 summarizes baseline characteristics assessed during the 365-day lookback period preceding the index date. During follow-up through December 31, 2019, 302 patients (302/1856, 16.27%) initiated dialysis. Kidney transplantation without prior dialysis was observed in only 2 patients. Due to small cell size restrictions intended to protect patient privacy in the NHIRD

XSL•FO
RenderX

data release process, transplantation events could not be analyzed separately; therefore, ESRD outcomes are presented primarily in terms of dialysis initiation. The remaining 1554 patients (1554/1856, 83.73%) did not initiate dialysis and were censored at death or end of follow-up.

XSL•FO

[a]PKD: polycystic kidney disease.
[b]CCI: Charlson Comorbidity Index.
[c]AF: atrial fibrillation.
[d]CHF: congestive heart failure.
[e]PVD: peripheral vascular disease.
[f]UTI: urinary tract infection.
[g]AKI: acute kidney injury.
[h]COPD: chronic obstructive pulmonary disease.
[i]DM: diabetes mellitus.
[j]ACEI: angiotensin-converting enzyme inhibitor.
[k]ARB: angiotensin II receptor blocker.
[l]CCB: calcium channel blocker.
[m]DPP4i: dipeptidyl peptidase-4 inhibitor.
[n]NSAID: nonsteroidal anti-inflammatory drug.
[o]mTOR: mechanistic target of rapamycin.

At baseline, the cohort had substantial cardiorenal comorbidity and medication use. The most prevalent comorbidities were hypertension (86.58%, 1606/1856) and UTI (50.38%, 935/1856), with pneumonia (29.26%, 543/1856), anemia (24.83%, 461/1856), and gout (23.01%, 427/1856) also common. Antihypertensive exposure was widespread (ACEI/ARB 161.30, SD 127.50 d; CCB 160.90, SD 133.70 d), and metabolic therapy was frequent (metformin 116.20, SD 137.10 d; long-acting insulin 91.71, SD 139.10 d).

Stratification by subsequent dialysis initiation highlighted clinically meaningful differences in baseline disease severity and management. Patients who later initiated dialysis were older (50.94, SD 11.94 vs 44.86, SD 13.39 y) and had higher comorbidity burden (Charlson Comorbidity Index [CCI] 4.18, SD 2.27 vs 2.27, SD 2.22; CCI≥6: 20.53% vs 7.72%), with the largest separations for anemia (65.89% vs 16.86%) and AKI (23.51% vs 6.56%). Baseline medication patterns were consistent with greater clinical complexity in the dialysis group, including lower metformin exposure (44.17, SD 95.41 vs 130.20, SD 148 d) and higher sodium bicarbonate exposure (20.52, SD 68.46 vs 7.25, SD 44.30 d).

Risk Analysis for Progression to Dialysis

Table 2 presents the multivariable Cox regression results. After adjustment for sex, age category, CCI category, and comorbidities, male sex was associated with a higher risk of dialysis initiation (aHR 1.55, 95% CI 1.13 - 2.11; *P*=.006). Age remained a strong predictor: compared with age younger than 55 years, the risk increased across categories. Among comorbidities, anemia showed the strongest association with dialysis initiation (aHR 4.33, 95% CI 3.25 - 5.78; *P*<.001). Congestive heart failure, AKI, and gout were also associated with a higher risk. Hypertension, COPD, and anxiety were associated with lower hazard in the adjusted model.

Feature Importance Across ML Models

Figure 2 presents the relative importance of variables in predicting dialysis risk, as determined by the 6 ML models. A consensus emerged across the different algorithms, highlighting several key predictors. The top-ranked predictors spanned comorbidity burden and medication patterns, including anticoagulant use, hypertension, CCB use, higher CCI category, loop diuretics, sodium bicarbonate, anemia, and ACEI or ARB use, together with age and sex. Additional contributors included cardiorespiratory comorbidities, UTI, gout, and neuropsychiatric conditions and related medications.

Performance Comparison of ML Models

Table 3 summarizes performance for 6 ML algorithms under 2 feature selection strategies: model-specific feature selection and a consensus feature set derived from rank aggregation. Using model-specific feature selection, XGBoost achieved the highest accuracy (0.9748) with specificity of 1, with an AUC of 0.9436 and a Brier score of 0.0254. Using the consensus feature set, performance improved across models. XGBoost achieved the highest accuracy (0.9832) and F_1-score (0.8), whereas MARS achieved the highest AUC (0.9762) and CatBoost achieved the lowest Brier score (0.0217), indicating strong discrimination with favorable calibration across top-performing models.

Optimization of the XGBoost Model via Feature Selection

Figure 3 shows the change in test set accuracy as top-ranked predictors from the consensus ranking were sequentially added to the XGBoost model. Accuracy increased rapidly as the highest-ranked predictors were included and reached its maximum with 27 predictors. This feature count was selected as the optimal balance between parsimony and predictive performance, and the 27-feature set was used for the final XGBoost model.

The plot shows the change in model accuracy (y-axis) as the number of top-ranked predictor variables (x-axis). The dashed vertical line indicates the point at which maximum accuracy was achieved with 27 variables.

Key Predictors in the Final XGBoost Model

The final XGBoost model used 27 baseline predictors selected during feature optimization (Table 4). This set included demographic and comorbidity burden measures (age, sex, and CCI category), major clinical conditions linked to renal risk or frailty (anemia, hypertension, ischemic heart disease, gout, pneumonia, COPD, UTI, anxiety, and depression), and multiple medication exposures. Key medication predictors included antihypertensive classes (ACEI or ARB, CCB, beta-blockers, and alpha-blockers), agents reflecting advanced renal management or metabolic status (loop diuretics, sodium bicarbonate, potassium-sparing diuretics, and rapid-acting insulin), and medications that may relate to underlying diseases (anticoagulants, antiplatelet agents, NSAIDs, sedative hypnotics, tranexamic acid, febuxostat, and statins). It is crucial to note that these medication-related predictors should be interpreted as proxies for underlying disease severity and complexity (ie, confounding by indication), rather than as direct causal risk factors.

Discussion

Principal Findings

This retrospective cohort study used data from the NHIRD to predict ESRD progression in ADPKD using 6 ML algorithms, with ESRD operationalized as initiation of maintenance dialysis. On the held-out temporal test set, XGBoost demonstrated the best overall performance after feature optimization (accuracy 0.9832; F_1 score 0.8). The final optimized XGBoost model was derived by sequentially adding top-ranked predictors and achieved peak accuracy with 27 variables. The most informative predictors reflected underlying disease severity and care intensity, including age, CCI, anemia, hypertension, ischemic heart disease, gout, pneumonia, COPD, UTI, anxiety, and depression, as well as medication exposures such as anticoagulants, loop diuretics, ACEI/ARB, CCB, and febuxostat.

Interpretation of Major Clinical Risk Factors

Hypertension is a common early manifestation of ADPKD, often developing before renal function declines. It affects up to 86.6% of patients with ADPKD, frequently appearing around 30 years of age, with up to 20% of them diagnosed before the age of 20 [24,25]. The underlying mechanisms involve intrarenal ischemia, renin-angiotensin-aldosterone system (RAAS) activation, and endothelial dysfunction. Progressive cyst expansion leads to renal hypoperfusion and sustained RAAS stimulation, further exacerbating hypertension and accelerating kidney damage [26,27]. This mechanistic framework is consistent with our results, where hypertension and cardiovascular comorbidity markers, including ischemic heart disease and related medication patterns, contributed meaningfully to dialysis risk prediction.

Age and overall comorbidity burden were among the highest-ranked predictors in both the consensus feature ranking and the final XGBoost feature set. This pattern suggests that administrative claims-based models capture the cumulative burden of systemic illness, frailty, and health care utilization that often accompanies advanced kidney disease trajectories [28,29]. In our cohort, ischemic heart disease and cardiovascular medication proxies (eg, anticoagulants, antiplatelet agents, beta-blockers, and loop diuretics) were repeatedly selected, indicating that cardiovascular disease severity and its treatment intensity provide informative signals of near-term dialysis risk [30,31].

In our cohort, anemia showed the strongest association with dialysis initiation in the adjusted Cox model and was consistently selected by the ML algorithms. A study conducted in Japan found that, despite higher hemoglobin levels in ADPKD than in other CKD types, anemia remains a key predictor of renal disease progression. In nondialysis patients with ADPKD, lower hemoglobin levels were associated with faster kidney function decline, with men with hemoglobin levels less than 12 g/dL and women with hemoglobin levels less than 11 g/dL at higher risk [32]. Together, these findings support anemia as a clinically accessible marker of advanced disease and progression risk in ADPKD.

AKI and infection-related diagnoses such as pneumonia and UTI also contributed to the prediction. These events may accelerate loss of residual kidney function through hemodynamic instability, inflammatory injury, or nephrotoxic exposures, and they may also serve as markers of vulnerability and more frequent clinical encounters. In parallel, medication predictors such as sodium bicarbonate and NSAIDs plausibly reflect clinically recognized metabolic acidosis and nephrotoxic exposure that often accompany advanced CKD and precede dialysis initiation [33].

Medication Predictors as Markers of Disease Severity

As highlighted earlier, a critical aspect of interpreting our findings is the potential for confounding by indication, particularly for medication-related predictors. In a retrospective cohort study, the use of a specific medication is often a marker of underlying disease severity rather than a cause of the outcome itself. Therefore, while these medications emerged as strong predictors in our model, they should be viewed primarily as indicators of a higher underlying risk profile, and our findings do not imply a causal relationship or recommend changes in prescribing practices. Consistent with prior work using administrative claims for kidney failure prediction, these medication patterns should be interpreted primarily as proxies for clinical complexity rather than as causal determinants of dialysis initiation [31].

Renin-angiotensin system inhibitors have been established as the first-line treatment due to their benefits in hypertension control [34]. In our model, the selection of additional antihypertensive classes (eg, alpha-blockers and CCB) and loop diuretics likely reflects difficult-to-control blood pressure, volume management needs, or concomitant cardiovascular disease rather than direct causal effects on renal decline. Similarly, anticoagulant and antiplatelet use may act as proxies for atrial fibrillation, vascular disease, or prior cardiovascular events, conditions that commonly cluster with advanced CKD and a higher risk of dialysis initiation.

Tranexamic acid was also selected among the final XGBoost predictors. In ADPKD, clinically significant gross hematuria is a common and clinically relevant event, and tranexamic acid has been used in small series for severe hematuria, although evidence remains limited [2,35]. Therefore, in claims-based modeling, tranexamic acid likely functions as a proxy for clinically significant hematuria or bleeding-related care that clusters with more advanced disease trajectories, rather than as a causal determinant of dialysis initiation.

Hyperuricemia is increasingly implicated in CKD progression, and our model identified gout and febuxostat as informative predictors of dialysis. This finding does not suggest a causal link but rather reflects prescribing patterns that align with both international guidelines and local reimbursement policies. Major clinical practice guidelines for ADPKD recommend allopurinol as the first-line urate-lowering therapy [2]. This standard is strictly reflected in Taiwan's National Health Insurance system, where reimbursement for the second-line agent, febuxostat, was restricted during our study period. These restrictions likely limited its use primarily to patients with substantial preexisting conditions, most notably advanced chronic kidney disease

XSL•FO
RenderX

(defined as eGFR <45 mL/min/1.73 m^2) or other complications such as urate nephrolithiasis or severe tophaceous gout. Consequently, the predictive signal from febuxostat in our model arises because it serves as a powerful proxy, identifying a patient subgroup with higher baseline renal risk and greater disease complexity. Further prospective studies are needed to determine if urate-lowering therapy itself modifies the disease course in ADPKD.

Statins, primarily known for their cholesterol-lowering effects, also possess anti-inflammatory and antioxidant properties that could be beneficial in PKD. Chronic inflammation and oxidative stress play roles in the pathophysiology of PKD, contributing to cyst growth and renal function decline. Evidence regarding the efficacy of statins in PKD is equivocal. Some cohort studies and animal research suggest that statins may slow the decline in renal function in patients with PKD by reducing inflammation and oxidative stress [9]. However, findings from definitive clinical trials in PKD populations, which are scarce, remain inconclusive.

Comparison With Existing Risk Stratification Tools

Our ML approach should be compared with existing clinical risk tools for ADPKD, such as the Mayo Imaging Classification and the PROPKD score. The primary advantage of our model lies in its broad accessibility. By leveraging nationwide administrative data, it bypasses the need for resource-intensive assessments, such as MRI for TKV measurement or genetic sequencing, making it a scalable and cost-effective tool for initial risk stratification across a large population. The main disadvantage, however, is the lack of direct pathophysiological data. Without TKV or genetic data, our model relies on surrogate markers of disease severity and cannot offer the same level of mechanistic insight or precision as the gold-standard tools. Therefore, our model should not be viewed as a replacement for these established methods but rather as a complementary instrument. Its optimal clinical role would be to serve as a first-line screening tool to efficiently identify high-risk patients who could then be prioritized for more definitive prognostic evaluations like imaging or genetic testing.

Strengths and Limitations

To our knowledge, this study represents the first nationwide ML-based analysis of dialysis risk in ADPKD using administrative data. It provides a scalable framework for population-level risk stratification. The use of the NHIRD, a large population-based dataset with long-term follow-up, ensures high generalizability to the nationwide population of Taiwan.

Several limitations of this study should be acknowledged. First, its retrospective design precludes the establishment of causality. Second, and most importantly, our study is constrained by the nature of the NHIRD, which lacks the gold-standard prognostic markers for ADPKD including genetic data (PKD1/PKD2 status) and imaging biomarkers like TKV, and key laboratory values such as eGFR or proteinuria. Without direct access to TKV or genetic data, our model inherently relies on surrogate markers such as comorbidity burden and medication patterns to infer underlying risk. Despite the use of a washout period and validation via the Catastrophic Illness Patient Registry, truly incident ADPKD cases cannot be fully guaranteed in claims-based data. We therefore wish to emphasize that our model is proposed as a complementary tool for broad-based risk stratification, not as a replacement for comprehensive clinical evaluation. Third, because observation windows vary by index year, the binary labeling framework may under-ascertain events among patients with shorter follow-up and can bias absolute risk interpretation. In addition, calibration curves were not presented, limiting assessment of absolute risk calibration. Fourth, because deaths occurring before ESRD were labeled as nonevents in the binary ML framework, patients with high competing mortality may be misclassified as having low renal risk. Fifth, the measurement of medication exposure, quantified by prescription days, is a proxy that does not capture actual patient adherence, dosage, or treatment adjustments. This limits our ability to make definitive conclusions about the role of specific pharmacological agents. Finally, our model was developed using a Taiwanese population, and its performance and the relative importance of predictors may vary across different ethnic and geographic groups, which may limit generalizability.

Future Work

Future studies should prioritize prospective validation in diverse external cohorts. Methodologically, fixed-horizon prediction and time-to-event approaches, including survival ML and competing-risk or multistate frameworks, should be evaluated to better align modeling with clinical trajectories. External validation datasets that include laboratory, genetic, and imaging biomarkers (eg, eGFR, proteinuria, PKD1/PKD2 status, and TKV) will enable integrated, multitiered risk stratification and more complete assessment of calibration and clinical utility. Moreover, instance-level explainability methods (eg, SHAP) can be explored to support clinical interpretability.

Conclusions

This study developed and evaluated 6 ML models to classify dialysis initiation risk in a nationwide ADPKD cohort using administrative claims data and a prespecified temporal validation design. On the held-out temporal test set, XGBoost showed the best overall performance. The most informative predictors primarily reflected disease severity and care intensity captured in claims data, including age, comorbidity burden, anemia, and hypertension, whereas medication variables should be interpreted as noncausal proxies of clinical complexity.

Acknowledgments

No generative artificial intelligence tools were used to generate the manuscript text, analyses, figures, tables, or multimedia appendix. All study design decisions, analyses, interpretations, and final wording were produced and verified by the authors.

Abstract

Background: There are multiple sources that document the date of a person's death in the United States. Unfortunately, this seemingly simple information is either incomplete or costly to obtain. Nevertheless, information on such events is critical for both health systems and clinical studies to assess the outcomes of operational and therapeutic interventions.

Objective: As part of a larger assessment of the quality of multisource death information, we compared the death data from two health systems serving the same region and the Social Security Administration Death Master File (SSADMF).

Methods: This study linked death records for patients seen in either health system with the SSADMF from 2007 to 2020 to identify concordant and discordant death data among sources. Analyses included cross-system matching, classification of death records by overlap, and calculation of agreement using the Fleiss κ.

Results: Among 904,581 matched patients, only 209 (0.02%) deaths were confirmed by all 3 sources. Large proportions of deaths were uniquely recorded by a single source: 54.32% (10,697/19,691) by health system A, 5.16% (1017/19,691) by health system B, and 20.17% (3972/19,691) by the SSADMF. The Fleiss κ was negative (−0.312), reflecting less agreement than expected by chance.

Conclusions: While this study is not generalizable, it showed that, without processes in place to obtain external data regarding patient deaths, health care facility death information should not be relied upon as a complete list of those who have died. The discordances observed highlight the potential for significant gaps in death reporting within health care systems, which could impact the accuracy of mortality-based analyses and quality assessments.

death record concordance; health systems; mortality data quality; electronic health record data quality; EHR data quality; Social Security Administration Death Master File

Introduction

Mortality is the ultimate outcome of health care and wellness interventions. As such, mortality data are important to many clinical studies. In the era of learning health systems and real-world evidence, institutions increasingly rely on routinely collected electronic health record (EHR) data to evaluate care delivery, monitor outcomes, and iteratively improve practice [1,2]. However, the accuracy and completeness of mortality information within these data remain uncertain, particularly for deaths that occur outside individual health systems [3,4].

Our clinical data warehouse, serving a large academic health center in the southwestern United States, is used for approximately 100 clinical studies per year. Many of these studies focus on our local population and address whether they improve or worsen particular outcomes and include tracking or intervening in health disparities in our region, including observational comparative effectiveness studies, local quality

XSL•FO
RenderX

improvement initiatives, and program evaluations targeting population health and health disparities in the surrounding region. These data are used primarily for retrospective and hybrid retrospective-prospective designs, where mortality end points are often ascertained from EHRs and linked administrative sources rather than from dedicated, trial-specific follow-up. Because findings from such studies can inform guideline development, institutional policies, and clinical decision support within learning health systems, inaccurate or incomplete mortality data can directly affect patient care.

In clinical research evaluating treatments for diseases with low mortality rates (eg, due to short follow-up), errors in the few available death data points can introduce significant bias, potentially compromising the validity of the study [5]. Clinical studies are increasingly using EHR real-world data in the United States, where recent regulatory guidance requires assessment of accuracy and completeness [1]. Unfortunately, many institutions lack comprehensive information about death for patients who die outside of their facilities, making the use of EHR real-world data less reliable in these studies. The increasing trend of in-home end-of-life care further limits mortality data in EHRs [6].

Researchers and clinicians in the United States have used public data sources such as the National Death Index (NDI) or the Social Security Administration Death Master File (SSADMF) to obtain mortality data [7-10]. The reports of NDI sensitivity range from 87% to 97%, with SSADMF sensitivity ranging from 71% to 83%, although performance varies by cohort, identifiers available, and period [3,11-15]. Importantly, a Social Security Administration policy change in November 2011 removed protected state death records from the publicly disseminated Death Master File, eliminating approximately 4.2 million existing records and sharply reducing capture of more recent deaths, with continuing implications for the completeness of SSADMF-based mortality ascertainment [16]. These national resources; near ubiquitous EHR adoption; and significant strides in EHR interoperability, such as health information exchanges supporting the long-used Health Level Seven Admission, Discharge, and Transfer message that can indicate a death, imply good availability of reliable death information. However, obtaining high-quality data for mortality end points in clinical studies remains a significant challenge [17,18].

These national sources are also costly and logistically constrained. The costs of obtaining external death information range from 15 cents per patient per year (NDI) to an approximately US $3000 initial fee and US $7000 annual subscription fee per user for the Limited Access SSADMF [4]. The NDI data are only available for research, their use is time limited, and reuse is constrained through a data use agreement. These limitations lead some health systems to purchase and routinely integrate such data and others to rely solely on local or regional sources [3].

Even when national mortality data are purchased and linked, there is no single contemporary gold standard for deaths occurring outside a given health system, and both national and local sources show imperfect sensitivity and date accuracy [19]. Increasing trends toward in-home and hospice end-of-life care further reduce the proportion of deaths directly captured within hospital EHR systems [20]. Consequently, one can reasonably argue that all health systems lack fully comprehensive information about out-of-hospital deaths, and that practical strategies rely on combining multiple imperfect data sources to approximate a gold standard for mortality ascertainment.

Academic health centers need a sustainable way to maintain high-quality mortality data linked to health care data. For example, our cancer registry requires death information, as do many clinical trials. In this context, we posed two major questions. (1) What is the accuracy of death data, such as occurrence and date? (2) What is the quality and relative contribution from available death data sources? To begin, we compared patient deaths reported in our health system, a neighboring health system serving the same region, and the SSADMF.

Methods

Data Sources and Linkage

This study evaluated the concordance of death information between 2 health systems serving the same geographic region and the SSADMF over a 13-year period (January 1, 2007, to July 10, 2020), as determined by the availability of data from both health systems. Patient records from the 2 health systems were linked using three approaches: (1) an existing identifier crosswalk; (2) matching first name, last name, gender, and birth date; and (3) matching medical record number. To link SSADMF data with the health system records, five distinct hash-based tokens were used: (1) last name, first initial of first name, gender, and birth date; (2) Soundex last name, Soundex first name, gender, and birth date; (3) last name, first name, gender, and birth date; (4) Social Security number, gender, and birth date; and (5) Social Security number and first name. For linkage, a match on both token 1 and token 2 was required, whereas tokens 3, 4, and 5 were each sufficient for linkage when matched individually.

Death Record Categorization

Death records were classified into mutually exclusive groups to capture concordance and discordance across the 3 sources. For the matched patient cohort (patients identified in both health systems), deaths were categorized as follows: (1) concordant deaths were deaths recorded in all 3 sources (health system A, health system B, and the SSADMF), and (2) discordant deaths were deaths recorded in only 1 or 2 sources among the matched patients, further subdivided into those recorded only in health system A, recorded only in health system B, recorded only in the SSADMF, and recorded in combinations of 2 sources (eg, health systems A and B, health system A and the SSADMF, or health system B and the SSADMF). For patients present in a single health system, deaths recorded exclusively in that system or in the SSADMF were also identified. This approach allowed us to distinguish between deaths that were consistently captured across all sources and those that were discordant, reflecting differences in reporting or population coverage.

To further investigate discordant death records, we analyzed “lost contact” patients, defined as individuals who had at least

XSL•FO
RenderX

1 encounter at 1 facility during the observation period (January 1, 2007, to July 10, 2020) but no subsequent encounters at that facility for at least 12 consecutive months after their last visit there while maintaining contact with the other facility after those 12 months. This analysis helped identify potential gaps in follow-up or differences in patient retention between systems.

In addition, we performed 2 exploratory analyses: date discrepancies of more than 1 month for deaths recorded between sources and postdeath encounters occurring more than 1 year after the recorded death date. The first analysis indicated inconsistencies in death reporting between sources, which can affect the accuracy of mortality statistics and clinical research. For postdeath encounters, we compared the death dates from the 3 sources to the encounter dates from both health systems. The analysis revealed potential issues in death recording or patient management, suggesting inaccuracies in encounter or death records or possible misuse of deceased individuals' health care credentials.

κ Analysis for Intersource Agreement

To measure the consistency of death reporting across the 3 data sources, we calculated observed agreement; expected agreement; and the Fleiss κ, a statistic used to evaluate agreement among multiple raters with categorical data. Each patient in the matched cohort was classified as either "dead" or "not dead" by each source. We then grouped patients into 8 mutually exclusive categories based on the combination of sources that reported their death. These metrics allowed us to assess the level of concordance in death classification across health system A, health system B, and the SSADMF.

Visualization

A 3-set Venn diagram was constructed to illustrate the overlap and unique contributions of each data source in identifying deaths within the matched patient cohort. Each region of the diagram was annotated with the corresponding patient counts, providing a comprehensive view of concordance and discordance in death ascertainment across health system A, health system B, and the SSADMF. This visualization facilitated the identification of patterns and gaps in death reporting among the 3 sources.

Ethical Considerations

This study was reviewed by the Institutional Review Board of the University of Texas Health Science Center at San Antonio and determined to meet the criteria for exemption from institutional review board review in accordance with Title 45 of the Code of Federal Regulations §46.104 [21] on February 21, 2024 (STUDY00000154). As this research involved secondary analysis of existing death data and no direct interaction with human participants, informed consent was not required. All data were handled in accordance with institutional and national ethical standards to ensure the privacy and confidentiality of the individuals' information.

Results

Health system A reported 1,708,399 unique patients, including 21,623 (1.27%) reported deaths, while health system B reported 1,535,936 unique patients, including 8740 (0.57%) reported deaths (Figure 1). A total of 11,052 death records from the SSADMF were linked to the combined cohort, encompassing both matched and unmatched patient records from the 2 health systems.

Among the 904,581 matched patients, health system A reported 14,659 (1.62%) deaths, health system B reported 3951 (0.44%) deaths, and the SSADMF identified 5295 (0.59%) deaths (Figure 2). Collectively, the total number of unique death records across these sources was 19,691. Figure 2 shows that 1.06% (209/19,691) of deaths were recorded by all 3 sources, whereas 54.32% (10,697/19,691) of deaths were identified exclusively by health system A, 5.16% (1017/19,691) were identified exclusively by health system B, and 20.17% (3972/19,691) were identified exclusively by the SSADMF. The proportion of death overlap between health system A and the SSADMF, health system B and the SSADMF, and the 2 health systems was 5.44% (1071/19,691), 0.22% (43/19,691), and 13.62% (2682/19,691), respectively. Health system A contributed 74.45% (14,659/19,691) of the unique deaths observed in at least one source, health system B contributed 20.07% (3951/19,691), and the SSADMF contributed 26.89% (5295/19,691).

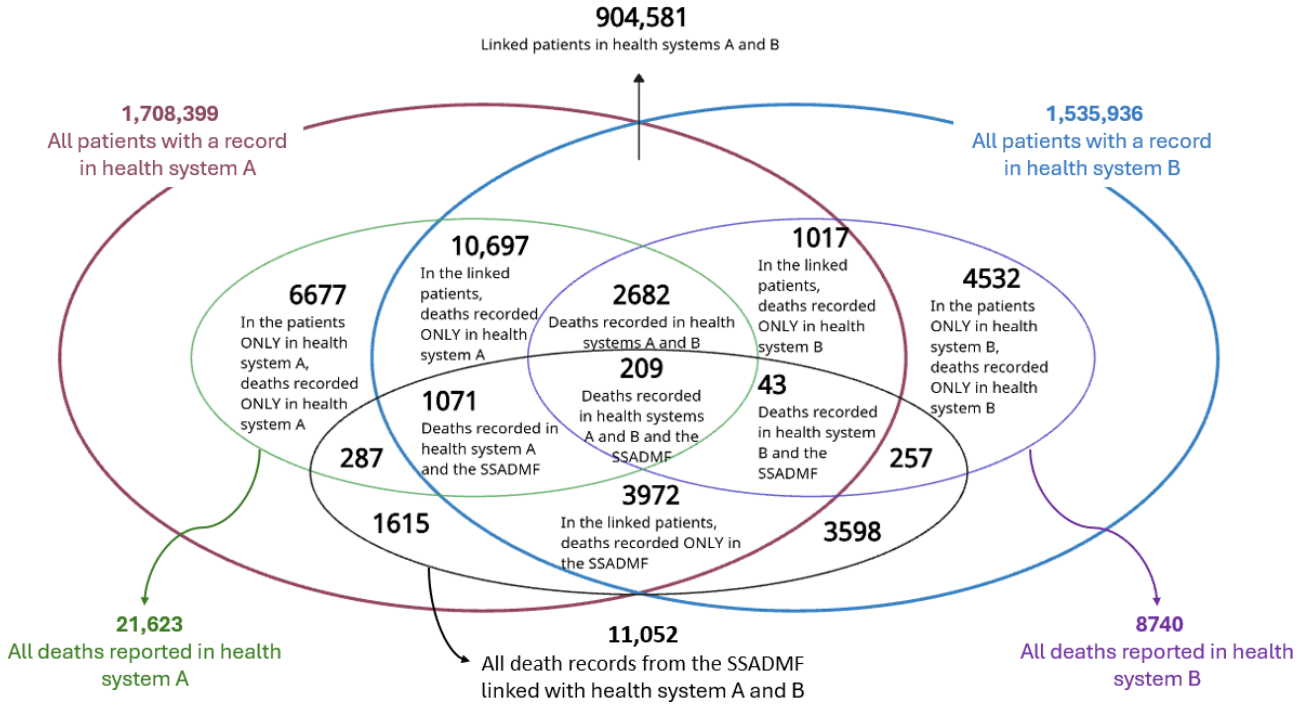
Figure 1. Patients and deaths reported among health systems A and B and the Social Security Administration Death Master File (SSADMF; encompassing matched and unmatched patient records).



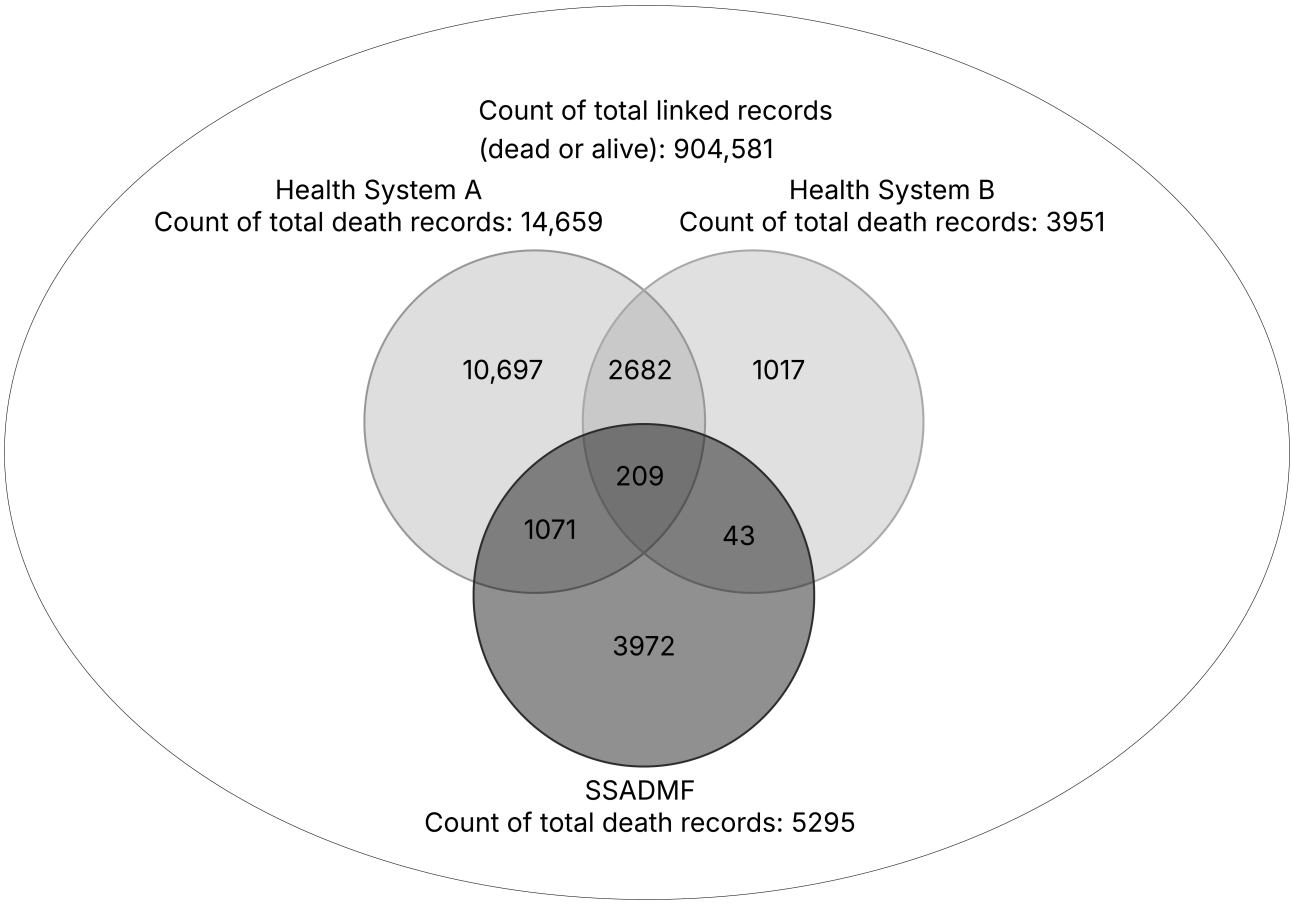


Figure 2. Three-set Venn diagram for the matched patient records. SSADMF: Social Security Administration Death Master File.

To quantify overall agreement in death classification among the 3 sources, the Fleiss κ was calculated using the distribution of death status assignments across all matched patients (Table 1). The observed agreement, defined as the proportion of patients for whom all 3 sources concurred on death status (either all "dead" or all "not dead"), was 0.9771. The expected agreement by chance based on the marginal probabilities of each source assigning "dead" or "not dead" was 0.9826. The Fleiss κ, summarizing agreement beyond chance, was −0.312, with a 95% CI from −0.330 to −0.294.

XSL•FO
RenderX

Table . Distribution of death status among the 3 sources in the matched cohort (N=904,581).

Overlap category	Patients, n (%)
Deaths in all 3 sources	209 (0.02)
Deaths in health systems A and B only	2682 (0.30)
Deaths in health system A and the SSADMF[a] only	1071 (0.12)
Deaths in health system B and the SSADMF only	43 (0.00)
Deaths in health system A only	10,697 (1.18)
Deaths in health system B only	1017 (0.11)
Deaths in the SSADMF only	3972 (0.44)
Not dead in any source	884,890 (97.82)

[a]SSADMF: Social Security Administration Death Master File.

Further investigation of discrepancies in matched patients revealed that, of the 11,768 patients recorded as deceased in health system A but not in health system B, 4796 (40.75%) lost-contact patients in health system B switched to health system A. Similarly, of the 1060 patients recorded as deceased in health system B but not in health system A, 44 (4.15%) lost-contact patients in health system A switched to health system B. These lost-contact patterns suggest that patient migration between facilities may contribute to the discordance in death reporting.

To explore the potential benefit of data quality checking rules, we identified 0.20% (39/19,691) of cases in which the date of death recorded in health system A differed by 1 month or more (median 2, range 1 to 20 months) from that recorded in health system B. Similarly, 0.23% (45/19,691) of the cases showed a discrepancy of at least 1 month (median 29; range 1-122 months) between the date of death recorded in health system A and the SSADMF, whereas 0.02% (3/19,691) of the cases showed a discrepancy of at least 1 month (median 52; range 49-122 months) between the date of death recorded in health system B and the SSADMF.

An analysis of postdeath encounters revealed that 1.22% (179/14,659) of the cases from health system A had visits recorded in either of the 2 health systems more than 1 year following their documented date of death. Similarly, 0.35% (14/3951) of such cases were identified in health system B, and 8.48% (449/5295) of cases were identified within the SSADMF.

Discussion

Principal Findings

Death records from 2 major health systems serving the same region and the SSADMF provide new insights into the complexities and limitations of mortality reporting in health care research. Ideally, each health system would maintain a complete and accurate record of all deaths, including precise date of death for every deceased patient. However, our study revealed substantial variability and discordance in mortality ascertainment across these 3 sources, underscoring the challenges inherent in relying solely on health care facility records for vital status determination.

Significant discrepancies were observed in both the identification of deaths and the recording of death dates among the 2 health systems and the SSADMF. The Venn diagram analysis demonstrated that a considerable number of deaths were uniquely captured by only 1 data source, with relatively few cases identified by all 3. This pattern highlights the risk of systematic bias and under-ascertainment when mortality surveillance depends on a single institutional record system. The presence of deaths recorded exclusively by the SSADMF (deaths not captured in either health system) emphasizes the value of integrating external sources to enhance completeness.

In Texas, hospitals are required to report deaths that occur within their facilities to the local registrar, who then forwards this information to the Texas Department of State Health Services Vital Statistics Section. This process ensures that deaths occurring in hospitals are captured in the official state vital records. However, a critical regulatory change further complicates the concordance between health system records and the SSADMF. Deaths reported solely to state vital record offices after November 1, 2011, may not appear in the publicly available SSADMF even if they are accurately captured in hospital or state databases. These reporting practices and regulatory constraints may explain the observed discrepancies between the health system data and the SSADMF. Deaths that occur in hospitals and are reported to the state may be present in the state's vital records but absent from the SSADMF if they are considered protected state records. Conversely, deaths reported directly to the Social Security Administration through other means (such as funeral directors or family members) may appear in the SSADMF but not in hospital records if the patient was not under active care at the time of death or if the hospital was not notified.

Analysis of lost-contact patients suggests that the discrepancies in death reporting may be partially explained by differences in patient engagement with each health system over time. Patients who continued to receive care primarily from one system or had no recorded visits in the other system were more likely to have their death recorded by the system with which they last interacted, potentially due to more up-to-date information or discovering deaths through postcare follow-up or billing interactions. The higher proportion of health system B–to–health system A switching compared to health system A–to–health

XSL•FO
RenderX

system B switching explains part of health system A's substantially greater volume of death records overall. These findings suggest that patient migration between systems contributes to death reporting discordance, although the reasons for migration require further investigation. While these findings offer insight into the discrepancies, they do not fully account for the substantial differences observed. This substantial difference suggests that additional factors such as institutional practices, death documentation processes, or data management systems may significantly influence death reporting.

The presence of postdeath encounters in both systems is particularly concerning. These instances could represent data entry errors, identity mix-ups, fraudulent use of a deceased patient's identity and health care coverage by another individual or entity, or other root causes. These should be investigated to identify opportunities for improvement. The results reported in this paper emphasize the importance of cross-referencing death information from multiple sources to identify discrepancies and incompleteness.

The integration of the SSADMF into our analysis allowed for a more robust assessment of concordance across sources. A high observed agreement was driven primarily by the predominance of patients classified as "not dead" by all sources. In the context of this highly imbalanced outcome, the negative κ should not be interpreted as strong paradoxical disagreement but rather as a statistical artifact of extreme class imbalance where chance agreement among "not dead" classifications is very high. Therefore, the Venn diagrams and Table 1 provide a more informative description of how often each source captured deaths and how frequently those deaths were uniquely identified by one source vs shared across sources. The finding is that the 3 sources showed limited concordance in identifying deaths themselves.

Limitations

A persistent limitation of our study is the absence of a definitive gold standard for mortality ascertainment. Without such a reference, we are unable to calculate accuracy statistics such as sensitivity and specificity and cannot definitively identify false positives or false negatives. While some potential false positives may be inferred from the presence of postdeath encounters, the true extent of missed deaths (false negatives) remains unknown and likely requires external validation. Errors in patient linkage, crosswalks, or record attribution may also contribute to misclassification. In addition, differences in linkage methodology may influence the observed discordance: the SSADMF linkage required agreement on 2 composite name–demographic tokens recommended by the data provider to balance tolerance for name variation, a design that may reduce missed matches but carries a higher risk of false linkages when names are similar yet pertain to different individuals. Future work should incorporate more reliable data sources, including the NDI, state death records, obituary data, and family-reported information. These additional sources would provide a more comprehensive and accurate picture of mortality, allowing for a better assessment of false positives and false negatives in health care facility death data.

We report this evaluation as a marker and example of significant discordance in death data among 2 health systems serving the same region and the SSADMF. While not an unexpected or groundbreaking result, such assessments serve as important reminders that, although we have come a long way toward EHR adoption and interoperability of health information, we have a long way to go before even the most basic health care data can be assumed to be accurate and complete.

Conclusions

This study demonstrates that death data from health care facilities, even when supplemented with data from the SSADMF, exhibit substantial discordance and should not be presumed to be accurate or complete without corroboration from additional sources. The persistent discrepancies among the 3 sources highlight the limitations and potential unreliability of depending solely on the EHR. Despite advances in EHR adoption and interoperability, obtaining high-quality, comprehensive mortality data for research remains challenging. Researchers and clinicians should not rely solely on facility death data for mortality end points in observational studies unless death information is systematically and prospectively collected as part of the study protocol; instead, they are strongly encouraged to incorporate external sources, such as the NDI or state vital records, to improve accuracy and completeness. Further research is needed to understand the causes of discordance and develop strategies for enhancing the quality of mortality information in clinical and epidemiological studies.

Abstract

Background: Electronic health records (EHRs) have the potential to improve service delivery through record keeping and monitoring health outcomes. As countries move toward universal health coverage, digital health tools such as EHRs are essential for achieving this goal. However, EHR implementation in middle-income countries like South Africa faces obstacles.

Objective: This study explores the reasons behind a stalled implementation of the electronic tick register (E-tick) system (an electronic version of a paper primary health care register to record services provided), using the Consolidated Framework for Implementation Research.

Methods: Using a qualitative design, in-depth interviews were conducted with 38 participants to explore their perceptions and experiences, and the factors surrounding the success and stalling of E-ticks. Participants included managers, stakeholders, implementers, and end users from the 3 implementation clinics. Data was collected using semistructured interview guides. The Thematic and Consolidated Framework for Implementation Research framework analysis (innovation, inner setting, individual characteristics, implementation process, and outer setting) was applied.

Results: The E-tick system was designed to improve data quality in paper health registers, addressing inaccuracies in reporting to district and provincial health departments (Innovation domain). Implementers iteratively developed the system through user input from managers and clinicians, and stakeholder engagement of software developers, funders, health managers, and decision-makers from the provincial health department (individual characteristics). Although the system was initially well adopted by end users, it stalled primarily due to outer setting factors, which included a change of developers, funding cuts, and limited support at the provincial health department level due to capacity gaps, political appointments, and mistrust stemming from corruption and abuse of the tender system. Moreover, resistance to leveraging lessons from locally developed small-scale systems further constrained institutional support for the E-tick.

Conclusions: Although successful implementation of EHRs can be facilitated by strong user engagement and co-design, outer setting factors such as governance, funding, and policy alignment can pose significant threats to sustainability. This underscores the importance of effective synergy between top-down and bottom-up processes for successful implementation.

Introduction

Overview

Electronic health records (EHRs) hold the promise of improving service delivery, monitoring and evaluation of health interventions, and record-keeping for public health [1]. As more countries work towards universal health coverage, leveraging digital health tools like EHRs becomes more important for enhancing service delivery and improving quality of care [2,3]. The World Health Organization's global digital health strategy emphasizes the need for accelerated adoption of EHRs to achieve health goals [4]. However, EHR implementation in many middle-income countries remains slow due to financial and technological challenges [5].

XSL•FO
RenderX

Implementing EHRs is an evolving process that requires adaptive and context-specific policies to meet ever-changing needs [6], and a clear vision to move from pilot to scaled implementation [2]. In some high-income countries where implementation has occurred [7], a "top-down" approach has typically been used, where systems are preconfigured, and users must adapt. Although this offers coordination and central oversight, it can limit flexibility. In contrast, bottom-up approaches emphasize co-design with end users and adaptation to local workflows, which often enhances usability and adoption [8]. Research suggests that successful EHR implementation in complex health systems requires balancing national coordination with local innovation, as this allows centralized oversight, while engaging local health communities and tailoring systems to user needs [8,9].

South Africa has made policy advances, such as the National Digital Health Strategy (NDHS) (2019 - 2024) [10], with considerable resources as a middle-income country and sufficient technical expertise, but progress toward a national EHR has been slow. This is because policy direction and technical capacity are sometimes impeded by systemic and political barriers. Within this context, most primary health care facilities continue to rely on manual paper-based systems, which are labor-intensive and prone to errors in data collection [11,12]. However, bottom-up efforts have been made to improve data quality and accuracy. These include Tier.net, an electronic record system used with patients living with HIV and tuberculosis, and the electronic tick register (E-tick), the electronic record system we studied. The E-tick is a digital version of the tick register, a book in each health care facility for recording patient attendance and care delivered. In this paper, we use the Consolidated Framework for Implementation Research (CFIR) to explore an attempted implementation of the E-tick, a system conceptually similar to an EHR, examining how its implementation stalled despite a consultative approach in its implementation.

Background

Digital Health Policy in South Africa

As a middle-income country, South Africa has made policy strides in line with the global developments, which should facilitate the adoption of EHRs, such as the National Health Act 61 of 2003 and the NDHS (2019 - 2024) [10,13]. The Health Act outlines the role of the National Department of Health in coordinating health information systems across national, provincial, and district levels [10]. Although policy direction is set at the national level, the federal system means that provinces can independently determine their own health care spending. Therefore, implementation largely occurs at provincial and district levels, with each maintaining its own health information systems within the national framework. This provincial autonomy has contributed to fragmentation, as different provinces and regions develop EHR systems through separate procurement processes [14]. This fragmentation is further compounded by a political economy of procurement, in which tenders are prone to corruption, mismanagement, and the absence of oversight structures [15]. These factors directly affect which innovations are funded, how resources are distributed, and whether systems can successfully reach scale, as funding decisions often prioritize large-scale centralized systems.

South Africa uses 2 health information systems in the public sector: the Health Patient Registration System (HPRS) and the District Health Information Software (DHIS; developed through a collaboration between the University of the Western Cape and the University of Oslo), jointly developed by the University of the Western Cape and the University of Oslo [16]. The HPRS is a manual patient registry that records patient contact details as well as legal identification numbers, while the DHIS is an electronic system used to collect aggregated data on services provided to patients in public health facilities [17]. The DHIS data is first collected manually, then captured into the DHIS software, where it is submitted to the district, provincial, and national health departments. The method used to record primary health care data is a tick register, a manual paper-based system where clinicians mark or tick off the services provided in a large logbook with columns for dates and types of services offered (antenatal care, vaccinations, or chronic disease management). However, this process can be arduous, time-consuming, and prone to many recording errors. Studies evaluating the DHIS have confirmed persistent data gaps, citing poor documentation, manual entry under heavy workloads, and errors as major contributors to discrepancies [18].

South African Health System

South Africa plans to implement a National Health Insurance fund to facilitate better purchasing decisions through more formal contracting relationships rather than the historical allocation of budgets by provinces [19]. In this case, EHRs are key in monitoring patient outcomes and assessing the value of care purchased. Although most provinces have had some type of operational EHR system in public hospitals [20], there is no national EHR at the primary care level, and different architectures still pose a challenge to their integration for nationally coordinated use [21].

Provincial health departments in South Africa are often run by political appointees, who work under directives from their affiliated political party. This has led to pervasive corruption in the country's health system, which has been reported at various levels of government [22]. For example, 150 million rand awarded to a communications company during the COVID pandemic was misappropriated, and the health minister was suspended as a result [23]. In another case, the provincial chief financial officer who exposed a 1-billion-rand tender fraud was assassinated [24]. Such cases illustrate how poor financial management systems and political appointments enable corruption, which acts as an impediment to the public trust in the health system [25]. For digital health innovations, such dynamics increase the risk that systems are chosen for political or financial interests rather than their impact or merit, which affects the health department's ability to work with other stakeholders, or source funds for large-scale projects, including projects to implement EHRs. Moreover, the absence of countermeasures such as accountability and transparency makes it difficult to implement large-scale projects like EHRs.

XSL•FO
RenderX

The E-Tick System

An electronic version of the paper-based tick register (E-tick) was developed and piloted in 3 public health care facilities in the Ekurhuleni district between 2017 and 2021. Clinicians record services provided directly into the digital system on a patient's record, which also allows facility managers to monitor daily activities such as headcount and services offered. Although this is not a full EHR, the system can be expanded to include diagnosis and lab results and to integrate with other systems that are currently used in public health facilities. Against this backdrop, the E-tick system sought to provide an alternative that could improve data accuracy at the facility level while feeding directly into the existing provincial and national reporting systems. However, such progress is dependent on not only user adoption factors but also broader contextual dynamics [26]. Thus, by situating the E-tick in relation to both micro-level realities and macro-level policy and political economy, we aim to provide a more holistic understanding of why grassroots digital health interventions may stall or fail.

Consolidated Framework for Implementation Research (CFIR)

Implementation research seeks to understand why some implementation efforts succeed and others do not, and the role of the context [27]. To explore the key factors affecting implementation in our case study, we used the CFIR, which integrates existing theories of implementation and behavior change into a unified framework [28]. The CFIR is a meta-theoretical tool with standardized constructs to examine enablers and barriers to implementation across different stages (preimplementation, during implementation, and postimplementation) [29].

The CFIR was developed through a review of published theories and reports on factors influencing implementation [30]. Hence, its strength lies in its broad applicability and potential for generalizability, which are useful for informing practice across diverse settings. The framework has 5 broad domains (Table 1), which include: innovation domain, inner setting domain, outer setting domain, individuals domain, and the implementation process domain, which together capture multilevel determinants of implementation [31]. Due to the framework's flexibility, researchers can tailor it to specific interventions and contexts [32], and it has been widely adopted in research, applied across different research designs, and cited in over 300 published articles [29]. Recent updates have been made to the framework, using responses from authors who used the framework, leading to refined construct names and definitions to make them more encompassing [31]. In this paper, we draw on the updated CFIR to guide both our analysis and reporting of findings.

Table . Consolidated Framework for Implementation Research (CFIR) domains by Damschroder et al [28].

CFIR domains	Definition
Innovation	• The "thing" being implemented, such as a new treatment, program, or service. • Key factors that affect innovation include its source, evidence base, advantages over existing practices, adaptability, trialability, complexity, design, and cost.
Individuals	• The roles and characteristics of people involved in innovation. • Key roles include high-level leaders, mid-level leaders, opinion leaders, facilitators, and implementation teams who guide and support the innovation. • It also highlights innovation deliverers and recipients.
Inner setting	• The environment where an innovation is implemented, such as a hospital or school. • Key elements include structural characteristics like physical and IT infrastructure, work organization, and staffing levels.
Outer setting	• The broader context or setting within which an organization or project operates, such as a hospital system or school district. • Factors influencing implementation in the Outer Setting include large-scale disruptions, local attitudes, socioeconomic conditions, external partnerships, and regulatory policies.
Implementation process	• The activities and strategies to introduce and sustain an innovation. • Key components include forming teams to collaborate on tasks, assessing the needs of both innovation deliverers and recipients, and evaluating the context to identify barriers and facilitators. • Planning, tailoring strategies, engaging participants, testing small-scale changes, and reflecting on outcomes are critical steps.

Methods

This study adopted a qualitative design to explore the perceptions and experiences of external stakeholders, senior health managers, implementers, and end users of the E-tick system.

Participants and Sampling

We recruited a total of 38 participants, categorized into three groups: (1) managers and stakeholders, (2) implementation team, and (3) end users. The senior health managers and external stakeholders category included decision makers and higher-level people who were not directly involved in the system's implementation but provided insights into the context and the decisions impacting it. The implementation team comprised individuals who were responsible for initiating and deploying the system and introducing it to the users, while the end user team consisted of the clinicians and managers from 3 recipient facilities. Participants from the managers and stakeholders, as well as the implementation team, were purposively selected through referrals from key individuals and recruited via email. For end users, convenience sampling was used, with the researcher recruiting available users with the aid of gatekeepers during facility visits. Our sample intentionally included stakeholders from multiple levels of the health system to minimize elite bias, ensuring that the perspectives of senior health managers were balanced with those of frontline users and mid-level implementers. Below is a summary table of the participants in this study (Table 2).

Table . Study participants (N=38).

Category and roles	Count (n)
Senior managers and stakeholders	
National, provincial and district health managers	7
Parastatal staff	2
NGO[a] managers and staff	4
Academics	2
Private sector managers	2
Implementers	
Originators	2
IT Technician	1
Data capturers	3
End users	
Facility managers	3
Administrative officer	1
Nurses and midwives	9
Admin clerks	2

[a]NGO: Non-Governmental Organization.

Data Collection and Management

Data collection took place between November 2021 and June 2022, which was after the E-tick project had stalled. Thus, participants, particularly implementers and end users, reflected retrospectively on the system's development, piloting, and discontinuation. Due to COVID-19 health restrictions at the time, some of the interviews with senior health managers and the implementation team were conducted via web using video conferencing software. Interviews with end users were conducted in person in health care facilities during work hours and were conducted primarily in English, which is the standard working language in the facilities. However, participants were free to use local language terms or expressions, which were translated during transcription to preserve meaning.

Different semistructured interview guides were used for the 3 categories of participants. For the managers, we inquired about the broader digital health policy landscape, existing health information systems, government readiness, and feasibility for EHR implementation and the necessary next steps to advance EHR adoption in South Africa. For the implementation team and end users, the interview guides covered topics on the purpose and origins of the E-tick, its piloting rollout, experiences with implementation and daily use, training and support, perceived benefits and challenges, and overall recommendations for improvement. Interviews varied in length, ranging from 10 to 64 minutes. Shorter interviews (under 20 min) were mostly with busy frontline staff, including clerks and clinicians during clinic hours, who provided concise but relevant insights into system use. Longer interviews were with senior health managers with authority over policy alignment, resource allocation, and procurement processes, and implementers who facilitated implementation in the 3 health facilities. Despite these differences, data saturation was reached across stakeholder groups, as no new themes emerged in later interviews. All interviews were audio recorded, and recordings were stored in

XSL•FO
RenderX

a password-protected computer to ensure privacy. Audio recordings were transcribed using transcription software and checked for accuracy, and transcripts were anonymized by removing participant-identifying information.

Data Analysis

The first author led the coding, followed by regular debriefing meetings with coauthors, who are also academic supervisors, to review coding and theme development, which strengthened reliability. In this case, coauthors read all the transcripts, and discrepancies were discussed until consensus was reached. The interview transcripts were coded using NVivo qualitative analysis software (QSR International). Through this process, emergent issues were identified and used to develop the themes, following a 6-step thematic analysis process [33]. An inductive approach guided the thematic analysis, with broad topics derived from the interview guide, leading to the 4 stages of implementation reported in this study (Purpose and origins, Initial development, Piloting and expansion, and Halt). The accounts from the two originators formed the foundation, providing the background story and backbone of the implementation narrative, whose detailed recollections provided a chronological anchor for mapping implementation processes. These accounts were not taken at face value, but were supplemented by other participants' accounts, which were used to triangulate and integrate the information into a cohesive story.

After coding, the CFIR was applied to the analysis, linking the framework's 5 domains to the implementation process as reported in the study's findings (Table 3) [31]. The CFIR framework guided our analysis and reporting of findings. In this case, CFIR constructs were operationalized as sensitizing concepts to guide coding, with data excerpts being coded against relevant constructs, while leaving space for inductive subthemes to emerge. Thus, the analysis combined deductive coding (using CFIR constructs) with inductive coding to capture novel themes. Multiple coders reviewed transcripts, with regular team discussions to minimize confirmation bias.

Table . Implementation stages and applied Consolidated Framework for Implementation Research (CFIR) domains.

Stages of implementation	Description	Applied CFIR domains
Origins and purpose of the system (2015 - 2017)	Conception of E-tick[a] by system originators; designed to digitize the existing tick register and reduce errors.	• Innovation • Individuals • Inner setting • Outer setting
Initial development (2017 - 2019)	Early technical build and adaptation of the system, involving stakeholder input and limited resource mobilization.	• Individuals • Inner setting • Outer setting • Implementation process
Piloting (2019 - 2020)	Deployment of E-tick system in 3 health facilities.	• Individuals • Inner setting • Implementation process
Halt (2021)	Expansion beyond pilot sites stalled due to barriers to scale up and institutionalization.	• Inner setting • Outer setting

[a]E-tick: electronic tick register.

Ethical Considerations

Ethics approval for this study was granted by the University of the Witwatersrand Medical Human Research Ethics Committee (M210213). Additional permissions were obtained from the Ekurhuleni district research committee and the Gauteng Provincial Department of Health (GP_202106_035). The study was conducted in accordance with local, institutional, and national regulations governing research involving human participants, as well as the principles of the Declaration of Helsinki. All participants provided written informed consent prior to participation. The study purpose, procedures, potential risks, benefits, and participants' rights, including the right to withdraw at any time without penalty, were explained before consent was obtained. Participant privacy and confidentiality were maintained as interviews were conducted in private settings, and no identifying information was included in transcripts. All data were anonymized, securely stored on password-protected devices, and were only accessible to the research team. Participants did not receive any compensation for their participation.

Results

Overview

This section presents the findings, which are ordered according to the domains of the CFIR: innovation, inner setting, individual characteristics, implementation process, and outer setting. This structure allows us to highlight how factors at multiple levels and stages of implementation shaped the processes, outcomes, and ultimately the stalling of the E-tick system. To illustrate the distribution of themes across the framework, Multimedia Appendix 1 provides a summary of implementation stages, CFIR domains and applicable constructs, thematic findings, and illustrative quotes.

Origins and Purpose of the E-Tick: Innovation and Individuals Domains (2015-2017)

Identifying the Problem

The development and implementation of the E-tick was initiated and led by a senior district manager and supported by a senior technician who was employed by the funder, labeled as Originators 1 and 2. The senior manager explained the rationale behind the project:

> *Annually, the National Department of Health audits our data for accuracy, and we've always had poor audit reports. The biggest problem was the quality of the data. That's why we started the E-tick, to improve the data quality.* [Originator 1]

The source of poor data quality was traced back to the tick register: "The data was very poorly filled into the tick register, the services provided not counted properly." (Originator 1). This was the stage where most errors occurred: "The data issues started in the consultation room, and then the counting and the transferring of the data into the DHIS accounted for about eighty percent of the mistakes." (Originator 1). Some clinicians echoed these remarks as one shared: "The purpose was to reduce workload and be able to say, reduce patients' waiting time by doing away with pen and paper and to be able to keep our records digitally, which makes it easier to keep them." (Nurse 12 – AR).

The second originator further describes how decision makers often overlook the importance of effective data collection processes:

> *The problem in South Africa is that the people who decide where the funding goes don't take data management records management seriously. They want this wealth of data so they put in these big paper registers, but they don't look at the process it takes to get that data.* [Originator 2]

This includes having too many registers:

> *We had twenty-seven different registers, like the antenatal register for a mother and child, and a chronic disease register for HIV. The problem was that while completing all the registers, users were creating their own registers because some information was missing.* [Originator 1]

Nurses similarly described the burden, with one stating:

> *So with the E-tick it was one less writing system… our patients were registered, all the follow up visits are registered, and… it gave a clear history of the patient.* [Nurse 13 – MM]

Finding the Solution

Against this backdrop, the idea of the E-tick began with an invitation to a staff development project to discuss potential solutions to data quality problems:

> *We received an invitation because we already recognized a problem with data quality in our tick registers. They proposed several ways to enhance the system, involving different levels of information. While some suggestions were overly complex and resembled an Electronic Health System.* [Originator 1]

Eventually, the originators decided to make use of an Excel-based E-tick system:

> *The organization that developed the District Health Information System …had an Electronic Tick Register and we thought we can use that to improve the data quality. But the system was just an excel sheet.* [Originator 1]

Thus, the originators built on the Excel-based system:

> *We decided to improve the front end, the user interface for the clients. That's how we developed the E-tick. It was basically to collect the data electronically and to be able to feed it directly into the DHIS, in a way that is easy for the nurses in the consultation rooms.*
>
> *[Originator 1]*

End users confirmed that the system was simpler and helpful. One nurse explained:

> *It was user friendly. If only we would use E-tick only… we will definitely be perfect.* [Nurse 10 – AR]

Another shared:

> *And it was also user friendly. It wasn't like I'm talking from somebody that's not very computer literate, basically… it made it very easy, accessible.* [Nurse 13 – MM]

Initial Development of E-Tick System: Inner Setting and Individual Domains (2017-2019)

Stakeholder Engagement

The first originator approached a nonprofit organization for funding to get the project off the ground: "After our experience, we approached organization X for financial assistance and shared our ideas with them, as [they were already] our long-term funding partner deeply involved in data collection" (Originator 1). After the funders agreed, this was followed by meetings with software developers for planning: "Once the funders agreed, we met with [software] developers to explore system development possibilities, discussed utilizing the HPRS as our registration system." (Originator 1). It was at this point that the second originator, who worked for the funding organization, became involved. Together, the two originators represented 2 groups of stakeholders, one with the Department of Health and all staff at recipient facilities, and the other with the funding organization and developers:

> *[Originator 1] was very good on the clinician side and I was very good on the software side. I had been working with my team [funders] for many years before we started the E-tick, and I developed many systems with them.* [Originator 2]

As an iterative process, the originators worked closely between clinicians and developers:

XSL•FO
RenderX

> *In a normal software development cycle, you scope your business requirements, hand it over to the team, and they will go develop what they think you want and then return to show it to you. We took a different approach. We were involved in the development, sitting with them every step of the way instead of waiting for weeks for changes. This worked extremely well.* [Originator 2]

Several clinicians further confirmed this engagement, with one manager explaining:

> *The first early step was that we had meetings which included facility managers, other stakeholders and our partner [funder], to explain to us what wants to be introduced, which is when we were first given the idea of the E-tick and what it's supposed to do.* [Administrative officer 19 – RK]

The originators then selected the facilities for piloting involving managers in the process: "We used random selection and cluster sampling, through a session with all operational clinic managers, who actively participated in this process." (Originator 1). A manager from one of the facilities described their involvement: "We were called to a district meeting, and this was pitched, the intention was discussed with us... So the facilities that were going to be pilots were selected." (Assistant Director 17 – RK).

System Development

After selecting the facilities for piloting, the system was taken to the recipient facilities as one clinician recalls:

> *They called us for like a mini meeting to inform us about E-tick and told us that we were one of the only clinics currently using it, and they were piloting to see if it's going to work.* [Nurse 10 – AR]

In the meetings, one of the goals was to find ways to streamline the patient consultation:

> *We focused on what made it easy for clinicians to help the patients without them waiting too long. But a bonus that came out of the system is that the system was also able to retrieve a patient's entire history.* [Originator 2]

The clinicians provided feedback:

> *The clinicians had great ideas. The first time we had the screens ready, we took it back to the clinicians and asked them if this is what they wanted, they approved it and gave suggestions for changes, which we did.* [Originator 2]

Several engagements were made with the provincial Department of Health to gain support and input on issues such as data storage:

> *When we began the pilot, we engaged the Provincial office and kept them informed about the program. A provincial manager suggested storing the data on provincial servers instead. However, they weren't prepared to proceed at that time.* [Originator 1]

To ensure this was possible later, the developers ensured the system was compliant:

> *We looked at the Departments of Health security and ICT standards, we worked with the Department of Health ICT team as well, and their data team.* [Originator 2]

However, this did not go as planned, as the data center was not ready in time:

> *The idea was to eventually transfer the system and its data to the department's data center once it was established. However, when we developed it, there was no data center for us to put it in, and we had complied with all the national standards for the developing systems.* [Originator 2]

Piloting and Expansion: Inner Setting and Implementation Process Domains (2019-2020)

Planning and Configuration

In all 3 chosen facilities, the originators conducted an infrastructural assessment before beginning the pilot:

> *We had to check that all computers were working, and that they all had network. The developers didn't want to have a local server for each clinic because it's too complicated. So they changed the system to an online system that worked with the cloud.* [Originator 1]

Some of the existing infrastructure was from the Department of Health:

> *We only had to get the computers for the Provincial clinics. So that already made life much easier. Because every clinic, every clinician had a computer, or most of them.* [Originator 1]

A technician from the health department was involved in configuring them:

> *My role was to check infrastructure, to see if it's there. But they also installed some private infrastructure because of some policies with our network which would require a lot of approvals before we can run it.* [IT Technician]

This was further supplemented by the funding to improve the infrastructure:

> *They [funders] assisted us and made sure that each room had a network cable. Sometimes there were no plugs, so they put in the plugs. They put in the routers.* [Originator 1]

The planning and configurations also informed decisions on devices that were to be used:

> *We wanted to see what the nurses and the clinicians felt more comfortable with, the tablets or the desktops. Due to a lack of space in some consultation rooms, which were too small to put a big desktop, it was easier to mount a tablet onto the wall.* [Originator 2]

Training and Learning

A comprehensive user training was provided in recipient facilities, which was tailored for specific roles:

XSL•FO
RenderX

> *There were different training categories, because the roles were different like, clerks, clinicians and so on. It was [also] not just one training, it was several; this was because the facility was working on shifts, so they had to accommodate everyone. During rollout, there was another in-service training just to remind the staff.* [Nurse 17 – RK]

Moreover, the training was supplemented by regular visits for support and monitoring:

> *Then we had regular visits from [the originator], often enough for us to deal with whatever issues we were having on the system.* [Nurse 2 – MM]

The training was simple and accommodated varying levels of skills:

> *Some people could not use computers, but it was made as basic as possible to include those that are not computer literate.* [Nurse 17 – RK]

However, some users' competency and reactions to the training were influenced by age:

> *For the young ones, it was easy for them. For the old ones, it was a problem because they wanted to understand what they were ticking as they were pressing.* [Data capturer - 1]

In response, the originators sought assistance from data capturers, acting as an immediate source of help:

> *We had person in each clinic who would be there all day long. So for the first day or two they would sit with them [older users] when they completed it, until they became comfortable with it.* [Originator 1]

Support and Feedback Channels

To supplement the training, the originators had different people involved to provide support to end users, including IT technicians:

> *We provided desktop support, we were the first line of support. My role firstly was on all applications and IT projects running within the district.* [IT Technician]

While data capturers were already involved, especially in the early stages, admin people also assisted with various tasks:

> *We also had three admin people, one for each clinic that assisted in the clinic to help people with the training, setting up the system and checking that the computers are all working.* [Originator 1]

The originators also established communication channels to receive feedback from users:

> *We had a little book for users to report issues and to add anything, and an E-tick admin person was there. I also got information from data capturers and I would also go and check on everybody and they would give me feedback. We would report back to them monthly, usually.* [Originator 1]

Perceived Benefits of System Use

End users reported several benefits of the system, with some sharing how it improved continuity of care:

> *At times you find that the client may have been seen previously but the file could not be found. But if the client's details were captured on the previous visit, you could see it in the E-tick. So it helped with continuation of care.* [Nurse 11 – AR]

For other users, such as clerks, this reduced patient waiting times:

> *It also reduced the waiting period for the patient, because the first thing that we do is to register the patient and create a folder on the E-tick system. It's easier to use than retrieving the manual files, searching the files in the cabinets. When you're using an E-tick, you just search on the system.* [Admin Clerk 8 – AR]

Facility managers also found operational benefits, such as quicker service delivery:

> *The benefits were that the patient consultation times were shortened. It was a little bit faster. That was the best advantage that I've seen from the E-tick.* [Operations Manager 18 – RK]

Some users shared that the system improved data quality and access to it:

> *It improved the reporting of data. We had very reliable, consistent, and accurate data, at all times of the day.* [Administrative officer 19 – RK]

For some, the system enabled the monitoring of the clinic's performance:

> *We are able to evaluate ourselves on the number of patients that we are seeing. When our stats are sent to the DHIS, they can see that we are really performing.* [Nurse 4 – MM]

Perceived Challenges of System Use

Users reported several challenges with using the system, including the simultaneous use of the system with the manual:

> *To be brutal, they [users] were against it at first. They did not understand why we're implementing extra work for them.* [Administrative officer 19 – RK]

For some participants, the early days before mastering the system were difficult:

> *If you're not used to it yet, it takes time to get used to anything, especially if you're overloaded with a lot of patients.* [Nurse 14 – MM]

In some cases, short staffing led nurses to do administrative work, as one nurse shared:

> *I think it was mostly shortage of staff, sometimes I had to enter a new patient into the E-tick as a nurse, which would waste time and to delay the queue. You'd end up having to turn some patients back. So it needs us to be well staffed.* [Nurse 12 – AR]

XSL•FO
RenderX

In response, the originators designated roles for receptionists, clerks, and data capturers as the first point of contact for patient registrations.

There were concerns about the hardware and infrastructure that already existed in the facilities: "The [DOH's] ICT equipment was very outdated. Some of the computers are so old and they haven't been updated." (Originator 1 – R). Some users had challenges with the network infrastructure:

> *Our network system was failing us a lot. You'd be prepared to start the day and notice that you have no network.* [Nurse 12 – AR]

In response to this challenge, a back capture function was introduced, which allowed information to be captured into the system at a later stage. In one site, hardware was frequently stolen:

> *First disadvantage was theft. I'd say more than more than 70% of the tablets disappeared. All the rooms that had extension cords, but in less than two weeks, all the rooms had no extension cords. They also stole the chargers.* [Administrative officer 19 – RK]

In one clinic, the piloting coincided with ongoing protests by nurses:

> *When we were trying to start the system, the nurses and others would be outside complaining about the conditions in the clinic [a protest organized by unions]. Most of the nurses were not working. There were other issues in the clinic. I think they saw the E-tick as another thing that was worth protesting about, because it increased their workload.* [Originator 1 – R]

Halt and Barriers to Scale Up and Institutionalization: Outer Setting Domain (2021)

Changing Developers

Despite its relative success in implementation, several complications affected the continued use and development of the system. One of the complications came when there was a change in the software development company:

> *Originally [funders] were working with [a software developing company], who were helping with developing district programs. They were taken over by [another company] so the people that worked on our system were taken off the project, and a new team took over the development.* [Originator 1 – R]

This affected further developments:

> *We needed to update the system to make sure it's fine. Then it got stuck in that development phase because of the new developers that we have.* [Originator 1 – R]

Some of the previous work was undone by the new developers:

> *There were a lot of upgrades to the system, such as integration with the DHIS. But they removed some of the functionalities that were working well in the process. We were never happy with the final products that we got from them.* [Originator 1 – R]

Funding Cuts

The change of developers brought higher costs:

> *They [funders] agreed to pay for the additional development, but the new developers came with a lot of red tape and were quite expensive. The funding got cut and they could only give us a small amount to continue with the development.* [Originator 1 – R]

Moreover, the funders were eventually withdrawn from operating in the health district:

> *They [funders] moved out of the district, because their funding got canceled completely. So what's happening with their funding will affect our funding.* [Originator 1 – R]

This had an impact on keeping the system operational:

> *So because it's not open source, it was built on the Microsoft platform and the cost to keep it running is high. It's also web based so no offline capability, and we need constantly running servers.* [Originator 2 – T]

Thus, the system needed new funders:

> *We're looking for partners to fund the service, license costs and the implementation in facilities. To date, we haven't found anyone, so it's been put to sleep.* [Originator 2 – T]

Provincial and District Support

The originators had buy-in from district officials, who were in support of the system:

> *I had meetings with my chief director, and my director, and they are still very keen. The clinics are still very keen… So the buy-in is there, even after two to three years, but the funding is not there.* [Originator 1 – R]

However, the provincial health office's priority was to develop a new system, as the department technician explained:

> *Currently the department is rolling out an HIS platform where all other applications will be layered under and integrated into.* [IT Technician]

He further explained how locally developed systems were not as prioritized:

> *There were some contrasting and opposing views. The system was started from scratch but the department in most cases doesn't want that. They want to go on the market and buy something on the shelf. I don't think approvals were going to be granted.* [IT Technician]

The participant further mentions how the IT staff are often not seen as essential to the role of delivering care:

> *Sometimes different services compete for resources. They will say it's essential when it's a clinic, a doctor*

XSL•FO
RenderX

> *or medication, and then we [IT personnel] come last.* [IT Technician]

The originators also expressed their frustration with navigating such terrain:

> *So this is where we are stuck now. I think what is important to me is how difficult it is to roll out a system within the Department of Health, in the politics, the corruption and the agendas of people. It makes the story very complicated because we developed it the bottom up, seeing the need, with the buy-in from the district, and from all the role players.* [Originator 1 – R]

Broader Context (Outer Setting Domain)

Senior managers and external stakeholders shared insights into the Department of Health's challenges in implementing EHRs in South Africa. One manager notes how implementation requires a joint and collaborative effort of various stakeholders:

> *I think it's a complex sociotechnical project to do which requires many different role players and expertise and costs, which needs high level support from the National Department of Health which has been lacking.* [NPO manager]

The provincial health departments hold most of the decision-making power in digital health spending:

> *The national office can come up with guidelines and frameworks and ask for reports but the actual spending on health information systems is done at provincial.* [NPO manager]

In this case, the provincial health department had decided to prioritize an off-the-shelf system:

> *There is a provincial initiative and anything new that comes in has to talk to this one, there should be interoperability…I saw it [E-tick], it works. I tried to support it but we didn't get provincial support from the CIO.* [Provincial manager]

However, NGOs have been supporting and implementing local efforts to build systems (such as E-tick) in health care facilities:

> *NGOs are doing better than the districts and the provincial health in terms of implementing efficient systems. Most efficient systems are systems that have been introduced by NGO's instead of our provincial department.* [Provincial IT technician]

Some participants raised a concern over political appointments in key decision-making positions:

> *I don't believe that we have the right people in government with the right industry experience. They are just given the title and suddenly, they now have to make decisions. I think it's very wrong and it sets them up for failure.* [NGO Technician]

A health department technician added:

> *Most of our activities are driven by politicians while our head of department has his own strategies. We get our mandate from politicians.* [DoH Technician]

As a result, some decisions are made with bias:

> *There are bureaucratic officials in Department of Health national, provincial and local. If they do not like you and your project, they will say you have to go through SETA [a parastatal] which is extraordinarily slow, not particularly technically competent, and staggeringly expensive.* [NPO manager]

Moreover, one academic shared their experience with the Department of Health's reluctance:

> *I think there's not sufficient trust on the part of Government certainly in my experience. They are not coming to partner with us. In fact, they're pushing us away. We only get close when we work with NGO's and so on. The Government definitely keeps us at arms-length.* [Health Academic]

Corruption and inefficiencies have also created barriers, with the tender system being one of the issues:

> *It [corruption] is part of the tender system in South Africa, unfortunately the tender system is open to abuse.* [Provincial health manager - IT]

Moreover, past corruption scandals have tainted the reputation of the Department of Health:

> *The perception is that you can't trust the National Department any longer to do anything. No one is going to give the National Department a big pot of money to run a tender until it can show that it's got systems and people in place who can do it without squandering the money.* [National health manager]

This mistrust has also led to a reluctance to work within the department:

> *Now people are reluctant to work for the department for several reasons. They fear being embroiled in controversy and putting their personal integrity at stake.* [National health manager]

Discussions

Principal Findings

The E-tick system, an innovation, was developed to address the issue of poor data quality stemming from errors in data collection, which were common with the use of paper-based registers. The implementation process involved an iterative co-design process with input from all involved individuals, including end users and stakeholders, to ensure users' needs were met and to streamline the data entry process while supporting scalability and integration with other systems. Despite the system's successful piloting and user adoption in the inner setting, the outer setting posed challenges in funding, change of developers, and lack of support from the provincial health government, leading to the implementation stalling. Using the CFIR, we explored the interaction of different elements, actors, and stakeholders and how they facilitated or impeded implementation. As such, we organize this discussion using CFIR domains, highlighting both facilitators and barriers.

RenderX

Innovation

Poor data quality is a problem that commonly affects routine monitoring of health outcomes [34]. The E-tick system had a clear relative advantage over paper-based registers to improve data quality and reporting, as errors that frequently compromised data quality and routine reporting were minimized, and users perceived the system as more streamlined than paper-based manual registers. At a national scale, this aligns with South Africa's policies that promote the digitization of record keeping and the establishment of a national EHR [10,35], a crucial component for strategic purchasing and health monitoring. The E-tick's co-design process enhanced usability and fostered buy-in, which is critical in adoption [36], yet innovation alone was insufficient to ensure sustainability.

Individuals

At the level of individuals, the originators showed strong commitment by providing vision, technical expertise, and persistence in driving the implementation of the E-tick system. Leadership practices are known to impact staff motivation, especially when they take a participatory approach [37,38]. Their leadership was instrumental in mobilizing resources, persuading managers and funders to support the system's adoption, acting as champions along with data capturers. Research shows how champions are crucial in promoting technology adoption through building enthusiasm and providing peer support [39]. End users also improved confidence in using the system as a result, especially after undergoing training, which sustained motivation during the pilot. However, while the successful adoption of the E-tick was due to the contribution of many actors, including external stakeholders, individuals in the inner setting were more affected by decisions in the outer setting. This reflects a broader challenge in digital health implementation in South Africa, that for locally developed systems to succeed, appropriate actors must be in place to provide leadership, vision, and sustained support, within an enabling environment that fosters continuity and long-term success [37,40].

Inner Setting

Within the inner setting, several facilitators supported early implementation, such as the co-design process and extensive user training. The originators successfully engaged a wide range of stakeholders, including senior managers and funders, which was pivotal in overcoming initial financial and political barriers. Involving end users was also crucial in enhancing the system's usability and promoting buy-in, an important aspect when ensuring effective user adoption [41,42]. Moreover, users' recognition of the system's value in improving data quality reinforced their motivation to adopt the system. Studies in other low- to middle-income countries show that organizational commitment is a critical success factor to sustain user motivation during piloting phases [43]. However, the sustained use of the E-tick required stable infrastructure, which often posed challenges for many users in the form of interrupted internet connectivity and power cuts. This mirrors challenges reported in other LMICs, where infrastructural fragilities, such as poor internet connectivity and unstable power supply, are common challenges to EHR adoption [44]. Moreover, without dedicated budgets to overcome these challenges, such as the use of mobile internet devices and backup power solutions, this creates uncertainty about sustained use.

Implementation Process

The implementation process revealed a mix of strengths and gaps, which were closely linked to the role of individuals and the inner setting. A key strength was the iterative co-design approach, which ensured that the system was not only technically functional but also responsive to user needs and compatible with existing workflows. Participatory design and user engagement are widely recognized in implementation science as best practice, as they enhance user ownership, adaptability, and long-term adoption, especially as most implementation efforts fail due to user resistance [45,46]. Thus, involving both clinicians and managers at early stages of the implementation process helped to align the E-tick system with user realities, reducing resistance to change. However, this process was undermined by a lack of a long-term financing mechanism and failed provincial support, despite the demonstrated proof of concept at the pilot phase. Therefore, while the implementation process was well executed, the system lacked the institutional anchoring and support for long-term use, a critical success factor of digital health efforts [47].

Outer Setting

We found that the most significant challenges were encountered in the outer setting, particularly the withdrawal of financial support, the change of developers, and the lack of support from the provincial health government due to its lack of capacity. Studies show that one of the main challenges to the initiation of digital health initiatives, including EHRs in South Africa, has been the poor governance and lack of political will [48,49]. For instance, the appointment of people without the required skills and competence has led to a chain of events that affect institutions such as the Gauteng provincial health department [50]. As a result, corruption has eroded the public's trust in the government. These issues are not isolated but rather reflective of the entrenched political economy dynamics that routinely affect digital health innovations in South Africa. Political appointments, who are put in place because they are easily manipulated, often make decisions driven by political interests rather than professional judgment, leading to the political control of government institutions and their spending [51]. As such, patronage networks often produce politically aligned rather than skilled appointments. This leaves room for corruption, irregular spending, fraud, and poor oversight to mitigate them, with procurement processes being vulnerable to perverse incentives, with contracts awarded to less qualified but politically connected vendors. Although efforts have been made to uncover large-scale corruption in South Africa, the necessary mechanisms have not yet been put in place to deal with the challenges [52,53]. Perverse incentives undermine sustainability as officials face pressure to launch new initiatives instead of sustaining existing ones to ensure full expenditure of budgets.

The administrative fragmentation can be seen as a product of South Africa's federal system, which means provinces can develop their own health information systems (bottom-up) or acquire them through separate procurement processes

XSL•FO
RenderX

(top-down) [8]. In this case, despite the provincial government's preference for a top-down approach by opting for an off-the-shelf system over the E-tick, they were unable to implement the former. High-income countries such as the United Kingdom, the United States, and Australia have taken top-down, bottom-up, and middle-out approaches, respectively, with varying outcomes [54]. Bottom-up approaches often build on existing systems, such as the E-tick, using interoperability standards to integrate them across facilities. In contrast, top-down approaches replace local systems with a centralized EHR, but this can be too complex, limiting flexibility and local adaptability, as in the case of the United Kingdom [55]. Therefore, our analysis shows that a single centralized model is not necessarily more effective, as lessons from these experiences, including Australia, suggest that a middle-out approach is more effective, as this blends both by offering central guidance while allowing for local systems to gradually align with national plans [56].

Implementing EHRs requires significant investment, vision, robust management systems, and strong oversight to sustain them, making effective leadership essential for success. Strong leadership plays an important role in guiding decision making, mobilizing the right expertise, and establishing mechanisms to prevent corruption, which increases the likelihood of successful implementation, particularly for large-scale EHRs [57]. Middle-income countries like South Africa and China have the capacity to finance and support EHR adoption, but such efforts can be undermined by corruption and poor governance [49,58]. In some cases, poor leadership and governance stand as significant barriers to achieving universal health coverage and strengthening health systems [59].

Implications for Policy and Practice

Our findings highlight several implications for policy and practice. One of them is the strengthening of accountability in health systems through transparent procurement systems and independent oversight to neutralize the effects of corruption and political patronage. In such cases, procurement frameworks could include pilot-to-scale pathways, where bottom-up innovations such as the E-tick could be formally assessed against national priorities and considered for integration with provincial and national systems. These steps could create a more enabling environment for similar innovations to scale sustainably. Moreover, while the E-tick system was locally hosted, it also incorporated cloud functionality, aligning with the cloud-based EHR architectures promoted in both the NDHS and the national data and cloud policy of South Africa [10,60]. Such policies can be leveraged to mitigate barriers such as reliance on facility servers or hardware failures, challenges already observed with the E-tick, which hold important lessons for similar middle-income country contexts.

Our findings also carry implications for digital health equity, a concept that examines how structural inequities shape the successes and challenges of digital health interventions [61]. In South Africa's dual health system, where private-sector facilities often have better infrastructure and resources than the public sector, grassroots innovations like E-tick are left to face compounded challenges, especially when implemented in low-resource contexts [62]. The stalled scale-up reflects not only outer system or structural barriers by the government but also the broader inequities in digital infrastructure, institutional support, and resourcing across the country's health system [63].

Limitations

Our study incorporates perspectives from a diverse range of stakeholders, including higher-level managers, decision makers, academics, and end users from recipient facilities. This diversity helped in capturing nuanced perspectives from different positions within the system and in closing information gaps through triangulation. A limitation of our study is that data collection from the implementation team, especially clinicians, occurred over a year after the system had halted. As a result, some participants struggled to accurately recall past events, while others had moved to different jobs by the time of data collection. As a result, formal member checking with participants was not possible due to staff turnover and the discontinuation of the E-tick project. However, we validated emerging findings through iterative review with coauthors who included experts in South African health systems and originators who led the implementation from the beginning and had contextual expertise.

Conclusions

In conclusion, the E-tick system is a valuable innovation that was developed from the ground up with user input. While the system showed promise, its long-term sustainability was undermined by external factors such as funding cuts and poor support, political appointments, and corruption, which led to the unwillingness of provincial officials to support local initiatives such as the E-tick. Such bureaucratic inefficiencies also affected the capacity to move forward with another system. This study demonstrates that without alignment to broader factors such as governance, corruption, and skilled leadership, innovative systems such as the E-tick will struggle to be implemented.

Acknowledgments

We would like to thank the study participants for generously sharing their time and experiences. We also acknowledge the support of the implementation team and the provincial and district health authorities for facilitating access to study sites.

Abstract

Background: When used correctly, electronic medical records (EMRs) can support clinical decision-making, provide information for research, facilitate coordination of care, reduce medical errors, and generate patient health summaries. Studies have reported large differences in the quality of EMR data.

Objective: Our study aimed to develop an evidence-based set of electronically extractable quality indicators (QIs) approved by expert consensus to assess the good use of EMRs by general practitioners (GPs) from a medical perspective.

Methods: The RAND-modified Delphi method was used in this study. The TRIP and MEDLINE databases were searched, and a selection of recommendations was filtered using the specific, measurable, assignable, realistic, and time-bound principles. The panel comprised 12 GPs and 6 EMR developers. The selected recommendations were transformed into QIs as percentages.

Results: A combined list of 20 indicators and 30 recommendations was created from 9 guidelines and 4 review articles. After the consensus round, 20 (100%) indicators and 20 (67%) recommendations were approved by the panel. All 20 recommendations were transformed into QIs. Most (16, 40%) QIs evaluated the completeness and adequacy of the problem list.

Conclusions: This study provided a set of 40 EMR-extractable QIs for the correct use of EMRs in primary care. These QIs can be used to map the completeness of EMRs by setting up an audit and feedback system, and to develop specific (computer-based) training for GPs.

KEYWORDS

electronic medical records; primary care; quality assessment; Delphi method; electronic audit and feedback

Introduction

With the advancement of digital technologies, electronic medical records (EMRs) have become the preferred method for recording, storing, and retrieving medical information [1]. The National Alliance for Health Information Technology defined the EMR as “an electronic record of health-related information on an individual that can be created, gathered, managed and consulted by authorised clinicians and staff within one health care organisation” [2,3]. Several studies have shown that the correct use of EMRs may improve the quality and efficiency of care and reduce mortality [4-6]. When used correctly, EMRs can support clinical decision-making (eg, monitoring medication safety) [7-9], facilitate care coordination, reduce medical errors,

XSL•FO
RenderX

and provide information for research [1,10]. EMR data can also be used to generate patient health summaries (PHSs). The PHS is a minimum set of clinically relevant data that can be transferred to other health care workers to support the continuity of care and deliver safe and high-quality care to patients [11,12].

Unfortunately, an observational analysis conducted by the Vlaams Agentschap Zorg en Gezondheid, based on approximately 2000 general practitioners' (GPs) consultations during weekends and holidays in Belgium between 2019 and 2020, revealed that only 32% of patients had a PHS. Several studies have shown that the amount of encoded data registered in EMRs is low (eg, the completeness of height and weight is <76%) [13-16]. Hamade et al [17] suggested that targeting EMR data quality or the use of EMR functions may significantly improve EMR use.

However, there remains a gap in knowledge regarding how to improve the correct use of EMRs [17]. Recently, Ngugi et al [18] developed and validated a set of indicators for the use of EMRs, focusing on the implementation of the EMR, in low- and middle-income countries. There are some guidelines on the good use of EMRs, but none are up to date [19,20]. Appropriate EMR training programs for health care workers and students can improve the use of EMRs; however, an exhaustive list of learning points is lacking [2,21]. Electronic audit and feedback (eA&F) can also be used to improve the correct use of the EMR and, more particularly, the quality of the data stored in the EMR [22]. Ivers et al [23] defined eA&F as "an electronic summary of the clinical performance of health care over a specified period of time aimed at providing information to health professionals to allow them to assess and adjust their performance." To this end, a validated set of quality indicators (QIs) is used. QIs are measurable items that refer to the structures, processes, and outcomes of care [24]. An evidence-based list of QIs, approved by expert consensus, could help develop appropriate training programs and eA&F interventions to improve EMR use [17,25,26]. This study aimed to develop an evidence-based set of electronically extractable QIs approved by expert consensus to assess the good use of EMRs by GPs from a medical perspective.

Methods

Study Design

The RAND-modified Delphi method was used to develop QIs for the use of EMRs from January 2024 to December 2024 based on the method used by Van den Bulck et al [27-29]. The process included the following: (1) development of a questionnaire based on recommendations and existing QIs from evidence-based guidelines and (2) rating procedure by an expert panel in 3 rounds, namely individual written questionnaire, online consensus meeting, and final appraisal.

Selection of Recommendations and Existing QIs

The TRIP database and MEDLINE were searched for guidelines and indicator sets using the following search terms: "Electronic medical records" AND ("Primary Health Care" OR "Primary Care" OR "General Practice") AND ("Standard of Care" OR "guideline" OR "recommendation" OR "quality indicator" OR "quality of health care" OR "quality of care"). The search was also extended to Google Scholar (accessed on April 2, 2024). The sources were selected by the primary researcher using the criteria specified in Textbox 1. Sources were not filtered based on the quality of the methodology because of the limited methodological information in any of the sources found in the first search. An exhaustive list of all indicators and recommendations relevant to EMR quality was compiled. For inclusion, indicators and recommendations were filtered using the specific, measurable, acceptable, realistic, and time-bound (SMART) principle [27-29]. A QI is defined by Grypdonck et al as "a measurable tool to assess the quality of care, including outcome-, process- and patient-oriented indicators" [30]. For recommendations, the following definition provided by the World Health Organization was used: "Recommendations are statements designed to help end-users make informed decisions on whether, when and how to undertake specific actions such as clinical interventions, diagnostic tests or public health measures, to achieve the best possible individual or collective health outcomes" [31]. Screening was performed by 2 independent researchers: a GP (primary researcher) and a methodologist. If there was a difference in the results for an indicator or recommendation between the 2 researchers, they discussed it until a consensus was reached. All remaining items (indicators and recommendations) were then categorized into topics according to the organization of the PHS in Belgium as explained by Domus Medica [19], and comparable with categories defined by Jabaaij et al [13] in the EMR scan for general practitioners: completeness and adequacy of the problem list, encoded registration in the EMR, completeness and actuality of medication list, risk factors and drug monitoring, patient identification and contact information, vaccination status, and patients' choices.

Textbox 1. Selection criteria used to filter articles in the literature.

Inclusion criteria

- Language: English, Dutch, or French
- Evaluation level: microlevel (evaluation at the patient level)
- Source age: indicator sets—any age; recommendations—maximum 10 years
- Target population: primary care providers

Exclusion criteria

- Language: other than English, Dutch, or French
- Evaluation level: mesolevel or macrolevel (regional, national, or other)
- Source age: recommendations published more than 10 years ago
- Target population: hospital physicians

Panel Selection

GPs and EMR developers were invited to participate in the panel via email. Using a purposive sampling technique, priority was given to representing all involved parties at the regional (Flanders, Wallonia, and Brussels) and occupational levels (solo GPs, GPs in group practices, programmers, and academic personnel). The final panel consisted of 18 participants: 11 (61%) Flemish-speaking participants and 7 (39%) French-speaking participants. There were 12 GPs (recently retired: n=1, 6%; worked in a community health center: n=1, 6%; had an individual practice: n=2, 11%; and worked in a group practice: n=8, 44%) and 6 (33%) EMR developers from different EMRs. They were provided with information about the aims and methodology of this study.

Written Questionnaire Round

Completion

An online LimeSurvey questionnaire was presented to a multidisciplinary expert panel (from August 2024 to November 2024) [32]. Each participant was asked to score each item for their capability to measure the quality of EMR use in primary care on a 9-point Likert scale (1=lowest score; 9=highest score). They were asked to base their assessment on the extractability of the indicator or recommendation from the EMR and its possible positive impact on the quality of care. Panel members could also label an item as “not assessable.” At the end of each topic, they were asked to give the top 5 (prioritization) of the items. If a topic did not contain enough items to create the top 5, participants were asked to order half of the indicators in the top X. Finally, all participants could write remarks and add new indicators.

Analysis

The results of the online survey were analyzed using a Node.js (OpenJS Foundation) script to subdivide each item into 3 categories: high, uncertain, or low potential as a QI [33]. The script generated a report for each participant with their responses, a general overview of the calculated parameters (Table 1), and a category based on these parameters (Table 2).

Table 1. Defined parameters to score each quality indicator and recommendation [28].

Parameter	Calculation
Total number of responses	N responses
Likert score	
For each score, the total number of responses	N responses for score
Median Likert score	Median Likert score of all responses
Highest ratings (%)	N responses with a score ≥7 divided by the total number of responses
Prioritization (top %)	Sum of the individual top X scores (eg, first place=score 3, second place=score 2, third place=score 1, and items not ranked in the top 3=score 0) divided by the maximum possible score (N responses × highest possible top score)

XSL•FO
RenderX

Table 2. Selection criteria for indicators and recommendations [28].

Criterion	Selection[a]	Discussion[a]	No selection[a]
Likert score: median	≥7	Any	Any
Likert score: distribution	≥70% with score ≥7	≥30% with score <3	Other
Prioritization (top %)	≥20%	≥1%	<1%

[a]Indicators and recommendations must fulfill all criteria, not only some, to be categorized as either "selection," "discussion," or "no selection."

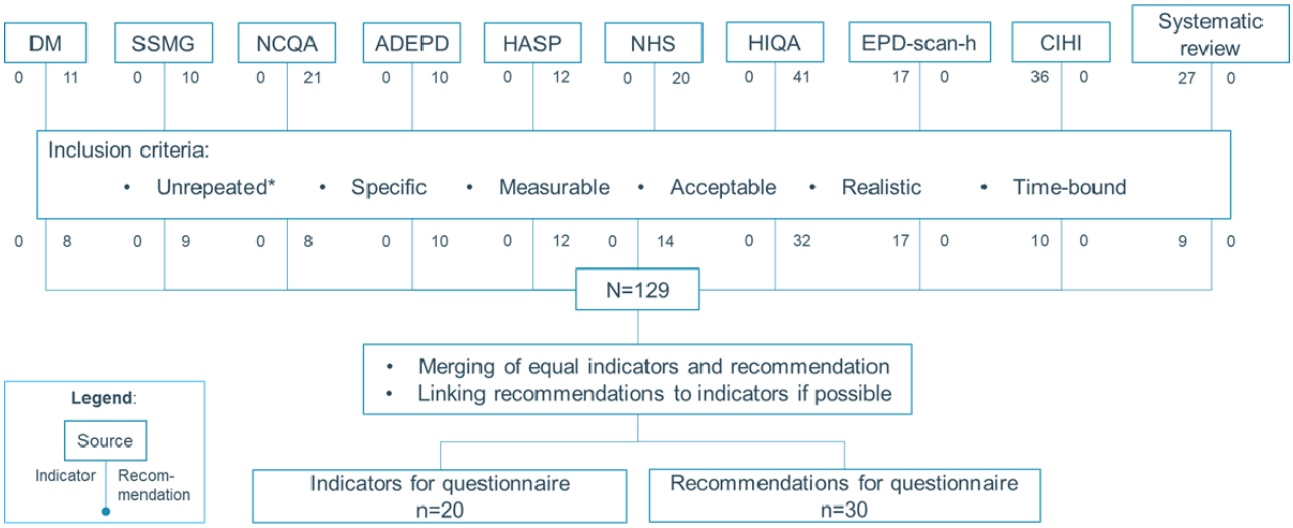
Consensus Meeting Round

Each panel member received an individual feedback report 2 weeks before the consensus meeting. It also included new recommendations and comments. The report contained all items with a color code representing their potential to reach a consensus (Multimedia Appendix 1).

An online consensus meeting was held using Microsoft Teams [34]. To improve the efficiency of the consensus meeting, focus was given to the items categorized as "uncertain," together with the newly added indicators proposed by the panelists. Items with high potential were automatically selected for the final selection unless panel members requested a decision-making discussion. Items with low potential were excluded from the final selection unless the panel members requested deliberation.

All accepted indicators and recommendations were adjusted to the conclusions of the consensus meeting and conformed to the SMART criteria [27-29]. The recommendations were transformed into QIs as percentages. The final report was sent to the panel members for final acceptance in Dutch and French. The final indicator set was translated into English by the researchers.

Ethical Considerations



This study was approved on June 25, 2024, by the Social and Societal Ethics Committee of KU Leuven (G-2024-8020-R2(AMD)). The project was also vetted and approved by KU Leuven's Privacy and Ethics platform in view of the principles and obligations laid down in the General Data Protection Regulation of the European Parliament and the Council of 27 April 2016 [35]. Participants were asked to digitally sign an informed consent form before participation. All data were pseudonymized after the written questionnaire round using a unique identifier. Personal information was separated from other research data in a second file with password protection. The personal data was used to provide the participants the feedback report, to invite them for the consensus meeting round, and to approve the final report. All personal information was deleted after the study was finished. No compensation was provided to the participants.

Results

Extraction of QI and Recommendations

A total of 4 review articles listed QIs for the use of EMRs, containing 27 QIs [13,15,36-38]. Nine guidelines contained 53 QIs and 125 recommendations [11,19,20,39-42]. Where possible, duplicate items were removed, and indicators were linked to similar recommendations in the guidelines. This resulted in a combined list of 20 QIs and 30 recommendations (Figure 1 [11,13,15,19,20,36-42]; Multimedia Appendices 2-4).

Figure 1. Overview of the recommendation and indicator extraction. *Unique: repetitive recommendations were removed. ADEPD: NHG-Richtlijn Adequate dossiervorming met het elektronisch patiëntdossier; CIHI: Canadian Institute for Health Information; DM: Domus Medica; HASP: NHG Richtlijn Informatie-uitwisseling tussen huisarts en medisch specialist; HIQA: Health Information and Quality Authority; NCQA: National Committee for Quality Assurance; NHS: National Health Service; SSMG: Société Scientifique de Médecine Générale [11,14,16,20,21,38-44].

XSL•FO
RenderX

Questionnaire Round

All panel members (18/18, 100%) completed the questionnaire. On the basis of these categories, out of 50 items, 21 (42%) were selected, 27 (54%) required further discussion, and 2 (4%) were excluded.

Consensus Round

Of the 18 panel members, 13 (72%) were present for the consensus meeting—9 (50%) GPs and 4 (22%) EMR developers—8 (44%) of whom were Flemish speaking and 5 (28%) French speaking. In the panel round, none of the preselected indicators (n=7) or recommendations (n=14) were discarded. Of the 10 indicators labeled as "discussion," 7 (70%) were selected, and 1 (10%) indicator was further divided into 7 specific indicators (Multimedia Appendix 1; indicator 3). Of the 17 recommendations labeled as "discussion," 6 (35%) were selected. This resulted in a list of 20 indicators and 20 recommendations (Multimedia Appendix 1). During the consensus meeting, some items that were not yet extractable were included because the panel members felt that their clinical importance should prompt EMR providers to adapt their software.

Final Evaluation

The 20 recommendations were transformed into QIs and added to the 20 other QIs, resulting in 16 (40%) QIs regarding the completeness and adequacy of the problem list, 4 (10%) QIs regarding encoded registration in the EMR, 3 (8%) QIs regarding the completeness and actuality of the medication list, 6 (15%) QIs regarding risk factors and drug monitoring, 4 (10%) QIs regarding patient identification and contact information, 3 (8%) QIs regarding vaccination status, and 4 (10%) QIs regarding patient choices (Textbox 2; Multimedia Appendix 5). All panel members present in the consensus meeting (13/13, 100%) approved the final report.

XSL•FO
RenderX

Textbox 2. Quality indicators for the good use of electronic medical records (EMRs) in primary care.

Topic 1: completeness and adequacy of the problem list

1.1 The mean of active problem items listed on a patient's problem list

1.2 Percentage of items on the problem list that are linked to an encoded diagnosis

1.3 Percentage of patients with medication for thyroid disease in their medication list with an encoded diagnosis of thyroid disease on the problem list

1.4 Percentage of patients with medication for epilepsy in their medication list with an encoded diagnosis of epilepsy on the problem list

1.5 Percentage of patients with medication for Parkinson disease in their medication list with an encoded diagnosis of Parkinson disease on the problem list

1.6 Percentage of patients with medication for depression in their medication list with an encoded diagnosis of depression on the problem list

1.7 Percentage of patients with medication for cardiovascular disease in their medication list with an encoded diagnosis of cardiovascular disease on the problem list

1.8 Percentage of patients with medication for asthma or chronic obstructive pulmonary disease in their medication list with an encoded diagnosis of asthma or chronic obstructive pulmonary disease on the problem list

1.9 Percentage of patients with medication for diabetes in their medication list with an encoded diagnosis of diabetes on the problem list

1.10 Percentage of encoded items in the problem list with an additional description or comment

1.11 Percentage of encoded items in the problem list for which the estimated or actual date of onset has been registered

1.12 Percentage of inactive items on the problem list for which the estimated or actual date the condition was resolved has been registered

1.13 Percentage of surgeries and other procedures that have been registered as an encoded item

1.14 Percentage of surgeries and other procedures in the patient history that have been linked to the related episode of care

1.15 Percentage of surgeries and other procedures in the patient's history with an additional description or comment

1.16 Percentage of surgeries and other procedures in the patient summary for which the date and/or time on which the procedure was or is intended to be performed is registered

Topic 2: encoded registration in the EMR

2.1 The mean number of subcontacts created per contact during the observation period

2.2 Percentage of subcontacts during the observation period connected with an episode of care

2.3 Percentage of subcontacts (registered as consultation, home visit, or teleconsultation) with a subjective, objective, evaluation, and planning item

2.4 The number of patients with a global medical record in the practice with changes in the status of tasks (procedures or actions) over the total number of patients with a global medical record in the practice

Topic 3: completeness and actuality of the medication list

3.1 Percentage of medications on the medication list labeled as *active* that are no longer active

3.2 Percentage of active medications on the medication list that are linked to a health condition on the problem list

3.3 Percentage of active medications on the medication list for which the dosage and treatment regimen are complete

Topic 4: risk factors and drug monitoring

4.1 Percentage of patients with at least 1 registration for a drug allergy or intolerance

4.2 Percentage of patients with a registration for a risk factor; risk factors include clinical information that is imperative to know so that the life or health of the patient is not threatened, for example, prophylaxis for adrenal crisis (Addison disease), endocarditis, bleeding disorders, endoprosthesis, patients who are immunocompromised, (functional) asplenia, thrombosis, or particularly resistant microorganisms

4.3 Percentage of patients with at least 1 encoded registration for a physical examination (weight, height, blood pressure, and pulse)

4.4 Percentage of patients with at least 1 registration of an item for social history

4.5 Percentage of patients aged 12 years and older for whom there is at least 1 notation concerning the use of cigarettes, alcohol, and substances

4.6 Percentage of patients with at least 1 registration of an item for family medical history

Topic 5: patient identification and contact information

5.1 Percentage of patients with a registration for hospital preference

5.2 Percentage of patients with at least 1 registration of contact information for a contact person, caregiver, or person designated as representative

5.3 Percentage of patients with at least 1 registration of a health care professional in their care team

XSL•FO
RenderX

5.4 Percentage of patients with at least 1 registration for address, email, employer, home and work phone, marital status, registration status on patient platform (eg, Helena [43]), or cohousing people and animals

Topic 6: vaccination status

6.1 Percentage of patients aged 7 years and older who have a registration for all the recommended primary childhood vaccines

6.2 Percentage of patients aged 65 years and older who have a registration for a yearly influenza vaccine

6.3 Percentage of vaccinations for which the date the vaccination was administered is registered

Topic 7: patient choices

7.1 Percentage of patients with a registration of treatment preferences: euthanasia request or refusal for intubation, resuscitation, organ donation, vaccination, or blood transfusion

7.2 Percentage of patients with at least 1 contact with a subjective, objective, evaluation, or planning item linked to an encoded diagnosis regarding treatment preferences or end-of-life care

7.3 Percentage of patients with at least 1 registration of a goal for personalized care (goal-oriented care)

7.4 Percentage of patients with at least 1 registration regarding preferences for preventive health care

Discussion

Principal Findings and Comparison With Prior Work

This study used the RAND-modified Delphi method to validate a set of 40 QIs for the correct use of EMRs by GPs based on the indicators and recommendations found in the literature. These indicators are (potentially) EMR extractable and evaluate key aspects of EMR use by GPs: completeness and adequacy of the problem list, encoded registration, completeness and actuality of the medication list, risk factors and drug monitoring, patient identification and contact information, vaccination status, and patient choices. Using the SMART principle, we ensured that the QIs could be evaluated in clinical practice [27-29,44-46].

Previously, Jabaaij et al [38] developed the EMR scan for general practitioners in the Netherlands to evaluate EMR use. However, the method they used to define QIs was unclear. Ngugi et al [18] developed and validated a set of indicators for the use of EMRs in low- and middle-income countries. Their QIs mostly evaluated the general use of the EMRs (eg, indicator 7, “% of required data elements contained in EHRs”). Our study focuses on how data are registered and encoded in EMRs, focusing on which data are registered [18]. Other indicator sets were either outdated (aged >20 years) [36], focused on clinical performance instead of use of the EMR [15], or evaluated EMR use on the mesolevel or macrolevel instead of the microlevel [37]. Hamade et al [17] noted that while there are many studies on the implementation of EMR, there is a scarcity of studies on its use.

Most of the selected indicators evaluated the completeness and adequacy of the problem list. The problem list provides important information for decision-making [47]. Our indicators are primarily process indicators because they focus on the process of EMR registration (ie, use). However, these QIs cannot be directly linked to patient outcomes. Process indicators are useful for quality assessment. They are more sensitive to differences in quality than outcome measures and are easier to interpret [48]. Recent literature shows an interest in eA&F [22,29], dashboard interface features to support reflection on practice (“barometers”) [27-29], and computer-based decision support in primary care [49]. The quality of data in EMRs impacts the effectiveness of these systems. Several studies have shown that improving data quality may improve the quality and efficiency of care and reduce mortality [4-6]. Unfortunately, data show that physicians spend approximately two-thirds of their work time interacting with EMRs in their offices. This administrative burden negatively impacts clinicians’ wellness, leading to an increased chance of burnout. Recently, the interest in the use of artificial intelligence for analyzing data, identifying hidden information, identifying risks, and providing suggestions for diagnosis has increased rapidly. This can greatly facilitate the process for GPs to easily improve data quality without spending more time entering data in the EMR and less time interacting with patients [50]. GPs should not need to adapt their working habits to the capabilities of their medical software; rather, EMRs should be adapted to the needs of GPs to facilitate the correct registration of data [51]. An important lever to encourage EMR developers to align their software more closely with clinicians’ data entry and retrieval needs lies in regulatory frameworks, such as homologation. This is a certification procedure to evaluate the mandatory standards and certification requirements that EMRs must fulfill to be approved for use within the health care system [52]. By embedding QIs derived through expert consensus, such as those developed in this study, into these frameworks, regulators can create explicit performance benchmarks that EMRs must meet. This alignment incentivizes developers to design functionalities that facilitate accurate, complete, and efficient data capture and reporting by clinicians [50].

Strengths and Limitations

Our panel included members working in all parts of Belgium and in all types of practices, giving it broad support. Because our panel included health professionals and EMR developers, we were able to define clinically relevant indicators that considered the technical requirements for extractability. During the consensus meeting, the EMR developers emphasized that these indicators could possibly stimulate GPs to use the features they have already developed more extensively. We are convinced that their opinion was a valuable addition to the panel. EMR developers were the most capable of assessing whether a QI could be automatically extracted from the EHR data. However, we cannot exclude a potential bias caused by their

XSL•FO
RenderX

inclusion (eg, the ease or cost of addressing a recommended QI outweighing the importance of making that QI available from a public health perspective). The scarcity of literature on the initial set of QIs and recommendations is a double-edged sword for our study. On the one hand, it limits the strengths of the initial set of QIs and recommendations because none of our sources used a systematic approach to evaluate the validity of their QIs and recommendations, had a well-explained methodology [13,15,36-38], or could be evaluated using the Appraisal of Guidelines for Research and Evaluation II method [11,19,20,39-42]. On the other hand, this allowed us to conduct a broad and general search on the topic, which could increase its universal applicability. There are many differences between countries in terms of how and which data are registered [11,19,20,39-42]. We attempted to generalize the QIs and recommendations as much as possible. However, adaptation to the local context is necessary. Another important limitation is that some indicators are not currently extractable. However, as mentioned earlier, these indicators reflect aspects of clinical practice that are important enough to warrant adaptation of EMRs to include this information.

Future Research Directions

This set of indicators is important for future research on EMR use. Developing a list of QIs is the first step in implementing a strategy and realizing a quality loop. The next essential step is to conduct practice testing for operational validity [29]. These results can be used to create an eA&F system [22,23]. This set of QIs can also be used to develop specific (computer based) training for GPs based on a set of learning goals [2]. It should be noted that our QIs can be used for the correct use of EMRs but cannot be used to quantify the quality of care provided by GPs. Further research is necessary to evaluate whether the correct use of the EMR, as proposed in this set of QIs, also affects the quality of care provided to patients and its possible effect on the data in the PHS.

Conclusions

This study provided a set of 40 EMR-extractable QIs for the correct use of EMRs in primary care based on international guidelines and approved by GPs and EMR developers. These QIs can be used as a framework to measure and improve the quality and completeness of EMRs in primary care.

Acknowledgments

The authors would like to thank all the participating panel members for the many hours they spent in this study.

Funding

This study was conducted by UZ Leuven and KU Leuven at the request of Rijksinstituut voor ziekte- en invaliditeitsverzekering–Institut national d’assurance maladie-invalidité and funded by Rijksinstituut voor ziekte- en invaliditeitsverzekering–Institut national d’assurance maladie-invalidité as part of a national project to improve medical care in Belgium.

Data Availability

The datasets generated or analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

RP conducted the literature search and organized each step of the Delphi procedure as part of his PhD project. LM assisted during each step of the Delphi procedure. SVdB oversaw the whole process and helped to draft the manuscript. BV and WR supervised the entire process from the beginning to the end and helped draft the manuscript. MDJ and BF were part of the panel during the Delphi procedure and helped draft the final manuscript. All the authors have read and approved the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: A rapidly aging population led to an increase in the number of patients with chronic diseases and polypharmacy. Although investigations on the appropriate number of drugs for older patients have been conducted, there is a shortage of studies on polypharmacy criteria in older inpatients from multiple institutions.

Objective: The aim of this study was to examine the patterns of polypharmacy and determine the criteria for the number of drugs defining polypharmacy in the geriatric inpatient population.

Methods: Electronic health records of 4 medical institutions for patients aged 65 years and older hospitalized between January 1, 2012, and December 31, 2020, were analyzed for the study. The maximum number of drugs prescribed was obtained for each patient and, along with a literature review, was used to determine the appropriate polypharmacy level for our population.

Results: We suggest a 4-level polypharmacy category system consisting of nonpolypharmacy, polypharmacy, major polypharmacy, and excessive polypharmacy based on a review of international guidelines and polypharmacy literature. Application of this system to our study population showed that the major polypharmacy category (use of 10-19 concurrent drugs) was an appropriate threshold for polypharmacy in hospitalized patients versus the traditional threshold of 5 or more concurrent drugs. The tendency of our study population to have a higher disease and drug count supports this threshold. Frequently prescribed therapeutic subgroups in this category were antibacterials for systemic use, anesthetics, and cardiac therapy.

XSL•FO
RenderX

Conclusions: This study proposes a polypharmacy categorization system for older inpatients, which differs from the common definition of the concomitant prescription of 5 or more drugs. The older population tends to have severe conditions including those requiring major surgeries; therefore, a drug count corresponding to the definition of major polypharmacy is appropriate.

KEYWORDS

polypharmacy; older patients; medication; electronic health record; Common Data Model

Introduction

South Korea is reported to have the highest rate of aging among the Organisation for Economic Cooperation and Development countries, where 8.2 of 51.8 (15.7%) million people in 2020 were aged 65 years or older [1]. The prevalence of chronic diseases in this population was found to be 8481 of 10,097 (84%) individuals aged 65 years or older, making it highly likely that the cost of health care is increasing [2]. This requires close review and consideration of effective measures to prevent and treat chronic diseases and adverse events from polypharmacy.

With the increase in lifespan and aging population in South Korea, patients commonly have multiple concomitant diseases. Consequently, patients visit 1 or more health care institutions and are prescribed medications that expose them to polypharmacy [3]. In 2006, Intercontinental Marketing Statistics Korea found that an average of 4.16 medications were prescribed per health care appointment, which was the highest among the 10 countries studied [2]. A study using the South Korean health claims data of 2016-2019 reported that in 2016, a total of 1548 of 47,631 (3.3%) individuals aged 45 years or older experienced polypharmacy, defined as the use of 10 or more medications for at least 60 days, and this rate increased gradually up to 2019, where 2012 of 48,249 (4.2%) individuals aged 45 years or older were on polypharmacy [4]. To ensure that older adult patients receive appropriate drug therapy, the Korean Health Insurance Review & Assessment Service launched the Drug Utilization Review program. This provides real-time assessment of inappropriate patient drug therapy, including the use of duplicative drug ingredients or drugs of different therapeutic classes, inappropriate drugs for older adults, or drugs not to be used in combination [5].

Considering that older adults have decreased physiological functions and often have several chronic diseases, they are at a higher risk of polypharmacy and hospitalization. The use of at least 5-6 drugs is a definition widely used for polypharmacy in the ambulatory population, and several studies report 25% or more older adults on polypharmacy [2,6-9]. However, this definition may not be practical for the hospitalized older adult population, as this demographic tends to receive more treatments for multiple diseases. Previously reported definitions of polypharmacy in the geriatric hospitalized population were the prescription of 5-9 medications and that of hyper-polypharmacy were 10 or more medications [10,11]. There were also cases of using 5 or more drugs as the definition of polypharmacy for hospitalized patients [12,13]. Although definitions of polypharmacy applicable to older hospitalized patients exist, most studies use single-institution prescription data, making the findings difficult to generalize. Studies from multiple institutions are needed to determine and apply definitions of polypharmacy in the geriatric inpatient population.

Previous studies have used various data sources and methods to define polypharmacy. Data sources included health insurance claims, electronic medical records, spontaneous adverse drug event (ADE) reports, and surveys. The methods used to define polypharmacy include simple numeric definitions, numeric definitions with terms of duration in a therapy or health care setting, and nonnumeric descriptive definitions [14]. Definitions of polypharmacy are diverse due to differing patient age, underlying disease, and disease severity. Accordingly, it is necessary to review the existing definitions of polypharmacy to understand the categories used in various clinical settings and to apply the most appropriate method when assessing the status of polypharmacy in the study population.

Kim et al [2] reported that approximately 6.30 million patients aged 65 years or older in South Korea were prescribed drugs for at least 90 days during 2018, and among this population, 2.64 (41.9%) million were prescribed 5 or more drugs, and 0.77 (13.9%) million were prescribed 10 or more drugs. Cresswell et al [15] reported an increased risk of ADEs with a higher number of prescribed drugs. The older adults were especially at risk of serious long-term outcomes, including death and disability, from these ADEs [15]. Ensuring safer therapy for this population is important. Hanlon et al [16] found that in 167 adults aged 65 years and older, ADEs occurred in 58 (35%), and the most frequent ADEs were gastrointestinal disorders. This was followed by ADEs of the nervous, respiratory, endocrine, skin, and subcutaneous systems [16]. Among the 58 patients who had an ADE, 49 (84%) patients required medical care: 37 (63%) were examined by a physician, 7 (11%) were hospitalized, and 5 (10%) visited the emergency room [16]. Mabuchi et al [17] compared the number of drugs used in patients with a spontaneous ADE report to the overall patient population in Japan using real-world data. In both populations, the number of drugs used increased with age [17].

This study used anonymized electronic health record (EHR) data converted to the Observational Medical Outcomes Partnership (OMOP) Common Data Model (CDM) format, a standardized data structure that accommodates retrospective observational studies [18]. The OMOP CDM data content is generated by extracting EHR data recorded during patient care, removing personal identifiable information, transforming the data into a standardized structure, and mapping hospital-specific terms to standardized, controlled vocabularies. Each CDM in the 4 institutions included patient demographic, condition, measurement, procedure, and drug prescription information [19]. Overall, we examined the characteristics and patterns of polypharmacy in older hospitalized adults across 4 health care

XSL•FO
RenderX

institutions (presented as medical institutions A-D) and created a polypharmacy categorization system for this population. Specifically, for each polypharmacy category, we characterized the drugs and drug classes prescribed to the population of interest and examined their drug use patterns.

Methods

Study Participants and Observation Period

EHR data of 4 medical institutions converted to the OMOP CDM format were used to analyze polypharmacy patterns. The study participants were patients aged 20 years or older hospitalized at one of these 4 institutions between January 1, 2012, and December 31, 2020. The number of patients aged 20 years or older who visited the medical institutions in the study period ranged from 494,875 to 3,349,795. The number of hospitalized patients, hospitalization events, hospitalized patients aged 60 years and older, and the number of drug classes prescribed to the overall hospitalized patients are presented in Table 1.

To extract study participants, we consulted clinicians from medical departments who frequently encountered polypharmacy. The patient visit types were restricted to inpatients. The earliest date of patient admission was the patient study entry date; if the discharge date of this admission and the admission date of the next admission were within 30 days, the 2 admissions were treated as a single continuous admission period. To investigate the status of discharge drug use, drug exposure data from the outpatient setting were followed up for 7 days after patient discharge. For example, if the patient had 2 admission episodes, the total admission period would be the sum of the duration of admission 1 in days, 7 days after discharge from admission 1, the duration of admission 2 in days, and 7 days after discharge from admission 2 (Figure 1).

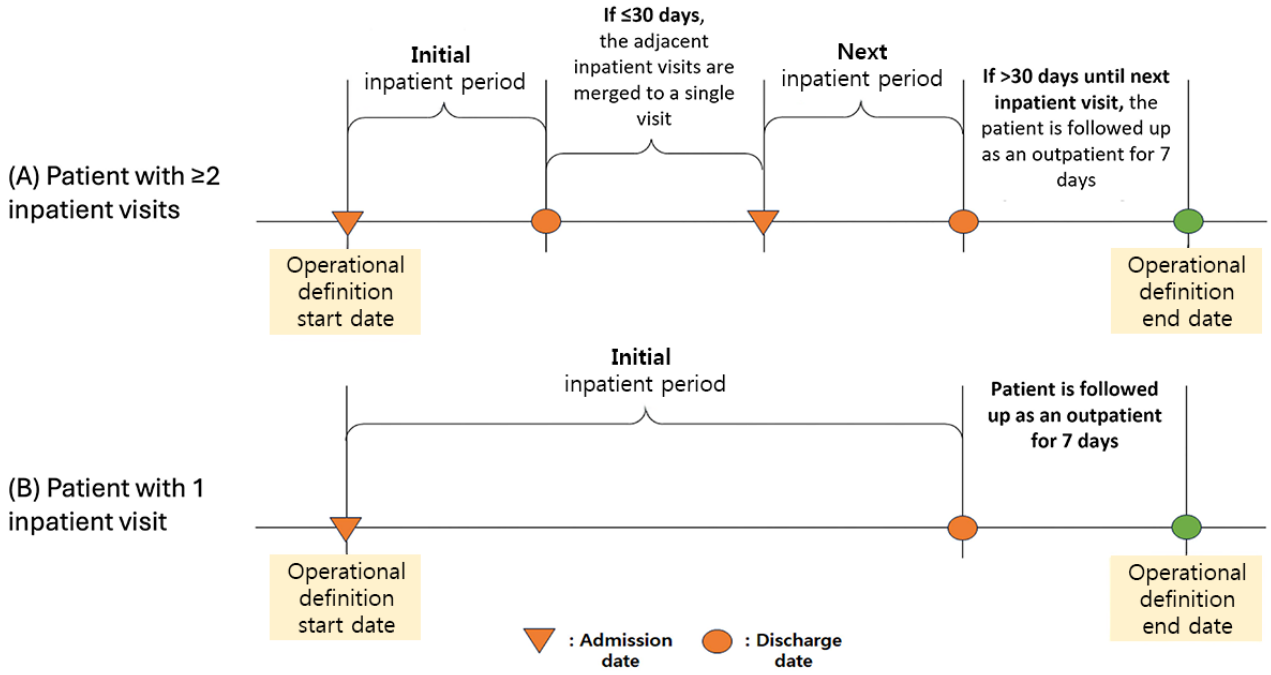

Table 1. Patient characteristics by medical institution.

	Medical institution A	Medical institution B	Medical institution C	Medical institution D
Patients, n (%)	602,483 (100)	1,944,140 (100)	3,349,795 (100)	494,875 (100)
Hospitalized patients, n (%)	169,931 (20.2)	405,956 (20.9)	419,460 (12.5)	128,700 (26)
Hospitalization events, n (%)	315,624 (100)	1,092,936 (100)	871,764 (100)	212,489 (100)
Older hospitalized adults aged ≥60 years, n (%)	48,512 (8.1)	166,071 (8.5)	113,573 (3.4)	33,997 (6.9)
Drug therapeutic subgroups (WHO[a] ATC[b] second-level codes [20]) prescribed, distinct n (%)	79 (84)	86 (91.5)	72 (76.6)	81 (81.2)

Polypharmacy Level

This study examined the distribution of patients by polypharmacy level for each medical institution. The polypharmacy levels increase by the number of concomitant drugs prescribed to the patient. The cutoff values for concomitant drug counts in each polypharmacy level were determined based on internationally recommended thresholds and existing literature on polypharmacy in older adults. The World Health Organization (WHO) and several countries defined the use of 5 or more drugs as polypharmacy [1,14]. WHO differentiates between appropriate and inappropriate polypharmacy by defining appropriate polypharmacy as evidence-based, personalized medication prescribing and inappropriate polypharmacy as irrational, excessive prescribing [21]. It emphasizes the importance of reducing inappropriate polypharmacy by continuously ensuring the appropriate, rational use of medications [21]. The European Geriatric Medicine Society states that polypharmacy patients should be closely managed through medication reviews to prevent inappropriate polypharmacy [22]. The National Institute for Health and Care Excellence recommends monitoring the benefits and harms of each drug taken by adults using 15 or more regular medications [23].

Masnoon et al [14] used concurrent drug counts, admission duration, and treatment duration to define polypharmacy, and Young et al [24] determined the category of polypharmacy by the number of concomitant drugs and the presence of high-risk drugs in the patient's drug regimen. Studies on hospitalized, older patients used polypharmacy levels other than the widespread definition of 5 or more drugs [25-27]. An investigation of the physical performance of hospitalized older patients defined polypharmacy as the use of 10 or more drugs during hospital stay [26]. A study analyzing risk factors of increased hospital stay in older adults defined polypharmacy as the concomitant use of 5 to 9 drugs and excessive polypharmacy as 10 or more drugs [25]. The polypharmacy definition for nursing home patients as well as older populations in general was also 5-9 concurrent drugs, and that of excessive polypharmacy was 10 or more concurrent drugs [27-29]. Kim et al [30] divided polypharmacy into 3 levels: concomitant use of 6 or more drugs as polypharmacy, 11 or more drugs as major polypharmacy, and 21 or more drugs as excessive polypharmacy [30].

Based on WHO recommendations and the literature search mentioned earlier, we suggested a polypharmacy categorization method to detect regimens, including an excessive number of drugs, with an aim to assist in detecting inappropriate polypharmacy (Table 2). Polypharmacy was defined as concomitant prescription of 5 or more drugs, which is consistent with the widespread definition [14] and based on previous studies on polypharmacy in older adults. The next severe polypharmacy level, which was major polypharmacy, was defined as the prescription of 10-19 drugs. This threshold was used, as it was commonly used in the older patient population [25-29]. The most severe polypharmacy level, excessive polypharmacy, was defined as the prescription of 20 or more drugs based on a previous study of polypharmacy use among older adults [30].

Table 2. Definition of polypharmacy based on the number of concomitant drugs.

Concomitant drugs, n	Polypharmacy category
<5	Nonpolypharmacy
5-9	Polypharmacy
10-19	Major polypharmacy
≥20	Excessive polypharmacy

Data Preprocessing and Data Analysis Environment

Preprocessing of the medical institution data was performed by converting the EHR to the OMOP CDM (version 5.3.1) format. We used the following inpatient data extracted from the CDM tables: person, drug_exposure, and visit_occurrence. The data for each CDM table were extracted for the years 2012-2020. Using drug_exposure OMOP CDM data, the severity of polypharmacy and drug use patterns in the patients were analyzed. Based on clinical professional consultation, the study patients were divided into those with 1 admission and those with 2 or more admissions. The operational definition of continuous admission was applied to the data of patients with multiple admissions within 30 days to obtain the final admission counts. Drug exposure data in the outpatient setting for 7 days after follow-up were extracted for each patient. We extracted the drug exposure data for all patients during their observation period and for each day of drug exposure and counted the number of drug ingredients exposed to the patient. The date of the maximum number of dispensed drug ingredients was determined. If the patient was exposed to this maximum number of drug ingredients for multiple days, the date closest to admission was used as the date of the maximum drug ingredient count. The drug ingredient count on that date was used to determine the patient's polypharmacy level. To perform the drug ingredient mapping process, we excluded patients without at least 7 days of drug exposure data after discharge.

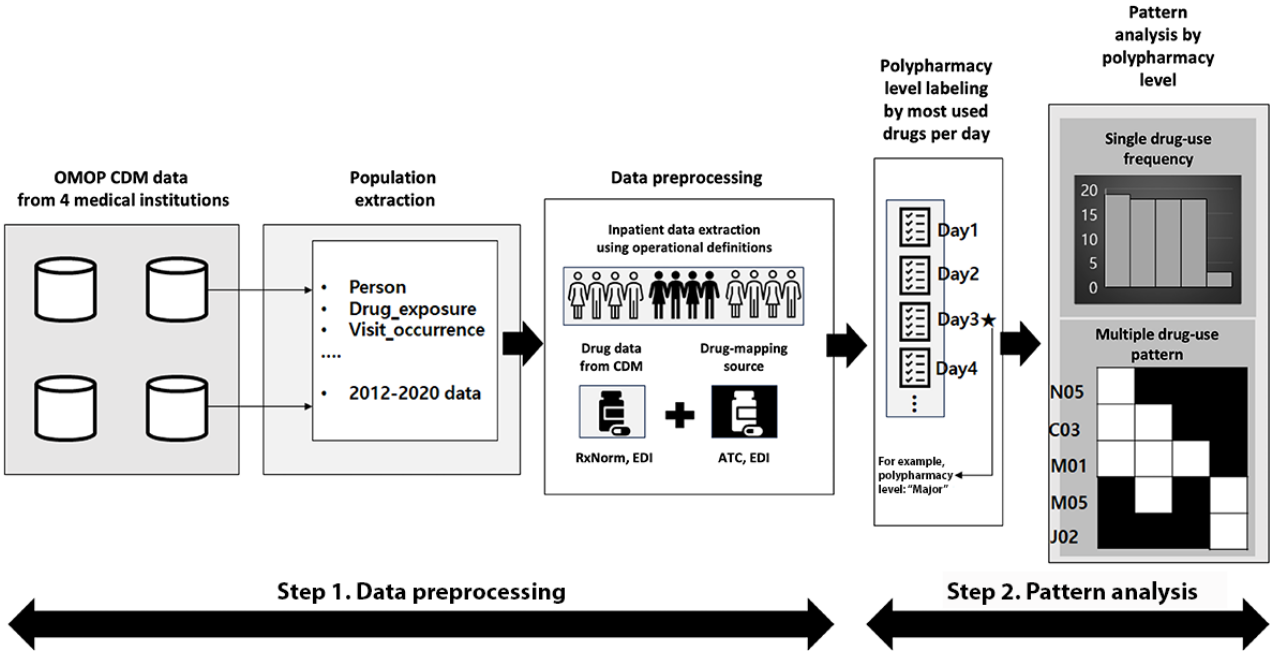
Data processing and analyses were performed using R (version 4.1.3; R Foundation for Statistical Computing). Specifically, CDM data access, extraction, and conversion into variables were performed using R packages *RpostgreSql* (version 0.7-8) [31] and *sqldf* (version 0.4-11) [32]. R packages used for data preprocessing were *dplyr* (version 0.8.3) [33] and *data.table* (version 1.12.2) [34], and that used for descriptive analyses was *moonBook* (version 0.3.1) [35]. The *ggplot2* (version 3.2.1) [36] R package was used for data visualization. Medical institute A used 16 GB RAM in the Windows operating system (OS), medical institutes B and C used 64 GB RAM in the Windows

XSL•FO
RenderX

OS, and medical institute D used 128 GB RAM in the Windows OS.

Polypharmacy Pattern Analysis

For each patient, we mapped the WHO Anatomical Therapeutic Chemical (ATC) code to each drug exposure event in the OMOP CDM. Medical institutions A, C, and D assigned WHO ATC codes to drugs in the OMOP CDM using electronic data interchange (EDI) codes. This is possible because the EDI codes are loaded into the institutional CDM. Mapping the WHO ATC codes to EDI codes required a file with code information for drugs distributed in South Korea provided by the Korea Pharmaceutical Information Service [37]. Korea Pharmaceutical Information Service, operated by the Health Insurance Review & Assessment Service, assigns WHO ATC codes to drugs approved in South Korea. The code information file includes EDI, WHO ATC, and drug ingredient codes for each drug approved; therefore, assigning WHO ATC and drug ingredients to each drug in the OMOP CDM was possible. Traditional Korean medications and drugs without WHO-ATC, EDI, and drug ingredient codes were excluded from the mapping process.



Medical institution B did not have EDI codes available in the OMOP CDM; therefore, a different approach was used to assign WHO ATC codes to the drug concept IDs. This institution maps the WHO ATC code to each drug in the CDM drug_exposure table using the concept and concept_ancestor tables. If the drug_concept_id in the drug_exposure table was a descendant_concept_id of an ancestor_concept_id indicating a fifth-level WHO ATC code, then the concept_id and WHO ATC codes were mapped to the drug_concept_id. The concept table was used to determine if the ancestor_concept_id was a WHO ATC code, and the concept_ancestor table was used to determine if drug_concept_id was a descendant_concept_id of a WHO ATC code.

The maximum daily drug ingredient count was used to determine the polypharmacy level. A maximum drug ingredient count of less than 5 drugs was considered nonpolypharmacy, 5-9 drug ingredients as polypharmacy, 10-19 drug ingredients as major polypharmacy, and 20 drug ingredients or more as excessive polypharmacy.

Demographic characteristics were analyzed using the processed CDM data. The characteristics examined included the total number of inpatients and their admissions, patient age, precautionary drug use, proportion of older adults, admission duration, and drug ingredient exposure distribution for the years 2012-2020.

We performed single and combination drug class pattern analyses using the second ATC level as the unit for the drug class. This level was selected, as it represents clinically meaningful therapeutic groups, allowing the comparison of prescribing trends across multiple health care institutions. We excluded drugs in the ATC second-level B05 (blood substitutes and perfusion solutions) for the analyses, as these drugs have a low risk of interacting with other drugs, have little clinical significance, and are used in the majority of inpatients. [38]. The drug use patterns were visualized using the *ggplot2* R package. Single-drug class use patterns were analyzed by determining the number of patients using each drug class at least once. Combination drug class patterns were analyzed by first determining the date of the highest number of drugs prescribed for each patient and examining the drug classes used on that date. The workflow of the study is depicted in Figure 2.

Ethical Considerations

The study was conducted in accordance with the Declaration of Helsinki and approved by the institutional review board of Konyang University Hospital (protocol code: KYUH2022-07-015-001, approved on September 21, 2022), Asan Medical Center (protocol code: 2022-0342, approved on October 21, 2022), Seoul National University Hospital (protocol code: E-2209-069-1358, approved on September 20, 2022), and Chungbuk University Hospital (protocol code: CBNUH2022-09-030, approved on October 18, 2022). Patient consent was waived, as the data were collected during the routine care of physicians and removed of personally identifiable information, therefore eliminating the risk of compromising patient privacy. There was no direct contact with any patients during the course of this study, and no compensation was provided to the participants.

Results

Polypharmacy Levels and Their Drug Use Patterns

The mean maximum daily drug counts in older adults aged 60-69, 70-79, and ≥80 years were highest in patients admitted to medical institution B followed by medical institution A. Duration of admission increased with higher age range in medical institution C. In all institutions except for institution A, the average hospitalization period of the population aged 70 years or older was longer than the population aged 60-69 years (Table 3).

Table 3. Multi-institutional maximum daily number of drugs prescribed and duration of hospitalization in older adults.

Older Adult Polypharmacy Levels Based on Multi-Institutional CDM Data

The level of polypharmacy with the most patients was major polypharmacy in medical institutions A, C, and D, while for medical institution B, this was excessive polypharmacy (Table 4).

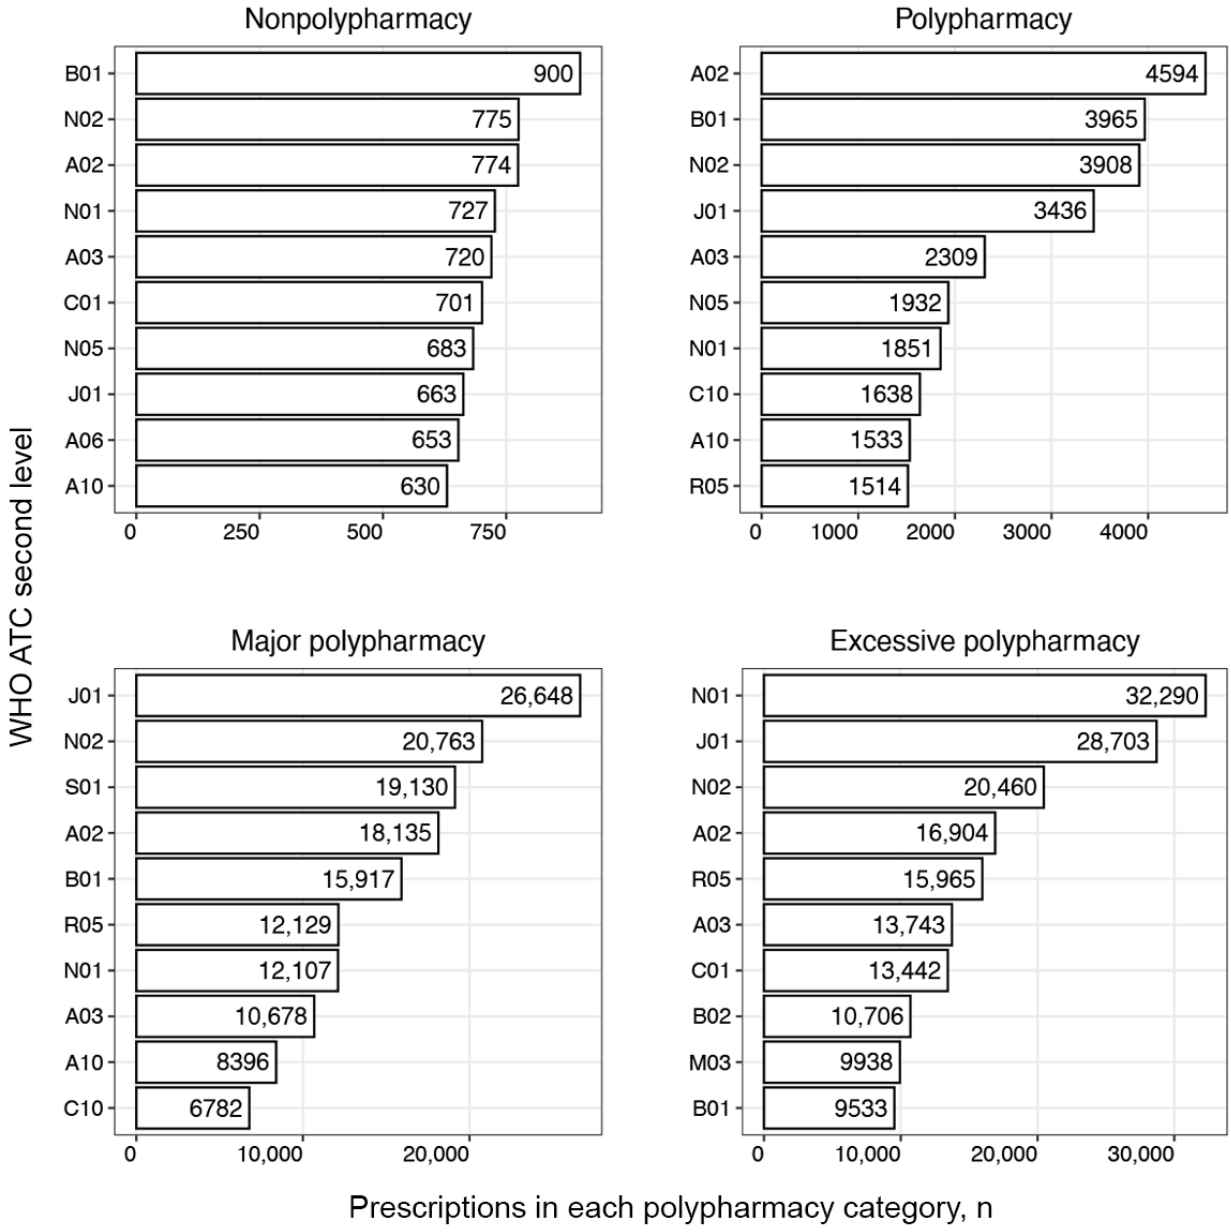
Multi-Institute CDM-Based Polypharmacy Pattern

The pattern of polypharmacy in the older adults was analyzed based on the use of single or combinations of drug therapeutic subgroups (WHO ATC second-level codes). The older population was defined as adults aged 65 years and older, based on the population grouping method of the National Statistical Office of Korea [1].

Single Drug Use Patterns

We examined frequently prescribed drug therapeutic subgroups using second-level WHO ATC codes as the subgroup unit. The 10 most frequently prescribed subgroups for each medical institution are presented in Figures 3-6. The horizontal axis represents the number of prescriptions for drugs included in the therapeutic subgroup specified on the vertical axis. According to the 10 most frequently prescribed therapeutic subgroups, the number of prescriptions tended to increase with higher levels of polypharmacy in all medical institutions, excluding institution C. The highest prescription frequency in this institution was observed at the major polypharmacy level.

For medical institution A, the antithrombotics (B01) therapeutic subgroup was frequently prescribed in patients in the nonpolypharmacy and polypharmacy levels compared to other levels and antibacterials for systemic use (J01) for the major and excessive polypharmacy levels. Notably, drugs in the anesthetic (N01) subgroup were most frequently prescribed to patients with excessive polypharmacy (Figure 3).



In medical institution B, patients in all polypharmacy levels except the excessive level were most frequently prescribed analgesics (N02). The most frequently prescribed therapeutic subgroups for patients with excessive polypharmacy included mineral supplements (A12) and antianemic preparations (B03). Patients in all polypharmacy levels were frequently prescribed antibacterial agents for systemic use (J01) and drugs for acid-related disorders (A02). Patients in the major polypharmacy level were frequently prescribed cardiac therapy (C01) and drugs for constipation (A06; Figure 4).

In medical institution C, the analgesic (N02) therapeutic subgroup was prescribed most frequently to patients in all polypharmacy levels. Cough and cold preparations (R05) were relatively frequently prescribed to patients in the nonpolypharmacy level, and lipid-modifying drugs (C10) and antithrombotics (B01) to patients in the polypharmacy level. Anesthetics (N01) were prescribed more frequently to patients in major and excessive polypharmacy levels than to those in other polypharmacy levels (Figure 5).

In medical institution D, antibacterials for systemic use (J01) and analgesics (N02) were prescribed frequently to patients across all polypharmacy levels. Drugs for acid-related disorders (A02) were frequently prescribed to patients in all polypharmacy levels, excluding the excessive level, whereas antihemorrhagics (B02) and anesthetics (N01) were most frequently prescribed to patients in the excessive level (Figure 6).

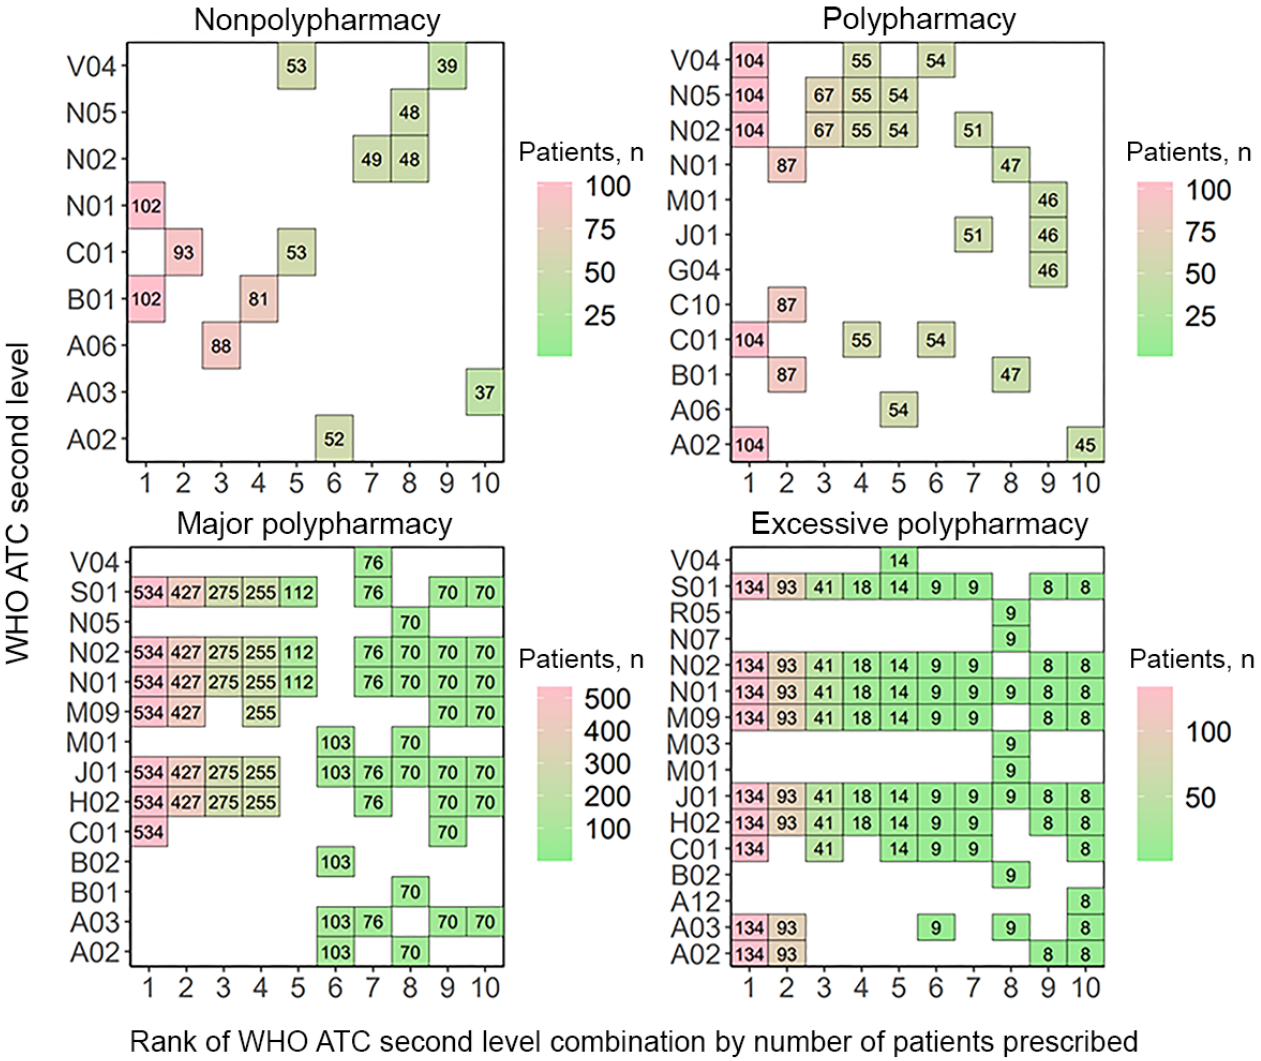
Concomitant Drug Use Patterns

Following the examination of single therapeutic subgroup patterns, concomitantly used therapeutic subgroups were analyzed to determine the trends in combination drug use in patients with polypharmacy. At medical institution A, the most frequently prescribed therapeutic subgroup combination for patients of the nonpolypharmacy level was B01 and N01. For patients in the polypharmacy level, A02-C01-N02-N05-V04 was the most frequently prescribed combination. Patients in the major polypharmacy level were most frequently prescribed with the therapeutic subgroup combination C01-H02-J01-M09-N01-N02-S01, while patients in the excessive polypharmacy group were most frequently prescribed the combination A02-A03-C01-H02-J01-M09-N01-N02-S01 (Figure 7). The full names for each of the therapeutic subgroups denoted as WHO ATC second-level codes are in Multimedia Appendix 1.

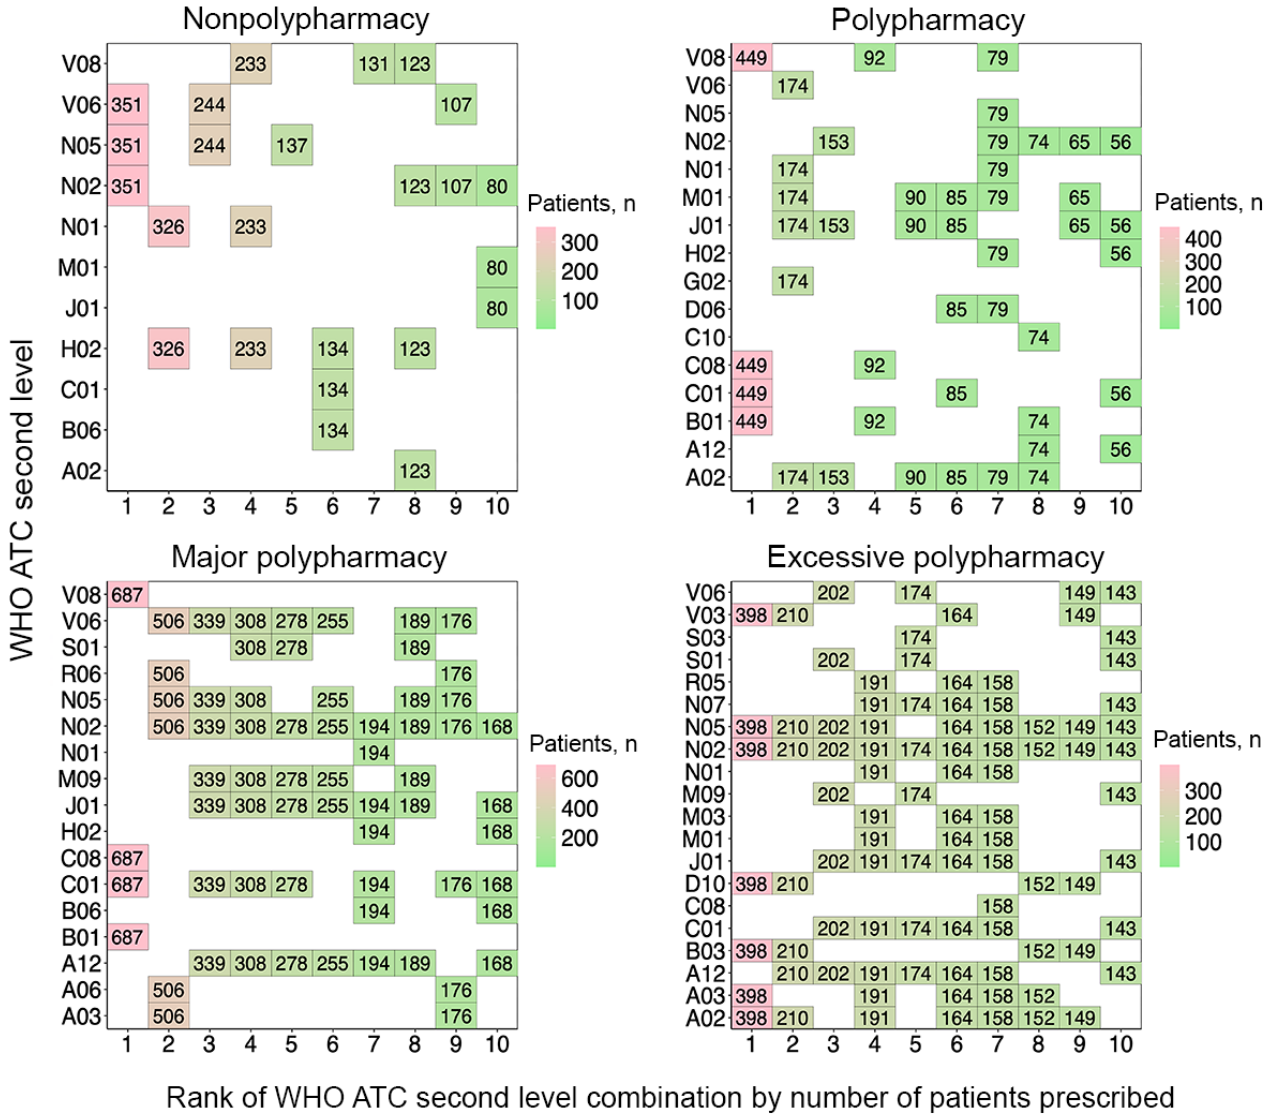
Results for medical institution B showed that patients in the nonpolypharmacy level were most frequently prescribed therapeutic subgroup combination N02-N05-V06, followed by combination H02-N01. The most frequent combination prescribed to patients at the polypharmacy level was B01-C01-C08-V08, followed by A02-G02-J01-M01-N01-V06 and A02-J01-N02. Patients in the major polypharmacy level were also most frequently prescribed the combination B01-C01-C08-V08. The second most frequently prescribed



XSL•FO
RenderX

combination at this level was A03-A06-N02-N05-R06-V06, and the third was A12-C01-J01-M09-N02-N05-V06. The most frequently prescribed subgroup combination for patients in the excessive polypharmacy level was A02-A03-B03-D10-N02-N05-V03, followed by A02-A12-B03-D10-N02-N05-V03 and A12-C01-J01-M09-N02-N05-S01-V06 (Figure 8).

In medical institution C, the 3 most frequent therapeutic subgroup combinations prescribed to patients at the nonpolypharmacy level each involved 1 subgroup: R05, N02, and J01. Patients in the polypharmacy level were most frequently prescribed therapeutic subgroup combination A03-M01-N01-S01. The most frequent subgroup combination prescribed for patients in the major polypharmacy level was A03-C01-M01-N01-S01, followed by A03-M01-N01-S01 and A02-A03-C01-N02-N05-V03. Patients in the excessive polypharmacy level were prescribed A02-A04-C01-J01-M03-N01-N02-R03-R05 most frequently. The second frequent combination was the same as the most frequent combination with the addition of subgroups A03 and A07. The third most frequent combination matched the second, excluding subgroup A02 (Figure 9).



In medical institution D, patients in the nonpolypharmacy level were prescribed therapeutic subgroup J01 most frequently, followed by individual subgroups A02, N02, and A06. Patients in the polypharmacy level were mostly prescribed the combination J01-N01-N02. Those in major polypharmacy level were prescribed B06-C01-H02-J01-N01-N02-S01, followed by J01-N02-R05-R06 and A02-J01-M01-N01-N05. Patients in the excessive polypharmacy level were prescribed combination A03-A04-B02-J01-M01-M03-N01-N02-N07-R05 most frequently, and the second and third most frequent combinations involved the addition of subgroup R03 and the removal of subgroup M01, respectively (Figure 10).

Discussion

Principal Findings

This study used EHR data converted to the OMOP CDM from 4 medical institutions for geriatric inpatients aged 65 years and older admitted over 9 years. Our study is the first to collect the EHR of patients and retrospectively study polypharmacy patterns over multiple institutions to determine a polypharmacy threshold in hospitalized older patients. The authors used data from 2 of the largest hospitals in the South Korean metropolitan area and 2 hospitals in the regional area to represent patients from distinct settings.

The use of OMOP CDM in all 4 study settings allowed the use of similar programming languages and software, thereby increasing the efficiency of the study. Although there were differences in the specific columns customized for each institution, the uniformity of the basic OMOP CDM tables and columns across institutions allowed for the distribution of a single analysis code customized for each institution, and the collection of analysis resulted in a standardized format.

We offer a possible definition of polypharmacy in hospitalized older adults. This was obtained by consulting clinical professionals to define the inpatient observation periods and reviewing previous studies [25,26,30] to determine the time point of drug exposure for polypharmacy level determination. We filtered out drugs that did not contribute to adverse events from polypharmacy (eg, WHO ATC code B05 and its lower-level codes), which improved the quality of our data.

The 4 health care institutions (A, B, C, and D) included in this study showed distinct differences in patient scale, proportion of older patients, sex and age distribution, and medication use patterns. Institution C had the largest patient population with 3,349,795 patients and demonstrated high proportions of older patients and excessive polypharmacy levels. Institution B had the next highest patient population with 1,944,140 patients and the highest number of hospitalization events with 1,092,936 events. This trend reflects that institutions located in metropolitan, urban settings had a higher patient population size and hospitalization event count than their rural counterparts. Institution A, despite having a relatively smaller scale with 602,483 patients, was characterized by the highest average

XSL•FO
RenderX

number of medications per age group and the longest hospital stays.

In terms of sex distribution, institution A showed higher male ratios in patients aged 5-60 years, but female patients were more prevalent in those aged 70 years and older. Institution C displayed higher female ratios in patients in their 50s and 80s or older, while male patients were more common in the 60- to 70-year age group. Institution D exhibited a unique pattern with higher female ratios in patients aged 80 years and older and higher male ratios in those aged 5-70 years. Overall, the proportion of female patients tended to increase in the older population, with sex ratios varying across institutions and age groups.

A tendency was observed for hospital length of stay to increase with advancing age across all institutions. Regarding polypharmacy prescriptions, institution B demonstrated the highest "excessive polypharmacy level" ratio across all age groups.

Comparison to Prior Work

The pattern of drug use among inpatients in the 4 medical institutions showed that patients in the major or excessive polypharmacy levels were most prevalent. This trend is consistent with the results of previous studies reporting 5-10 drugs or more as the polypharmacy threshold. A study using nationwide health care claims data found that hospital admission was significantly associated with polypharmacy (use of 5 or more drugs) and hyper-polypharmacy (use of 10 or more drugs) [39]. Another study reported an increase from 5.6 drugs taken per patient on average at admission to 7.6 drugs at discharge [40]. Considering that the number of drugs prescribed tended to increase during hospital admission, the use of 10-19 or more drugs (major polypharmacy or higher) as the threshold for inpatient polypharmacy was considered appropriate. All data were obtained and analyzed within the securely blocked environment of each medical institution.

The mean number of drugs used in medical institution B was higher than that used in other institutions by 3-10 drugs. The prescription frequency of drugs in the cardiac therapy (C01) WHO ATC therapeutic subgroups tended to increase with the severity of polypharmacy in all medical institutions, and the anti-inflammatory and antirheumatic product (M01) therapeutic subgroups increased across all institutions, excluding institution B. These results correspond with those of a study in which hypertension, osteoarthritis, and rheumatoid arthritis were reported to be prevalent in older individuals aged 65 years or older [41].

The patterns of concomitant therapeutic subgroups differed among the medical institutions. In the major polypharmacy category, medical institution A patients were frequently prescribed ophthalmologicals (WHO ATC second-level code S01), along with other therapeutic subgroups. This drug class has been consistently used in most prescribed combinations of therapeutic subgroups. Medical institution B prescribed drugs in various therapeutic categories including acid-related disorders (A02), functional gastrointestinal disorders (A03), antianemic preparations (B03), antithrombotics (B01), and cardiac therapies (C01) to patients in the major and excessive polypharmacy levels. Medical institution C, which had the highest number of study patients, prescribed drugs for WHO ATC second-level functional gastrointestinal disorders (A03), anti-inflammatory and antirheumatic products (M01), and ophthalmologicals (S01). These drug classes were in the 1-3 highest rank of concomitant drugs prescribed.

Distinct polypharmacy patterns in the polypharmacy group were that patients in all 4 institutions were more frequently prescribed lipid-modifying agents (C10), and in 3 institutions, antidiabetics (A10) were more frequently prescribed, compared to other polypharmacy groups (Figures 3-6). This reflects the increased prevalence of chronic diseases in the older population and their demand for multiple medications to treat the disease [42]. Furthermore, the result is consistent with a finding that older patients with diabetes have a high prevalence of polypharmacy, as these patients commonly have multiple concomitant diseases including cardiovascular, renal, and respiratory disorders [43]. The higher prescription frequencies of ophthalmic agents (S01) and anti-inflammatory and analgesic drugs (M01) observed in institution C reflect that this institution is highly specialized in ophthalmology or rheumatology. The major polypharmacy group was frequently prescribed cough and cold preparations (R05) compared to other polypharmacy groups (Figures 3-6). This trend was consistent with results of a previous study, which reported patients on 5 or more drugs having an odds ratio of 3.18 and 6 or more drugs having an odds ratio of 4.57 to receive prescriptions for cough and cold drugs [44].

Distinctive polypharmacy patterns observed in the excessive polypharmacy group were that cardiac drugs (C01) were frequently prescribed in all 4 institutions (Figures 3-6). This observation suggests that patients in the excessive polypharmacy group may have a higher burden of cardiovascular diseases or more severe cardiac comorbidities requiring complex medication regimens [45]. The frequent prescription of cardiac drugs in this group indicates that managing heart-related conditions—such as heart failure, arrhythmia, or ischemic heart disease—contributes substantially to the overall medication load. This reflects that the patients in the excessive polypharmacy group are clinically more fragile, thus requiring multiple medications for symptom control, prevention of complications, and comorbidity management. This group was also frequently prescribed functional gastrointestinal disorder drugs (A03), antihemorrhagics (B02), and muscle relaxants (M03; Figures 7-10). The reason for the high prevalence of antihemorrhagics prescribing indicates frequent surgeries or procedures in this population [46,47]. Muscle relaxants were found to be frequently prescribed in older polypharmacy patients and coprescribed with opioids [48]. This medication was shown to increase the risk of adverse outcomes including all-cause and cardiovascular mortality, warranting enhanced monitoring of drug therapy [48]. Gastrointestinal drugs may be used for the gastric protection caused by polypharmacy or due to the decreased physiological function of the gastrointestinal system [49].

Although each institution had a distinctive pattern, we observed that drugs related to surgeries, including those needed after the operation (eg, WHO ATC second-level codes C01, H02, J01,

XSL•FO
RenderX

N01, and N02), were commonly prescribed across institutions (Figures 7-10). This reflects the trend from 2011 to 2015, where 3,146,452 of 8,497,443 (37%) surgeries were performed in patients aged 65 years or older, and the surgeries were for high-risk conditions, such as glaucoma [50]. We observed that older inpatients frequently underwent surgeries and were prescribed several drugs during admission for these procedures. The high frequency of antibacterials (WHO ATC second-level code J01), anesthetics (N01), and analgesics (N02) in all polypharmacy levels in the older population reflects the complex clinical conditions of hospitalized older patients, who often require management of infections, surgeries or procedures, and pain control [51]. This population has a high prevalence of osteoarthritis, fractures, and cancer-related pain, increasing the risk of anesthetic and analgesic use [52].

Limitations

This study has several limitations. First, we included 4 medical institutions, which restricts the generalizability of the study results to the institutions of interest. Second, drugs without a mapped WHO ATC code were excluded; therefore, the prevalence of polypharmacy might have been underestimated. Third, we analyzed the pattern of polypharmacy using the second-level ATC code; thus, polypharmacy patterns at the ingredient level were not determined. Fourth, although we examined outpatient drug prescriptions up to 7 days after discharge, polypharmacy use in older outpatients was not comprehensively analyzed. This is a topic of interest for future studies. Fifth, we did not assess the appropriateness of polypharmacy based on linking prescribed drugs and their indications. Although an estimate of the drug-indication linkage is possible, the precise linkage is challenging, as the indications for the drugs were not explicitly recorded in the OMOP CDM database. Finally, the tables used for the analyses did not include the note table, which includes clinical results or interpretations in free-text format, and is a potential resource for detecting polypharmacy.

Conclusions

Based on well-established EHR-based CDM datasets in South Korea, we suggest a polypharmacy definition for older inpatients that is different from the commonly used definition of the concurrent prescription of 5 or more drugs. This is because, based on the severity of the patients' condition and the treatment they require, which includes major surgeries, the number of concomitant drugs used was higher than the commonly used definition of polypharmacy in the majority of patients in this study. Therefore, we suggest that 10 or more drugs is a more suitable definition of polypharmacy for geriatric inpatients. As the geriatric population increases, evaluating the appropriateness of existing polypharmacy definitions and serious outcomes of polypharmacy in this population, including renal failure, falls, and fractures, is necessary for future studies.

Abstract

Background: The expanding use of multisource real-world electronic health record (EHR) and claims data offers major opportunities for research, drug discovery, and clinical decision support. While standards such as Logical Observation Identifiers Names and Codes (LOINC) can ensure semantic interoperability for laboratory observations, clinical documents, and other clinical terms, properly assigning these concepts remains a challenge. Studies show that 6% to 19% of laboratory tests cannot be accurately mapped to LOINC. Existing systems try to address this challenge but often depend on source data strings and other input features that may be absent, null, or incorrect. This underscores the need for a scalable approach to correct LOINC code assignments, standardize units, and ensure data integrity across multisource laboratory data.

Objective: This paper presents a universally applicable framework that identifies and corrects observable errors in quantitative laboratory results coded to LOINC and the Systematized Nomenclature of Medicine for the unit of measure without relying on raw source data strings. The process seeks to improve the accuracy, conformance, consistency, and completeness of laboratory data while maintaining complete provenance.

Methods: The proposed framework uses a 2-step process. First, LOINC codes are corrected using the associated unit of measure. Second, units are adjusted or populated to match a preferred unit for that LOINC code. In both steps, the quantitative result is checked against a predefined acceptable range to determine validity. The process is driven by 3 knowledge tables. The framework is applied to datasets derived from the ConcertAI database of approximately 10 million patients with cancer, evaluating improvements in LOINC code–unit conformance and unit completeness. Analyses are performed on 4 independently LOINC-coded datasets: the full ConcertAI dataset and 3 high-volume diverse subsets grouped by data source or EHR vendor.

Results: A total of 428 LOINC codes were observed across 6.34 billion records in the ConcertAI database. All 4 datasets were processed using the proposed framework. Before applying the framework, 73.1% (4,634,610,173/6,337,101,453) of records in the ConcertAI dataset had correctly assigned units based on the laboratory reasonable range table; after application, this increased to 99.7% (6,322,375,200/6,341,230,213). Similar improvements were observed across the 3 EHR-specific datasets, increasing from 78.5% (691,315,390/880,250,137) to 99.8% (879,626,472/881,157,852; source 1), 71.4% (2,132,455,936/2,985,465,124) to 99.8% (2,982,319,644/2,988,173,959; source 2), and 63.3% (2,936,710,502/4,640,432,294) to 99.6% (4,618,714,114/4,638,862,412; source 3). Unit completeness also improved substantially, increasing from 92.7% (5,879,071,858/6,341,230,213) to 99.8% (6,331,923,060/6,341,230,213) in the ConcertAI dataset and from 92.5% (814,867,241/881,157,852) to 100% (880,816,133/881,157,852), 94.4% (2,822,107,252/2,988,173,959) to 99.9% (2,986,624,027/2,988,173,959), and 91.7% (4,254,054,966/4,638,862,412) to 99.8% (4,632,935,919/4,638,862,412) in sources 1 to 3, respectively.

Conclusions: Laboratory data quality is crucial in oncology systems for therapy selection, monitoring, and disease progression assessment. This proposed solution is a first-of-its-kind, system-agnostic, and scalable normalization process that addresses key gaps in laboratory data quality across multiple dimensions.

Introduction

Background: Real-World Data in Health Care

Multisourced, comprehensive patient health data have seen a recent rise in prominence and utility in supporting research, drug discovery, pharmacovigilance, and clinical decision support [1]. These real-world data (RWD) are collected for individual patient care and reimbursement in often unconnected systems such as electronic health records (EHRs) and claims clearing houses [2]. Secondary use of RWD holds immense potential for improving health due to its volume, variety, and ubiquity [3].

The different source systems producing RWD bring individual challenges and opportunities, and it is often necessary to stitch together disparate sources to cover a complete patient journey [3]. For instance, medical claims may contain procedures and tests performed on a patient and their associated costs, but the results of those tests are only present in the EHR [4].

Data Quality and Semantic Interoperability Challenges

The path to a usable RWD dataset is fraught with challenges [2]. Errors can arise from any system or actor that generates, transmits, transforms, or persists the data during its lifetime [5]. Errors can be discernible from patterns observed in the data or can be hidden from downstream users when information is lost [6]. Information loss can result in incorrectness or missingness of variables, records, tables, or complete data sources [7]. Monitoring and minimizing information loss is a critical requirement of an RWD pipeline.

Semantic interoperability (SI), or the ability to ensure the same meaning and interpretation of data shared between systems [8], is a well-established and ongoing challenge in RWD [5]. It can manifest as redundant representations of the same concept, such as one EHR using the *International Classification of Diseases, 10th Revision, Clinical Modification*, and another using the Systematized Nomenclature of Medicine (SNOMED) to represent the same disease. Use of data standards and common ontologies can alleviate SI challenges but can also introduce errors if used incorrectly [5], which can commonly occur when a concept is assigned to a string by either a human or machine [9]. As health care data systems continue to evolve, the importance of SI is underscored by the increasing adoption of standards such as Fast Healthcare Interoperability Resources (FHIR) [10] with its associated code system bindings supported by the Food and Drug Administration, which are designed to ensure consistent data interpretation and improve interoperability across systems. Even FHIR-based representations may fall short in fully addressing semantic mismatches, particularly for complex domains such as laboratory data, in which variability in coding, units, and local conventions persists despite standardization efforts [11].

Laboratory Data and Logical Observation Identifiers Names and Codes Mapping Challenges

Laboratory result data are both valuable and particularly challenging in RWD [9]. To address SI, laboratory data primarily rely on codes from the Logical Observation Identifiers Names and Codes (LOINC) code system [12,13]. LOINC is the dominant global coding system for laboratory concepts but also extends to a broader range of clinical terms, including clinical questions and documents [12-15]. LOINC consists of concepts that have 6 attributes each. These include the analyte tested, how it is observed, the duration of observation, and the sample type that the observation is performed on [13]. Precoordinating that much information into a single concept makes it convenient for transmission by reducing the potential for misinterpretation but also makes it difficult to use when mapping to LOINC [14,15]. The complete information for LOINC mapping is rarely present in a single string, column, or record [15]. Relevant information may be spread across one or more fields in a record or laboratory information system, such as the observation's display string (eg, glucose), the data type of the result (numeric or categorical), the unit of measure (mass over volume or molarity), the associated order name or panel name (complete blood count or urinalysis), the associated sample (urine or blood), the device or equipment used to make the observation (urine dipstick or continuous glucose monitor), or other observations that occurred as part of the same panel of tests (Is the patient fasting?). Despite the abundance of resources, accurately translating these fields to the correct LOINC code remains a challenge.

This semantic and translational complexity means that laboratory results in RWD can frequently present with errors introduced during terminology binding to LOINC [16]. Prior studies have shown that LOINC codes could not be assigned for 6% to 19% of laboratory tests due to incomplete or incorrect information [17]. Systems have been proposed to reduce this error by coding via automated means in RWD [9,16,18] and clinical trial data [19]. These algorithms rely on source data strings and other input features that may be absent, null, or observably incorrect.

Unit of Measure and Normalization Challenges

The diversity of information required for LOINC mapping increases the likelihood of mapping difficulty [20] and significant information loss. If a result's unit of measure is absent or recorded in the wrong place or the associated panel name, order name, or sample type is missing from the data, it can mean insufficient information to properly assign the LOINC code [15]. Contextually appropriate filling in of absent units of measure has been shown to be effective in a system that extracts logical expressions from clinical trial inclusion criteria pertaining to quantitative laboratory results but not within RWD [21].

XSL•FO
RenderX

A laboratory result may present with a correct concept code, but it is possible to represent the same result using multiple scales (g or mg), and certain units are used interchangeably between sources (mg per day or mg per 24 hours). Unit normalization is necessary to ensure comparable results during data analysis and aggregation, and the variety of representation, the missingness, and the level of incorrectness can all lead to loss of utility of RWD. Even with a correct LOINC code, missing or inconsistent units have been shown to affect as much as 14% of laboratory records in some systems [22,23]. Mechanisms to normalize synonymous units exist, but these techniques do not handle situations in which the unit is incomplete, incorrect, or completely absent [24].

Proposed Framework and Objective: Correcting Quantitative Laboratory Results

In this paper, we present a framework to identify and correct observable errors in quantitative laboratory results that have already been coded to LOINC for the observation and SNOMED for the unit of measure without reliance on source data strings. This 2-step process first adjusts the LOINC code by using information contained in the associated unit of measure. Next, we use the quantitative result to inform whether we can safely populate a missing unit of measure or correct an erroneous unit of measure. Finally, all synonymous or related units are normalized to a single preselected unit for each LOINC code. We characterize the prevalence of these errors and then use this framework to correct laboratory results in a multisource RWD pipeline of oncology patient data from EHRs, laboratory information systems, and medical claims.

Methods

This section outlines the data collection and study design used to develop this framework.

Data Collection

Laboratory result data were extracted from the ConcertAI database, a US-based, deidentified, patient-level dataset from approximately 10 million patients with cancer aged ≥18 years during the period from 2015 to 2025. The data used in this study were sourced from EHRs, including oncology practices, hospitals, and academic medical centers. To evaluate the framework, we analyzed 4 laboratory datasets: the full ConcertAI database and 3 subsets corresponding to the individual EHR sources (represented as source 1, source 2, and source 3) that transmitted data to ConcertAI. These 3 subsets were selected because they were the top contributors of laboratory data by volume and represented a broad diversity of laboratory tests. Specifically, the ConcertAI database accounted for 6.34 billion records, source 1 included 880 million records, source 2 included 2.98 billion records, and source 3 included 4.64 billion records.

Data were contributed by multiple clinical sites and laboratories across the United States, representing a diverse group of care settings. Each dataset was standardized using LOINC codes for laboratory observations and SNOMED codes for units of measure. For records from the full ConcertAI database, LOINC codification was performed using ConcertAI's internal system; for EHR or data source–derived subsets, the LOINC codes that were delivered with those data were used. Only records with a numeric value were used in this study. All datasets used ConcertAI's unit codification that maps unit strings to SNOMED.

System Design

The laboratory correction framework was applied after standardization to LOINC and SNOMED. The laboratory correction system relies on 3 knowledge tables that have been manually created after careful examination of the ConcertAI laboratory data, as outlined below. Their role in supporting the logical framework is discussed later in this section. Below, we provide the formal definitions of these tables, including their constituent fields and primary keys. The procedures used to create each table and the column definitions are documented in Multimedia Appendix 1.

The LOINC conversion map (LCM) relates a LOINC concept and unit concept that are incongruous to a new LOINC code that is compatible with the unit of measure. The table structure incorporates the following computable fields: "old_loinc_code," "old_loinc_display," "old_loinc_system," "unit_code," "unit_display," "unit_system," "new_loinc_code," "new_loinc_display," and "new_loinc_system." The primary key for the table is defined as the composite of "old_loinc_code" and "unit_code." Examples are shown in Table 1, which has been formatted for readability. The complete computable version is available in Multimedia Appendix 1 and in the accompanying GitHub repository to support transparency and reproducibility.

Table 1. Logical Observation Identifiers Names and Codes (LOINC) conversion map.

LOINC code	Unit (SNOMED[a])	Corrected LOINC code
Platelets (#/volume) in blood (26515-7)	fL (258775009)	Platelet (entitic mean volume) in blood (28542-9)
Glucose (mass/volume) in blood (26515-7)	mEq/L (258865000)	Glucose (moles/volume) in blood (15074-8)
Glucose (mass/volume) in blood (26515-7)	mmol/L (258813002)	Glucose (moles/volume) in blood (15074-8)
Kappa light chains (mass/volume) in serum or plasma (11050-2)	Percentage (118582008)	Kappa lymphocytes/lymphocytes in blood (17096-9)

[a]SNOMED: Systematized Nomenclature of Medicine.

The reasonable range map defines metadata about a single LOINC code, including its assigned correct unit of measure, a minimum and maximum value that the laboratory test can reasonably take, and the mean and median of records with that LOINC code and unit across all 4 datasets. The correct unit of measure for each LOINC code was determined using the

XSL•FO
RenderX

"example_unit" supplied in the official LOINC distribution. These units were mapped to the corresponding SNOMED codes. For LOINC codes that listed more than one example unit, we examined the empirical distribution of units observed in our dataset and selected the unit with the highest frequency. This made the choice of the correct unit data driven and ensured that the process could be consistently reproduced in any system. If Unified Code for Units of Measure (UCUM) units are preferred, LOINC also provides "example_ucum_units," which can be incorporated similarly. Minimum and maximum reasonable values for each LOINC code were defined by estimating the empirical distribution of the data through quantiles of 0.005, 0.025, 0.16, 0.5 (median), 0.84, 0.975, and 0.995. The range was set at or near the highest and lowest of those quantiles, providing broad yet data-anchored thresholds for plausibility checking.

This knowledge table includes the following computable fields: "loinc_code, loinc_name," "unit_code," "unit_name," "min_reasonable," "max_reasonable," "mean," and "median." The primary key for this table is the "loinc_code." A readability-optimized version is shown in Table 2, whereas the complete computable version is provided in Multimedia Appendix 1 and the GitHub repository.

Table 2. Reasonable range map.

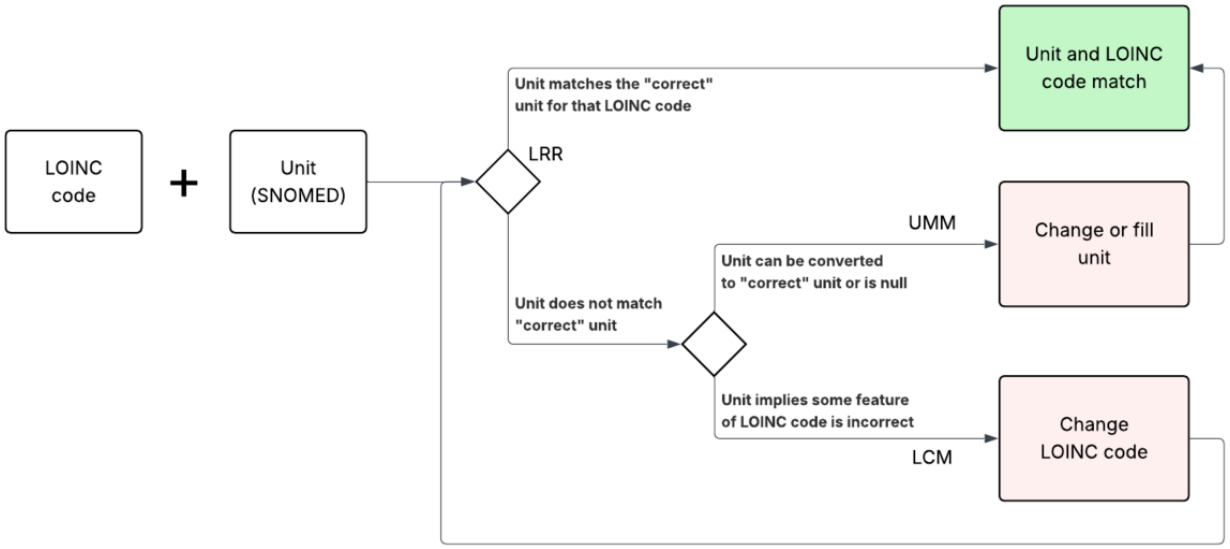
LOINC[a] code	Unit (SNOMED[b])	Reasonable range	Median	Mean
Platelets (#/volume) in blood (26515-7)	×10(3)/mcL (1287856009)	1-800	223.5	215.0
Glucose (mass/volume) in blood (2339-0)	mg/dL (258797006)	40-400	138.8	121
Kappa light chains (mass/volume) in serum or plasma (11050-2)	mg/L (258796002)	0.1-5000	68.7	25.9

[a]LOINC: Logical Observation Identifiers Names and Codes.

[b]SNOMED: Systematized Nomenclature of Medicine.

The unit multiplier map relates a correct unit to a synonymous, convertible, or incorrect unit along with a multiplier value, an additive scalar value, and a description of the relationship between the 2 units (eg, incorrect, synonym, or convertible). The scalar value is only used for temperature conversions. An empty "incorrect unit" represents a null unit field and is used to populate absent units. This knowledge table includes the following computable fields: "incorrect_unit_code," "incorrect_unit_name," "correct_unit_code," "correct_unit_name," "multiplier," "scalar_constant," and "multiplier_type." The primary key is the composite of "incorrect_unit_code," "correct_unit_code," and "multiplier_type." A readability-optimized version is shown in Table 3, with the full computable version available in Multimedia Appendix 1 and the GitHub repository.

Table 3. Unit multiplier map.



Incorrect unit (SNOMED[a])	Correct unit (SNOMED)	Multiplier	Scalar	Multiplier type (description)
<null>	×10(3)/mcL (1287856009)	1	0	"nullfill" (unit absent)
10*9/L (277288007)	×10(3)/mcL (1287856009)	1	0	"synonym"
cells/µL (258878000)	×10(3)/mcL (1287856009)	0.001	0	"unit_conversion" (convertible unit)
cells/µL (258878000)	×10(3)/mcL (1287856009)	1	0	"unit_typo" (known unit error)
g/dL (258795003)	mg/dL (258797006)	1000	0	"unit_conversion" (convertible unit)
g/dL (258795003)	mg/dL (258797006)	1	0	"unit_typo" (known unit error)
g/L (258794004)	mg/dL (258797006)	1	0	"unit_conversion" (convertible unit)

[a]SNOMED: Systematized Nomenclature of Medicine.

The framework logic is shown in Figure 1. Conformance to the selected "correct" unit is checked against the laboratory reasonable range (LRR) table entry. If the unit does not conform, the LCM provides a better LOINC code if one is known for the unit that is present in the record. In the second transformation, the unit is altered according to the unit multiplier map, normalized if it is a synonym, converted using a multiplier value, or swapped for the correct unit if it is a known error pattern or absent altogether. For example, the LOINC code 1920-8 (glucose [mass/volume] in blood) has the correct unit "mg/dL." If a record with this LOINC code has the unit "mmol/L," the LOINC code is changed using the LCM to 15074-8 (glucose [moles/volume] in blood). The process is only 2 steps, although not all records require both. Records may begin with LOINC code–unit conformance and skip the process altogether. Some require only LOINC conversion, some require only unit normalization, and many require LOINC conversion and then unit normalization.

XSL•FO
RenderX

Figure 1. Framework logic and knowledge table use. LCM: Logical Observation Identifiers Names and Codes (LOINC) conversion map; LRR: laboratory reasonable range; SNOMED: Systematized Nomenclature of Medicine; UMM: unit multiplier map.

Each of these transformations only proceeds when the record's result value falls within the reasonable range associated with the LOINC code–unit pair that would appear in the transformed record. These ranges were selected using known correct data and designed to capture most possible values in that laboratory's value distribution.

In rare instances, the system must select between 2 possible transformations for the same record. This might occur in the situation visible in rows 5 and 6 in Table 3 when trying to convert from g/dL to mg/dL. We identified a common error in many records in which a unit's prefix was absent. A g/dL unit might be a simple data entry error at the source, or it may, in fact, require conversion by multiplying the result by 1000. The system uses the reasonable ranges to determine which of these 2 situations is more likely. If the reasonable ranges are not disparate enough to discern which transformation is required, proximity to the median of the target LOINC code–unit's distribution is compared. The transformation resulting in a record closer to that median is selected. If the compared laboratory results have medians of 0, distance from the mean is used.

To evaluate the success of each transformation, the value distribution of the output for any individual transformation was compared with the value distribution of known correct data with that LOINC code–unit pair. If the distribution of the numeric result of the transformed data matched that of known correct data, it was considered successful. If the distribution did not match, the discrepancy was investigated. These investigations led to the discovery of common error patterns that could then be accounted for in the next iteration by adding to the 3 knowledge tables.

To summarize, the precedence of the rules described above is as follows:

1. LRR conformance check—if the LOINC code–unit pair conforms to the LRR table, no transformation is applied.
2. LOINC conversion (LCM)—if the unit is incompatible with the LOINC code, the framework first selects the appropriate LOINC code.
3. Unit normalization or conversion (unit multiplier map)—after the LOINC code is finalized, unit normalization or conversion is applied.
4. Range validation—a transformation is only accepted if the resulting value falls within the target LOINC code's reasonable range.
5. Conflict resolution—when more than one unit transformation falls within the reasonable range, the system resolves this by checking proximity to the median of the known correct distribution or proximity to the mean when the distribution median is 0.

A few examples of LOINC code–unit incongruencies and framework processing are outlined in Multimedia Appendix 1.

Provenance is maintained within each transformed record in an attribute that acts as a ledger of each transformation that alters that record. This attribute is an array of objects that includes a descriptive string that details what features of the record were adjusted and what features were used to justify that adjustment for human readability. For computability, "object" includes the adjusted attribute names and preadjustment values for those attributes, ensuring transparency to downstream users and reversibility if necessary.

A summary of the steps for this framework is illustrated in Figure 2.

Figure 3 shows an example of LOINC code–unit pairs before transformation, each step of the transformation, and the final output after transformation.

Ethical Considerations

This study used retrospective, deidentified data collected for clinical purposes. All data were fully anonymized before analysis, and unique patient identifiers were removed. Analysis of deidentified secondary data does not constitute human subjects research and does not require formal review or approval by an institutional review board, and thus, no institutional review board approval number was sought. Because only deidentified data were used, informed consent from individual patients was not required. Privacy and confidentiality were maintained throughout the study in accordance with all applicable regulations.

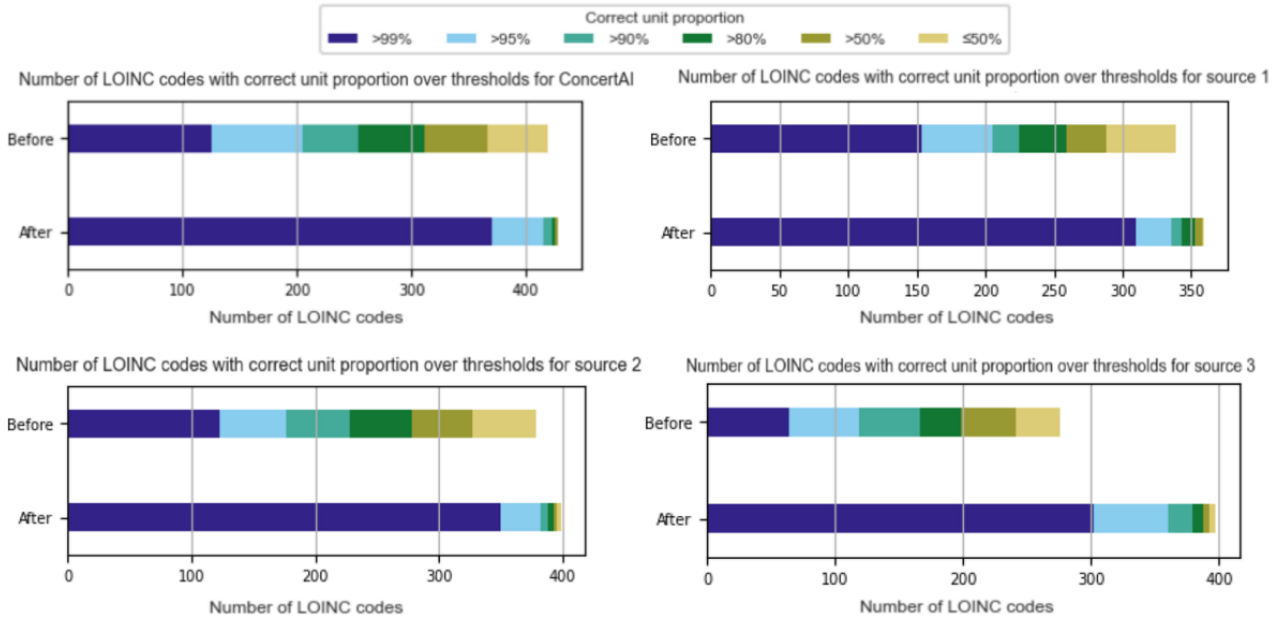
Results

Dataset Collection: Overview and LOINC Coverage

All 4 sets of laboratory data underwent the LOINC code and unit correction process, and the proportion of records exhibiting each LOINC code–unit pattern was calculated both before and after the framework execution. A total of 428 LOINC codes were included in this study, chosen based on their prevalence in the ConcertAI database. Not all datasets contained all 428 LOINC codes. These LOINC codes accounted for 6.34 billion records in the ConcertAI database and 880 million, 2.98 billion, and 4.64 billion records in the source-specific datasets from sources 1, 2, and 3, respectively.

System Design

Impact of Framework on Unit Correction



Before the application of the framework, 73.1% (4,634,610,173/6,337,101,453) records in the ConcertAI dataset with these LOINC codes had the correct unit as assigned by the LRR table. Following the application, this increased to 99.7% (6,322,375,200/6,341,230,213) of records. A similar trend was observed in each of the EHR-specific datasets: 78.5% (691,315,390/880,250,137) to 99.8% (879,626,472/881,157,852), 71.4% (2,132,455,936/2,985,465,124) to 99.8% (2,982,319,644/2,988,173,959), and 63.3% (2,936,710,502/4,640,432,294) to 99.6% (4,618,714,114/4,638,862,412) for sources 1, 2, and 3, respectively. The system increased the completion rate of units, defined as the proportion of records with nonmissing units, from 92.7% (5,879,071,858/6,341,230,213) to 99.8% (6,331,923,060/6,341,230,213) in the ConcertAI dataset and similarly in the other 3 datasets: 92.5% (814,867,241/881,157,852) to 100.0% (880,816,133/881,157,852), 94.4% (2,822,107,252/2,988,173,959) to 99.9% (2,986,624,027/2,988,173,959), and 91.7% (4,254,054,966/4,638,862,412) to 99.9% (4,632,935,919/4,638,862,412) for sources 1, 2, and 3, respectively. Because the framework assigns validated units to previously missing values, improvements in the correct unit rate reflect both corrections to misassigned units and the assignment of correct units to previously missing entries. As a result, the correct unit and completion rate metrics are related but not redundant: the correct unit rate captures accuracy among all populated units, whereas the completion rate captures overall presence of any unit.

LOINC-Level Quality Threshold

Not all LOINC codes start with the same degree of incorrectness. To evaluate the proportion of LOINC codes that reached specific data quality thresholds before and after framework application, records with each LOINC code were evaluated for unit correctness, and the number of LOINC codes passing certain unit correctness proportion thresholds was counted. These counts for each dataset are shown in Figure 4. Of the 428 LOINC codes, the number meeting the 99% threshold of unit correctness in the full ConcertAI dataset increased from 125 (29.2%) to 370 (86.4%). Similar improvements were observed across the 3 source datasets, which contained different total proportions of evaluated LOINC codes: 83.9% (359/428) of LOINC codes in source 1, a total of 93.2% (399/428) of LOINC codes in source 2, and 88.6% (379/428) of LOINC codes in source 3. In source 1, the proportion meeting the 99% threshold increased from 42.9% (154/359) to 86.4% (310/359); in source 2, it increased from 30.8% (123/399) to 87.7% (350/399); and in source 3, it increased from 16.9% (64/379) to 79.7% (302/379).

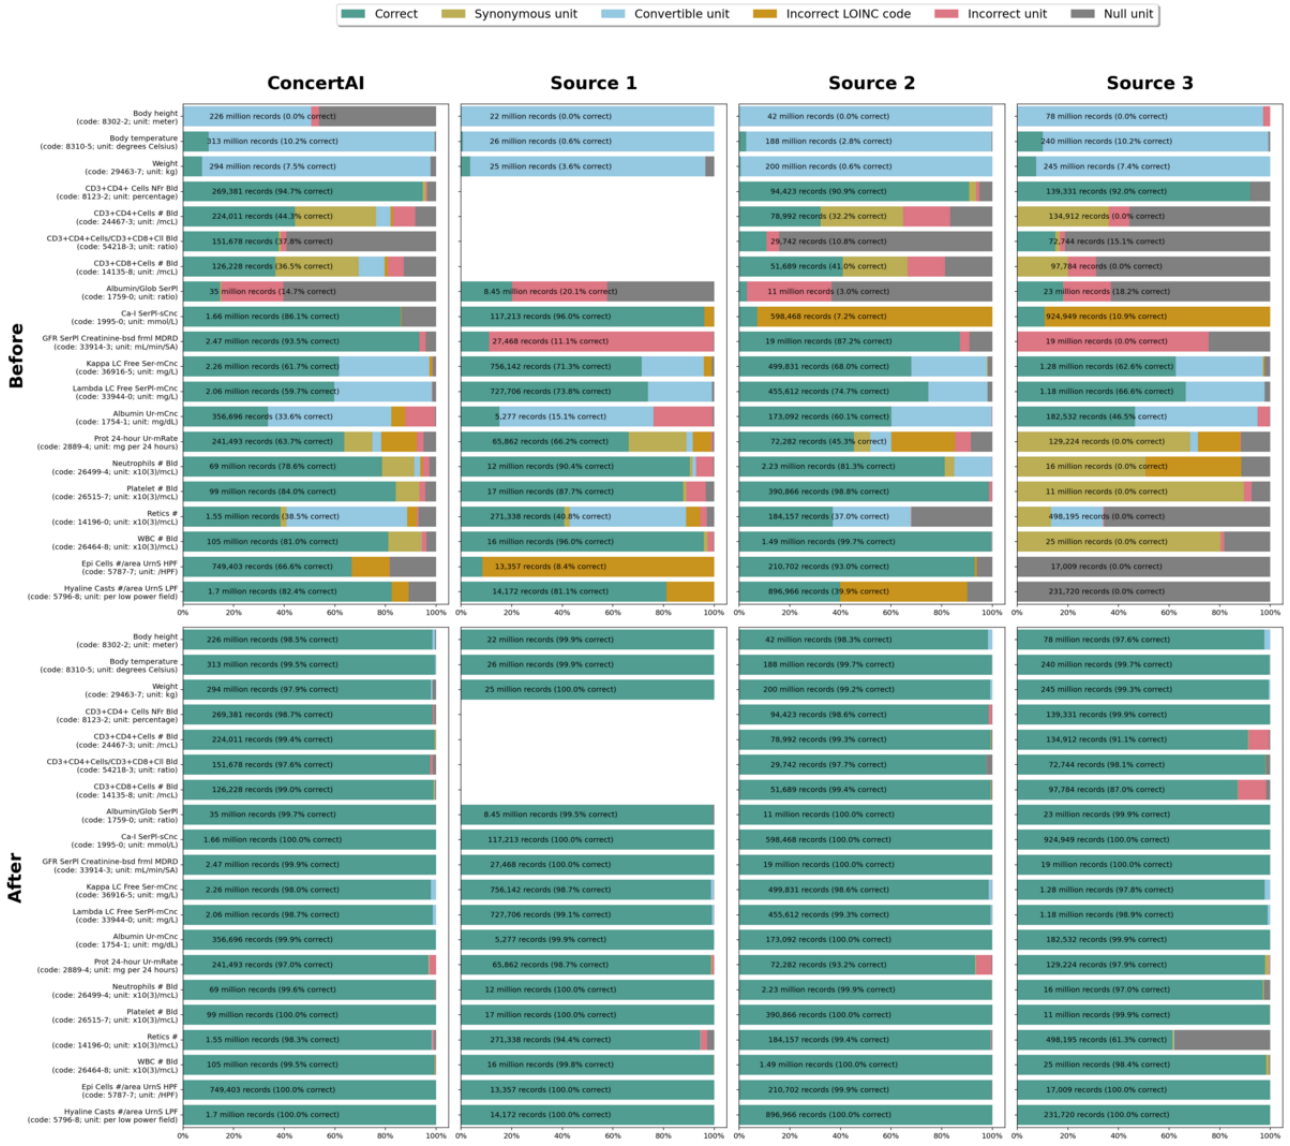
Figure 4. Number of Logical Observation Identifiers Names and Codes (LOINC)–coded records meeting unit correctness thresholds.

Illustrative Subset Analysis



To provide a more detailed view of the framework's impact, Figure 5 presents a closer look at 20 specific LOINC codes. These codes were selected for their varied domains and types of incongruencies in the starting data.

Records with each of these 20 LOINC codes had their unit classified as correct, synonymous to correct, absent, or incorrect. Incorrect units were subclassified as incorrect and suggestive of a LOINC change, incorrect but convertible to the correct unit through a multiplier, or incorrect but not convertible. These unit categories represent the types of errors that this system is designed to correct. The proportions in each category were calculated before and after the framework application and are shown in Figure 5 for each system.

A detailed report showing the proportion of correctness for each LOINC code across all 4 datasets before and after the framework application is available in Multimedia Appendix 2.

Discussion

Principal Findings

The proposed normalization framework significantly improved LOINC code–unit congruence and unit absentia across all evaluated datasets, demonstrating generalizability to any clinical data system using standard medical terminologies for observation and unit representation. The method improved LOINC code–unit congruence overall in the ConcertAI laboratory dataset from 73.1% (4,634,610,173/6,337,101,453) to 99.7% (6,322,375,200/6,341,230,213), with similar trends in the other 3 data sources. The method and knowledge tables were developed using the ConcertAI data and applied to these independent datasets to demonstrate generalizability. To the best of our knowledge, this framework is the first of its kind to address 2 key gaps: the absence of a system-agnostic process for cleaning multisource laboratory data for secondary use [18] and an approach tailored to RWD. RWD, where data quality is both challenging [25] and critical to data usability, may lack source-specific semantics such as the local observation concept display name. This would impede the use of a standardization process designed to take advantage of those strings [18].

Mechanism of Framework

The process, driven by 3 small, shareable knowledge tables, uses the observation concept (LOINC), the unit concept (SNOMED), and the numeric result as input. It first adjusts the LOINC code if the unit suggests a better LOINC code. It then normalizes the unit to a predetermined preferred unit for that LOINC code by filling null units, converting related units, or correcting units with overt errors. All transformations only proceed when the numeric result aligns with the predetermined distribution for the target LOINC code–unit pair. This “reasonable range” constraint addresses a shortcoming in existing proposed methodologies [19,21] that handle units without consideration of the numeric result. This range can be used to flag records that fall outside the reasonable distribution for exclusion from analysis or closer review.

XSL•FO
RenderX

Impact on Data Quality Dimensions

Ensuring that laboratory values fall within a reasonable distribution contributes to accuracy, or the degree to which the data represent the true value of what is intended to be measured, and plausibility, 2 prominent dimensions [25] of RWD quality. The results demonstrate improvements across a number of established quality dimensions [25] other than accuracy and plausibility, including conformance, consistency, completeness, and provenance [25-29]. The technique primarily addresses conformance to the approved LOINC code–unit pair set by the LRR table and consistency of semantic representation regardless of data source. Completeness is improved by populating the unit when null. This contextually appropriate population of absent units has not been addressed in prior studies of similar techniques [19,21].

Data Provenance

Data provenance is recognized as critical metadata for systems transmitting, storing, or using health data [30]. Records in RWD pipelines may undergo many transformations on their path to integration into a single dataset, and these transformations must all be tracked to enable error correction and improve trustworthiness with downstream consumers. Data provenance has been defined in many ways [31], and there are established specifications for recording provenance in health care data, such as the FHIR Provenance resource [32] based on the World Wide Web Consortium provenance specification [33]. Establishing the best method for provenance tracking within a system requires an assessment of the stakeholders for those data. The stakeholders for the transformations described in this paper were internal data analysts, informaticists, and quality assurance engineers. Provenance is maintained within each transformed record in an attribute that acts as a ledger of each transformation that altered that record. This attribute is an array of structures that include a descriptive, human-readable string detailing the transformation, as well as the altered attributes and preadjustment values that those attributes took. By consulting this array, transformations are fully reversible, original values are preserved, and a complete audit trail is available to support transparency and verification by downstream users.

Clinical and Research Relevance

Laboratory data quality and usability are critical in systems handling oncology data, where these results are used to select and monitor therapies and assess disease severity and progression [34]. LOINC code–unit incongruence, unit absentia, and lack of unit standardization put an undue burden on any analyst or application attempting to use laboratory data for clinical decision support, retrospective studies, or clinical trial eligibility [35,36]. Improving unit completeness at the source is challenging because units are often inconsistently documented or transmitted in EHR systems [37,38]. Potential upstream improvements could include enforcing unit capture at the point of entry, not allowing free-text entry of units, ensuring consistent transmission in Health Level Seven and FHIR messages, or applying unit standardization at the health system level before data export. However, such approaches depend on local workflows and vendor configurations and cannot be guaranteed for multisource RWD. Consequently, postcodification harmonization frameworks such as the one described in this paper provide a practical and reproducible solution. The technique outlined in this paper presents a minimal set of logical steps to correct these problems within the pipeline of a multisourced data system handling RWD. Enforcing semantic consistency between LOINC and unit improves data usability [24] but can also foster better data exchange [39] between systems by reducing semantic differences. Ultimately, this framework ensures that laboratory data are both accurate and complete, enabling faster data-driven decisions that can enhance patient care, data exchange, clinical trials, and RWD analysis.

Limitations and Future Work

The technique is presently limited by its capacity to correct the body system, which will reduce effectiveness for laboratory tests in which the potential body systems are relatively evenly distributed and share similar units when tested in either sample type. Information related to the body system can be present in the observation name but also in the panel name, the order name, discretely in another attribute in the laboratory result, or in other observations related to the result in question. Efforts are currently underway to evolve the process by incorporating panel or order-related information. The choice of SNOMED for unit may have been less ideal than UCUM [40,41], which is more flexible and more closely aligned with LOINC [42], which suggests a UCUM unit for some of its concepts. The FHIR [43] and Interoperability Standards Platform [44] also suggest that UCUM be used to represent units. However, the framework is easily adaptable by simply replacing the SNOMED codes used in the knowledge tables with UCUM codes without requiring any further changes in script. In addition, the steps described in this paper specifically address quantitative LOINC codes and require modification to be applicable to qualitative scale–type LOINC codes. Another limitation is that the creation of the knowledge tables requires clinical and terminologist expertise to recognize errors and prepare the tables, as well as a large dataset to prepare laboratory value distributions. This framework is designed for secondary use in RWD, where inconsistencies, missing values, and heterogeneous coding practices complicate analysis, and is not intended for integration into direct point-of-care clinical decision-making. Therefore, its use does not pose any direct safety risk to patients. The harmonization of LOINC code–unit combinations and the potential flagging of outlier values can influence downstream analyses such as cohort definitions or outlier detection. It enables data analysts to use laboratory data that would otherwise have required a significant time investment to clean. The primary aim of these corrections is to reduce inconsistencies and facilitate reliable data aggregation for secondary research purposes. Future work will focus on integrating the framework with emerging technologies such as artificial intelligence.

Practical Implementation

To support practical implementation, we have released a starter kit supporting normalization of 146 LOINC codes from blood or serum, covering the “Hematology and cell counts” class and “Chemistry” glucose codes. It has 3 knowledge tables and an accompanying Python script available via a public GitHub repository [45]. The knowledge tables incorporate LOINC and

XSL•FO
RenderX

SNOMED, which are maintained in multiple languages, allowing the tables to be used with datasets in different linguistic contexts. The numeric values in the tables are language independent and do not require conversion, supporting their generalizability to different languages. The Python script executing the rules takes FHIR Observation resources as input, and 6 example resources are provided.

Currently, the framework leverages SNOMED codes for units. However, the design is adaptable: implementers preferring UCUM codes can replace SNOMED codes with UCUM codes in the tables without any modification to the transformation script, allowing for seamless adoption of alternative unit standards. This flexibility ensures that the framework can be applied in diverse institutional or research contexts with minimal overhead.

A key component of the framework is its structured provenance tracking, which records all transformations applied to each laboratory record in a way that allows the original data to be reconstructed if needed. For each modification, information such as the applied rule, details of the transformation, which fields were changed, the original values, and the reference values used in the conversion is systematically captured. Collectively, these elements enable full traceability, providing a clear lineage from the transformed value back to the original measurement. This approach not only supports reproducibility and auditing but also ensures transparency, allowing researchers and data analysts to confidently interpret and validate the standardized data while retaining the ability to recover the source information.

By combining reproducible tables, adaptable unit standards, and robust provenance tracking, the framework provides a practical pathway for implementing consistent laboratory data harmonization in diverse settings while maintaining the transparency and traceability of each transformation.

Conclusions

As the demand for multisourced RWD datasets grows, ensuring data quality and semantic consistency becomes increasingly vital. Persistent challenges regarding SI in laboratory data continue to limit the full potential of these data assets. Common issues include missing or incorrect units and misassigned LOINC codes, all of which can hinder integration and analysis. This framework addresses these challenges by systematically identifying and correcting discrepancies in quantitative laboratory data and has been shown to improve unit accuracy to above 99% for all evaluated datasets. It enables scalable, system-agnostic normalization of laboratory data, addressing critical gaps in several data quality dimensions. By improving laboratory data quality at the foundational level, it strengthens the reliability of RWD for data analysis, insight generation, and utility in software applications.

Acknowledgments

The authors would like to express their sincere gratitude to the ConcertAI reviewers Sheenu Chandwani, Jannette Hanna, Jennifer Rider, and Jocelyn Benson for their constructive feedback and insightful comments, which greatly enhanced the quality of this paper.

Funding

ConcertAI, LLC, sponsored this study and provided financial support for the conduct of this research and preparation of this paper.

Data Availability

The datasets generated or analyzed during this study are not publicly available due to proprietary and licensing restrictions but may be available from ConcertAI, LLC, upon reasonable request and subject to applicable data use agreements and approval processes [46].

Abstract

Background: Inflammation plays a pivotal role in the progression of diabetes and its cardiovascular complications, particularly acute myocardial infarction (AMI). Patients with AMI often face high mortality and morbidity, making accurate prognosis crucial for clinical decision-making and outcome improvement.

Objective: This study aims to develop and validate a stacked predictive model using inflammation-related indices to predict 3-year all-cause mortality among patients with severe diabetes who experience acute myocardial infarction (AMI), aiming to improve patient prognosis.

Methods: We included 833 patients with severe diabetes combined with AMI from the Medical Information Mart for Intensive Care IV (MIMIC-IV) database (training/test cohort) and 166 cases from Zhongnan Hospital, China (external validation cohort with 3-year follow-up). A total of 5 inflammation-related indices (lymphocyte-to-monocyte ratio [LMR], neutrophil-to-lymphocyte ratio [NLR], neutrophil-to-platelet ratio [NPR], platelet-to-lymphocyte ratio [PLR], prognostic inflammatory value [PIV]) were analyzed for their association with mortality using Cox proportional hazards models. Kaplan-Meier curves and restricted cubic spline analysis explored survival probabilities and dose-response relationships. A stacked predictive model incorporating these indices was constructed, and its performance was evaluated using the area under the curve.

Results: LMR was a protective factor (hazard ratio [HR] 0.44, 95% CI 0.25-0.77; *P*<.001), while NLR (HR 1.78, 95% CI 1.19-2.65; *P*=.004) and PIV (HR 1.59, 95% CI 1.09-2.30; *P*=.01) were associated with increased mortality risk. Kaplan-Meier analysis showed mortality increased with decreasing LMR quartiles and increasing NLR, NPR, PLR, and PIV quartiles. Restricted cubic spline confirmed that decreasing LMR and increasing NLR, NPR, PLR, and PIV were associated with higher adverse event risk. The predictive model achieved an area under the curve of 0.803 (95% CI 0.736-0.871) in internal testing and 0.781 (95% CI 0.704-0.858) in the external validation cohort.

Conclusions: The stacked predictive model serves as a robust tool for predicting 3-year outcomes in patients with diabetes combined with AMI. Its reliance on routine, low-cost indices highlights its economic viability and potential for widespread clinical implementation, particularly for optimizing resource allocation in resource-limited settings. However, considering the single-center nature of the derivation data, future multicenter validation is essential to verify the model's generalizability across different health care systems before establishing it as a standard policy for risk stratification.

Introduction

Diabetes and its complications represent a growing global health challenge, affecting an increasing number of individuals worldwide. According to the International Diabetes Federation, an estimated 537 million individuals were living with diabetes in 2021, and this number is projected to 1.31 billion by 2050, underscoring the urgent need for effective prevention and management strategies [1].

Type 2 diabetes is characterized by systemic inflammation, driven by complex crosstalk between immune cells and β-cells, which plays a pivotal role in disease progression [2]. Importantly, inflammation not only contributes to the pathogenesis of diabetes itself but also plays a critical role in the development of its complications, including cardiovascular diseases (CVDs) such as atherosclerosis and acute myocardial infarction (AMI) [3-5].

CVD remains one of the leading causes of mortality in patients with diabetes, with AMI being one of the most devastating complications [6]. Patients with diabetes not only exhibit a higher incidence of AMI but also experience worse prognoses compared to individuals without diabetes [7]. Hyperglycemia has been implicated in these outcomes by promoting oxidative stress, endothelial dysfunction, and proinflammatory processes, including M1 macrophage polarization and enhanced monocyte adhesion to activated endothelial cells [8]. These inflammatory changes disrupt vascular homeostasis and contribute to microvascular damage [8]. Long-term prognosis in high-risk patients with diabetes combined with AMI plays a critical role in guiding clinical decision-making and improving outcomes. Prognostic studies provide valuable tools for identifying high-risk patients, enabling timely and targeted interventions to reduce mortality and improve survival rates.

Given the pivotal role of inflammation in both diabetes and AMI, there is growing interest in inflammatory markers as prognostic tools. Markers such as the lymphocyte-to-monocyte ratio (LMR), neutrophil-to-platelet ratio (NPR), platelet-to-lymphocyte ratio (PLR), neutrophil-to-lymphocyte ratio (NLR), and prognostic inflammatory value (PIV) have been widely used to reflect systemic inflammation and predict outcomes in CVDs and cancers [9-12]. Importantly, these indices derived from complete blood count (CBC) inherit its advantages of being stable, cost-effective, and widely accessible, making them potentially applicable for routine clinical use and large-scale prognostic studies. However, whether these inflammatory markers could be used for predicting clinical outcomes of patients with diabetes combined with AMI remains unclear. To address this gap, we leveraged data from the Medical Information Mart for Intensive Care IV (MIMIC-IV) database and the Department of Critical Care Medicine, Zhongnan Hospital of Wuhan University, China, to systematically compare and evaluate the prognostic utility of LMR, NPR, PLR, NLR, and PIV in predicting long-term mortality risk and clinical outcomes in this vulnerable population.

Methods

Ethical Considerations

This study adheres to the principles declared in the Declaration of Helsinki and STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guidelines and was approved by the Medical Ethics Committee of Zhongnan Hospital of Wuhan University (approval: 2020009). The Institutional Review Board of Beth Israel Deaconess Medical Center (BIDMC) granted a waiver of informed consent and approved the sharing of research resources. The authors obtained access to the MIMIC-IV database (certificate number: 65461627).

Source of Data

This study conducted a retrospective analysis using the large, publicly available intensive care database MIMIC-IV (version 3.0).

For external validation, data were obtained from Zhongnan Hospital of Wuhan University, China. This cohort included 166 patients admitted between January 1, 2021, and June 30, 2022. The final follow-up for outcome ascertainment was completed on July 22, 2025, by hospital record review and telephone interviews. During this period, 56 mortality events were recorded.

Case Inclusion and Exclusion Criteria

Patients diagnosed with both diabetes and AMI were included in this study. Patient identification was based on diagnostic codes from the *ICD-9* (*International Classification of Diseases, Ninth Revision*), and the *ICD-10* (*International Statistical Classification of Diseases, Tenth Revision*). AMI and diabetes mellitus were identified using *ICD-9* and *ICD-10* codes.

The exclusion criteria were as follows: (1) age <18 years; (2) an intensive care unit (ICU) stay of <24 hours; (3) multiple admissions, with only data from the first hospitalization included; and (4) missing data on lymphocyte, monocyte, neutrophil, or platelet count levels.

Data Extraction

The *psql* tool of PostgreSQL was used to extract the data. Laboratory variables were extracted from the first result recorded within 24 hours of ICU admission. Features with a missing data rate exceeding 30% were excluded, while multiple imputation was applied to those with a missing data rate below 30%. Missing data were handled using multiple imputation by chained equations. We used the predictive mean matching method with 5 imputations (m=5) and set the random seed to 1 for reproducibility. All predictor variables were included in the imputation model.

The LMR was calculated as lymphocyte count (10^9/L) / monocyte count (10^9/L), NPR as neutrophil count (10^9/L) / platelet count (10^9/L), the PLR as platelet count (10^9/L) / lymphocyte count (10^9/L), the NLR as neutrophil count (10^9/L) / lymphocyte count (10^9/L), and the PIV as lymphocyte count

XSL•FO
RenderX

(10^9/L) × platelet count (10^9/L) × monocyte count (10^9/L)/ lymphocyte count (10^9/L) [10-12].

Time-Zero Alignment

All predictor variables (including CBC components and inflammatory indices) were extracted as the first recorded value on admission to prevent any look-ahead bias. To ensure transportability, this identical protocol—using the admission baseline—was applied to the external validation cohort.

Outcomes

The start date of follow-up was defined as the date of hospital admission, and the study outcome was 3-year mortality.

Statistical Analysis

As this study is a retrospective analysis, sample size calculations were not performed. For categorical variables, the chi-square test or Fisher exact test was performed for analysis. Student 2-tailed *t* test and the Wilcoxon rank-sum test were used for continuous variables. Kaplan-Meier (K-M) curves and Cox proportional hazards models were used to determine the relationships between LMR, NPR, PLR, NLR, PIV, and the risk of mortality. In Model 1, adjustments were made for age, gender, BMI. In Model 2, further adjustments were made for age, gender, BMI, troponin T, creatine kinase isoenzymes (CK-MB), insulin, history of revascularization (percutaneous coronary intervention and coronary artery bypass grafting), hyperlipidemia, atrial fibrillation, and stroke. Subgroup analysis was performed to examine the relationship between the continuous inflammation index and 3-year mortality across different subgroups. Restricted cubic spline (RCS) analysis was conducted to explore the associations between the 5 indices and mortality in a dose–response manner.

Feature Selection

The variance inflation factor (VIF) was used to assess multicollinearity among features. Features with a VIF greater than 5 were removed due to concerns about multicollinearity (Table S1 in Multimedia Appendix 1).

To identify the most important features associated with prognosis, the Boruta (version 9.0.0; R packages) algorithm was used. As a robust feature selection method, Boruta identifies all relevant predictors by iteratively comparing the importance of real features with random shadow features. Features marked as important (green) were selected for subsequent machine learning model construction.

Construction and Validation of Predictive Models

To construct the predictive model, the important features were identified using the Boruta algorithm. Subsequently, the dataset was randomly split into a training set (666/833, 80%) and a testing set (176/833, 20%) with a fixed random seed of 123. Machine learning models were then developed using the H2O AutoML platform (version 3.44.0.3) in R (R Foundation for Statistical Computing). The AutoML process was configured with the following hyperparameters: maximum number of models = 200, maximum runtime = 24 hours, and class balancing enabled (balance_classes = TRUE) to address outcome imbalance. Finally, models were ranked based on the area under the curve (AUC), and a stacked ensemble model was generated using the top-performing base models.

Each base model was trained on prognostic outcomes derived from the training data, and prognostic scores for each patient were calculated and scaled to a range of 0 to 1, with higher scores indicated worse prognosis. An ensemble method was then applied by compiling the top 5 base models, ranked according to their area under the receiver operating characteristic curve, into a matrix of prognostic scores. A second-layer generalized linear model algorithm was then used to create the final model. Five-fold cross-validation was performed during model training to minimize overfitting and ensure the robustness of the results. A probability threshold of .5 was used to classify patients into high- and low-risk groups for the confusion matrix analysis.

Here, 5 inflammation-related indices—LMR, NPR, PLR, NLR, and PIV—were also selected as features for model construction. Separate models were built for each individual feature following the methodology described above. Additionally, a stacked ensemble model incorporating all 5 indices was constructed to explore their combined predictive performance.

Results

Baseline Characteristics

Following the inclusion and exclusion criteria, 833 patients with diabetes combined with AMI from the MIMIC-IV database were used as the training and test cohorts, and 166 cases from Zhongnan Hospital of Wuhan University, China, were enrolled as an external validation cohort. Figure 1 illustrates the flow of patient selection for this study.

XSL•FO
RenderX

Figure 1. Patient screening and feature selection. Inclusion and exclusion criteria for patients from the Medical Information Mart for Intensive Care IV (MIMIC-IV) database. AMI: acute myocardial infarction; ICU: intensive care unit.

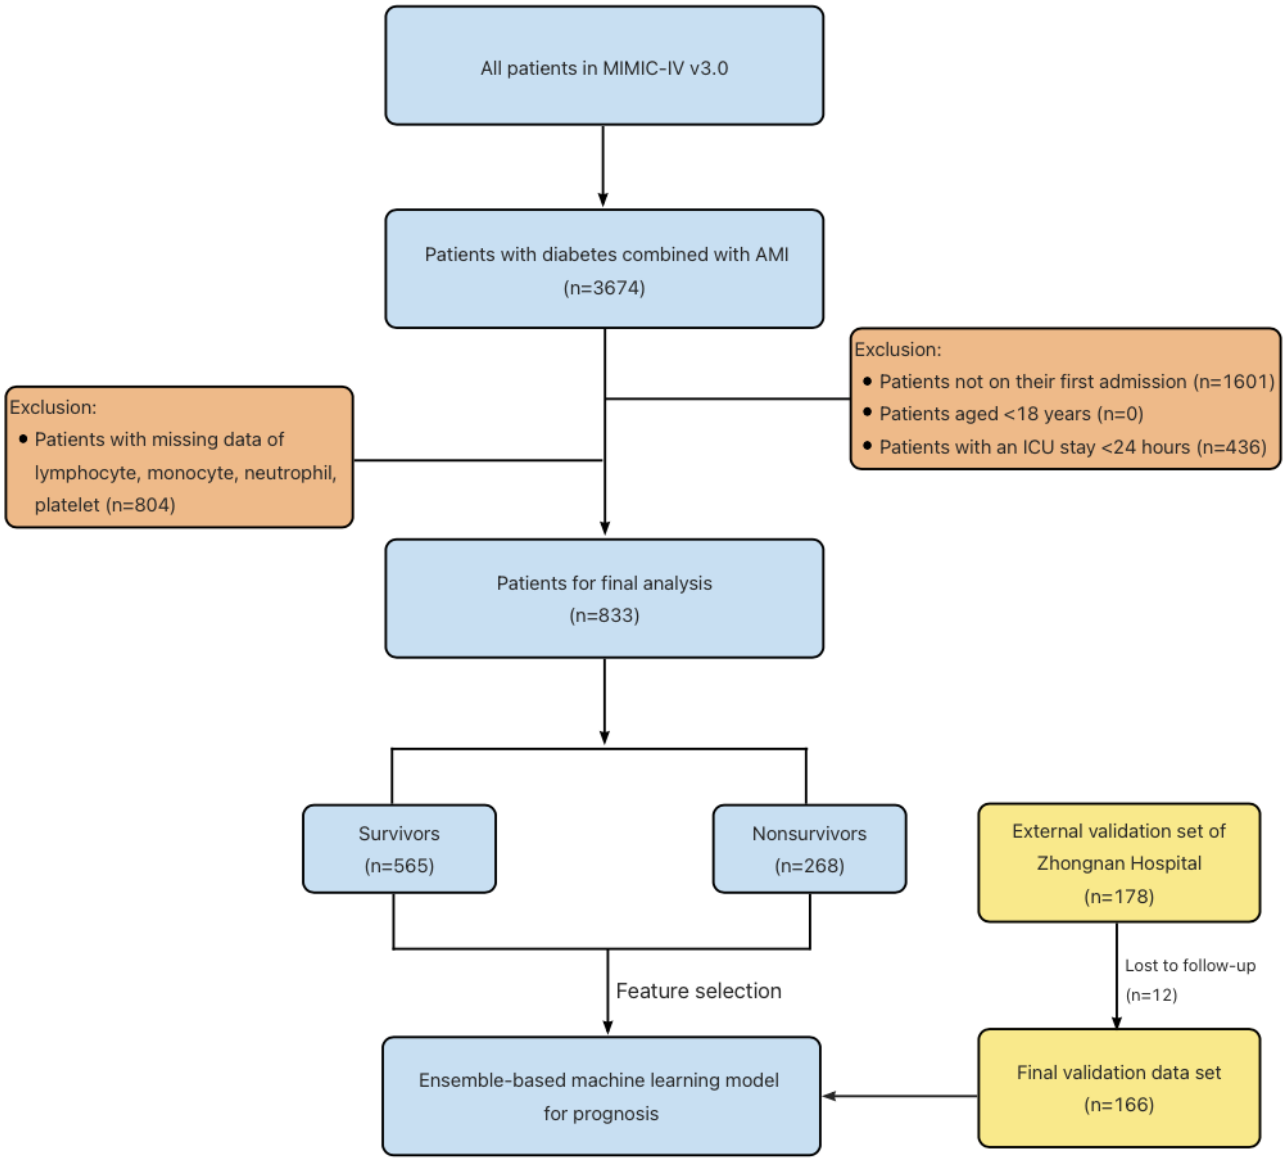

Table 1 provides a detailed comparison of baseline characteristics between survivors and nonsurvivors in the MIMIC-IV cohort (n=833), based on the 3-year mortality outcomes. Overall, the nonsurvivors were older and had a lower proportion of males compared with survivors. Among the comorbidities, the nonsurvivors exhibited significantly higher incidences of stroke, atrial fibrillation, and heart failure. Notably, the proportion of patients undergoing coronary artery bypass grafting was significantly lower in the nonsurvivor group. The nonsurvivors also exhibited significant differences in vital signs, including higher heart rate and respiratory rate, as well as higher diastolic blood pressure. As for laboratory parameters, the nonsurvivors had markedly elevated levels of mean corpuscular volume, red cell distribution width, white blood cells, phosphate, potassium, magnesium, alkaline phosphatase, creatinine, and urea nitrogen, suggesting metabolic and immune disturbance. Furthermore, inflammation-related indices also differed significantly between the 2 groups, with nonsurvivors exhibiting higher levels of NPR, PLR, NLR, and PIV, while LMR was lower. However, there was no significant change in troponin T or CK-MB between the survivors and nonsurvivors, demonstrating that these 2 markers typically show a significant increase during the acute phase of myocardial infarction and decrease rapidly during the recovery phase. These findings suggest that CBC-derived inflammation-related indices hold promise for predicting long-term prognosis in patients with diabetes combined with AMI.

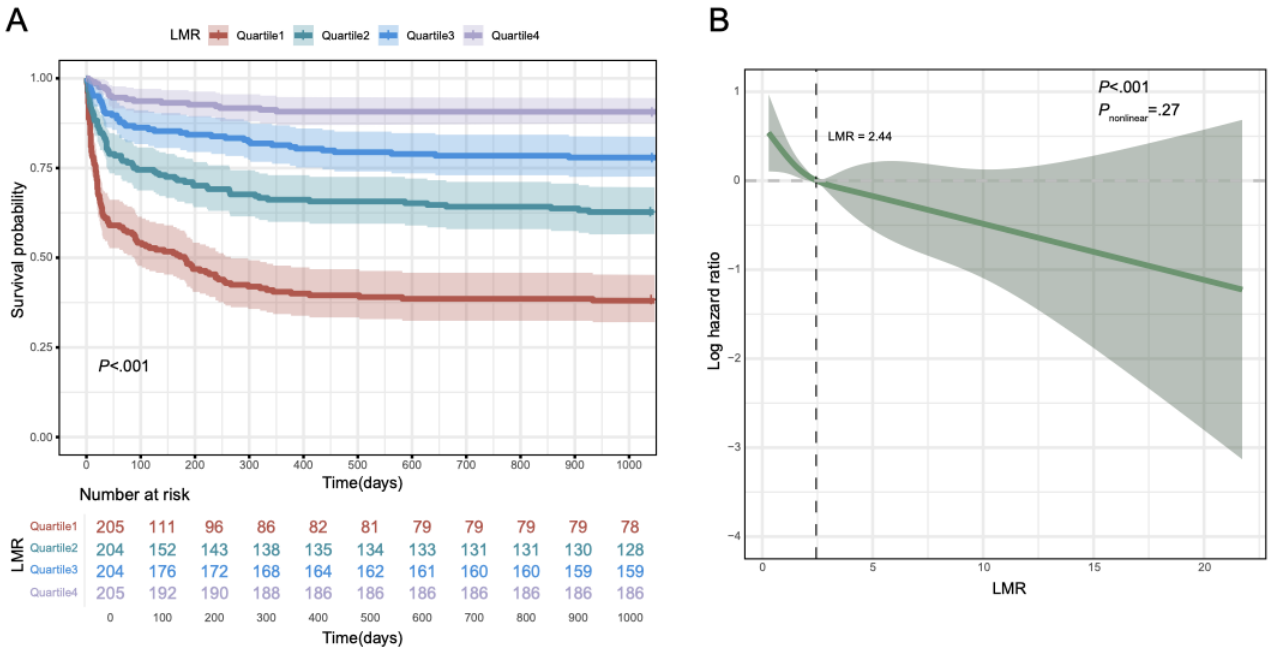
For the external validation cohort (n=166), baseline analysis focused specifically on CBC data and indices in the prognostic model (LMR, NLR, NPR, PIV, and PLR). The detailed comparison between survivors and nonsurvivors based on the 3-year mortality outcomes are presented in Table S2 in Multimedia Appendix 1.

Associations Between the Inflammation-Related Indices and Mortality Risk



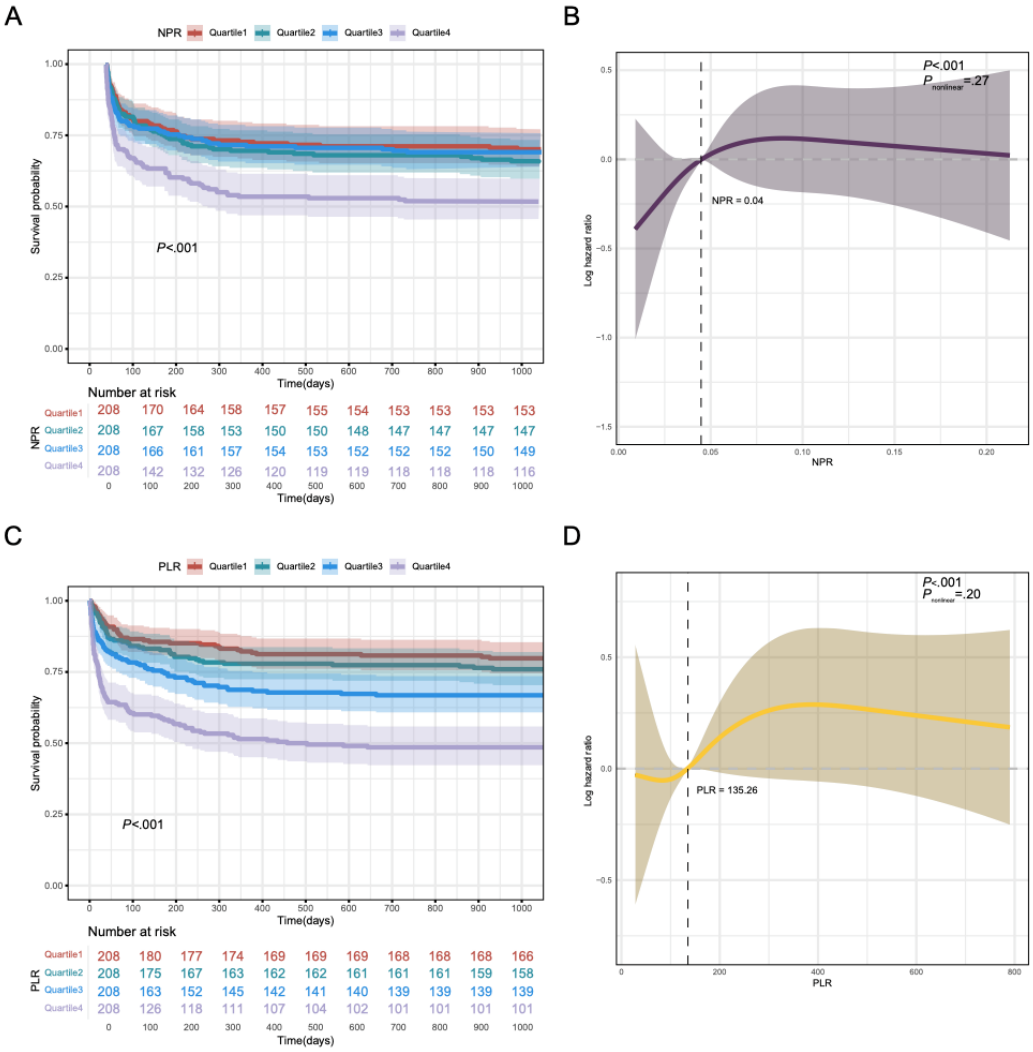
Cox proportional hazards analysis identified significant associations between inflammation-related indices (LMR, NPR, PLR, NLR, and PIV) and 3-year mortality risk (Table S3 in Multimedia Appendix 1). LMR was determined to be a protective factor, while NPR, PLR, NLR, and PIV were associated with an increased risk of mortality. These findings underscore the prognostic value of systemic inflammation markers in predicting long-term outcomes in this population.

LMR and Mortality Risk

Patients were stratified into quartiles based on LMR values: quartile 1 (LMR≤1.17; n=205), quartile 2 (1.17<LMR≤2.48; n=204), quartile 3 (2.48<LMR≤4.60; n=204), and quartile 4 (LMR>4.60; n=205). In Cox proportional hazards models, quartiles 2, 3, and 4 were significantly associated with reduced 3-year mortality risk compared to quartile 1, in both unadjusted and adjusted models (Table S3 in Multimedia Appendix 1). K-M survival analysis further demonstrated that patients in quartile 1 had the lowest 3-year survival probability, indicating the detrimental impact of low LMR (Figure 2A). RCS analysis revealed a decreasing trend between LMR and mortality risk, with a critical inflection point at LMR=2.44 (Figure 2B). Below this threshold, lower LMR values were strongly associated with increased mortality risk.

XSL•FO
RenderX

Figure 2. Kaplan Meier (K-M) survival analysis curves and restricted cubic spline (RCS) regression analysis of lymphocyte-to-monocyte ratio (LMR) for 3-year mortality. (A) K-M curves of LMR. (B) RCS analysis of LMR.



NPR and Mortality Risk

For NPR, patients were divided into 4 quartiles: quartile 1 (NPR≤0.033), quartile 2 (0.033<NPR≤0.046), quartile 3 (0.046<NPR≤0.064), and quartile 4 (NPR>0.064). In the unadjusted model, higher NPR values were significantly associated with increased mortality risk. However, this association was attenuated and lost statistical significance after adjustment for potential confounders (Table S3 in Multimedia Appendix 1). K-M survival analysis demonstrated that patients in quartile 4 (highest NPR) had the lowest 3-year survival probability compared with other quartiles, underscoring the detrimental impact of elevated NPR values (Figure 3A). RCS analysis revealed a nonlinear trend in the association between NPR and mortality risk, with a potential threshold observed around NPR=0.04. However, the test for nonlinearity did not reach statistical significance ($P_{\text{nonlinearity}}$=.27), suggesting that a linear relationship between these variables cannot be excluded (Figure 3B).

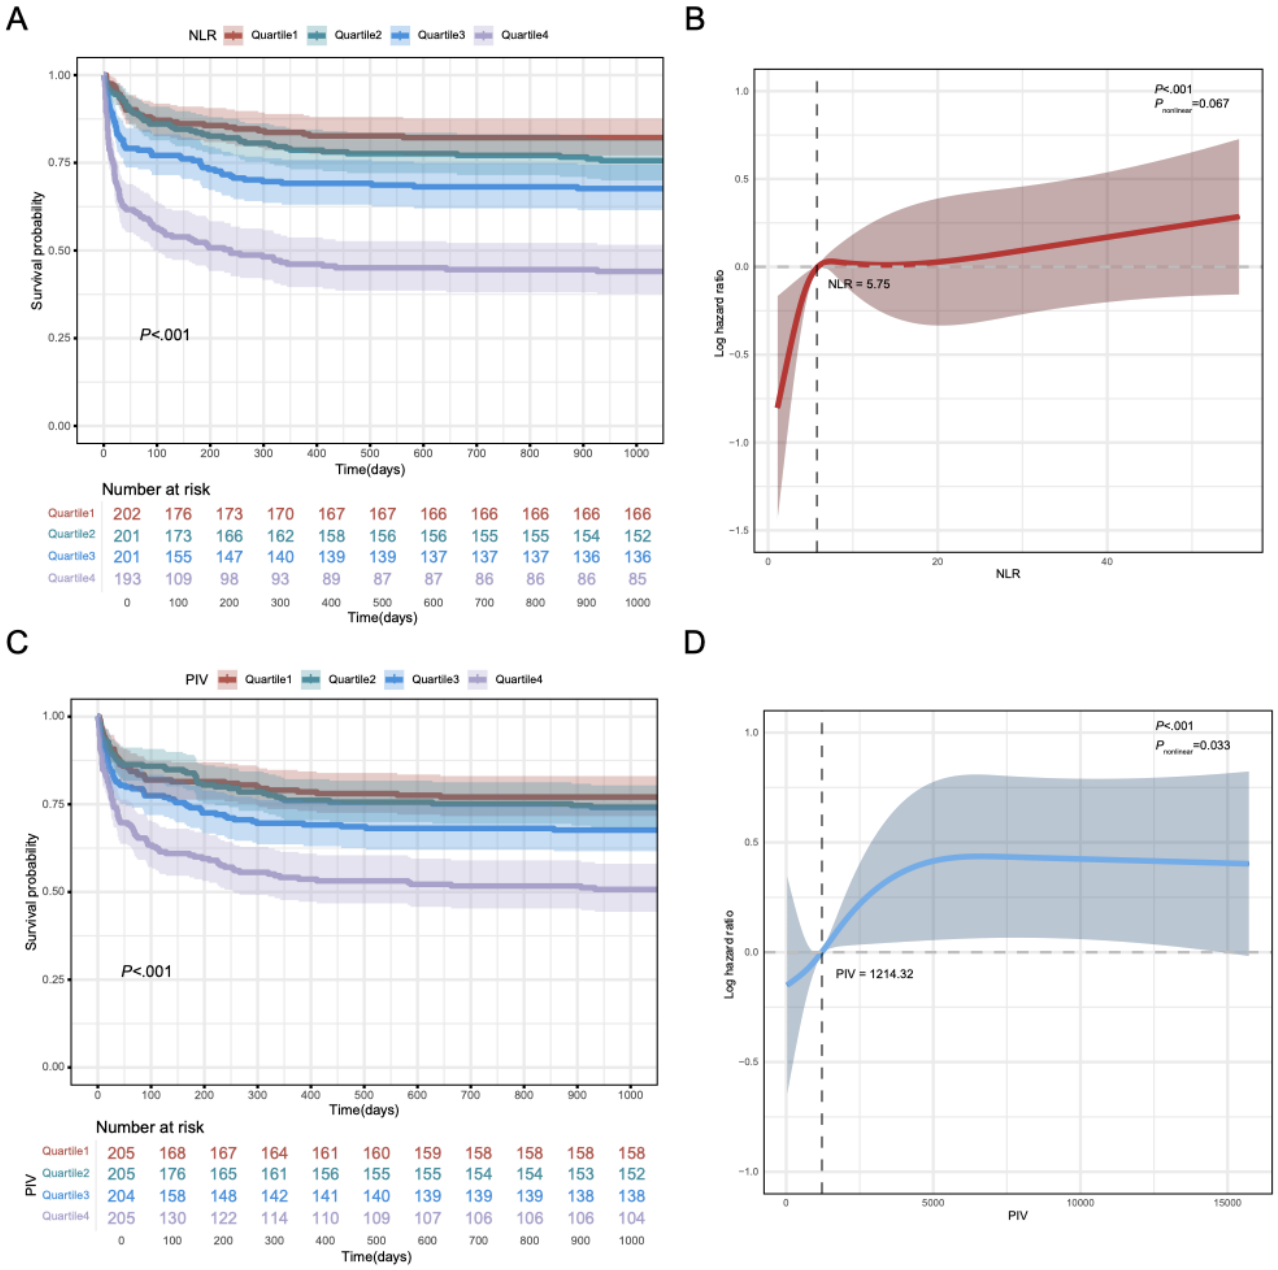
Figure 3. Kaplan-Meier (KM) survival analysis curves and restricted cubic spline (RCS) regression analysis of neutrophil-to-platelet ratio (NPR) and platelet-to-lymphocyte ratio (PLR) for 3-year mortality. (A) K-M curves of NPR. (B) RCS analysis of NPR. (C) K-M curves of PLR. (D) RCS analysis of PLR.

PLR and Mortality Risk



PLR was categorized into quartile 1 (PLR≤83.50), quartile 2 (83.50<PLR≤134.37), quartile 3 (134.37<PLR≤255.65), and quartile 4 (PLR>255.65). In the unadjusted model, higher PLR values were associated with increased mortality risk. However, after adjustment for confounding variables, this association was no longer statistically significant, suggesting potential confounding effects (Table S3 in Multimedia Appendix 1). K-M survival analysis demonstrated that patients in quartile 4 (highest PLR) had the lowest 3-year survival probability, consistent with the hypothesis that elevated PLR reflects a heightened inflammatory state (Figure 3C). RCS analysis indicated that as PLR increased, mortality risk also increased, with a notable value at PLR=135.26 (Figure 3D).

NLR and Mortality Risk

NLR quartiles were defined as follows: quartile 1 (NLR≤3.50), quartile 2 (3.50<NLR≤5.86), quartile 3 (5.86<NLR≤10.62), and quartile 4 (NLR>10.62). In both unadjusted and adjusted Cox proportional hazards models, patients in quartile 4 (highest NLR) exhibited a significantly increased risk of 3-year mortality compared with those in lower quartiles (Table S3 in Multimedia Appendix 1). K-M survival analysis further demonstrated that quartile 4 had the lowest 3-year survival probability, indicating the adverse prognostic impact of elevated NLR (Figure 4A). RCS analysis indicated that lower NLR values were associated with lower mortality risk, whereas higher NLR values significantly increased mortality risk, especially beyond a threshold of 5.75. Although the *P*=.07 suggests the nonlinear relationship was not fully significant, the trend between NLR and mortality risk is noteworthy (Figure 4B).

RenderX

Figure 4. Kaplan-Meier (KM) survival analysis curves and restricted cubic spline (RCS) regression analysis of neutrophil-to-lymphocyte ratio (NLR) and prognostic inflammatory value (PIV) for 3-year mortality. (A) K-M curves of NLR. (B) RCS analysis of NLR. (C) K-M curves of PIV. (D) RCS analysis of PIV.

PIV and Mortality Risk

For PIV, the quartiles were defined as quartile 1 (PIV≤550.46), quartile 2 (550.46<PIV≤1207.40), quartile 3 (1207.40<PIV≤2619.32), and quartile 4 (PIV>2619.32). Similarly, in both unadjusted and adjusted Cox models, quartile 4 (highest PIV) was significantly associated with increased 3-year mortality risk compared with lower quartiles (Table S3 in Multimedia Appendix 1). K-M survival analysis demonstrated that patients in quartile 4 had the lowest 3-year survival probability (Figure 4C), suggesting an association between elevated PIV and poor outcomes. The RCS curve shows that 1214.32 is a risk turning point; beyond this value, risk increased significantly (Figure 4D).

Stratified Analyses

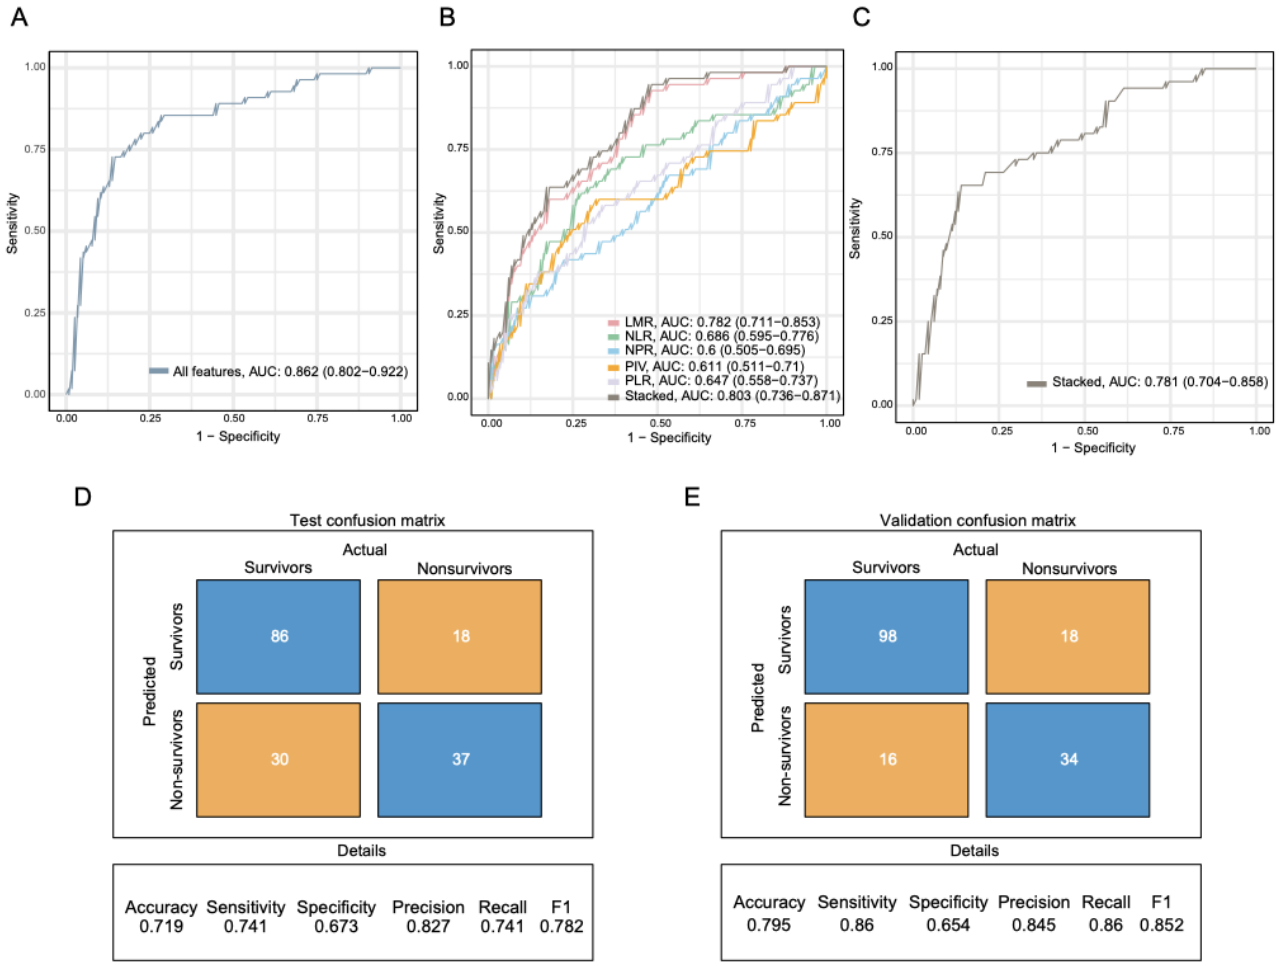
To further explore whether the relationship between inflammation-related indices and 3-year all-cause mortality persists under different conditions, subgroup analyses were conducted based on gender, age, BMI, hypertension, and hyperlipidemia. In the subgroup of patients aged ≥60 years, the hazard ratios (HRs) for all indices related to 3-year all-cause mortality were significant (Figures S1 and S2 in Multimedia Appendix 2). However, in the subgroup of patients aged <60 years, the HRs for NPR, PLR, and PIV did not show statistical significance. Furthermore, the HR for NPR was not statistically significant in the subgroup of patients with BMI<18 kg/m^2 and the subgroup of patients with hypertension. Similarly, the HRs for NPR and PIV were not statistically significant in the

XSL•FO
RenderX

subgroup of patients with BMI>28 kg/m^2 (Figures S1 and S2 in Multimedia Appendix 2).

Feature Selection

Initially, we compared the prognostic performance of individual CBC counts (lymphocyte, monocyte, neutrophil, and platelet counts) with inflammation-related indices using Cox regression models. The C-index values for individual cell counts ranged from 0.62 to 0.68, significantly lower than those of composite indices (0.72-0.79; Figure S3 in Multimedia Appendix 2). This disparity highlights the limited utility of isolated cell counts in capturing systemic inflammatory states. Given that the inflammation-related indices are derived from these individual cell counts, they inherently exhibit a higher degree of collinearity. Therefore, to focus more on the inflammation-related features themselves and minimize the impact of collinearity in the analysis, we excluded the individual immune cell counts before performing the VIF calculation.



We then examined the VIF to detect multicollinearity among variables, and features with a VIF>5 were removed (Table S1 in Multimedia Appendix 1). Subsequently, feature selection was performed using the Boruta algorithm, in which variables in the green area were identified as important features, whereas those in the red area were deemed unimportant (Figure S4 in Multimedia Appendix 2). Both CK-MB and troponin T were classified as unimportant (red box in Figure S4 in Multimedia Appendix 2), corroborating their limited prognostic value observed in baseline and Cox analysis (Table 1 and Figure S3 in Multimedia Appendix 2). This exclusion by the algorithm suggests that, although CK-MB and troponin T are critical for diagnosing acute myocardial injury, their transient elevation may not reflect the chronic inflammatory processes that drive long-term mortality in patients with diabetes combined with AMI.

Development and Validation of an Ensemble Machine Learning Model for Prognostic Prediction

After feature selection, we constructed a stacked model using all the important features, achieving an AUC of 0.862 in the test cohort (Figure 5A). To further explore the effectiveness of inflammation-related indices in predicting mortality risk in patients with diabetes combined with AMI, we built models based on individual inflammation-related indices, with AUCs of 0.782, 0.686, 0.598, 0.611, and 0.648 for LMR, NLR, NPR, PIV, and PLR, respectively, in the test cohort. We also combined these 5 indices into a stacked model, which achieved an AUC of 0.803 in the test cohort (Figure 5B; detailed parameters are shown in Figure 5D). Importantly, this combined inflammation-related indices model demonstrated robust generalizability, achieving an AUC of 0.781 in the external validation cohort (Figure 5C), with its predictive performance detailed in the confusion matrix (Figure 5E).

XSL•FO
RenderX

Figure 5. Receiver operating characteristic (ROC) curves of the machine learning prognostic models. (A) ROC curve for the model constructed using all important features in the test cohort. (B) ROC curves for models based on individual inflammation-related indices (lymphocyte-to-monocyte ratio [LMR], neutrophil-to-lymphocyte ratio [NLR], neutrophil-to-platelet ratio [NPR], prognostic inflammatory value [PIV], platelet-to-lymphocyte ratio [PLR]) and their combined model in the test cohort. (C) ROC curve for the combined inflammation-related indices model in the external validation cohort (area under the curve [AUC]=0.781). (D) Confusion matrix for the combined inflammation-related indices model in the test cohort. (E) Confusion matrix for the combined inflammation-related indices model in the external validation cohort.

Although the combined model performed slightly worse than the model using all important features in the test cohort, it demonstrated comparable and generalizable prognostic ability. The combined inflammation-related indices model may contribute to future prognostic prediction by offering a simplified and cost-effective alternative for clinical applications.

Beyond discrimination, we evaluated the calibration and clinical utility of the model. The calibration plots displayed good agreement between predicted probabilities and observed outcomes, with Brier scores of 0.146 in the validation set and 0.155 in the external cohort (Figure S5 in Multimedia Appendix 2). Furthermore, decision curve analysis (DCA) indicated that the model provided a substantial net benefit over the "treat-all" or "treat-none" strategies across a wide range of threshold probabilities in both cohorts (Figure S5 in Multimedia Appendix 2).

In the external validation cohort, we also evaluated an enhanced model incorporating readily available vitals (age, heart rate, blood pressure, respiration rate). This "Indices + Vitals" model showed marginal improvement (AUC=0.788) and overlapping net benefit curves in DCA (Figure S6 in Multimedia Appendix 2), supporting the use of the 5-index model as a parsimonious stand-alone tool.

We further compared the stacked model with the best-performing single index LMR (Figure S8 in Multimedia Appendix 2). Although the improvements in net reclassification improvement and discrimination improvement were not statistically significant, the stacked model demonstrated superior overall performance. Specifically, it achieved a higher AUC (0.781 vs 0.771 in external validation) and, more importantly, better calibration (Brier score: 0.155 vs 0.183; calibration slope: 1.589 vs 3.147), suggesting that the multi-index approach provides more robust and accurate risk estimates than any single biomarker.

Application of the Model

Using the above model, we developed a web tool to predict the prognosis of patients with diabetes and acute myocardial infarction (Figure S9 in Multimedia Appendix 2). Users can get prediction results by directly inputting features on the web page [13].

Discussion

Overview

To the best of our knowledge, this study is the first to systematically compare 5 inflammation-related indices (LMR, NLR, NPR, PLR, and PIV) derived from CBC in relation to the 3-year mortality risk of patients with diabetes combined with AMI, and to explore their potential application in predicting long-term mortality risk. The findings indicate that inflammation may play a critical role in the long-term prognosis of patients with diabetes combined with AMI. By constructing both single-indicator models and combined predictive models, we demonstrated that these inflammation indices can effectively assess mortality risk while also providing a reference for rapid and straightforward clinical risk assessment methods. Interestingly, adding readily available vital signs to the inflammation-related indices provided limited incremental value in the external cohort, with minimal improvement. This suggests that the 5-index model may offer a streamlined tool for risk stratification (Figure S6 in Multimedia Appendix 2).

From a clinical perspective, the proposed model primarily relies on routine CBC components, which are widely available, rapid, and inexpensive. This accessibility could make the model a potentially useful tool for early risk stratification in settings such as emergency departments and ICUs, potentially helping clinicians to prioritize resource allocation.

The prognostic value of these CBC-derived inflammation-related indices likely stems from the synergistic pathophysiology of diabetes and AMI. The chronic hyperglycemia and insulin resistance unique to patients with diabetes induce low-grade chronic inflammation, which not only exacerbates cardiovascular damage but also drives disease progression through various mechanisms [14]. When AMI occurs, it triggers an acute stress response involving the sympathetic nervous system and the hypothalamic–pituitary–adrenal axis [15]. Both chronic metabolic inflammation and acute ischemic injury leads to a profound dysregulation of hematopoiesis, manifesting as the specific alterations in leukocytes and platelets observed in this study [16].

The elevated risk associated with high NLR, PLR, and PIV can be mechanically explained by the exacerbated proinflammatory and prothrombotic phenotype in patients with diabetes. Hyperglycemia and insulin resistance prime neutrophils to overreact during myocardial ischemia. A critical mechanism linking these cells to poor prognosis is the formation of neutrophil extracellular traps. In a diabetic environment, activated neutrophils release excessive neutrophil extracellular traps, which not only directly damage cardiomyocytes but also serve as a scaffold for platelet aggregation and thrombosis [17,18]. This interaction is particularly detrimental in AMI, as it contributes to microvascular obstruction and extends the infarct size [19]. Furthermore, diabetic platelets exhibit surface protein glycation and increased reactivity, making them more prone to adhering to leukocytes [20]. PIV (the systemic immune-inflammation index), which integrates neutrophils, platelets, and monocytes, essentially captures this extensive interplay between coagulation and inflammation, explaining its strong association with mortality in our cohort of patients with diabetes.

Conversely, the protective role of LMR highlights the importance of adaptive immunity in healing. Lymphocytes, particularly regulatory T cells, are essential for transitioning the immune response from the inflammatory phase to the reparative phase [21]. However, in patients with diabetes complicated by AMI, lymphocytes face dual suppression: chronic oxidative stress from hyperglycemia induces lymphocyte apoptosis, while the acute cortisol surge from AMI causes massive lymphopenia [22,23]. This severe depletion of lymphocytes impairs the containment of the inflammatory storm. Simultaneously, hyperglycemia promotes differentiation of monocytes into the proinflammatory M1 phenotype rather than the reparative M2 phenotype, further delaying scar healing and promoting adverse ventricular remodeling [24,25]. Therefore, a reduced LMR serves as a composite marker indicating an uncontrolled inflammatory response correlating with worse long-term survival.

The elevated levels of NLR, PLR, NPR, and PIV may reflect a proinflammatory state driven by interactions among platelets, neutrophils, and lymphocytes, which could be a critical driver of poor prognosis in patients with diabetes and CVDs. For instance, PIV, as an integrative inflammatory marker, captures the interplay between platelets, neutrophils, and lymphocytes. Studies have shown that elevated PIV levels are associated with worse outcomes in patients with hypertension [20]. Additionally, previous research has demonstrated that high NLR and PLR values are not only independent predictors of in-hospital mortality in patients with heart failure but are also closely associated with the risk of cardiac death [26,27]. Elevated NLR may indicate enhanced proinflammatory neutrophil activity and impaired lymphocyte function, whereas increased PLR may reflect both platelet activation and reduced lymphocyte-mediated immune function. In contrast, NPR primarily reflects the ratio between neutrophils and platelets, and its elevation has been associated with worse outcomes in patients with myocardial infarction with nonobstructive coronary arteries [28].

The protective role of LMR and the risk-associated roles of NLR, NPR, PLR, and PIV further underscore the critical importance of systemic inflammation and immune balance in the prognosis of patients with diabetes combined with AMI. These mechanisms suggest that protective and risk-related inflammatory markers may influence the prognosis of patients with diabetes combined with AMI through distinct pathways, providing a theoretical basis for future research on underlying mechanisms and advancements in diagnostic and therapeutic strategies.

In addition, the findings of this study highlight the significant value of inflammation-related indices in predicting the long-term prognosis of patients with diabetes combined with AMI.

Compared with traditional complex biomarkers or imaging techniques, these inflammation indices are derived from CBC, which is a widely available and affordable diagnostic tool. Furthermore, CBC results are highly stable and reproducible, making them reliable for both research and clinical practice [29]. These advantages highlight their practicality and feasibility

XSL•FO
RenderX

for preliminary prognostic assessment in patients with diabetes combined with AMI. The combined predictive model constructed based on these 5 indices (AUC=0.803) demonstrated a predictive ability comparable to that of the full importance features model (AUC=0.862). Moreover, our DCA confirmed that using this model to guide clinical decisions provides a higher net benefit than default strategies across a wide range of threshold probabilities (Figures 5A and B in Multimedia Appendix 2). By identifying high-risk patients, such prognostic models may facilitate early clinical interventions and potentially improve survival rates.

Limitations

Despite confirming the potential role of inflammation-related indices in predicting the long-term prognosis of patients with diabetes combined with AMI, this study has several limitations.

First, the regulatory mechanisms of inflammation in diabetes and AMI are highly complex, with different types of inflammatory cells potentially exerting bidirectional effects during disease progression. This intricate cellular regulation may not be fully captured by simplified inflammation-related indices.

Second, although 5 commonly used inflammation-related indices were analyzed, other potentially important inflammatory markers (eg, interleukin 6 and tumor necrosis factor α) were not included, which may underestimate the comprehensive impact of inflammation. Additionally, these indices primarily reflect systemic inflammation and may not adequately capture the influence of local immune microenvironments.

Third, a direct comparison with established scoring systems, such as the Global Registry of Acute Coronary Events or the Thrombolysis in Myocardial Infarction score, was not feasible in this study. Critical variables required for these scores—specifically cardiac arrest at admission, Killip classification, and coronary artery stenosis severity—were not systematically recorded or exhibited high levels of missingness in the structured electronic health records of the MIMIC-IV database. Regarding clinical utility, the DCA results suggest that using our model to guide clinical decisions would yield a net benefit over default strategies within a broad threshold range. However, the observed calibration drift in the external validation cohort highlights the heterogeneity between populations (Figures 5A and B in Multimedia Appendix 2). While the model's discriminative power remains robust, this finding emphasizes the necessity of model recalibration to adjust for baseline risk differences before local clinical implementation.

Fourth, the external validation was asymmetrical. While the primary 5-index model was successfully validated externally, we could not validate the full model containing ancillary covariates because these specific variables were not available in the external center's dataset. This limitation restricts the generalizability of the covariate-adjusted analysis to the derivation cohort.

Fifth, while MIMIC-IV provides a large-scale, high-quality dataset, it represents a single-center experience in the United States. Consequently, practice patterns, patient demographics, and admission criteria may differ from those in other institutions or countries, potentially limiting the direct generalizability of our findings. Although external validation was performed to assess transportability, future multicenter prospective studies are widely recommended.

Finally, regarding model transparency, while our model demonstrated excellent calibration in the internal validation, calibration drift was observed in the external validation cohort (Figures 5C and D in Multimedia Appendix 2), showing a tendency to underestimate risk in the new population. This suggests that while the model is effective for risk ranking, it may require recalibration using local data to optimize absolute probability estimates for different clinical settings.

Abstract

Background: Adult-type diffuse glioma (ADG) is the most common primary malignant tumor of the central nervous system. Its highly invasive nature, marked heterogeneity, and resistance to therapy contribute to a high risk of recurrence and poor prognosis. At present, the lack of reliable prognostic tools poses a significant barrier to the development of individualized treatment strategies.

Objective: This study aimed to develop an effective prognostic model for ADG by integrating multiple machine learning algorithms, in order to enhance the precision of individualized clinical decision-making.

Methods: In this retrospective study, 160 newly diagnosed patients with ADG who underwent surgical resection and histopathological confirmation at our institution between June 2019 and September 2021 were included. A total of 32 variables, including clinical characteristics, molecular biomarkers, and preoperative hematological indicators, were collected. Overall survival (OS) and progression-free survival (PFS) were defined as the study endpoints. Feature selection was performed using least absolute shrinkage and selection operator regression, extreme gradient boosting, and random forest algorithms. Kaplan-Meier survival curves and log-rank tests were used for survival analysis. Multivariate Cox proportional hazards models were constructed to identify independent prognostic factors, and nomograms were developed accordingly. The model's discriminative ability, calibration, and clinical utility were evaluated using the concordance index, area under the receiver operating characteristic curve (area under the curve), calibration plots, and Kaplan-Meier analysis.

Results: Age, neutrophil percentage–to-albumin ratio (NPAR), and platelet-to-mean platelet volume ratio were identified as independent prognostic factors for OS, while age and NPAR were independent predictors for PFS (all $P<.001$). The prognostic models based on these variables demonstrated good predictive performance, with concordance index values of 0.731 and 0.763 for the training and validation cohorts in the OS model, respectively. The PFS model also showed robust performance. Area under the curve values and calibration curves further supported the models' accuracy and stability. Risk stratification analysis revealed clear survival differences between risk groups (all $P<.05$), indicating strong clinical applicability.

Conclusions: This study is the first to identify preoperative NPAR as a significant prognostic biomarker for ADG using machine learning approaches. The prognostic model incorporating NPAR, platelet-to-mean platelet volume ratio, and age demonstrated favorable predictive performance, offering a novel perspective for accurate risk stratification and personalized treatment in patients with ADG.

KEYWORDS

adult-type diffuse glioma; machine learning; neutrophil percentage-to-albumin ratio; NPAR; prediction model; prognosis

Introduction

Glioma is the most common primary malignant tumor of the central nervous system, with an annual incidence of approximately 4.5 per 100,000 individuals [1]. Among its subtypes, adult-type diffuse glioma (ADG) constitutes the predominant pathological category, characterized by high invasiveness, frequent postoperative recurrence, and poor overall survival (OS) [2]. Epidemiological data indicate that ADG incidence exhibits age and sex specificity, with the highest prevalence observed in individuals aged 45-70 years (peak incidence at age 65-75 years) and a male predominance (male-to-female ratio: 1.3-1.6:1) [3].

Despite advances in multimodal treatment—including maximal surgical resection combined with radiochemotherapy—ADG survival outcomes have shown limited improvement over the past decade [4,5]. Novel therapies such as immune checkpoint inhibitors (eg, anti–PD-1 monoclonal antibodies) and targeted agents (eg, epidermal growth factor receptor inhibitors) offer promise, but their clinical benefits are restricted to specific molecular subgroups and are frequently accompanied by immune-related adverse events, such as pneumonitis (reported in 15%-20% of cases) and acquired resistance [6]. As such, there remains an urgent need for precise prognostic tools to identify treatment-sensitive subpopulations and guide individualized therapeutic decision-making.

Currently, prognostic evaluation of ADG largely depends on traditional clinicopathological parameters, including age, isocitrate dehydrogenase 1 (IDH1) mutation status, and O6-methylguanine-DNA methyltransferase (MGMT) promoter methylation [7,8]. However, these markers alone exhibit limited predictive accuracy for treatment response or survival. Emerging evidence suggests that inflammation within the tumor microenvironment (TME) plays a critical role in glioma progression by promoting angiogenesis and suppressing antitumor immune activity [9]. Peripheral blood–derived inflammatory biomarkers, such as the neutrophil-to-lymphocyte ratio (NLR), lymphocyte-to-monocyte ratio (LMR), and platelet-to-lymphocyte ratio (PLR), have demonstrated prognostic relevance in several malignancies, including breast and colorectal cancer [10,11]. However, their utility in ADG remains underinvestigated.

Recently, the neutrophil percentage-to-albumin ratio (NPAR)—a composite marker integrating systemic inflammation and nutritional status—has been proposed as a novel prognostic indicator in solid tumors [12]. Nevertheless, its prognostic value in ADG, particularly in the context of long-term survival and treatment response, remains unclear.

Moreover, most existing prognostic models in gliomas are based on conventional Cox regression analysis, which is limited in handling high-dimensional data and complex nonlinear interactions [13,14]. In contrast, machine learning algorithms such as least absolute shrinkage and selection operator (LASSO) regression, extreme gradient boosting (XGBoost), and random forest (RF) have shown superior performance in variable selection and pattern recognition [15-18]. However, no studies to date have integrated these 3 algorithms to enhance the robustness of prognostic modeling in ADG.

Therefore, this study proposes an innovative machine learning–based approach that integrates LASSO regression (for feature selection), XGBoost (a gradient-boosted decision tree method), and RF (an ensemble learning model) to develop a multidimensional prognostic tool based on clinical, molecular, and inflammatory parameters. The objective is to improve predictive accuracy and provide refined support for clinical decision-making in patients with ADG.

Methods

Ethical Considerations

This retrospective study was conducted in accordance with the Declaration of Helsinki and was approved by the Ethics Committee of The First Affiliated Hospital of Zhengzhou University (Approval No 2023-KY-0223-002). Given the retrospective nature of this study, the requirement for informed consent was waived by the ethics committee. All patient data were anonymized and deidentified prior to analysis. Personal identifiers were removed, and each patient was assigned a unique study code to ensure confidentiality throughout the research process. No financial compensation was provided to the participants.

Study Population

This retrospective study enrolled 160 treatment-naïve patients with ADG who underwent maximal safe surgical resection with histopathological confirmation at our institution between June 2019 and September 2021. The postoperative treatment regimen followed the standard protocol, consisting of concurrent chemoradiotherapy followed by adjuvant temozolomide chemotherapy. In cases of disease progression, targeted therapies such as bevacizumab or BRAF (B-Raf proto-oncogene, serine/threonine kinase) inhibitors (eg, for tumors harboring the BRAF V600E mutation) were administered based on clinical indications [19].

Inclusion criteria were as follows: (1) age ≥18 years, diagnosis of ADG in accordance with the 5th edition of the *WHO Classification of Tumors of the Central Nervous System* (World Health Organization [WHO] grade 3-4); (2) completion of preoperative magnetic resonance imaging or computed tomography evaluation; (3) no prior antitumor therapy; (4) receipt of standard treatment protocol; (5) availability of complete clinical data, including general characteristics, preoperative blood tests, cardiac, hepatic, and renal function assessments, as well as postoperative immunohistochemistry and molecular profiling; and (6) complete follow-up records.

Exclusion criteria were (1) postoperative mortality within 30 days due to surgical complications or nonneoplastic causes; (2) presence of severe systemic disease or active infection

XSL•FO
RenderX

potentially affecting study outcomes; (3) diagnosis of other concurrent malignancies; (4) significant cardiac, hepatic, or renal dysfunction; and (5) history of prior cranial surgery.

Postoperative follow-up included clinical and radiological evaluations every 3 months during the first year and every 6 months thereafter, until October 1, 2024. Progression-free survival (PFS) was defined as the time from diagnosis to radiographic or clinical disease progression or death from any cause. OS was defined as the time from diagnosis to death or the last follow-up.

Study Variables

Clinical data were collected from patients with ADG who met the inclusion and exclusion criteria. The variables analyzed in this study included: clinical characteristics, molecular biomarkers, genetic alteration markers, preoperative peripheral hematological indicators, and inflammation-related ratios.

Clinical Characteristics

Age, gender, preoperative tumor location, extent of tumor resection, maximum tumor diameter, and midline shift.

Molecular Biomarkers

Immunohistochemical markers included P53 protein (P53), oligodendrocyte transcription factor 2 (Olig-2), S100 calcium-binding protein (S100), epithelial membrane antigen (EMA), synuclein (SYN), alpha-thalassemia/mental retardation syndrome X-linked (ATRX), cluster of differentiation 34 (CD34), neuronal nuclei (NeuN), glial fibrillary acidic protein (GFAP), and proliferation cell nuclear antigen-67 (Ki-67).

Genetic Alteration Markers

IDH1 immunophenotype, telomerase reverse transcriptase (TERT) promoter region mutation, BRAF V600E point mutation, epidermal growth factor receptor (EGFR) amplification, MGMT promoter methylation status, 1p loss of heterozygosity (1pLOH), and 19q loss of heterozygosity (19qLOH).

Preoperative Peripheral Hematological Indicators

White blood cell (WBC), platelet (PLT), neutrophil (Neut), monocyte (Mono), lymphocyte (Lym), prothrombin time (PT), activated partial thromboplastin time (APTT), lactate dehydrogenase (LDH), and serum albumin (ALB). All preoperative peripheral hematological indicators, including NPAR, were measured from blood samples collected within 1 week prior to surgery, before the administration of any corticosteroids or other interventions that could significantly alter these values.

Inflammation-Related Ratios

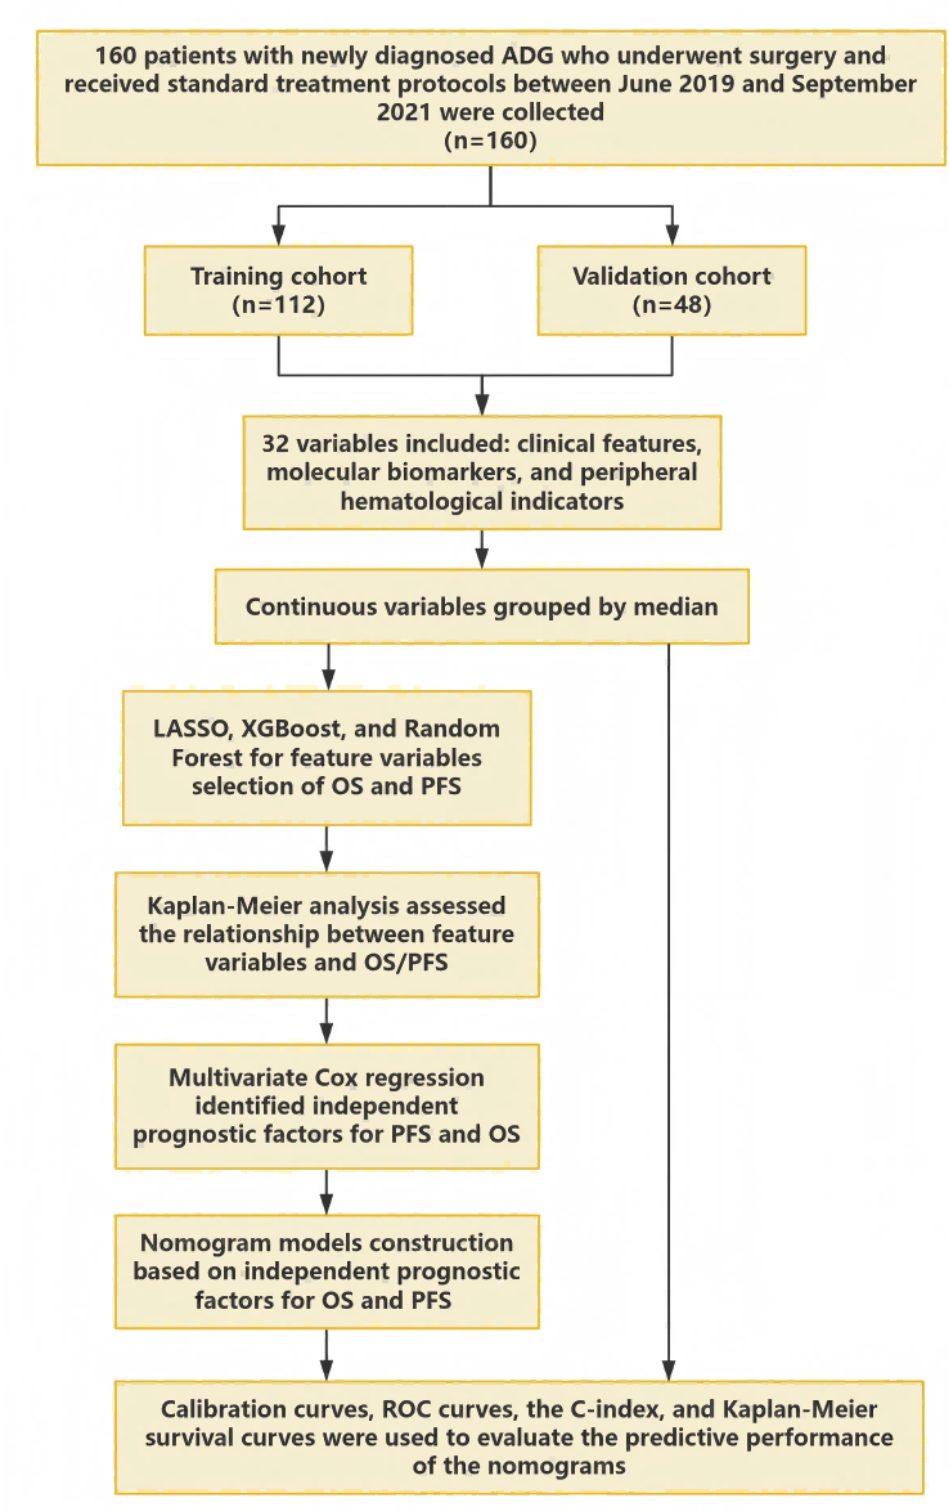
According to international standards for inflammatory biomarkers, the following parameters were calculated and defined: PLR = PLT/Neut, NLR = Neut/Lym, LMR = Lym/Mono, monocyte-to-lymphocyte ratio (MLR) = Mono/Lym, prognostic nutritional index (PNI) = ALB + 5 × Lym, systemic inflammation response index (SIRI) = (Neut × Mono)/Lym, systemic immune-inflammation index (SII) = (PLT × Neut)/Lym, aggregate index of systemic inflammation (AISI) = (Neut × PLT × Mono)/Lym, NPAR = (Neut/WBC%)/ALB, neutrophil-lymphocyte-platelet ratio (NLPR) = Neut/(Lym × PLT).

Study Design and Statistical Analysis

The study design is illustrated in Figure 1.

A random seed was set to divide the 160 cases into a training cohort (n=112) and a validation cohort (n=48) at a 7:3 ratio. The primary endpoint was OS, and the secondary endpoint was PFS. A total of 32 variables were included, encompassing clinical characteristics (age, gender, tumor location, etc), molecular biomarkers (Ki-67, IDH1, R132H, etc), and inflammatory indicators (NPAR, NLR, etc).

Continuous variables were dichotomized using the median as the cutoff. This approach was chosen to simplify the clinical interpretation of the model and to facilitate risk stratification, while also mitigating the impact of potential outliers and meeting the model's assumption of proportional hazards for categorical predictors. Categorical variables were expressed as frequencies (percentages), and group comparisons were conducted using the chi-square test (expected frequency ≥5) or Fisher exact test (expected frequency <5). The Shapiro-Wilk test was used to assess the normality of continuous variables. For normally distributed data, comparisons between groups were performed using the 2-tailed independent-samples *t* test (2 groups) or 1-way ANOVA (3 or more groups), with data presented as mean (SD). For nonnormally distributed data, comparisons were performed using the Mann-Whitney *U* test (2 groups) or the Kruskal-Wallis H test (3 or more groups), with post hoc pairwise comparisons adjusted using the Bonferroni method. These data were reported as median (IQR). A 2-tailed *P* value <.05 was considered statistically significant for all analyses.



A total of 3 machine learning algorithms were applied: LASSO regression (using the *glmnet* package with 10-fold cross-validation to optimize λ), XGBoost (using the *xgboost* package with max depth=6 and learning rate=0.01), and RF (using the *randomForest* package with *ntree*=1000). Venn diagrams were used to identify overlapping important variables selected by all 3 algorithms. Survival differences between groups were visualized using Kaplan-Meier (KM) curves and compared using the log-rank test.

A Cox proportional hazards regression model was constructed to estimate hazard ratios (HRs) and 95% CIs. Based on multivariate Cox results, a nomogram was developed using the *rms* package. Time-dependent receiver operating characteristic (ROC) curves were generated, and the area under the curve (AUC) at 1, 3, and 5 years was calculated. The concordance index (C-index) was used to evaluate the model's discrimination ability. Calibration was assessed using calibration curves based on 1000 bootstrap resamples. KM survival analysis based on the median nomogram score was performed to evaluate clinical utility. The validation cohort was used to assess the model's predictive performance.

All statistical analyses were conducted using R software (version 4.4.1; R Foundation for Statistical Computing). A 2-sided *P* value <.05 was considered statistically significant.

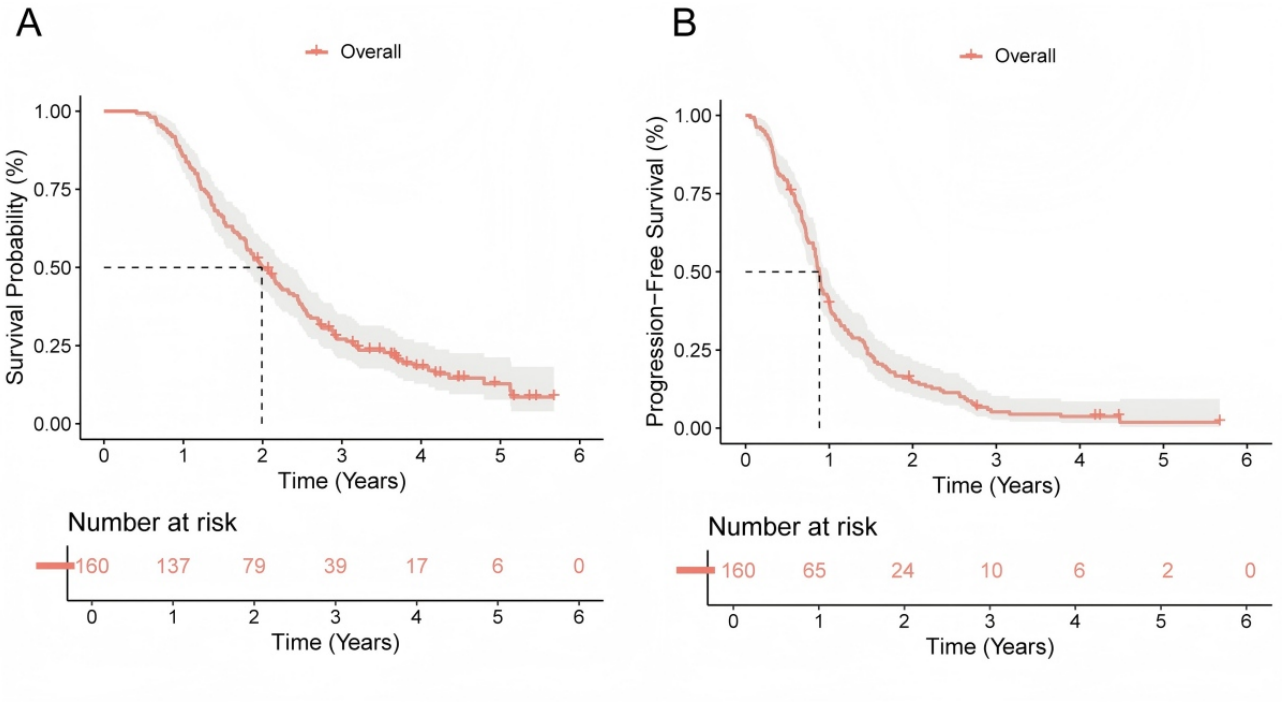
Figure 1. Flowchart of the study design.



Results

Survival Outcomes

Among the 160 patients included in this study, a total of 132 (82.5%) experienced death events, and 152 (95%) experienced disease progression. The median OS was 23.0 months (IQR 15.0-38.3 months), while the median PFS was 10.5 months (IQR 6.8-17.5 months). The 1-, 3-, and 5-year OS rates were 85.6%, 27.1%, and 12.8%, respectively. The corresponding 1-, 3-, and 5-year PFS rates were 40.0%, 6.5%, and 3.4%, respectively. KM survival curves are presented in Figure 2.

XSL•FO
RenderX

Figure 2. Postoperative survival curves of 160 patients with adult-type diffuse glioma: (A) overall survival (OS) and (B) progression-free survival (PFS).

Baseline Characteristics

A total of 160 patients were included in this study, with a male-to-female ratio of approximately 1.4:1. The mean age was 51.3 (SD 13.6) years, and the median age was 53 (IQR 44-61) years. The maximum tumor diameter ranged from 1.0 to 9.5 cm, with a mean of 4.7 (SD 1.7) cm and a median of 5.0 cm (IQR 3.4-5.9 cm). Tumors were predominantly unilateral, with 76 cases (47.5%) on the left, 80 (50%) on the right, and 2 (2.5%) involving both sides. Midline shift was observed in 59.4% (95/160) of patients. All cases were classified as WHO grade 3-4. No significant differences in baseline characteristics were found between the training and validation cohorts (all P>.05). Detailed information is provided in Table 1.

Differences in PFS and OS Between Groups

Since the measurement data did not meet the assumption of normality according to the Shapiro-Wilk test, the nonparametric Wilcoxon rank-sum test was applied to evaluate the impact of different clinical characteristics on PFS and OS. Data are presented as median (IQR).

Using PFS as the outcome variable, significant differences (all $P<.05$) were observed in the following 10 variables: age ($P<.001$), tumor location ($P=.03$), NPAR ($P=.002$), NLR ($P=.002$), PNI ($P=.01$), SYN ($P=.003$), MGMT promoter methylation ($P=.004$), IDH1 R132 ($P<.001$), 1pLOH ($P=.04$), and 19qLOH ($P<.001$).

Using OS as the outcome variable, a total of 12 variables showed significant associations (all $P<.05$): age ($P<.001$), NPAR ($P<.001$), LMR ($P=.03$), NLR ($P=.02$), MLR ($P=.03$), PNI ($P=.01$), LDH ($P=.04$), SYN ($P=.009$), MGMT ($P=.04$), IDH1 R132 ($P<.001$), 1pLOH ($P=.003$), and 19qLOH ($P<.001$). Detailed results are presented in Table 2.

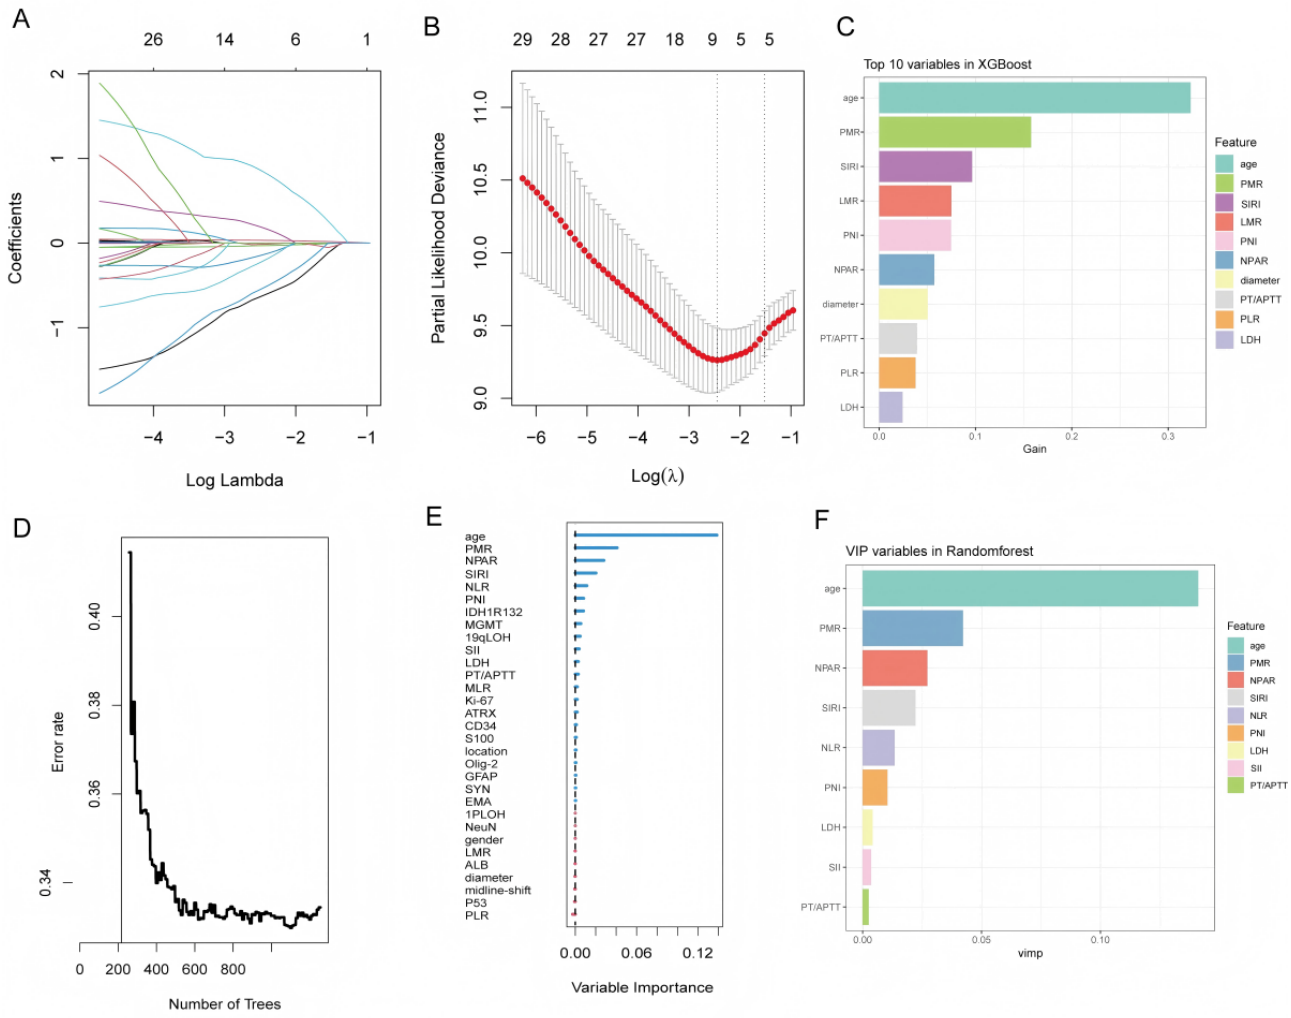
Construction and Validation of an OS-Based Prediction Model

Feature Variable Selection

Using OS as the outcome variable, a total of 3 machine learning algorithms—LASSO regression, XGBoost, and RF—were used to screen feature variables.



LASSO regression: based on the minimum λ value (λ_min), a total of 9 variables with nonzero coefficients were selected, including age, NPAR, platelet-to-mean platelet volume ratio (PMR), CD34 expression, SYN expression, EMA expression, IDH1 R132, 19qLOH, and MGMT promoter methylation (Figures 3A and B).

XGBoost model: according to feature importance scores, a total of 10 variables were selected, including age, PMR, SIRI, LMR, PNI, NPAR, maximum tumor diameter, PT/APTT, PLR, and LDH (Figure 3C).

RF: based on the mean decrease in Gini index, a total of 9 variables were selected, including age, PMR, NPAR, SIRI, NLR, PNI, LDH, SII, and PT/APTT (Figures 3D-F).

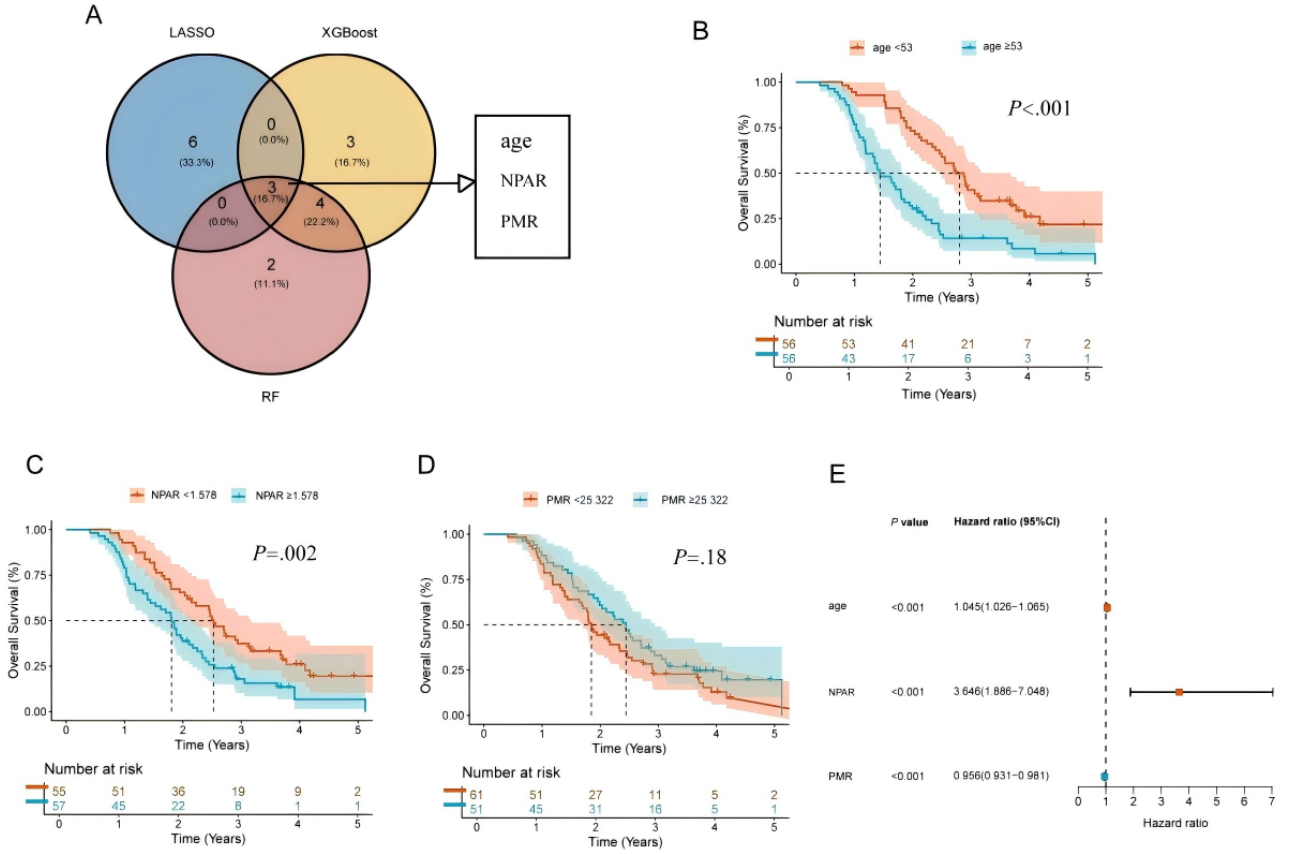
Survival Analysis



Based on the combined screening results from LASSO, XGBoost, and RF, Venn diagram intersection analysis identified age, NPAR, and PMR as key factors influencing OS (Figure 4A).

The prognostic impact of each individual variable was assessed using KM survival analysis (Figures 4B-D). Log-rank test results indicated that patients aged <53 years had significantly longer OS compared to those aged ≥53 years (P<.001), patients with NPAR <1.578 had significantly better OS than those with NPAR ≥1.578 (P<.001), while no significant difference in OS was observed between patients with PMR <25.322 and those with PMR ≥25.322 (P=.18).

Multivariate Cox proportional hazards regression analysis identified age (HR 1.05, 95% CI 1.03-1.07; P<.001), NPAR (HR 3.65, 95% CI 1.89-7.05; P<.001), and PMR (HR 0.96, 95% CI 0.93-0.98; P<.001) as independent prognostic factors for OS.

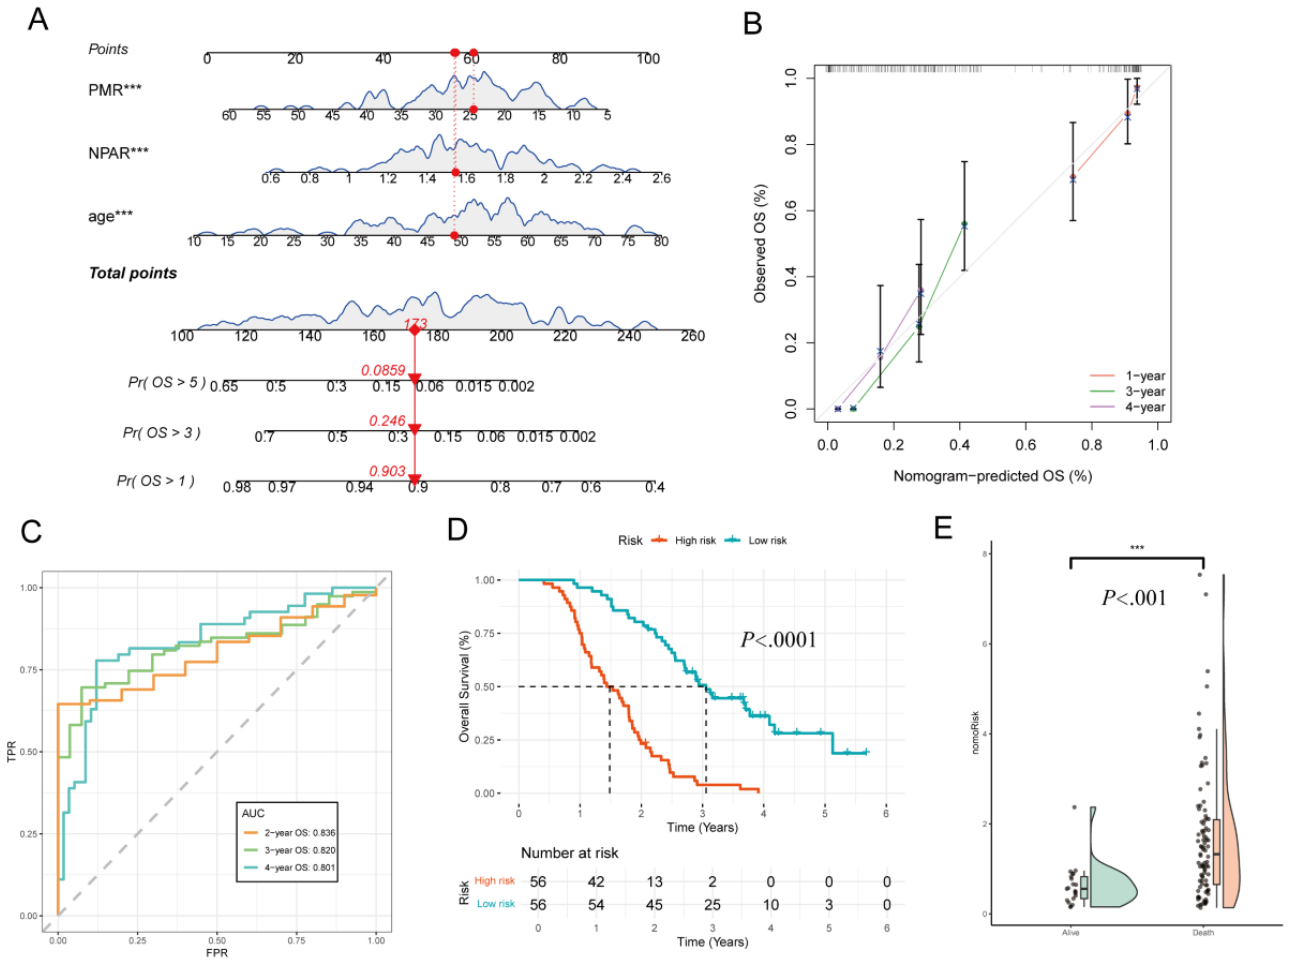
Construction and Validation of the OS Nomogram

Based on the multivariate Cox regression analysis, age, NPAR, and PMR were identified as independent prognostic factors for OS. A nomogram was constructed using these variables to predict 1-, 3-, and 5-year OS probabilities. Each variable was assigned a corresponding risk score, and the total score was used to estimate individual survival probability (Figure 5A). The calibration curve showed good agreement between the predicted and observed 1-, 3-, and 5-year OS rates (Figure 5B). Time-dependent ROC analysis demonstrated that the AUCs for 2-, 3-, and 4-year OS in the training cohort were 0.836, 0.820, and 0.801, respectively, indicating strong predictive performance across multiple timepoints (Figure 5C).



Patients were stratified into high- and low-risk groups based on the median nomogram score. KM survival analysis revealed that the high-risk group had significantly poorer OS compared with the low-risk group (P<.001), supporting the nomogram's utility in risk stratification (Figure 5D).

To further evaluate the discriminative ability of the nomogram score, a raincloud plot was used to visualize the score distribution between the survival and death groups. This plot, which integrates a density plot, box plot, and scatter plot, clearly illustrated the differences in score distribution, providing additional evidence of the nomogram's effectiveness in prognostic assessment (Figure 5E).

The calibration curve in the validation group indicated good predictive accuracy of the model for 1-, 2-, and 3-year survival in patients with ADG (Figure 6A). Time-dependent ROC analysis showed that the AUCs for 1-, 3-, and 4-year OS were 0.822, 0.797, and 0.722, respectively (Figure 6B). Risk stratification based on the nomogram score revealed a significant difference in score distribution between survivors and nonsurvivors. Patients in the high-risk group had significantly poorer OS compared with those in the low-risk group (P<.01), supporting the prognostic discriminatory power of the nomogram (Figure 6C). The C-index remained high in both the training and validation sets, suggesting robust and consistent predictive performance (Figure 6D).

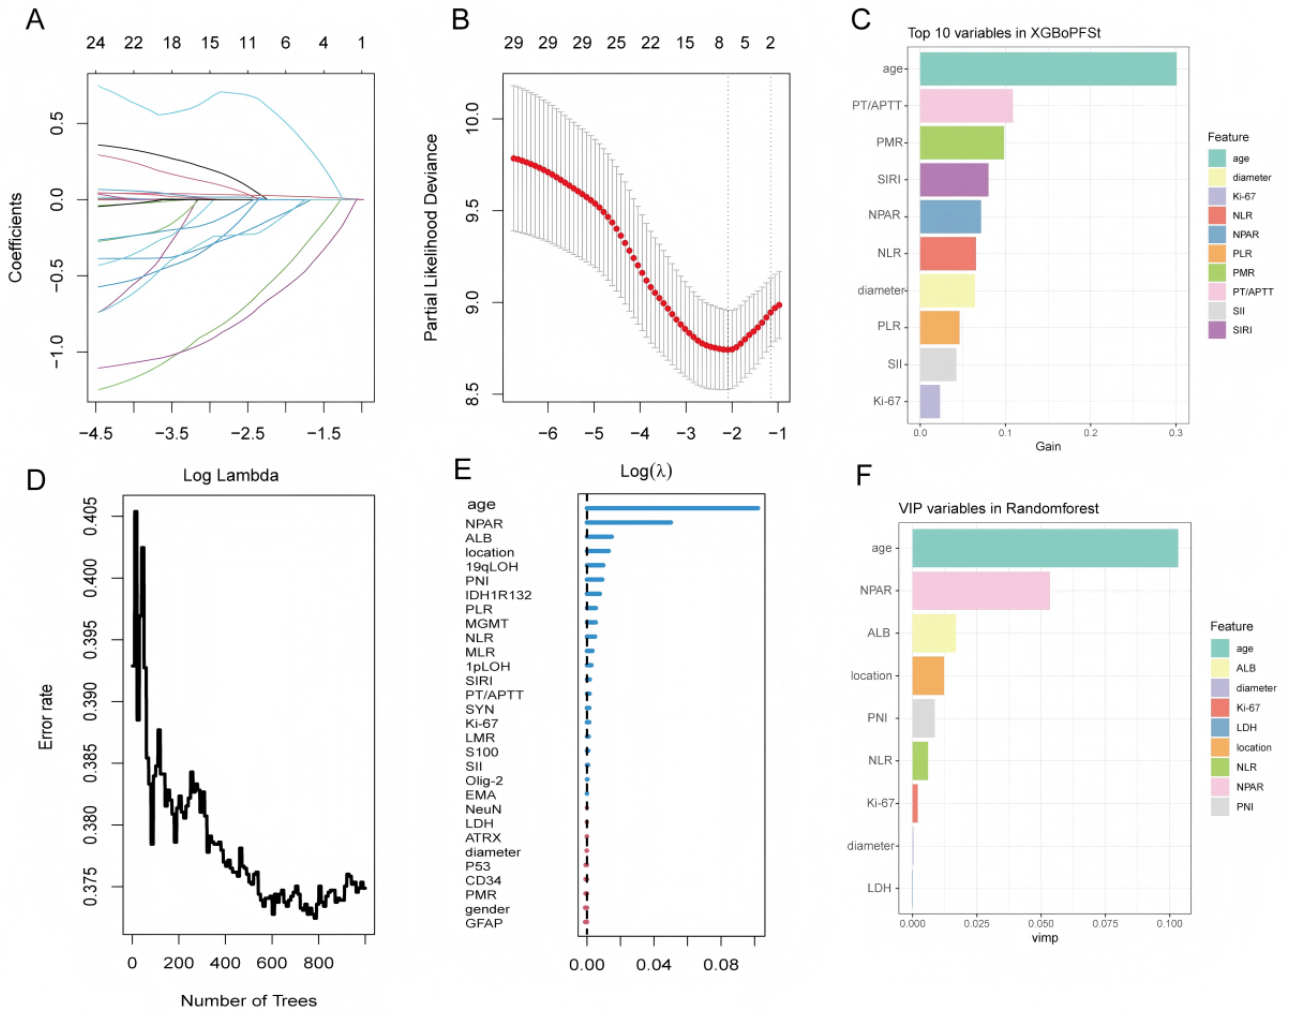
Construction and Validation of the PFS Prediction Model for ADG

Feature Variable Selection

Using PFS as the outcome variable, 3 machine learning algorithms—LASSO regression, XGBoost, and RF—were used to screen feature variables.



LASSO regression: based on the minimum λ value (λ_min), a total of 6 nonzero coefficient variables were selected, including age, NPAR, MLR, MGMT methylation, 1pLOH, and 19qLOH (Figure 7A and B).

XGBoost model: based on feature importance scores, a total of 10 variables were selected, including age, PT/APTT, PMR, SIRI, NPAR, NLR, maximum tumor diameter, PLR, SII, and Ki-67 expression (Figure 7C).

RF: based on the mean decrease in Gini index, a total of 9 variables were selected, including age, NPAR, ALB, tumor location, PNI, NLR, Ki-67, maximum tumor diameter, and LDH (Figures 7D and E).

Survival Analysis

Based on the important variables screened by LASSO, XGBoost, and RF, Venn diagram intersection analysis identified age and NPAR as key factors influencing PFS (Figure 8A). The impact of each single factor on prognosis was assessed using KM survival analysis (Figures 8B and C). Log-rank test results showed that patients in the age <53 years group had significantly longer PFS than those in the age ≥53 years group (P<.001); patients in the NPAR <1.578 group had significantly longer PFS than those in the NPAR ≥1.578 group (P<.001). Multivariate Cox proportional hazards regression analysis revealed that age (HR 1.04, 95% CI 1.02-1.05; P<.001) and NPAR (HR 3.04, 95% CI 1.58-5.86; P<.001) were independent prognostic factors for PFS (Figure 8D).

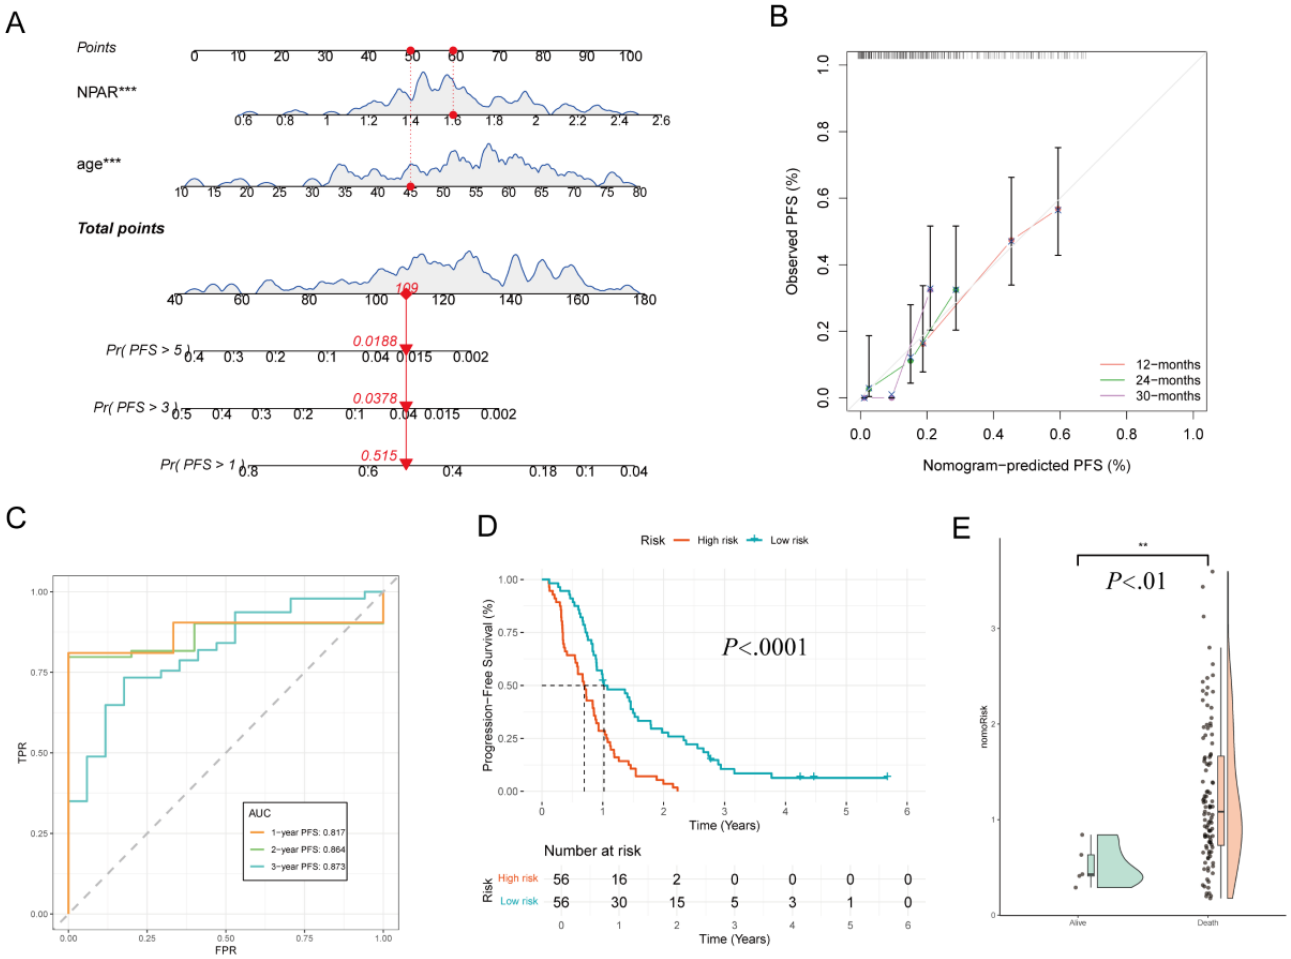
XSL•FO
RenderX

Figure 8. Identification of independent prognostic factors for progression-free survival (PFS): (A) intersection analysis of feature variables from 3 models, (B) impact of age group on patient PFS, (C) impact of neutrophil percentage-to-albumin ratio (NPAR) level on patient PFS, and (D) forest plot of multivariate Cox regression analysis for PFS. LASSO: least absolute shrinkage and selection operator.

Construction and Validation of the PFS Nomogram

Based on multivariate Cox regression analysis, age and NPAR were identified as independent prognostic factors for PFS. A nomogram was constructed using these variables to predict 1-, 3-, and 5-year PFS rates. Each predictive variable was assigned a corresponding risk score, and the total score estimated the patient's probability of disease progression (Figure 9A).

The calibration curve demonstrated good agreement between the model-predicted and observed 12-, 24-, and 30-month PFS rates (Figure 9B). Time-dependent ROC curve analysis showed that the AUC for 1-, 2-, and 3-year PFS in the training group was 0.817, 0.864, and 0.873, respectively, indicating high predictive accuracy of the model at different timepoints (Figure 9C). Patients were divided into high-risk and low-risk groups based on the median nomogram score. KM survival curves revealed that the high-risk group had significantly lower PFS than the low-risk group (P<.001), demonstrating that the nomogram score effectively stratified patients' prognostic risk (Figure 9D).



The raincloud plot provides a visual representation of the score distribution differences between the 2 groups and further supporting the effectiveness of the nomogram score in prognostic assessment (Figure 9E).

Due to the high risk of patient recurrence, the calibration curve for the validation group demonstrated good predictive performance for 6-, 12-, and 18-month disease progression risk in patients with ADG (Figure 10A). Time-dependent ROC curve analysis showed that the AUC for 1-, 3-, and 5-year PFS in the validation group was 0.709, 0.843, and 0.953, respectively (Figure 10B). Based on the median nomogram score, patients in the validation group were divided into high-risk and low-risk groups. KM survival curves revealed significant differences in OS between the 2 groups (P<.05), further validating the prognostic discriminative ability of the nomogram score (Figure 10C).

The C-index of the model was excellent in both the training and validation groups, indicating stable predictive performance across different datasets (Figure 10D).

Discussion

Principal Results

ADG, characterized by high malignancy and strong invasiveness, accounts for 45% of all gliomas [20,21]. The tumor heterogeneity and infiltrative growth patterns of ADG often lead to progressive neurological impairment, posing significant challenges for clinical management [9,22]. This study demonstrated that standardized comprehensive treatment (surgery combined with concurrent chemoradiotherapy and temozolomide) extended the median overall survival (mOS) to 23.0 (IQR 15.0-38.3) months, which is superior to the approximately 15 months reported in previous studies [2,23,24]. However, 95% (152/160) of patients experienced postoperative recurrence, with a median progression-free survival (mPFS) of only 10.8 months and a 5-year PFS rate of merely 1.9% (3/160). Moreover, the long-term prognosis remains poor, with a 5-year OS rate of just 12.8% (20/160) [25]. Therefore, it is of great significance to further explore the key prognostic factors affecting patients with ADG, establish novel prognostic models, and develop effective preventive strategies.

The key methodological advance of our work lies in the robust feature selection achieved by integrating 3 distinct machine learning algorithms (LASSO, XGBoost, and RF) [26]. This integrative approach circumvents the inherent pitfalls of relying on a single method, be it traditional Cox regression or an

XSL•FO
RenderX

individual machine learning model [13,14]. Consequently, it ensures that the identified prognostic factors (age, NPAR, and PMR) are consistently salient across different modeling paradigms, thereby significantly strengthening the credibility of our results.

Compared to existing prognostic models for ADG, our model demonstrates superior predictive performance. While Kim et al [27] reported a C-index of 0.70 using a single machine learning approach, the OS model in this study achieved C-indices of 0.731 and 0.763 in the training and validation cohorts, respectively. Furthermore, the model maintained high time-dependent AUC values at multiple timepoints (AUCs of 0.836, 0.820, and 0.801 for 2-, 3-, and 4-year OS, respectively) along with favorable calibration. Importantly, our model innovatively incorporates readily accessible hematological biomarkers (NPAR and PMR). This provides a more cost-effective and clinically feasible prognostic assessment tool compared to traditional models that rely solely on clinical and molecular parameters [7,8].

Analysis of 32 variables showed that longer survival was observed in patients with canonical molecular markers such as IDH1 mutation and MGMT promoter methylation, implicating them as potential prognostic factors. IDH1 mutations play a critical role in suppressing tumor metabolism and proliferation [28,29]. Patients with IDH1-mutant astrocytoma included had an mOS of 40.0 (IQR 33.6–NA, NA is censored data—some patients remained alive at follow-up cutoff, so the upper quartile was not observed) months, markedly better than the 22.2 (IQR 14.4–34.7) months observed in IDH1 wild-type patients. Similarly, MGMT methylation enhances sensitivity of tumor cells to alkylating agents such as temozolomide by inhibiting MGMT transcription and reducing DNA repair capacity, thereby significantly prolonging both PFS and OS [29-31]. In this study, a 30-year-old patient with IDH-mutant astrocytoma and MGMT methylation achieved a survival period exceeding 64 months, demonstrating significant survival benefit [32].

Furthermore, by integrating multiple machine learning methods, the study systematically identified age, the inflammation-nutrition marker NPAR, and the platelet quantity and function marker PMR as independent prognostic factors for patients with ADG [16]. These variables demonstrated significant predictive power in forecasting the prognosis of patients with ADG [33,34].

Age was confirmed as a key prognostic factor in our model. Patients aged ≥53 years had a higher risk of disease progression and significantly shorter survival time compared with those aged <53 years. This finding aligns with previous research trends regarding the prognosis of older adults with ADG, which may be related to reduced treatment tolerance and alterations in tumor biological characteristics in older individuals. It suggests that clinicians should pay attention to age stratification and develop personalized treatment plans accordingly [28].

This study is the first to identify NPAR as an independent prognostic factor for ADG. Patients with high NPAR levels had significantly shorter mOS and mPFS, along with a markedly increased risk of disease recurrence and worse prognosis. As a novel indicator that comprehensively reflects systemic inflammation and nutritional status, the NPAR has increasingly been recognized for its prognostic value in various cancers such as pancreatic and urological cancers in recent years. The NPAR integrates both systemic inflammation (reflected by neutrophil percentage) and nutritional status (reflected by serum ALB), 2 key pathophysiological processes known to influence cancer prognosis. Neutrophils can impair immune surveillance by suppressing natural killer cell function and promote tumor cell proliferation and metastasis [12,35]. Serum ALB levels not only reflect the body's protein metabolic status but are also closely associated with immune dysfunction [36]. The prognostic value of NPAR may stem from its correlation with systemic inflammatory responses mediated by proinflammatory cytokines in the TME. This pathophysiological cascade can accelerate the progression of cachexia and facilitate the evolution of malignant tumor phenotypes by modulating the TME [37,38].

The prognostic value of NPAR stems from its integration of 2 pivotal pathophysiological pathways: protumor inflammation and host nutritional status. The neutrophil component reflects systemic inflammation. Within the glioma TME, neutrophils are polarized into tumor-associated neutrophils (TANs), which facilitate tumor progression by secreting matrix metalloproteinases to enhance invasion, releasing proangiogenic factors like vascular endothelial growth factor, and contributing to T-cell dysfunction [39]. Emerging evidence specifically links this protumorigenic neutrophil activity to glioma progression [40]. Conversely, hypoalbuminemia, indicative of poor nutritional status and diminished physiological reserve, is a well-established marker of impaired immune competence and poorer outcomes in patients with cancer [41]. Thus, NPAR comprehensively captures this detrimental interplay between a proinflammatory TME and a compromised host state.

Furthermore, this study identified a higher PMR as an independent prognostic factor for prolonged overall survival in patients with ADG. This finding is consistent with a study on angiosarcoma, which also reported that a high mean platelet volume–to–platelet count ratio served as an independent risk factor for patient mortality [42]. This consistent pattern across malignancies highlights the biological significance of composite indices based on platelet count and volume.

While studies have established that platelets can facilitate glioma progression by releasing factors like platelet-derived growth factor to stimulate proliferation [43] and by modulating the immune microenvironment to promote an M2 phenotype and immune escape [44], our discovery of PMR as a protective factor suggests a more nuanced role. We hypothesize that an elevated PMR reflects a distinct platelet phenotype characterized by a lower mean platelet volume which is generally associated with diminished platelet reactivity. Consequently, a high PMR may indicate a reduced capacity of platelets to engage in these documented protumorigenic processes, thereby explaining its association with improved survival in ADG.

The prognostic nomogram developed from the aforementioned factors demonstrates significant translational potential. This tool can be integrated into electronic medical record systems to enable automated risk stratification at the time of diagnosis. Consequently, high-risk patients could be considered for more

XSL•FO
RenderX

aggressive treatment strategies—such as intensified chemoradiation following maximal safe resection—or more intensive follow-up (eg, neuroimaging every 2-3 months), and even enrollment in novel clinical trials. Conversely, low-risk patients may be suitable candidates for treatment de-escalation, such as shortened adjuvant chemotherapy cycles or reduced radiation doses, aiming to preserve oncological control while enhancing quality of life. This nomogram-based decision-making model represents a constructive step toward precision neuro-oncology.

Limitations

This study is subject to several limitations, including its single-center retrospective design, which may limit generalizability, and a variable-to-sample size ratio that raises concerns about overfitting despite internal validation. These limitations underscore the necessity for external validation in independent multicenter cohorts as an essential next step. Moreover, the molecular mechanisms linking NPAR and PMR to glioma prognosis are not fully understood. To address these points and advance this research, future work must focus on multicenter prospective validation, augmenting the model's power through the integration of radiomics and genomics, and leveraging single-cell and multi-omics technologies to decipher the functional roles of these circulating biomarkers in glioma pathogenesis.

Conclusion

In conclusion, this study significantly improved the robustness of prognostic biomarkers through a multimodel cross-validation strategy. Among the numerous factors, age, the preoperative inflammation-nutrition composite indicator NPAR, and platelet quantity and function marker PMR were key prognostic factors. Patients with ADG with younger age and lower NPAR values had a lower risk of disease progression and better prognosis; meanwhile, patients with higher PMR exhibited longer survival. These biomarkers are not only easily accessible and cost-effective but also highly beneficial, offering a new perspective for personalized treatment of ADG.

Acknowledgments

We gratefully acknowledge the use of R statistical software and thank the funding agencies for their support of this research.

Authors' Contributions

CZ conceived the study concept, CZ and JA designed the study protocol and performed statistical analysis and interpretation, JA and LZ retrieved and selected the data, CZ and JA completed the draft writing and manuscript revision, and LZ oversaw the integration of the entire study and approved the final version. All authors have approved the submission of the final manuscript.

Abstract

Background: Thyroid carcinoma is the most prevalent endocrine malignancy, with a worldwide increasing incidence. Capsular invasion and neural invasion (NI) are pivotal prognostic factors for recurrence and survival; however, their preoperative noninvasive assessment remains challenging.

Objective: We aimed to identify computed tomography (CT) radiomic biomarkers associated with capsular invasion in thyroid carcinoma, construct machine learning models integrating radiomic and clinical data, and evaluate their utility for NI risk stratification.

Methods: In this retrospective cohort, 111 patients with thyroid carcinoma were divided into capsular invasion–positive (n=63) and capsular invasion–negative (n=48) groups, with 37 (33.3%) cases presenting concurrent NI. Radiomic features were extracted from arterial and venous phase CT images at original resolution, including 111 gray-level co-occurrence matrix features. Nine key radiomic features (A1-A9) were selected via least absolute shrinkage and selection operator regression (λ=0.017). To preserve the physical meaning of texture features (eg, spatial correlation and contrast reflecting tumor microstructural heterogeneity), no resampling or scaling was performed on the regions of interest during radiomic feature extraction. Nomogram models and random forest (RF) models were constructed based on clinical indicators (galectin-3, etc) and radiomic features, respectively. Additionally, a neural network (NN) model integrating multimodal data was developed. Model stability was verified using 5-fold cross-validation and 1000-time bootstrap resampling, while performance was evaluated via receiver operating characteristic curves, calibration curves, and decision curve analysis.

Results: Model performance analysis revealed that among the nomogram models, the clinical indicator-based nomogram achieved an internally estimated area under the curve (AUC) of 0.9418 (95% CI 0.892 - 0.976) in the capsular invasion prediction task. The radiomic-based nomogram had an internally estimated AUC of 0.9334 (95% CI 0.881 - 0.968) in the capsular invasion prediction task and 0.8001 (95% CI 0.663 - 0.898) in the cross-label association analysis task. In RF models, clinical indicator-based and radiomic-based RFs exhibited an AUC of 0.7646 (95% CI 0.651 - 0.857) and 0.8102 (95% CI 0.703 - 0.892) in the cross-label association analysis task, respectively. The NN model performed promisingly, with an AUC of 0.775 (95% CI 0.621 - 0.903) in the cross-label association analysis task and a mean absolute error of <0.05 on the calibration curve.

Conclusions: Capsular invasion is a strong predictor of NI risk in thyroid carcinoma. Radiomic models based solely on preoperative CT images show potential for preoperative NI risk stratification. Models incorporating clinical parameters (obtained from postoperative tissue), including the integrated multimodal model, are more accurately characterized as postoperative risk stratification tools. The NN model, which integrated raw CT images with clinical data, achieved an AUC of 0.775 (95% CI 0.621 - 0.903), underscoring the potential of such multimodal analysis to capture complex relationships between imaging phenotypes and tissue-level biomarkers for enhanced postoperative assessment. This framework's radiomic component points toward purely image-based, preoperative evaluation tools' development.

Introduction

Thyroid carcinoma represents the most prevalent malignancy of the endocrine system, with a worldwide increasing incidence in recent years [1]. The biological behavior of thyroid carcinoma varies considerably. Some patients experience favorable outcomes, while others face higher risks of recurrence and metastasis [2]. Accurate assessment of tumor aggressiveness and prognostic factors is critical for developing personalized therapeutic strategies and improving patients' quality of life. Capsular invasion and neural invasion (NI) are key prognostic determinants in thyroid carcinoma. Research has demonstrated that thyroid carcinoma patients with capsular invasion or NI exhibit significantly higher postoperative recurrence and mortality rates compared to those without such invasive features [3]. According to previous studies, thyroid carcinoma biomarkers galectin-3 (Gal-3), Hector Battifora Mesothelial Epitope-1 (HBME-1), and cytokeratin 19 (CK19) are often overexpressed in malignant tumors compared to benign lesions. However, whether they are related to capsular invasion and NI is unclear [4]. Radiomics, an emerging computational technology, enables high-throughput extraction of quantitative features from medical imaging data, which reflect multidimensional tumor characteristics, including morphology (eg, ranges of tumor boundaries), texture, and functional heterogeneity [5,6]. Computed tomography (CT)–based radiomic analysis holds promise for identifying imaging biomarkers closely associated with tumor biology and may provide novel insights for diagnosis and prognosis [7,8]. The development of CT-derived radiomic biomarkers linked to capsular invasion in thyroid carcinoma may facilitate early and precise prediction of tumor aggressiveness. Furthermore, clarifying the stratification value of these biomarkers for NI risk could empower clinicians to more accurately assess risk preoperatively and provide a reliable basis for targeted neuroprotective strategies [9]. Nevertheless, current research on molecular imaging biomarkers for capsular invasion in thyroid carcinoma remains in its exploratory phase, and their potential for stratifying NI risks needs further investigation. This study aims to systematically identify CT-based radiomic biomarkers associated with capsular invasion in thyroid carcinoma and comprehensively evaluate their risk stratification utility for NI, thereby advancing novel methodologies for precision oncology in thyroid carcinoma management.

Methods

Study Population

A total of 111 patients diagnosed with thyroid carcinoma and hospitalized were retrospectively enrolled. Based on the presence of capsular invasion, patients were categorized into a control group (capsular invasion–negative, n=48) and a study group (capsular invasion–positive, n=63). No significant differences in baseline characteristics were observed between the 2 groups (Table 1), ensuring comparability for subsequent analyses.

XSL•FO
RenderX

Table . Comparative analysis of baseline characteristics between patients with and without membrane invasion.[a]

		Control group (n=48)	Study group (n=63)	Statistics	*P* value
Gal-3[b], n (%)				9.3 (1)[c]	.002
	High expression	18 (37.5)	42 (66.67)		
	Low or no expression	30 (62.5)	21 (33.33)		
HBME-1[d], n (%)				1.7 (1)[c]	.19
	High expression	45 (93.75)	62 (98.41)		
	Low or no expression	3 (6.25)	1 (1.59)		
CK19[e], n (%)				29.3 (1)[c]	.001
	High expression	26 (54.17)	61 (96.83)		
	Low or no expression	22 (45.83)	2 (3.17)

BMI (kg/m^2), mean (SD)		21.83 (2.16)	22.51 (2.17)	−1.49（109）[h]	.14

[a]High expression was defined as ≥2-fold expression relative to peripheral blood mononuclear cell controls.
[b]Gal-3: galectin-3.
[c]Chi-square test.
[d]HBME-1: Hector Battifora Mesothelial Epitope-1.
[e]CK19: cytokeratin 19.
[f]NI: neural invasion.
[g]CEA: carcinoembryonic antigen.
[h]*t* test.
[i]CCSA-2: circulating cancer-specific antigen.
[j]CA199: carbohydrate antigen 199.
[k]CA125: carbohydrate antigen 125.

Inclusion criteria were as follows: (1) diagnosis of thyroid carcinoma confirmed by postoperative histopathological examination and compliance with the SEOM-GETNE-TTCC （ Spanish Society of Medical Oncology, Spanish Group for Neuroendocrine and Endocrine Tumors, and Spanish Group for Head and Neck Tumors） Clinical guideline for thyroid cancer (2023) [10]; (2) preoperative neck CT scan; (3) availability of complete clinical records, including postoperative histopathological reports explicitly documenting capsular invasion and NI status; and (4) high-quality imaging data with standardized acquisition protocols, clearly delineated tumor boundaries, and absence of motion artifacts. Exclusion criteria included having (1) concurrent diagnosis of other malignancies or (2) severe hepatic or renal dysfunction, active autoimmune diseases, or pregnancy or lactation.

Ethical Considerations

This study was approved by the Ethics Committee of Air Force Medical Center, Air Force Medical University (No. 2025‐47-YJ01) and adhered to the principles outlined in the Declaration of Helsinki. The ethics committee specifically evaluated and approved a waiver of informed consent for this retrospective study, considering the use of anonymized imaging and clinical data and the impracticability of obtaining individual consent. All data were anonymized and deidentified before analysis to ensure patient privacy and confidentiality. Participants did not receive any compensation.

Imaging Feature Extraction

CT scans were performed on 2 scanner models: a GE Discovery energy-spectrum CT (GE Healthcare) and a Siemens SOMATOM Definition Flash dual source CT (IncSiemens Healthineers). Scanner parameters were as follows: GE

XSL•FO
RenderX

parameters: 120 kV, automatic tube current (250 - 465 mA), 512 × 512 matrix, pitch 0.9. Siemens parameters: 120 kV, reference 210 mAs (CARE Dose4D), 512 × 512 matrix, pitch 0.8. All scans used iohexol contrast (2 mL/kg, 3 - 4 mL/s) with arterial/venous phases at 30/50 seconds. Contiguous 5 mm slices were acquired, and 1.25 mm thin-section reconstructions were generated for analysis.

For data harmonization, to mitigate interscanner variability, all images were reconstructed to a 1.25 mm slice thickness. For radiomic features (A1-A9), *z* score normalization was applied across the entire dataset. For deep learning input, minimum-maximum scaling to [0,1] was applied per scan.

Before feature extraction, raw CT images underwent preprocessing to enhance image quality and ensure accurate subsequent analyses. Thyroid cancer lesion boundaries were independently delineated by 2 associate chief physicians with 6 and 8 years of experience in head and neck imaging diagnosis, using ITK-SNAP (developed by the ITK-SNAP Development Team, University of Pennsylvania) software to manually delineate regions of interest (ROIs) on arterial phase CT images. For venous-phase features (A3, A5, A7, and A9), arterial-phase ROIs were propagated to venous-phase images using rigid image registration, followed by manual verification and adjustment. To verify consistency, CT images of 30 (27% of the cohort) randomly selected patients were analyzed. Intraclass correlation coefficients (ICC) were calculated to assess both ROI volume consistency and numerical consistency of core gray level cooccurrence matrix (GLCM) features (contrast, correlation, and energy; distance d=1, angle θ=0°, 45°, 90°, 135°). The ICC for ROI volume was 0.92 (95% CI 0.85 - 0.96, P<.001), and the ICC value range of GLCM core features was 0.88 - 0.94 (both P<.001), indicating excellent reproducibility. Discrepancies in 3 (10%) cases were resolved through consensus review with postoperative pathology as reference.

Dimensionality reduction was performed via principal component analysis (PCA) and linear discriminant analysis (LDA). Intensity-based features were concurrently extracted and subjected to least absolute shrinkage and selection operator (LASSO) regression to identify robust predictors. To mitigate interscan variability in gray-level intensity values caused by heterogeneous acquisition protocols, for the extraction of hand-crafted radiomic features (A1-A9), *z* score normalization was applied across the entire dataset to standardize the gray-scale distribution and eliminate interscan variability caused by heterogeneous CT acquisition protocols. It should be noted that applying normalization to the full dataset before cross-validation could lead to potential information leakage, as the mean and SD used for normalization may inadvertently include information from samples designated for validation. Although our primary aim was to compare the relative performance of different models rather than to provide absolute performance estimates, we acknowledge this methodological limitation and have further addressed its potential impact in the Discussion section. For the deep learning model (DenseNet121) input only: the original-resolution ROIs were first normalized to a [0, 1] range using minimum-maximum scaling, then resized to 224×224 pixels (to meet the fixed-size input requirement of the pretrained DenseNet121 backbone) and converted to 3-channel format by duplicating the grayscale image across RGB (red, green, and blue) channels. This 224×224 resizing step was exclusive to deep learning model training and did not involve radiomic feature extraction.

Notably on ROI resolution for feature extraction, a critical distinction was made between radiomic feature extraction and deep learning model input preparation in this study. All radiomic texture features (111 GLCM features and 9 LASSO-selected A1-A9 features) were extracted from original-resolution CT ROIs to avoid systematic scaling bias and retain the physical meaning of texture metrics. The resizing of ROIs to 224×224 pixels was a dedicated preprocessing step for the DenseNet121-based deep learning model, as pretrained convolutional neural networks (NN) typically require fixed-size inputs. This separation of technical processes ensures the reliability of both radiomic feature analysis and deep learning model training.

Model Development

Given the limited total sample size (111 patients), to maximize the use of data, a full-sample modeling approach was adopted.

Model construction: all 111 cases were used as the analysis cohort, with capsular invasion status (1=capsular invasion–positive, n=63; 0=capsular invasion–negative, n=48) as the labeling variable. Input features were tailored to each model type: a common set of clinical biomarkers (for the complete list, see Table 1) was used across all models, while pixel-level CT features A1-A9 (selected via LASSO regression from GLCM texture features of CT ROIs) were used specifically in the traditional radiomic models (nomogram and random forest [RF]).

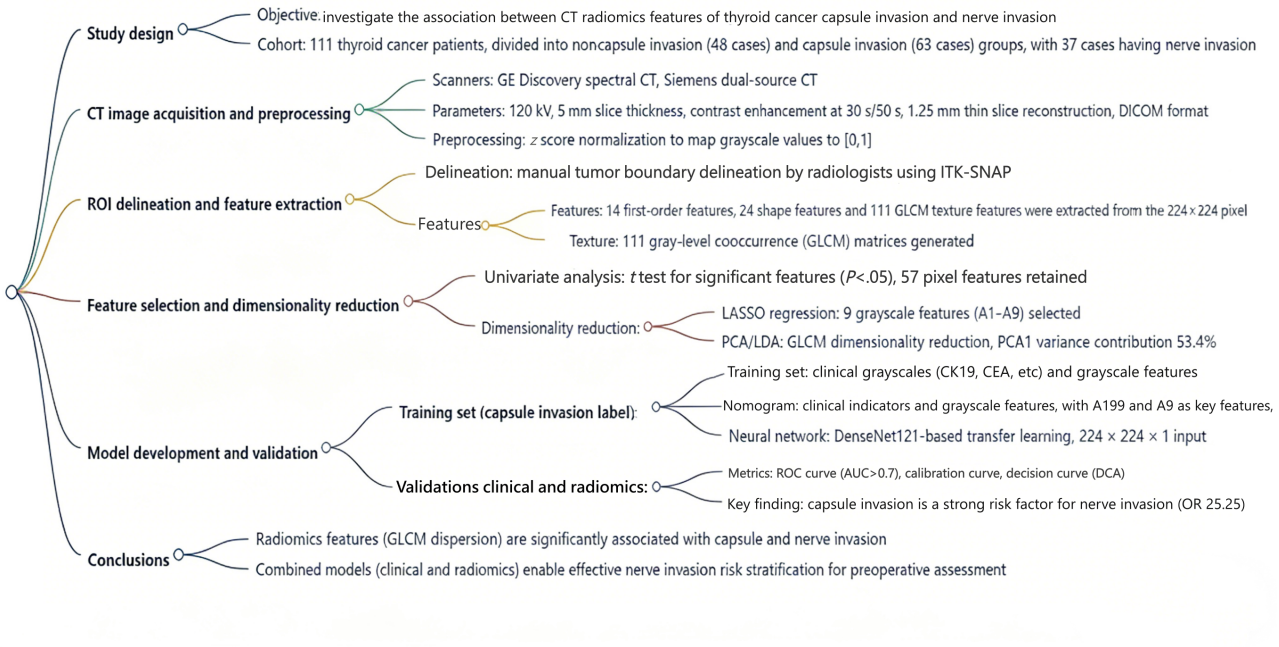
The NN model used a multimodal input, comprising both raw arterial-phase CT ROI images and the suite of clinical biomarkers (for the complete list, see Table 1), to autonomously learn high-level spatial and clinical patterns associated with capsular invasion (Multimedia Appendix 1). It is crucial to note that the hand-crafted radiomic features (A1-A9) were not direct inputs to this NN model. For each patient, a single 2D axial slice with the largest tumor cross-section was selected, standardized to 224×224 pixels, and converted to 3-channel format. Rationale for arterial-phase only input: this single-phase design was implemented for two primary reasons: (1) to maintain model simplicity and mitigate overfitting risk given the limited sample size, and (2) because the arterial phase provides the most direct imaging correlate of tumor vascularity, a key biological process underlying invasion. We hypothesized that the convolutional NN could learn high-level features from the arterial phase that are informative for predicting outcomes potentially associated with venous-phase patterns. Rationale despite venous-phase radiomic feature importance: it is noteworthy that in our traditional radiomics analysis, a feature derived from the venous phase (A9) showed high importance. The decision to use only arterial-phase images for the deep learning model was based on a complementary hypothesis: that the convolutional NN could learn high-level, abstract features from the arterial phase that are biologically or spatially correlated with the tumor properties captured by the venous-phase radiomic signature (A9). This approach allowed

XSL•FO
RenderX

us to test whether a single, routinely acquired phase could provide sufficient information for the NN to make accurate predictions, thereby simplifying the model and its potential clinical translation.

Concerning model validation, NI status (1=NI-positive, n=37; 0=NI-negative, n=74) was used for a cross-label association analysis. The core goal was to evaluate whether the features associated with capsular invasion (as captured by our models) were also rank-informative for NI status within the same cohort. The full 111-case dataset was used for both (1) model training (with capsular invasion status as the label) and (2) cross-label association evaluation (with NI status as the label). It is crucial to note that this analysis evaluates the association between capsular invasion–related features and NI status on the same samples, primarily reflecting their strong pathological correlation rather than constituting an independent predictive validation on unseen data. The full 111-case cohort, labeled based on the presence or absence of capsular invasion, was used to construct 3 predictive models (nomogram, RF, and NN) to capture capsular invasion–associated features. The same full cohort, labeled based on the presence or absence of NI, was then used to evaluate the models' cross-predictive performance for NI risk stratification. To address potential concerns regarding the unconventional data usage design and to empirically validate our model's generalizability, we performed a supplementary traditional 7:3 hold-out validation.

For the nomogram development, clinically significant variables associated with capsular invasion were incorporated into a clinical nomogram, while gray-level features selected via LASSO regression were integrated into an imaging-based nomogram. Calibration curves (predicted probability vs observed probability) were generated to assess agreement between model predictions and observed outcomes, with internal validation performed using a bootstrap resampling method (B=1000 iterations).



The RF model architecture comprised 2 components: a clinical RF model incorporating capsular invasion–associated variables and an imaging RF model integrating LASSO-selected radiomic features. Hyperparameter optimization was conducted via 5-fold cross-validation using the caret package, with the number of trees (ntree) tuned from 50 to 500 (step size=5) and the minimum number of features per node split (mtry) ranging from 2 to 10. Model interpretability was enhanced through feature importance plots, decision tree visualization, receiver operating characteristic (ROC) curves, and out-of-bag error analysis.

For the input of the NN model (based on DenseNet121): to comply with the fixed-size input requirement of the pretrained DenseNet121 backbone, the original-resolution ROIs were first normalized to a [0, 1] range using minimum-maximum scaling, then resized to 224×224 pixels. The single-channel grayscale images were further converted to a 3-channel format by duplication across RGB channels. The first 10 convolution blocks of DenseNet121 were reserved for extracting high-level image features, and the feature map was compressed into fixed-length vectors through global average pooling. Image feature vectors (extracted by DenseNet121) and clinical feature vectors were normalized, respectively, and directly spliced into multimodal feature vectors. The spliced features were input to the fully connected layer and were finally classified (capsular invasion: positive or negative) through the Sigmoid output layer. The 9 radiomic features (A1-A9) were selected from GLCM features of the ROI via LASSO regression. The model was optimized using the Adam optimizer (learning rate=1×10^{4}) with binary cross-entropy loss over 50 training epochs (batch size=16). Early stopping was triggered if validation loss plateaued for 10 consecutive epochs (Multimedia Appendices 1 and 2).

The technical workflow is illustrated in Figure 1.

XSL•FO

Model Interpretability Analysis

To interpret the NN's predictions and derive the importance scores in Figure 2B, we used Shapley Additive Explanations (SHAP). The analysis pipeline was as in the following paragraphs.

Concerning calculation for the validation set, SHAP values were computed for each input feature (clinical variables and the high-dimensional features extracted from raw CT images by DenseNet121). These values quantify a feature's contribution to a specific prediction.

Figure 2. Neural network model performance. (A) Mean training accuracy curves across the 5-fold cross-validation splits, plotted for different numbers of hidden units. (B) SHAP-based feature importance (normalized 0-100). Blue: clinical biomarkers (direct inputs); red: image patterns (learned from raw CT). (C) ROC curve for neural invasion prediction. Note for (B): normalized importance scores derived from SHAP analysis (see subsection in Methods: Model interpretability analysis). Imaging patterns were semantically annotated based on activation map visualizations. CA125: carbohydrate antigen 125; CA199: carbohydrate antigen 199; CCSA-2: circulating cancer-specific antigen; CEA: carcinoembryonic antigen; CK19: cytokeratin 19; CT: computed tomography; Gal-3: galectin-3; NI: neural invasion; NN: neural network; ROC: receiver operating characteristic; SHAP: Shapley Additive Explanations.

For aggregation and semantic mapping, global importance for each clinical variable was defined as its mean absolute SHAP value. For image features, activation maps corresponding to features with high mean absolute SHAP values were analyzed. Recurring visual patterns were inductively categorized into 3 semantic concepts: "Image_Heterogeneity," "Image_Boundary," and "Enhancement_Dynamics." The importance score for each concept was calculated as the mean absolute SHAP value of its constituent image feature dimensions.

In normalization, all resulting scores (for clinical variables and image concepts) were linearly normalized to a 0 - 100 scale for comparative visualization in Figure 2B.

Data Collection

All thyroid carcinoma tissue specimens were collected immediately after surgical resection, and 10% neutral buffered formalin was used for fixation within 30 minutes for morphological preservation. After paraffin embedding, 5-µm-thick sections were prepared, and tumor tissue areas (with

XSL•FO
RenderX

tumor cell content ≥80%, confirmed by 2 pathologists) were microdissected for quantitative polymerase chain reaction (qPCR) analysis. This ensured that the detected expression of Gal-3, HBME-1, and CK19 accurately reflected the biological characteristics of thyroid carcinoma cells.

Real-time fluorescence qPCR was performed to measure the levels of Gal-3, HBME-1, and CK19 in thyroid carcinoma tissue specimens from the 111 enrolled patients. Glyceraldehyde-3-phosphate dehydrogenase served as the endogenous reference gene for normalization. Peripheral blood mononuclear cells (PBMCs) from age- and sex-matched healthy individuals undergoing routine health screenings were used as the control group for qPCR analysis. Relative gene expression levels ≥2-fold compared to PBMC controls were pragmatically defined as high expression for subsequent categorical analysis. It is important to note that the use of PBMCs as a control group is a methodological consideration due to the practical and ethical challenges in obtaining matched healthy thyroid tissue samples. As PBMCs (of nonepithelial origin) and thyroid epithelial cells have fundamentally different baseline gene expression profiles, this comparison is intended to establish a highly sensitive detection threshold for identifying genes that are actively expressed at levels substantially above this technical background in tumor tissue, rather than to provide precise biological fold-change values across tissue types. The ≥2-fold threshold therefore serves as a pragmatic cutoff for distinguishing tumors with detectably high expression of the target genes. Therefore, it is crucial to emphasize that “high expression” as defined in this study indicates detectability above a nonepithelial (PBMC) baseline, and should not be interpreted as pathological overexpression relative to normal thyroid tissue.

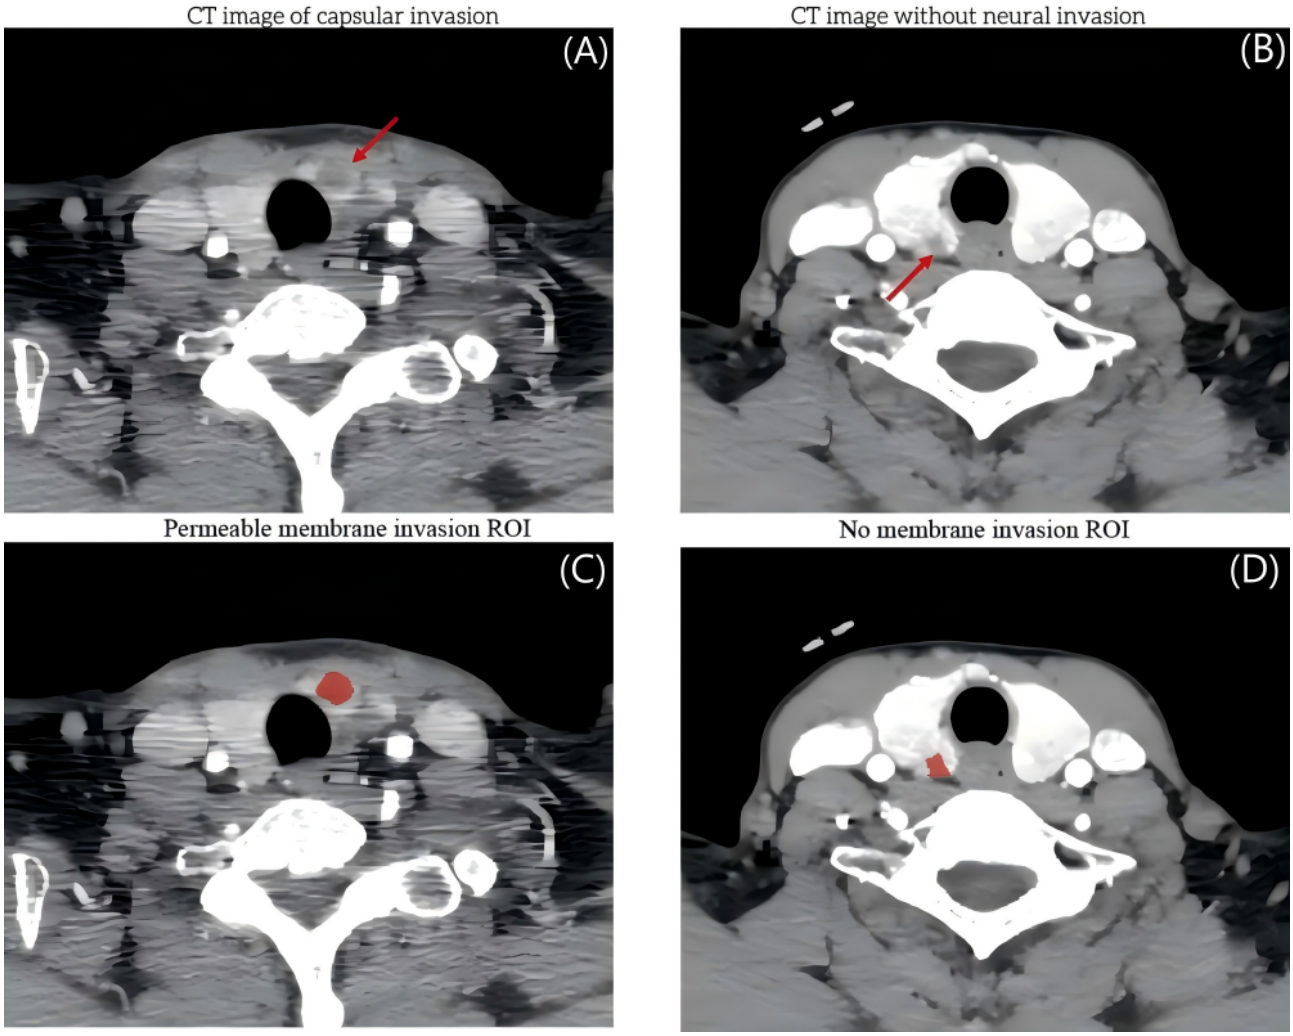
Concurrently, baseline characteristics and serum levels of tumor biomarkers, including carcinoembryonic antigen (CEA), carbohydrate antigen 199 (CA199), and carbohydrate antigen 125 (CA125), and the second-generation assay for circulating cancer-specific antigen, were systematically collected.

Statistical Methods

All statistical analyses were performed using SPSS Statistics (version 27.0; IBM Corp) and R software (version 4.4.3; R Foundation). Continuous variables with normal distribution were expressed as mean ± SD ($x^{-}\pm s$), while categorical data were presented as n (%). Intergroup comparisons were conducted using independent samples *t* tests for continuous variables and chi-square tests for categorical variables. Multivariable binary logistic regression analysis was used to identify independent risk factors. The RF model was developed using the randomForestSRC, *ggRandomForests*, *pdp*, and *GGally* packages in R. Nomogram construction and calibration were implemented with the *rms*, *dcurves*, and *pROC* packages in R. NN architecture was built using the keras interface in R. Model accuracy was evaluated via the confusionMatrix() function from the *caret* package. All visualizations were generated using the *ggplot2* package in R. A *P* value <.05 was considered statistically significant.

Results

Overview



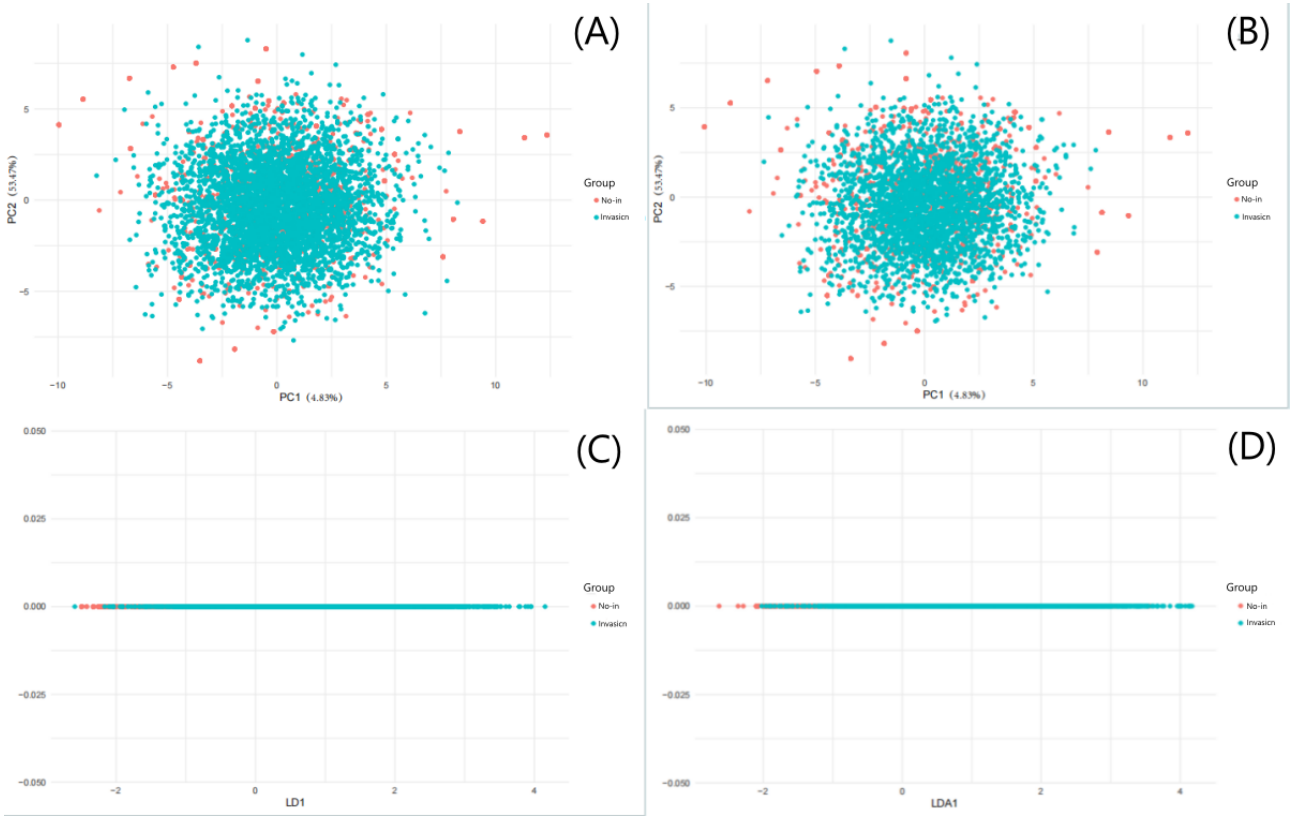
In this section, Table 1 presents the baseline characteristics of patients. The detailed multivariate logistic regression results (originally Tables 2 and 3) have been moved to the supplementary material; see Tables S1 and S2 in Multimedia Appendix 3.

Baseline Characteristics Comparison

The comparative analysis of baseline characteristics between patients with and without capsular invasion revealed statistically significant differences in the categorized expression levels (high vs low or no expression) of Gal-3 and CK19, as well as in the serum concentrations of tumor markers including CEA, CA199, and CA125 (*P*<.05, Table 1). Representative arterial-phase CT images and corresponding ROI delineations from patients with thyroid carcinoma are shown in Figure 3A-D.

XSL•FO
RenderX

(B-D) A case without NI demonstrating well-defined tumor boundaries. CT: computed tomography; NI: neural invasion; ROI: regions of interest.



GLCM Analysis

The GLCM analysis yielded 111 texture features, which were subsequently subjected to dimensionality reduction via PCA and LDA. A total of 14 principal components were extracted for capsular invasion classification, with PCA1 and PCA2 accounting for 53.47% and 4.83% of the total variance, respectively. Significant intergroup differences were observed in PCA1 (t_{109}=11.671, P=.001, 2-tailed), where patients without capsular invasion exhibited greater dispersion in GLCM patterns, as evidenced by their larger Euclidean distance (6.98 vs 4.12 in the capsular invasion group). Similarly, NI analysis demonstrated significant differences in both PCA1 (t_{109}=10.339, P=.001) and PCA2 (t_{109}=−2.0187, P=.04). Non-NI cases again displayed greater GLCM dispersion, with Euclidean distances measuring 7.02 vs 4.05 in the NI group, a pattern consistent with the capsular invasion findings. LDA projections further corroborated this dispersion pattern, showing broader distribution clusters in noninvasion groups compared to their invasion counterparts. Visual representations of these analytical outcomes are provided in Figure 4.

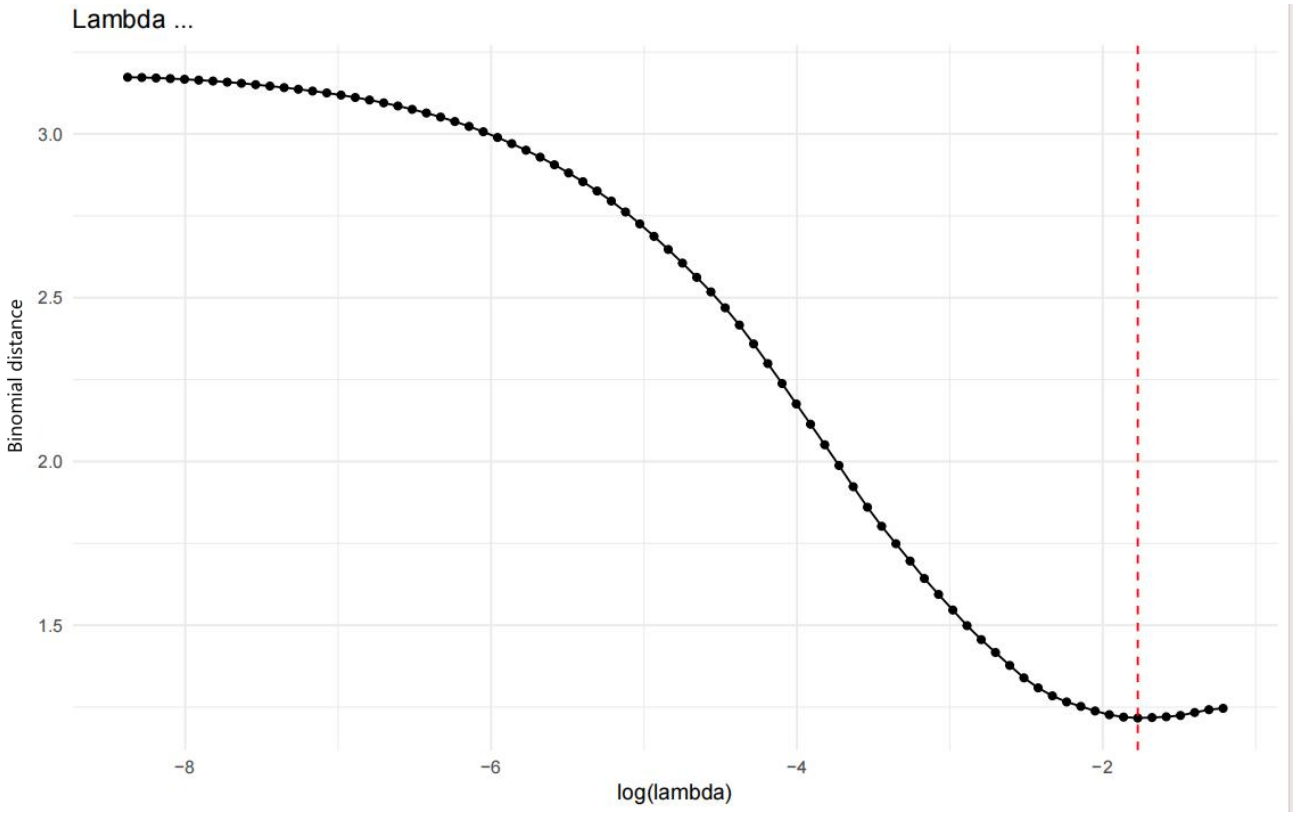
Multivariate Binary Logistic Regression Analysis Based on Clinical Indicators

It is important to emphasize that the following multivariate logistic regression analyses are intended to explore factors associated with the co-occurrence of pathological features, rather than to build preoperative predictive models. As both capsular invasion and NI are postoperative pathological diagnoses, their inclusion as variables in models predicting each other primarily reflects their strong pathological correlation, not a causal predictive relationship usable for preoperative assessment.

A multivariate binary logistic regression model was constructed with capsular invasion status as the dependent variable (1=presence, 0=absence). The analysis identified CK19, CEA, CA199, CA125, and NI as significant independent risk factors for capsular invasion. Notably, CK19 demonstrated an exceptionally strong association with capsular invasion, yielding an odds ratio (OR) of 60.491 (P<.05, see Table S1 in Multimedia Appendix 3).

A parallel analysis was performed with NI status as the dependent variable (1=presence, 0=absence). Among all clinical indicators, only capsular invasion emerged as a significant predictor of NI, with an OR of 25.25 (P<.05, Table S2 in Multimedia Appendix 3), underscoring the pronounced influence of capsular invasion on NI risk.



Gray-Level Feature Selection via LASSO Regression Analysis

A set of radiomic features was extracted from the pixels within the ROI. Following exclusion of features without significant differential expression, 57 discriminative features were retained for LASSO regression analysis. During variable selection, the penalty coefficient (λ) was iteratively adjusted to compress the initial 57 predictors. Optimal λ value (λ=0.017) was determined through cross-validation, achieving minimal model deviance while balancing parsimony and predictive accuracy. This process yielded a refined model incorporating 9 pivotal features (designated A1-A9), as presented in Figure 5. The 9 pixel-level features (A1-A9) selected in this study directly reflect the heterogeneity of contrast enhancement and tissue composition of thyroid carcinoma on CT images. Specifically: (1) differences in arterial-phase pixel intensity mean (A1) reflect variations in tumor vascular density: tumors with higher A1 values (stronger arterial enhancement) are more likely to have capsular invasion/NI, as increased angiogenesis provides conditions for tumor invasion; (2) variations in pixel intensity SD (A2) correspond to intratumoral necrosis: higher A2 values (uneven enhancement) often indicate necrotic foci, which are associated with poor differentiation (CK19 positivity) and higher NI risk; and (3) changes in venous-phase pixel percentile (A3 and A8) reflect capsule integrity: lower A3 or A8 values suggest capsule rupture, a direct marker of capsular invasion. These imaging phenotypes serve as quantifiable surrogates for pathological characteristics, such as vascular density, necrosis, and capsular status, enabling noninvasive preoperative assessment of tumor aggressiveness. Detailed feature definitions are provided in

RenderX

Multimedia Appendix 2, with additional descriptions in Multimedia Appendix 1.

Figure 5. Cross-validated deviance profile versus log(λ) values.

Development of Nomogram Models for Predicting NI Based on Capsular Invasion

A tumor biomarker-derived nomogram was constructed to assess the predictive value of capsular invasion for NI. ROC curve analysis demonstrated robust discriminative performance, with an internally estimated area under the curve (AUC) of 0.9418 for the capsular invasion-prediction task (modeled on the full 111-case dataset) and 0.7253 for the cross-label association analysis task (evaluated on the full 111-case dataset). Calibration curves indicated high consistency between predicted probabilities and observed outcomes across both tasks. Decision curve analysis further validated the clinical utility of the model, as its net benefit across all threshold probabilities outperformed the “treat-all” and “treat-none” strategies (Figure 6).

XSL•FO
RenderX

Figure 6. Clinically parameterized nomogram model for neural invasion prediction. (A) Nomogram integrating clinical biomarkers (Gal-3, CK19, CEA, CA199, and CA125) to predict NI risk, with key variables (CK19 and CA199) marked by "*" (high OR values from Tables S1 and S2 in Multimedia Appendix 3); red dashed lines guide point assignment for each variable. (B and C) Calibration curves for the capsular invasion–prediction task ((B) modeled on full 111-case dataset) and the cross-label association analysis task ((C) cross-prediction on full 111-case dataset), showing agreement between predicted NI probability (x-axis) and observed NI status (y-axis); 95% CI bands (light blue or red) and MAE are labeled. (D and E) DCA curves for both tasks (using the full 111-case dataset, with no traditional train or test split), comparing the net benefit of the nomogram (dark blue line) with "treat all" (red line) and "treat none" (gray line) strategies across different NI risk thresholds. (F and G) ROC curves for the capsular invasion-prediction task ((F) modeled on full 111-case dataset) and the cross-label association analysis task ((G) evaluated on full 111-case dataset), with exact AUC values and 95% CIs labeled; light blue or red bands represent 95% CIs. All analyses were based on the full 111-case cohort (capsular invasion–labeled modeling and NI-labeled evaluation). AUC: area under the curve; CA125: carbohydrate antigen 125; CA199: carbohydrate antigen 199; CCSA-2: circulating cancer-specific antigen; CEA: carcinoembryonic antigen; CK19: cytokeratin 19; DCA: decision curve analysis; Gal-3: galectin-3; MAE: mean absolute error; NI: neural invasion; OR: odds ratio; Prob: probability; RDATA: research data; ROC: receiver operating characteristic; .

XSL•FO
RenderX

A parallel nomogram model incorporating gray-level radiomic features achieved internally estimated AUC values of 0.9334 for the capsular invasion-prediction task (full 111-case dataset) and 0.8001 for the cross-label association analysis task (full 111-case dataset). Calibration curves similarly confirmed strong predictive accuracy for both tasks, and decision curve analysis revealed that the model achieved superior net clinical benefit across the entire spectrum of risk thresholds compared to reference strategies (Figure 7).

RF Model Development

An RF model was constructed using tumor biomarkers, with CA199 demonstrating the highest feature importance (visualized in Figure 8A). A representative surrogate tree from the RF ensemble (visualized in Figure 8B) initiated classification through sequential partitioning: the root node split on "CA199<76," followed by a "yes" branch subdivided by "CK19=1," and further partitioned via "CEA<28." Out-of-bag error curves (visualized in Figure 8C) revealed stabilized misclassification rates for both training and validation sets as tree numbers increased, with training set errors consistently exceeding validation set values. The 5-fold cross-validation AUC (for capsular invasion prediction) was 0.782 (95% CI 0.671 - 0.874), and the out-of-bag error rate stabilized at 0.213 when ntree ≥300 (visualized in Figure 8D). When this model was used to predict NI (full-sample NI label), the model exhibited discriminative efficacy with an AUC of 0.7646, only 2.5% lower than the cross-validation AUC for capsular invasion, confirming no significant overfitting (Figure 8).

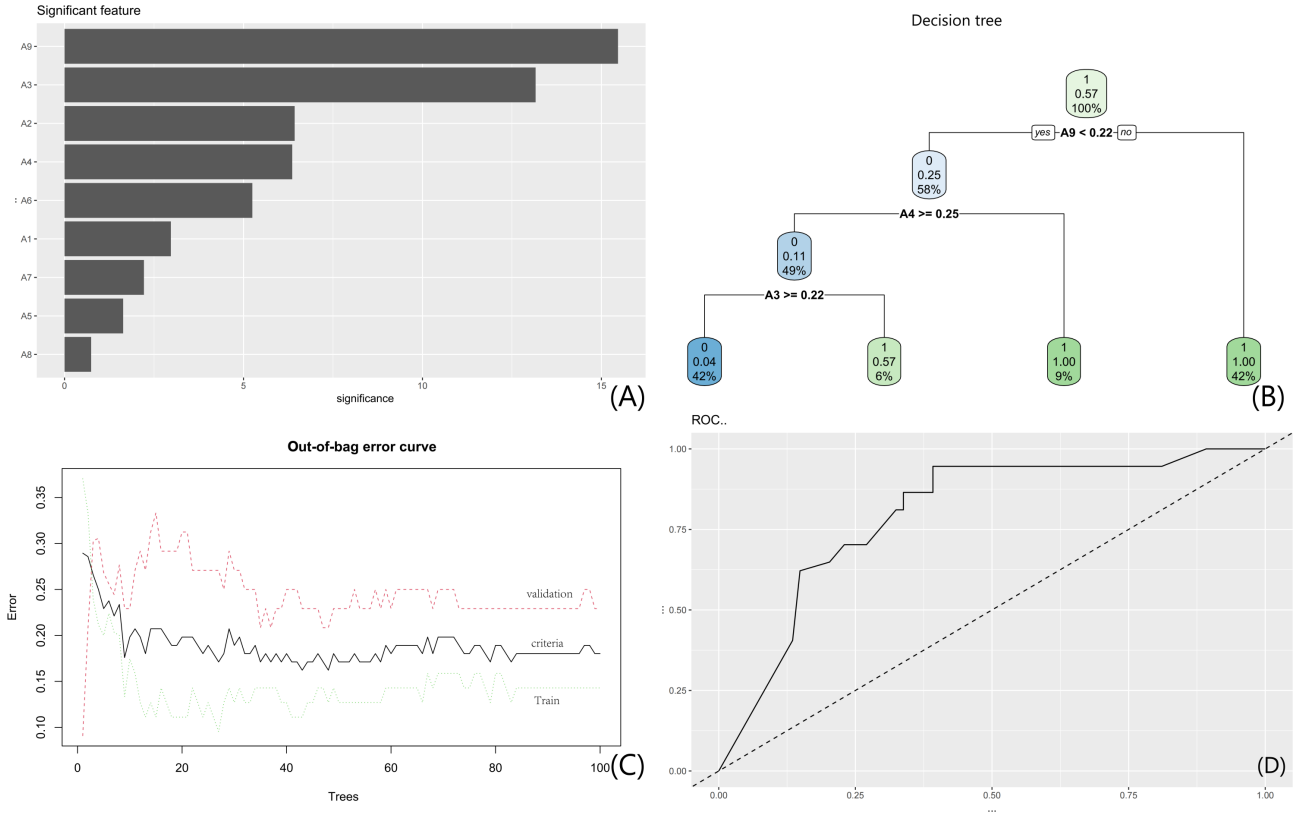

Figure 8. RF model based on clinical biomarkers. (A) Feature importance plot; (B) a representative surrogate tree from the RF ensemble; (C) out-of-bag error trajectories; and (D) ROC curve. CA125: carbohydrate antigen 125; CA199: carbohydrate antigen 199; CCSA2: colon cancer-specific antigen-2; CEA: carcinoembryonic antigen; CK19: cytokeratin 19; Gal3: galectin-3; RF: random forest; ROC: receiver operating characteristic.

A parallel RF model incorporating gray-level features identified feature A9 as the primary contributor (corresponding to Figure 9A). A representative surrogate tree from the RF ensemble (corresponding to Figure 9B) partitioned data at "A9 <0.22," with subsequent splits at "A4 ≥0.25" and "A3 ≥0.22." Out-of-bag error curves mirrored the tumor biomarker-based model, showing convergence to stability with increasing tree numbers (corresponding to Figure 9C). The 5-fold cross-validation AUC (for capsular invasion prediction) was 0.825 (95% CI 0.723 - 0.906), and the out-of-bag error rate stabilized at 0.187 when ntree ≥350. ROC analysis confirmed enhanced predictive performance (corresponding to Figure 9D); its AUC for NI prediction was 0.8102% - 1.8% lower than the capsular invasion cross-validation AUC, further confirming low overfitting risk (Figure 9). These data collectively validate the clinical utility of both RF models.

Figure 9. RF model based on gray-level features. (A) Feature importance plot (features A1-A9 represent the 9 key radiomic grayscale features selected via LASSO regression from GLCM texture features of CT regions of interest. They quantify tumor heterogeneity in arterial and venous phases (eg, A1, A9); (B) a representative surrogate tree from the RF ensemble; (C) out-of-bag error trajectories; (D) ROC curve. A1: arterial-phase mean intensity; A9: venous-phase coefficient of variation; CT: computed tomography

NN Model Development

The NN model used exclusively two input modalities: (1) raw arterial-phase CT ROI images and (2) clinical biomarkers. No hand-crafted radiomic features (A1-A9) were directly input to the NN.

An NN model integrating multimodal data demonstrated high learning efficiency, with training accuracy values exceeding 0.99 across learning curves (Figure 2A). It is important to note that Figure 2A displays the mean training accuracy across the 5-fold cross-validation splits, not a cross-validated test accuracy. The significant gap between the near-perfect training accuracy (>0.99) and the more moderate cross-validation AUC for the primary capsular invasion prediction task (0.798) is indicative of overfitting, a common challenge in training complex models on limited datasets. While early stopping was used to mitigate overtraining by halting training when validation loss plateaued, this gap suggests that the model still learned patterns highly specific to the training samples. The architecture used hidden units ranging from 10 to 30, where variations in hidden unit counts under distinct weight decay coefficients differentially influenced cross-validated accuracy values. Feature importance analysis based on SHAP values (as detailed in the Model Interpretability Analysis section) revealed that clinical biomarkers were the most influential predictors for NI risk, particularly CK19 (normalized importance score: 95) and CEA (normalized importance score: 88; Figure 2B). Concurrently, the semantically annotated image patterns—"Image_Heterogeneity" (score: 82), "Image_Boundary" (score: 75), and "Enhancement_Dynamics" (score: 68), which were autonomously learned and inductively summarized by the NN from the raw CT inputs, also contributed substantially to the predictions. Importantly, these image patterns were learned directly from raw CT images and are conceptually distinct from the hand-crafted radiomic features (A1-A9) used in traditional radiomic models. The model achieved an AUC of 0.775 in the validation set, confirming its satisfactory generalizability beyond the training cohort. The 5-fold cross-validation AUC (for capsular invasion prediction) of the integrated NN model was 0.798 (95% CI 0.695 - 0.883), with a coefficient of variation of 7.2% across folds—indicating stable performance. Early stopping was triggered at an average of 32 (SD 2.8, range: 28 - 35 epochs) across the 5 folds, effectively preventing overtraining. When predicting NI (full-sample NI label), the model achieved an AUC of 0.775 (95% CI 0.621 - 0.903)—only 2.3% lower than the capsular invasion cross-validation AUC, indicating that the model's predictive ability for NI remains robust despite some degree of overfitting on the primary capsular invasion task. Detailed architectural and performance metrics are illustrated in Figure 2. Feature importance analysis within the NN identified that its predictions were driven by several key learned representations: an image pattern capturing intratumoral heterogeneity, a feature related to venous-phase enhancement dynamics, and another reflecting textural uniformity, in conjunction with the clinical biomarkers CK19 and CEA. Feature importance analysis indicated that intratumoral heterogeneity was the most influential learned representation (importance score 0.82, full score=1.0).

XSL•FO
RenderX

About validation on an internal hold-out set, to further assess generalizability, a traditional 7:3 hold-out validation was performed. The RF model based on radiomic features (A1-A9) was trained on a subset of 78 cases and was subsequently evaluated on the separate, internal hold-out set of 33 cases. The observed AUC of 0.827 was promising, but the extremely wide 95% CI (0.652 - 0.981) indicates substantial uncertainty due to the small test sample size (n=33), necessitating cautious interpretation of the model's generalizability. This additional validation yielded a promising but variable performance (AUC=0.827, 95% CI 0.652 - 0.981) for NI prediction (see Multimedia Appendices 1 and 4 for details).

Discussion

Research Background and Basis

Thyroid carcinoma, the most prevalent malignancy of the head and neck region, has exhibited a rapid surge in incidence over the past decade, emerging as a critical threat to global human health [11]. Beyond its capacity to disrupt thyroid function and induce hormonal dysregulation, thyroid carcinoma frequently metastasizes to adjacent cervical tissues, lymph nodes, and even distant organs such as the lungs, liver, and bones, severely compromising physiological integrity [12]. Equally concerning are its profound psychosocial impacts, as patients endure debilitating fear, anxiety, and uncertainty regarding prognosis and treatment outcomes [13]. Current advances in thyroid carcinoma research have identified molecular markers such as *BRAF* (OMIM 164757) and *NRAS* (OMIM 164790) gene mutations, which have emerged as critical tools for diagnosis, prognostic stratification, and therapeutic decision-making [14]. Nevertheless, significant gaps persist in risk stratification for capsular invasion and NI, 2 pivotal prognostic determinants. Capsular invasion serves as a key predictor of lymph node metastasis, whereas NI directly correlates with postoperative survival quality and recurrence risk [3]. Elucidating the relationship between capsular invasion and NI is therefore essential for precise clinical assessment and optimized treatment planning. Therefore, the identification of radiogenomic biomarkers for capsular invasion using CT radiomics and the evaluation of their stratification value for NI are both scientifically imperative and clinically urgent.

Identification of Radiomic Signatures for Invasion Risk

In this study, GLCM analysis of CT images from thyroid carcinoma patients revealed distinct radiomic signatures between tumors with and without capsular invasion or NI. A total of 111 GLCM features were extracted and subjected to dimensionality reduction via PCA and LDA, which uncovered critical associations between key imaging biomarkers and invasion risk. The heterogeneous distribution of GLCM features in noninvasive cohorts, characterized by greater dispersion, reflects heightened spatial heterogeneity in gray-level pixel relationships within tumor microenvironments. This phenomenon may correlate with histopathological characteristics such as tumor boundary demarcation and cellular alignment integrity, a concept supported by the work of Wei et al [11], who demonstrated that radiomic features from multiparametric magnetic resonance imaging could effectively predict extrathyroidal extension in papillary thyroid carcinoma by capturing similar underlying tumor heterogeneity. In contrast, tumors with capsular invasion demonstrate enhanced propensity for boundary breaching [15], resulting in homogenization of imaging features. Noninvasive lesions, by comparison, maintained relatively intact tissue architecture [16,17], which manifests as increased textural complexity on imaging. This inverse relationship is further corroborated by a recent meta-analysis [18], which confirmed that textural homogenization in medical imaging often reflects the loss of normal tissue architecture due to invasive growth patterns. Thus, these findings suggest that GLCM feature dispersion may serve as a universal imaging biomarker of tumor invasiveness [19].

Mechanistically, tumors with NI exhibit the proliferative spread of malignant cells along nerve bundles [20], resulting in textural homogeneity on imaging. In contrast, noninvasive lesions present greater histological heterogeneity in interstitial architecture and cellular distribution [21]. Although direct radiomic studies on NI in thyroid carcinoma are scarce, the work of Mu et al [22] reinforces this biological rationale by showing that a radiomic signature on CT could effectively detect metastatic lymph nodes in thyroid carcinoma, demonstrating that imaging features can capture the tumor's propensity for local invasion and spread. LDA further corroborated these findings, demonstrating broader feature dispersion in noninvasive groups and supporting PCA findings, which suggest the utility of radiomic heterogeneity as a quantifiable biomarker for invasion risk in thyroid carcinoma [18].

Key Molecular Markers and Risk Pathways for Invasion

Notably, 3 (6.25%) patients in the capsular invasion–negative group were pathologically diagnosed with NI. This observation indicates that while capsular invasion is a dominant driver, NI can occur through alternative pathways (eg, direct perineural infiltration). Moreover, multivariate binary logistic regression identified CK19, CEA, CA199, CA125, and NI as independent risk factors for capsular invasion. Notably, CK19, a member of the cytokeratin family, exhibited an OR of 60.491, indicating that patients with significant CK19 expression had approximately 60.5 times the odds of having capsular invasion compared to those with nonsignificant expression. This finding is consistent with prior studies reporting CK19 overexpression in papillary thyroid carcinoma [23], where its upregulation enhances tumor cell proliferation and invasive potential via disruption of intercellular adhesion molecules, thereby facilitating tumor penetration through capsular barriers [24]. Laishram et al [25] further identified CK19 as a highly sensitive and specific immunohistochemical marker for thyroid carcinoma in a cross-sectional study using histopathology as the reference standard. Elevated serum levels of CEA, CA199, and CA125 further signify increased tumor burden and epithelial-mesenchymal transition, synergistically promoting invasive phenotypes [26,27]. Intriguingly, NI itself emerged as a covariate for capsular invasion, implying shared molecular pathways or microenvironmental crosstalk. Conversely, when NI was modeled as the dependent variable, only capsular invasion remained significant, underscoring its role as a

XSL•FO
RenderX

dominant predictor for NI. This finding is in line with the anatomical invasion pathway of thyroid carcinoma. Following capsular penetration, tumors demonstrate increased propensity for either direct NI (eg, recurrent laryngeal nerve involvement) or chemokine-mediated perineural infiltration through paracrine signaling modulation [28]. The resultant loss of tumor boundary integrity and disruption of the local microenvironment may jointly provide a structural basis and inflammatory background for NI. Importantly, the exclusion of variables such as age and tumor size from the model highlights the preeminence of capsular status in neural risk stratification, offering clinicians an actionable biomarker for preoperative assessment.

Predictive Model Construction and Clinical Translation Value

For preoperative assessment, the radiomic model prioritizes spatial heterogeneity derived from preoperative CT, enabling noninvasive risk prediction via texture features [6]. Such insights may guide surgical planning, such as the extent of resection or the consideration of intraoperative nerve monitoring. For postoperative stratification, the clinical biomarker-based nomogram and the integrated multimodal model use data available after surgery. They emphasize the biological aggressiveness associated with capsular invasion, aiding in postoperative pathological substaging and recurrence risk prediction. For instance, concurrent positivity for CA199 and CK19 in patients with capsular invasion could signal high-risk subgroups for NI, indicating the need for intensified adjuvant therapy. Specifically, by integrating quantitative molecular data with imaging phenotypes, these postoperative models could provide a supplementary risk assessment that might identify patients with occult invasive features or a higher propensity for recurrence, thereby adding prognostic granularity beyond standard histopathological examination alone. NN architectures further synergized clinical and imaging data, capturing nonlinear interactions between capsular invasion and neural risk [29]. Biological markers such as CEA may reflect intrinsic invasive potential, whereas radiomic features (eg, A9) represent its spatial manifestation. Notably, tumors with capsular invasion characterized by elevated CEA levels and disorganized textures (low A9 values) exhibited markedly increased NI rates, illustrating the model's ability to decode multifactorial invasion pathways. The high performance of all models in the cross-label association analysis (eg, AUCs ≈0.80) is largely concordant with the strong pathological correlation between capsular invasion and NI identified by logistic regression (OR=25.25). This indicates that the models effectively captured the shared features underlying both invasion types, rather than demonstrating independent predictive power for NI on entirely unseen data.

Concerning clinical translation and distinction between model types, it is crucial to distinguish the intended clinical context of the different models developed in this study. The radiomic models (nomogram and RF based on features A1-A9), derived solely from preoperative CT, hold promise as preoperative decision-support tools. They could inform surgical planning, such as the extent of resection or the need for intraoperative nerve monitoring, based on noninvasive imaging. In contrast, the clinical biomarker-based models and the multimodal NN model integrate data (Gal-3 and CK19) that are only available postoperatively from resected tissue. Therefore, their primary utility lies in postoperative risk stratification. They may help pathologists and clinicians identify high-risk subsets among patients already diagnosed with capsular invasion, potentially predicting the likelihood of concurrent or subsequent NI, and thus informing adjuvant therapy strategies or the intensity of follow-up. This postoperative application remains valuable, as it could refine prognostic assessment beyond standard histology.

Limitations and Future Directions

However, this study has several limitations. First, the multivariate logistic regression models (Tables S1 and S2 in Multimedia Appendix 3) are methodologically limited by circular reasoning. Using 1 postoperative pathological finding (eg, NI) to predict another (eg, capsular invasion) inflates the observed associations. The resultant astronomically high ORs with extremely wide CIs are classic signs of overfitting and multicollinearity within our dataset, rather than reliable measures of preoperative risk. These results should be interpreted as strong indicators of pathological co-occurrence, not as valid predictive effects.

Second, the single-center design, limited sample size (n=111), absence of external validation, and reliance on CT scanners from a single manufacturer may restrict generalizability and introduce selection bias.

Third, an additional limitation is the unconventional data usage design: the full dataset was used for both capsular invasion-modeling and cross-label association analysis without a separate held-out test set. Therefore, the reported AUCs for NI prediction are not directly comparable to studies using independent test sets. However, this design was necessary to maximize data use given the small sample size and to specifically test the cross-predictive value of capsular invasion–related features for NI, an exploratory goal that prioritizes verifying feature relevance across related clinical outcomes. Supplementary traditional 7:3 split validation confirmed consistent performance, mitigating concerns about overfitting to some extent (Multimedia Appendix 4).

Fourth is the sampling bias from single-slice analysis. Our NN model used only the single 2D slice with the largest cross-sectional tumor area. As capsular invasion predominantly occurs at the tumor boundaries or poles, this central slice may systematically exclude the imaging features most directly associated with capsular invasion, potentially limiting the model's sensitivity to capture these specific patterns. Consequently, the "Image_Boundary" pattern identified by the network (Figure 2B) likely reflects the general sharpness or regularity of the tumor-parenchyma interface on the central slice, rather than specific imaging signs of focal capsular penetration at the tumor periphery.

Fifth, there is a limitation regarding the control group for qPCR analysis. The use of PBMCs from healthy individuals as a control does not yield biologically precise fold-change values for epithelial markers such as CK19, due to their near absence in PBMCs. In this study, the ≥2-fold threshold was used primarily as a sensitive, technical cutoff to categorize tumors

XSL•FO
RenderX

into those with detectably high versus low or no expression of the target genes, facilitating subsequent clinical correlation analysis. This pragmatic approach should be distinguished from a biologically rigorous quantification of overexpression. Future studies should use paired adjacent normal thyroid tissue as the control to obtain accurate biological quantifications.

Sixth is the normalization-induced information leakage. The *z* score normalization of radiomic features was performed on the entire dataset before model development and cross-validation. This approach could theoretically allow information from validation samples (mean and SD) to leak into the training process, potentially inflating the model's performance estimates. While we used cross-validation and an independent hold-out set to mitigate overfitting, this methodological choice may still contribute to an optimistic bias in the reported metrics. Future studies should consider performing normalization within each fold of the cross-validation loop to provide a more rigorous and unbiased evaluation of model generalizability.

Seventh is feature selection bias. In this study, the LASSO regression was applied to the entire dataset to select the 9 key radiomic features (A1-A9) before model development and cross-validation. Performing feature selection outside the cross-validation loop can introduce selection bias, as the selection process is informed by data that would later serve for validation. This may lead to overfitting and an optimistic estimation of the model's generalizable performance. Consequently, the independence of the hold-out validation for the RF model is partially compromised. Future work should use a nested cross-validation framework, where feature selection is performed independently within each training fold, to obtain unbiased feature sets and more rigorous performance estimates.

Eighth is the potential misalignment from rigid registration. This study used rigid image registration to propagate arterial-phase ROIs to the venous-phase images for feature extraction (eg, feature A9, the venous-phase coefficient of variation). While efficient and commonly used, rigid registration assumes no tissue deformation between phases. Given that the thyroid is a soft organ susceptible to movement from swallowing or breathing, perfect alignment cannot be guaranteed. Any misalignment could cause venous-phase features to partially capture the texture of the tumor's immediate periphery or surrounding tissue rather than the tumor itself. This may introduce noise or bias, particularly for texture-based features such as A9. Therefore, the high importance score of A9 in our model may partially reflect registration artifacts (such as edge effects at the ROI boundaries) rather than solely genuine intratumoral heterogeneity. Although we performed manual verification and adjustment of the propagated ROIs, minor residual misalignments may persist. Future studies could consider using deformable (nonrigid) registration techniques or independent manual delineation on venous-phase images to ensure more accurate feature localization and interpretation.

Ninth is the resolution loss due to image resizing for deep learning. In this study, to comply with the input requirements of the pretrained DenseNet121 network, the entire ROI was resized as a whole from its original resolution to 224×224 pixels. This means that no prior cropping to a tumor-specific bounding box was performed. For smaller thyroid tumors, this global down-sampling can substantially reduce the number of pixels representing the tumor tissue, leading to a loss of fine spatial detail and high-frequency texture information. This process may diminish the model's ability to learn subtle textural patterns that are crucial for predicting capsular invasion, particularly in small lesions. Future studies could improve upon this by implementing a crop-to-bound-box step before resizing or by using NN architectures that support variable input sizes. Furthermore, the "learned image patterns" (eg, "Image_Heterogeneity" and "Image_Boundary") identified through our interpretability analysis (SHAP) may therefore reflect macrolevel structures or artifacts introduced by the global down-sampling process, rather than solely the fine, tumor-specific textural details that are theoretically of interest. For instance, patterns interpreted as heterogeneity could be influenced by the interpolation artifacts during resizing or by the inclusion of nontumoral perinodular tissues within the ROI. While these patterns still contributed to the model's predictive performance, their biological interpretability in relation to capsular invasion should be interpreted with this technical limitation in mind.

Tenth is the uncertainty in hold-out set performance. The performance of the NN model on the small independent hold-out set (n=33; AUC=0.827, 95% CI 0.652 - 0.981) showed a point estimate higher than that from the full-sample cross-validation (AUC=0.775). The wide 95% CI reflects the substantial uncertainty inherent in evaluating a model with such a limited test sample. While the hold-out set was constructed using stratified sampling to maintain a representative distribution of capsular invasion status, the observed difference in point estimates may be attributable to the small sample size and its associated variability. Therefore, the hold-out performance should be interpreted with caution, and the model's generalizability needs to be confirmed in larger, prospective cohorts.

Eleventh is the potential confounding in model comparison due to input differences. The radiomic RF model identified a venous-phase feature (A9) as highly predictive, while the NN was designed with arterial-phase-only inputs for simplicity and to mitigate overfitting. This design difference means that the lower AUC of the NN model (0.775) compared to the RF model (0.8102) may be partially attributable to the exclusion of venous-phase information rather than an inherent limitation of the deep learning architecture itself. Our study aimed to test whether a single phase (arterial) could provide a sufficient predictive signal for a deep learning model; however, this choice introduces a confounding factor when directly comparing performance across methodologies. Future studies could develop multimodal NN architectures incorporating both arterial and venous phases to enable a more equitable comparison and potentially enhance performance.

Future work will expand multicenter collaboration to include over 300 cases across diverse CT devices, incorporate data augmentation and explainable artificial intelligence methods, and establish standardized protocols to improve robustness. Most importantly, future models will focus on using exclusively

XSL•FO
RenderX

preoperative variables to achieve genuine preoperative risk stratification.

Conclusions

In conclusion, our exploratory analysis confirms a strong association between capsular invasion and NI in thyroid carcinoma. This study delineates complementary approaches for invasion risk assessment: (1) radiomic signatures from preoperative CT alone demonstrate potential for noninvasive, preoperative risk stratification; and (2) models incorporating postoperative tissue-derived biomarkers (eg, Gal-3 and CK19), including the multimodal model, provide a valuable framework for postoperative risk stratification. These postoperative tools could aid in identifying patients with high-risk pathological features, potentially guiding decisions on adjuvant therapy or surveillance intensity following surgery. The performance of the radiomic models lays the groundwork for future research toward fully preoperative predictive tools.

Acknowledgments

This study used traditional radiomics and machine learning methodologies for CT (computed tomography)-based capsular or neural invasion risk stratification in thyroid carcinoma. No generative artificial intelligence (GenAI) tools were used in data collection, preprocessing, feature extraction, model development, or interpretation. All analyses followed institutional ethics guidelines, with authors retaining full responsibility for methodological rigor and result validity.

Funding

This research received no specific grant from any funding agency in the public, commercial, or not-for-profit sectors.

Data Availability

The datasets used are available from the corresponding author upon reasonable request.

Authors' Contributions

FfC and KT designed this study. FW and QG collected and analyzed the data. PS and NX wrote and reviewed this paper. All authors have read and approved the final version.

Abstract

Background: Questionnaires assessing symptoms in chronic obstructive pulmonary disease (COPD) rely on retrospective reporting, introducing recall bias and missing symptom variability. Ecological momentary assessment (EMA) addresses these limitations by capturing real-time symptom data.

Objective: The aim of this study was to compare EMA symptom ratings with traditional questionnaires in patients with COPD.

Methods: A subsample from the FAntasTIGUE study rated symptoms using questionnaires (visual analog scale, modified Medical Research Council Dyspnea Scale, Physical Activity Rating Scale-Dyspnea Questionnaire, Checklist Individual Strength-subscale Subjective Fatigue, Hospital Anxiety and Depression Scale, and COPD Assessment Test) and EMA. Participants rated breathlessness, fatigue, anxiety, and energy level on a 7-point Likert scale during 8 random EMA prompts daily for 5 days.

Results: Among 54 participants (mean age 67, SD 7 y; forced expiratory volume in 1 s 53%, SD 20% predicted; n=35, 65% men), the EMA response rate was 76.1%. EMA scores were moderately to strongly correlated with questionnaire scores (r_s=0.49-0.78, all P<.05) and varied across severity groups (all P<.05). EMA captured significant intraday and interday symptom variability.

Conclusions: EMA is a valid tool for COPD symptom assessment, capturing real-time fluctuations to improve symptom management.

KEYWORDS

chronic obstructive pulmonary disease; COPD; ecological momentary assessment; questionnaires; symptom assessment

Introduction

Chronic obstructive pulmonary disease (COPD) is a heterogeneous chronic lung condition characterized by persistent airflow limitation and respiratory symptoms such as breathlessness and fatigue [1,2]. Additionally, patients with COPD often experience psychological symptoms like anxious and depressed mood and lack of energy, which can substantially affect their health-related quality of life and functional status [3,4]. Despite this, breathlessness, fatigue, anxiety, and lack of energy are frequently underreported [5]. In both daily clinical practice and research, these symptoms are assessed using questionnaires, such as the modified Medical Research Council (mMRC) Dyspnea Scale, Checklist Individual Strength-subscale Subjective Fatigue (CIS-Fatigue), and Hospital Anxiety and Depression Scale (HADS) [6,7]. However, these traditional tools rely on retrospective self-reports, which may be limited by recall bias and fail to fully capture the expected dynamic nature of symptoms both intraday and interday [1,8-13].

Ecological momentary assessment (EMA) is a real-time data collection approach that seeks to overcome these limitations by facilitating data capture in patients' natural environment [1,8,9,14]. By prompting patients to report breathlessness, fatigue, anxiety, and lack of energy at repeated intervals throughout the day, EMA minimizes memory-related biases and provides a more detailed depiction of symptom variability, offering a comprehensive view of daily symptom burden in patients with COPD. Despite the growing use of EMA in chronic respiratory disease research, there remains a limited understanding of how well EMA-based symptom ratings align with traditional questionnaires [9,15,16]. Establishing this relationship is essential to evaluate the measurement properties of EMA, specifically its convergent validity with questionnaires. By exploring to which extent EMA-derived symptom ratings correlate with well-established validated questionnaire scores, it can be determined whether EMA can serve as a valid complementary tool for symptom assessment in COPD.

This study aims to assess the convergent validity of EMA symptom ratings by exploring the associations between EMA-based and questionnaire-based measurements of breathlessness, fatigue, anxiety, and energy in patients with COPD. We seek to determine whether EMA provides unique insights into daily symptom fluctuations in COPD by examining moment-to-moment variability of symptoms both intraday and interday, which cannot be captured by traditional retrospective questionnaires. Our findings may have implications for improving symptom monitoring and management in daily clinical practice and research. By identifying moment-to-moment fluctuations in symptoms such as breathlessness, fatigue, anxiety, and lack of energy, EMA may enable timely and personalized adjustments in treatment or self-management strategies, potentially leading to more responsive and individualized care for patients with COPD. It is hypothesized that EMA symptom ratings would show significant positive correlations with traditional questionnaire scores, supporting convergent validity. Furthermore, we expect EMA to reveal substantial intraday and interday variability in breathlessness, fatigue, anxiety, and lack of energy that is not captured by retrospective questionnaires.

Methods

Design

This research was conducted as part of a multicenter, longitudinal, observational study in patients with COPD investigating physical, systemic, psychological, and behavioral factors associated with fatigue (FAntasTIGUE study) [17]. The prevalence of fatigue in patients with COPD was previously reported, as well as the association between physical activity, sedentarism, and EMA-derived symptom scores [3,18,19].

Ethical Considerations

The study received approval from the Medical Research Ethics Committee United, Nieuwegein, The Netherlands (R17.036/NL60484.100.17), and written informed consent was obtained from all participants. Participation was entirely voluntary, and participants could withdraw at any time without consequence. Participants did not receive any financial compensation. Data were deidentified before analysis.

Recruitment

Patients were recruited between 2018 and 2021 at outpatient clinics of the Department of Respiratory Medicine in Maastricht University Medical Center and the Department of Pulmonary Diseases of the Radboud University Medical Center in Nijmegen, as well as via general practitioners (Research Network Family Medicine Maastricht [20] and the Academic General Practitioner Network in the Nijmegen region). Additionally, patients with COPD who attended a peer support group meeting in Maastricht or Nijmegen, as well as patients recruited from primary and secondary care who previously participated in the Chance Study (NTR3416) and had consented to follow-up research, were invited to take part in the FAntasTIGUE study. To participate in the EMA substudy, patients had to meet the following inclusion criteria:

1. A diagnosis of COPD according to the Global Strategy for the Diagnosis, Management and Prevention of COPD (Global Initiative for Chronic Obstructive Lung Disease, grade 1A–4D) [2].
2. No exacerbation-related hospitalization and/or use of oral corticosteroids and/or antibiotics less than 4 weeks preceding enrollment.
3. Provided written informed consent.
4. Able to use an iPod.

XSL•FO
RenderX

Patients lacking sufficient understanding of the Dutch language and/or participating in concurrent intervention studies were excluded.

Measurements

During baseline assessment, sociodemographic, physical, psychological, and behavioral characteristics were assessed as described elsewhere [17].

Questionnaires

Breathlessness was assessed using 3 methods: mMRC Dyspnea Scale, item 1 of the Physical Activity Rating Scale-Dyspnea Questionnaire (PARS-D), and visual analog scale (VAS). The mMRC Dyspnea Scale assesses the current severity of activity-related dyspnea on a scale ranging from 0 (“only gets breathless with strenuous exercise”) to 4 (“too breathless to leave the house or breathless when dressing”) [21]. An mMRC score of 2 or higher is used as a threshold for separating “less breathlessness” from “more breathlessness” [2]. On item 1 of the PARS-D, patients had to rate the level of breathlessness on most days of the previous month from 1 (“not at all breathless”) to 10 (“very breathless”) [22]. Patients rated their level of breathlessness over the past 2 weeks using a VAS, which ranged from 0 (“not”) to 100 mm (“worst possible”) [23,24].

Fatigue was assessed using 2 methods: CIS-Fatigue and VAS. The CIS-Fatigue contains questions about fatigue-related complaints in the previous 2 weeks. For these analyses, we used both the score from item 1 and the CIS-Fatigue total score. Item 1 asks the patient if they are tired, ranging from 1 (“yes, that’s true”) to 7 (“no, that’s not true”). A total score of 26 points or lower on the CIS-Fatigue indicates normal fatigue, between 27 and 35 reflects mild fatigue, and 36 points or higher signifies severe fatigue [6]. Patients rated their level of fatigue over the past 2 weeks using the VAS, which ranged from 0 (“not”) to 100 mm (“worst possible”) [23,24].

Symptoms of anxiety and depression were measured using 2 methods: HADS and VAS. The HADS is divided into an anxiety and a depression subscale. Each subscale consists of 7 items and ranges from 0 to 21 points. A higher score on these subscales indicates a higher level of symptoms of anxiety or depression, respectively. A subscale score of 8 points or higher indicates possible symptoms of anxiety or depression, while a score of 11 points or higher indicates probable symptoms of anxiety or depression [7]. Patients rated their level of anxiety over the past 2 weeks using the VAS, which ranged from 0 (“not”) to 100 mm (“worst possible”) [23,24].

Energy was assessed with item 8 of the COPD Assessment Test (CAT), which assesses the current energy level on a scale from 0 to 5, with a higher score indicating less energy [25]. All questionnaires used in this study are well-validated and widely applied instruments for assessing symptoms in patients with COPD [2,26,27]. However, for some analyses, single items from these questionnaires were used to allow direct comparison with specific EMA items reflecting corresponding symptom dimensions.

Ecological Momentary Assessment

Electronic EMA questionnaires were administered over 5 consecutive days using an Apple iPod Touch with a custom-installed app PsyMate (version 1.1b). If possible, the EMA assessments began the day immediately following the baseline assessment. Patients were instructed to respond to each questionnaire as soon as possible upon hearing the beep and to keep their usual day and night routine. If patients did not respond within 15 minutes after the beep, the questionnaire was skipped. PsyMate generated a beep at 8 random times each day between 7:30 AM and 10:30 PM. Patients had to rate 10 symptoms (“I feel: relaxed; short of breath; energetic; cheerful; insecure; irritated; satisfied; anxious; tired; and mentally fit”) with a 7-point Likert scale ranging from 1 (“Not”) to 7 (“Very”). For these analyses, 4 symptoms were included: breathlessness, fatigue, anxiety, and energy. Patients who completed less than one-third of the total beeps (ie, <13 out of 40 beeps) were excluded [28]. An EMA questionnaire completion time of 10 minutes or longer was considered invalid, and this EMA data point was excluded.

Data Analyses

All analyses were performed using SPSS (version 28.0.1.1) and R statistical software (version 4.4.2). The distribution of data was tested using the Shapiro-Wilk test with a 2-tailed significance of less than .05. Data were reported as mean (SD), median (IQR), percentages, and numbers, where appropriate. In the analyses, EMA item “I feel short of breath” was compared with mMRC Dyspnea Scale score, PARS-D score, and VAS breathlessness score. EMA item “I feel tired” was compared with CIS-Fatigue item 1 score, CIS-Fatigue total score, and VAS Fatigue score. EMA item “I feel anxious” was compared with HADS anxiety score and VAS anxiety score, while EMA item “I feel energetic” was compared with CAT item 8 score. To evaluate the convergent validity of EMA measures, associations between EMA symptom ratings and corresponding questionnaire scores were examined using Spearman correlation coefficients and multilevel linear mixed models (MLMs).

Median EMA scores for all patients were calculated. Spearman correlation analyses were performed between median EMA scores and corresponding questionnaire scores [29]. Subsequently, MLMs were applied to analyze all EMA data points. In these models, EMA scores were treated as dependent variables, while questionnaire scores were included as fixed effects. Patient ID was specified as a random intercept to account for the correlation of intraindividual repeated observations. MLMs were performed using the “mixed” command, restricted maximum likelihood estimations, and a significance of less than .05. Mann-Whitney *U* tests were used to assess differences in median EMA scores across symptom severity groups based on established cutoff values of the mMRC Dyspnea Scale (0 - 1/≥2), CIS-Fatigue (8 - 35/≥36), and HADS questionnaire (1 - 7/≥8). Patients were categorized into the symptom severity groups based on their corresponding questionnaire scores.

To assess intraday and interday symptom variability, we used MLMs with EMA symptom scores as the dependent variable. For each symptom (breathlessness, fatigue, anxiety, and energy), time of day (expressed as hours since 8:00 AM) and day number

XSL•FO
RenderX

(days 1 - 5) were included as fixed effects to model temporal trends. Random intercepts for each participant accounted for interindividual differences in baseline symptom levels, while random slopes for time of day allowed the trajectory of symptoms to change throughout the day to vary interindividuals. Variance components were extracted from the MLMs to estimate the proportion of total variance attributable to intraindividual fluctuations and interindividual differences. Intraclass correlation coefficients (ICC) were calculated as the ratio of interindividual variance to total variance after accounting for time of day and day effects. ICC values close to 1 indicate that most variability is explained by differences between individuals, whereas lower ICC values indicate greater intraindividual variability.

Results

Overview

Sixty patients were assessed for eligibility. Six patients were excluded because of no available EMA data (n=2), invalid EMA data (<13 beeps in total; n=3), or incorrect loading of the EMA data (n=1). Consequently, 54 patients were included in the current analysis.

Participants

The majority of patients were men (35/54, 65%) with an average age of 67 years (Table 1). Most patients had moderate-to-severe COPD (49/54, 91%), and almost half had at least one exacerbation in the previous 12 months (25/54, 46%). Across the 9 questionnaires that were used in the analysis, the overall response rate was high (471/486, 97%). Severe dyspnea was reported by 39% (21/52) and 43% (23/53) experienced severe fatigue. In addition, 9% (5/52) and 11% (6/52) of the patients had symptoms of anxiety and depression, respectively. The EMA subsample included in the current analyses is highly comparable to the overall FAntasTIGUE cohort in terms of key demographic and clinical characteristics. Results of the full FAntasTIGUE cohort have recently been published [19].

[k]CAT: COPD Assessment Test.

Ecological Momentary Assessment

One patient completed 4 days of EMA measurements, and 53 patients completed 5 days. Of the 2160 maximal possible EMA responses (54 participants × 5 days × 8 prompts per day), 1644 EMA responses were valid and could be analyzed (response rate: 76.1%). Median (IQR) time of completing the EMA questionnaire was 1 minute and 2 seconds (00:49–01:21). During the 5 days, patients generally rated feeling somewhat energetic (median 5 points, IQR 2), somewhat tired (median 3 points, IQR 2), not short of breath (median 2 points, IQR 3), and not anxious (median 1 point, IQR 0). Nevertheless, a large variation across the 7-point Likert scale was observed between patients (Figure 1). In Multimedia Appendix 1, the median EMA scores and total number of EMA responses per patient are shown.

Figure 1. Jittered scatterplot of the ecological momentary assessment–based symptoms scored on a 7-point Likert scale for 5 consecutive days.

Association

Median EMA scores and corresponding questionnaires showed moderate-to-strong correlations (Table 2). Patients with an mMRC grade of 0 to 1 reported significantly lower EMA scores for “I feel short of breath” compared to those with an mMRC grade of 2 or higher (P<.001; Figure 2). Similarly, patients with normal-to-mild CIS-Fatigue total scores reported significantly lower EMA scores for “I feel tired” compared to those with severe CIS-Fatigue scores (P<.001). Patients with no symptoms of anxiety had significantly lower EMA scores for “I feel anxious” compared to those with possible or probable anxiety (P=.01).

Figure 2. Ecological momentary assessment (EMA) breathlessness scores divided by the modified Medical Research Council (mMRC) Dyspnea cutoff values. EMA tiredness scores divided by Checklist Individual Strength-subscale Subjective Fatigue (CIS-Fatigue) cutoff values. EMA anxious scores divided by the Hospital Anxiety and Depression Scale (HADS) cutoff values.

Multilevel models revealed that higher scores on the mMRC Dyspnea Scale, PARS-D item 1, and VAS breathlessness were associated with higher EMA scores for “I feel short of breath” (Table 3). Specifically, a one-unit increase in mMRC Dyspnea Scale score corresponded to a 0.6-point increase in EMA score. For example, a patient with an mMRC score of 1 (the median in our sample) would be expected to report an average EMA breathlessness score of approximately 3.1 on the 7-point scale. Corresponding expected EMA scores for each questionnaire value are provided in Multimedia Appendix 2. Similarly, higher scores on CIS-Fatigue item 1, CIS-Fatigue total score, and VAS Fatigue were associated with higher EMA scores for “I feel tired.” Elevated HADS-Anxiety and VAS anxiety scores were also associated with higher EMA scores for “I feel anxious.” Conversely, higher scores on CAT item 8 were associated with lower EMA scores for “I feel energetic.”

I feel energetic		
	CAT[h] Item 8 (I have a lot of energy) (0-5)	−0.602 (0.099)

[a]EMA: ecological momentary assessment.

[b]$P<.001$.

[c]mMRC: Modified Medical Research Council Dyspnea Scale.

[d]PARS-D: Physical Activity Rating Scale-Dyspnea Questionnaire.

[e]VAS: visual analog scale.

[f]CIS-Fatigue: Checklist Individual Strength-subscale Subjective Fatigue.

[g]HADS: Hospital Anxiety and Depression Scale.

[h]CAT: COPD Assessment Test.

Variability

The ICC for EMA “I feel short of breath” was 0.624, indicating that 62.4% of the variance in EMA scores was explained by interindividual differences, while 37.6% was attributable to intraindividual fluctuations over time. Time of day (expressed as hours since 8:00 AM) had a significant negative association with EMA breathlessness ratings ($\beta=-1.3\times10^{-2}$, $P=.03$; Table 4), with scores being highest in the morning and declining throughout the day. Additionally, scores on day 2 were significantly lower than day 1 ($\beta=-1.6\times10^{-1}$, $P=.03$), whereas differences for subsequent days were not statistically significant.

Table . Intraclass correlation coefficient (ICC) and associations between the ecological momentary assessment (EMA) symptoms, time of day, and day number, with the first day being the reference day.

EMA item[a]	ICC[b]	Estimate (SE)				
		Time of day[c]	Day 2[d]	Day 3[d]	Day 4[d]	Day 5[d]
I feel short of breath	0.624	-1.3×10^{-2} (5.8×10^{-3})[e]	-1.6×10^{-1} (7.8×10^{-2})[e]	-1.4×10^{-1} (7.8×10^{-2})	-9.7×10^{-2} (7.9×10^{-2})	-1.3×10^{-1} (7.9×10^{-2})
I feel tired	0.584	3.7×10^{-2} (1.1×10^{-2})[f]	8.9×10^{-3} (9.0×10^{-2})	-8.1×10^{-3} (9.1×10^{-2})	4.4×10^{-2} (9.2×10^{-2})	-2.1×10^{-2} (9.2×10^{-2})
I feel anxious	0.683	5.2×10^{-4} (3.9×10^{-3})	-1.2×10^{-1} (5.4×10^{-2})[e]	-8.6×10^{-2} (5.4×10^{-2})	-1.1×10^{-1} (5.5×10^{-2})	-1.0×10^{-1} (5.5×10^{-2})
I feel energetic	0.605	-1.6×10^{-2} (9.1×10^{-3})	7.6×10^{-2} (7.7×10^{-2})	6.0×10^{-2} (7.7×10^{-2})	9.4×10^{-3} (7.8×10^{-2})	1.8×10^{-2} (7.8×10^{-2})

[a]EMA: ecological momentary assessment.

[b]The ICC represents the proportion of total variance in EMA scores attributable to interindividual differences, after accounting for temporal effects.

[c]Estimates (β) for time of day indicate the change in symptom rating per hour since 8:00 AM. Positive β values indicate increasing symptom ratings per hour and negative β values indicate decreasing ratings. SEs are provided in parentheses.

[d]Estimates for days 2-5 represent the difference in symptom ratings compared to the first day (reference).

[e]$P<.05$.

[f]$P<.01$.

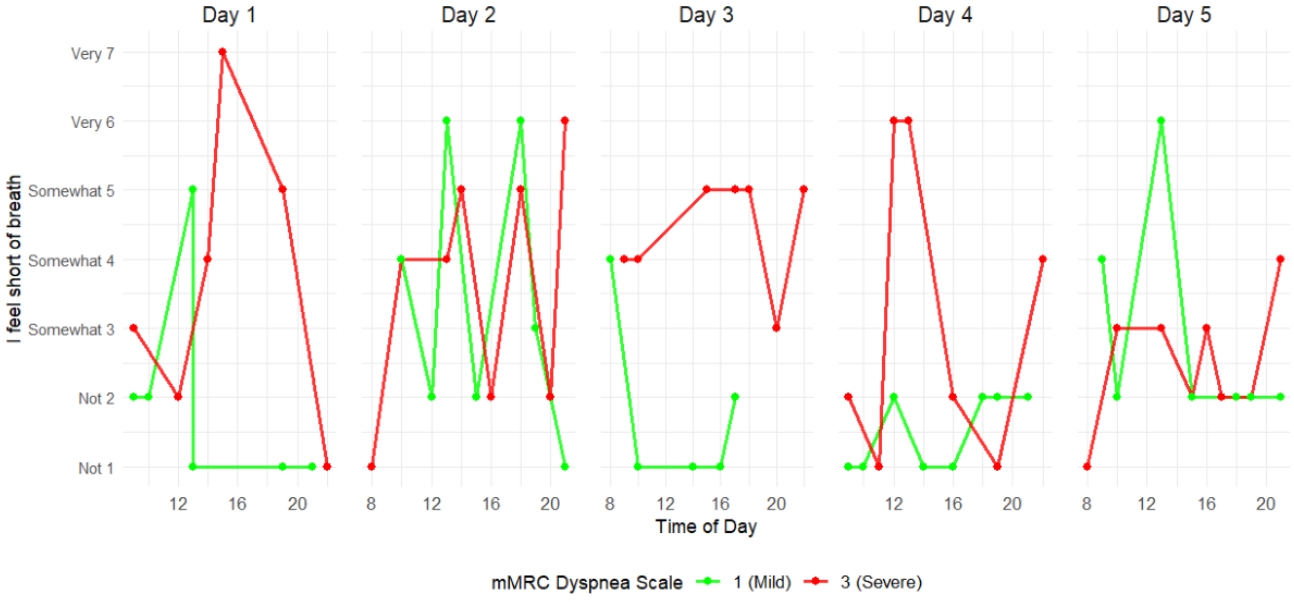

Figure 3 illustrates EMA data for "I feel short of breath" for 2 patients with low and high mMRC grades. The figure demonstrates substantial intraday and interday variability in scores for both patients, showing that low and high EMA scores occurred regardless of the mMRC dyspnea grade.

For EMA "I feel tired," the ICC was 0.584. Time of day had a significant effect on EMA scores ($\beta=3.7\times10^{-2}$, $P=.002$), where scores were lowest in the morning (≈8:00 AM) and increased during the day. Day number had no significant effect. Figure 4 depicts daily intraday variations in EMA scores for patients in both normal, mild, and severe CIS-Fatigue groups.

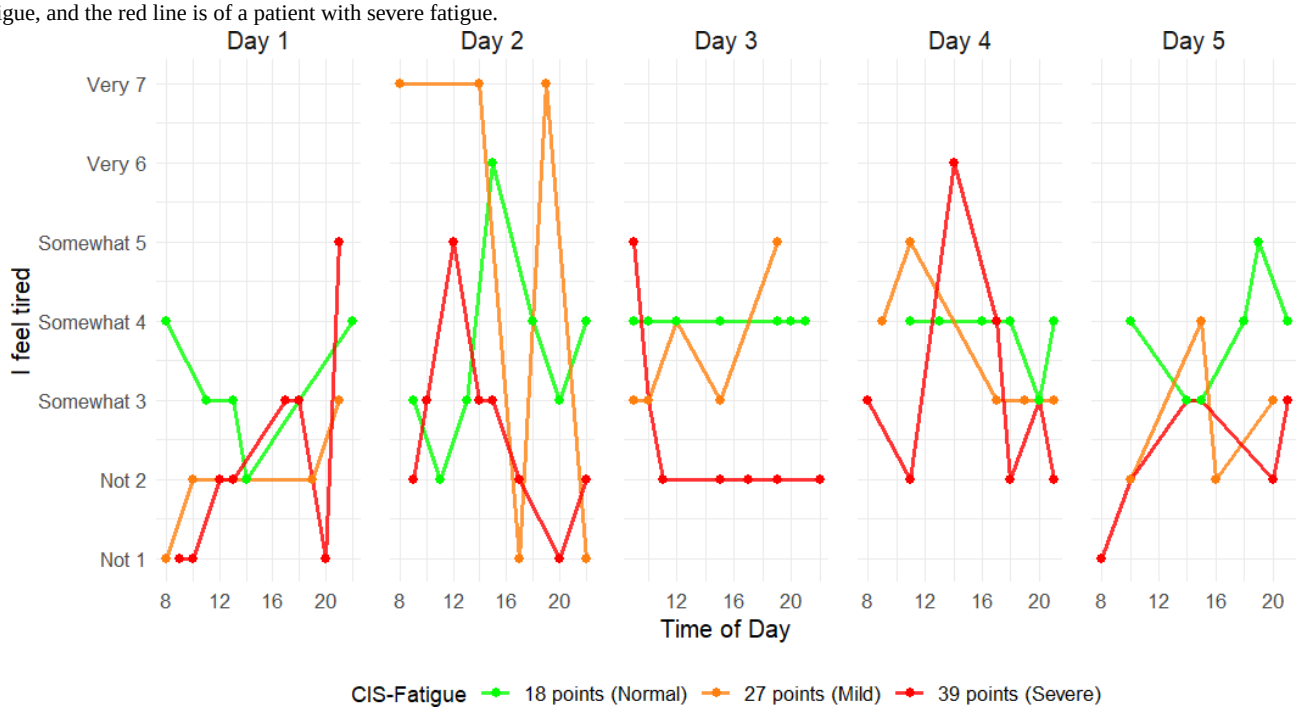
ICC for EMA "I feel anxious" showed the highest interindividual variability, which was 0.683. Day 2 scores were significantly lower than day 1 ($\beta=-1.2\times10^{-1}$, $P=.02$), but there was no significant effect of time of day. Figure 5 highlights intraday fluctuations in EMA scores across all patient groups, irrespective of their HADS subgroup.

For EMA "I feel energetic," the ICC was 0.605. Neither time of day nor day number showed significant effects in the model.

Figure 3. Five consecutive days of ecological momentary assessment breathlessness scores of 2 patients from different modified Medical Research Council (mMRC) Dyspnea subgroups. Each point represents a momentary breathlessness rating (1="not at all breathless" to 7="very breathless") collected across 8 random prompts per day. The green line is of a patient with low breathlessness severity according to the mMRC Dyspnea Scale, and the red line is of a patient with high breathlessness severity.

XSL•FO
RenderX

Figure 4. Five consecutive days of ecological momentary assessment fatigue scores of three patients from different Checklist Individual Strength-subscale Subjective Fatigue (CIS-Fatigue) subgroups. Each point represents a momentary tiredness rating (1="not at all tired" to 7="very tired") collected across 8 random prompts per day. The green line is of a patient with normal fatigue according to the CIS-Fatigue, the orange line is of a patient with mild fatigue, and the red line is of a patient with severe fatigue.



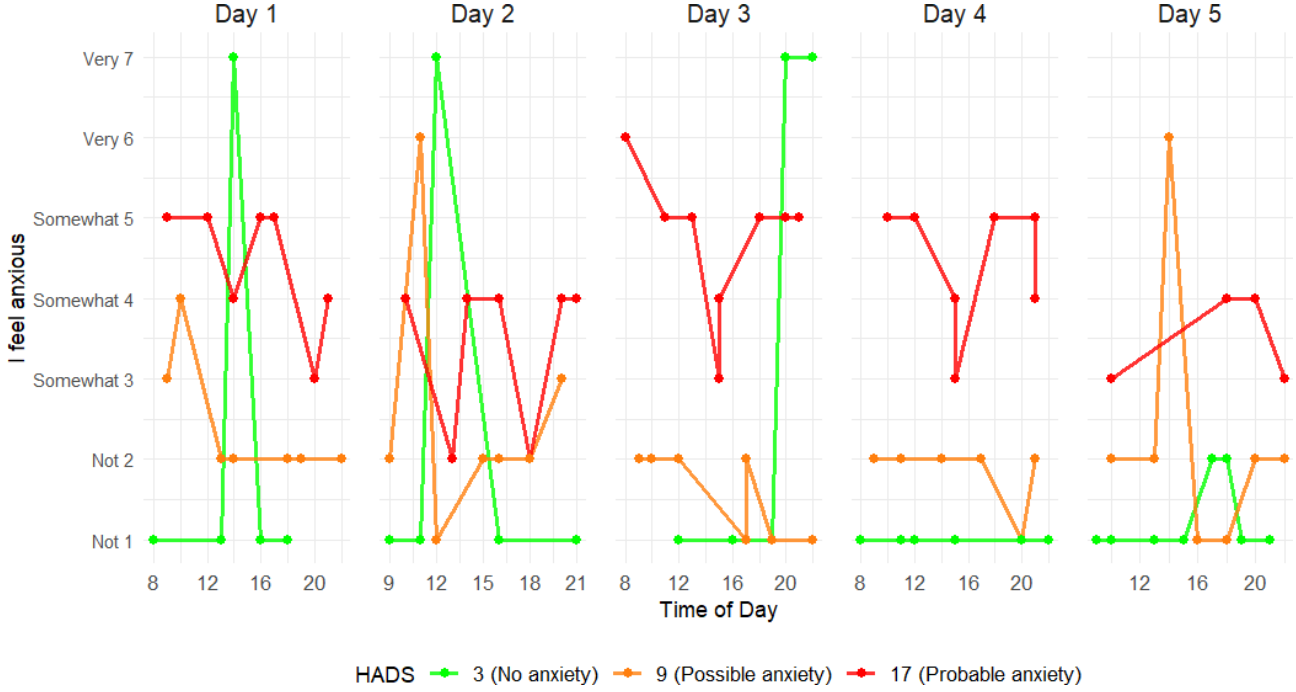


Figure 5. Five consecutive days of ecological momentary assessment anxiety scores of 3 patients from different Hospital Anxiety and Depression Scale (HADS) subgroups. Each point represents a momentary anxious rating (1="not at all anxious" to 7="very anxious") collected across 8 random prompts per day. The green line is a patient with no anxiety symptoms according to the HADS, the orange line is a patient with possible symptoms of anxiety, and the red line is a patient with probable symptoms of anxiety.

Discussion

Principal Findings

This study aimed to assess convergent validity of EMA symptom ratings by exploring associations between measuring symptoms with established questionnaires and EMA in patients with COPD. Moderate-to-strong correlations and significant associations support the convergent validity of EMA symptom ratings, with EMA effectively differentiating symptom severity and capturing intraday and interday variability which is present in the current study population.

Questionnaires provide a retrospective single-point observation that summarizes symptoms experienced over the previous weeks or months, whereas EMA collects real-time data in patients'

XSL•FO
RenderX

natural environment, minimizing recall bias [8]. While questionnaires may rely on patients' general recollection of symptom burden, EMA focuses on the immediate context in which symptoms are experienced, offering a complementary perspective. Our findings indicate that both assessment tools measure symptoms accordingly; however, EMA can measure variability. Interestingly, the moderate-to-strong correlations observed in our study align with findings from previous studies conducted in different populations, which reported similar relationships between EMA and retrospective self-report measures in assessing clinical symptoms and behaviors [30-33]. This consistency across studies suggests that, despite their methodological differences, both approaches approximate the same symptom burden over time. However, momentary assessments using EMA may also capture subtle fluctuations influenced by contextual factors, which retrospective self-reports may overlook [34].

The substantial interday and intraday variability observed in EMA scores for breathlessness, fatigue, and anxiety highlights a key advantage of EMA over traditional assessments [16]. This emphasizes that traditional self-report measures often fail to capture such variability due to recall biases and the aggregation of experiences over extended timeframes. In the study of Solhan et al [16], EMA indices only showed modest agreement with retrospective reports of affective instability, further underscoring the limitations of relying solely on retrospective assessment. Similarly, our findings showed that patients with low mMRC, CIS-Fatigue, and HADS scores sometimes reported high EMA scores of the corresponding symptoms, illustrating the heterogeneity of symptoms intraindividual and across different time points [10].

Clinical Practice and Research

EMA's ability to capture real-time symptom variability provides clinicians with a richer and more nuanced dataset to inform personalized treatment plans. For example, when patients report a consistent pattern of increasing fatigue through EMA, this could lead to targeted behavioral strategies such as activity pacing (eg, scheduling lower-demand activities during that period) and timing of short rest breaks. Similarly, if EMA reveals increased feelings of anxiety around specific situations (eg, during exertion, social activity, or waking up), then this could trigger timely psychological-support interventions such as brief monitored relaxation techniques, guided breathing exercises, or preemptive alert via a mobile app to initiate mindfulness at forecasted high-risk times. In pulmonary rehabilitation, incorporating EMA can help patients gain insight into how daily lifestyle behaviors trigger certain symptoms and identify windows of vulnerability when symptoms tend to worsen. By visualizing the intraday and interday symptom fluctuations, clinicians and patients can co-develop personalized coping strategies such as adjusting nonpharmacological tactics (eg, paced walking, energy-conserving breathing techniques) during windows of higher symptom burden to remind patients to apply these tactics when indicated. EMA has been shown to enhance the detection of treatment effects, as evidenced in studies where EMA demonstrated superior sensitivity to change and convergence with structured clinical assessments [9,35]. By incorporating EMA alongside traditional measures, researchers can achieve a more comprehensive understanding of symptom variability and treatment efficacy. A potential drawback is that patient burden for completing EMA could be high, particularly for patients who are not very technically proficient or not stable [16].

Methodological Considerations and Limitations

Both assessment tools demonstrated high response rates. While the EMA response rate in this study was comparable to previous research, adherence remains a critical factor for its successful implementation. Strategies to improve compliance, such as financial incentives or tailored EMA schedules, could enhance data quality [9]. Additionally, exclusion of patients with insufficient EMA data underscores the importance of establishing minimum response thresholds to ensure data reliability. Another limitation is that the self-reported symptoms may still be influenced by momentary factors such as mood, context, or tasks, even with EMA. The integration of EMA with objective measures, such as actigraphy or physiological monitoring, could provide a better understanding of how symptoms relate to specific activities and daily behaviors. This approach gives a more nuanced and objective assessment of symptom burden, capturing the dynamic interplay between symptoms and activity levels and potentially enhancing the validity of findings [15]. The median EMA score was used to summarize symptom burden across the 5-day period, which reduces the influence of extreme values and aligns with questionnaire measures. However, this approach does not capture fluctuations at specific times of day, such as morning or evening peaks. Future studies could explore time-specific EMA scores to provide more detailed insight into diurnal symptom variability. Additionally, symptom experiences often differ between sexes, and the predominance of male participants in this study may have influenced the results [36,37]. Furthermore, selection bias should also be considered, as participants who are more technologically proficient or motivated may be more likely to adhere to EMA protocols [38]. This may limit generalizability, particularly among older adults or those with severe COPD who could find frequent digital reporting burdensome [39]. Future studies should explore adaptive EMA designs or simplified interfaces to minimize this barrier and broaden participation. Despite these limitations, convergent validity remained high, even though EMA assessments were conducted after patients completed the questionnaires. Patients may have experienced a better or worse week in terms of symptoms before or during the EMA assessment period. Notably, some questionnaires assess symptoms over longer time frames, such as the past month or two weeks, which may capture a different temporal perspective on symptom burden. Another important methodological aspect concerns potential recall bias inherent in retrospective questionnaires. Traditional self-report instruments require participants to summarize symptoms experienced over extended periods, which may lead to distortions due to memory limitations or recency effects [12,13]. EMA mitigates this limitation by collecting data in real time, reducing recall-related error and providing a more accurate temporal representation of symptom burden. Furthermore, this study used single items from validated questionnaires (eg, PARS-D item 1, CIS-Fatigue item 1, CAT

XSL•FO
RenderX

item 8). Although these items originate from instruments with well-established psychometric properties, individual items may not fully represent the multidimensional constructs assessed by the complete questionnaires. Together, these findings underscore the complementary strengths of EMA to provide a more nuanced understanding of symptom variability while still aligning with traditional measures of symptom severity.

Conclusions

This study demonstrates that EMA is a validated tool for symptom assessment in patients with COPD. EMA showed moderate-to-strong correlations and significant associations with established questionnaires while capturing both interday and intraday symptom variability. The ability to reflect real-time fluctuations provides a more detailed and dynamic understanding of daily symptom burden, underscoring EMA's added value for enhancing symptom monitoring and informing personalized management in COPD.

Funding

This project is supported by grant 4.1.16.085 from Lung Foundation Netherlands, Leusden, the Netherlands; AstraZeneca Netherlands; Boehringer Ingelheim Netherlands; and Stichting Astma Bestrijding, Amsterdam, the Netherlands.

Data Availability

Participants in this study did not provide written consent for their data to be shared publicly. Therefore, due to the sensitive nature of the research, supporting data are not publicly available.

Authors' Contributions

Conceptualization: MVH, YMJG, ZE, MSYT, CB, JBP, EFMW, MAGS, JHV, DJAJ, MAS
Data curation: MVH, YMJG, ZE, JBP, RTMS, EWMAB, JHV, AWV
Formal analysis: BP, QD

Abstract

Background: Deep learning models have shown strong potential for automated fracture detection in medical images. However, their robustness under varying image quality remains uncertain, particularly for small and subtle fractures, such as scaphoid fractures. Understanding how different types of image perturbations affect model performance is crucial for ensuring reliable deployment in clinical practice.

Objective: This study aimed to evaluate the robustness of a deep learning model trained to detect scaphoid fractures in radiographs when exposed to various image perturbations. We sought to identify which perturbations most strongly impact performance and to explore strategies to mitigate performance degradation.

Methods: Radiographic datasets were systematically modified by applying Gaussian noise, blurring, JPEG compression, contrast-limited adaptive histogram equalization, resizing, and geometric offsets. Model accuracy was evaluated across different perturbation types and levels. Image quality was quantified using peak signal-to-noise ratio and structural similarity index measure to assess correlations between degradation and model performance.

Results: Model accuracy declined with increasing perturbation severity, but the extent varied across perturbation types. Gaussian blur caused the most substantial performance drop, whereas contrast-limited adaptive histogram equalization increased the false-negative rate. The model demonstrated higher resilience to color perturbations than to grayscale degradations. A strong linear correlation was found between peak signal-to-noise ratio–structural similarity index measure and accuracy, suggesting that better image quality led to improved detection. Geometric offsets and pixel value rescaling had minimal influence, whereas resolution was the dominant factor affecting performance.

Conclusions: The findings indicate that image quality, especially resolution and blurring, substantially influences the robustness of deep learning–based fracture detection models. Ensuring adequate image resolution and quality control can enhance diagnostic reliability. These results provide valuable insights for designing more accurate and resilient medical imaging models under real-world variability.

Introduction

Significant advances in computer vision have led to remarkable improvements in deep neural network (DNN) performance on tasks such as medical image classification [1]. Despite these achievements, DNN-based systems exhibit limited robustness compared with human perception, especially in the context of image perturbations and corruption [2]. Adversarial attacks can cause substantial misclassifications, and even minor noise can adversely affect performance [3-5]. Nevertheless, state-of-the-art classifiers appear to exhibit some ability to overcome random noise [6].

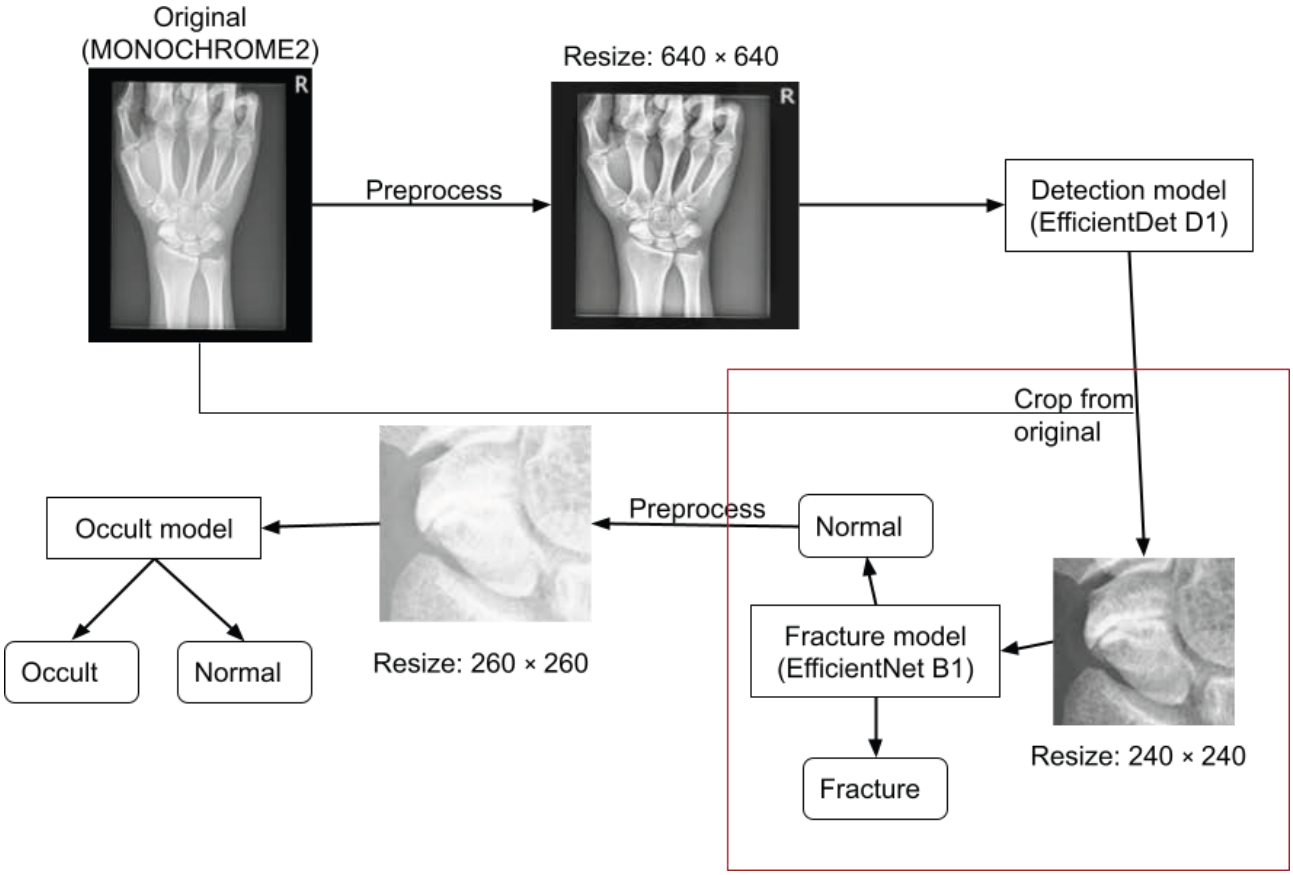
In real-world medical imaging, DNN model robustness is critical because low-quality images and noise are not uncommon; these issues include radiographic underexposures and motion artifacts as well as downstream processing or transfer distortions that can alter image fidelity and affect artificial intelligence (AI) performance [7,8]. In addition, real-world clinical workflows may involve low-resolution screen recapturing or smartphone-captured radiographs in urgent or resource-limited settings, which introduce compounded degradations, such as resizing, compression, and display-related artifacts [9]. Our previous work on a DNN model that detected both visible and occult scaphoid fractures demonstrated that it was possible to reliably detect fractures of small bones and to assist in the radiographic detection of occult fractures that are not visible to human observers [10]. This experience indicated that image preprocessing, file formatting, and data storage could negatively impact model performance. We discovered that image processing techniques introduced noise into input files, potentially misleading the DNN model. Such noise, often imperceptible to the human eye, can significantly affect model performance and potentially lead to incorrect diagnoses [11]. Consequently, evaluation of performance is vital in convolutional neural network (CNN)–based models that process noisy images; this evaluation poses frequent challenges in clinical settings. Prior studies have revealed that neural networks are most accurate when the data to be classified exhibit quality similar to that of the model training data; it was recommended that noise be injected into the training data to increase model robustness [12]. However, the addition of many possible noises to a training dataset is both computationally expensive and impractical. To the best of our knowledge, no study has investigated the impacts of different types of noise on neural networks designed for fracture classification when radiographs serve as inputs.

This study investigated the robustness of our CNN-based scaphoid fracture classification model when various types of image noise were present. To comprehensively evaluate model performance, we simulated real-world conditions that yield low-quality clinical images. Using fine-tuning techniques to create noisy samples, we sought to enhance model performance under noisy or degraded conditions, thereby mitigating the adverse effects of image corruption [7]. Additionally, we examined the impacts of specific forms of image degradation on model performance; we explored particular model vulnerabilities that might warrant further refinement. Our goals were to ascertain model accuracy when processing low-quality clinical images and to identify the types of noise that most confounded the model, thereby providing valuable insights to aid the development of more resilient DNN-based medical image classifiers appropriate for real-world applications.

Methods

Ethical Considerations

The study protocol was approved by the institutional review board of Chang Gung Memorial Hospital (202202256B0).



Scaphoid Fracture Classification Model

As previously described in our earlier work [10], the scaphoid fracture classification model was built using an EfficientNetB1 [13] backbone and 240×240-pixel red, green, and blue (RGB) images with a classification threshold of 0.5. In a study by Yoon et al [10], the model was originally trained and validated using 3991 scaphoid fracture radiographs and 5542 normal scaphoid radiographs.

In this study, we adopted the same model architecture as in the study by Yoon et al [10] and initialized the network with the finalized pretrained weights from that study, as shown in Figure 1. We then further fine-tuned this model using the 5286 training radiographs from the dataset described in the “Dataset and Preprocessing” section and evaluated it on an independent test set. Fine-tuning was performed using the AdamW optimizer, with appropriate adjustments to the learning rate, weight decay, and batch size. The learning rate was reduced if the validation loss failed to improve over 6 epochs, and training was stopped early when model performance did not increase further after 15 epochs.

RenderX

Figure 1. Complete pipeline for inference of a scaphoid fracture, including fracture (red box) and occult fracture. This report solely focuses on the performance of the fracture model.

Dataset and Preprocessing

The scaphoid fracture classification model used in this study was fine-tuned and evaluated using 5954 radiographs stored in Chang Gung Memorial Hospital in Taiwan. Of these radiographs, 1483 were of fractured scaphoids, and the remaining 4471 were of normal scaphoids. Images were captured by commercially available x-ray machines from multiple manufacturers. All radiographs were reviewed by 3 experienced radiologists and labeled as *fractured* or *normal*. This dataset is distinct from the dataset used in our previous work [10], in which the model was originally developed using 3991 fracture and 5542 normal radiographs. In this study, we adopted the same model architecture as in the study by Yoon et al [10], initialized the network with the finalized pretrained weights from that study, and further fine-tuned the model using the 5286 training images described below before evaluating it on an independent test set.

The training dataset consisted of 5286 images, and the test dataset comprised 668 images. A total of 28 images were excluded for reasons including anatomical anomalies secondary to arthritis (12 images), 3 due to unclear laterality, 2 due to wrong-sided imaging, image artifacts introduced by the hardware (1 image), and imaging findings of likely previous fractures or chronic nonunion (10 images). Thus, the final test dataset contained 640 images. The images varied in size and position, but all were 12-bit grayscale images of posteroanterior views of the wrist. Most images were rectangular, with widths ranging from 1000 to 1600 pixels, and heights ranging from 1600 to 2200 pixels. If the photometric interpretation of an image was MONOCHROME1, the image was converted to MONOCHROME2. The scaphoid was isolated from each hand radiograph using a bounding box generated by a separate scaphoid detection model. This detector (not to be confused with the scaphoid fracture classifier) was not the focus of this study because its performance is robust against common perturbations.

Rescaling Images to 8-Bit Depth

All radiographs were 12-bit grayscale posteroanterior wrist views that varied in terms of size and position, with widths between 1000 and 1600 pixels, and heights between 1600 and 2200 pixels. The images were rescaled to 8-bit grayscale and compiled into RGB images using the value of interest (VOI) lookup table and windowing operations that were also used during model training.

The DICOM images were stored in 12-bit grayscale, but the model accepted only 24-bit RGB (color) images. Thus, the images were first rescaled to 8-bit grayscale (with pixel values ranging from 0 to 255) and then compiled into RGB images for interpretation. This rescaling process was based on the maximum and minimum values of the image, rather than the actual bit depth. A VOI lookup table and windowing operations were applied to all images to adjust the pixel values based on the DICOM VOI LUT and windowing tags (pydicom. pixel_data_handlers.apply_voi_lut, version 1.4, 2022).

Differences emerge when images do not contain the lowest and highest pixel values. For 12-bit grayscale images, these pixel

XSL•FO
RenderX

values are 0 and 4095, respectively. The resulting difference can brighten or darken the entire image. Furthermore, the use of a VOI lookup process may change the brightness and contrast. These differences are minor and usually imperceptible to the human eye.

Generating Datasets for Noise Testing

Overview

To assess model performance in the presence of distortions, we generated several low-quality datasets using different noise perturbations. First, we read the test images using method 1. Images were cropped to the scaphoid regions demarcated by the bounding boxes, resized to 240×240 pixels, converted to 8-bit grayscale, and saved in PNG format. We refer to these baseline images (without noise) as “clean” hereafter.

To systematically evaluate the robustness of our scaphoid fracture classification model, we created multiple “noisy” or “degraded” datasets by applying a variety of image perturbations to our *clean baseline test set* of 640 scaphoid radiographs. Each perturbation type and severity level corresponds to a row in Table 1, which lists the name of the treatment, the number of images, and the specific operation performed. Next, we describe the main categories of perturbations and their implementations.

[a]CLAHE: contrast-limited adaptive histogram equalization.

Clean Dataset

We refer to the original 640 cropped scaphoid images (taken directly from DICOM files and converted to 8-bit depth) as the "clean" dataset (row 1 in Table 1). This set serves as our baseline for comparison.

Gaussian Blur

We simulated *blur* by convolving each scaphoid region with a Gaussian kernel using SDs (σ) ranging from 0.5 to 3.0 (rows 2-7 in Table 1). Specifically, we used a Python image-augmentation library (eg, *imgaug*; Python Software Foundation) to apply GaussianBlur(σ=x). Each σ setting generated a separate dataset of 640 images.

Gaussian Noise

For grayscale noise (rows 8-13 in Table 1), we converted each cropped scaphoid image to 8-bit grayscale, then added random Gaussian noise with SD values in the set {1, 2, 3, 4, 5, 6}. The resulting noised images were reconverted to RGB (by replicating the grayscale channel 3 times) to match the model's 3-channel input requirement.

For color (RGB) noise (rows 14-19 in Table 1), we similarly added Gaussian noise to the 3 RGB channels, resulting in "colored" noise. SD values were identical (1-6). Each level produced 640 modified images.

JPEG Compression

We degraded the quality of the cropped scaphoid images by JPEG compression (rows 20-24 in Table 1), with a compression strength of 10, 30, 50, 70, and 90 (higher values indicating more severe compression in our chosen library). Each compression level formed a dataset of 640 images.

This process simulates the impact of lossy image storage on fracture detection performance.

Contrast-Limited Adaptive Histogram Equalization

Contrast-limited adaptive histogram equalization (CLAHE; rows 25-29 in Table 1) enhances local contrast in radiographs, potentially exaggerating edges and intensifying noise. We generated 5 datasets by applying OpenCV's createCLAHE() with *cliplimit* in {1.0, 2.0, 3.0, 4.0, 5.0} and tileGridSize=(8,8). Each CLAHE setting yielded 640 images.

Resizing Whole Images

Before cropping the scaphoid region, we resized the *entire* original wrist radiograph (rows 30-35 in Table 1) to widths of 400, 600, 800, 1000, 1200, or 1400 pixels (preserving the aspect ratio), then reapplied our scaphoid bounding box coordinates to crop out the scaphoid. Finally, the cropped regions were resized to 240×240 pixels for model input. This procedure mimics variations in image resolution and scaling during clinical acquisition or display.

Geometric Offsets

To examine the robustness of our model to bounding box inaccuracies, we systematically shifted or distorted the bounding box coordinates by ±5%, 10%, or ±20% of the bounding box size. This sometimes resulted in only partial scaphoid capture. Four separate datasets (Geometrics_1 to Geometrics_4) covered different offset ranges (rows 36-39 in Table 1). Each row includes multiple transformations, so the total number of images can exceed 640.

Twelve-bit Rescaling

Instead of converting the DICOM images with our typical method (method 1), we used an alternative approach (method

XSL•FO
RenderX

2) that directly scales 12-bit raw pixel values (0-4095) into 8-bit (0-255). We generated 2 variations: (1) 12-bit-rescale_1: recorded bounding box coordinates were applied to these rescaled images; (2) 12-bit-rescale_2: we reran the scaphoid detection model on these rescaled images to obtain new bounding boxes.

Screenshot Datasets

We opened the original DICOM files in different DICOM viewing software (eg, MicroDicom; ImageJ developed by National Institutes of Health and the Laboratory for Optical and Computational Instrumentation), adjusted the default display or resolution, and took screenshots of the entire wrist X-ray. Screen resolutions varied (eg, 550×780 or 900×1050; rows 42-44 in Table 1). We then cropped out the scaphoid region using our detection model, resizing the final images to 240×240. Each screenshot setting introduced different display parameters, simulating suboptimal clinical scenarios where images may be shared or interpreted via screenshots instead of original DICOM files.

Each of these modifications produced a new dataset of 640 images (except when multiple bounding box transformations were applied, resulting in a large number of images). Collectively, these datasets allowed us to evaluate the effects of image degradations on the classification model's performance. Table 1 provides a concise summary of all transformations, whereas Multimedia Appendix 1 contains more detailed code snippets and pseudocode for each operation.

Additionally, 5 datasets were produced using the rescale method or by capturing screenshots from the original DICOM files on image viewers. Figure 2 and Table 1 detail all 44 perturbations. The details of noise introduction into the dataset are described in Multimedia Appendix 1.

Figure 2. Flowchart of the pipeline used to generate clean and noisy datasets. CLAHE: contrast-limited adaptive histogram equalization;

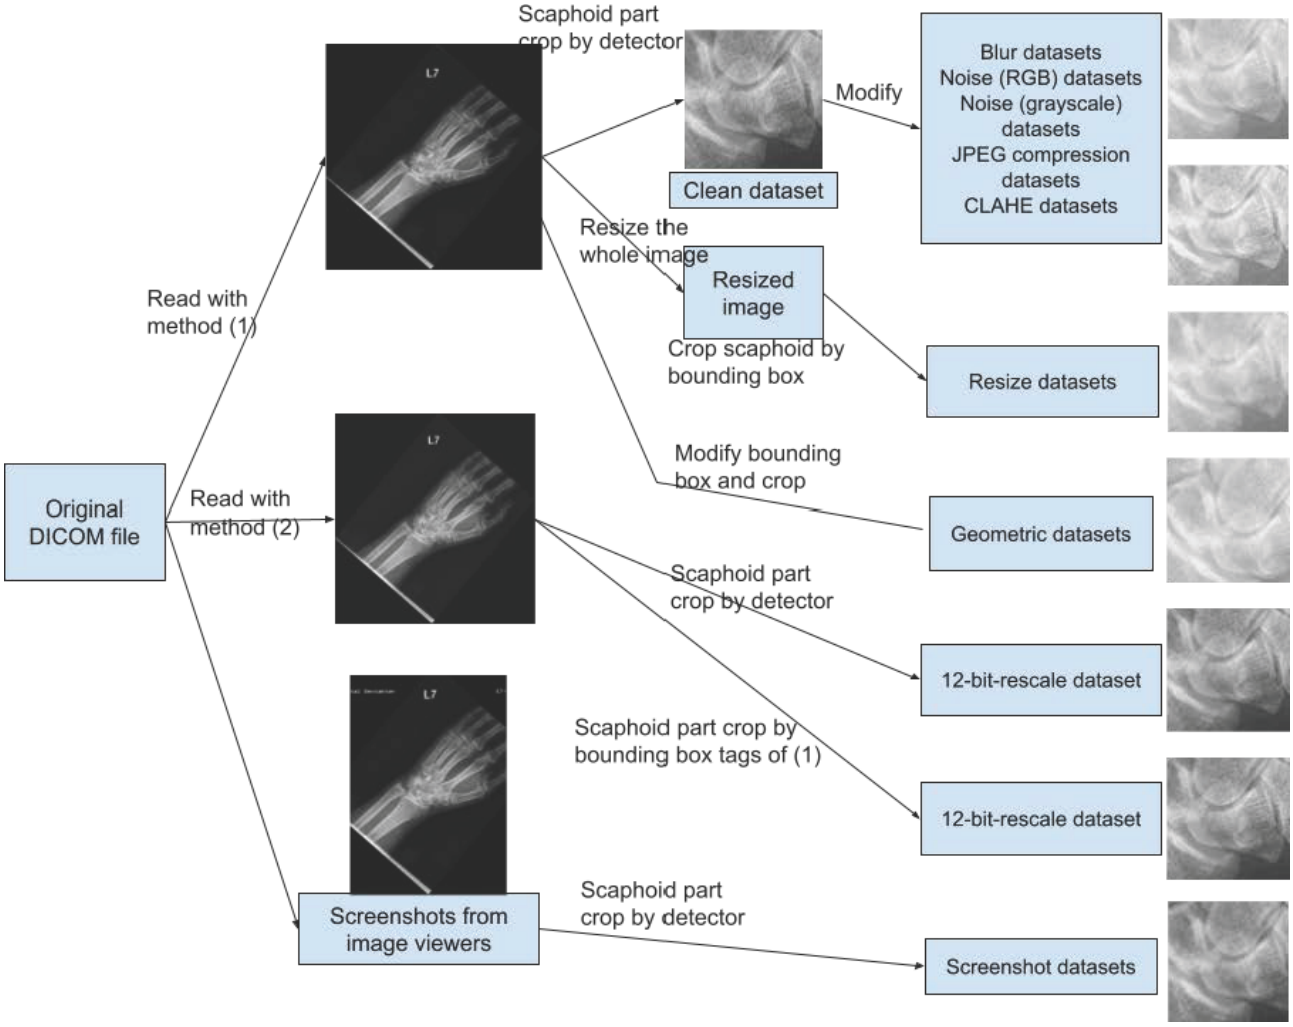

Image Quality Assessment

The peak signal-to-noise ratio (PSNR) and the structural similarity indexing method (SSIM) [14,15] were used as image quality assessment methods when gauging alterations in images. PSNR is a widely used metric that assesses the fidelity of an image compared with its original or uncompressed version. PSNR quantifies the difference between 2 images by calculating the ratio of the maximum possible power of the signal (the image) to the power of the noise (the error that is introduced). A higher PSNR value indicates better image quality because less noise is introduced during changes. In contrast, SSIM is a more advanced metric for measuring image quality that considers structural information, luminance, and contrast when comparing 2 images. SSIM calculates local similarities between the 2 images and combines them into a single score, ranging

XSL•FO
RenderX

from −1 to 1, where a higher value indicates greater similarity between the images. Both PSNR and SSIM values were calculated using TensorFlow image module (TensorFlow Module: tf.image), which allows efficient and accurate computations of both metrics. However, neither PSNR nor SSIM can be used for geometric transformations, such as affine and rotational adjustments, because both rely on pixel-by-pixel comparisons. Such comparisons become less meaningful when the spatial arrangement of image content is altered via geometric transformations. Consequently, datasets with modifications to the labeled scaphoid regions were excluded from comparison to maintain assessment integrity.

We calculated and compared PSNR and SSIM values for the clean and noisy images. Importantly, neither assessment is amenable to geometric transformations, such as affine and rotational adjustments. Therefore, the following datasets with modifications to the labeled scaphoid regions were excluded from the PSNR and SSIM comparisons: the 4 geometric datasets, the 12-bit rescale_2 datasets, and the 3 screenshot datasets. Both PSNR and SSIM were calculated using TensorFlow image functions (PSNR and SSIM).

Model Evaluation and Performance Metrics

The scaphoid fracture classification model was evaluated by analyzing its performance on various test datasets that included clean images and distorted images with diverse noise levels. Performance metrics, including model accuracy, sensitivity, specificity, and F_1-score, were calculated by comparing the model predictions with ground truth labels provided by experienced orthopedic and hand surgeons.

Robustness Against Image Quality Degradation

To assess model robustness against image quality degradation, model performances on distorted images were compared with model performances on clean images. This comparison sought to estimate fracture classification accuracy when perturbations were present, offering insights into potential real-world applications of the model and its robustness when image quality varies in clinical settings.

The Environment

Model inferences were executed on Linux Ubuntu 18.04 LTS (GPU: NVIDIA GeForce RTX 3080 (10 GB); Python version 3.7.13). Implementation was conducted with a TensorFlow backend and TensorFlow version 2.9.1.

Results

Performance of the Deep Learning Model With Varied Perturbations

We investigated the efficacy of a deep learning model designed to detect scaphoid fractures in radiographs, specifically when image quality had been deliberately compromised by adding perturbations. The primary datasets were altered using various methods: addition of Gaussian noise, blurring, JPEG compression, CLAHE, resizing, and geometric adjustments. Table 2 presents the quality assessment and model performance results across the evaluated datasets. Specifically, datasets that underwent blurring, Gaussian noise addition, JPEG corruption, CLAHE, or resizing are reported in rows 1–35; geometric datasets in rows 36–39; bit-rescaled datasets in rows 40–41; and screenshot datasets in rows 42–44. The model achieved an accuracy of 92.03% on the original unaltered dataset, which thus served as the performance benchmark for other evaluations.

The Effects of Noise and Perturbations

This section discusses model performance on datasets directly modified from the cropped scaphoid radiographs and resized datasets without geometric modifications. Table 2 presents the quality assessment and model performance results across the evaluated datasets. Specifically, datasets that underwent blurring, Gaussian noise addition, JPEG corruption, CLAHE, or resizing are reported in rows 1–35; geometric datasets in rows 36-39; bit-rescaled datasets in rows 40-41; and screenshot datasets in rows 42-44. Further details can be found in Multimedia Appendix 1.

For datasets that included cropped scaphoid radiographs and resized images, if the severity of image degradation was minimal, the effect on model accuracy was negligible. An important observation was that the model exhibited varying degrees of resilience against different image perturbations. Even in some datasets with similar PSNR and SSIM values and comparable image quality, some discrepancies in model performances were observed. These findings underscore the nuanced robustness of the deep learning model against different image distortions.

On some noisy datasets, such as Gaussian blur_0.5, Gaussian noise (RGB)_1, Gaussian noise (grayscale)_1, and JPEG compression_10, the model performances were similar to that on the clean dataset. These datasets had the least severe distortions; the pixel values changed minimally, as indicated by the high PSNR and SSIM values. However, as the perturbations increased in severity, image features deteriorated further, and model performance declined. This trend was observed across all treatments, although the extent of performance decline varied according to the type of perturbation. We conclude that if the severity of a perturbation can be maintained below a specific level in degraded images, the model can maintain good performance.

Robustness Against Different Types of Perturbations

Next, we compared model robustness across different image perturbations. Although some datasets yielded similar average PSNR and SSIM assessments, model performances differed. This finding suggested that the model is more robust against certain types of distortions but more vulnerable to others.

Color and Grayscale Gaussian Noise

We expected that the PSNR and SSIM assessments would be similar after the introduction of Gaussian noise, regardless of whether the noise was in color or grayscale. This expectation was confirmed by the similar average PSNR and SSIM values of the corresponding RGB and grayscale Gaussian noise datasets. Nevertheless, model accuracy was considerably lower when grayscale noise was present, suggesting that the model solely enhanced resilience to color perturbations. This may be explained by the fact that the training set was exclusively composed of grayscale samples, although the model input layer accepted 3-channel color images.

Gaussian Blurring

Gaussian blurring substantially degraded model performance, comparatively more than other noises with similar image quality metrics. For images with PSNR values between 35 and 50, linear regression analysis revealed that Gaussian blurring was associated with a 5% to 12% decrease in accuracy compared with other nongeometric transformation techniques. Although blurring an image does not significantly decrease image quality, blurring likely affects fracture features and thus negatively

XSL•FO
RenderX

affects detection. This finding is consistent with the results of a previous study, which concluded that neural networks are very sensitive to blurring, probably because textures and edges are removed [16-18].

JPEG Compression

The effect of JPEG compression on model performance was similar to the effect of grayscale Gaussian noise. The neural network was surprisingly resilient to JPEG compression. Even after a 90% file size reduction via JPEG compression, the model achieved an accuracy of greater than 81%. This finding has important clinical implications: DICOM images, which are often larger than 20 MB, can be compressed by up to 70% via JPEG, but the model will maintain 90% accuracy in terms of detecting scaphoid fractures. This capability will render model implementation more computationally efficient.

Resizing

The resizing perturbations were designed to simulate a realistic low-resolution workflow in which radiographs may be downsampled before region extraction and later rescaled for AI inference; therefore, this setting reflects the combined effects of downscaling information loss and upscaling or interpolation artifacts from small cropped regions of interest (ROIs), rather than a purely isolated resolution test. The downscaling treatments required the new image to store information using fewer pixels than the original, which forced the image to compress its content. As a result, a substantial amount of information was lost when the number of available storage units was reduced, leading to blurry images and lowered image quality, as demonstrated by the PSNR and SSIM values. However, fracture detection accuracy did not significantly decline until the PSNR values fell below 30. Compared with other noise treatments, resizing an image may adequately preserve the features required for fracture detection.

Contrast-Limited Adaptive Histogram Equalization

CLAHE treatment enhances image contrast and thus dramatically alters the image [19,20]. A CLAHE-enhanced image can inadvertently mislead the model, especially if the model has not been trained with CLAHE-augmented data. Model accuracy decreased as the parameter “clip limit” (maximum limit of the adaptive histogram equalization) increased, considerably lowering the PSNR and SSIM values. However, the poor metric values do not necessarily imply that CLAHE transformation worsens the model performance more severely than that of other perturbations. Even at a cliplimit of 2, the PSNR declined to 21, lower than the PSNR after any Gaussian blur or JPEG treatment, and the model accuracy decreased to 83%. As the cliplimit was subsequently increased, the accuracy precipitously fell to 77% (Table 2). This finding differs from the result of a previous study, in which neural networks were resilient against changes in image contrast [17]. This discrepancy may be because Dodge and Karam [5] investigated contrast reduction only via grayscale image superimposition and assessed correct image classification (eg, a dog and a cat) using network models. In contrast, a scaphoid DNN must detect subtle linear features when identifying fractures, and CLAHE likely obscures contrast along the fracture line. CLAHE is useful when enhancing x-ray images before human interpretation, but it should only be used in neural networks that are trained via CLAHE augmentation. Additionally, if a chosen medical imaging software exhibits built-in CLAHE-enhancing features, the neural network must be trained with CLAHE-augmented data.

Differences in the Reductions of Precision and Recall Rates

The prevalence of scaphoid fractures in the test dataset was 46%. As all noisy datasets were derived from this dataset, the prevalences were identical. Accordingly, a decline in model accuracy can be attributed to either reduced precision or recall rates, with the former creating more false positives and the latter creating more false negatives.

In the last step of training, the model was fine-tuned to achieve precision and recall rates of 91%. We expected that these performance metrics would decrease when interpreting noisy datasets. Intriguingly, the severities of performance decline differed for precision and recall. Although most noisy datasets triggered declines in both precision and recall, the performance deteriorations exhibited by the precision rates were more pronounced. However, the recall rate was usually acceptable, even in heavily altered datasets. As the model seeks to identify all possibly useful scaphoid fractures, it remains clinically robust in terms of detecting fractures despite image perturbation, but at the cost of increased false-positive rates.

Only a few datasets showed the opposite, with a precision rate much greater than the recall rate; these were the JPEG compression_50, JPEG compression_70, and all CLAHE datasets. Conversely, the remaining JPEG compression datasets demonstrated a higher recall than precision rate, similar to other changes. Therefore, JPEG compression is likely not the principal explanation for such findings.

However, we found that CLAHE image treatment must be performed with caution. CLAHE primarily reduces recall (increasing false negatives) while precision tends to increase, indicating a heightened risk of missed fractures at higher clip limits (Table 2). If the images to be interpreted are of low quality and CLAHE enhancements are applied, machine learning scientists should be wary of inadvertently increasing the false-negative rates.

Relationship Between Image Quality Assessments and Model Performance

We combined all noisy datasets (excluding the CLAHE datasets, given their heterogeneity) into a single dataset with 18,560 samples exhibiting various perturbations. We used this combined dataset to investigate the relationship between image quality and model performance.

We calculated 25 quantiles of SSIM value distributions and grouped the images according to quantile; this approach yielded 25 groups with 742 or 743 samples each. Our grouping method effectively randomized the images and eliminated the effect of any particular degradation treatment when grouping images from different datasets by image quality. We regrouped images by SSIM quantiles, rather than PSNR quantiles, because the

XSL•FO
RenderX

distributions of SSIM values within each noisy dataset were wider and enabled easier stratification.

For each group, the average PSNR, average SSIM, and model accuracy were calculated (Figure 3). We found a strong linear relationship between average image quality and model accuracy. The model performed better on images with higher quality assessments.

XSL•FO
RenderX

Figure 3. The images were divided into 25 groups according to the structural similarity index measure (SSIM) value quantiles. PSNR: peak signal-to-noise ratio.

XSL•FO
RenderX

The average PSNR, average SSIM, and group accuracy for each were plotted; the accuracy exhibited strong linear relationships with both image quality assessments.

Both PSNR and SSIM regressions yielded high adjusted R-squared values (P<.001). As the PSNR and SSIM values are not independent, it is reasonable to expect that the 2 assessments would yield similar results for most image degradations [21]. However, the SSIM was normalized, whereas the PSNR was not. Robust linear associations between image quality evaluations and model performances were evident. Specifically, PSNR and SSIM, indicators of image quality, served as reliable independent tests that predicted AI performance under various perturbations. Higher image quality evaluations were invariably correlated with superior model performances. Although certain perturbations, such as geometric offsets or pixel value rescaling, did not appear to influence model performance, resolution was identified as a key factor, particularly in screenshot images. An enhanced focus on the ROI, such as zooming, effectively averted accuracy reduction. Recent research introduced a framework for the creation of Robust Medical Imaging AI models, which focuses on developing robust AI models for chest radiographs by addressing real-world sources of image degradation such as device heterogeneity, screen-captured inputs, and compression artifacts [22].

Effects of Geometric Offsets

CNN models extract hierarchical features from local regions of an image through convolution and pooling operations. In principle, a moderate change in object location within the image should therefore not drastically confuse the model. Our results generally reflected this expectation: the 4 geometrically modified datasets retained good overall accuracy when the scaphoid remained fully within the field of view. However, accuracy declined as the strength of the affine transformations increased. A likely explanation is that parts of the scaphoid were shifted outside the image boundaries, resulting in cropped or incomplete scaphoid regions being presented to the model. Such extreme geometric distortions are unlikely to occur under real-world clinical conditions.

To further assess whether the detection model contributed to performance degradation under realistic settings, we evaluated its robustness on the 3 real-world screenshot datasets and the 12-bit-rescale_2 dataset and compared these results with those from the 4 geometric offset datasets. As summarized in Table 3, the mean intersection over union (IoU) values for the screenshot and 12-bit-rescale_2 datasets (0.8728, SD 0.0679 to 0.9836, SD 0.0268) were consistently higher than those of the geometric offset datasets (0.5752, SD 0.0952 to 0.8530, SD 0.0222). The geometric offset datasets (Geometrics_1 - 4) were intentionally designed as synthetic baselines to simulate pure localization errors of the detector. The lower IoU values in Geometrics_1 - 3 (0.5752 - 0.7546) correspond to increasingly large artificial offsets, whereas Geometrics_4 (mean 0.8530, SD 0.0222) represents the least-modified geometric condition in which the scaphoid remains fully visible after offset treatment. Notably, Table 3 presents that the detector achieved IoU values exceeding Geometrics_4 on all screenshot datasets, suggesting that the detection model remains stable under realistic screenshot-related degradation.

Table . IoU values of the datasets which the detection model was involved with and the geometric datasets.

Datasets involve detection model	IoU[a], mean (SD)
Screenshot_MicroDicom_1	0.8768 (0.0625)
Screenshot_MicroDicom_2	0.8728 (0.0679)
Screenshot_ImageJ	0.8907 (0.0554)
12-bit-rescale_2	0.9836 (0.0268)
Geometric datasets[b]	
Geometrics_1	0.5752 (0.0952)
Geometrics_2	0.7546 (0.0662)
Geometrics_3	0.7063 (0.0529)
Geometrics_4	0.8530 (0.0222)

[a]IoU: intersection over union.

[b]Considering geometric datasets IoU as baseline, the detection model performed better on all the screenshot datasets, showing its robustness toward perturbations, and that the performance of the detection model would not be a major factor leading to failure of the classification model when image degradation occurs.

As the classification model still maintained reasonable accuracy across the geometric baselines, IoU values comparable to or higher than Geometrics_4 indicate that under real-world screenshot- and rescaling-related perturbations, the detector's localization accuracy is at least similar to its best geometric baseline performance and therefore is less likely to be a dominant contributor to the observed classification performance changes. Overall, these findings suggest that detector-related bounding box offsets likely play a limited role in the performance degradation observed in these realistic conditions.

Effects of Pixel Value Rescaling Methods

The 2 methods for rescaling images from 12-bit to 8-bit did not materially affect model performance. The 2 datasets derived from the alternative rescaling method, 12-bit-rescale_1 and 12-bit-rescale_2, showed only a minor decrease in accuracy

XSL•FO
RenderX

(<1%), although the rescaled images were nearly identical. Examination of the few inconsistent cases revealed that the classification confidence scores for "fracture" and "nonfracture" were much closer in these instances, with differences typically on the order of 10^2. In contrast, in most other cases, the confidence score gap exceeded 10^3, indicating stronger and more stable model decisions. These relatively uncertain confidence scores suggest that the inconsistent cases were inherently difficult for the model to judge, even without perturbation. As the model's decisions for such cases were already unstable, slight modifications introduced by the alternative rescaling algorithms—despite causing only minimal pixel value changes—could flip the predicted label. This likely explains the minor performance differences observed among the clean dataset and the 2 rescaled datasets (12-bit-rescale_1 and 12-bit-rescale_2).

Screenshot Datasets

Taking screenshots was the most complex perturbation of all the studied treatments. Resolution may be the factor that most strongly affects model performance. The only difference between the datasets Screenshot_MicroDicom_1 and Screenshot_MicroDicom_2 was the resolution; changing the resolution from 900×1050 to 550×780 pixels resulted in an accuracy reduction from 86.3% to 82.8%. The dataset Screenshot_ImageJ, the dataset with images resized to a width of 600 pixels while keeping the aspect ratio collected using ImageJ, exhibited the worst resolution and worst read accuracy (78.1%). Such declines in accuracy, precision rate, and recall rate were similar to declines observed in the corresponding resized datasets (Screenshot_MicroDicom_1 with Resize_600, Screenshot_MicroDicom_2 with Resize_1000, and Screenshot_ImageJ with Resize_600). Although the detection model had been involved in the preparation of these datasets, Table 3 implies that in these cases, scaphoids were correctly detected and cropped. In conjunction with the fact that the classification performance of screenshot datasets was worse than that of any of the geometric datasets, the degradation in model performance indeed stems from resizing effects. We also observed that although resolution deterioration was the major factor, the screenshot process did not impact model performance identically to pure resizing. Specifically, Screenshot_ImageJ showed a modest but consistent performance drop compared with its corresponding resized dataset (Resize_600) and also performed worse than another screenshot dataset (Screenshot_MicroDicom_1) collected at a similar resolution. This suggests that viewer-specific display or resampling algorithms during screenshot capture may also influence model performance.

On the basis of these results, one strategy that may prevent accuracy reduction after taking screenshots would be to zoom into the image and then take a screenshot at the 100% level. Although the radiographic image subsequently may not fit within the screen display, it is unnecessary to capture the entire image because the only ROI is the scaphoid.

Computational Cost and Inference Time

We evaluated the average inference time by running through the 640 whole-hand x-ray images from the clean testing dataset using the complete preprocessing, bounding box detection, and classification inference pipeline. We obtained a computation time of approximately 6 to 8 ms per image on an NVIDIA RTX 3080 (10 GB RAM), while warmup runs were not included. The end-to-end pipeline used less than 200 MB GPU memory per 240×240×3 input (including framework overhead), enabling near real-time inference on a single RTX 3080. Consequently, our approach is compatible with near-real-time applications, assuming a well-optimized implementation. Although resizing or blurring images may incur a minor preprocessing overhead, these operations add only approximately 1 ms to the total inference time, indicating that real-time usage in clinical workflow is feasible on a modern GPU.

Discussion

Principal Findings

Taken together, our findings highlight that the deep learning model's performance is inversely related to the severity of image degradation, with Gaussian blur, grayscale noise, and CLAHE standing out as the most disruptive factors. These types of distortions can destroy or obscure the crucial edge information that the network relies upon for detecting subtle fracture lines. In contrast, moderate JPEG compression, resizing, or color noise had a less pronounced effect. Notably, the resizing experiments in this study reflect a realistic low-resolution workflow involving downscaling, then cropping, and then upscaling, which is consistent with real-world recaptured or low-resolution imaging scenarios described in the literature [9]. While accuracy decreases were comparable between Screenshot_ImageJ and the corresponding Resize datasets, Screenshot_ImageJ showed a modest additional reduction in recall, suggesting that screenshot recapture can affect sensitivity beyond pure resizing.

From a clinical perspective, these results underscore the importance of maintaining sufficient image fidelity and avoiding overly aggressive postprocessing steps. If CLAHE-based enhancement or heavy contrast adjustments are used, training the model with matching augmentations may be necessary to preserve performance. Similarly, our analysis indicates that modest compression does not necessarily compromise diagnostic accuracy, suggesting an avenue for reducing file sizes without compromising model output.

Although the network proved fairly robust across various perturbations, investigators should remain cautious when applying transformations, such as extreme blurring, under or overexposure, or very low-resolution screenshots. In these scenarios, crucial details may be irretrievably lost, leading to significantly higher misclassification rates. Our results also emphasize that the precision rate is especially sensitive to noise, often dropping faster than recall. This behavior means that some perturbations can inflate false positives, which may still be acceptable in screening contexts that favor high recall but could impact workflows that depend on precise diagnoses.

XSL•FO
RenderX

In certain clinical scenarios, obtaining the original radiographic file may not be immediately feasible—such as in emergency settings, remote consultations, or when imaging systems have limited data access privileges. In such situations—particularly in emergency department workflows where the original radiographic DICOM file may not be readily accessible because of time pressure, remote consultation needs, or limited system privileges—clinicians or technicians may rely on on-screen screenshots or smartphone photographs for rapid review, sharing, or AI-assisted interpretation. Although practical, these recaptured images can introduce unintended degradation due to variations in capture resolution, scaling distortions, and secondary compression, which may obscure subtle fracture cues. This real-world practice motivated our inclusion of screenshot-based perturbations as a clinically relevant proxy for urgent or resource-limited conditions. To replicate such real-world conditions, our study incorporated a "screenshot" perturbation by capturing radiographs at different image sizes and resolutions. The resulting artifacts mimic the geometric and pixel-level distortions that may arise in urgent or resource-limited workflows, providing insight into how these factors influence model performance.

Although this study was conducted using data from a single institution, the dataset represents one of the largest and most diverse radiographic collections in Taiwan, drawn from multiple campuses within the Chang Gung Memorial Hospital system, with different scanners and protocols, introducing natural variability while maintaining consistent image quality and annotation standards. The main objective of this study was to test a methodological approach for evaluating model robustness to image degradation, rather than to claim broad generalization to all clinical environments. The single-institution design, therefore, provided a stable yet sufficiently varied dataset for controlled experimentation.

Comparison With Prior Work

Our findings are consistent with prior studies showing that CNNs are sensitive to image degradation and domain shifts in medical imaging. Recent research introduced the RoMIA framework, which aims to develop robust AI models for chest radiographs by addressing real-world sources of image degradation, such as device heterogeneity, screen-captured inputs, and compression artifacts. In parallel, previous studies have shown that AI can enhance image quality and improve diagnostic reliability across multiple imaging modalities, including computed tomography and radiography [1,7,23]. Moreover, real-world deployments have demonstrated that recaptured or smartphone-captured radiographs introduce compounded degradations (eg, scaling, compression, and display artifacts) that can alter AI outputs, underscoring the clinical relevance of evaluating robustness under such workflows [9]. Taken together, these studies highlight the growing emphasis on image fidelity and consistent acquisition parameters as key factors for ensuring robust and generalizable AI performance. Previous research [18] has demonstrated that blurring and contrast alteration primarily affect the high-frequency components essential for delineating structural boundaries—similar to the degradation patterns observed in this study. The alignment between our results and those of earlier works reinforces that these degradation effects are likely intrinsic to CNN-based architectures rather than model-specific artifacts.

Limitations

This study has several limitations. First, the robustness results reported here are relative to our standard clinical preprocessing pipeline. Specifically, the "clean" baseline was generated by detector-based cropping followed by resizing each scaphoid ROI to 240×240 pixels to match the fixed input size of EfficientNetB1. As this crop-and-resize step is itself a lossy operation, our robustness conclusions should be interpreted within this trained-and-deployed pipeline context, rather than as absolute performance relative to the raw, unprocessed DICOM images. Second, our analysis was confined to a single deep learning architecture, EfficientNetB1. Different backbones (eg, ResNet and DenseNet) may exhibit varying levels of robustness to specific noise types, such as Gaussian blur or CLAHE. Nevertheless, we expect that many of the general trends—such as vulnerability to edge-destroying blur—would hold true across CNN-based architectures. Third, all experiments were performed on retrospective datasets from a single institution and focused on controlled pixel-level perturbations. As a result, the data may not fully capture the diversity of real-world clinical acquisition conditions or additional artifacts, such as motion blur, partial occlusions, and multiview variability. Future prospective, multi-institutional studies incorporating these realistic factors would provide a more comprehensive assessment of model resilience and generalizability.

Future Directions

Future work could extend our methodology by evaluating multiple architectures under identical perturbations to quantify differences in susceptibility and to determine whether certain network designs are inherently more robust. Incorporating multiview data and realistic clinical artifacts (eg, motion blur and underexposure) may also help develop more generalizable models. Additionally, advanced data augmentation strategies that simulate image degradation during training could enhance robustness. Exploring hybrid or ensemble models that integrate texture- and shape-based cues, as well as integrating domain-specific priors, could further mitigate the impact of low-quality inputs.

Conclusions

Neural network models designed to complement radiographic interpretation in clinical practice will inevitably encounter image quality distortions due to variations in acquisition, processing, and storage. In this study, we systematically evaluated the effects of image degradation on the performance of a DNN for scaphoid fracture classification. We found a strong negative correlation between image quality and model accuracy, with Gaussian blur, grayscale Gaussian noise, and CLAHE exerting the greatest influence on performance.

Performance decline was primarily driven by decreases in precision, whereas recall remained relatively stable. When developing neural networks for fracture detection in clinical radiography, training with targeted perturbations—particularly

XSL•FO
RenderX

Gaussian blur, grayscale noise, and CLAHE—may improve the model robustness and ensure more reliable performance in diverse clinical environments.

Abstract

Background: Exploring user satisfaction is crucial for enhancing and ensuring the sustainable development of mobile health (mHealth) apps, particularly in the fitness and weight management sectors. Analyzing user types and developing user profiles are valuable for understanding differences in satisfaction. However, prior research lacks a classification of user types based on self-management characteristics and an analysis of satisfaction disparities among these types.

Objective: This study analyzes user heterogeneity from a self-management perspective among fitness and weight management app users by identifying user types and constructing profiles. It further explores differences in satisfaction with the functional design of these mHealth apps across user types.

Methods: First, 8 feature indicators were selected based on the Health Belief Model and the Behavior Change Wheel to evaluate users' levels of health knowledge and beliefs, as well as self-regulation related to self-management. Existing research was integrated to categorize mHealth app functional design into 5 categories: health guidance, health education, health monitoring, social features, and gamification. Second, a questionnaire survey was used to collect data on users' 8 health management characteristics and their satisfaction with the 5 functional design categories. A total of 2518 responses were collected, of which 1025 were included in the analysis. Cluster analysis was conducted to classify users into distinct types based on the 8 health management characteristics, and user profiles were constructed according to the distribution of these characteristics within each

XSL•FO
RenderX

type. Finally, the Kruskal-Wallis test was used to analyze differences in satisfaction across user types with respect to the 5 functional design categories of mHealth apps.

Results: Cluster analysis revealed that users could be categorized into 6 types based on the 8 self-management characteristics: positively proactive energizers, proactive intenders, negatively proactive energizers, low health management demanders, potential health management demanders, and passive attitude holders. Significant differences were observed across all 8 health management characteristics among the 6 user types (all P<.001). The Kruskal-Wallis test indicated significant variations in user satisfaction with the 5 functional designs of mHealth apps: H(4)=445.388, (P<.001). Overall, users reported the highest satisfaction with health guidance and health monitoring (median 4.00, IQR 1.00) and the lowest satisfaction with gamification (median 3.00, IQR 1.00). Positively proactive energizers, proactive intenders, and negatively proactive energizers demonstrated the highest satisfaction with health education and health guidance (median 4.00). Potential health management demanders, proactive intenders, positively proactive energizers, and negatively proactive energizers reported the highest satisfaction with health monitoring (median 4.00). Proactive intenders reported the highest satisfaction with social features and gamification (median 4.00).

Conclusions: Users of mHealth apps exhibit diverse types, with significant differences in health management characteristics and satisfaction with the 5 functional designs of fitness and weight management apps. This study clarifies individual-level differences in user satisfaction with mHealth apps.

KEYWORDS

mHealth app; user satisfaction; self-management characteristics; user profile; unsupervised learning

Introduction

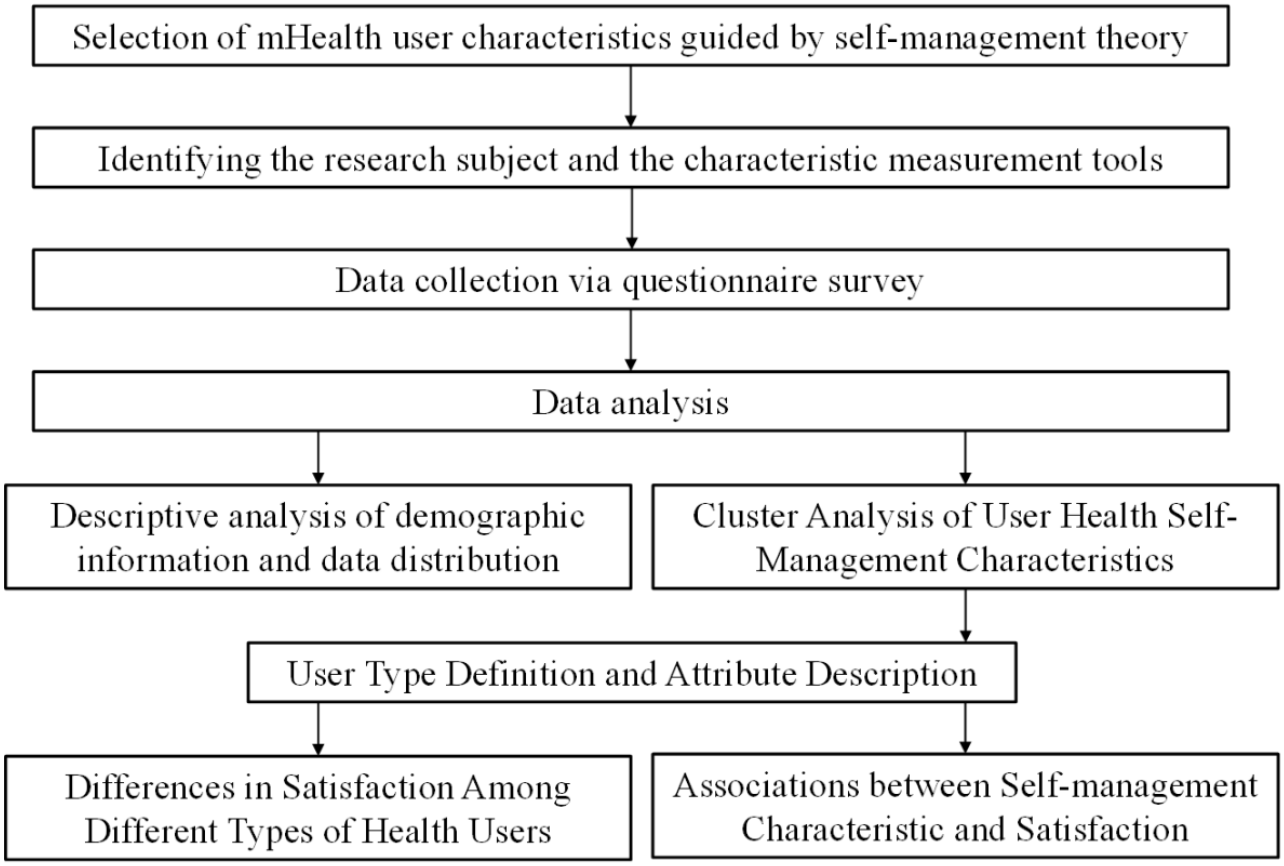
The poor continued use of mobile health (mHealth) apps poses a significant threat to the sustainability of the mHealth industry, while also weakening the benefits of health management for users. Approximately 40% of smartphone users utilize mHealth apps [1]. Research indicates that health management based on mHealth apps often requires continued use for over 3 weeks to demonstrate effective outcomes [2]. However, a real-world observational study revealed that only 2.58% of the 189,770 users who downloaded mHealth apps actively used them for at least one week [3], indicating that continued use of mHealth faces serious challenges. Furthermore, app uninstallations result in average monthly losses of US $57,000 for app companies [4], highlighting the negative impact of poor continued use on the industry. Therefore, it is necessary to research the usability of mHealth. Previous studies have shown that user satisfaction is a key determinant of acceptance and continued use [5].

User satisfaction is an important indicator for measuring the quality of mHealth services and has a significant impact on the continued usage and intention to use mHealth [6]. Exploring the factors related to user satisfaction has important reference value for promoting the use of mHealth. A review of existing research on mHealth satisfaction shows that studies mainly follow 3 perspectives: technology acceptance, functional design, and user characteristics. Research from the perspective of technology acceptance is primarily based on the technology acceptance model and its derivative theories, focusing on how users' perceived characteristics of mHealth technology influence satisfaction [7-11]. Studies on the influencing factors of satisfaction have gradually expanded from a practical dimension to multidimensional value [12], including perceived entertainment and other nonpractical characteristics [13]. Research from the perspective of functional design mainly focuses on how specific functional characteristics of mHealth meet user needs and improve satisfaction, such as data analysis, monitoring, and information sharing [14,15]. This line of research shows a trend of transition from overall evaluation to modular analysis, with the research focus shifting from overall satisfaction with mHealth to the exploration of multidimensional satisfaction [16-18].

Current research has conducted relatively in-depth explorations of mHealth satisfaction from the perspectives of technology acceptance and functional design; however, evidence regarding the relationship between heterogeneity in user characteristics and satisfaction remains limited [19]. A survey on the use of digital health tools among the US population revealed that there is no "one-size-fits-all" model in digital health, as consumers are not a homogeneous group [20]. However, digital health users cannot be classified solely based on sociodemographic characteristics, as each generation interacts with technology differently due to its unique experiences, needs, and levels of trust in the health care system [21]. Previous studies have confirmed that eHealth literacy [22], strong self-reporting capabilities [19], health needs [23], and poor health status [24] significantly influence mHealth satisfaction. Intrinsic characteristics, such as health knowledge, beliefs, and self-regulation skills and abilities, are central to self-management [25]. These findings suggest that self-management attributes provide important explanations for user heterogeneity and differences in satisfaction among users. Compared with traditional health care models, mHealth relies more heavily on self-management service models [26]. Systematic exploration of individual self-management–related characteristics can help construct user classifications that more deeply capture internal features, thereby promoting personalized and refined mHealth design [27]. However, there is a lack of research systematically integrating self-management characteristics and analyzing user-group heterogeneity based on combinations of these characteristics. In addition, empirical evidence on the differential distribution of satisfaction across different user types with respect to mHealth function design remains scarce, posing challenges for developers seeking to deliver mHealth services that meet the needs of diverse users.

XSL•FO
RenderX

To address the above limitations, this study, guided by self-management theory, analyzes relevant self-management characteristics based on the Health Belief Model (HBM) and Behavior Change Wheel (BCW) among users of fitness and weight management apps. A refined classification of these mHealth users is conducted based on characteristic attributes, and differences in satisfaction with mHealth functional design across user types are examined. Through this investigation, the study seeks to address the following research questions:



- Research question 1: User typology: How can users of fitness and weight management apps be systematically categorized using quantitative methods based on self-management characteristics? What are the defining attributes of each user type?
- Research question 2: Satisfaction differences. Do user groups with distinct self-management characteristics demonstrate statistically significant differences in satisfaction with various mHealth functional designs? What are the specific manifestations of these differences, and which factors are relevant?

Methods

Design

Guided by self-management theory, this study utilizes the HBM and BCW to select variables representing the self-management characteristics of mHealth users. Data were collected through a questionnaire survey, and unsupervised clustering analysis was used to identify user clusters. Subsequently, the characteristic distributions of different user clusters were analyzed to construct user profiles. Through intergroup difference analysis, this study compared satisfaction levels across user types with respect to various mHealth functional designs and examined the correlations between user characteristics and satisfaction with functional designs. The overall workflow of the study is illustrated in Figure 1.

Figure 1. Study flowchart. mHealth: mobile health.

Selection of Self-Management–Related Characteristics

mHealth mainly improves health outcomes by empowering self-management abilities [28]. Therefore, this study selects variables representing user characteristics guided by self-management theory. In individual and family self-management theory [29], self-management refers to the process by which individuals and families use knowledge and beliefs, self-regulation skills and abilities, and social facilitation strategies to achieve health-related outcomes in their real-life environments. Among these components, knowledge and beliefs refer to information and perceptions related to a health condition or health behavior. The HBM is one of the most widely used models for explaining beliefs and perceptions underlying health behaviors [30]. HBM posits that individuals' perceptions of their susceptibility to a health issue and the potential severity of its consequences, together with perceived benefits of adhering to health recommendations and their intention and ability to engage in health management, are the most direct drivers of health behaviors [31]. HBM operationalizes these factors through perceived susceptibility, perceived severity, perceived benefits, perceived barriers, and self-efficacy [32]. Accordingly,

XSL•FO
RenderX

this study adopts these 5 variables from HBM to characterize the knowledge and beliefs component of self-management theory.

Self-regulation within self-management theory is an iterative process in which individuals utilize a variety of skills and abilities to achieve healthy behavior change [29]. The BCW, a classic theoretical model for explaining behavior change—particularly in the contexts of health promotion and disease prevention [33]—provides an important reference for selecting self-regulation–related characteristic variables in this study. The BCW posits that healthy behavior change can be achieved only when individuals possess capability, motivation, and opportunity [34]. Capability refers to the knowledge and skills required to engage in a particular behavior [35]. In the context of using mHealth for health management, essential knowledge and skills are reflected in 2 aspects: health management and the use of digital technology. eHealth literacy is among the most commonly used indicators for assessing an individual's ability to acquire health management information and utilize electronic health information to address health issues [36,37]. Accordingly, this study selects eHealth literacy to characterize self-regulation skills and abilities. In addition, motivation in the BCW refers to the beliefs that trigger behavioral change, encompassing reflective motivation and intrinsic motivation [34]. Motivation for health management can be divided into proactive health management intention and passive health management intention triggered by perceived health status, corresponding to reflective motivation and intrinsic motivation, respectively. Therefore, this study selects health management intention [38] and perceived health status [39] to further characterize the motivational dimension of self-management behavior. In summary, this study selects a total of 8 variables to analyze self-management characteristics among mHealth users. The definitions of each variable are presented in Table 1.

Table 1. mHealth[a] user self-management characteristics: a framework of 8 variables for user categorization.

User self-management characteristics	Definition
Perceived susceptibility	Beliefs about the likelihood of getting a disease or condition [31].
Perceived severity	Feelings about the seriousness of contracting an illness or of leaving it untreated, including evaluations of both medical and clinical consequences and possible social consequences [31].
Perceived benefits	Beliefs that engaging in health behaviors can help decrease the risk of diseases and health problems [40].
Perceived barriers	An individual's assessment of the difficulties and cost of adopting behaviors [32].
Health self-efficacy	The confidence individuals have in their ability to use their skills to complete health management tasks [41].
eHealth literacy	The ability to seek, find, evaluate, and use electronic health information from electronic resources to address health issues [36].
Perceived health status	The perception of one's own health status [39].
Health management intention	The degree of intention to engage in health protection [38].

[a]mHealth: mobile health.

Identification of Study Targets

The main purpose of this study is to delineate individuals' health management characteristics and classify users based on their levels of health management characteristics, and to further analyze differences in satisfaction with various mHealth app functional designs across user categories. Therefore, it is necessary to clarify the main functional designs of mHealth apps. Previous studies have summarized common mHealth app functional designs through systematic reviews and content analyses [42-44], categorizing functions according to their primary implementation purposes, such as education, tracking, social interaction, gamification, and motivational features [42]. Building on prior research, this study reorganizes the functional characteristics reported in the literature to propose a classification of mHealth app functional designs for analysis (see Table 2).

XSL•FO
RenderX

Table 2. Five functional designs and features of the mHealth[a] apps analyzed in this study

Functional designs	Definition	Features
Health guidance	Providing advice based on health plans and applications may provide real-time feedback and advice based on health plans and status [45], or offer strategies for behavior change that can contribute to improving health conditions [46].	Intelligent virtual assistants and communication with health care personnel [43]; interaction with medical staff [45]; and development of health plans and goal setting [46].
Health education	Offering necessary knowledge to achieve health behavior change [47].	Personalized education and general knowledge education [42]; image-based education, video education, and audio education [47].
Health monitoring	Recording past and current health statuses [47].	Health records and health diaries [43]; trackers, data entry, and data export [42]; and self-tracking [46].
Social function	Providing a platform for user interaction, communication, and maintaining connections [47].	Community forums and social media [42]; and social sharing [47].
Gamification	Integrating gaming mechanisms or elements into mHealth apps and enhancing the user experience with gamelike features [48].	Personalized avatars, challenges, tasks, health, and rewards [43]; points, badges, and levels [42].

[a]mHealth: mobile health.

To achieve the aforementioned research objectives, this study selected appropriate objects of study for empirical analysis. First, the comparability of different mHealth app functional designs was considered. To minimize the influence of differences in core service content across app types on comparability, this study selected a homogeneous category of apps as the empirical focus, thereby reducing potential confounding effects. Second, the application domains of different mHealth app categories were considered. Exercise, fitness, and weight management align with substantial health needs. These domains represent important modalities for primary prevention, and exercise therapy also serves as a key approach for tertiary prevention (disease management) in various conditions, such as cardiac rehabilitation, pulmonary rehabilitation, tumor rehabilitation, and metabolic disease management [49]. Given that exercise, fitness, and weight management apps account for more than half of all mHealth apps [50], and that these functions represent 48.37% of users' motivations for using mHealth apps [51], we selected exercise, fitness, and weight management apps as the units of analysis to represent a broader and more heterogeneous user population.

This study did not restrict respondents to users of a specific app for the following reasons. First, as the aim of this study is to examine the satisfaction of different user types with various mHealth functional designs in real-world contexts and to provide generalizable recommendations, the focus is on mHealth functional modules rather than on specific app design implementations. Accordingly, the research sample was not limited to users of a single app. Moreover, this questionnaire-based data collection approach captures multiple implementations of the same functional module (eg, health education), thereby enhancing sample diversity and improving the generalizability of the findings [52,53]. Second, this study was conducted in real-world settings, which differ from laboratory-based studies that examine factors influencing mHealth satisfaction. In laboratory environments, variables must be tightly controlled to quantify the idealized effects of specific factors, often requiring the use of a single app as the research object. By contrast, this study emphasizes user satisfaction with mHealth in real-world contexts, where the use of multiple similar apps by the same user is common. Analyzing such data provides real-world evidence that can inform future research and practical mHealth design.

Measurement Instrument

Based on the constructed User Health Management Characteristics Framework, this study measures 8 independent variables and 5 dependent variables reflecting satisfaction with mHealth functionalities. To achieve the aforementioned research objectives, it was necessary to select appropriate and measurable items corresponding to the characteristics defined within the framework. To ensure the rational design of the measurement scale, this study undertook a careful process of adapting previously validated scales, making nuanced adjustments to align them with the specific research objectives.

Specifically, the User Health Management Characteristics Framework includes 4 variables derived from the HBM (perceived severity, perceived susceptibility, perceived barriers, and perceived benefits), with measurement items adapted from HBM-related studies by Ahadzadeh et al [54], Saghafi-Asl et al [32], and McArthur et al [55]. Two variables were derived from the BCW (eHealth literacy and perceived health status), with measurement items drawn from BCW-related studies [39,56,57] and the Brief Health Literacy Screen scale [58]. In addition, 2 variables integrating both models (health self-efficacy and health management intention) were included, with measurement items adapted from health management–related studies, such as Zhou et al [59] and Li et al [38]. For the measurement of satisfaction with the 5 mHealth functional designs, this study first provided definitions and specific design examples of each function in the questionnaire, followed by item-based measurement. The satisfaction items were adapted from relevant studies on mHealth satisfaction [8]. All measurement items used a 5-point Likert scale, ranging from 1 (strongly disagree) to 5 (strongly agree).

A multistage validation and refinement process was implemented to ensure the conceptual accuracy and cultural

XSL•FO
RenderX

appropriateness of the English-originated scales within the Chinese context. First, the preliminary translation and adaptation of the scale items were collaboratively conducted by research team members proficient in both Chinese and English and with expertise in health informatics. Through group discussions, each item was refined to preserve the core meaning of the original construct while aligning with Chinese linguistic norms and the research context. Second, before the formal survey, 24 participants with backgrounds in medical informatics were invited to complete a pretest of the questionnaire. Participants were asked not only to respond to the questionnaire but also to provide feedback on the clarity and contextual appropriateness of the items. Based on this feedback, the wording of the questionnaire was further refined to eliminate ambiguities and improve readability, resulting in the final version used in the formal survey. Finally, during the data analysis phase, reliability and validity tests were conducted on the measurement model, thereby verifying the effectiveness and reliability of the measurement instrument from a data-driven perspective (see Multimedia Appendix 1).

Data Collection

The survey targeted individuals who had used exercise, fitness, or weight loss apps within the preceding 3 months. According to the N:q hypothesis [60], the ratio of sample size to item parameters in a scale should range from 20:1 to 10:1. In this study, a total of 51 items were included for measurement; therefore, applying the more conservative ratio of 20:1, the required sample size was approximately 1020.

From June 28, 2022, to September 8, 2022, a snowball sampling survey was conducted via the WeChat platform (Tencent Holdings Limited). The questionnaire link, generated using Wenjuanxing, was distributed through Moments (Tencent Holdings Limited) and various group chats. In total, 2518 questionnaires were collected. Of these, 902 respondents reported that they had not used the target apps within the preceding 3 months. A quality control item was included in the questionnaire: “This question is an attention test to ensure careful completion of the questionnaire. For this question, please select ‘strongly disagree’.” The correct response to this item was “1. strongly disagree.” Responses that answered this item incorrectly were considered to have failed the quality control check. In addition, given the length of the questionnaire, responses completed in less than 3 minutes or with identical answers across all scale items were deemed insufficiently attentive and were also excluded. Through this screening process, 591 responses were removed. Consequently, 1025 valid questionnaires remained for subsequent analysis. Before completing the questionnaire, all participants were informed of the study’s overall purpose and detailed procedures.

In this study, item-level missing data were addressed using mode imputation based on each respondent’s answers to other items within the same variable. Specifically, there were 3 missing values in total: 1 in perceived susceptibility, 1 in eHealth literacy, and 1 in gamification. As the questionnaire employed Likert scales, which represent ordinal rather than strictly continuous data, each missing value was replaced with the mode of the remaining items within the same scale for that respondent. The imputed values were 3, 5, and 3, respectively. Given that the dataset comprised a total of 45,100 item responses, the proportion of missing values was 0.0067%, which is negligible and unlikely to affect the results.

Data Analysis

To address the question “What are the common combinations of health management characteristics in users during the process of using mHealth?” we employed cluster analysis. Cluster analysis is an unsupervised machine learning technique that divides a set of observations into multiple clusters composed of similar objects and can identify the structural composition of different clusters. In clustering, similarity between observations within the same cluster is high, whereas similarity between observations from different clusters is low. Among various clustering methods, the k-means algorithm produces results that are easy to interpret, are suitable for clustering high-dimensional data, and demonstrate good scalability and efficiency when dealing with large datasets [61]. The clustering in this study was based on 8 health management characteristics (Table 1), and the sample size was moderate; therefore, k-means was appropriate for this study. The k-means algorithm requires the number of clusters to be predetermined. We determined the optimal number of clusters by integrating the Elbow Method and the Silhouette Coefficient. The Elbow Method identifies the inflection point by analyzing the relationship between the within-cluster sum of squared errors (SSE) and the number of clusters, while the Silhouette Coefficient is used to mathematically assess the compactness and separation of the clustering structure. The results showed that when the number of clusters was 6, an inflection point appeared in the SSE curve, and the Silhouette Coefficient reached a locally optimal value of 0.1514 (see Multimedia Appendix 2), indicating that this clustering solution maintains good within-cluster compactness while achieving favorable between-cluster separation. Therefore, we ultimately set the number of clusters to 6. To further verify the stability of this 6-cluster solution, we performed 10 repeated experiments with random initializations. The results showed a relative fluctuation rate of only 0.002% in the SSE values, demonstrating that the 6-cluster solution exhibits high repeatability and stability. We conducted the cluster analysis to determine the grouping of mHealth app users using sklearn.cluster in Python 3.8 (Python Foundation; see Multimedia Appendix 3).

To answer the question “Is there a difference in satisfaction with the functional design of mHealth apps among different types of users?” we performed rank sum tests to examine satisfaction and preferences regarding functionalities across user groups using SPSS 26 (IBM Corp). To address the question “How do health management characteristics affect users’ satisfaction and preferences for the functional design of mHealth apps?” we conducted a partial least squares analysis using SmartPLS 4 (SmartPLS GmbH). The significance level was set at $P<.05$ for 2-tailed tests.

The data collected for this study were analyzed to assess potential nonresponse bias. To accomplish this and examine nonresponse bias [11], the Mann-Whitney *U* test was used to compare responses from the first 20% (205/1025) and the last

XSL•FO
RenderX

20% (205/1025) of the sample. The results showed no significant differences between the 2 groups for the health guidance (z=−0.728, P=.47), health education (z=−1.171, P=.24), health monitoring (z=−0.857, P=.39), social function (z=−1.794, P=.07), and gamification (z=−0.260, P=.80) constructs. Therefore, nonresponse bias was not a concern in this study. This study followed the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) reporting standard (see Multimedia Appendix 4).

Ethical Considerations

This study utilized an online questionnaire survey. On the first page of the questionnaire, the research purpose, content, potential risks, data usage, confidentiality terms, and researcher contact information were clearly explained to participants. By checking a box, participants confirmed that they had read and understood the above information and voluntarily agreed to participate in the study, thereby providing informed consent. Participants who did not agree with the above content were directed to exit the online questionnaire. The questionnaire materials for this study were destroyed after the completion of quality control and transcription, within 6 months after the survey concluded. Any associated information, such as source IP addresses, collection time stamps, and serial numbers, was also destroyed to ensure privacy protection. Following transcription, the data were renumbered sequentially, starting from 1. All images and data presented in the manuscript or multimedia appendices are fully anonymized and cannot be used to identify any individual participant or user. No financial compensation was provided to participants. Approval was obtained from the Biomedical Ethics Committee of the Second Affiliated Hospital, School of Medicine, Zhejiang University, China (approval number IRB-2021-841).

Results

Demographic Information

The demographic characteristics of the included sample are presented in Table 3. The sample exhibited a balanced gender distribution (female: 553/1025, 53.95%; male: 472/1025, 46.05%), with participants predominantly aged 19-30 years (500/1025, 48.78%). In terms of education, most respondents held college degrees (519/1025, 50.63%), followed by master's degrees (269/1025, 26.24%). Income distribution showed that nearly one-quarter of participants (244/1025, 23.80%) earned ≤2500 RMB (1 RMB=US $0.14) monthly, whereas a smaller proportion (49/1025, 4.78%) reported incomes of 50,001 or higher. Regarding usage patterns, the largest group reported using the service 2-3 times per week (370/1025, 36.10%), while a minority were frequent users (>7 times per week: 59/1025, 5.76%). In terms of occupation, students constituted the largest subgroup (283/1025, 27.61%), followed by public servants/clerks (208/1025, 20.29%) and professional technical personnel (196/1025, 19.12%). Overall, 664 of 1025 (64.78%) users reported using 1 app.

Data Characteristics

A descriptive analysis of the 8 self-management characteristics and satisfaction with the 5 functional designs was conducted. First, we calculated the average score of multiple items measuring each characteristic variable to represent the level of that variable. However, because the distributions of the average

XSL•FO
RenderX

values for each variable were not normally distributed, medians and IQRs were used for presentation, as shown in Table 4.

Table 4. Descriptive statistics (median and IQR) of the 8 health management characteristics and satisfaction with the 5 functional designs for the analyzed sample (n=1025).

Characteristics	Median	First quartile (Q1)	Third quartile (Q3)	IQR
Health-specific determinants				
Perceived severity	4.25	3.75	5.00	1.25
Perceived susceptibility	3.50	3.00	4.00	1.00
Perceived barrier	2.50	2.00	3.50	1.50
Perceived benefit	4.75	4.00	5.00	1.00
Health self-efficacy	4.00	3.33	4.33	1.00
Perceived health status	3.67	3.00	4.00	1.00
eHealth literacy	4.00	3.50	4.50	1.00
Health management intention	4.00	3.33	4.33	1.00
Satisfaction				
Satisfaction with health guidance	4.00	3.00	4.00	1.00
Satisfaction with health education	3.67	3.00	4.00	1.00
Satisfaction with health monitoring	4.00	3.33	4.33	1.00
Satisfaction with social function	3.33	3.00	4.00	1.00
Satisfaction with gamification	3.00	3.00	4.00	1.00

Cluster Analysis of User Self-Management Characteristics and Determination of User Types

The determination of the optimal number of clusters in this study, which was set at 6, was based on the relationship between the within-cluster SSE and the number of clusters. Subsequently, cluster analysis was performed on the sample using *z* score–standardized values of the 8 health management indicators. The distribution across the 6 clusters was relatively uniform (140, 135, 189, 218, 180, and 163). Figure 2 shows the distribution of each indicator across the 6 clusters obtained from the analysis. A *z* score close to 0 indicates that the corresponding indicator in a given cluster approximates the overall average level, whereas a positive *z* score indicates that the indicator is above the average level in that cluster.

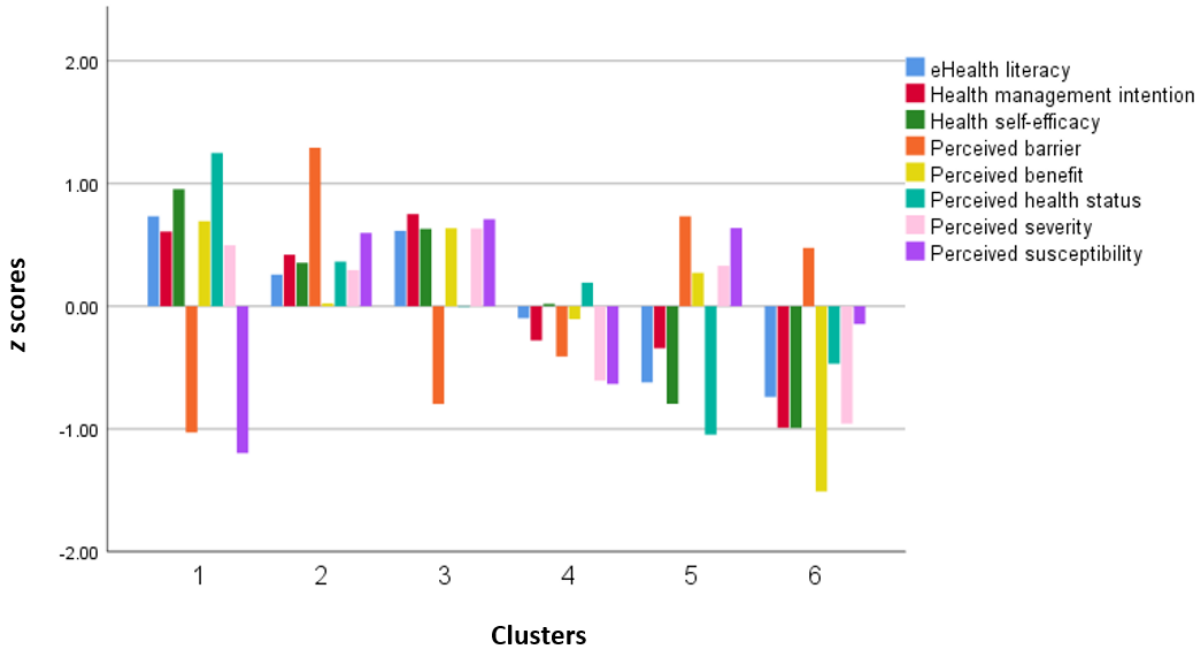
We further analyzed differences in each indicator across the 6 clusters using the Kruskal-Wallis test to assess the distinctiveness of each cluster. The results of the Kruskal-Wallis test demonstrated statistically significant differences in the *z* scores of all indicators across the 6 clusters ($P<.001$ for all). Specifically, significant differences were observed for the following: perceived severity, $H(5)=400.947$ ($P<.001$); perceived susceptibility, $H(5)=522.425$, ($P<.001$); perceived barrier, $H(5)=673.985$, ($P<.001$); perceived benefit, $H(5)=492.630$, ($P<.001$;) health self-efficacy, $H(5)=518.298$, ($P<.001$); perceived health status, $H(5)=490.411$, ($P<.001$); eHealth literacy, $H(5)=362.910$, ($P<.001$); and health management intention, $H(5)=390.573$, ($P<.001$). These findings indicate that the 6 clusters exhibit distinct patterns and magnitudes of health management characteristics, as reflected by the significant differences in the *z* scores of the respective indicators. The detailed *z* scores and pairwise comparison results for each indicator across the 6 clusters are presented in Table 5, allowing for a detailed examination of how each cluster differs from the others in terms of specific health management characteristics. Detailed test statistics are provided in Multimedia Appendix 5, which presents pairwise comparisons of health management characteristics among user groups.

The distribution of the 8 health management traits varied across individual users. To further understand user health management characteristics and provide references for personalized services in mHealth apps, this study categorized users based on combinations of their 8 current health management factors. Given the distinctiveness of each user group, the 6 types were named according to the indicator profiles within each cluster to reflect the main health management characteristics of users in each type. Cluster 1 was labeled “positively proactive energizers.” Users in this cluster exhibited higher perceived health status, health management self-efficacy, and health management intention than proactive intenders, along with substantially lower perceived barriers and perceived susceptibility.

Cluster 2 was labeled “proactive intenders,” characterized by users whose perceived health status, eHealth literacy, and health management intention are all above average, but who also report higher perceived barriers and perceived susceptibility. Proactive intenders (135/1025, 13.17%), the smallest group, represent users who demonstrate strong proactivity in health management, recognize their potential risk for health problems, and actively manage their health despite the presence of perceived barriers.

Cluster 3 was labeled “negatively proactive energizers.” Compared with positively proactive energizers, users in this cluster have slightly below-average perceived health status and

XSL•FO
RenderX



higher perceived susceptibility, yet they exhibit higher health management intention, health management self-efficacy, and eHealth literacy. Both positively proactive energizers (140/1025, 13.66%) and negatively proactive energizers (189/1025, 18.44%) represent groups with high levels of health management cognition, literacy, and capability, along with strong health management intention, making them the primary beneficiaries of current mHealth apps. The key difference between these 2 groups lies in perceived health status, which is higher among positively proactive energizers and below average among negatively proactive energizers. Cluster 4 was labeled "low health management demanders." Users in this cluster tend to have average perceived health status, with perceived susceptibility, perceived severity, and health management intention all below the average level. Low health management demanders constitute the largest proportion of users (218/1025, 21.27%) and represent a group with relatively good current health, limited emphasis on health management, insufficient awareness of health risks and potential harm, and consequently lower intention to engage in health management.

Cluster 5 was labeled "potential health management demanders." Users in this cluster have below-average perceived health status and, although their perceived benefits, perceived susceptibility, and perceived severity are above average, they exhibit lower health management intention and higher perceived barriers. Potential health management demanders (180/1025, 17.56%) represent individuals with poor current health status who are aware of the harms associated with health risks and recognize the benefits of health management for improving their condition, yet face substantial barriers to engaging in health management and therefore have a lower intention to do so. This group has both a clear recognition of the importance of health management and an objective need for it due to their poor health status.

Cluster 6 was labeled "passive attitude holders," comprising users whose perceived health status is below average and who report very low perceived benefits, health management self-efficacy, perceived severity, and health management intention. Passive attitude holders (163/1025, 15.90%) share similarities with low health management demanders, including low perceived benefits, health management self-efficacy, perceived severity, and intention for health management. However, they differ in that passive attitude holders perceive their health status as below average and face higher perceived barriers. This group perceives a decline in health status but lacks the willingness to improve it, placing them at high risk for illness.

From the perspective of age distribution, the 6 user categories exhibited distinct age-structure characteristics. Positively proactive energizers (n=140) comprised 48 (34.3%) aged 19-30 years, 48 (34.3%) aged 31-45 years, 42 (30.0%) aged 46-60 years, and 2 (1.4%) aged ≥61. Proactive intenders (n=135) consisted of 71 (52.6%) aged 19-30 years, 50 (37.0%) aged 31-45 years, 12 (8.9%) aged 46-60 years, and 2 (1.5%) aged ≥61. Negatively proactive energizers (n=189) included 2 (1.1%) aged ≤18, 65 (34.4%) aged 19-30 years, 79 (41.8%) aged 31-45 years, 41 (21.7%) aged 46-60 years, and 2 (1.1%) aged ≥61. Low health management demanders (n=218) comprised 1 (0.5%) aged ≤18, 103 (47.2%) aged 19-30 years, 69 (31.7%) aged 31-45 years, 44 (20.2%) aged 46-60 years, and 1 (0.5%) aged ≥61. Potential health management demanders (n=180) included 2 (1.1%) aged ≤18, 97 (53.9%) aged 19-30 years, 54 (30.0%) aged 31-45 years, 26 (14.4%) aged 46-60 years, and 1 (0.6%) aged ≥61. Passive attitude holders (n=163) were distributed as 1 (0.6%) aged ≤18, 116 (71.2%) aged 19-30 years, 37 (22.7%) aged 31-45 years, and 9 (5.5%) aged 46-60 years. Chi-square tests indicated that the associations between user clusters and both age (Cramer *V*=0.145) and education (Cramer *V*=0.116) groups were weak.

Figure 2. Cluster analysis–derived profiles of 6 user groups across 8 health management characteristics (*z* scores).

Table 5. Mean z scores and Kruskal-Wallis group comparisons of the 8 health management characteristics across the 6 user clusters.

Clustering variables	Cluster 1: positively proactive energizers (n=140)	Cluster 2: proactive intenders (n=135)	Cluster 3: negatively proactive energizers (n=189)	Cluster 4: low health management demanders (n=218)	Cluster 5: potential health management demanders (n=180)	Cluster 6: passive attitude holders (n=163)
Perceived severity	0.496[a,b,c]	0.294[b,e]	0.632[c]	–0.607[d]	0.331[a,e]	–0.956[f]
Perceived susceptibility	–1.197[a]	0.598[b,c,e]	0.709[c,e]	–0.634[d]	0.638[e]	–0.146[f]
Perceived barrier	–1.029[a,c]	1.292[b]	–0.796[c]	–0.410[d]	0.733[e,f]	0.476[f]
Perceived benefit	0.693[a,c]	0.022[b,d]	0.636[c]	–0.106[d]	0.273[e]	–1.510[f]
Health self-efficacy	0.955[a]	0.354[b,c]	0.630[c]	0.020[d]	–0.795[e,f]	–0.993[f]
Perceived health status	1.249[a]	0.363[b,d]	–0.004[c,d]	0.192[d]	–1.047[e]	–0.469[f]
eHealth literacy	0.733[a,c]	0.258[b]	0.615[c]	–0.097[d]	–0.621[e,f]	–0.740[f]
Health management intention	0.608[a,b,c]	0.419[b]	0.751[c]	–0.278[d,e]	–0.342[e]	–0.990[f]

[a-f]In the same row of data, if the same characteristic across the 6 clusters shares the same superscript (eg, "b"), it indicates that the difference between them is not statistically significant. Conversely, if the same characteristic across the 6 clusters does not share the same superscript, it suggests that the difference between them is statistically significant. For instance, cluster 1's perceived barrier is denoted as –1.029[a,c], and cluster 3's perceived barrier is denoted as –0.796[c]; the presence of the superscript "c" in both indicates that the Kruskal-Wallis test for the *z* scores of perceived barrier between cluster 1 and cluster 3 is not statistically significant. Conversely, cluster 2's perceived barrier is denoted as 1.292[b]. The absence of a common superscript implies that the Kruskal-Wallis test for the *z* scores of perceived barrier between cluster 1 and cluster 2 is statistically significant.

Differences in Satisfaction With mHealth App Functional Design Among Different Types of Health Users

First, the Kruskal-Wallis test was used to analyze differences in satisfaction with the 5 functional designs of the mHealth app among all users. The Kruskal-Wallis test indicated significant variations in user satisfaction with the 5 functional designs of mHealth apps—$H(4)=445.388$, $P<.001$. Specifically, the median satisfaction levels for the 5 functional dimensions among all users are presented in Table 6. Among these dimensions, health monitoring and health guidance exhibited the highest levels of satisfaction. Detailed satisfaction scores for the 5 functional designs, as well as pairwise comparisons of satisfaction among the 6 clusters, are also presented in Table 6. These results allow for a detailed examination of how each cluster differs from the others in terms of satisfaction with specific functional designs. Detailed test statistics are provided in Multimedia Appendix 6, which presents pairwise comparisons of satisfaction with the 5 functions across user groups.

Specifically, satisfaction with health guidance was higher in clusters 1, 2, 3, and 5 than in cluster 6. Pairwise comparisons revealed that clusters 1 ($z=6.246$, Bonferroni-adjusted $P<.001$), 2 ($z=8.404$, Bonferroni-adjusted $P<.001$), 3 ($z=6.887$, Bonferroni-adjusted $P<.001$), and 5 ($z=3.674$, Bonferroni-adjusted $P=.004$) differed significantly from cluster 6. Satisfaction with health education and health monitoring was significantly higher in clusters 1–3 than in clusters 4–6, with all 9 cross-group pairwise comparisons for each domain yielding statistically significant differences (health education: $z=2.77$-7.95, Bonferroni-adjusted $P<.001$ to .02 and health monitoring: $z=3.05$-7.88, Bonferroni-adjusted $P<.001$ to .03). With respect to social functions and gamification, users in cluster 2 reported higher satisfaction than those in the other 5 clusters. Pairwise comparisons revealed that cluster 2 differed significantly from cluster 1 ($z=–3.584$, Bonferroni-adjusted $P=.005$), cluster 3 ($z=4.599$, Bonferroni-adjusted $P<.001$), cluster 4 ($z=6.857$, Bonferroni-adjusted $P<.001$), cluster 5 ($z=7.392$, Bonferroni-adjusted $P<.001$), and cluster 6 ($z=5.992$, Bonferroni-adjusted $P<.001$) in social function; and from cluster 1 ($z=–3.999$, Bonferroni-adjusted $P=.001$), cluster 3 ($z=5.015$, Bonferroni-adjusted $P<.001$), cluster 4 ($z=5.880$, Bonferroni-adjusted $P<.001$), cluster 5 ($z=7.200$, Bonferroni-adjusted $P<.001$), and cluster 6 ($z=6.083$, Bonferroni-adjusted $P<.001$) in gamification.

Table 6. Median satisfaction and Kruskal-Wallis group comparisons regarding the 5 functional designs across the 6 user types.

Dependent variables	Median (IQR)						
	All users (n=1025)	Cluster 1: positively proactive energizers (n=140)	Cluster 2: proactive intenders (n=135)	Cluster 3: negatively proactive energizers (n=189)	Cluster 4: low health management demanders (n=218)	Cluster 5: potential health management demanders (n=180)	Cluster 6: passive attitude holders (n=163)
Satisfaction with health guidance	4.00 (1.00)	4.00[a,b,c,e] (1.67)	4.00[b,c] (1.00)	4.00[c] (1.00)	3.67[d,e,f] (1.00)	4.00[e] (1.00)	3.33[f] (1.00)
Satisfaction with health education	3.67 (1.00)	4.00[a,b,c] (1.67)	4.00[b,c] (1.33)	4.00[c] (1.33)	3.67[d,e] (1.00)	3.67[e,f] (1.00)	3.33[f] (1.00)
Satisfaction with health monitoring	4.00 (1.00)	4.00[a,b,c] (0.92)	4.00[b,c] (1.00)	4.00[c] (1.33)	3.67[d,e,f] (1.00)	4.00[e] (0.67)	3.67[f] (1.00)
Satisfaction with social function	3.33 (1.00)	3.33[a,f,c] (1.00)	4.00[b] (1.00)	3.33[c,d,f] (1.00)	3.00[d,e,f] (0.67)	3.00[e,f] (1.00)	3.33[f] (0.67)
Satisfaction with gamification	3.00 (1.00)	3.00[a,c,d,f] (1.00)	4.00[b] (1.33)	3.00[c,d,e,f] (1.33)	3.00[d,e,f] (0.67)	3.00[e,f] (1.33)	3.00[f] (0.33)

[a]In the same row of data, the group with a superscript "a" is statistically distinct from that with "b," "c," "d," and "e". However, the group with a superscript "b" is statistically not distinct from that with "b, c" because they share the superscript "b." Differing grouping labels indicate the heterogeneity across clusters.

Associations Between User Self-Management Characteristics and Satisfaction With mHealth App Functional Design

In this study, confirmatory factor analysis was used to test the reliability and validity of the questionnaire. The results, as shown in Multimedia Appendix 7, indicate that all constructs had Cronbach α and composite reliability values above 0.7; the average variance extracted for each construct was greater than 0.6; and the factor loadings for all items exceeded 0.7, demonstrating good reliability and convergent validity for all constructs. The heterotrait-monotrait ratio (HTMT) method was used to assess discriminant validity. The commonly accepted criterion for establishing discriminant validity is an HTMT value below 0.85. The results indicate that all construct pairs exhibited HTMT values below 0.85, supporting the discriminant validity of the measurement model. Using 8 health management characteristics as independent variables and satisfaction with 5 feature designs as dependent variables, partial least squares analysis was conducted to examine the impact of health management characteristics on satisfaction with the functional design of mHealth apps. The R^2 value represents the proportion of variance in the dependent variable explained by the independent variables and is used to interpret the goodness-of-fit of the regression equation, while β indicates the correlation between variables. Table 7 displays the β values and statistical significance of R^2 for the independent and dependent variables. Specifically, perceived barriers (β=.177, *z*=3.586, *P*<.001), perceived susceptibility (β=.076, *z*=2.056, *P*=.04), health self-efficacy (β=.140, *z*=3.307, *P*=.001), perceived health status (β=.111, *z*=2.967, *P*=.003), eHealth literacy (β=.153, *z*=3.947, *P*<.001), and health management intention (β=.148, *z*=3.966, *P*<.001) had a significant positive impact on satisfaction with health guidance; perceived barriers (β=0.143, *z*=3.130, *P*=.002), health self-efficacy (β=0.147, *z*=3.491, *P*<.001), perceived health status (β= 0.120, *z*=3.072, *P*=.002), eHealth literacy (β= 0.131, *z*=3.362, *P*=.001), and health management intention (β= 0.175, *z*=4.670, *P*<.001) had a significant positive impact on satisfaction with health education; perceived severity (β=.118, *z*=3.235, *P*=.001), perceived barriers (β=.107, *z*=2.194, *P*=.03), perceived benefits (β=.089, *z*=2.428, *P*=.02), perceived health status (β=.088, *z*=2.188, *P*=.03), eHealth literacy (β=.170, *z*=4.561, *P*<.001), and health management intention (β=.083, *z*=2.064, *P*=.04) had a significant positive impact on satisfaction with health monitoring; perceived susceptibility (β=.098, *z*=2.314, *P*=.02), perceived barriers (β=.150, *z*=3.032, *P*=.002), health self-efficacy (β=.195, *z*=4.598, *P*<.001), perceived health status (β=.135, *z*=3.391, *P*=.001), eHealth literacy (β=.118, *z*=2.805, *P*=.005), and health management intention (β=.139, *z*=3.396, *P*=.001) had a significant positive impact on satisfaction with social functions, whereas perceived benefits (β=–.210, *z*=5.906, *P*<.001) had a significant negative impact and perceived susceptibility (β=.099, *z*=2.200, *P*=.03), perceived barriers (β=.139, *z*=3.074, *P*=.002), health self-efficacy (β=.137, *z*=3.076, *P*=.002), perceived health status (β=.122, *z*=2.834, *P*=.005), eHealth literacy (β=.119, *z*=2.771, *P*=.006), and health management intention (β=.100, *z*=2.354, *P*=.02) had a significant positive impact on satisfaction with gamification, while perceived benefits (β=–.165, *z*=5.011, *P*<.001) had a significant negative impact. These results help explain why different types of users exhibit varying levels of satisfaction with different functional designs. The statistical analysis results for each path are presented in Multimedia Appendix 8.

XSL•FO

Discussion

Principal Findings

Understanding the heterogeneity of mHealth users and analyzing distribution differences in satisfaction with mHealth function design among user groups with distinct characteristics have significant referential value for personalized mHealth design. Therefore, guided by self-management theory and driven by self-management characteristics, this study constructed mHealth user personas encompassing 6 categories, analyzed the main characteristics and attributes of these 6 types of mHealth users, and examined differences in satisfaction with various mHealth function designs across user types. The results show that levels of user self-management characteristics are unevenly distributed and that different combinations of self-management characteristics can explain user heterogeneity. Moreover, a clear correlation exists between user heterogeneity arising from self-management characteristics and satisfaction with specific function designs. The findings of this study mutually confirm and extend existing literature on differences in mHealth intervention effects, user participation motivation, and technology design principles.

User Profiles of Fitness and Weight Management Apps Based on Health Management Characteristics

This study categorizes mHealth users into 6 distinct groups based on their self-management characteristics, revealing a complex classification derived from self-management–related attributes such as knowledge, beliefs, self-regulation skills and abilities, and motivation. This classification system differs from traditional approaches that rely on broad demographic labels (such as age and education level), offering a more refined and interpretable psychographic user profile. Although the sample in this study is predominantly composed of young-to-middle-aged and highly educated users, comparison with the 50th Statistical Report on China's Internet Development (2022) [62] shows that while individuals aged 20-49 account for 56.6% of all Chinese internet users, only 28.5% have used online medical services. This indicates that even within the broadly age-eligible internet population, active adopters of digital health services constitute a specific subgroup. Accordingly, this study employed an online snowball sampling method to reach and recruit active users with genuine interest and engagement in mHealth management. The "young-to-middle-aged, well-educated" characteristics of the sample, to some extent, reflect the profile of individuals who pay close attention to such apps. However, chi-square test results show that the associations between user classification and age (Cramer V=0.145) and education level (Cramer V=0.116) are weak. Furthermore, analysis of the age composition of each user group revealed that every category spans multiple age layers, suggesting that single demographic labels are insufficient to capture the characteristics of the 6 user categories identified in this analysis. The uneven distribution of multiple features across different user categories indicates that there is no complete positive correlation between individuals' perceived health status and their health management abilities and motivations. The differentiation of users' characteristic attributes is consistent with relevant theories such as BCWs. Potential health management demanders and passive attitude holders both exhibit low health management intention, but their underlying mechanisms differ: the former perceive susceptibility and severity but face higher perceived barriers, whereas the latter generally lack recognition of the perceived benefits and health self-efficacy of health management. This is consistent with phenomena observed in studies of smoking cessation apps [63], namely that when users remain at the level of understanding health information but fail to convert it into personalized risk perception and action confidence, behavioral intentions are difficult to activate. Based on the results of this study, targeted interventions in mHealth management are needed according to individuals' motivation status and health perceptions, to facilitate the transformation of different perception characteristics into internal motivation and to address differences

XSL•FO
RenderX

in health management behaviors arising from varying motivation statuses [64]. In addition, although negatively proactive energizers perceive an average health status, they exhibit high health management intention and self-efficacy. This finding indicates that perceived health status alone is not the sole determinant of mHealth service use, which is also supported by existing studies [65], showing that patients' satisfaction with mHealth services may be influenced by individual differences in disease progression, perceived service attitudes, and understanding of diagnostic and treatment outcomes. Correspondingly, passive attitude holders exhibit low levels of perceived health status, perceived benefits, health self-efficacy, and health management intention, which aligns with a previous study [66] identifying lack of motivation and low perceived value as significant barriers to mHealth participation. In general, obtaining a positive mHealth service experience often depends on whether services can be personalized or adaptively adjusted to accommodate different user needs and motivations, and user heterogeneity is strongly correlated with self-management characteristics [67].

Satisfaction of Various User Types With mHealth App Functionality Design

There are significant differences in satisfaction with mHealth function designs among different user types, providing counterevidence to the "one-size-fits-all" function design strategy and underscoring the necessity of personalized design. This study found that proactive intenders and positively proactive energizers, characterized by high self-efficacy and strong health management intention, reported higher satisfaction with goal-oriented and interactive functions such as health guidance, health education, and health monitoring. This finding is consistent with multiple studies [63,68,69], indicating that users who actively focus on their own well-being demonstrate higher levels of engagement with mHealth. Features such as progress tracking, personalized feedback, and access to educational content are often welcomed and perceived as useful by these users.

Low health management demanders and passive attitude holders report lower satisfaction with most mHealth functions. This finding is consistent with a previous study [70], which indicated that for users with low intrinsic motivation or insufficient perceived value, complex functions or interfaces may act as barriers to use; such users require designs that are concise, intuitive, provide immediate and intuitive feedback, and involve low operational barriers. Notably, prior research has demonstrated a positive correlation between eHealth literacy and mHealth usage [71]. However, our findings offer a contrasting perspective, showing that potential health management demanders, despite having lower-than-average eHealth literacy, report high satisfaction with health guidance and health monitoring functions. This may be because this group's higher perceived benefits and perceived susceptibility compensate for their lower capability, thereby increasing their interest in tools that enhance health benefits and reduce health risks. This phenomenon may also be partially explained by the Dunning-Kruger effect, whereby users lacking specialized knowledge may be less able to critically evaluate application limitations, leading to inflated satisfaction ratings for mHealth. Individuals with low health literacy have been shown to report levels of confidence about their knowledge comparable to, or even higher than, those with high literacy [72]. Conversely, users with stronger health knowledge reserves tend to use educational materials and support functions in mHealth apps more frequently, thereby enhancing recognition and evaluation of specific functions [73]. The user-centered design concept, combined with the user types constructed in this study, can therefore provide valuable reference for mHealth designs that address the diverse needs of different user groups.

Recommendations

The findings of this study provide clear implications for the personalized design and practical application of mHealth. mHealth developers should adopt a user-centered design approach and, based on the user types constructed in this study, tailor functional modules accordingly. For positively proactive energizers, further development of data tracking, personalized goal setting, and systematic educational content can be pursued, alongside the appropriate introduction of gamification elements to enhance users' sense of enjoyment [74]. For potential health management demanders, design efforts should focus on lowering usage barriers, providing clear and step-by-step health guidance and monitoring tools, and strengthening health-related beliefs. For passive attitude holders, the primary objective may be to establish initial engagement and trust through simple designs and light-touch interventions, while incorporating social features to help this group build social support [75], increase awareness of health risks, and enhance beliefs in health management. Furthermore, the study's results suggest that when evaluating the effectiveness of mHealth functions, user heterogeneity must be considered, as overall average satisfaction may obscure substantial differences among user subgroups.

Limitations and Future Research

Although this study was carefully designed in terms of methodology and empirical analysis, several limitations should be acknowledged. First, to avoid comparability issues arising from differences in functional design across mHealth apps with different core service content, and to recruit as diverse a user sample as possible, this study selected exercise, fitness, and weight management apps as the objects of study. However, these apps cannot fully represent all types of mHealth apps. Nevertheless, by conducting empirical research on one of the most widely used and numerous categories of mHealth apps, this study verifies that individuals' self-management characteristics have important referential value for mHealth user classification. The results demonstrate significant differences in satisfaction with various functional designs across user types, and that the effects of self-management characteristics on satisfaction differ across functional design dimensions. These results provide direct empirical reference for the personalized design of fitness and weight loss apps, and the research conclusions may also offer inspiration for user classification–related studies in other types of mHealth apps. Second, although questionnaires are an effective research method, they cannot fully represent all users. Access to feedback data from the entire mHealth user population would enable a more refined classification of user types. At present, limited

XSL•FO
RenderX

research on mHealth apps has focused on users' health cognition and self-management abilities, which constrains the analysis of comprehensive user characteristics from a big data perspective. To mitigate sampling bias, data were collected from 34 regions across China, and the sample size was substantially larger than that of comparable studies, supporting the representativeness of the findings. Third, although empirical results indicate that 8 self-management characteristics significantly influence user satisfaction, these characteristics explain only a limited proportion of the variance in satisfaction with mHealth (R^2=0.094-0.183). Although the identified pathways were statistically significant, a substantial proportion of the variance in satisfaction remains unexplained by these characteristics. Given that the primary aim of this study was to examine whether the effects of heterogeneous user types on satisfaction differ—that is, to construct user profiles based on self-management characteristics and analyze differences in satisfaction across user types—we did not conduct an in-depth examination of other potential determinants of satisfaction (eg, usage context, service quality, and user experience). Future research on factors influencing mHealth satisfaction could incorporate additional predictive variables to improve the explanatory power of the model.

Conclusions

This study identified 6 distinct mHealth user typologies (fitness and weight management apps) derived from a comprehensive set of self-management characteristics. The results reveal an uneven distribution of multidimensional characteristics across different user categories. This granular classification provides a deeper understanding of user heterogeneity than traditional demographic-based approaches. Overall, the primary contribution of this work is an empirically validated framework that offers a structured approach to understanding mHealth user diversity. The identified user typologies and their differential functional satisfaction profiles yield actionable insights for the personalized design of fitness and weight management apps. Specifically, for health guidance and education features, proactive intenders, positively proactive energizers, and negatively proactive energizers report higher satisfaction. For health monitoring functions, potential health management demanders, proactive intenders, positively proactive energizers, and negatively proactive energizers demonstrate higher satisfaction. For social features and gamification design, proactive intenders exhibit significantly higher satisfaction than the other 5 user types. From a practical perspective, these findings underscore the importance of adapting mHealth features to the distinct self-management needs and preferences of specific user groups. Such adaptation is essential for enhancing user satisfaction, fostering sustained engagement, and ultimately improving the perceived usefulness of digital health solutions.

Abstract

Background: Electronic health records are essential for advancing research aimed at improving clinical outcomes. However, stringent data protection and privacy concerns severely limit the accessibility and use of real clinical data, particularly within Child and Adolescent Mental Health Services (CAMHS) involving vulnerable young individuals. This challenge can be effectively addressed through synthetic data generation, which safeguards individual privacy while facilitating comprehensive analyses of clinical information.

Objective: This study aims to investigate whether hierarchical synthetic data generators (SDGs) can effectively replicate the statistical properties, preserve the utility, and maintain the privacy of real CAMHS clinical data, thereby enabling data sharing and broader access to research-ready datasets.

Methods: This retrospective cohort study used electronic medical record data from 6924 distinct patients from CAMHS in Stavanger, Norway, comprising 7730 referral periods and 58,524 episodes of care. An 80%-20% split was used for training and testing. A hierarchical synthetic data generation model was trained to generate synthetic referral periods and associated episodes of care. Data quality was evaluated using SDMetrics for distribution (Kolmogorov-Smirnov Complement [KSC]/Total Variation Complement [TVC]), correlation (CorrelationSimilarity [CS]), and cardinality (CardinalityShapeSimilarity [CSS]) similarity. Privacy was evaluated using the Anonymeter library to simulate singling out, linkability, and inference reidentification attacks. Utility was assessed using the train synthetic test real (TSTR) pattern, comparing the predictive performance using precision-recall area under the curve [PRAUC] of models trained on synthetic vs real data for classifying the intensity of care.

Results: The hierarchical SDG created highly reproducible synthetic CAMHS data. The average statistical similarity scores were high across all metrics: KSC/TVC at 0.92, CS at 0.77 (intertable CS at 0.75), and CSS at 0.92. The synthetic data also demonstrated a low risk under simulated privacy attacks on a control dataset (n=1546): the average success rate was 6/1546 (0.39%) for singling out and 77/1546 (5%) for multivariate attacks. The average linkability risk was 54/1546 (0.5%), and the highest inference risk for a sensitive variable was 2/1546 (0.12%). The classification model trained on synthetic data (TSTR) produced comparable predictive performance (PRAUC=0.40) to the model trained on real data (PRAUC=0.43) for classifying

XSL•FO
RenderX

the intensity of care (low vs medium or higher). Shapley additive explanations analysis confirmed that the synthetic model's explanations aligned with real-world insights, validating its ability to capture fundamental predictive patterns.

Conclusions: Synthetic data can be used to build trust and promote collaboration among CAMHS researchers by offering access to extensive, representative samples with a low risk of patient identification. This approach expands the breadth of research while safeguarding patient privacy. Effective implementation of synthetic data generation depends on the model's ability to accurately identify and replicate the complex, sequential patterns present in real data.

CAMHS; classification; length of referral; mental health; synthetic data generation

Introduction

The preservation of patient confidentiality is frequently identified as a significant barrier to conducting research with mental health care datasets [1]. Researchers appropriately face strict regulations and ethical considerations that limit access to real patient data. This is further complicated by selection bias [2], digital barriers [3], and high levels of sensitivity of mental health information, which, if disclosed, could lead to additional stigma, discrimination, and other negative consequences for individuals [4].

While these challenges are present across all mental health research, the use of large-scale data from patient records becomes significantly more complex with Child and Adolescent Mental Health Services (CAMHS) data. This is due to a set of problems associated with this vulnerable population. First, the variability in developmental stages among children and adolescents means that symptoms and diagnoses manifest differently across age groups (eg, anxiety in a 5-year-old compared to a 16-year-old), making data standardization and longitudinal analysis inherently difficult. Second, the necessity for age-appropriate interventions and evolving care pathways creates complex, nonlinear data structures that are challenging to model consistently [5]. Perhaps most critically, the ethical considerations surrounding privacy and consent for minors are far more stringent than for adult populations. Researchers must navigate nuanced consent processes involving both parents or guardians and the child's assent, often with varying legal requirements based on age and local jurisdiction [6,7]. This multilayered consent, coupled with heightened safeguarding responsibilities, severely restricts data sharing. Furthermore, due to their inherent nature, which includes stringent privacy regulations and the fragmented structure of care pathways, CAMHS datasets are typically smaller, exhibit greater structural fragmentation, and are consequently more challenging to access large-scale, generalizable research than adult health datasets.

These challenges can be effectively addressed by the generation of synthetic data. Synthetic data not only safeguard individual privacy but also permit comprehensive analyses of large-scale clinical data obtained directly from electronic medical records (EMRs) and other clinical data sources, even in sensitive areas such as CAMHS.

Previous studies have applied synthetic mental health data in data augmentation, privacy preservation, and fairness [8]. The SynthNotes framework, developed by Begoli et al [9], is notable for its ability to produce realistic and high-fidelity synthetic mental health documentation on a large scale. The framework facilitates benchmarking, optimization, and training for biomedical NLP, information extraction, and machine learning systems, all while ensuring strict privacy preservation. To ensure accurate and generalizable research results, synthetic data must accurately represent diverse minority subgroups. This is particularly important in addressing child and adolescent mental health inequities exacerbated by events like the COVID-19 pandemic [10]. Addressing these biases requires expertise in the underlying model and an understanding of fairness concepts like unawareness, demographic parity, and conditional fairness [8]. One approach involves directly de-biasing existing datasets to create "fair data," a process similar to synthetic data generation [11,12]. Alternatively, some researchers view data de-biasing as a "ground-up" generation problem, focusing on developing generative models that inherently incorporate fairness [13].

Predictive models trained on synthetic data for mental health have yielded encouraging findings in numerous studies, highlighting the critical importance of data quality, ethical considerations, and the necessity for ongoing research. A study by Rankin et al [14] used a deep learning approach to predict mental health quality using synthetic data derived from functional network connectivity data from resting-state functional magnetic resonance imaging, achieving high accuracy in classifying mental health quality. Using models trained on synthetic data, Ajith et al [15] combined data from multiple longitudinal mobile sensing studies to predict mental health symptoms, showing improved generalization across different datasets. While these models frequently failed to capture intricate patterns and subtleties, especially within diverse populations [16], their results highlight the potential of synthetic data to enhance predictive modeling in mental health, while addressing privacy and fairness concerns.

While prior synthetic health data studies focused on adult mental health, our research specifically examines how synthetic data generators (SDGs) effectively capture complex patterns and relationships in CAMHS data. We assess the essential trade-offs involving data quality, patient privacy, analytical utility, and optimal synthetic sample size to ensure generated data remains representative and valuable for research.

Methods

Data Source

This study was conducted using a retrospectively collected cohort from the Child and Adolescent Mental Health Department (CAMHD) at Stavanger University Hospital (SUS). The hospital functions as a referral center for about half a million inhabitants in the Rogaland metropolitan area and had an annual admission ranging from 17,000 to 19,000 during the study period. CAMHD at SUS provides assessment, diagnosis, and treatment for young people aged 18 years or younger, experiencing mental health issues such as depression, anxiety, trauma, developmental disorders like autism or attention-deficit/hyperactivity disorder (ADHD), and psychosis.

As detailed in Table 1, the dataset included 6924 distinct patients, 7730 referral periods, and a total of 58,524 episodes of care. Data extraction was performed using the electronic health record system (Distrubuert Informasjons og Pasientdatasystem i Sykehuset [DIPS]; Helse Vest IKT). The system provided access to administrative details like time of admission, department, and clinical personnel, as well as clinical information such as age, sex, and diagnosis for each episode of care.

Each episode is directly linked to a specific referral through a unique identifier. Allowing for comprehensive and continuous tracking of a patient's journey from their initial referral through all subsequent clinical interactions.

cond1axisVGrp	Consultation/stay	*ICD-10* Axis V (psychiatric disorders and somatic diseases)	• Unique values=6 • Most frequent=N/A
cond1axisVIGrp	Consultation/stay	*ICD-10* Axis VI, global functioning (CGAS[c])	• Unique values=7 • Most frequent=6999

[a]N/A: not applicable.

[b]ICD-10: International Statistical Classification of Diseases, Tenth Revision.

[c]CGAS: Children Global Assessment Score.

Missing Data

The dataset contains *ICD-10* (*International Statistical Classification of Diseases, Tenth Revision*) diagnostic codes categorized across different axes or levels of detail. The *ICD-10* uses a multiaxial system for mental and behavioral disorders, including Axis I (clinical syndromes), Axis II (disabilities), and Axis III (environmental/lifestyle factors).

XSL•FO
RenderX

A key characteristic of the Axis columns is the high rate of missing data, which indicates "not applicable" rather than an error, as is common in clinical coding. For instance, the first condition in Axis I is nearly complete (0.7% missing), but subsequent codes within the same axis show drastically increased missingness (eg, 6th condition, 99.8% missing). This trend continues across other axes, like Axis II (eg, 3rd condition 99.6% missing). This consistent pattern of missing values signifies that a code was not relevant to a clinical episode, making data imputation inappropriate.

Ethical Considerations

The study is a quality assurance initiative directly building on the results of the "PILOT SYNDATA" project. The project was conducted as a collaboration between CAMHD SUS, the analytical department at SUS, and Helse Vest IKT (the regional IT service delivery company). The project's main purpose was to explore the safe use of synthetic data in mental health care.

The data for the "PILOT SYNDATA" project were collected from DIPS, and Helse Vest IKT performed the deidentification and aggregation procedures, with the resulting anonymized data then being used for synthetic data generation in the next phase. This entire process was conducted under a formal agreement that permits the secondary use of health data for research and quality assurance while ensuring patient privacy and confidentiality. Due to the complete deidentification and aggregation of the data, a waiver was not required to use the data in this study.

The study used a synthetic data generation process that creates entirely new, statistically representative data points. The process is fully compliant with HIPAA (Health Insurance Portability and Accountability Act) and GDPR (General Data Protection Regulation) regulations, significantly reducing the risk of an attacker reidentifying individuals or uncovering sensitive patient details from the original dataset.

As this was a retrospective analysis of existing data, no financial compensation was provided to participants. Additionally, it is not possible to identify any individual participants in the figures or supplementary materials. The images are illustrative and use a "real-like path" to represent an anonymized, generalized patient journey.

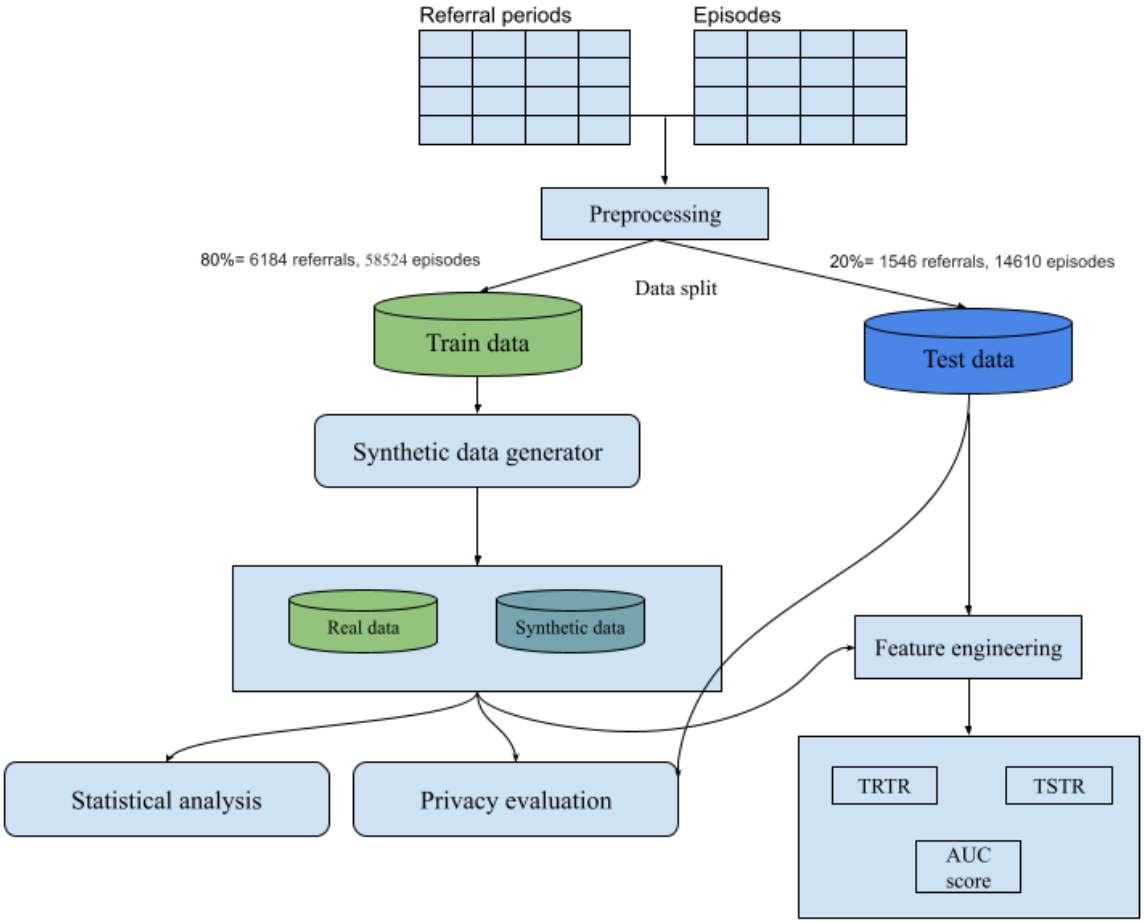
Synthetic Data Generation

We use HMASynthetiser, a multitable algorithm within the Synthetic Data Vault framework [17]. HMASynthetiser is a class model that implements a "hierarchical modeling algorithm" to analyze data structured in multiple levels, often called nested data. These models are particularly useful when dealing with complex datasets in which observations are grouped at different levels, such as referral periods and episodes of care (Multimedia Appendix 1).

The SDG systematically processes the real CAMHS dataset, examining how information is structured across the referrals and episodes of care tables. It uses a Gaussian copula to map the complex relationships between every data field. A Gaussian Copula [18] is a statistical model used to identify the dependency structure between the nested dataset (referrals/episodes). The approach ensures that the SDG process accurately mirrors the statistical patterns and distributions present in the original patient records, even for variables with nonstandard or highly dependent relationships. In addition, the parameters of the SDG are customized for each individual table in the hierarchy, allowing fine-tuning of the synthetic data generation process. Hierarchical modeling, combined with the statistical method, is essential for accurately capturing the complex dependency structures within CAMHS variables.

Data Modeling

To optimize data utility and patient privacy, the real CAMHS dataset underwent comprehensive preprocessing prior to synthetic data generation. This involved the systematic categorization of variables, such as age and admission type, into broader, analytically meaningful groupings. Specifically, age was discretized into decennial intervals, while variables, such as "performing personnel" and "admission type," were recorded by mapping their original granular values to more generalized, descriptive categories. Additionally, diagnostic Axes I-IV were grouped based on the *ICD-10* hierarchy, and Axis VI (Children's Global Assessment Score) underwent specific binning and categorization to abstract sensitive medical codes.



These comprehensive preprocessing steps ensured the data were optimally structured for generating high-fidelity synthetic data and accurately reflected real-world patterns while rigorously upholding patient data protection.

Experimental Setup

Figure 1 displays the experimental setup. The experiments performed in this study followed 3 structures: sample size, privacy risk assessment, and utility assessment.

XSL•FO
RenderX

Figure 1. General study design. AUC: area under the curve; TRTR: train real test real; TSTR: train synthetic test real.

Sample Size

To evaluate the impact of sample size on predictive model performance (Multimedia Appendix 2), 4 distinct training sets (619, 1546, 3092, and 6184 referrals) were created from the real-world CAMHS data. For each of these sizes, a corresponding synthetic dataset was generated to enable a comparison of predictive model performance using both real and synthetic data across various data availability scenarios.

Privacy Risk Assessment

To measure the privacy risk in the generated synthetic data, we used the experimental approach via the Python library Anonymeter [19] (Multimedia Appendix 3). Initially, the attack uses synthetic data to create a series of guesses. The model then evaluates these guesses by comparing them to the values present in the original dataset, thereby assessing the effectiveness of the attack. The privacy model requires the adversary to conduct the same attack on a control dataset (records that were not used in the SDG). By contrasting the success rates of the attack on both training records and control records, a sensitive and significant measure of risk is established. Three types of privacy risk attacks were simulated and analyzed to evaluate the potential for reidentification: singling out, linkability, and inference risks.

Utility Assessment

Prediction tasks represent a robust and frequently used methodology for evaluating synthetic data utility, offering distinct advantages beyond conventional statistical comparisons. The method directly confirms the data's real-world applicability by assessing its capacity to replicate complex, nonlinear relationships for applications such as individualized mental health care planning or treatment pathway optimization. Furthermore, the approach validates the functional equivalence of synthetic data and provides a user-centric, interpretable metric of its inherent value, thereby facilitating the detection of subtle discrepancies overlooked by simpler analytical techniques [20]. To assess synthetic data utility, we formulated a downstream prediction task (Multimedia Appendix 4): classifying patient referral periods by intensity of care. Following Beckers et al [21], "intensity of care" was initially defined as low (<15 sessions/year), medium (15-51 sessions/year), or high (≥52 sessions/year). We extracted primary diagnosis of the first episode, sex, age, and total past referrals as predictor variables. Due to significant skewness (386/7730 high, 2087/7730 medium, and 5874/7730 low), the "medium intensity" and "high intensity" categories were merged into a "medium- or higher-intensity care" group. The combined group was selected to create a sufficiently sized positive class for stable model training, given the constraints of the severely skewed original distribution.

XSL•FO
RenderX

The dataset was then stratified by intensity and split into an 80% training set (6184 referral periods and 58,527 episodes) and a 20% independent test set (1546 referral periods and 14,610 episodes; Multimedia Appendix 5). The stratification ensured balanced distribution and kept all related patient data within either the training or test set; the test set was used solely for evaluation. A random forest model [22] was then trained using synthetic data generated at various scale factors (1, 2, 5, 10). The trained models were evaluated using the Train Synthetic, Test Real evaluation method [23], which involves training a model on synthetic data and testing it on real data.

Model performances were measured using precision-recall area under the curve (PRAUC), a robust metric particularly suited for imbalanced datasets [24,25]. We specifically chose PRAUC over the traditional area under the receiver operating characteristic curve because PRAUC is less susceptible to inflation from the majority (low intensity) class, providing a more accurate and rigorous measure of performance on the positive (medium- or higher-intensity care) class [24]. Results are presented as the median of a stratified 4-fold cross-validation.

Finally, SHAP (Shapley additive explanations) values [26] were computed for both models to assess variable interactions.

Statistical Analysis

To quantify the similarity between real and synthetic data, we used 4 key metrics from the SDMetrics Python library [23]. For numerical column distributions, we used the Kolmogorov-Smirnov Complement (KSC), while the Total Variation Complement (TVC) measured discrete column distributions. The preservation of intercolumn correlation patterns was evaluated using CorrelationSimilarity (CS), and CardinalityShapeSimilarity (CSS) was applied to assess the similarity in cardinality distributions within multitable datasets.

For privacy risk evaluation, we conducted 3 attack-based assessments focused on factual anonymization indicators: singling out determined the potential for identifying individual records; linkability assessed the risk of linking synthetic data back to the real dataset; and an inference attack was used to attempt to deduce sensitive individual information from seemingly nonsensitive data. A low inference risk means it is highly unlikely that an attacker could uncover specific, private details about individual patients from the original dataset.

Qualitative Visualization of Care Pathways

For the qualitative assessment, the specific “real patient path” was selected randomly from the overall real dataset after the synthetic data generation process was completed to ensure the visualization was not conditioned on the selected patient’s attributes prior to generation. This patient, a 12-year-old male diagnosed with “behavioral and emotional disorders” (F90-F98), represents a highly frequent and common clinical profile in our cohort. The corresponding “synthetic path” was then extracted from the synthetic data by identifying a synthetic patient with identical starting attributes (age, sex, and primary diagnosis) to provide a valid, anonymized, and attribute-matched comparison for event sequencing and density.

Results

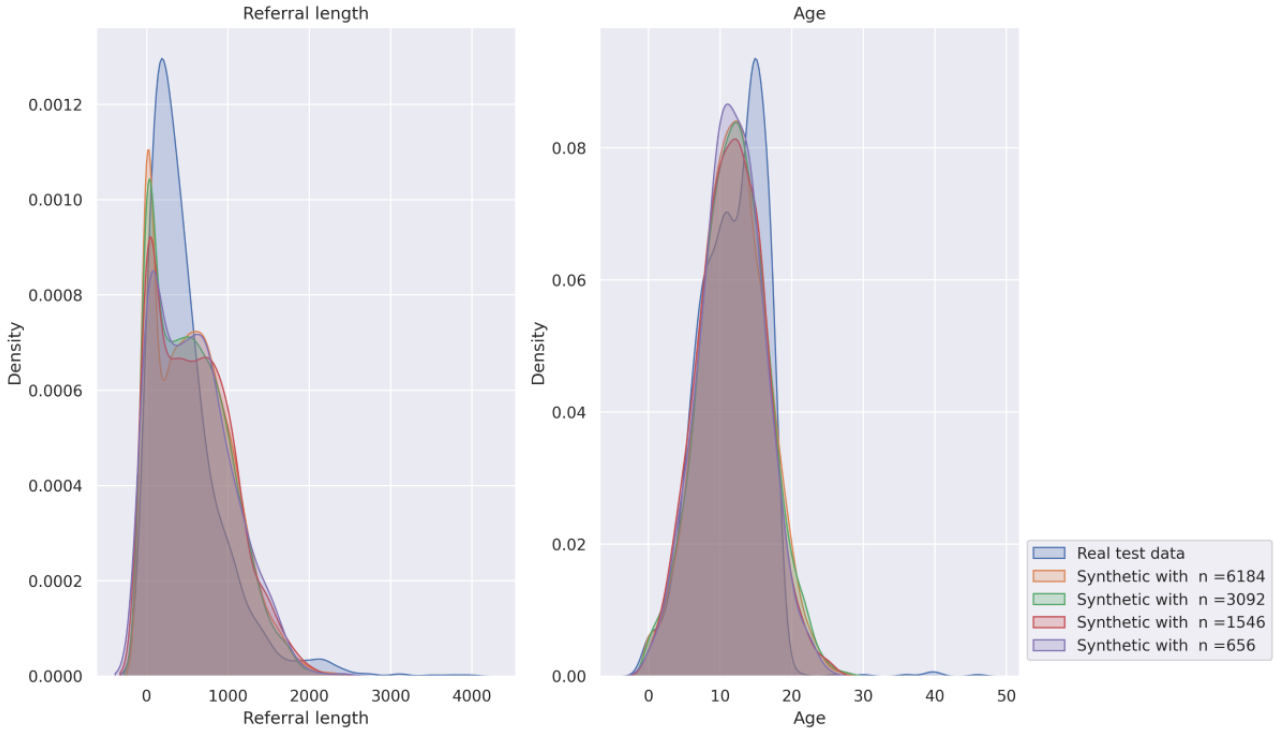
Similarity and Quality Assessment of Synthetic CAMHS Data

As detailed in Table 2, the SDG produced CAMHS data that demonstrated high statistical similarity to the “real-world” CAMHS dataset. The result was evident across all reported metrics (KSC/TVC score=0.92; CS=0.75; CS (intertable)=0.73; CSS=0.9), with good fidelity remaining consistent regardless of the amount of “real-world” training samples provided to the algorithm.

Figure 2 presents 2 kernel density estimate plots, offering a visual comparison of feature distributions between real-world CAMHS data and synthetic data generated at various sample sizes. The left plot, illustrating “referral length,” reveals that the synthetic data distributions, particularly those derived from larger sample sizes (n=6184 and n=3092), closely align with the real test data’s distribution in the high-density range. While the synthetic data effectively captures the predominant patterns of referral lengths, there are minor deviations observed in the extreme tails, suggesting a slight challenge in perfectly replicating infrequent, very long referrals.

Similarly, the right plot, depicting “age,” demonstrates exceptionally high fidelity. All synthetic age distributions, regardless of the sample size, exhibit remarkable overlap with the real test data’s distribution. The peaks and overall shapes are nearly identical, indicating that the synthetic data generation process is highly successful in preserving the univariate statistical characteristics of patient age.

The observed high scores across the various quality metrics and kernel density estimates provide robust evidence that the synthetic data accurately replicates the original patient information’s characteristics and inherent relationships. Specifically, the significant KSC/TVC scores confirm that individual statistical distributions of each variable within the synthetic dataset demonstrate strong consistency with those observed in the real data, which implies that features like patient age ranges or referral lengths exhibit statistical properties consistent with their real-world counterparts. Furthermore, the high CS scores, including both intratable and intertable relationships, confirm the accurate preservation of complex dependencies and interactions between distinct variables. For example, critical correlational structures, such as the frequent association of specific diagnoses with treatment pathways or demographic profiles in the real data, are accurately maintained within the synthetic dataset. Finally, the high CSS scores confirm that the structural properties of the data, including the diversity of unique values within categorical fields and the overall shape of numerical distributions, are accurately replicated.



The consistent high scores underscore that the synthetic data not only replicates individual variable characteristics but also captures the intervariable relationships and the overall statistical integrity of the original, sensitive CAMHS patient information. The observed fidelity is critical for establishing synthetic data’s suitability for subsequent analytical and research applications.

Table 2. Average Kolmogorov-Smirnov Complement (KSC)/Total Variation Complement (TVC), CorrelationSimilarity (CS; single and intertable), and CardinalityShapeSimilarity (CSS) metrics from synthetic data evaluation experiments using different synthetic scale factor sizes.

	656 referrals	1546 referrals	3092 referrals	6184 referrals
KSC/TVC	0.91	0.92	0.92	0.92
CS	0.73	0.77	0.75	0.77
CS (intertable)	0.69	0.73	0.73	0.75
CSS	0.87	0.90	0.91	0.92

Figure 2. Visual comparison of the density distribution of the real and the derived synthetic Child and Adolescent Mental Health Services features. Density distributions for 2 selected features, “referral length” and “age,” and their synthetic derivatives are compared.

Synthetic Data Privacy Evaluation

To assess the potential for patient reidentification and information revelation, we performed 3 attack-based privacy evaluations: singling out, linkability, and attribute inference. Table 3 provides an overview of the success rate associated with the 3 simulated privacy attacks using synthetic data on a control real dataset (n=1546), highlighting the success rate achieved with various sample sizes. Specifically, the analysis reveals that both univariate and multivariate singling out attacks yield minimal average success rates, recorded at just 6/1546 (0.4%) and 77/1546 (5%), respectively. This indicates that the likelihood of successfully executing these types of attacks is low, regardless of the volume of data being analyzed. Furthermore, the table presents insights into the risk of linkability when using clinical and demographic variables as auxiliary data. The average risk of linkability is calculated to be 0.5% (8/1546), suggesting that while there is some potential for linking data to individuals, the overall risk remains quite low.

Similarly, inference risk of sensitive variables from patient age and sex was minimal for most attributes (Figure 3), with “admission week number” presenting the highest, yet still low, risk (2/1546, 0.12%).

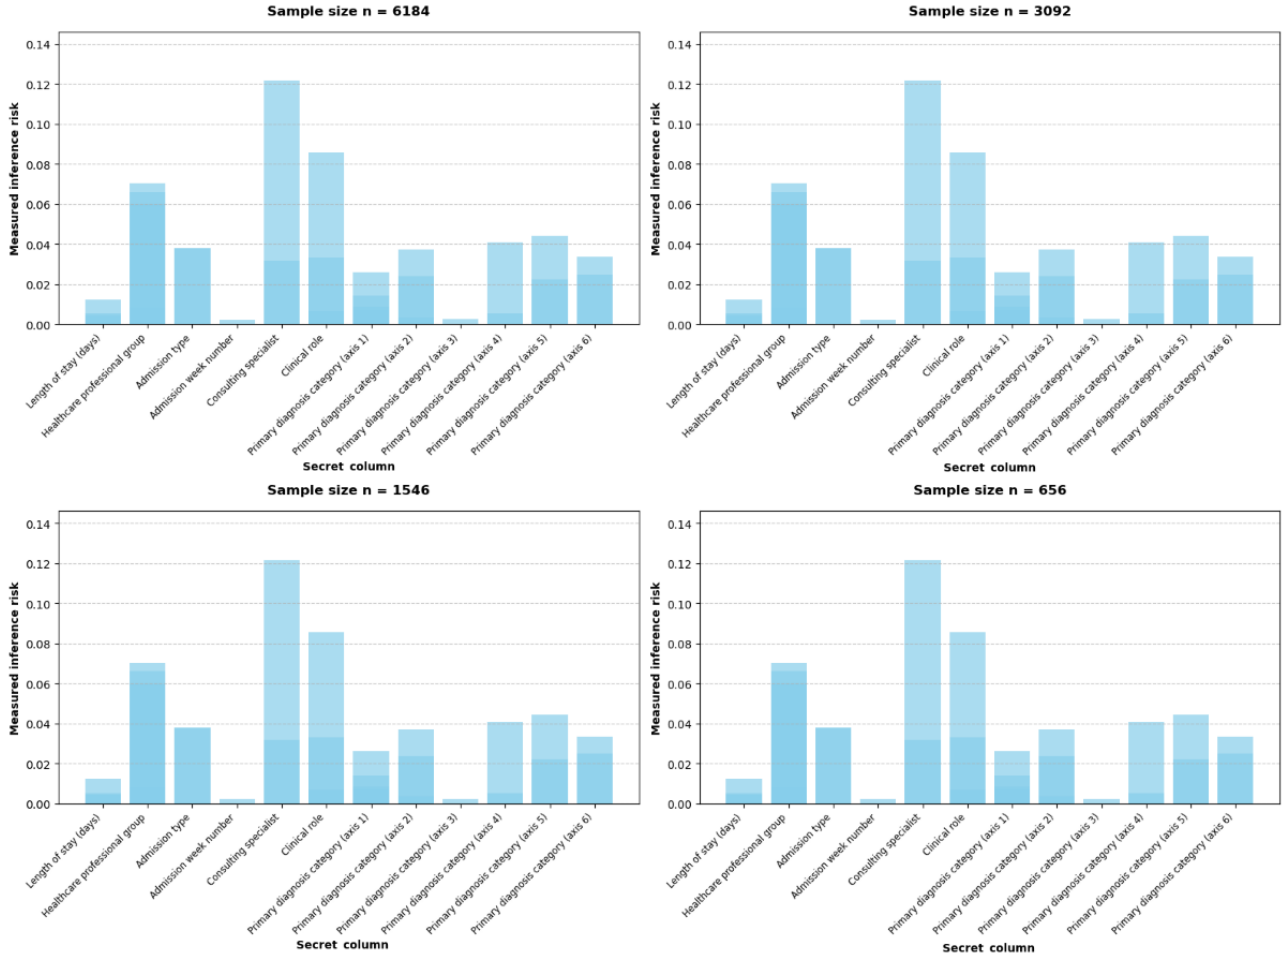
A low percentage, for instance, a range of 0%-5%, indicates that an attacker’s capacity to deduce private details from the synthetic data is only marginally superior to random chance. To contextualize this, if Figure 3 reveals an inference risk of, for example, 2%, it signifies that an attacker possessing auxiliary nonsensitive information (eg, a patient’s age and gender from an external source) would still have only a 2% likelihood of accurately determining a specific sensitive attribute, such as a rare mental health diagnosis, from the synthetic dataset. The low probability demonstrates the robust privacy preservation achieved, reinforcing the suitability of this approach for sensitive health care data.

The results clearly demonstrate the robust capability of the synthetic data to effectively protect individual privacy. The protection is provided by the synthetic data generation process, which creates entirely new, statistically representative data points rather than simply masking or perturbing original records, thereby breaking any direct link to individual patients. As a result, it becomes highly unlikely for an attacker to reidentify specific individuals or uncover private, sensitive details about

XSL•FO
RenderX

patients from the original dataset, even if they possess some auxiliary information. This significantly mitigates risks associated with reidentification or attribute inference attacks, enabling a secure environment for data sharing.

Table 3. Success rate of singling out, linkability, and inference attacks on control data using various synthetic Child and Adolescent Mental Health Services data samples.



Risk type	6184 referrals, n/N (%)	3092 referrals, n/N (%)	1546 referrals, n/N (%)	619 referrals, n/N (%)
Singling out (univariate)[a] success rate	6/1546 (0.38)	6/1546 (0.38)	6/1546 (0.38)	7/1546 (0.43)
Singling out (multivariate)[b] success rate	46/1546 (3)	93/1546 (6)	62/1546 (4)	108/1546 (7)
Linkability[c] success rate	2/1546 (0.13)	5/1546 (0.34)	11/1546 (0.69)	13/1546 (0.84)

[a]Singling out (univariate) represents the percentage of successful attempts to uniquely identify an individual in the synthetic dataset using a single characteristic (based on 500 attacks). Lower values indicate better privacy.

[b]Singling out (multivariate) represents the percentage of successful attempts to uniquely identify an individual in the synthetic dataset using multiple combined characteristics (based on 100 attacks). Lower values indicate better privacy.

[c]Linkability represents the percentage of successful attempts to link synthetic records back to their original real records (based on 2000 attacks and 10 neighbors). Lower values indicate better privacy.

Figure 3. Inference risk.

Synthetic Data Utility Evaluation

The target variable to be classified (intensity of care) in the utility evaluation was highly unbalanced in the real dataset, with 4111/6136 (67%) categorized as low intensity (<15 sessions annually), 2024/6136 (33%) as medium or higher intensity of care (>15 per year). We use the PRAUC metric to compare the predictive performance of machine learning models trained on real CAMHS data versus those trained on synthetic CAMHS data across different input sizes. Given the positive class prevalence of 33%, the random chance baseline (PRAUC baseline) is 0.33. As Table 4 illustrates, increasing sample size consistently improved predictive performance for both real and synthetic data models. In the most data-scarce setting (619 records), the random forest model's ability to classify medium-

XSL•FO
RenderX

or higher-intensity care patients was limited (real data: average PRAUC=0.39; synthetic data: PRAUC=0.32), However, when we increase the training set size to 6184 records, the model performance improved, with the average PRAUC for real data rising to 0.43 (a 30% increase over baseline) and for synthetic data to 0.40 (a 21% increase over baseline) demonstrating that the synthetic data preserves the analytical utility necessary to exceed the random threshold and capture real-world signals.

Our findings suggest that while privacy safeguards around children's data are paramount and often lead to smaller datasets, the value of more data in building accurate and robust predictive tools cannot be overstated. Simply put, the more comprehensive the data, the better equipped the models are to provide meaningful insights that can ultimately support patient care.

Table 4. Comparison of random forest–based prediction models trained on real, tested on real (TRTR) Child and Adolescent Mental Health Services (CAMHS) data alone versus those trained on synthetic, tested on real (TSTR) CAMHS data.

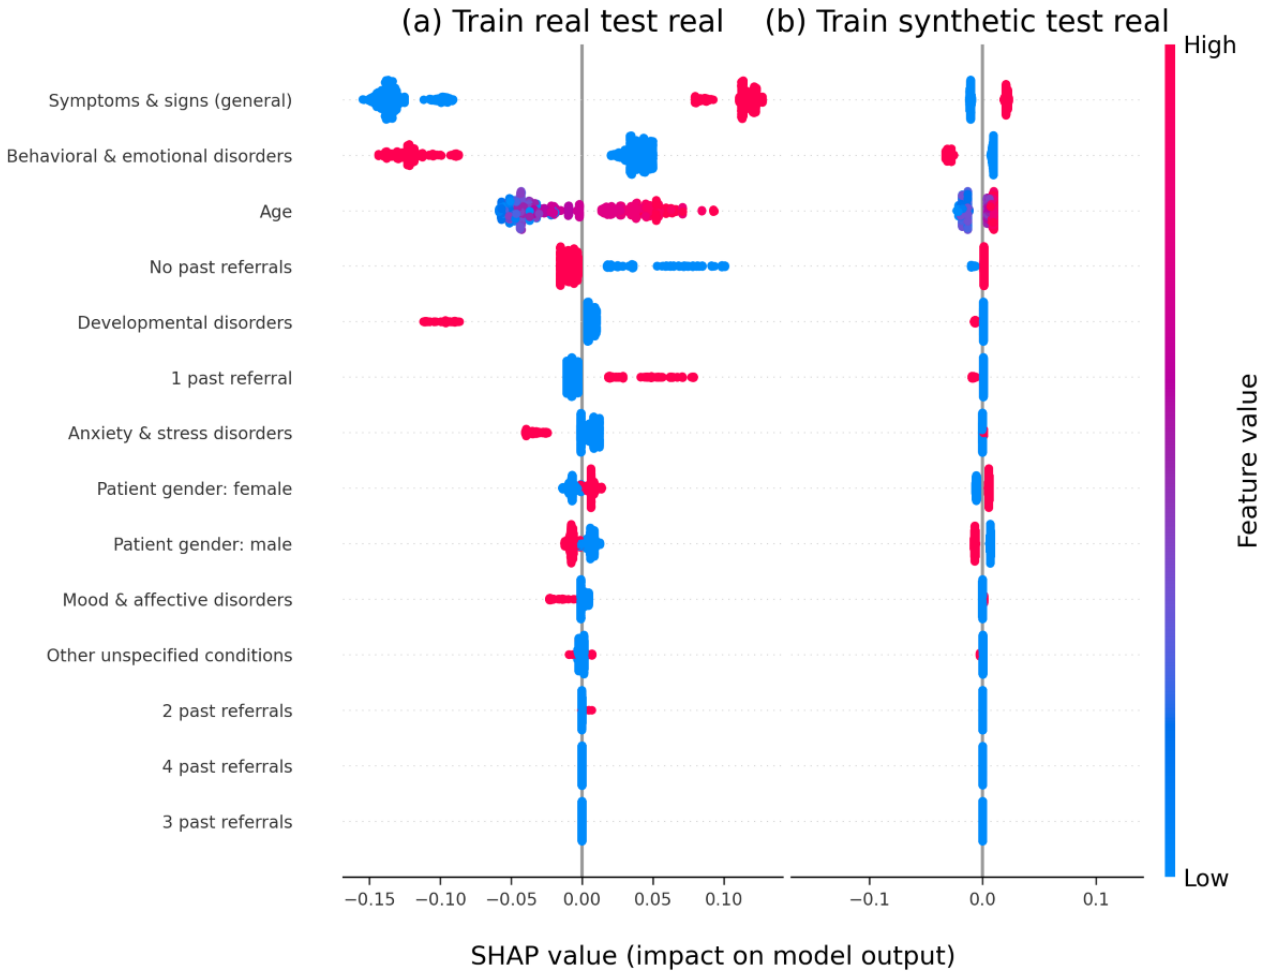
Sample size	TRTR, PRAUC[a] (range)	TSTR, PRAUC (range)
619 referrals	0.39 (0.34-0.44)	0.32 (0.28-0.38)
1546 referrals	0.40 (0.36-0.47)	0.33 (0.29-0.38)
3092 referrals	0.41 (0.37-0.47)	0.34 (0.30-0.39)
6184 referrals	0.43 (0.38-0.49)	0.40 (0.35-0.45)

[a]PRAUC: precision-recall area under the curve.

Reproducibility of Feature Interpretability (SHAP)

SHAP analysis, presented in Figure 4, provides an insight into how different patient characteristics impact the predicted intensity of care, both when the model is trained on real patient data and when it is trained on synthetic patient data.

The model consistently showed that a lower prevalence of "behavioral and emotional disorders" (F90-F98) led to a higher predicted intensity of care. This finding is a clinically meaningful observation rooted in the structure of CAMHS resource allocation; because F90-F98 diagnoses (eg, ADHD, externalizing difficulties) are highly prevalent and typically managed via lower-intensity, first-line support, their presence is not a strong predictor of high-intensity service use. Therefore, the absence of this common, low-intensity diagnosis in a patient referred for complex care suggests the presence of a less common, more severe, or highly comorbid condition that immediately necessitates the allocation of higher-intensity resources [27].



Conversely, a greater presence of "symptoms and signs (general)" (R40-R46) or "developmental disorders" (F80-F89) contributed to a lower predicted intensity of care. Patient age also presented a clear and consistent trend; younger patients were generally predicted to require higher intensity care, while older patients were associated with lower predicted intensity. On the plots, lower values for a feature are typically shown in gray, higher values in black; features increasing predicted intensity extend to the right, while those decreasing it extend to the left.

While the models showed consistent variable impact on the target prediction (intensity of care), we noted a significant difference in the strength of this impact between the synthetic and the real prediction models. The model trained on actual patient data showed a much wider range of impacts from individual features (SHAP values ranging from approximately –0.15 to 0.15), suggesting that real patient characteristics could lead to more pronounced shifts in the predicted intensity of care. In contrast, the model trained on synthetic data displayed a significantly narrower range of influence (approximately –0.03 to 0.03). The "flattening" of the variables' impact on the predicted intensity of care implies that while synthetic data helps the model learn the general direction of how patient characteristics relate to care intensity, it reduces the overall sensitivity of the model to the nuanced, individual variations found in real patient data. This effect, however, can be mitigated by using more advanced synthetic data generation techniques.

Despite the observed reduced variable impact in the synthetic model, the consistency in the direction of SHAP-based explanations remains clinically valuable. It effectively validates synthetic data's ability to capture fundamental predictive patterns in sensitive health care records, making synthetic datasets particularly useful for privacy-preserving exploratory research and facilitating hypothesis generation and validation. While acknowledging the continued need for further efforts to precisely replicate nuanced quantitative impacts for high-stakes clinical predictions, the qualitative fidelity of the result offers an effective tool for initial understanding and safe experimentation in CAMHS health research.

Synthetic and Real Individual Care Paths

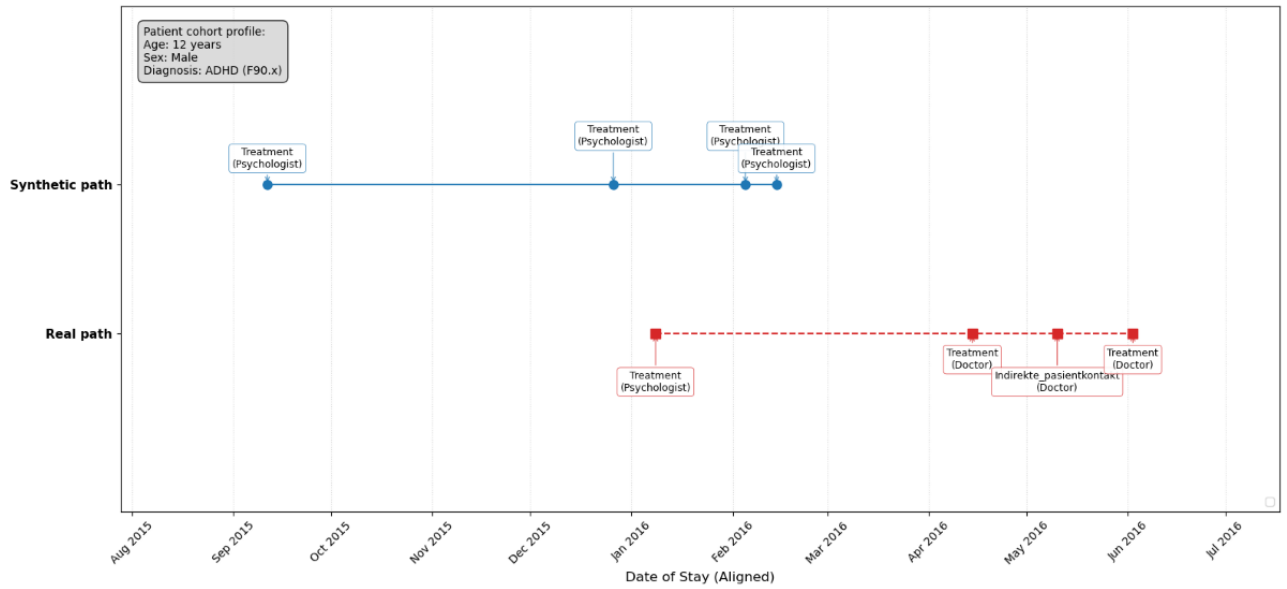

Figure 5 compares 2 distinct care pathways for a 12-year-old male patient diagnosed with "behavioral and emotional disorders" (F90-F98). Both paths are presented on a shared timeline (x-axis) that has been aligned to start at a common point, allowing for direct comparison of event sequencing and density.

The figure serves as a comparative visualization, highlighting potential differences in the flow, types of interventions, and personnel involvement between a synthetic and a more real care path.

While synthetic CAMHS data successfully captures the overarching statistical patterns of the real CAMHS dataset, divergences at the individual patient level offer valuable insights. The differences result from synthetic data representing the most common trajectories, an average derived from the entire dataset that naturally filters out the unique noise and unobserved idiosyncratic factors influencing real-world care. Real CAMHS care is inherently nonlinear and dynamic, shaped by patient responses, unforeseen crises, resource constraints, and patient/family agency. These complexities, including feedback loops and real-world bottlenecks such as waiting lists, are challenging for synthetic data to perfectly replicate at an individual level, leading to the observed divergence.

XSL•FO
RenderX

Figure 5. Comparison of real-like and synthetic care paths for an attention-deficit/hyperactivity disorder (ADHD) patient. The x-axis (Date of stay [Aligned]) shows the progression of time. The y-axis separates the "Synthetic path" (top, solid line) from the "Real path" (bottom, dashed line). Individual markers represent stay events, annotated with stay types and personnel categories. The grey box (top left) indicates shared patient demographics for both trajectories.

Discussion

Principal Findings

This study demonstrates the significant potential of synthetic data to enhance the utility of electronic health care records within CAMHS. Our methodology, using a hierarchical SDG, generated synthetic datasets that exhibited high statistical fidelity to real-world CAMHS data, as confirmed by various quality metrics (KSC/TVC, CS, CSS) and visual density comparisons. While minor quality variations were observed with decreasing sample sizes [28], the results confirm that our approach broadly preserves variable behaviors and dependencies between variables in the generated synthetic datasets [29]. However, identifying the precise minimum real data sample size for generating truly useful and high-fidelity synthetic CAMHS data is complex and highly dependent on the specific research scope and applications.

Models trained on synthetic data demonstrated predictive performance in classifying patient “intensity of care” (low vs medium or higher) that was comparable to models trained on real data. While the absolute predictive power of the model was modest (PRAUC=0.40-0.43 over a 0.33 random baseline), the key finding is the preservation of this utility in the synthetic data, as evidenced by the comparable scores**.**

The SHAP analysis confirmed that the synthetic model’s explainability aligned with real-world insights, underscoring the consistent importance of age and CAMHS diagnosis (eg, anxiety disorders, depression, ADHD, and autism spectrum disorder) in assessing care needs [30,31]. Furthermore, our findings provide strong evidence that synthetic data effectively protects individual privacy. The data generation process makes it highly unlikely for attackers to reidentify patients or uncover sensitive details from the original dataset, a critical requirement given the highly personal nature of CAMHS data.

The implications of high-fidelity, privacy-preserving synthetic CAMHS datasets are profound for children and adolescent mental health research and practice. Their availability removes critical barriers to data sharing and collaborative research, enabling more thorough investigations into mental health aspects across diverse populations [32], especially for vulnerable ones like those served by CAMHS. This capability facilitates a deeper understanding of mental disorder patterns and contributes to the development of more effective, personalized treatment methodologies [33]. Moreover, given that young adolescents often withhold important information from health care providers due to privacy concerns, which hinders effective diagnosis and treatment [34], synthetic data allows researchers to explore critical questions that would be impossible with real, incomplete data. These include understanding the impact of stigma on treatment adherence, evaluating novel personalized interventions, investigating the influence of “hidden” family dynamics, and simulating the effects of systemic barriers on access to care for vulnerable groups.

Furthermore, maintaining highly accurate long-term temporal and sequential relationships across numerous event types remains challenging in synthetic data generation. Most synthetic data quality metrics prioritize aggregate statistical properties over the exact fidelity of unique individual sequences. This means a synthetic dataset can be excellent at the population level but still show microlevel divergence in individual trajectories. Despite these differences, the divergence is valuable. It highlights that synthetic data, while not predicting exact individual pathways, excels at understanding general care models, developing system-level interventions via cohort simulations, and creating privacy-preserving case studies for training. It effectively complements the detailed study of highly personalized real-world clinical journeys.

XSL•FO
RenderX

Future Work

To improve upon the findings of this investigation, future research can focus on enhancing the synthetic data generation process. Conditional generative models, such as variational autoencoders [35] and generative adversarial networks [36], could be trained to produce synthetic data that reflects specific referral reasons or treatment modalities, conditioned on existing basic patient information. These advanced models are adept at learning complex data distributions, leading to higher-quality and more diverse synthetic outputs, which are crucial for capturing the varied presentations within CAMHS.

Beyond static data generation, further research can also explore integrating synthetic data with process mining techniques to enhance the modeling of complex care sequences. Specifically, synthetic process mining offers a powerful avenue for generating and analyzing event logs that mimic real patient journeys, but with full privacy control [37]. This would enable the creation of highly detailed, longitudinal synthetic care pathways, allowing researchers to simulate and analyze "what if" scenarios for process optimization without touching real patient data (eg, assessing the impact of adding a new therapy step or reducing wait times on patient flow). Furthermore, synthetic process mining could also generate diverse and comprehensive training data for predictive models focused on patient trajectories and outcomes, especially for rare events or complex multistage interventions where real CAMHS data are scarce or incomplete. This capability would significantly advance our understanding of care delivery dynamics and improve operational efficiency in CAMHS, ultimately benefiting young people awaiting and receiving support.

Limitations

It is important to recognize that our dataset had limitations in terms of clinical parameters. Our analysis revealed modest predictive power in the classification model (PRAUC approximately 0.43 on real data and 0.40 on synthetic data), necessitating caution in interpreting the absolute predictive accuracy. While the primary goal of this work was to establish the comparable utility between the synthetic and real datasets—which the similar PRAUC scores confirm—the absolute performance remains constrained. This constraint is likely attributable to 2 factors: severe class imbalance in the target variable (necessitating the aggregation of the rare high-intensity category into the 33% positive class) and the inherently limited, aggregated feature set available from administrative EMR. These limitations emphasize that the model should not be used in isolation for clinical prediction but rather that the synthetic data successfully preserves the utility inherent in the original feature space.

Furthermore, our dataset had limitations in terms of clinical parameters. Although we had access to basic data such as sex, age, and clinical primary diagnosis, our dataset lacked detailed information on the specific reason for the referral and the amount of additional care (eg, medication, group sessions, art therapy, physical therapy, and sheltered workshop). These clinical details are crucial for accurately assessing and classifying service intensity. The absence of these detailed clinical parameters may have impacted the accuracy of our analyses and the general applicability of our findings to a broader clinical context. Future research will benefit from a more comprehensive dataset that includes these key clinical parameters.

Regarding fairness evaluation, Norway's highly inclusive public health care system inherently minimizes selection bias. However, we acknowledge the potential for underrepresentation of underserved minorities and rare diagnoses. These issues can be effectively addressed by augmenting the data with synthetic samples of these specific groups and applying fairness measures tailored to the analytical goals of research aimed at serving these minority populations. While the methodology for creating synthetic CAMHS data is highly generalizable across different data environments and health care systems, it is crucial to recognize that the interpretation and applicability of findings derived from such synthetic data would always need to be contextualized within the specific health care system from which the original data was sourced. This underscores the need for localized validation and careful consideration of systemic differences when applying research findings across international borders.

Conclusions

This study provides evidence that synthetic data can be generated from CAMHS EMR that achieves a favorable balance between utility and privacy. The main findings confirm that the hierarchical synthetic data model produces datasets with high statistical fidelity and comparable predictive utility to real data, while simultaneously demonstrating a reduced risk of patient reidentification. This pilot study suggests that synthetic data, developed from standard EMR clinic records, offers a method compliant with HIPAA and GDPR regulations, facilitating clinical and administrative research that was previously unattainable. This advancement creates critical new opportunities for CAMHS research to progress despite confidentiality restrictions.

Acknowledgments

We gratefully acknowledge the invaluable help of the Individualized Digital Decision Assist System project, BUP Helse Stavanger, and Helse Vest IKT, Synnøve Olset, for bringing the collaborators together and providing valuable feedback in preparing this manuscript.

The authors confirm that generative artificial intelligence tools, specifically Gemini by Google, were used for three specific and limited purposes during the preparation of this manuscript and the revision process:

Multimedia Appendix 3
Privacy evaluation. The Main attack (1) uses synthetic data to create a series of guesses. Anonymeter evaluates (2) these guesses by comparing them to the values present in the original dataset, to assess the effectiveness of the attack. Anonymeter requires the adversary to conduct the same attack on a control dataset (control attack), which consists of records that were not utilized in the generation of the synthetic data. Any insights the attacker gains regarding the control records from the synthetic dataset cannot be linked to privacy violations, as the design ensures that no information from the control dataset is incorporated into the synthetic dataset. By contrasting the success rates of the attack on both training records and control records, a sensitive measure of risk (3) is calculated.

Multimedia Appendix 4
Train synthetic test real. To evaluate model efficacy, the train synthetic test real (TSTR) approach was used. Two machine learning models were developed: one trained on real data and the other on synthetic data, both targeting patients with referral duration under 18 months to predict Child and Adolescent Mental Health Services (CAMHS) care intensity across three categories: fewer than 15 sessions, 15 or more sessions annually. The latter two categories were combined due to low occurrence of high intensity. Model performance was assessed using a 20% test subset from the real dataset, allowing comparison of synthetic and real data effectiveness. SHAP values were computed to analyze feature significance.

Abstract

Background: Primary care in Thailand often uses mixed Thai-English free-text documentation for diagnoses and clinical problems, limiting standardization, interoperability, and secondary data use. Clinical terminologies like Systematized Nomenclature of Medicine Clinical Terms (SNOMED CT), a comprehensive reference terminology, can bridge this gap through the use of structured clinical data. Developing and mapping a local user interface terminology (UIT) is one of the key strategies for implementing SNOMED CT in real-world clinical settings.

Objective: This study aimed to develop a Thai UIT derived from frequently used terms in real-world primary care practice, map these terms to SNOMED CT concepts, and evaluate the extent of concept coverage.

Methods: Frequently used clinical terms were extracted from outpatient medical records from the family, emergency, and internal medicine departments using a customized tokenization method, N-gram analysis, and expert review. This process yielded 2054 Thai-specific terms. All terms were normalized and mapped to SNOMED CT through manual expert-driven and semiautomated tools. Unmapped terms were subsequently analyzed to identify mapping barriers and solutions.

Results: Of the 2054 Thai-specific terms, 2012 were successfully mapped to 2041 (97.98%) SNOMED CT concepts, including 1781 (85.50%) fully, 123 (5.90%) broader, 56 (2.69%) narrower, 81 (3.89%) inexact mappings, and 42 (2.02%) remained unmapped. Most mappings were one-to-one (1984), with 28 terms mapped to multiple concepts (57), covering 1486 unique SNOMED CT concepts. The remaining 42 unmapped terms were mostly due to culturally specific expressions or concepts not yet represented in SNOMED CT. These were categorized for potential postcoordination, exclusion, or national extension development.

Conclusions: This study demonstrates the feasibility of developing a Thai UIT mapped to SNOMED CT and describes mapping challenges. The resulting UIT enhances semantic clarity in clinical documentation and supports better interoperability, clinical decision-making, and health data analytics within Thailand's health care system.

Introduction

Health care provision is a knowledge-intensive industry, but the quality and accessibility of health care data often fail to adequately meet these needs [1]. This is partly due to the data collection process, which commonly takes place in a fast-paced, high-pressure point-of-care environment [2], leading to the generation of data sufficient to meet the immediate clinical tasks but often lacking the completeness, standardization, and structure necessary for secondary use, for example, research, that drives health care improvement [3,4]. This limitation may compromise patient safety, care quality, and the ability to generate actionable insights [2,5]. To harness the full potential of health care data, it is essential to prioritize structured data collection that supports timely and effective use across the health care ecosystem [3,4]. Standardized clinical terminology, structured representations of clinical concepts understandable to both humans and computer systems, is an essential technology improvement required for developing reusable data that enables interoperable health care delivery [6].

Because clinical terminology must be comprehensive and support multilingual use, the Systematized Nomenclature of Medicine Clinical Terms (SNOMED CT) has been widely adopted internationally as a reference terminology standard that is indispensable for standardized information exchange across clinical care and research settings [7]. SNOMED CT adopts a concept-oriented structure; each unique clinical idea is represented by a concept identified by a language-independent, machine-readable unique identifier.

SNOMED CT consists of 3 core components, including concepts, descriptions, and relationships. Concepts represent the underlying clinical meaning; descriptions provide human-readable terms in multiple languages; and relationships define how concepts are linked within the ontology. A single concept can have multiple descriptions, enabling flexible, precise, and multilingual representation of clinical ideas. Relationships form a poly-hierarchical graph structure to express, distinguish, and connect each clinical concept, maximizing practicality while minimizing ambiguity [8]. For example, the concept “Nodule of lung (disorder)” can be described by multiple terms across languages (eg, English, French, and Swedish), and its meaning is defined through relationships as the child of both “Lesion of lung (disorder)” and “Lung mass (finding),” the associated morphology “Nodule (morphologic abnormality),” and the finding site “Lung structure (body structure).” This structure enables consistent clinical data representation and supports semantic interoperability. Successfully implementing SNOMED CT not only improves data quality and standardization of clinical data but also enhances the quality of health care through more efficient data use for both clinical and research applications [9,10]. While SNOMED CT offers a robust, language-independent conceptual framework, it does not automatically capture the variability of clinical expressions used in routine practice, particularly in multilingual or mixed-language documentation environments.

User interface terminology (UIT) refers to the set of terms clinicians use during routine clinical documentation. It consists of user-friendly and context-specific expressions that reflect the natural phrasing and cognitive patterns of clinical practice [11]. UITs are typically designed to be used by a defined user group and certain settings, prioritizing efficiency and usability [12]. Within the Open Medical Record System (OpenMRS; OpenMRS Inc) ecosystem, many implementations rely on Columbia International eHealth Laboratory (CIEL), an openly maintained UIT that serves as a common starting point for clinical data capture in OpenMRS deployments [13]. CIEL supports user-friendly clinical data capture while providing mappings to international reference terminologies (including SNOMED CT) [14], enabling the harmonization of locally meaningful data for use with global standards, facilitating secondary data use, interoperability, and research usability [3,4]. Combining the advantages of both terminologies leverages their complementary strengths, enhancing communication accuracy, data quality, and adoption among clinicians, while providing semantic precision, computability, and cross-system interoperability [10,11]. Together, they facilitate the standardization of a clinical narrative into more structured data [15,16].

Despite its advantages, implementing SNOMED CT presents challenges, particularly in non–English-speaking contexts [7,10,17]. Studies investigating the performance of SNOMED CT in multilingual contexts report 2 important indicators. Concept coverage refers to the proportion of source clinical ideas that can be represented by a concept, while term coverage refers to the proportion of source terms included in the SNOMED CT description, reflecting comprehensiveness of concept and the usability of descriptions, respectively [18]. For example, European-based studies demonstrate varying degrees of success in translation and implementation efforts. A fully translated Swedish version of SNOMED CT achieved good concept coverage (87%) but lower term coverage (47%), reflecting limited alignment with real-world clinical language [19]. In contrast, a German UIT without the use of SNOMED CT reached comparable term coverage (46%) despite the lack of codes in some key semantic areas, such as procedures, devices, or genes [16,19]. These findings suggest that constructing or adopting language-specific UITs, linked to SNOMED CT’s richer semantics and logical structure, is urgently needed and more effective than simply relying on direct translation [10,15].

Thailand became a member of SNOMED International in 2022, signaling a national commitment to adopt SNOMED CT as the reference terminology for addressing the country’s interoperability and health care data quality challenges [20]. Since joining, SNOMED CT codes have been incorporated into the national reporting and reimbursement datasets for diagnostic data. In clinical practice, a few health care institutes have begun integrating SNOMED CT’s abundant descriptions into their diagnosis entry systems. This approach complements the previous process, in which physicians manually selected *International Classification of Diseases (ICD)* codes. However, the potential benefits of adopting SNOMED CT (eg, improved data granularity, semantic interoperability, and enhanced secondary data use) have yet to be fully realized across the country [9,10]. A prior study in Thailand attempted to auto-map

XSL•FO
RenderX

Thai discharge summary terms to *ICD* codes through SNOMED CT descriptions but excluded all non-English characters, limiting its ability to interpret locally used abbreviations and mixed-language expressions common in Thai clinical documentation [21].

This study was conducted with the following 3 main objectives. First, to develop a Thai-language UIT derived from real-world clinical practice. Using a dynamic corpus of clinical texts, we apply a term collection methodology that integrates clinical expertise with natural language processing (NLP) techniques. The resulting UIT is expected to facilitate and support standardized data entry, enhance data quality, and improve user acceptance of SNOMED CT within Thailand's health care system.

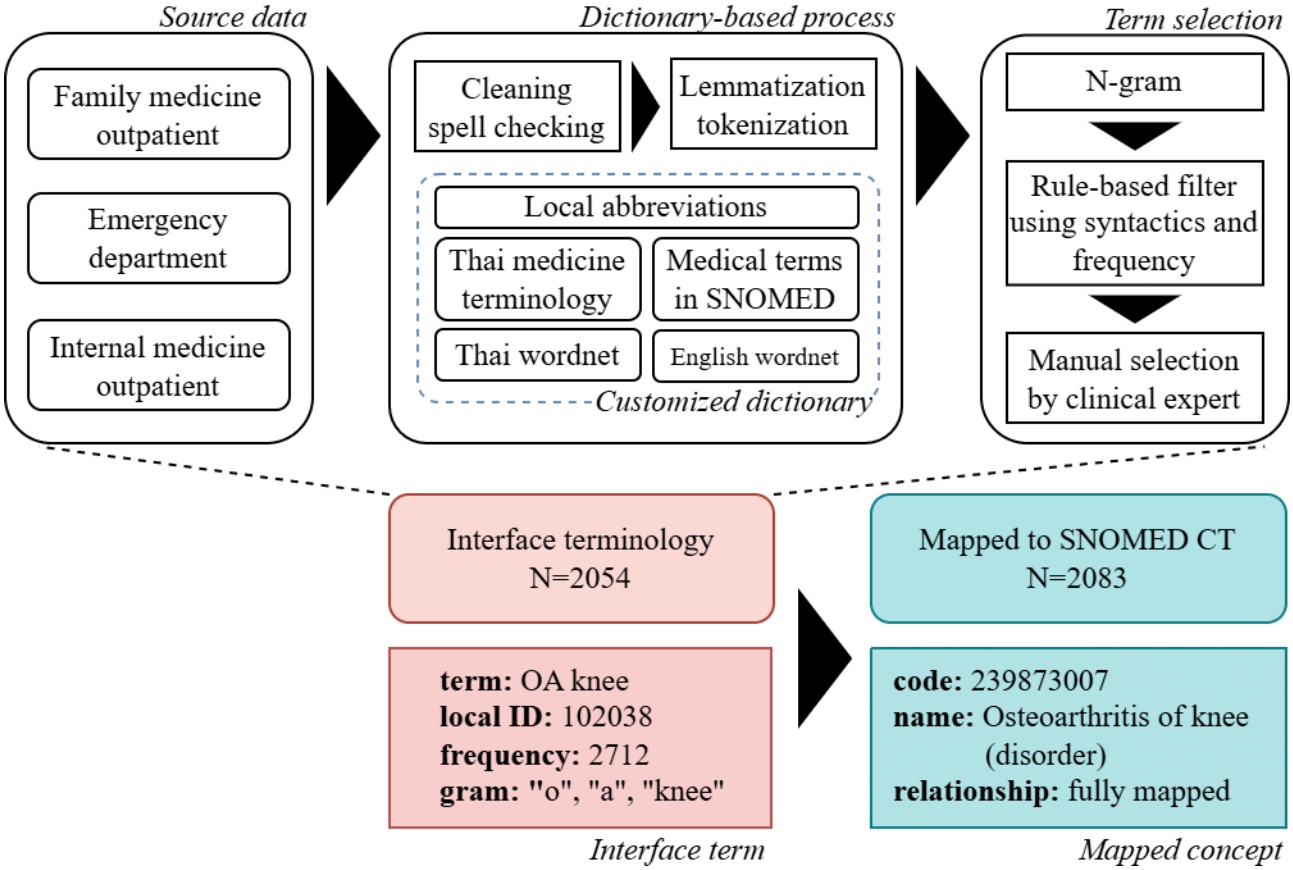
Second, to evaluate the content coverage of SNOMED CT, defined as the proportion of clinical ideas in the Thai context that can be represented through international reference terminology.

Third, to perform mapping analysis of partially mapped and unmapped terms in order to identify potential areas where SNOMED CT or the Thai national extension may need further refinement to better represent Thai health care data.

Methods

Data Source

Data used for the development of the UIT were retrospectively retrieved from the chief complaint and present illness sections of electronic medical records (EMRs) at Chakri Naruebodindra Medical Institute, Ramathibodi Hospital, Mahidol University, covering the period from January 2019 to April 2023. Data were obtained from outpatient clinics in the family medicine (FM) and emergency departments, representing primary care settings. To enhance lexical diversity and coverage, additional data were obtained from the high-volume internal medicine (IM) department. Records lacking both the chief complaint and present illness sections were excluded from the study.



UIT

In this study, UIT was defined as a set of clinically relevant terms used by clinicians to express their clinical ideas within the EMRs. These terms can be presented in either the semistructured or unstructured free-text entries. To qualify as UIT, the terms must contain adequate meaning, clarity, and clinical specificity to support accurate documentation and enable secondary uses, as assessed by medical doctors (eg, " " [chest pain], " " [vomiting blood], " " [ischemic heart disease]), whereas terms that were vague or noninformative (eg, "1 pta" [1 month prior to admission] or "without evidence of") were not considered UIT.

The content of the UIT was harvested from the free-text documents produced during actual patient encounters. Clinician-entered free-text data (chief complaint and present illness) from the EMRs were preprocessed and transformed into clinical terms using NLP techniques, including cleaning, tokenization using our customized method, and N-gram generation. Term frequencies were then calculated, and terms meeting predefined threshold criteria were included in the UIT. The overall process is illustrated as follows (see Figure 1):

XSL•FO
RenderX

Figure 1. Summary overview of the mapping process. Collecting data from all sources (left upper box). Turning free text to N-gram using a customized dictionary from 5 sources (middle upper box). Interface terms selected by term frequency and experts (right upper box). Indexing the interface terms (pink). Mapping to the semantically equivalent SNOMED CT concept (blue). OA: osteoarthritis; SNOMED CT: Systematized Nomenclature of Medicine Clinical Terms.

Text Preprocessing and Tokenization

Free-text data were preprocessed using the Python library for Thai NLP (ie, PyThaiNLP version 4.0.2) [22], which normalized texts by applying case normalization, correcting misplaced Thai tone marks and vowels, removing punctuation, and eliminating duplicate entries (eg, repeated sentences from prior visits). This process removed approximately 11.4% of the total characters, improving data consistency and validity. The code used for implementing text preprocessing and tokenization is provided in the GitHub repository [23].

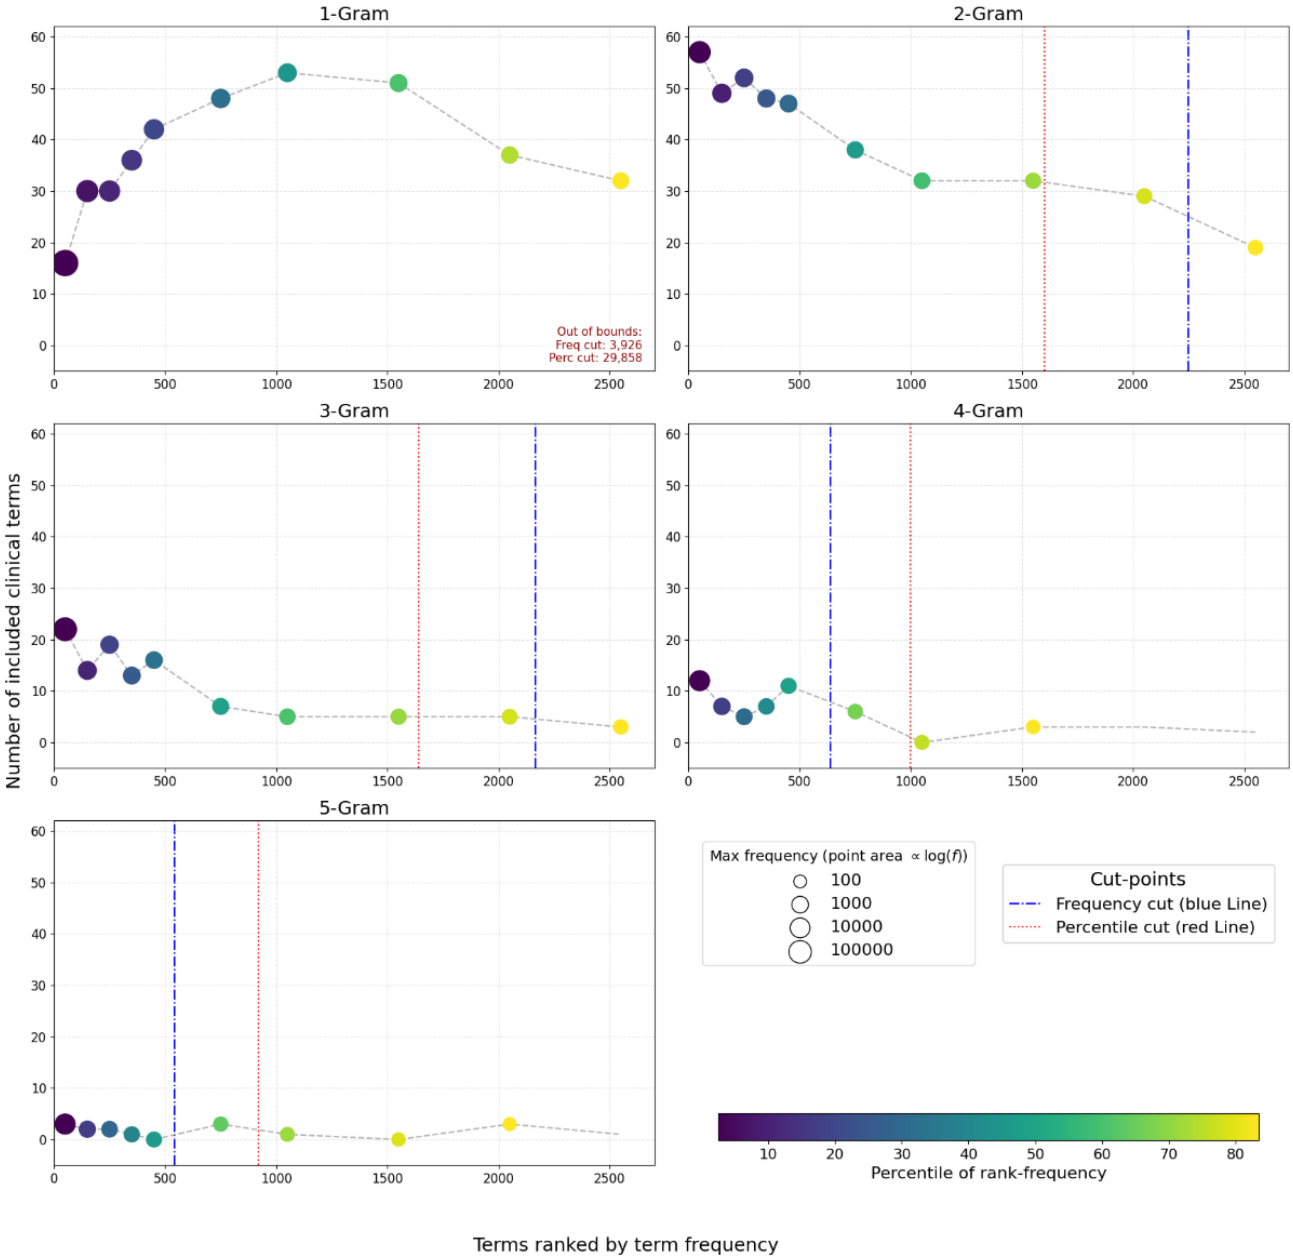
Because Thai is a continuous-script language, which has no word and sentence boundaries (eg, “ ” [ischemic heart disease] consists of 4 lexical units: “ ”(disease), “ ”(heart), “ ”(deficiency), “ ”(blood)), standard Thai tokenizers trained on general Thai corpora perform poorly, particularly for medical text [24]. We therefore used a customized maximum matching algorithm, a greedy approach that segments text by repeatedly choosing the longest possible valid term from a dictionary that matches the current position. The dictionary was expanded to include medical jargon, drug names, and local abbreviations to optimize tokenization accuracy for clinical narratives.

Formally, given an input string S and a dictionary D, at each position j, the algorithm identifies all candidate substrings of S beginning at j that appear in D, and selects the candidate with the maximum length. This substring is then appended to the output sequence of tokens, and the process continues from the next unmatched character until the entire string is segmented.

This left-to-right longest-match strategy enables more accurate tokenization of Thai medical terms.

The custom dictionary D integrated five sources (Figure 1) (1) English WordNet; (2) Thai WordNet; (3) SNOMED CT descriptions (providing English clinical terms and medical jargon); (4) Thai medicine terminology (the national medicine database contains drug ingredients, generic names, trade names, and herbal medicine); and (5) a manually curated abbreviation dictionary (Multimedia Appendix 1), comprising abbreviations with ≥2 capital letters occurring >100 times in the dataset. These abbreviations were reviewed by physicians, validated using 5 random samples of medical records, and mapped to SNOMED CT. This custom dictionary was also used to spell-check before tokenization, ensuring that incorrect or nonstandard spellings were corrected before segmentation (Figure 1).

The N-grams of length 1 - 5, representing continuous sequences of N tokens (or grams), were generated to identify meaningful patterns and construct candidate terms or phrases.



For example, words contained unigram to 5-grams were: “ ” (fever) for unigram, “ ” (abdominal pain) for bigram, “ ” (oral cavity wound) for trigram, “ ” (both legs are swelled) for 4-gram, and “ ” (abnormal bleeding from vagina) for 5-gram. Syntactically irrelevant N-grams (ie, those containing >50% stop words, punctuation,

XSL•FO
RenderX

or numbers; or terms beginning or ending with stop words or prepositions) were excluded. The remaining N-grams were ranked by frequency and carefully reviewed by experienced clinicians. Clinically relevant terms were defined as those that conveyed sufficient meaning for documenting patient conditions.

In the first round, medical doctors reviewed intervals of ranked lists (Multimedia Appendix 1), marked the terms that are clinically meaningful and appropriate for representing as structured data, and selected the terms by applying the following inclusion criteria: (1) frequency rank within the top 70th percentile or (2) absolute frequency ≥300 occurrences, thresholds that reflected diminishing returns in identifying clinically relevant terms (Figure 2). After the second round, 2054 terms were selected from the pool of 10,260 candidate terms for inclusion in the interface terminology, representing commonly used clinical expressions across EMRs.

Figure 2. Numbers of included clinical terms per interval of rank-frequency categorized by the N of N-gram. Blue vertical lines indicate the cut point where term frequency was 300. Red vertical lines indicate the cut point where the percentile of rank-frequency reaches 70.

Mapping to SNOMED CT

Each UIT term was mapped to a semantically equivalent SNOMED CT concept using Snap2SNOMED, an open-source, publicly available mapping tool developed and maintained by SNOMED International. The tool provides key functionalities, including a built-in SNOMED CT browser, versioning, and automated lexical mapping (applicable to English-language terms only). Because automated mapping requires English input, 946 Thai terms were translated into English using Google Translate (Google LLC), and these translated terms were used as source terms for mapping. The automated mapping results were manually reviewed and validated by 2 clinical domain experts (NT and JS). To ensure semantic equivalency to the original Thai terms, 5 clinical usage contexts were supplied to the mappers for each term, selected at random from different patients. Manual mappings were guided by semantic equivalence

XSL•FO
RenderX

criteria recommended in the Snap2SNOMED User Guide, prioritizing alignment for meaning, clinical intent, and hierarchical appropriateness. Disagreements between mappers were resolved through iterative discussion and consensus-based remapping.

Mapping results were classified into three categories, as illustrated in Figure 1: (1) fully mapped: SNOMED CT concepts that fully captured the semantics of the source term (eg, "valvular heart disease" mapped to "Heart valve disorder [disorder]"); (2) partially mapped: SNOMED CT concepts that were close but not fully semantically equivalent to the source term (eg, "home SBP" mapped to the narrower concept "Average home systolic blood pressure [observable entity]"); and (3) unmapped: source terms that lacked sufficient representation in existing SNOMED CT concepts.

A single source term could be potentially mapped to multiple SNOMED CT concepts (referred to as one-to-many mapping), resulting in more mapping pairs than source terms. This arose from one of two scenarios (1) homonyms, terms carried multiple distinct meanings, each represented by different SNOMED CT concepts following guidelines from SNOMED CT managing conventions and (2) ambiguous terms explicitly excluded from SNOMED CT due to insufficient contextual specificity (eg, "fundus" referring to either a hollow organ apex or the eye's interior surface). These ambiguous terms were conservatively classified as unmapped to preserve terminological clarity and precision.

Partially mapped pairs were further classified into broader, narrower, and inexact relationships to quantify mapping quality. The broader referred to the SNOMED CT concept, which encompasses the meaning of the source term. Narrower referred to when the SNOMED CT concept represented only part of the source term's meaning. In cases where semantic equivalence required postcoordination with multiple SNOMED CT concepts, we selected a single precoordinated concept in the same hierarchy as the narrower one. For example, "nodule at right upper lung" was mapped to the broader concept "Nodule of lung (disorder)" rather than combining a finding with "Upper lobe of right lung (body structure)." Inexact referred to mappings where the best available SNOMED CT concept differed in lexical and semantic characteristics but provided a clinically relevant approximation. For example, "over-the-counter drug use" was inexactly mapped to "Patient on self-medication (finding)."

Mapping Analysis

Terms unable to be mapped by mappers were discussed and categorized into either partially mapped or unmapped terms, including ambiguous terms and terms for which no semantic equivalency was found in SNOMED CT. For the terms that can be represented using postcoordination of 2 or more concepts from the same hierarchy, for example, " " (sweating and palpitation), we decided to categorize them as unmapped terms for further analysis. Partially mapped and unmapped terms were analyzed to assess their potential for practical implementation within our research team. Specifically, the analysis examined whether these terms could be adequately represented through SNOMED CT postcoordination or should be proposed for inclusion in an updated national edition of SNOMED CT. This evaluation helped identify specific content areas where concept expansion would better align the terminology with local clinical practice and ensure comprehensive coverage in the national edition.

Ethical Considerations

The study protocol was reviewed and approved by the Ramathibodi Human Research Ethics Committee (Approval number COA.MURA2023/469). The informed consent was waived due to the retrospective nature of the dataset and minimal risk to participants. All personally identifiable information (eg, names, surnames, dates of birth, addresses, hospital numbers, and visit dates) was removed from the dataset prior to analysis to ensure privacy and confidentiality.

Results

Dataset Characteristics

A total of 1,88,468 documents were initially retrieved from the EMRs during the study period. After excluding records with missing data, 1,83,557 documents from 53,142 patients were included in the analysis to develop the interface terminology. Characteristics of the 53,142 patients are described in Table 1. IM patients were the oldest (mean 59.3, SD 16.9), followed by FM (mean 54.4, SD 15.2), and emergency department (mean 43.4, SD 28.0). The percentage of males was highest in emergency (44.3%), followed by IM (39.7%) and FM (36.94%).

At the document level, the IM department contributed the largest volume (1,18,382/1,83,557, 64.5%), followed by the emergency (34,829/1,83,557, 19.0%) and FM departments (30,346/1,83,557, 16.5%). The median number of documents per patient (IQR) was 2 (1-5) for IM, 1 (1-2) for emergency, and 1 (1-3) for FM (Table 1).

Text-level analysis of 1,83,557 documents yielded 14,946,559 total words. IM contributed the majority (10,471,768/14,946,559, 70.1%), followed by emergency (2,750,896/14,946,559, 18.4%) and FM (1,723,895/14,946,559, 11.5%). Median (IQR) words per document were 107 (62-175) for IM, 74 (44-125) for ER, and 60 (38-99) for FM. Thai words were varied by department. Emergency department documents had the highest proportion of Thai words (1,752,756/2,750,896, 63.7%), followed by FM (1,016,914/1,723,895, 59.0%), while IM contained the lowest proportion (4,154,255/10,471,768, 39.7%).

[c]IM: internal medicine.

Coverage

A total of 2054 frequently used clinical source terms met the inclusion criteria and were integrated into the interface terminology. Of these, 2012 terms were successfully mapped to 2041 SNOMED CT concepts. Most terms were mapped one-to-one (1984 terms), while 28 terms were mapped to 57 multiconcepts through one-to-many mappings, yielding a total of 2083 entries while covering 1486 unique SNOMED CT codes. The final mappings are provided in Multimedia Appendix 2. Mapping characteristics are as follows:

- Language: English (1140 out of 2083 terms [54.73%]) and Thai (943 out of 2083 terms [45.27%]).
- N-gram: unigrams (1098 terms), bigrams (741 terms), trigrams (189 terms), 4-grams (45 terms), and 5-grams (10 terms).
- Equivalency: 1781 (85.50%) fully mapped terms, 123 (5.90%) mapped to broader concepts, 56 (2.69%) mapped to narrower concepts, and 81 (3.89%) inexactly mapped terms (Table 2). The remaining 42 terms (2.02%) could not be mapped due to culturally specific expressions or clinical concepts not yet represented in any SNOMED CT concept.
- Overall, the concept coverage was 85.50%. Combining fully and partially mapped terms yielded an overall concept coverage of 97.98%.

Term coverage is defined as the percentage of local clinical terms that can be accurately mapped to an existing SNOMED CT description. Among 1140 English terms, 656 terms (31.49%) had direct lexical matches with English SNOMED CT descriptions, including simple variations of writing, for example, “wound dressing” versus “Dressing wound.” The remaining 484 English terms (23.24%) did not have an exact lexical match and were still mappable through contextual interpretation, such as local abbreviations (eg, “f/u” → “Follow-up visit [procedure]”), or variation in writing style (eg, “contact tb” → “Exposure to tuberculosis [situation]”). As expected, no Thai terms were considered direct lexical matches because SNOMED CT descriptions are not yet translated into Thai.

Table . Concept coverage of Systematized Nomenclature of Medicine Clinical Terms (SNOMED CT) for Thai interface terminology.

Concept equivalency	English	Thai	Total
Fully mapped, n (%)	973 (46.71)	808 (38.79)	1781 (85.50)
Partially mapped, n (%)	140 (6.72)	120 (5.75)	260 (14.48)
Broader	65 (3.12)	58 (2.78)	123 (5.90)
Narrower	38 (1.82)	18(0.86)	56 (2.69)
Inexact	37 (1.78)	44 (2.11)	81 (3.89)
Unmapped, n (%)	27 (1.30)	15 (0.72)	42 (2.02)
Total, n (%)	1140 (54.73)	943 (45.27)	2083 (100)

Mapping Analysis

Mapping analysis of the 260 partially mapped terms revealed linguistic and semantic challenges. All 123 broader (5.90%) and 56 narrower (2.69%) pairs comprised of concepts differed in granularity, where terms belonged to the same semantic domain, but they were at different levels of clinical detail or abstraction. On the other hand, inexact terms arose when clinical intention aligned, but lexical or cultural expression differed. For example, “ ” (sleep with multiple pillows) was used to indicate the situation when a patient cannot sleep lying down due to shortness of breath; it was inexactly mapped to “Orthopnea (finding)” and “ (taking medicine regularly)” and its variations were the patient-reported concept “Drug compliance good (finding).”

We also observed that culture and linguistic characteristics contributed to mismatches. Some Thai expressions convey complex clinical scenarios through idiomatic phrasing, complicating alignment with SNOMED CT. For example, “over-the-counter drug use” in the Thai context often implies access to medications that would require prescriptions in many other countries. After deliberation in our team, although this was mapped to “Patient on self-medication (finding),” this concept does not fully capture its implications within Thailand’s health care system.

Forty-two unmapped terms (2.02%) were further categorized into 3 categories based on their characteristics (see Table 3).

Ambiguous terms (23/42, 54.76%) violated SNOMED CT naming conventions and required additional contexts for appropriate representation (eg, “lobe,” “node,” and “septum”).

Multiple clinical concepts (10/42, 23.81%) represented multiple distinct findings or events (eg, “s1 s2” [heart sounds], “ ” [sweating and palpitation], “ ” [fall and head collision]). Many terms reflect Thai-specific linguistic constructions and could potentially be addressed through postcoordination.

Clinically meaningful terms without SNOMED CT equivalents (9/42, 21.43%). Some terms were (locally) nationally specific (eg, “ ” [fear of heights or a feeling of butterflies in the stomach]) while others were universally applicable but absent from SNOMED CT (eg, “ ” [antipyretic medicine] and “DOI” [date of infection]). The terms were exhaustively searched using both lexical and graph properties of SNOMED CT through the use of SNOMED CT Expression Constraint Language.

Table . Categories for unmapped concepts.

Characteristics	Ambiguous terms	Multiconcept terms	No concept terms
Value, n (%)	23 (54.76)	10 (23.81)	9 (21.43)
Further intervention	Exclusion from terminology or addition of contextual information	Postcoordination or separation to multiple distinct concepts	Creation of new concept
Examples	• Lobe • Node • Septum	• S1S2 (Heart sounds) • (sweating and palpitation) • (fall and head collision)	• DOI (Date of Infection) • (Antipyretic medicine) • (fear of heights or a feeling of butterflies in the stomach)

Discussion

Principal Findings

This study developed a multilingual UIT derived from real-world clinical documents across the FM, emergency, and IM departments and evaluated its alignment with SNOMED CT. The resulting UIT reflects a nearly balanced linguistic composition (54.49% English terms and 45.51% Thai terms). Consistent with the bilingual nature of Thai medical records. SNOMED CT demonstrated strong concept coverage with 85.50% full and 97.98% full plus partial coverage, confirming its suitability as a reference terminology even in the setting where nearly half of the source terms are non-English. However, term coverage remained modest (31.49%) because SNOMED CT descriptions have not yet been translated into Thai, making exact lexical matches possible only for English-language terms.

The source data also showed different patterns in clinical documentation practices. For instance, IM generated the highest volume of text but had the lowest proportion of Thai words, consistent with its more technical and specialty-oriented clinical activities. In contrast, emergency and FM documents contained more Thai narrative language, which may reflect more direct patient-provider interaction, brief encounters, and patient-reported symptoms. These differences emphasize the need for UITs that can accommodate both biomedical language and colloquial Thai expressions.

We also found that only a small proportion of terms remained unmapped (2.02%), underscoring that the majority of local expressions can be integrated into SNOMED CT without major structural changes. These relatively small, unmapped concepts may help identify where efforts should be strategically concentrated at the national level. Moreover, the moderate-term coverage (31.49%), driven entirely by English lexical matches, reinforces the need for localized terminology tools and translation strategies if Thailand aims to scale SNOMED CT adoption nationwide.

Comparison With Previous Work

Despite differences in term extraction methods, particularly our focus on commonly used clinical terms and the use of a more recent SNOMED CT release, our findings generally align with previous evaluations of SNOMED CT concept coverage. Prior studies have reported a strong preference for high coverage in

XSL•FO
RenderX

the English-language international edition (86% fully mapped and 92% partially mapped) and similar strong performance in the fully translated Swedish edition when applied to Swedish clinical datasets (87% fully mapped and 92% partially mapped) [19]. In comparison, our findings showed 85.50% full and 97.98% full plus partial coverage, demonstrating that SNOMED CT remains robust even in bilingual and partially non-English documentation environments.

Comparable evidence has also been observed in low- and middle-income country settings. For example, an evaluation from Argentina reported 83% coverage based on user feedback during real-world implementation [12]. Other specific domains targeting nationwide data collection and surveillance objectives have very high coverage, 99% precoordinated and 100% postcoordinated concept coverage for AIDS-defining illnesses in Kenya [25], and high correspondence for tuberculosis-related terminology, although the latter did not include a formal concept coverage analysis [14].

In Thailand, a prior study mapped Thai discharge summary notes to SNOMED CT but removed non-English content and did not report concept coverage [21]. Our study extends this work by incorporating both English and Thai clinical terms from 3 departments, performing concept coverage, term coverage, and mapping analysis, and examining implications for national UIT development. This provides a more comprehensive and representative assessment of SNOMED CT's applicability for Thai primary care and hospital settings.

Partially mapped terms frequently reflect homonyms (eg, " " meaning both abdominal colic and a cigarette unit), mismatches in granularity (eg, "hypoglycemic symptom" mapped to hypoglycemia [disorder]), or culturally shaped usage patterns. These challenges are consistent with those reported in other multilingual SNOMED CT mapping studies [10,26]. In the Thai language, many biomedical concepts and terms are not readily expressed in Thai. Unlike languages that share linguistic roots (eg, English, French, and Swedish), Thai lacks direct lexical equivalents for some medical terms, creating communication barriers between clinicians, patients, and even health care providers. To ensure mutual understanding, clinicians need to phrase simple questions that patients can comprehend, allowing information to be collected accurately. For example, "compliance" is simply conveyed as "taking medicine regularly" or "never miss a dose," which is reflected in how these terms appeared in the EMRs. This observation has also been reported in other languages, not from the same roots as the English language [27].

Term coverage in our dataset was modest (31.49%), driven entirely by English lexical matches. The observed term coverage is comparable with countries whose SNOMED CT editions are only partially translated, for example, Dutch (35%) and French (39%) [19]. A considerable proportion of our Thai clinical terms were synonymous with globally common English medical jargon, reflecting Thailand's long-standing integration of English terminology in medical education and clinical communication. As shown in Table 1, Thai language use was more prevalent in primary care departments (FM and emergency), while IM documents contained more specialized English terminology, consistent with previous reports [28].

Challenges in Expressing Clinical Concepts in the Thai Context

Our mapping analysis of partially mapped terms highlighted several challenges in representing Thai clinical concepts within SNOMED CT. Many partially mapped terms require determining whether they should (1) be represented through postcoordination with existing SNOMED CT concepts (thereby supporting international interoperability) or (2) be introduced as new concepts in the Thai national extension to preserve locally specific meaning.

Postcoordination can be beneficial for international interoperability but may lose nuanced local semantics. Conversely, creating new concepts preserves the locally used expression but introduces a long-term maintenance burden and requires clear criteria for inclusion. No standardized national guidelines currently exist; decisions must consider clinical relevance, documentation frequency, clinical importance, and anticipated use cases within Thailand's EMR ecosystem. A representative example from our study is "over-the-counter drug use," which frequently appeared in our dataset and reflects a long-standing public health challenge in unsupervised medication access in Thailand [29], which contributes to national issues such as antimicrobial resistance and drug misuse [30]. While "Patient on self-medication (finding)" is the most relevant concept in SNOMED CT, it does not fully represent Thailand's regulatory distinctions and safety concerns. If more granular differentiation is required in Thailand for surveillance or policy purposes, a new child concept under "Patient on self-medication (finding)" may be warranted.

The analysis of unmapped terms also highlighted the role of language-specific and culturally specific expressions that are not directly translatable into English (see Table 3). In our data, 20.93% of unmapped terms reflected culturally unique, ambiguous, or context-dependent meanings. These findings suggested three key strategies for terminology management and strengthening (1) exclude ambiguous terms or add contextual information to the context-dependent terms. For example, the Thai term " " has multiple meanings (fear of heights or a feeling of butterflies in the stomach). Instead of mapping it directly, adding the more specific term " " (giddiness in the heart) mapped to "Palpitations (finding)" can ensure clarity and avoid misclassification. (2) Use postcoordination for multiconcept or idiomatic expressions. This pattern was also found in the English context, for example, the concept "Nausea and vomiting (finding)," which exists as a precoordinated concept within the international edition of SNOMED CT. However, since separated distinct concepts are presented, we suggest mapping to separate entities to preserve legacy information and also interoperability with the international context. (3) Recommend new concepts for national extension or international inclusion for globally relevant but unsupported terms. This should be done with a well-established concept with clear practical implications. One example we found was a local abbreviation, "DOI (Date of Infection)," which we believe has seen an increase in occurrences during the pandemic, particularly

XSL•FO
RenderX

in cases where infectious history has been thoroughly collected. Additionally, some of these represent global clinically relevant concepts insufficiently addressed by SNOMED CT, indicating areas for future expansion [7].

Overall, these challenges highlight the need for national governance structures, clearly defined criteria for new concept creation, and a systematic strategy for translation and localization to ensure accurate, consistent, and interoperable representation of Thai clinical terminology. Regional guidance from the Asia eHealth Information Network (AeHIN) similarly emphasizes that successful and sustainable interoperability depends not only on the technical standards but also on governance, architecture, workforce capacity, and institutional processes [31]. Centralized governance through a national health data dictionary and terminology services, as described in many interoperability architectures, like Open Health Information Exchange (OpenHIE; Linux Foundation Public Health), can standardize terminological assets and reduce fragmentation across implementation sites [32]. Such services can support the controlled use of postcoordination and governed concept creation and enable local expressiveness while preserving semantic consistency and international interoperability. Importantly, these functions are best managed at the terminology service level rather than within individual EMR implementations, thereby reducing duplication and implementation burden. In addition, mappings between shared UITs and reference terminologies or classification systems (eg, the *ICD* family) should be centrally maintained, versioned, and routinely updated. For example, the OpenMRS ecosystem also adopts the similar implementation pattern, where many deployments rely on the CIEL interface terminology, centrally managed and distributed via Open Concept Lab, supporting reuse and reducing divergence across implementations [13].

Strengths and Limitations

To our knowledge, this is the first study in Thailand—and among the few resource-limited countries—to develop a UIT and evaluate both concept- and term-level coverage of SNOMED CT in a real-world clinical setting. A key strength of this study lies in its data source, free-text entries from actual clinical encounters, which ensures that the extracted terms are grounded in real-world usage. Moreover, the terminology development process integrated clinical expertise with NLP techniques in a resource-limited setting, offering valuable insights for similar environments. The final UIT is composed of the commonly used clinical term. Although it is small in numbers, we believe this terminology to be generally applicable for use within Thailand. Although SNOMED CT concept coverage has been examined in a few resource-limited country settings, evidence remains scarce. This study extends the discussion to Southeast Asia by evaluating Thai-language primary care data, constructing a UIT mapped to SNOMED CT, and reporting concept coverage.

Several limitations should be acknowledged. First, source data were collected from a single hospital, which may limit the generalizability of the developed UIT. Consequently, the developed UIT may not fully capture the diversity of expression terms used across Thailand's broader health care system, particularly in regions where distinct dialects or documentation styles prevail. Nevertheless, this study achieved its goal of constructing a realistic UIT to inform national implementation strategies and evaluate the feasibility of adopting SNOMED CT as a national standard. As new clinical terms and concepts emerge, the UTI can be continuously expanded through routine monitoring, domain-expert review, and integration of automated extraction tools to ensure incremental improvement over time. Second, although the mapping and term extraction processes were performed by clinically trained physicians, the subjective nature of manual mapping introduces the potential for interpretation bias or human error. An interannotator agreement score was not assessed due to constraints in available personnel and resources; consequently, only one mapper and one reviewer contributed to the final mapping. Third, the coverage results may be overestimated compared to those reported in previous studies because our term list was developed from commonly used clinical expressions and mapped to a more recent SNOMED CT release. At the same time, the mapping tool Snap2SNOMED does not support postcoordination at the time of this writing, which may lead to a potential underestimation of full SNOMED CT content coverage. However, since postcoordination has not been generally performed in previous studies, the results remain broadly comparable with existing evidence [19].

Recommendation for Future Research

Future research should expand the evaluation of concept and term coverage across hospitals of varying sizes and settings, including northern, northeastern, and southern regions of Thailand, where specific dialects may influence clinical documentation practices. Extending these methods beyond a single institution will help determine the generalizability of the UIT and support efforts toward national standardization.

Automated methods should also be explored. Advanced NLP techniques and large language models may substantially improve the efficiency and accuracy of term extraction, disambiguation, and SNOMED CT mapping, particularly as our team is already beginning to implement these tools in parallel methodological work. Additional studies should examine how postcoordination can be operationalized in real-world EMRs, with the goal of identifying best practices that maintain semantic precision without burdening clinicians during documentation.

Finally, future research should include more diverse document types (eg, operative notes, procedure reports, and specialty consults) and a broader population. Doing such improves characterization of locally used clinical concepts, strengthens coverage estimates, and supports the development of a more comprehensive national UIT that accurately reflects the linguistic and clinical diversity of Thailand's health care system.

Conclusions

In conclusion, SNOMED CT represents most common clinical concepts but lacks sufficient local language coverage. With the interpretation of local clinical terms, a Thai UIT mapped to SNOMED CT can serve as a comprehensive standard for clinical documentation. This hybrid approach can enhance data quality, promote interoperability, and facilitate better use of health care

XSL•FO

data, contributing to improved patient care and creating opportunities for international collaboration.

Abstract

Background: Psychiatric disorders are diagnostically challenging and often rely on subjective clinical judgment, particularly in resource-limited settings. Large language models (LLMs) have demonstrated potential in supporting psychiatric diagnosis; however, robust evidence from large-scale, real-world clinical data remains limited.

Objective: This study aimed to evaluate and compare the diagnostic performance of multiple LLMs for psychiatric disorders using multicenter real-world electronic health records (EHRs).

Methods: We retrospectively analyzed 9923 inpatient EHRs collected from 6 psychiatric centers across China, encompassing all ICD-10 (International Statistical Classification of Diseases, Tenth Revision) psychiatric categories. In total, 3 LLMs—GPT-4.0 (OpenAI), GPT-3.5 (OpenAI), and GLM-4-Plus (Zhipu AI)—were evaluated against physician-confirmed discharge diagnoses. Diagnostic performance was assessed using strict accuracy criteria and lenient classification metrics, with subgroup analyses conducted across diagnostic categories and age groups.

Results: GPT-4.0 achieved the highest overall strict diagnostic accuracy (71.7%) and the highest weighted F1-score under lenient evaluation (0.881), particularly for high-prevalence disorders, such as mood disorders and schizophrenia spectrum disorders. Diagnostic performance varied across age groups, with the highest accuracy observed in older adult patients (up to 79.5%) and lower accuracy in adolescents. Across centers, model performance remained stable, with no significant intercenter differences.

Conclusions: LLMs—especially GPT-4.0—demonstrate promising capability in supporting psychiatric diagnosis using real-world EHRs. However, diagnostic performance varies by age group and disorder category. LLMs should be regarded as assistive tools rather than replacements for clinical judgment, and further validation is needed before routine clinical implementation.

Introduction

Mental disorders are a significant public health concern worldwide; they have high prevalence rates, which are continuously increasing each year [1]. About 20% of the global population is estimated to experience mental illness in their lifetime, placing a substantial burden on both society and health care systems [2]. However, there is an acute scarcity of psychiatric professionals. Many countries have fewer than 5 psychiatrists per 100,000 individuals; this results in delays in providing timely, high-quality diagnostic and therapeutic services for patients with mental health disorders, particularly in resource-limited regions, including China [3]. This medical resource shortage further underscores the urgent need to increase the accuracy and efficiency of psychiatric diagnoses. In addition, psychiatric diagnoses are inherently complex and challenging. Complex etiologies and high symptom heterogeneity characterize mental disorders. The symptom descriptions of patients often depend on subjective expression, with physicians' medical records and clinical diagnoses also based on their subjective experience [4]. This subjectivity makes diagnoses susceptible to variation among physicians, leading to inconsistent diagnostic outcomes. Therefore, in psychiatry, there is a crucial need to use modern technologies to increase diagnostic efficiency and accuracy [5].

Recently, the widespread adoption of electronic health records (EHRs) has provided a wealth of unstructured data to support the application of artificial intelligence technologies in medical diagnostics, offering new opportunities for diagnosing psychiatric disorders [6]. Large language models (LLMs), including the GPT series, exhibit powerful capabilities in natural language processing and semantic understanding. They can efficiently process unstructured text and have shown great potential in medical diagnostic assistance [7-10].

At present, studies on the application of LLMs in other medical fields have further confirmed their clinical potential. For example, Hasani et al [11] assessed the performance of GPT-4.0 (OpenAI) in standardizing radiology reports; they reported that it generates high-quality standardized radiology reports and significantly improves the efficiency of report generation and data analysis capabilities. Liu et al [12] compared GPT-4.0 with senior neurosurgeons and reported that the performance of GPT-4.0 in complex medical tasks is comparable with that of experienced experts, demonstrating its value in facilitating the diagnosis of complex cases. In addition, Horiuchi et al [13] reported that GPT-4.0 has demonstrated superior diagnostic accuracy in challenging neuroradiology cases, suggesting that generative artificial intelligence technologies can serve as important supplements to physician cognition in complex diagnostic scenarios. Overall, these studies demonstrate the potential application of GPT-4.0 in multidomain diagnostic tasks.

In psychiatry, LLMs have also begun to garner attention. Because psychiatric diagnoses heavily depend on textual descriptions of patient complaints and medical history, LLMs naturally possess significant application advantages in this field. Previous studies have revealed that ChatGPT-4 (OpenAI) can achieve an accuracy rate of 96.1% in the diagnosis of obsessive-compulsive disorder, significantly outperforming that of clinical psychologists (81.5%) and primary care physicians (49.5%) [14]. In 1 study, researchers used the UTH-BERT model and reported that its diagnostic accuracy for medical history in EHRs (74.3%) surpassed that of psychiatrists with intermediate experience (71.5%) [15]. Despite these advances, prior studies on LLM-based psychiatric diagnosis have several limitations. First, the scope of diseases in previous LLM research has often been narrow, with most studies focusing on a single or a small subset of psychiatric disorders (eg, major depressive disorder and obsessive-compulsive disorder) [16]. In contrast, our study simultaneously included all major *ICD-10* (*International Statistical Classification of Diseases, Tenth Revision*) psychiatric categories (F00-F99), thereby providing broader coverage than previous studies. Nevertheless, our analysis was conducted at the level of primary diagnoses within each category, without explicitly addressing comorbidity patterns, which remains an important direction for future research. Second, data sources are often single and lack validation in real-world clinical settings. Current studies rely primarily on simulated cases or data from a single institution [17], making it challenging to capture patient characteristics across diverse regions and health care practices. In the Chinese context, several studies have begun to explore the use of LLMs for psychiatric diagnosis and Chinese-language medical records; however, comprehensive, large-scale validation in real-world psychiatric EHRs—especially with direct comparisons between international and Chinese models—remains limited. Third, the diagnostic performance across age groups has not been thoroughly investigated, with most studies focusing solely on overall accuracy without examining differences in diagnostic performance across age groups (eg, adolescents and older adult patients). Symptoms, disease progression, and treatment plans for psychiatric disorders significantly differ across different age groups. Whether LLMs can adapt to these differences remains unexplored.

To address the aforementioned issues, this study optimized 3 key aspects: data sources, disease coverage, and population segmentation. First, we incorporated real-world EHR data from 6 representative provincial and municipal psychiatric centers across different regions of China. By directly using clinical records to evaluate the model, this approach is better aligned with real-world medical settings, filling the gap left by previous studies that lacked real-world data validation in the Chinese language. Second, we covered all psychiatric disorders listed in the *ICD-10* classification (F0-F9), overcoming the limitations of previous studies, which focused primarily on a single or a few disease types. This design allowed us to evaluate the model's generalization ability across a broad range of clinical diagnostic tasks. In addition, we conducted fine-grained age stratification, systematically comparing the model's diagnostic performance across 4 age groups: adolescents, young adults, middle-aged individuals, and older adult patients. This allowed the identification of the model's adaptation differences across different age groups. In summary, our study, based on large-scale, multicenter real-world data, is the first to comprehensively evaluate the clinical potential of LLMs for psychiatric diagnosis in China.

Methods

Research Design and Data Sources

The study data were sourced from 6 provincial and municipal psychiatric centers in China. These centers are located in Sichuan, Gansu, Shanxi, Guangdong, Jiangxi, and other regions, covering Southwest China, Northwest China, North China, South China, and East China, thereby ensuring good regional representation. The dataset included the EHRs of psychiatric inpatients between July 2017 and July 2024. In total, 12,819 cases were initially screened. Among them, 2896 cases were excluded owing to incomplete records or unclear diagnoses. Therefore, 9923 eligible cases were included. The EHR data used in this study consisted exclusively of unstructured narrative text fields, including chief complaints, history of present illness, and psychiatric examination notes. Structured data, such as laboratory test results, medication prescriptions, vital signs, nursing notes, and imaging reports, were not included, as psychiatric diagnosis primarily depends on descriptive symptomatology and mental status examination rather than auxiliary tests. All records included in the model were noted down by attending psychiatrists at the time of admission only. Clinical notes taken during hospitalization were not included, ensuring that the model received only information available at the initial diagnostic encounter and preventing potential temporal information leakage.

Ethical Considerations

The Ethics Committee of the Sichuan Provincial Mental Health Center approved this study (approval 202460). Considering the retrospective nature of the study, the Ethics Committee exempted the need for informed consent from the patients. All EHR data were fully deidentified in accordance with the Health Insurance Portability and Accountability Act safe harbor method (45 CFR 164.514(b)), with direct identifiers (eg, names, addresses, contact details, and hospital IDs) removed before analysis. In addition, because narrative clinical text can contain residual indirect identifiers, a stratified manual audit of 500 randomly sampled EHR narratives (approximately 5% of the dataset) was conducted to further minimize reidentification risk. Among these 500 records, 7 (1.4%) instances of potential indirect identifiers were identified and corrected before model inference. No direct identifiers were detected in the sampled records.

Model queries were transmitted through encrypted API calls (HTTPS/TLS) rather than public chat interfaces. Although no formal data processing agreement was established with the external provider, the institutional review board explicitly approved the use of deidentified clinical narratives for inference on external LLM servers. It was assured that the procedure complied with local data governance regulations and did not include identifiable personal information. Only deidentified free text—without metadata, patient identifiers, or institutional information—was transmitted, and no protected health information left the institution.

The study adhered to relevant international and domestic privacy frameworks, including General Data Protection Regulation Article 46 for cross-border data transfer, China's Personal Information Protection Law, and ISO/IEC 27018 guidelines for the protection of personal data in public cloud environments. Nevertheless, we acknowledge that narrative EHR text has inherent deidentification limitations, and we minimized data transmission to mitigate privacy risks.

Data Preprocessing

To closely replicate real-world clinical settings, the admission diagnosis names were removed from the medical history; no other data were modified, thereby preserving the integrity of the original data [18]. The diagnoses were classified into 11 categories by extracting only the first letter and the 10-digit *ICD-10* codes from Chapter V (Mental and Behavioral Disorders; F0-F9) and other related codes. Specifically, F0 includes organic mental disorders such as dementia; F1 includes substance-related disorders such as alcohol addiction; F2 includes schizophrenia and associated psychotic conditions; F3 includes mood disorders such as depression; F4 includes anxiety and stress-related disorders; F5 includes disorders associated with physiological conditions, such as eating disorders; F6 includes personality and behavioral disorders in adults; F7 includes intellectual disabilities; F8 includes developmental disorders such as autism; and F9 includes behavioral and emotional conditions beginning in childhood, including attention-deficit or hyperactivity disorders [19]. For subgroup analysis, patients were stratified into 4 age groups: adolescents (≤17 years), young adults (18-35 years), middle-aged adults (36-59 years), and older adult individuals (≥60 years). The thresholds at 18 and 60 years follow established conventions in psychiatric and geriatric research [20]. The adult group was further subdivided into young and middle-aged categories to capture differences in onset age, symptom presentation, and comorbidity patterns of major psychiatric disorders across life stages.

Research Tools and Model Setup

In total, 3 LLMs were selected for evaluation: GPT-4.0 and GPT-3.5 (OpenAI) and GLM-4-Plus (Zhipu AI). GPT-3.5 was chosen as a widely used baseline model because of its broad accessibility and extensive application in previous medical natural language processing tasks, providing a reference point for evaluation [21]. GPT-4.0, a more advanced successor in the GPT series, was included to assess performance improvements driven by enhanced semantic understanding and reasoning capabilities [22]. GLM-4-Plus is one of the most advanced Chinese-optimized LLMs [23]. It was selected to examine the adaptability and potential of domestic LLMs in psychiatric diagnosis using Chinese-language EHRs and to compare their performance with that of international mainstream models under localized application scenarios.

In addition, a unified prompt was used: "请根据以下患者信息给出最可能的诊断。" ("Please provide the most likely diagnosis based on the following patient information"). Because the clinical input consisted of Chinese-language EHR narratives, the instruction prompt was also written in Chinese to maintain monolingual consistency and avoid potential cross-lingual prompting effects. This prompt was intentionally selected to ensure methodological consistency and fair comparability across all LLMs, as varying prompt strategies may introduce

XSL•FO
RenderX

model-specific advantages. Zero-shot prompts also reflect a realistic clinical scenario in which clinicians typically expect the model to provide a diagnostic impression directly without additional examples. No English prompt or mixed-language prompt was used at any stage. No prompt engineering or chain-of-thought prompting was applied, as the study aimed to evaluate each model's baseline diagnostic capability under identical input conditions. The preprocessed data included the patient's sex, age, chief complaints, medical history, and psychiatric examination results. The psychiatric examination results included narrative descriptions of key mental status domains, such as appearance and behavior, mood and affect, thought process and content, cognitive function, and insight, which were documented in a standardized format across all participating centers to ensure structural consistency and data comparability. These inputs were provided to the model to generate diagnostic results. All diagnostic analyses by the LLMs were completed between January 1 and January 31, 2025. The discharge diagnosis served as the reference standard and was confirmed by a senior associate chief physician with over 10 years of clinical experience.

Model outputs were evaluated using a 0-2 point scoring system: 2 points for a completely correct diagnosis (exact *ICD-10* match), 1 point for a partially correct diagnosis, and 0 points for an incorrect diagnosis. "Partially correct" was operationally defined as cases in which the predicted diagnosis was clinically close to, but not an exact, *ICD-10* match. Examples included (1) misclassification within the schizophrenia spectrum (eg, schizotypal disorder scored as schizophrenia), (2) assigning a broader category within mood disorders without specifying the exact episode (eg, manic episode scored as mood disorder), or (3) capturing the correct diagnostic domain at a broader level of granularity (eg, generalized anxiety disorder scored as anxiety disorder). Predictions that did not meet these criteria were considered incorrect.

To ensure reliability and minimize bias, multiple 2-rater groups were formed, each comprising 2 attending psychiatrists with more than 5 years of independent clinical experience. Both raters independently scored each case after the model outputs were anonymized and randomized, which blinded them to the source model. Disagreements were resolved by consensus with a senior psychiatrist. Interrater reliability was assessed using Cohen κ coefficient, which demonstrated substantial agreement (Cohen κ=0.82).

Data Analysis

Statistical analyses were conducted using SPSS Statistics (version 27.0; IBM Corp). Descriptive statistics were used to present the demographic characteristics and distributions of disease categories. Model performance was evaluated by comparing the predicted diagnoses with the discharge diagnoses, which served as the reference standard. Accuracy was calculated as the proportion of correct predictions (score=2). In this study, strict evaluation criteria were used as the primary analytic framework. Under this explicit definition, only exact matches between the model-predicted *ICD-10* diagnosis and the discharge diagnosis (score=2) were considered correct, whereas partially correct predictions (score=1) were treated as incorrect.

For the classification performance metrics—namely, precision, recall, and F_1-score—we also applied a lenient evaluation. Under this lenient definition, both exact matches (score=2) and partially correct predictions (score=1) were treated as correct and counted as true positives (TPs). In this framework, TPs were predictions that were exactly or partially consistent with the true diagnosis (score=2 or score=1); false positives (FPs) were predictions for a class when the true diagnosis belonged to another class; and false negatives (FNs) were cases in which the true diagnosis belonged to a class, but the model prediction did not. Predictions with score=0 were always treated as incorrect. These lenient metrics were used exclusively for the classification performance results and are clearly labeled as such. All other analyses throughout the manuscript relied solely on the strict evaluation criteria. In addition, performance metrics, including precision, recall, and F_1-score, were computed under a strict definition: only exact matches between the model-predicted *ICD-10* diagnosis and the discharge diagnosis were considered correct. In this framework, TPs are cases where the prediction exactly matches the true diagnosis; FPs are predictions for a class when the true diagnosis belongs to another class; and FNs are cases where the true diagnosis belongs to a class, but the model prediction does not. Partially correct outputs (score=1) were treated as incorrect predictions and classified as FPs or FNs depending on the prediction-reference mismatch; only score=2 outputs were counted as TPs.

The macro- and weighted-average F_1-scores were calculated to measure overall performance. Because the F8 category contained only 8 cases (0.1% of the dataset), macroaverage F_1-scores were additionally reported, both including and excluding this extremely rare category, to provide a more stable estimate of overall performance. Tests of normality and homogeneity of variance were conducted. The Shapiro-Wilk test indicated that the score data significantly deviated from normality across all model groups, and the Levene test confirmed unequal variances (Table S1 in Multimedia Appendix 1). Therefore, nonparametric rank-sum tests were applied for intergroup comparisons. In addition, Kruskal-Wallis tests were used to examine whether diagnostic accuracy differed across the 6 centers for each model (Table S2 in Multimedia Appendix 1). A P value of <.05 indicated significance. To further compare diagnostic performance across LLMs, an ordinal logistic regression analysis was conducted. Because the diagnostic outcome was an ordered 0-2 score (0=incorrect, 1=partially correct, and 2=correct), a proportional odds model was applied to estimate the likelihood of achieving a higher diagnostic score for each model. GPT-3.5 served as the reference category. Odds ratios (ORs) and 95% CIs were calculated to quantify differences in diagnostic performance. The results of this analysis are presented in Table S3 in Multimedia Appendix 1.

Results

Demographic Characteristics and Disease Category Distribution

In total, 9923 patients (3665, 36.93% males and 6258, 63.07% females) were included in this study. Across age groups, 1881 (18.96%) were adolescents (≤17 years), 2468 (24.87%) were

XSL•FO
RenderX

young adults (18-35 years), 3695 (37.24%) were middle-aged adults (36-59 years), and 1879 (18.94%) were older adults (≥60 years). The disease categories were distributed as follows (Table 1): mood disorders (F3) were the most common, accounting for 36.7% (3646/9923) of the cases, followed by schizophrenia, schizotypal, and delusional disorders (F2, 2470/9923, 24.9%), and neurotic disorders (F4, 1991/9923, 20.1%). The distribution of other disorders was relatively low.

Table 1. Demographic data and clinical characteristics.

Characteristics	Value
Sex, n (%)	
Male	3665 (36.93)
Female	6258 (63.07)
Age (y), mean (SD)	40.5 (20.03)
Age category, n (%)	
Adolescent (≤17 y)	1881 (19)
Young adult (18-35 y)	2468 (24.9)
Middle-aged (36-59 y)	3695 (37.2)
Older adult (≥60 y)	1879 (18.9)
Disorder category, n (%)	
F0 (Organic disorders)	597 (6)
F1 (Substance use disorders)	243 (2)
F2 (Schizophrenia, schizotypal, and delusional disorders)	2470 (24.9)
F3 (Mood disorders)	3646 (36.7)
F4 (Neurotic disorders)	1991 (20.1)
F5 (Eating disorders, etc)	70 (0.7)
F6 (Personality disorders)	86 (0.9)
F7 (Mental retardation)	177 (1.8)
F8 (Autism, etc)	8 (0.1)
F9 (Behavioral disorders)	635 (6.4)

Diagnostic Accuracy of the 3 Models

Overall, GPT-4.0 achieved an overall accuracy of 71.7%, outperforming GLM-4-Plus (69.3%) and GPT-3.5 (68.8%). In terms of category-specific performance, GPT-4.0 exhibited higher overall accuracy than the other models in the F1, F3, and F6 categories. However, in the F2 and F4 categories, the diagnostic accuracy rates of the 3 models were similar, with no significant differences. Among the different age groups, diagnostic accuracy was higher in the older adult group (with an overall accuracy rate of 74.3%-79.5%). Additional analysis using the rank-sum test revealed significant differences between adolescents and middle-aged adults, adolescents and older adults, young adults and middle-aged adults, and young adults and older adults (P<.001). The results are summarized in Tables 2 and 3, and the category-level diagnostic score patterns across the 3 models are visualized in Figure 1.

Figure 1. Heatmap of the diagnostic scores. The color intensity indicates the model's diagnostic score (on a 2-point scale), with darker colors indicating higher scores. This reflects the diagnostic accuracy of the models in each category.

Center-Level Diagnostic Performance

To evaluate whether model performance varied across institutions, a supplementary center-level analysis was conducted. The diagnostic accuracies of all 3 models demonstrated only minor numerical fluctuations across the 6 centers. Importantly, the Kruskal-Wallis test indicated no statistically significant differences for any of the models (GPT-4.0: P=.52; GPT-3.5: P=.47; and GLM-4-Plus: P=.61). The detailed results for each center are provided in Table S2 in Multimedia Appendix 1.

Analysis of Differences in Scoring Distribution of 3 Models

The rank-sum test was used to compare differences in the scoring distributions of GPT-4.0, GPT-3.5, and GLM-4-Plus across various *ICD-10* categories. We observed that GPT-4.0 had higher scores than GPT-3.5 in the F0 (P<.001), F6 (P<.001), and F7 (P<.001) categories. Furthermore, GLM-4-Plus exhibited differences in its scoring distribution compared with GPT-3.5 in the F0 (P<.001) and F7 (P<.001) categories. Overall, the score distribution of GPT-4.0 was superior to that of both GPT-3.5 (P<.001) and GLM-4-Plus (P<.001). However, the difference in the scoring distribution between GPT-3.5 and GLM-4-Plus was not statistically significant (P=.09). Table 4 summarizes the results.

F7	<.001	.63	<.001
F8	.38	.17	.59
F9	.65	.72	.42
Total	<.001	<.001	.09

Comparison of the Classification Performance of 3 Models

Table 5 summarizes the precision, recall, and F_1-scores of the GPT-4.0, GPT-3.5, and GLM-4-Plus models across various *ICD-10* disease categories. To enhance interpretability, these classification metrics were computed using a lenient evaluation framework, in which both exact matches (score=2) and partially correct predictions (score=1) were treated as correct. GPT-4.0 achieved the highest F_1-scores in the F0 (0.915), F1 (0.926), and F2 (0.929) categories. GLM-4-Plus achieved the highest precision in the F2 category (0.951), whereas GPT-4.0 had a superior recall rate (0.959). Small-sample categories exhibited significant fluctuations, including the F8 category, where GPT-4.0's recall rate reached 1.00, while its precision was only 0.308. This phenomenon reflects class imbalance and overprediction in rare categories. The macroaverage F_1-scores (including F8) were 0.655, 0.410, and 0.712 for GPT-4.0, GPT-3.5, and GLM-4-Plus, respectively. The weighted average F_1-score of GPT-4.0 (0.881) was superior to that of both GPT-3.5 (0.849) and GLM-4-Plus (0.873). To mitigate the instability caused by the extremely small F8 category, macroaverage F_1-scores were also calculated after excluding F8. The exclusion yielded more stable macrolevel estimates: 0.821 for GPT-4.0, 0.745 for GPT-3.5, and 0.806 for GLM-4-Plus.

To further complement this evaluation, we also performed an ordinal logistic regression analysis using the 0-2 scoring system (0=incorrect, 1=partially correct, and 2=correct) as the outcome variable, accounting for its ordinal nature. The results were consistent with the overall performance patterns observed in the main analysis. GPT-4.0 was significantly more likely to achieve a higher diagnostic score compared with GPT-3.5 (OR 1.18, 95% CI 1.11-1.25; *P*<.001). In contrast, GLM-4-Plus showed slightly lower odds of achieving a higher score relative to GPT-3.5 (OR 0.95, 95% CI 0.90-1.01). Although this difference did not reach statistical significance (*P*=.09; Table S3 in Multimedia Appendix 1).

F5	0.549	0.714	0.621	0.519	0.586	0.550	0.785	0.607	0.685
F6	0.554	0.721	0.626	0.405	0.372	0.388	0.750	0.409	0.529
F7	0.973	0.819	0.890	0.979	0.525	0.684	0.820	0.913	0.864
F8	0.308	1.000	0.471	0.159	0.875	0.269	0.667	0.500	0.571
F9	0.962	0.592	0.733	0.971	0.589	0.733	0.576	0.960	0.720
Macro average	0.653	0.701	0.655	0.436	0.428	0.410	0.730	0.717	0.712
Macro average (excluding F8)	—[b]	—	0.821	—	—	0.745	—	—	0.806
Weighted average	0.888	0.882	0.881	0.859	0.851	0.849	0.882	0.871	0.873

[a]A lenient evaluation framework was used for all metrics in this table. Both score=2 (exact match) and score=1 (partially correct) predictions were considered as correct.

[b]Not applicable.

Discussion

Principal Findings

This multicenter real-world study is the first to systematically evaluate the diagnostic performance of 3 LLMs—GPT-4.0, GPT-3.5, and GLM-4-Plus—across the full spectrum of *ICD-10* psychiatric categories via Chinese psychiatric EHRs. The results demonstrate that GPT-4.0 achieved the highest overall strict diagnostic accuracy (71.7%), followed by GLM-4-Plus (69.3%) and GPT-3.5 (68.8%), showing a clear performance gradient across model generations. In addition to strict accuracy, GPT-4.0 also achieved a higher lenient F_1-score (0.881), indicating performance when partially correct predictions are counted as correct. These complementary metrics highlight different aspects of diagnostic ability under distinct evaluation frameworks.

Consistent with these findings, the ordinal logistic regression provided a quantitative estimate of these differences: GPT-4.0 was significantly more likely to achieve a higher diagnostic score compared with GPT-3.5 (OR 1.18, 95% CI 1.11-1.25; P<.001). In contrast, GLM-4-Plus demonstrated ORs comparable with those of GPT-3.5 (OR 0.95, 95% CI 0.90-1.01), indicating no statistically significant difference in performance between the 2 models. These results further support the interpretation that GPT-4.0 provides a measurable performance advantage, whereas GLM-4-Plus and GPT-3.5 exhibit broadly similar diagnostic capability.

Significant differences were observed across most age groups, with diagnostic accuracy generally increasing with age. Older adult patients exhibited notably better diagnostic performance than adolescents and young adults. For GPT-4.0 and GLM-4-Plus, all pairwise adjacent age-group comparisons were statistically significant (all P<.001). For GPT-3.5, accuracy also increased with age overall; however, the comparison between middle-aged and older adult patients did not reach statistical significance (P=.15). This trend likely reflects several clinical and documentation-related factors: older adults typically present with more stable symptom trajectories, longer disease histories, and more structured and complete EHR documentation, whereas younger patients often exhibit heterogeneous and fluctuating emotional and behavioral symptoms, which increase diagnostic uncertainty.

Across diagnostic categories, GPT-4.0 consistently showed stronger contextual reasoning ability and more accurate extraction of relevant diagnostic cues. It performed particularly well in mood disorders (F3), personality disorders (F6), and several neurotic and stress-related disorders (F4). GLM-4-Plus demonstrated strong performance in schizophrenia spectrum disorders (F2), suggesting an advantage in identifying disorders with clearly structured symptom patterns. GPT-3.5 exhibited the highest rate of misclassification, particularly between disorders with overlapping emotional or behavioral symptoms.

In low-prevalence categories, such as pervasive developmental disorders (F8), all 3 models showed instability in performance. GPT-4.0 achieved perfect recall but exhibited low precision, suggesting overidentification in categories with limited diagnostic cues. These patterns highlight the ongoing challenge

XSL•FO
RenderX

for general-purpose LLMs in identifying rare psychiatric conditions.

Beyond model comparison, this study demonstrates the overall feasibility of applying large-scale language models to real-world psychiatric EHRs covering all *ICD-10* categories. The results indicate that GPT-4.0 can extract diagnostically relevant information efficiently and generate multidimensional diagnostic suggestions, thereby supporting initial clinical screening, reducing physician workload, and improving efficiency in high-volume psychiatric settings. However, LLM-based diagnosis remains dependent on the quality of EHRs, symptom clarity, and physician interpretation, and cannot be used as a substitute for clinical expertise or individualized assessment.

Overall, GPT-4.0 demonstrated the strongest, most stable, and most clinically meaningful diagnostic performance across age groups and psychiatric categories, supporting its potential value as a diagnostic assistance tool within real-world psychiatric workflows.

Center-Level Consistency and Its Implications

Although the 6 centers differed in documentation habits, patient demographics, and narrative styles, all 3 LLMs demonstrated stable diagnostic performance across sites. This consistency suggests that the models rely primarily on core clinical symptom patterns rather than center-specific narrative conventions, which may explain their robustness in real-world settings. The absence of center-level variability also indicates that LLM-based diagnostic support may generalize well across institutions with heterogeneous clinical workflows—a critical requirement for real-world deployment. From an implementation perspective, these findings imply that LLM-assisted diagnostic tools may not require site-specific retraining or local optimization, substantially reducing the technical and operational burden associated with clinical adoption. Collectively, these observations highlight the scalability and practical utility of LLMs in psychiatric diagnostic workflows.

Misclassification Patterns in the F8 Category

The extreme imbalance between recall and precision in the F8 category warrants further clinical interpretation. Although GPT-4.0 successfully identified all true F8 cases, its low precision indicates a substantial number of FP predictions. Upon reviewing these cases, we found that most FPs originated from F9 (behavioral and attention-deficit/hyperactivity disorder–related disorders), with a smaller proportion from F7 (intellectual disabilities). These diagnostic groups share overlapping behavioral and neurodevelopmental characteristics with F8—including impulsivity, irritability, social dysfunction, and developmental impairment—which may lead the model to rely on broad behavioral descriptors when more specific differentiating features are not explicitly documented in the narrative EHR. This overdiagnosis pattern suggests that GPT-4.0 is sensitive to general behavioral dysregulation but is less effective in distinguishing between rare neurodevelopmental disorders with partially overlapping phenotypes. Understanding this tendency toward misclassification is essential for evaluating the model's safety profile when applied to clinically rare categories.

Comparison With Previous Work

The superior diagnostic performance of GPT-4.0 observed in this study is consistent with previous evaluations, which report that newer-generation LLMs outperform earlier versions in clinical reasoning tasks [24-26]. This performance advantage has been attributed to the enhanced ability of GPT-4.0 to capture semantic associations and long-range contextual patterns in complex textual inputs [27]. Previous studies have demonstrated that GPT-4.0 provides higher diagnostic accuracy, better contextual understanding, and more stable reasoning patterns than does GPT-3.5 across diverse clinical applications. Our findings extend this body of evidence to the domain of psychiatric diagnosis via Chinese-language EHRs in real-world settings.

A major distinction between our study and earlier work is the use of multicenter real-world psychiatric EHR narratives rather than simulated vignettes or single-institution datasets. The complexity and variability of real-world clinical documentation allow for a more realistic assessment of LLM behavior in routine psychiatric practice, thereby providing stronger ecological validity.

Consistent with the broader literature, earlier-generation models, such as the GPT-3.5, tend to perform less reliably in disorders characterized by overlapping emotional or behavioral symptoms [24-26]. In our study, this general pattern was reflected in GPT-3.5's tendency to misclassify personality disorders (F6) as mood disorders (F3), likely due to the similarity and ambiguity of symptom descriptions in these categories within real-world psychiatric EHRs. This observation aligns with the known challenges faced by earlier LLMs in distinguishing clinically overlapping symptom domains. In contrast, GLM-4-Plus demonstrated strong performance in schizophrenia spectrum disorders (F2), suggesting that models trained on Chinese corpus characteristics may perform well in categories with clear and structured symptom patterns.

Beyond diagnostic accuracy, prior studies have highlighted the potential role of LLMs as clinical decision support tools capable of improving workflow efficiency and reducing clinician workload in real-world health care settings [28]. In psychiatry, recent evaluations have summarized the diagnostic accuracy of LLMs and emphasized their potential utility in assisting clinicians with complex diagnostic decisions [29]. More broadly, advances in deep learning–based electronic health record analytics have demonstrated the feasibility of extracting clinically meaningful information from narrative EHRs to support timely screening and downstream decision-making processes [30].

Taken together, our findings reinforce the performance advantages of GPT-4.0 observed in previous work and highlight the importance of evaluating both international and domestic LLMs in localized, real-world psychiatric contexts.

Limitations

This study has several limitations. First, although we used multicenter real-world psychiatric EHRs, differences in documentation style—including variability in narrative structure, terminology, completeness of information, and implicit

XSL•FO
RenderX

diagnostic cues—may have influenced model performance. These inconsistencies can alter the prominence, clarity, and temporal linkage of symptom descriptions, potentially affecting diagnostic outputs. Broader validation in institutions with diverse linguistic and cultural backgrounds is needed to assess cross-system and cross-national generalizability more fully [31].

Second, this study adopted a single unified prompting strategy to ensure consistent comparability across models. However, previous research has shown that more advanced prompting techniques can improve diagnostic reasoning. For example, Savage et al [32] reported that diagnostic reasoning prompts enhance LLMs' ability to emulate stepwise clinical reasoning compared with standard prompts. In our setting, a small exploratory pilot study using chain-of-thought prompts on 200 randomly selected cases suggested a modest improvement in exact-match accuracy (about 2-3 percentage points), particularly for mood and anxiety disorder categories. Although this was not a full comparative experiment, the results suggest that the prompting strategy may influence diagnostic performance. Future studies should systematically evaluate zero-shot, few-shot, and chain-of-thought prompt approaches across diagnostic categories and age groups.

Third, the study used a single-label classification framework based on primary discharge diagnoses. While this reflects routine clinical practice, it does not capture psychiatric comorbidities, which are common and clinically important. Multilabel diagnostic frameworks may be necessary to better reflect the real-world complexity of diagnosis.

Fourth, our analysis relied on static EHR text and did not incorporate longitudinal or multimodal clinical information. Real-world psychiatric care involves dynamic symptom progression and treatment trajectories, which cannot be fully captured in static narratives. Integrating time series EHR data, imaging, or laboratory results may increase the diagnostic robustness of LLMs [33].

Fifth, the dataset did not include key socioeconomic variables—such as education level, employment or income status, or urban versus rural residence—which limited our ability to examine potential algorithmic bias or fairness across different social strata. These factors can shape health care access, diagnostic pathways, and linguistic characteristics of clinical documentation, and their absence prevented a systematic assessment of whether model performance varied across sociodemographic groups. Future studies incorporating richer socioeconomic status–related demographic information will be essential for evaluating equity in LLM-assisted diagnostic workflows.

Sixth, although admission diagnoses were removed from model inputs, sections, such as the history of present illness, may still include implicit diagnostic tendencies embedded within physicians' narrative styles. To address this concern, we manually reviewed a subset of correctly and incorrectly classified cases to determine whether the model relied on "giveaway" phrases or diagnosis-specific linguistic cues. We did not identify consistent or systematic patterns—such as psychopharmacological keywords, standardized phrasing, or clinician-specific formulations—that uniquely pointed to a specific diagnosis. When such terms occurred (eg, references to antidepressants or antipsychotics), they were typically nonspecific and appeared across multiple diagnostic categories.

However, certain unmasked psychotropic medications—particularly lithium and clozapine, which function as strong diagnostic proxies—may have allowed the models to infer diagnoses through medication extraction rather than full clinical reasoning, potentially inflating accuracy in specific categories. These observations suggest that while soft leakage cannot be entirely eliminated in narrative EHRs, its impact on model performance in this dataset was likely limited. Future studies should consider masking medication names or evaluating model behavior under medication-removed conditions to better isolate true diagnostic reasoning.

In addition, this study has privacy-related limitations. Although all EHR narratives were deidentified before transmission to external LLM servers, narrative clinical text carries inherent challenges for complete anonymization. Despite multiple safeguards, the possibility of residual identifiers cannot be entirely eliminated, and future research should prioritize on-premise or institution-governed LLM deployment to avoid external data transmission fully. Moreover, because the manual deidentification audit was conducted on a sampled subset of 500 records rather than the full dataset, a small risk of undetected residual identifiers cannot be completely excluded.

Furthermore, the study did not include a human benchmark for comparison, such as the diagnostic accuracy of junior clinicians, admitting psychiatrists, or structured admission diagnoses. Without this comparative context, it is difficult to ascertain whether the observed strict accuracy of 71.7% represents a clinically meaningful performance threshold. Future research should incorporate human-model comparison frameworks or prospective reader studies to more clearly establish the clinical utility of LLM-assisted diagnostic workflows.

Finally, although multicenter data improved external validity, further validation through prospective observational designs or randomized controlled trials is necessary to robustly establish the real-world clinical utility of LLMs in psychiatric diagnostic workflows [31].

Future Directions

Future research should expand the diversity of data sources to evaluate the generalizability of LLMs across different health care systems, linguistic environments, and cultural contexts. The incorporation of longitudinal EHR data, time series symptom trajectories, and multimodal clinical information—such as laboratory tests and imaging—may further enhance the ability of LLMs to capture dynamic clinical changes and improve diagnostic robustness.

Furthermore, more sophisticated strategies warrant systematic investigation. Comparative evaluations of zero-shot, few-shot, and chain-of-thought prompts across different psychiatric categories and age groups may help optimize the integration of LLMs into clinical workflows. Future studies should also explore multilabel diagnostic frameworks to capture psychiatric comorbidities better and reflect the complexity of real-world clinical presentations.

XSL•FO
RenderX

Finally, prospective validation—particularly through observational studies or randomized controlled trials—will be essential for establishing the real-world clinical utility, reliability, and safety of LLM-assisted diagnostic tools in psychiatric practice.

Conclusions

This multicenter real-world study systematically evaluated the diagnostic performance of the GPT-4.0, GPT-3.5, and GLM-4-Plus across all *ICD-10* psychiatric categories using Chinese psychiatric EHRs. GPT-4.0 demonstrated the strongest and most stable diagnostic performance in this study across age groups and diagnostic categories and showed clear advantages in interpreting complex psychiatric narratives. All models performed less reliably in low-prevalence categories, and diagnostic accuracy varied substantially across age groups, with lower accuracy observed in adolescents and young adults.

These findings confirm the feasibility of applying LLMs to real-world psychiatric EHRs and highlight the potential value of GPT-4.0 as a diagnostic support tool. However, the diagnostic outputs of LLMs remain constrained by the quality of documentation, symptom clarity, and the limitations of the models. LLMs should therefore be viewed as complementary tools that can assist clinicians but cannot replace clinical expertise, individualized assessment, or professional decision-making in psychiatric practice.

Abstract

Background: Effective postdischarge management is essential for maintaining disease control and improving long-term outcomes in rheumatoid arthritis (RA). Digital health technologies, particularly intelligent management platforms, provide new opportunities for continuous care and self-management in real-world settings.

Objective: This study aimed to develop a nurse-led artificial intelligence (AI)–assisted interactive management platform for postdischarge RA care and examine its association with patient outcomes in a real-world clinical setting.

Methods: A single-center, multicampus, real-world observational study with a quasi-experimental framework was conducted at Tongji Hospital between November 2024 and October 2025. Participants were allocated to either a platform-based management group (campus 1; n=184) or a comparison group receiving routine postdischarge care (campus 2; n=157). The platform enabled remote monitoring through a smartphone app, which collected information on joint symptoms, fatigue, medication adherence, laboratory results, and emotional status, with data uploaded to a secure cloud server. The AI system analyzed data in real time and alerted health care providers to abnormalities. Nurses and health coaches delivered personalized education and interventions. Primary outcomes were changes in Disease Activity Score in 28 Joints and Health Assessment Questionnaire–II scores at discharge and the 6-month follow-up. Secondary outcomes included medication adherence measured as the proportion of prescribed doses taken and patient satisfaction assessed via a 5-point Likert-scale questionnaire at 6 months.

Results: A total of 341 patients with RA completed the 6-month follow-up. Disease Activity Score in 28 Joints values decreased significantly in the platform-based management group at 6 months (mean 5.04, SD 1.38 at discharge to mean 4.27, SD 1.20 at 6 months; P<.001), showing a greater reduction than in the comparison group (mean 4.86, SD 1.19 at discharge to mean 4.59, SD 1.36 at 6 months; within-group P=.03; between-group P=.02). Health Assessment Questionnaire–II scores improved significantly in the platform-based management group (mean 2.45, SD 0.75 at discharge to mean 1.67, SD 0.56 at 6 months; P<.001), while the comparison group showed no significant change (P=.12; between-group P<.001). Medication adherence was higher in the platform-based group (166/184, 90.2% vs 125/157, 79.6%; χ_1^2=7.6; P=.006). Overall health care satisfaction was also higher in the platform-based group (176/184, 95.7% vs 120/157, 76.4%; χ_1^2=27.8; P<.001), with a greater proportion reporting to be “very satisfied” in this group (150/184, 81.5% vs 59/157, 37.6%).

Conclusions: The intelligent interactive management platform markedly enhanced disease control, functional status, medication adherence, and satisfaction among patients with RA after discharge. This nurse-led, AI-assisted system represents a promising model for improving outpatient RA management.

KEYWORDS

rheumatoid arthritis; intelligent interactive platform; disease activity; medication adherence; patient satisfaction; artificial intelligence; AI

Introduction

Rheumatoid arthritis (RA) is a chronic systemic autoimmune disease with a global prevalence of approximately 1% to 2% [1]. It predominantly affects middle-aged and older adults, with higher prevalence among women aged 40 to 60 years [1,2]. RA is frequently complicated by extra-articular manifestations, including cardiovascular disease, pulmonary dysfunction, neurological involvement, gastrointestinal disturbances, and malnutrition [3]. Although no curative therapy exists, timely and standardized treatment can effectively control disease activity, relieve symptoms, and delay disability [4]. Long-term management commonly involves pharmacological therapy, intra-articular injections, physical rehabilitation, regular follow-up visits, and surgical intervention when indicated [5]. Nevertheless, despite ongoing treatment, many patients experience varying degrees of joint deformity and functional impairment, substantially limiting their daily activities and compromising overall well-being [6].

Given the chronic and progressive nature of RA, effective self-management is essential for maintaining patients' quality of life and delaying disease progression [7]. Conventional nursing models primarily focus on inpatient care, whereas postdischarge management often relies heavily on patient self-management, leading to suboptimal outcomes [8]. Successful RA management requires patients to develop both the confidence and the necessary skills to manage their condition independently [9]. Key components of self-management include self-monitoring of symptoms and disease flares, setting achievable goals, adopting behavioral modifications, adhering to medication, adjusting physical activity levels, and enhancing problem-solving abilities [3]. Robust self-management practices have been shown to improve adherence, reduce disease activity, and slow progression of RA [10,11]. Therefore, innovative and sustainable strategies are needed to enhance postdischarge self-management and continuity of care.

The rapid proliferation of mobile technologies has transformed health service delivery worldwide [12]. As mobile apps become increasingly embedded in routine activities, the delivery of health care through digital platforms has emerged as an inevitable evolution in line with technological advancement [13]. In the context of RA management, mobile health (mHealth) technologies, including smartphones, wearable devices, and disease-specific apps, are playing an increasingly pivotal role [12,14]. These tools enable real-time health data collection, thereby facilitating early detection of disease fluctuations. They empower both patients and health professionals by enhancing disease monitoring, improving medication adherence, and enhancing timely personalized interventions [15]. Such innovations improve the efficiency of disease management by reducing unnecessary hospital visits and optimizing health care resource allocation. Furthermore, instant feedback mechanisms reinforce patients' self-management capabilities and promote active engagement in their own care [16].

Building on our institution's "internet hospital" infrastructure and standardized RA management protocols, we developed an intelligent, nurse-led interactive management platform to support postdischarge care for patients with RA. This study aimed to evaluate the real-world effectiveness of this platform by comparing patients managed through platform-based follow-up to those receiving routine postdischarge care across different hospital campuses under unified clinical standards.

Methods

Study Design and Population

This study used a single-center, multicampus observational design with a quasi-experimental framework conducted at the Department of Rheumatology and Immunology, Tongji Hospital, between November 2024 and October 2025. Tongji Hospital consists of multiple hospital campuses operating under unified clinical guidelines and standardized treatment protocols for RA. An intelligent interactive follow-up platform was first implemented at campus 1 as part of routine postdischarge care, whereas campus 2 had not yet adopted the platform at the time of the study. This natural difference in platform availability allowed for the formation of a platform-based management group (campus 1) and a comparison group receiving usual postdischarge care (campus 2) without individual-level assignment by the research team. Eligible participants were adults (aged ≥18 years) diagnosed with RA according to the 2010 American College of Rheumatology and European Alliance of Associations for Rheumatology classification criteria, receiving standardized RA therapy, and capable of using a smartphone or having a caregiver assist with platform access. Exclusion criteria included inability to comply with follow-up, severe psychiatric or cognitive disorders, visual or hearing impairment precluding platform use, severe systemic comorbidities (eg, advanced cardiac, hepatic, or renal disease), or discontinuation of RA treatment during the follow-up period.

Group Allocation and Blinding

Participants were allocated to study groups based on hospital campus rather than through randomization. Patients discharged from campus 1 were included in the platform-based management group, whereas those discharged from campus 2 constituted the comparison group receiving routine postdischarge care. This campus-based allocation reflected real-world clinical implementation and helped avoid ethical concerns related to unequal access to a newly introduced digital management platform. Given the nature of the platform-based management model, blinding of patients and health care providers was not feasible. However, outcome assessors and data analysts were blinded to group allocation to reduce assessment and analysis bias.

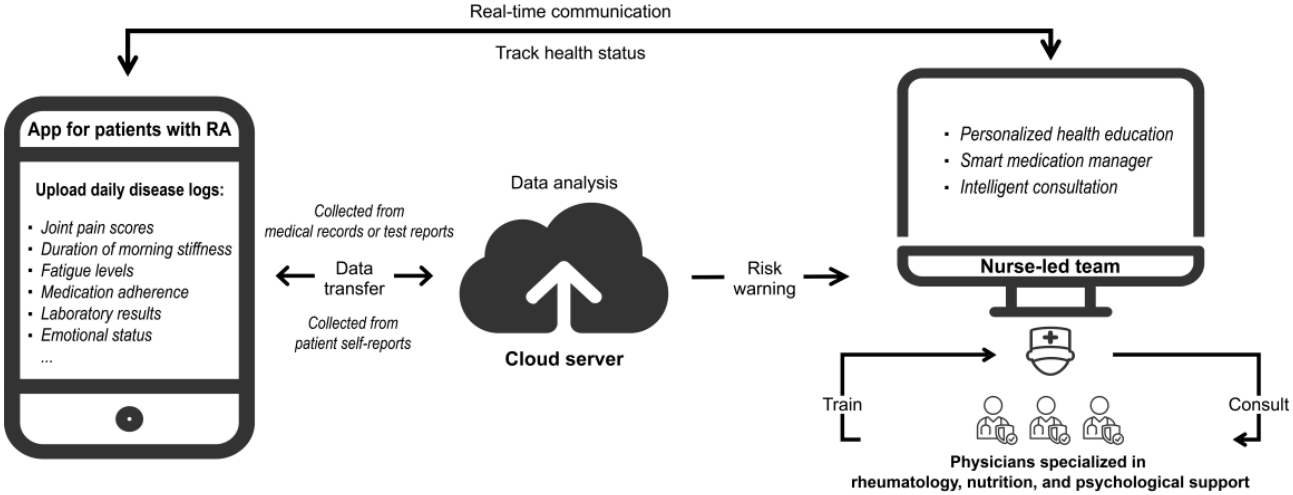
RenderX

Technical Design and Platform-Based Management Model

Platform Overview

The intelligent interactive platform for RA is a multidisciplinary, nurse-led, and patient-centered digital health management system established within the smart health care ecosystem of Tongji Hospital. Designed to enhance routine outpatient care, the platform incorporates artificial intelligence (AI) and is operated by a specialized team of rheumatology nurses, with additional support from health coaches trained in rheumatology, nutrition, and psychological support.



The primary objective of the platform is to extend continuous care beyond hospital discharge. Timely responses to self-reported symptoms and system-generated alerts support individualized guidance and facilitate timely clinical decision-making during routine follow-up. It also facilitates complication monitoring, self-care education, and psychological support, helping patients manage their condition more effectively during home-based recovery. Integrated communication tools ensure that patients have continuous access to their care team.

Technical Architecture and Core Functions

Overview

The platform was developed collaboratively by the hospital's Information Center and technology partners. Its architecture comprises 3 core components: a patient-facing mobile app, a web-based dashboard for nurses and health coaches, and a cloud-based AI data processing system (Figure 1).

Figure 1. Framework of the intelligent interactive platform for rheumatoid arthritis (RA).

Data Input and Processing

Patients use the mobile app to submit health logs either daily or as needed based on their symptom fluctuations. These logs include joint pain scores measured using a visual analog scale from 1 to 100, duration of morning stiffness, fatigue levels, medication adherence, laboratory results, emotional status, and sleep quality. While the "Smart Medication Manager" provides automated daily notifications for drug intake, other health logs are recorded voluntarily by patients without daily reminders to avoid excessive burden. All data are securely encrypted and transmitted to the cloud server. For image-based data, such as medical records or test reports, a deep learning–based optical character recognition system automatically extracts key information, which is manually verified and structured into the database.

AI-Driven Clinical Decision Support

An embedded AI engine continuously analyzes patient data in real time. Unlike traditional rule-based systems that rely on static, predefined thresholds, our AI engine uses a multilayered approach. A deep learning–based optical character recognition system processes unstructured data from patient-uploaded images (eg, external laboratory reports). In addition, the engine uses longitudinal data processing to monitor trends in disease activity and medication adherence over time. When abnormalities are detected, such as elevated disease activity, decreased medication adherence, or signs of relapse, the system immediately generates alerts for the clinical care team through the dashboard even if individual parameters have not yet exceeded traditional laboratory triggers. Nurses and health coaches can then respond promptly via the app, providing timely follow-up support and facilitating triage for further outpatient or inpatient care if necessary (Multimedia Appendix 1).

Personalized Education and Self-Management Support

Beyond reactive support, the platform provides proactive, personalized health education. On the basis of individual patient assessments and preferences, the care team delivers guidance on diet, exercise, and psychological well-being. This is facilitated by an integrated intelligent education module that pushes customized content to patients (Multimedia Appendix 2). A "Smart Medication Manager" feature allows patients to log their prescribed oral medications and receive automated reminders to enhance adherence (Multimedia Appendix 3). Furthermore, an "Intelligent Consultation" module serves as a knowledge base for frequently asked questions related to RA care, covering topics such as appointments, insurance, follow-ups, and common rheumatological concerns, thereby improving accessibility and potentially reducing unnecessary clinic visits (Multimedia Appendix 4).

XSL•FO
RenderX

Pilot Feasibility Assessment

Prior to the main study, an internal, unpublished pilot test was conducted to evaluate the platform's feasibility and support its user-centered design. The pilot involved 25 patients with RA over a 4-week period. During this phase, the platform demonstrated high levels of engagement. Specifically, the patient self-assessment completion rate rose from 68.0% (17/25) to 88.0% (22/25). To ensure that the intervention was not solely investigator driven, we collected qualitative feedback from participants via telephone interviews and structured satisfaction surveys. Users identified several areas for improvement, such as the need for a more intuitive user interface for joint symptom logging and more flexible medication reminder settings. On the basis of the feedback, the platform underwent iterative refinements, including optimizing user interface responsiveness and streamlining the data entry process before the formal study commenced. While traditional clinical measures such as inflammatory markers and disease activity scores did not show statistically significant changes in the short-term pilot, promising improvements were observed in behavioral outcomes, including follow-up completion rates, platform log-in frequency, and consultation response times, indicating good usability and feasibility for real-world implementation.

Data Collection and Study Procedure

Between November 7, 2024, and April 20, 2025, eligible patients with RA who were clinically stable and scheduled for discharge were consecutively recruited. Baseline data were collected prior to discharge. Participants were allocated to study groups based on hospital campus, reflecting routine clinical implementation of the intelligent interactive platform. All participants were followed up on for 6 months after enrollment, and the final follow-up assessment was completed on October 20, 2025.

During hospitalization, patients in both groups received standardized nursing care and health education in accordance with unified clinical protocols across campuses. This included RA-related disease education, psychological support, medication management, symptom monitoring, rehabilitation guidance, complication prevention, routine follow-up planning, and discharge counseling.

After discharge, patients in the comparison group received routine postdischarge follow-up care, which consisted of periodic assessments of disease status, emotional well-being, medication adherence, and rehabilitation activities. Follow-up was conducted using conventional approaches, including scheduled outpatient visits, telephone consultations, or home visits, during which health care professionals provided individualized guidance and addressed patient concerns as needed.

In addition to routine care, patients in the platform-based management group were supported through the platform. One to 2 days prior to discharge, designated rheumatology nurses introduced the platform to eligible patients using standardized instructions and obtained written informed consent. Nurses then provided individualized, hands-on guidance on platform access, account setup, and creation of a personal health record. Patients were guided through key functional modules to ensure independent use after discharge. For patients without access to a smartphone or those unfamiliar with mobile apps, family members or caregivers were instructed on how to operate the platform on the patient's behalf to support ongoing disease management.

Outcome Measures

Overview

Primary outcomes were disease activity and functional status assessments. Secondary outcomes included medication adherence and health care satisfaction. These outcomes were assessed to examine differences between groups rather than to evaluate causal effects of the platform. Disease activity and functional status were evaluated both at discharge and the 6-month follow-up, whereas secondary outcomes were assessed only at 6 months as many patients were treatment naive at baseline or satisfaction could not be measured until follow-up.

Disease Activity

The Disease Activity Score in 28 Joints (DAS28) was used to assess RA disease activity [17]. It combines a count of 28 swollen and tender joints, a laboratory marker of inflammation (either C-reactive protein or erythrocyte sedimentation rate), and a patient global health assessment. Higher DAS28 scores indicate more severe disease activity.

Functional Status

Functional disability was measured using the Health Assessment Questionnaire–II (HAQ-II) [18]. The HAQ-II is a validated instrument that assesses difficulty in performing activities of daily living across 8 domains (dressing, arising, eating, walking, hygiene, reach, grip, and common activities). It contains 10 items, each scored on a scale from 0 to 3 (0="without difficulty"; 3="unable to do"). The total score is the average of the category scores, with higher scores indicating greater functional impairment. The HAQ-II showed good internal consistency in this study (Cronbach α=0.83), consistent with its original validation (Cronbach α=0.88) [18].

Medication Adherence

Medication adherence was assessed based on participants' self-reported medication intake during the follow-up period. Adherence was operationally defined as the proportion of prescribed doses reportedly taken. Consistent with commonly used adherence definitions in chronic disease management, participants were classified as having good adherence if they reported taking 85% or more of the prescribed medication regimen and poor adherence otherwise [19].

Health Care Satisfaction

Patient satisfaction with care was assessed using a department-developed questionnaire. Responses were recorded on a 5-point Likert scale ("very satisfied," "satisfied," "neutral," "dissatisfied," and "very dissatisfied"). The satisfaction rate was calculated as the percentage of participants reporting being "very satisfied" or "satisfied" among the total respondents. The scale's content validity index was 0.92 as evaluated by a panel of 5 rheumatology experts, and the questionnaire demonstrated good reliability in this study (Cronbach α=0.86).

XSL•FO
RenderX

Data Analysis

Statistical analyses were performed using R (version 4.4.1; R Foundation for Statistical Computing). Continuous variables were described as means and SDs for normally distributed data or medians and IQRs for nonnormally distributed data. Normality was assessed using the Shapiro-Wilk test. Variance homogeneity was evaluated using the Levene test. Between-group comparisons were performed using 2-tailed Student *t* test or Welch *t* test for normally distributed variables and the Mann-Whitney *U* test (Wilcoxon rank-sum test) for nonnormally distributed variables. Categorical variables were compared using the chi-square test or Fisher exact test, as appropriate. All *P* values were 2 sided and are reported as exact values in accordance with JMIR Publications' statistical reporting guidelines.

Ethical Considerations

This study was approved by the Medical Ethics Committee of Tongji Hospital, Tongji Medical College of Huazhong University of Science and Technology (TJ-IRB202411023). The study was conducted in accordance with the Declaration of Helsinki. Participation was voluntary, and written informed consent was obtained from all participants prior to enrollment. Participants retained the right to withdraw from the study at any time without penalty or explanation. All collected data were deidentified and stored securely in compliance with the hospital's scientific research data management standards. Deidentification was performed using a key-encoded system, with reidentification keys securely stored by the study team. No financial incentives were offered to participants. The trial was prospectively registered at the Chinese Clinical Trial Registry (ChiCTR2500115743). This study is reported in accordance with the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guidelines (Checklist 1).

Results

Demographic Characteristics

Between November 7, 2024, and April 20, 2025, a total of 459 patients with RA who met the inclusion criteria were identified at our hospital. Of these 459 patients, 401 (87.4%) consented to participate in the study, including 206 (44.9%) from campus 1 (platform-based management group) and 195 (42.5%) from campus 2 (comparison group). Following baseline assessment, 10.2% (21/206) of the patients from campus 1 and 20.0% (39/195) of the patients from campus 2 were lost to follow-up. The higher retention rate in the platform-based group may reflect the impact of continuous digital engagement. Ultimately, 89.3% (184/206) of the patients from campus 1 and 80.5% (157/195) of the patients from campus 2 completed the 6-month follow-up, resulting in a total of 341 (74.3%) participants included in the final analysis.

The baseline characteristics of the participants are summarized in Table 1. The mean age of the participants was 57.41 (SD 13.45) years in the platform-based management group and 55.47 (SD 13.57) years in the comparison group. Female individuals comprised most of both groups, accounting for 76.1% (140/184) and 78.3% (123/157) in the campus 1 and campus 2 groups, respectively. RA duration was similar between the 2 groups (median 4, IQR 2-12 years vs median 4, IQR 2-10 years). Educational levels, residence, smoking and alcohol consumption, BMI, RA disease duration, comorbidities including hypertension and diabetes, and RA-related complications did not differ significantly between the groups.

[a]Student *t* test. Age: t_{339}=1.321.

[b]Chi-square test.

[c]RA: rheumatoid arthritis.

[d]Mann-Whitney *U* test (Wilcoxon rank-sum test). RA disease duration: *W*=15,003. BMI: *W*=14,695.

[e]Primarily comprising interstitial lung disease, osteoporosis, and femoral head avascular necrosis.

Changes in DAS28 Scores

Changes in disease activity over the 6-month follow-up are shown in Table 2. In the comparison group, the mean DAS28 score decreased from 4.86 (SD 1.19) at discharge to 4.59 (SD 1.36) at 6 months, with a statistically significant within-group change (*P*=.03). In the platform-based management group, the mean DAS28 score decreased from 5.04 (SD 1.38) at discharge to 4.27 (SD 1.20) at 6 months, with a larger within-group change (*P*<.001). Between-group comparison at 6 months indicated a significantly greater reduction in DAS28 scores in the

XSL•FO
RenderX

platform-based management group than in the comparison group (*P*=.02).

Table . Disease Activity Score in 28 Joints values of the participants. t_{339}=–1.293 and *P*=.20 at discharge and t_{339}=2.286 and *P*=.02 at the 6-month follow-up. Disease Activity Score in 28 joints: range 0-9.4; higher scores indicate more activity.

Group	At discharge, mean (SD)	6-month follow-up, mean (SD)	Paired *t* test (*df*)	*P* value
Comparison group	4.86 (1.19)	4.59 (1.36)	2.172 (156)	.03
Platform-based management group	5.04 (1.38)	4.27 (1.20)	7.404 (183)	<.001

Changes in HAQ-II Scores

At discharge, HAQ-II scores were comparable between the comparison group and the platform-based management group (*P*=.79; Table 3). At the 6-month follow-up, the comparison group showed no significant change from baseline (*P*=.12), whereas the platform-based management group exhibited a significant reduction (*P*<.001). Between-group comparison at 6 months indicated a significantly greater improvement in functional status in the platform-based management group than in the comparison group (*P*<.001).

Table . Health Assessment Questionnaire–II scores of the participants. t_{339}=–1.293 and *P*=.20 at discharge and t_{339}=2.286 and *P*=.02 at the 6-month follow-up. Disease Activity Score in 28 joints: range 0-9.4; higher scores indicate more activity.

Group	At discharge, mean (SD)	6-month follow-up, mean (SD)	Paired *t* test (*df*)	*P* value
Comparison group	2.47 (0.60)	2.39 (0.58)	1.565 (156)	.12
Platform-based management group	2.45 (0.75)	1.67 (0.56)	14.529 (183)	<.001

Changes in Medication Adherence

On the basis of the predefined adherence criterion (≥85% of prescribed doses reportedly taken), 90.2% (166/184) of the participants in the platform-based management group exhibited good adherence compared with 79.6% (125/157) in the comparison group (χ_1^2=7.6; *P*=.006) at the 6-month follow-up.

Changes in Health Care Satisfaction

Table 4 presents the health care satisfaction levels of participants in both groups. The overall satisfaction rates were 76.4% (120/157) in the comparison group and 95.7% (176/184) in the platform-based management group (*P*<.001). Notably, a greater proportion of participants in the platform-based management group reported being very satisfied compared to the comparison group (150/184, 81.5% vs 59/157, 37.6%, respectively).

Table . Health care satisfaction of the participants.

Group	Very satisfied, n (%)	Satisfied, n (%)	Neutral, n (%)	Dissatisfied, n (%)	Very dissatisfied, n (%)	Satisfaction rate (participants who were very satisfied or satisfied), n (%)[a]
Comparison group (n=157)	59 (37.6)	61 (38.9)	24 (15.3)	13 (8.3)	0 (0.0)	120 (76.4)
Platform-based management group (n=184)	150 (81.5)	26 (14.1)	5 (2.7)	3 (1.6)	0 (0.0)	176 (95.7)

[a]χ_1^2=27.8; *P*<.001.

Discussion

In this quasi-experimental study conducted in real-world clinical settings, we demonstrated that a nurse-led, AI-assisted intelligent interactive platform significantly improved disease activity, functional status, medication adherence, and satisfaction in patients with RA over a 6-month follow-up period. Specifically, participants in the platform-based management group showed greater reductions in DAS28 scores and more substantial improvements in HAQ-II scores compared with those receiving routine postdischarge care. These findings highlight the potential of digital health interventions to enhance real-world RA management beyond conventional postdischarge care.

Our results align with and expand on evidence from large, multicenter studies showing that digital health apps can contribute to disease control in RA. In a pragmatic randomized clinical trial involving more than 2000 patients with RA, patients using a digital health app to assess patient-reported outcomes had higher rates of achieving a DAS28 based on C-reactive protein score of 3.2 or less at 6 months compared with controls, reflecting improved disease control with digital monitoring and clinician intervention [20]. Additionally, smaller prospective

XSL•FO
RenderX

studies have reported clinically meaningful improvements in disease activity and other patient-reported outcomes following mHealth interventions for patients with inflammatory arthritis, underscoring the potential for mobile platforms to complement standard therapies [21]. There is systematic evidence further suggesting that asynchronous mHealth tools, including smartphone apps, web apps, and SMS text message reminders, are associated with desirable outcomes in RA self-management and health behaviors, although the heterogeneity of existing studies highlights the need for more rigorous designs [22]. Moreover, systematic reviews of digital health interventions for arthritis broadly support the role of these tools in enhancing medication adherence and quality of life, with most randomized controlled trials showing positive contributions of digital health in arthritis populations [23]. Together, these data contextualize our findings and indicate that digital tools, particularly those integrating real-time monitoring and clinician feedback, may improve RA outcomes beyond traditional follow-up models.

The mechanisms underlying observed improvements likely reflect multiple synergistic components of the platform. First, continuous data capture and AI-driven alerts enabled early identification of disease activity fluctuations, facilitating prompt clinical decision-making and adjustment of treatment plans consistent with treat-to-target strategies [24]. Second, personalized patient education modules and self-management support improved disease understanding, reduced anxiety-induced nonadherence, and reinforced positive health behaviors [25,26]. Third, integrated communication tools and nurse-led remote engagement fostered sustained patient-health care team interaction, thereby empowering patients and enhancing self-management [26-28], which are factors strongly associated with improved adherence in chronic disease management models. Collectively, this multimodal approach may underpin the greater improvements in functional status, symptom control, and engagement observed in the platform-based management group.

Importantly, enhanced functional outcomes (as measured using the HAQ-II) in the platform-based management group suggest that early and sustained control of inflammatory activity may translate into preserved musculoskeletal function and reduced disability progression. Remote access to rehabilitation guidance, individualized exercise recommendations, and rehabilitation education likely reduced care barriers for patients with mobility limitations or geographic challenges, expanding continuous care delivery beyond periodic clinic visits [14,25,28]. These effects are consistent with those observed in prior research [13,16] emphasizing the value of remote monitoring and patient engagement in optimizing long-term functional outcomes in chronic musculoskeletal diseases.

The platform significantly improved both medication adherence and patient satisfaction, which is consistent with findings from prior digital health interventions targeting chronic disease management [7,12,28]. Traditional outpatient follow-up is frequently constrained by logistical and geographical barriers, especially in rural or underserved areas, leading to delays in care and reduced compliance [9]. To address these challenges, the platform's integrated "Medication Manager" provided automated medication reminders, individualized dosage guidance, and symptom reporting functions, thereby enabling timely clinical interventions in response to adverse events. Previous studies have provided evidence that such digital tools can decrease medication omissions and enhance treatment persistence in patients with RA and similar chronic conditions [10,23,29]. Moreover, the nurse-led, patient-centered platform empowered patients through shared decision-making, self-monitoring, and goal setting, which contributed to improved self-management. Personalized care plans and ongoing professional support not only reinforced adherence but also enhanced patient and nurse satisfaction with the care process [30,31]. These findings highlight the effectiveness of technology-assisted, nurse-led interventions in promoting satisfaction alongside adherence in remote care [32].

However, several limitations should be acknowledged. The quasi-experimental, campus-based allocation does not fully replicate randomized assignment, although this design reflects real-world implementation and enhances external validity. Participant and provider blinding was not feasible, which might introduce reporting bias; however, outcome assessors and analysts were blinded to mitigate this risk. The high-frequency data collected by the platform, such as daily pain and stiffness scores, were not included in this statistical analysis. Future research should leverage these real-time metrics to better characterize disease trajectories. A notable attrition rate was observed during the 6-month follow-up. Preliminary observations indicated that older patients with limited digital literacy or those with lower treatment compliance were more likely to drop out. These individuals represent a vulnerable population that might benefit the most from digital support but faces significant barriers to technology adoption. The lack of detailed demographics for these participants may limit the generalizability of our results regarding digital health equity. While the 6-month follow-up period was adequate to observe significant clinical improvements, longer follow-up is warranted to evaluate sustained disease control, radiographic progression, long-term disability outcomes, and cost-effectiveness. Future multicenter implementation studies with diverse patient populations, combined with qualitative research to explore user preferences, will be valuable to further validate and optimize digital care strategies for RA.

In conclusion, our study demonstrates that a nurse-led, AI-assisted intelligent interactive platform significantly improved clinical and patient-centered outcomes in postdischarge RA care. By facilitating continuous monitoring, timely clinical action, personalized education, and sustained engagement, this digital intervention offers a scalable model to enhance disease control and patient empowerment in routine rheumatology practice.

Abstract

Background: The increasing reliance on online surveys for collecting patient-reported feedback for health care research has led to growing concerns over fraudulent responses generated by bots. These automated responses threaten data integrity by fabricating survey results, distorting statistical analyses, and potentially misguiding policy decisions. Addressing this issue is critical for maintaining the validity of research findings that inform health care practice and policy.

Objective: This study aimed to develop a robust set of criteria for identifying bot-generated responses in online health care surveys and to examine how these responses impact data quality. We then explored differences in survey results between probable human and suspected bot respondents in a survey assessing patient-reported outcome measures and patient-reported experience measures within a geographic region in Ontario, Canada.

Methods: A survey was conducted from July to October 2023 using Research Electronic Data Capture (REDCap; Vanderbilt University), distributed with a generic link via email, and later shared on social media. The survey collected data on health care use, patient experiences, health outcomes, digital health care engagement, and demographics. A 3-tier classification system was developed to detect bot responses based on predefined "red flags," including duplicate open-ended responses, inconsistent demographic reporting, identical timestamps, and location discrepancies. Quantitative analysis included chi-square tests to assess differences between probable human and suspected bot responses and Spearman correlation tests to examine relationships among health care indicators.

Results:: Analysis included 1154 responses, with 58% (n=668) classified as suspected bot-generated. The most frequent suspected bot-identification criterion was duplicated open-ended responses (293/668, 44%). Chi-square tests revealed statistically significant differences (P<.05) between suspected bots and probable humans across most survey items. Suspected bots demonstrated response patterns concentrated in the middle of Likert scales, whereas probable humans were more likely to select extreme values. Correlation analyses showed that expected relationships between key health indicators (eg, depression symptoms) were present in probable human responses but reversed in suspected bot-generated data, highlighting the potential for compromised validity in unfiltered survey datasets.

Conclusions: The findings underscore the necessity of implementing bot prevention and detection methods in online health care surveys to preserve data integrity. Failure to do so risks distorting research conclusions, particularly in health equity studies where demographic misclassification may bias results. The study highlights effective bot detection strategies, including open-text analysis, timestamp evaluation, and geographic validation, and recommends integrating these techniques into survey design. As bots continue to evolve, ongoing advancements in bot prevention and detection will be crucial to maintaining the reliability of digital health research.

Introduction

Patient-reported outcome measures (PROMs) and patient-reported experience measures (PREMs) are invaluable tools for understanding and improving health care from the patient's perspective. PROMs assess health status, functional abilities, symptoms, and quality of life directly from patients, often through self-reported questionnaires, providing insights into the impact of interventions and overall care quality [1-3]. PREMs, on the other hand, capture patients' perceptions of their health care experience, focusing on whether key processes

XSL•FO
RenderX

occurred and how care was delivered [2]. These measures are essential for implementing person-centered care, as they enable health care providers to align their practices with patient needs and experiences [4]. PROMs and PREMs have also been incorporated into care routines to support quality improvement initiatives [4]. By prioritizing patient-reported data, health care systems can address inequities, promote patient-centered and value-based care, and ensure that care delivery aligns with the priorities and needs of diverse patient populations [4].

A common approach to collecting PROMs and PREMs is through online surveys. Online surveys have become an increasingly prominent tool for research, particularly in social and behavioral health fields, due to their efficiency, cost-effectiveness, and ability to overcome challenges faced by traditional data collection methods such as face-to-face, mail, or telephone surveys [5,6]. These challenges include declining response rates, rising costs, and the need for social distancing during events like the COVID-19 pandemic [5,7-10]. Internet-based platforms such as Qualtrics (Qualtrics International) Inc., SurveyMonkey (Momentive Inc.), and Research Electronic Data Capture (REDCap; Vanderbilt University) have enabled researchers to collect data remotely, making it possible to reach large general populations [5,7,10]. These tools reduce the resources required for data collection, minimize participant burden, and offer greater anonymity, encouraging honest disclosure of personal or sensitive information [7,10]. Additionally, the limited availability of a sampling frame with accurate contact information has necessitated the use of distribution methods involving generic survey links and promotion through online platforms and social media. Unfortunately, recruiting participants through generic links creates susceptibility to data quality issues [11].

While early guidance on online surveys for health research warned of the risk of hoax responses [12], the increasing use of online surveys has been accompanied by a growing concern over fraudulent responses, particularly from bots - applications that automatically complete surveys – producing insincere data and inaccurate results [13]. These bots are capable of mimicking human behavior by selecting multiple-choice answers and generating plausible open-ended responses, making them difficult to detect. Bots can submit hundreds of fabricated responses within hours, potentially overwhelming researchers with invalid data and causing significant financial loss if participant incentives are misallocated [8]. Their presence threatens data quality, which can distort statistical analyses and compromise research findings [10]. Researchers, evaluators, and program analysts also face challenges in identifying fraudulent responses due to the increasing sophistication of bots and the anonymity of online participants [14]. Despite the implementation of data protection mechanisms to prevent bot responses, such as reCAPTCHA (Google LLC), bot programmers easily bypass these safeguards using virtual private networks or servers [7]. As bots become more prevalent and capable, addressing this issue is critical to ensuring data integrity and the validity of research findings that inform policy and practice.

This study adds to this literature by proposing a structured 3-tier classification system that integrates multiple indicators of responses by suspected bots, offering a robust and transparent protocol for identifying suspected bot responses. Additionally, this study goes beyond merely identifying suspected bot-generated responses in online surveys; it systematically examines how suspected bots influence response patterns in a health care experience survey. While existing research has focused on detecting fraudulent responses, fewer studies have examined how suspected bot-generated data may distort patient-reported experience and outcome measures in health care contexts. Our study extends this work by analyzing discrepancies between suspected bot and probable human responses in a survey of PROMs and PREMs. Such differences provide an assessment of potential bias and the relative importance of detection.

Methods

Survey

This study was undertaken within a broader evaluation of Ontario Health Teams (OHT), focusing on patient experiences and outcomes. A patient survey was implemented to support planning and evaluation of integrated care for attributed populations in Ontario, Canada. Consent was obtained from all respondents included in the analysis. The survey was intended for patients from a large OHT, gathering data on PREMs and PROMs. Questions included Likert scale items on health care use, health outcomes, accessing care, having someone to count on, being heard, managing health, safety, care transitions, digital health care use, demographics; as well as an open-text section to provide additional feedback. Six timestamps were programmed throughout the survey at multiple points to track survey progress. Data were collected between July 2023 and October 2023 using REDCap. REDCap is a web-based platform designed for research data capture, widely used in academic and clinical studies. The survey was distributed through the OHT's email lists and social media platforms. Social media distribution occurred primarily through Facebook (Meta), which was the OHT's main platform. Posts containing the survey link and QR code were shared periodically between July and October 2023, and a paid Facebook advertisement was implemented in early October to boost participation. Participants were invited to enter a draw for a $25 CAD (US $18.62) gift card as an incentive. Entry into the draw was voluntary and completed through a separate form linked on the survey's thank-you page, allowing respondents to opt out and ensuring that contact information was stored separately from survey responses. A copy of the survey is provided in Multimedia Appendix 1.

Suspected Bot Identification

Upon reviewing the qualitative responses and timestamp data, the research team identified clear evidence of suspected bot-generated responses in the survey. Many responses were duplicative, contained overly formal or generic language, or were nonsensical. The response patterns, combined with irregular timestamp data, confirmed the presence of suspected bots. As a result, the team developed specific criteria to systematically identify and remove suspected bot-generated responses from the dataset.

XSL•FO
RenderX

Criteria to identify suspected bots were developed using the following themes: generic and duplicative open-ended responses; concerns with location as determined by postal code (including postal codes that were invalid or nonsensical); timing irregularities; identical timestamps to other participants; illogical demographic reporting; and discrepancies in reporting health care use. In addition, a "bot takeover day" (October 10 onward) was included as a criterion, reflecting the sudden influx of suspicious responses observed on or after that date.

To identify bots in the survey data, we developed a 3-tier classification system based on specific "red flags" (concerning or questionable features or responses in the data). This approach builds on prior research that has typically relied on individual indicators or sets of criteria considered in parallel to flag fraudulent responses [5,7-9]. By combining multiple indicators into a structured, tiered framework, our system increases the robustness and transparency of suspected bot identification. Tier 1 criteria identified a respondent as a suspected bot if any single criterion occurred on its own (eg, duplicate open-ended responses that were exact full-text matches, not brief "No"-type replies, invalid postal codes, or identical timestamps). Tier 2 classified a respondent as a suspected bot if 2 or more criteria from its list were observed. For example, one tier 2 criterion included having a valid postal code outside of the region where participants received health care services. This criterion was not sufficient on its own to categorize a respondent as a suspected bot, as some participants may legitimately live elsewhere and receive care in the area where the participants were sampled. However, when combined with other criteria, it strengthened the likelihood of being a suspected bot-generated response. Finally, tier 3 flagged respondents as suspected bots if any tier 3 criterion was combined with at least 2 additional criteria from either tier 2 or tier 3, resulting in a total of 3 or more issues. One Tier 3 indicator reflected a sudden influx of suspicious responses observed on October 10, 2023 ("bot takeover day"). This indicator was not used as a standalone criterion and had minimal influence on classification: more than 99% of suspected bot responses were already identified using Tier 1 and/or Tier 2 criteria alone, with only 3 additional responses flagged through the use of this indicator. Demographic characteristics such as race or ethnicity, gender, and sexual orientation were not used as criteria for suspected bot identification. Demographic variables were analyzed only after classification to describe group-level differences between suspected bots and probable humans.

One criterion for identifying suspected bots was the presence of open-text responses that were deemed to be either (1) generic or informal, or (2) had a similar sentence structure to other responses. To evaluate this more subjective criterion, 2 reviewers (LC and SU) independently coded open-ended responses based on these criteria. Responses were categorized as suspected bots if reviewers agreed they met either criterion. When reviewers disagreed on whether open-ended responses should be classified as generic or informal, a third member of the research team (KM) provided the final determination. Interrater reliability between the 2 independent coders was substantial (Cohen κ=0.63, P<.001).

Although this study applied the identification criteria for a survey implemented on the REDCap platform, the 3-tier system is designed to be adaptable across different survey platforms, including Qualtrics, SurveyMonkey, and other online tools. The criteria used (such as duplicated open-text responses, timestamp irregularities, and geographic inconsistencies) are not platform-specific.

Suspected Bot Response Analysis

To examine differences in survey responses between probable humans and suspected bots, bar charts were created to visually compare response patterns. Chi-square tests were conducted to identify significant differences in the proportions of responses between the 2 groups. For select-all-that-apply items, including "Who did you receive care from?," responses were summarized into a mutually exclusive categorical variable prior to analysis. Respondents selecting more than 1 option were classified as having received care from "multiple providers," while those selecting a single option were classified according to that provider type.

To account for multiple comparisons across survey items, a Bonferroni correction was applied (adjusted α=.05/59=0.00085) to control for Type I error. We quantified the magnitude of group differences by calculating effect sizes for each chi-square test. Cramer V was computed for all categorical comparisons, along with 95% CIs.

Additionally, Spearman correlation tests were conducted to evaluate significant relationships between 2 health indicators, analyzed separately for probable humans and suspected bots, to identify patterns that align with or deviate from expected human perception and behavior. Two sets of correlations were examined: (1) the correlation between "little interest or pleasure in doing things" and "feeling down, depressed, or hopeless," and (2) the correlation between self-rated health and the frequency of interaction with the health system. The first pair represents the 2 core items of the Patient Health Questionnaire–2 (PHQ-2), a validated depression screener in which these items are strongly and positively correlated with one another [15]. The second pair was selected because extensive literature has shown that poorer self-rated health is associated with increased health care use, including higher rates of hospitalization and outpatient visits [16,17]. These 2 pairs, therefore, provide theoretically justified validity checks.

Ethical Considerations

This study received approval from the University of Toronto Research Ethics Board (#38072). All procedures were conducted in accordance with institutional ethical standards and the principles of the Declaration of Helsinki. Participants provided informed consent electronically prior to beginning the survey. The consent form outlined the purpose of the study, the voluntary nature of participation, potential risks and benefits, and data management procedures. Participants were informed that they could decline to answer any question or withdraw at any time prior to survey submission. To protect privacy and confidentiality, survey responses were collected anonymously. Any contact information provided for entry into the incentive draw was submitted through a separate form and stored

XSL•FO
RenderX

separately from survey data. Data were stored on secure, password-protected institutional servers accessible only to authorized members of the research team.

Results

Frequency of Suspected Bot Identification

Table 1 illustrates the final criteria for identifying suspected bots and the frequency with which each criterion was met among respondents ultimately classified as suspected bots or probable humans. While some probable human respondents exhibited isolated red flags, they did not meet the necessary combination of criteria required for suspected bot classification. After removing survey responses where substantive questions were not answered (n=231), 1154 survey respondents remained. Among them, 58% (n=668) were categorized as suspected bots, and 42% (n=486) were categorized as probable humans. Table 1 illustrates the number of respondents who met the eligibility criteria for each identification criterion. Overall, 529 survey respondents met the criteria for Tier 1, 570 respondents met the criteria for Tier 2 (136 of whom did not meet the criteria for Tier 1), and 551 respondents met the criteria for Tier 3 (3 of whom did not meet the criteria for Tier 1 or Tier 2).

XSL•FO
RenderX

Table . Frequency of each suspected bot identification criteria. Percentages within each tier sum to greater than 100% because a single respondent may meet multiple identification criteria.

Criteria	Assessed categories		
	Suspected bot (n)	Probable human (n)	Respondents identified as suspected bots who met criteria, n (%)
Tier 1			
Had an identical open-ended question response identical to at least one other respondent (Duplicate open-ended responses that were exact full-text matches, not brief "No"-type replies)	293	0	(293/668) 44%
Open text is generic, informal, or similar sentencing structure	49	0	(49/668) 7%
Duplicate invalid postal codes that were completed on the same day	189	0	(189/668) 28%
Duplicate out-of-province postal codes (excluding Quebec) that were completed on the same day	152	0	(152/668) 23%
Tier 2			
Identical open-ended question marked as "no" that also fell within the same day and similar time frame	80	0	(80/668) 12%
2 or more survey respondents entered their surveys within 30 seconds of one another (but not identical), and this is the case in 3 or more timestamps	340	2	(340/668) 51%
Had an identical timestamp (identical hours, minutes, and seconds) with at least one other respondent on the following timestamps:			
First timestamp	114	0	(114/668) 17%
Second timestamp	93	0	(93/668) 14%
Third timestamp	75	1	(75/668) 11%
Fourth timestamp	80	0	(80/668) 12%
Fifth timestamp	69	2	(69/668) 10%
Sixth timestamp	75	0	(75/668) 11%
Survey was completed between 1 AM and 5:00 AM Eastern Time (as identified on any of the timestamps)	154	7	(154/668) 23%
Time spent on survey is 3 minutes or less (among respondents who completed the survey)	42	11	(42/668) 6%
Invalid postal code (gibberish or numeric)	189	0	(189/668) 28%
Valid postal code but outside of Ontario	153	0	(153/668) 23%
Valid Ontario postal code but outside of the region of the primary care center in which respondents were recruited	165	5	(165/668) 25%

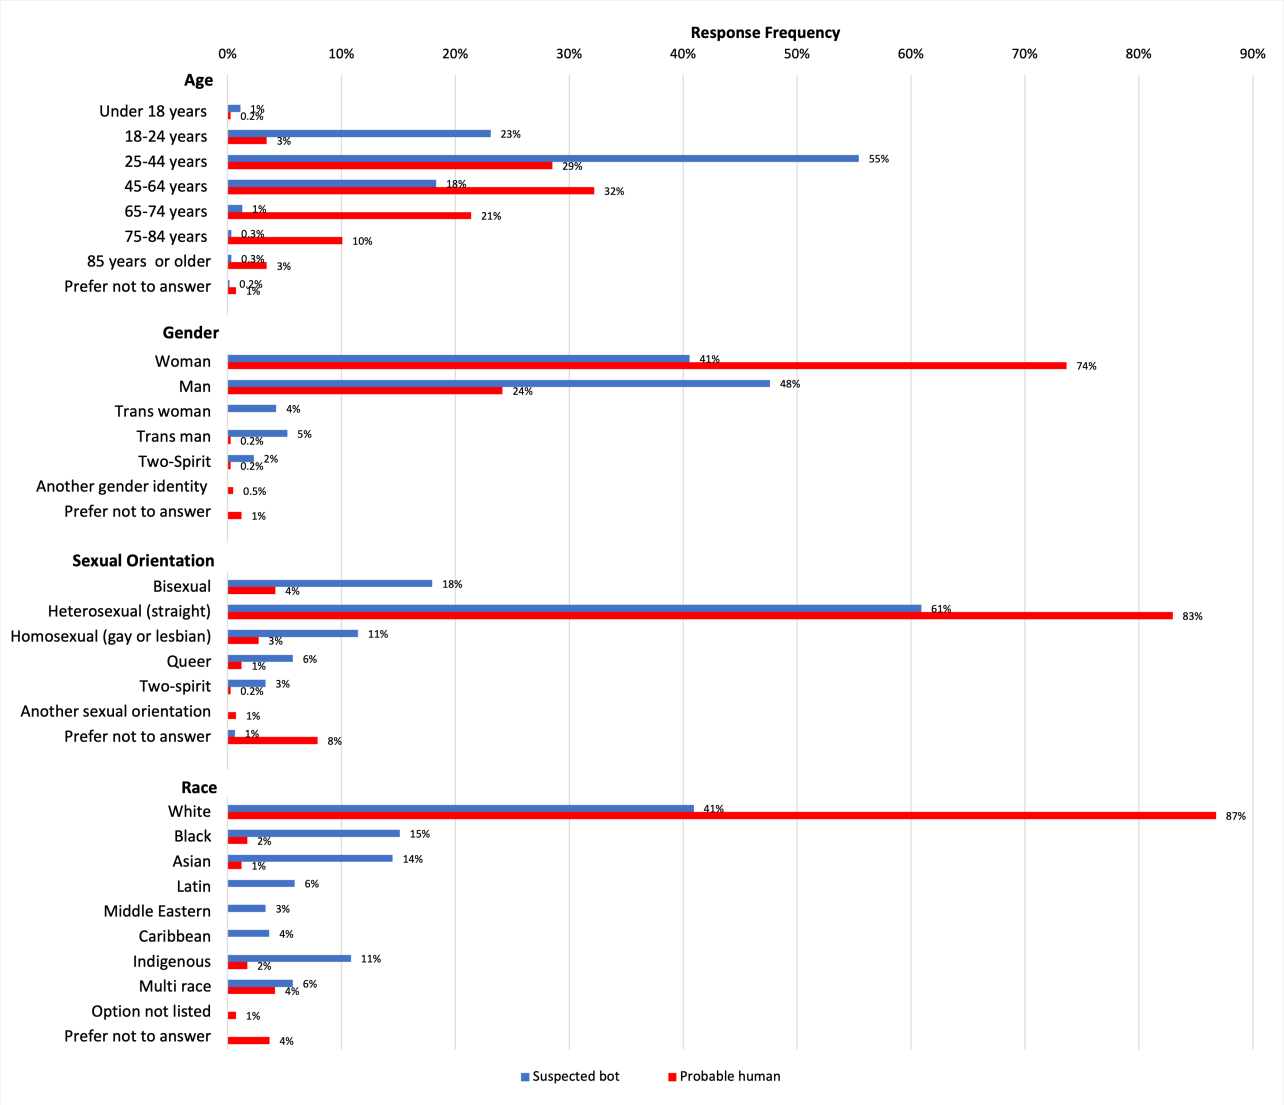
XSL•FO
RenderX

Criteria	Assessed categories		
	Suspected bot (n)	Probable human (n)	Respondents identified as suspected bots who met criteria, n (%)
Discrepancy in reporting ED[a] visits	347	55	(347/668) 52%
Between the ages of <18 - 44 years but reported living in a retirement home or long-term care facility.	123	1	(123/668)18%
Tier 3			
Bot takeover day of October 10 or after	618	94	(618/668) 93%
Postal code from neighboring province	55	3	(55/668) 8%

[a]ED: emergency department.

In tier 1, the most commonly reported “red flag” was having an identical open-ended response to another survey respondent. In tier 2, the most common ’red flag’ was a discrepancy in reporting an emergency department visit, where respondents indicated they had received care from the emergency department in 1 question but later reported that they had not been to the emergency department in the past 12 months. There was also a high frequency of respondents completing their surveys within similar timeframes (completing 3 or more of the same sections within 30 s of another respondent).

Differences in Responses Between Suspected Bots and Probable Humans



Overall, probable humans had a higher average percentage of missingness on all questions (mean 13% [for probable humans vs mean 5% for suspected bots).

Chi-square tests revealed significant differences ($P<.05$) in response distributions between probable humans and suspected bots for 55 out of 59 survey questions. After Bonferroni correction for multiple comparisons (adjusted $\alpha=.00085$), 50 of 59 valid comparisons remained statistically significant (Table S1 in Multimedia Appendix 2). The magnitude of effect sizes ranged from Cramer V=0.01 (“When you left the hospital were you provided with easy to follow instructions on whom to contact if you had a question about your treatment or if your condition became worse?”) to Cramer V=0.72 (“In general, do your health care providers encourage you to bring someone with you to your appointments?”), with a mean Cramer V of 0.31 (Table S1 in Multimedia Appendix 2). Among the 9 survey questions that showed no statistically significant difference between probable humans and suspected bots, most items were binary (yes or no) questions that followed branching logic and were therefore presented only to a subset of respondents. The remaining non-significant items were measured on a 5-point response scale, where probable humans tended to provide slightly less positively skewed responses (for example, being more likely to select experiencing “slight pain or discomfort” rather than “no pain or discomfort”).

In terms of demographics (Figure 1), suspected bots more often reported younger ages (under 18–44 years) and being male, while probable humans more often reported being female. Both groups most frequently identified as heterosexual and White, but suspected bots more often selected minority sexual orientations (eg, bisexual, queer, and two-spirit) and racial or ethnic categories (eg, Black, Asian, Latin, and Indigenous).

XSL•FO
RenderX

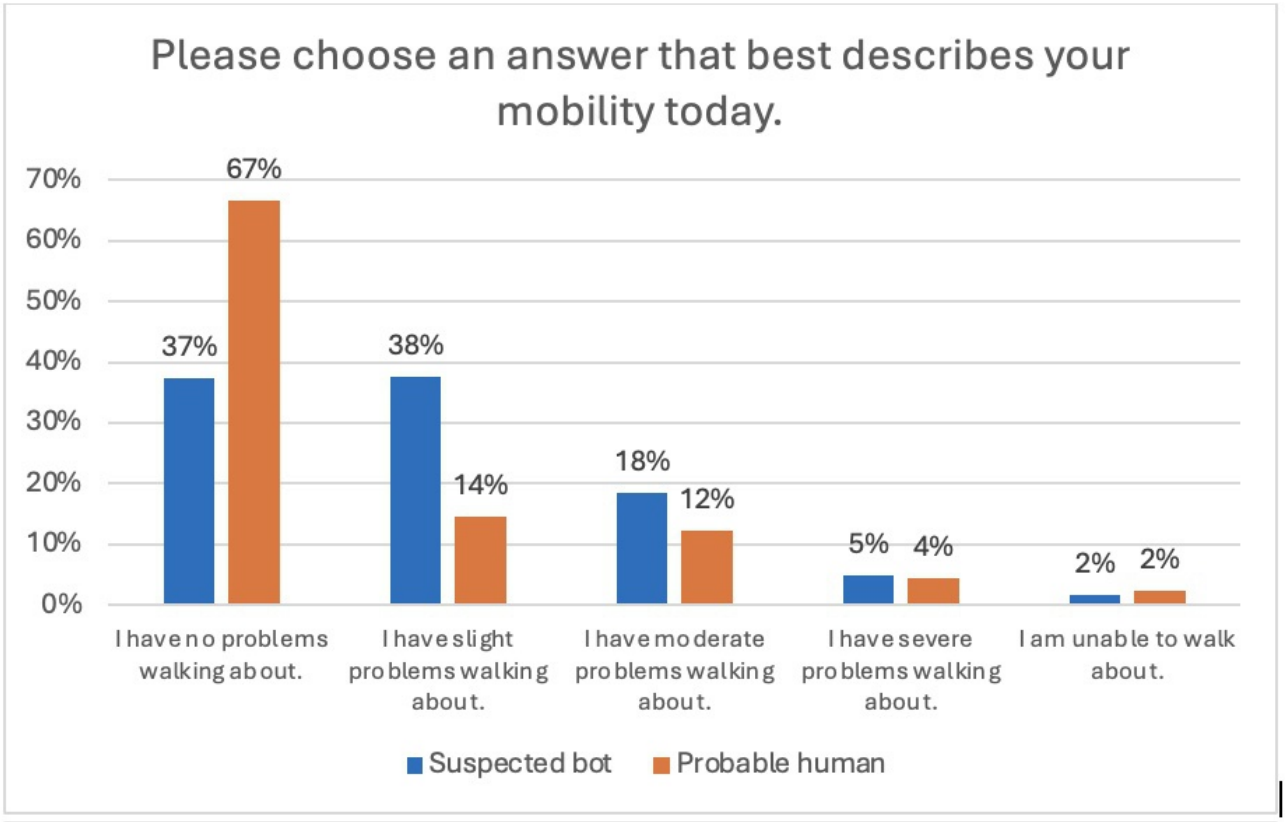


Figure 1. Distribution of demographics for suspected bots versus probable humans.

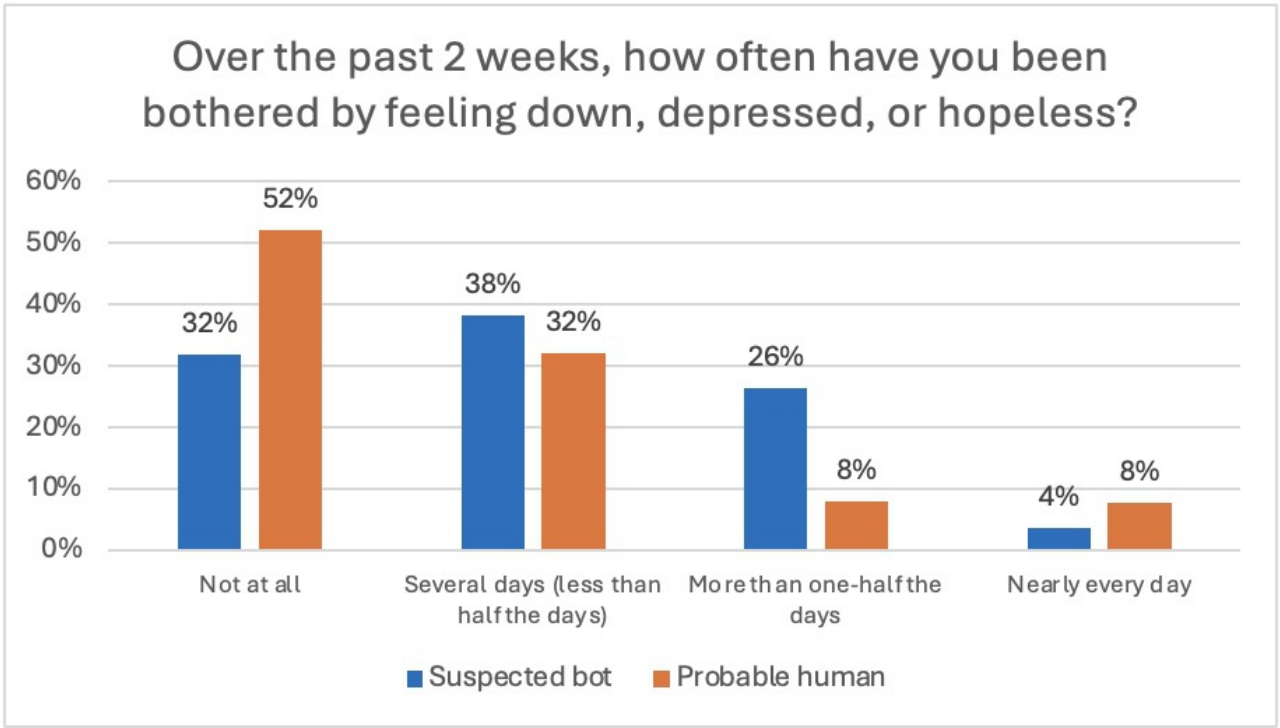
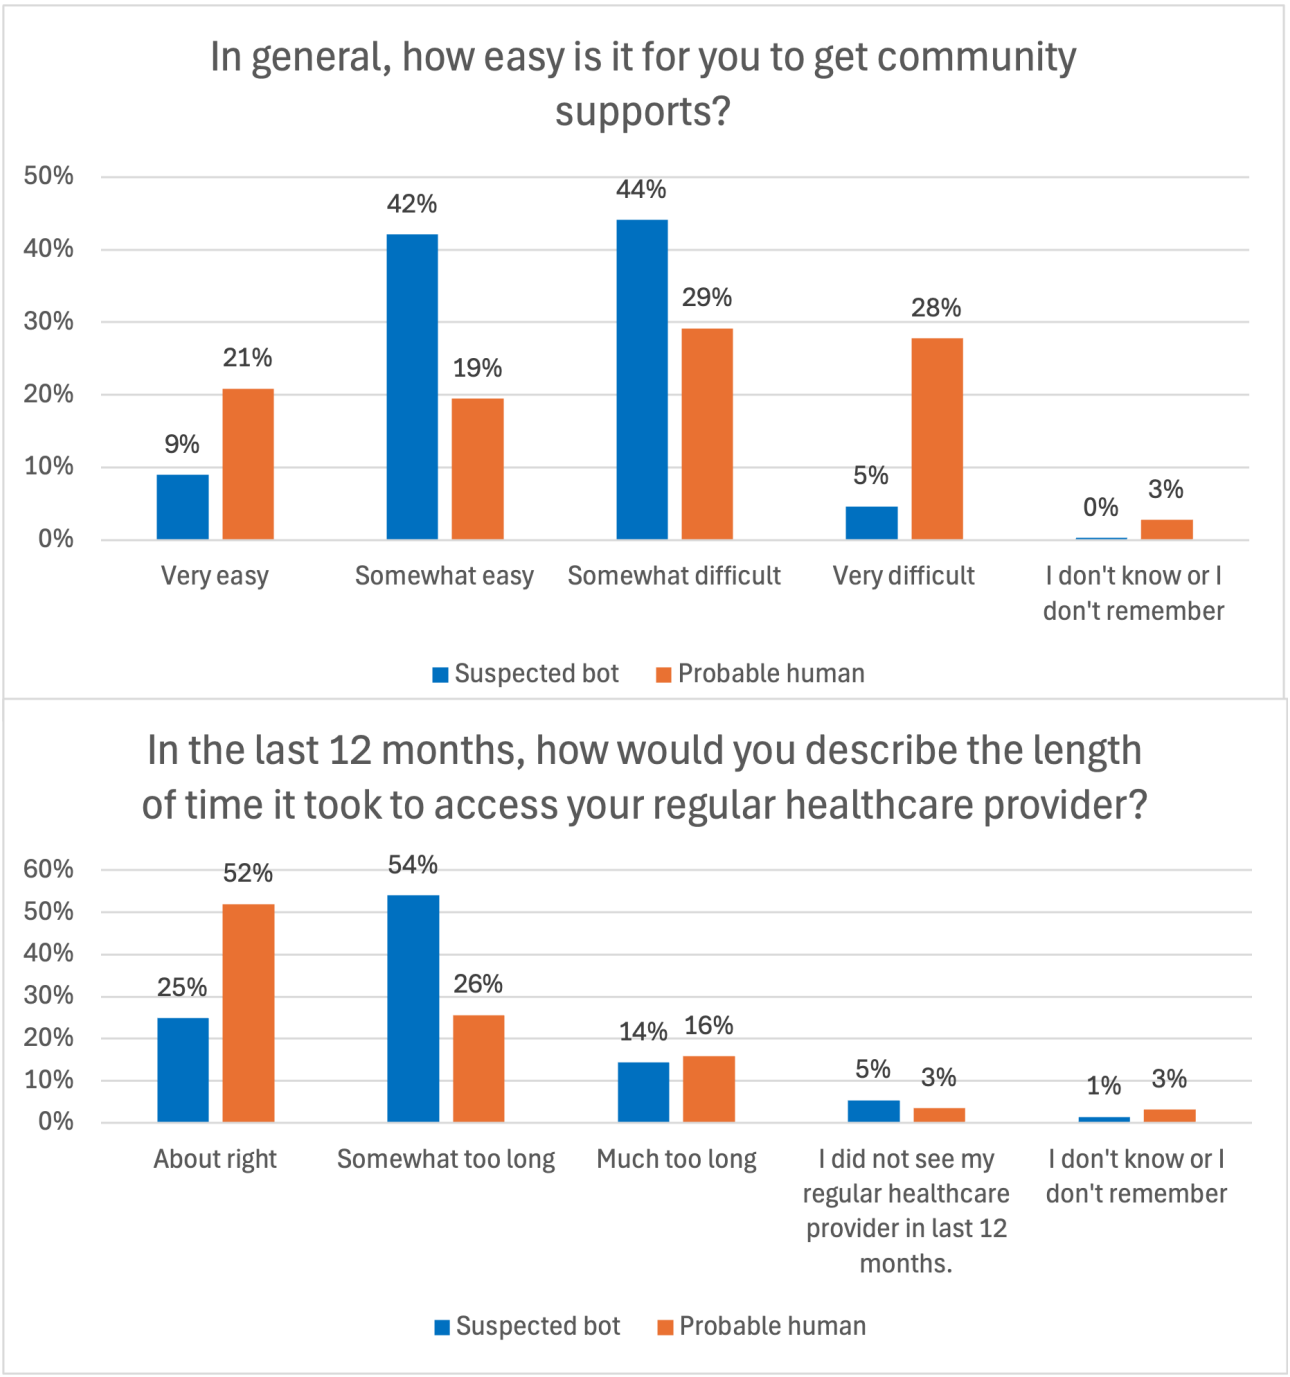


Visualizations (Figures 2 and 3) showed that suspected bots tended to cluster at mid-scale responses, while probable humans more often selected extreme values. For PROMs, probable humans were more likely to report the most favorable outcomes (eg, “no problems walking about”) and the least favorable (eg, “nearly every day” feeling depressed), whereas suspected bots gravitated toward midpoints (eg, “slight problems,” “several days”). Similar patterns appeared in PREMs, where suspected bots more frequently selected “somewhat” responses (eg, “somewhat easy” to access supports, “somewhat too long” to get care), while probable humans showed a greater spread across extremes.

XSL•FO
RenderX

Figure 2. Distribution of probable human and suspected bot responses for patient-reported outcome measures.



The survey also assessed health service use, including emergency department visits, hospitalizations, and specialist care in the past year. Suspected bots more frequently reported using the emergency department and being hospitalized compared to probable humans. When asked yes or no questions about these services (such as whether an emergency department visit could have been managed by a regular provider, whether their provider was informed after hospital discharge, or whether a specialist had relevant medical information), suspected bots were more likely to respond "yes" than probable humans. This was consistent with other patterns, such as reporting "somewhat confident" when asked about managing health post-emergency department visit, while probable humans were more likely to select "very confident" or "not at all confident."

The survey included 1 nominal question, which asked about the main reason participants had not looked at their medical records online (for those who indicated this to be the case). There did not appear to be any trend or pattern for the distribution of

XSL•FO
RenderX

responses. Ironically, a substantially higher percentage of suspected bots (compared to probable humans) indicated that a reason for not having looked at medical records online was not having reliable access to the internet.

Figure 3. Distribution of probable human and suspected bot responses for patient-reported experience measures.

Correlations

Spearman correlations indicated significant correlations between the indicators of having "little interest or pleasure in doing things" and "feeling down, depressed, or hopeless," both of which are indicators of depression. For probable humans, the Spearman correlation was 0.48 (P<.001), indicating a moderate positive correlation between the 2 variables, whereas for suspected bots, the Spearman correlation of −0.33 (P<.001) indicated a moderate negative correlation between the 2 variables.

When analyzing the correlation between self-rated health ("how do you rate your own health?") and frequency of interacting with the health system ("how often do you interact with the health system?"), a Spearman correlation of −0.07 for probable humans indicated a weak negative correlation; however, this was not significant (P=.15). For suspected bots, the Spearman correlation was 0.06, indicating a weak positive correlation; however, this was also not significant (P=.15).

Discussion

Principal Findings

The results of this study demonstrate the imperative need for researchers, evaluators, and program analysts in the health care field to recognize and address the potential threats posed by bots in online survey research. Failure to detect and remove bot-generated responses can lead to compromised data quality and incorrect inferences. Implementing robust data screening strategies is important for reducing fraudulent responses and improving the likelihood that valid data are retained. These responses respect the integrity of genuine participants whose experiences deserve to be accurately reported.

Implications of Including Bot Data in Health Care Surveys

Our findings extend prior work on bot response patterns by demonstrating how these differences manifest in PROMs and PREMs, with implications for health care survey research. Across multiple survey domains—health outcomes, health care access, and experiences—probable humans were more likely than suspected bots to select the most favorable outcomes (or in some cases, the least favorable response options). In contrast, suspected bots exhibited a tendency to select responses clustered around the middle of the scale. As a result, the presence of bot-generated data could dilute the strength of human responses, skewing average scores toward the midpoint and diminishing the ability to detect meaningful trends. This issue extends beyond scaled responses; even in nominal questions, such as the reason for not accessing medical records online, suspected bots disproportionately selected specific response options, such as lacking reliable internet access. This discrepancy suggests that bot-generated data may introduce artificial patterns in categorical variables, leading to inaccurate estimates of barriers to health care access and potentially misinforming policy decisions. This distortion may undermine construct validity, as the data fail to capture real-world experiences. Additionally, probable humans demonstrated a higher level of missingness compared to suspected bots. This likely reflects natural variation in survey completion behavior (such as skipped or unanswered questions). In contrast, the lower level of missingness among suspected bots may indicate automated completion rather than a marker of higher data quality. This difference underscores the importance of evaluating missing data patterns alongside other indicators when assessing data integrity.

Beyond response patterns, the inclusion of bot-generated data introduces a significant risk of bias, particularly in research focusing on health equity. The demographics of suspected bot responses differed notably from those of probable human participants. These patterns may reflect random bot response patterns inflating less common categories; however, this pattern may be partially driven by the ordering of the race or ethnicity response options. In the survey, several minority categories appear in the middle of the list, whereas “White” appears at the bottom. Given the tendency of suspected bots to select middle-of-the-scale responses, the positioning of race or ethnicity response options likely contributed to the higher selection of minority categories among bots. We also acknowledge the possibility that some marginalized respondents were misclassified as suspected bots. This discrepancy poses a major threat to the validity of studies that examine health care use and outcomes among specific demographic subgroups. In equity-focused research, where accurate representation of marginalized populations is crucial, failing to filter out bots could lead to misleading conclusions and inappropriate policy recommendations.

The impact of suspected bot interference is further underscored when examining the relationship between key indicators of depression. Among probable human respondents, the correlation between “having little interest or pleasure in doing things” and “feeling down, depressed, or hopeless” aligned with established patterns in the literature, reflecting a logical association between these 2 related constructs. However, among suspected bot-generated responses, this relationship was unexpectedly reversed, indicating a negative correlation that does not align with theoretical expectations. Notably, a moderate negative correlation suggests a systematic response pattern (such as contradictory response selection) rather than a pattern consistent with genuine symptom co-occurrence. This inconsistency suggests that suspected bot responses do not accurately reflect underlying psychological constructs, reinforcing the need to identify and eliminate suspected bots from survey research. The inconsistency also provides face validity to our bot-detection algorithm.

Bot Detection Strategies

Several methods to identify suspected bots that were used in this study align with those used in similar research. These include: analyzing open-ended responses for nonsensical, duplicative, or inconsistent data [5,8,10,18]; tracking survey completion times [5,7,8,13,19,20]; flagging surveys that were completed at unusual times of the day [8]; and identifying suspicious patterns related to zip codes and geographic location [20]. We applied all applicable bot detection strategies for which we had data available. There are additional bot detection techniques that were not used in this study but have been used in prior research. These include: checking participants' responses to questions that are asked in 2 ways [8,14,19], (such as “how old are you?” and “what y were you born?”); using IP addresses to check for responses that were completed in the same household or very close to one another in relation to the time the survey was submitted [5,14]; and examining email addresses for suspicious wording or similar content [8,20]. Another strategy involves external validation of participant information, such as verifying names, addresses, phone numbers, and birth dates to ensure responses are unique and legitimate [21]. Investigators can also cross-reference participants’ details using publicly available databases, social media, or professional networking sites to further confirm authenticity, although ethical considerations must be weighed when implementing such approaches [21]. While these strategies may help reduce fraudulent responses, they can also create additional burdens and reduce anonymity for legitimate participants.

Among the bot detection strategies used in this study, some were particularly effective in identifying suspected bot-generated responses. Notably, open-ended responses provided valuable

XSL•FO
RenderX

insight, as suspected bot-generated answers often contained repetitive, illogical, or off-topic content across multiple responses. Unusual quantitative responses alone can be difficult to interpret, as they might seem plausible despite being artificially generated. However, open-ended responses can provide valuable context that may help in assessing the authenticity of data. Unlike structured response options, which bots can randomly or systematically select, qualitative responses require coherence and reasoning, making them a powerful tool for distinguishing between genuine participants and automated responses. That said, recent advances in generative artificial intelligence mean that open-text answers are becoming increasingly sophisticated and may no longer be a fully reliable safeguard against fraud [22]. Geographic inconsistencies, such as invalid or duplicate postal codes, or locations outside the intended survey region, were also strong indicators of suspected bot activity, although individual respondents may misreport to preserve anonymity. Additionally, anomalies in time-related metrics, including extremely short survey completion times, completion at unusual hours, or multiple surveys submitted at identical timestamps, further helped differentiate suspected bots from probable human respondents. Based on these findings, we recommend collecting postal or ZIP codes and incorporating multiple timestamps within surveys to enhance suspected bot detection. While no single strategy is universally effective across all surveys, we recommend using a combination of detection methods tailored to the specific survey and target population.

While several strategies are outlined to detect bots, it is also important to prevent bots from entering surveys in the first place. Tools such as Completely Automated Public Turing test to tell Computers and Humans Apart (CAPTCHA) have been developed to offer an additional level of security against bot infiltration [23]. However, research has shown that these tools can be bypassed, as bots are increasingly programmed to recognize and circumvent such challenges [7,20,24]. Similarly, honeypot questions (hidden prompts designed to engage only automated respondents) have also proven ineffective, as more sophisticated bots can now avoid these traps [8,20]. Indeed, researchers who have used this method have reported that bots did not provide responses to these questions [8]. Given the growing complexity of automated survey fraud, it is essential for technology companies to continue developing advanced bot detection solutions. Survey platforms such as REDCap and Qualtrics should integrate these technologies to automate bot prevention, reducing the burden on researchers and ensuring more consistent data quality measures.

Recommendations

It is recommended that bot detection strategies be implemented at multiple stages in the research process. This includes prior to data collection (eg, using targeted recruitment with specific distribution lists), during data collection (eg, monitoring data daily to identify potential fraud), and following data collection (eg, implementing a systemic check of potential fraud) [18]. Finally, increasing awareness among researchers about the impact of bots in survey research is crucial. We recommend that training in bot prevention and detection be incorporated into research methods and survey design coursework to equip researchers with the necessary skills to safeguard data integrity. There will continue to be a value and need to reach out with surveys to broad groups of public and enabling survey research in this context will continue to be important.

As internet-based research (and survey research in particular) continues to expand, there is a growing opportunity for researchers across disciplines to contribute to the development of comprehensive bot detection methodologies. Moving forward, greater efforts should be directed toward developing universal technologies and initiatives for bot detection. Standardized approaches that can be seamlessly integrated across different research platforms will help safeguard the validity of online data collection and ensure that digital survey research remains a trusted tool for generating meaningful insights.

Limitations

While this study offers valuable insights, several limitations must be acknowledged. Since bot detection methods were applied to a single case study, their effectiveness has yet to be evaluated across different datasets, which may limit generalizability. Additionally, the data were collected within one region of Ontario, and the characteristics of the probable human responses, and their differences from suspected bot responses, may not be representative of broader populations. As response patterns may vary across settings, researchers working in other regions or with different populations should assess whether similar differences between suspected bot and probable human data are observed. However, the bot identification framework is adaptable, as criteria, such as postal or ZIP code validation, open-text analysis, and completion times can be tailored to reflect local contexts. Differences observed between probable human and suspected bot responses may also partially reflect differences between recruitment channels, such as respondents reached through email lists versus social media postings. Survey respondents recruited via open online platforms may differ systematically in demographics or response behaviors, independent of bot activity. Although some degree of misclassification is therefore possible, our detection framework was deliberately conservative and assumed responses were human unless sufficient evidence across multiple indicators suggested otherwise. Despite using various suspected bot detection strategies, there is also potential for undetected sophisticated bots, which could still impact the dataset's validity. Furthermore, the study was conducted at a specific point in time, and as automated response technologies evolve, the effectiveness of these detection methods may diminish. The study relied on assumed response patterns to identify suspected bots, but without absolute verification, such as IP tracking or manual validation, there remains some uncertainty in classification. Finally, while we observed that suspected bot responses reversed an expected positive correlation between depression-related items, this pattern was not incorporated into our 3-tier classification framework. Such a pattern would align conceptually with a Tier 3 criterion, as it represents a complex and context-dependent anomaly that would require corroboration from additional indicators to support classification. Future research should examine whether anomalies in response patterns, in addition to structural indicators, can serve as reliable markers of fraudulent responses.

XSL•FO
RenderX

Conclusions

This study provides criteria for identifying bots in online surveys. In comparing survey results from the suspected bots and probable humans, identified by the developed criteria, we found important differences in response patterns that would jeopardize data validity if bots were not correctly identified. By incorporating robust data validation protocols early in the research process, researchers can minimize bias and prevent the inclusion of inauthentic data, strengthening the reliability of findings. This study should be interpreted as a cautionary case rather than a prescriptive template. Without verified contact lists or other forms of participant validation, open online surveys will remain vulnerable to contamination despite the use of screening methods.

Acknowledgments

Artificial intelligence tools were used to assist with technical tasks such as formatting tables and supporting code refinement during data analysis. All analytic decisions, code implementation, result verification, and manuscript content were developed and reviewed by the authors.

Funding

This research was supported by a grant from the Ontario Ministry of Health to the Health System Performance Network (#694). The funders had no role in data analysis, decision to publish, or preparation of the report.

Data Availability

The datasets that were created and analyzed during this study are not publicly available, as public data sharing was not included in the original research ethics approval and participant consent form. Deidentified data may be made available for research purposes upon reasonable request to the corresponding author, subject to institutional approvals and data-sharing agreements, and provided that participant confidentiality can be maintained.

Authors' Contributions

EH and KM contributed to the conceptualization and methodology of the study, curated the data, and developed and implemented the coding criteria to identify suspected bots (with oversight from WW). EH completed the analysis and drafted the manuscript. KM and WW provided critical revision and editing of the manuscript.

Abstract

Background: As health care delivery shifts toward value-based care, proactive strategies to close preventive care gaps are essential. However, patient engagement remains suboptimal due to logistical, behavioral, and socioeconomic barriers. Traditional outreach methods, such as phone calls, emails, and postal mail, have long been used, but emerging digital approaches, such as chatbot-based messaging, offer potential advantages in scalability and personalization. Their comparative effectiveness, however, remains underexplored.

Objective: This study aimed to evaluate the effectiveness of chatbot outreach compared with traditional communication methods (phone, email, mail, and multichannel) in promoting compliance with preventive screenings and wellness visits defined by the Healthcare Effectiveness Data and Information Set and the Centers for Medicare & Medicaid Services guidelines.

Methods: This retrospective study evaluated patient outreach campaigns conducted from 2021 to 2023 across an integrated health system in New York. The final analytic sample included 50,145 care gaps from 41,959 eligible participants, predominantly female (29,989/50,145, 60%), White (31,857/50,145, 64%), with mean age ranging from 49.36 to 72.81 years over the study period. All participants were residents of New York state, and 81% (40,553/50,145) maintained an active relationship with a primary care provider during the participation year. Outreach modalities included automated chatbot SMS text messages, nonautomated phone calls, and organization-led email or mail campaigns. Participant data were enriched with social vulnerability scores to account for community-level disadvantages. Exposure was defined as the outreach method (chatbot, phone, email, mail, or multichannel), with assignment based on engagement history and operational protocols. The primary outcome was care-gap closure or compliance with identified measure gaps annually. Logistic regression and chi-square analyses examined associations between outreach method, patient demographics, primary care physician relationship, social vulnerability index (SVI), and compliance.

Results: Phone outreach consistently achieved higher compliance than chatbot or multichannel outreach across most groups and years. Chatbot messages outperformed phone calls only in diabetes care in 2023 (odds ratio [OR] 1.81, 95% CI 1.48-2.21; $P<.001$). Primary care physician continuity remained a strong predictor of gap closure, especially in primary care (ORs ranged 1.36-2.61; $P<.001$). Higher SVI quartiles were associated with lower compliance in blood pressure, cancer care, and diabetes care groups; however, primary care outcomes showed higher odds of compliance in the third quartile of SVI, contradicting the typical linear-deprivation narrative. Women, Hispanic or Latino individuals, and Asian patients demonstrated higher odds of compliance in some groups and years.

Conclusions: Outreach modality is an important, modifiable factor in preventive care adherence. While phone-based outreach remains the most effective overall approach, chatbot-based strategies may have targeted applications in digitally engaged

XSL•FO
RenderX

populations such as the diabetic group. Segmented, equity-informed outreach strategies that integrate technology, patient preferences, and primary care continuity are essential to achieving high-impact, scalable outcomes in value-based care settings.

KEYWORDS

chatbot outreach; digital health; health communications; health equity, preventive care gaps; value-based care

Introduction

Background and Rationale

The development of health care delivery in the United States over the past decade has increasingly centered on value-based care (VBC), which emphasizes quality, outcomes, and cost-effectiveness over service volume. Promoted by the Centers for Medicare & Medicaid Services (CMS), the value-based preventive care concept represents a focused application of the VBC framework that prioritizes proactive prevention and early disease detection, aligning financial incentives with population health goals [1,2]. This approach is particularly relevant for managing chronic diseases and addressing preventive care needs in large, diverse patient populations [3].

Despite widespread consensus on the benefits of preventive services such as annual wellness visits, cancer screenings (CXs), diabetes care (DB), and blood pressure (BP) monitoring, patient adherence remains suboptimal [4-6]. Barriers to engagement include socioeconomic challenges, low health literacy, lack of awareness, and fragmented communication between care providers [7,8]. Health systems have historically used outreach methods such as telephone calls, emails, and postal mail to notify and engage patients with gaps in preventive care. However, these approaches can be resource-intensive and vary in their reach and effectiveness, particularly among hard-to-engage populations [9].

Emerging digital outreach tools, including automated chatbots and SMS text messaging, may offer a promising alternative for improving engagement at scale. These technologies can support bidirectional communication, personalize patient interactions, and reduce administrative burdens [10]. Several public health campaigns, particularly during the COVID-19 pandemic, have demonstrated the feasibility of chatbot-based outreach in promoting vaccine uptake and disseminating timely health information. However, the use of these tools for broader preventive care engagement, particularly in chronic disease management and CX, remains underexplored [11].

Based on a previous systematic review conducted on this topic by Chacko et al [11], the current state indicates a limited body of evidence on chatbot outreach beyond immunization programs, highlighting a need for further research into their effectiveness, cost-efficiency, and equity impact. Studies reporting on outreach mechanisms for preventive care have varied in their implementation approaches and study methodologies. Therefore, drawing a generalizable conclusion is not possible. It is uncertain if benefits of chatbot outreach apply uniformly across various demographic and clinical groups. Moreover, the integration of these tools into large health systems workflows may present unique challenges that remain underexplored in the literature [11].

Objectives

To address these gaps, this study aims to evaluate the impact of emerging technology, such as chatbot-based outreach, on preventive screening uptake compared to conventional methods, such as outreach via phone calls and email communications. The authors posited that the use of chatbots in preventive care will significantly increase the uptake of screening for annual wellness visits, hypertension, diabetes, and CXs compared to traditional methods of communication. Conducted at a large integrated delivery network in New York, the study focused on patients identified as having care gaps using the Healthcare Effectiveness Data and Information Set (HEDIS) and CMS preventive screening criteria. This study builds upon recent findings that suggest automated outreach tools may offer scalable and equitable solutions for preventive health engagement [11]. By evaluating their effectiveness across multiple screening domains, which included CXs, DB, and hypertension screening, along with primary care (PC) measures such as annual wellness visits, the study contributes to the growing body of evidence informing digital outreach strategies in VBC-aligned care delivery. Findings from this evaluation may help guide future investments in digital health infrastructure and support the implementation of targeted, technology-enabled outreach programs.

Methods

Study Design

This study retrospectively evaluated data collected from VBC outreach activities conducted over a 3-year period, from 2021 to 2023. Members identified by their insurance carrier as having care gaps, attributed to the health system, were targeted for outreach. Outreach was conducted using phone calls, web-based chatbots, email messages, mailed letters, and sometimes a combination of these methods. The strategy for outreach method allocation was dependent on operational capacity and technology adoption. During year 1 (2021), due to reduced operational capacity following the 2020 pandemic year, new technology was piloted to aid in outreach. The subsequent years' attribution strategy was adjusted to maintain a balance between outreach methods with increased volume of gaps, capacity in the workforce, and efficiencies found in technology adoption. Multichannel outreach involves the sequential use of 2 or more methods within the same measurement year when initial outreach attempts fail to result in engagement. Due to the inability to attribute the outcome to any single method alone, outreach using multiple methods was grouped into 1 category. Outreach method assignments followed operational protocols

XSL•FO
RenderX

and capacities that varied each year, rather than being randomized. Therefore, this study is exploratory in nature, focused on understanding trends that may drive empirical decisions about the modality of outreach in the future.

Data Sources

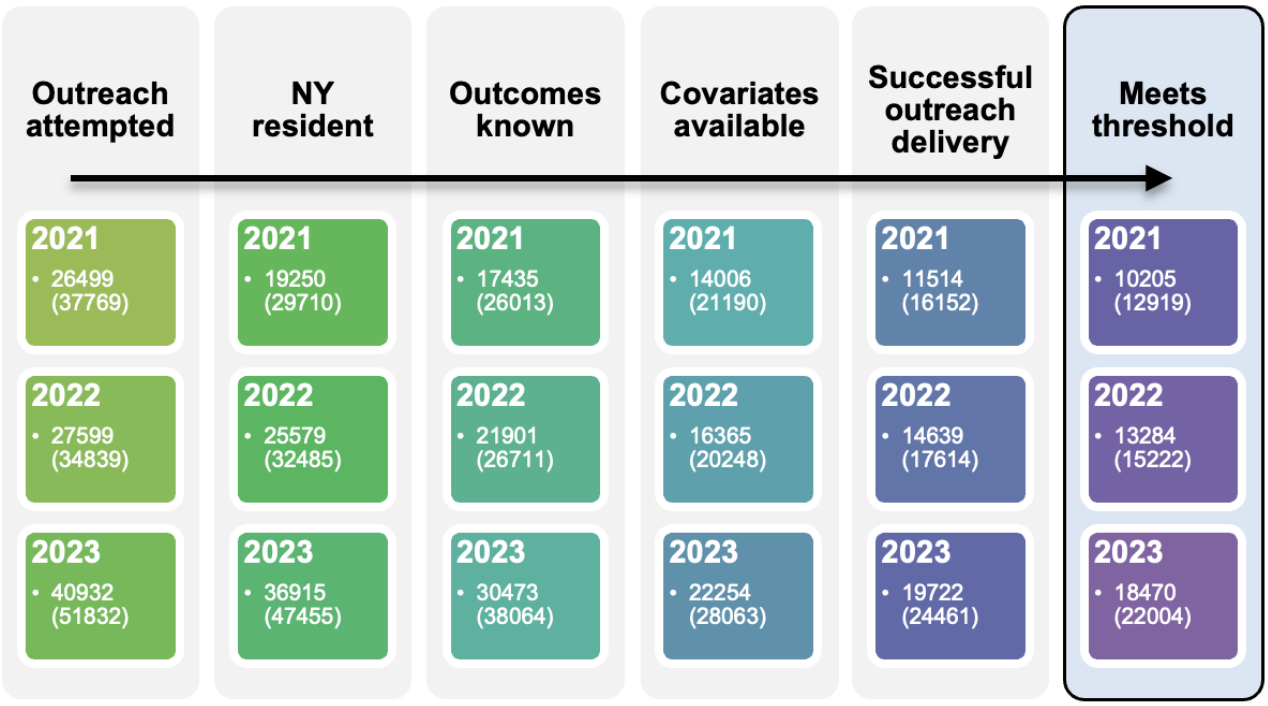
Participant demographic information was collected from the health system's electronic medical record (EMR). Outreach process measures and final compliance data were collected 3 months post each study year from the respective operational teams performing outreach. These data included an indicator for participant relationship with primary care provider (PCP) within the health system and the total number of care gaps for the given year per participant. Deidentification was completed before the data were shared with researchers. The social vulnerability index (SVI) was acquired from the 2022 dataset compiled by the Centers for Disease Control and Prevention [12]. The census tract level SVI was mapped to participant zip code with the aid of cross-mapping from the Department of Housing and Urban Development, accessed in June 2024 [13].

Inclusion Criteria

Participant eligibility for the identified gap measures was a primary inclusion criterion. Clinical criteria for eligibility are industry-defined guidelines (electronic Clinical Quality Measures), maintained by CMS [14], or HEDIS specifications provided by the National Committee for Quality Assurance [15], with changes published each year publicly. These define the required age ranges, diagnosis inclusion, and completion intervals for preventive services such as wellness visits, CX, BP, and DB. The other important criterion determining inclusion in the final analysis was having at least one outreach attempt using a phone, chatbot, email, or letter during the measurement year. As the study focused on understanding the efficiency of outreach methods, the population that received no outreach was outside the scope of this study.

Exclusion Criteria

Preventive measure groups and individual measures with an insufficient sample size (n<10) were excluded due to the need for valid statistical and comparative testing. Records with unknown outcomes (ie, unverified or missing documentation of care gap closure) or missing demographic variables (age, gender, race, ethnicity, and address [needed for SVI grouping]) were excluded. For example, if there was no known address for the patient documented, it would not be possible to map an SVI and include the participant in the stratified analysis, and therefore, such participants' data were removed from all study datasets before any analysis was conducted. Process measures such as documented patient engagement steps (eg, message opened or call answered) were collected and used to define successful outreach delivery. Unsuccessful outreach deliveries (eg, in case of erroneous contact information) were excluded.



The dataset remained representative of the population served by the health system and met eligibility criteria for each measure throughout this process. Four measure groups remained eligible for analysis after the applied exclusions: PC, BP, CX, and DB. Multimedia Appendix 1 provides the distribution of participants and measure gaps within each group.

Data Management

Deidentified data were aggregated at the patient-gap-year granularity using Microsoft Power BI [16]. Individual preventive measures were grouped into care domains (eg, PC, CX, etc) based on clinical relevance and alignment with HEDIS and CMS quality measurement categories. The grouping was determined by the study team using established measure definitions to facilitate domain-level comparisons. The case of multiple SVIs mapped to a single participant due to geographic overlap in the data was resolved by assigning the SVI from the most populous county to the participant, which is a common approach in health care research. Figure 1 shows the flow of participants and gaps volume through the applied exclusions.

XSL•FO
RenderX

Figure 1. Participant and measure gap flow diagram for each year in the study, listing participant volume first and gaps (n) in parentheses. NY: New York.

Study Variables

The primary independent variable, also referred to as the outreach method or intervention, was coded as 1 of the 4 single-channel methods (phone, chatbot, email, and mail) or multichannel to indicate any combination of these methods. Multichannel methods were grouped because the sample sizes in individual groups did not meet the statistical validity requirements for comparison.

The primary outcome or dependent variable evaluated was the completion of or compliance with the identified measure, measured 3 months following each study year (eg, March 2022 for the study year of 2021). It was documented separately for each year of the study, 3 months post end of year, and represented as a binary variable, indicated by 1 for "yes" and 0 for "no." The primary outcome was collected as part of the operational process of verifying completion of or compliance with the measure gap within the reporting period. This may include a verification by patient report, EMR validation, or a confirmation by payor data sharing. The authors collected this information retrospectively from data reported to governing agencies for each year.

Demographic data, including age, gender, race, ethnicity, and the SVI, were used to study covariates that could potentially impact the outcomes of outreach. Additionally, covariates included the presence of an active relationship with a PCP (defined as having a designated PCP of record within the health system and at least 1 documented encounter with that provider or associated practice within the preceding 18 months) and the burden of unmet care (defined as the total count of gaps for each participant per year).

Among the continuous variables, age was capped at 89 years to prevent reidentification. The count of gaps variable was used to assess potential imbalances in record weighting within the grouped measure files, as the datasets were analyzed at a gap level (n=1 gap per participant) rather than at a participant level. Tables S1-S4 in Multimedia Appendix 2 demonstrate the range and mean of the count of gaps per year for each measure group.

Categorical variables included demographic factors, gender, race group, ethnicity, socioeconomic factors, SVI, and active PCP relationship. Gender was coded into male/female as collected in the EMR. Race was grouped into White, Black or African American, Asian, and other. The other race group included Pacific Islander, Alaskan, and Native Americans, as well as patient self-reported "other" race identity. Ethnicity was only collected as a bivariate containing options for Hispanic and Latino or not Hispanic or Latino. Each participant was assigned an SVI quartile (1-4), where quartile 1 was the group with the least social vulnerability, and quartile 4 was the group with the most social vulnerability.

Statistical Analysis

All statistical analyses were conducted using IBM SPSS Statistics for Windows (version 29.0) [17]. The dataset was divided into measure-group files for each year. Analysis was performed for each measure group, with BP as an exception because it contained only 1 measure. Textbox 1 provides a list of subgroups (measures) within each measure group that were included in the final analysis. Descriptive statistics and contingency tables verified adequate cell counts (n≥10) for bivariate analyses per measure group, and any variables not meeting the threshold were excluded from final analysis for the respective measure group [18,19]. Notably, SVI quartile 2 often did not meet the valid n threshold, as was the case when the outreach method was email only. These were excluded from statistical analysis. This conservative approach ensured the robustness of the reported associations while maintaining data

XSL•FO
RenderX

integrity across all measure groups. Effect sizes are reported as odds ratios (ORs) with 95% CI and *P* values. Categorical variables were converted into dummy variables using reference coding (eg, phone outreach, male, White, non-Hispanic/Latino, SVI quartile 1, and no active PCP as baseline categories) before logistic regression analysis.

Textbox 1. Measure groups and subgroups 2021-2023.

Primary care

- Annual wellness visit
- Pediatric well-care visit

Blood pressure (single measure only)

Cancer screening

- Breast cancer screening
- Cervical cancer screening
- Colorectal cancer screening

Diabetes care

- Hemoglobin A1c control <8.0% in diabetes
- Hemoglobin A1c poor control >9.0% in diabetes
- Hemoglobin A1c testing in diabetes
- Nephropathy assessment
- Retinal eye examination
- Kidney health evaluation for participants with diabetes

Collinearity was assessed between included variables, which led to the exclusion of the insurance group from the final analysis due to its high correlation with age in this dataset. Chi-square tests identified preliminary predictors among the categorical variables, after which a 2-step backward stepwise logistic regression was performed. Step 1 entered all demographic variables and PCP relationship. Step 2 introduced outreach modality to quantify its independent association with the final compliance outcome, that is, gap closure after controlling significant covariates in the previous step. A chi-square test was also conducted between the PCP relationship variable and outreach methods to examine any existing associations before both were included in the regression model. Statistical significance was set at α=.05.

Ethical Considerations

The Northwell Institutional Review Board reviewed this study protocol and approved it on August 15, 2024 (HSRD24-0151), with a waiver of consent requirements in accordance with research involving deidentified secondary data. No patient contact or intervention occurred as part of the study, and all data were fully anonymized prior to analysis. To minimize analytic bias, eligibility and exclusion criteria were applied consistently using standardized definitions from HEDIS and CMS electronic Clinical Quality Measures.

Results

Participant Characteristics and Descriptive Statistics

After applying exclusions, the analytic dataset contained 12,919, 15,222, and 22,004 care gaps for 2021, 2022, and 2023, respectively, bringing the overall volume of gaps to 50,145. Gap volumes increased by approximately 18% (15,222/12,919) in 2022 and 45% (22,004/15,222) in 2023, with PC accounting for 47% (23,481/50,145) of gaps, CX 31% (15,335/50,145), BP 12% (5891/50,145), and DB 11% (5438/50,145). A total of 81% (40,553/50,145) of gaps came from participants who had an active relationship with the PCP during the participating year. Women predominated in all groups except diabetes in 2021-2022, and the cancer cohort showed an expected skew due to female-targeted measures. Among the 50,145 gaps, participants mostly belonged to the White racial group at 64% (31,857), followed by other 18% (8812), Black at 12% (6230), Asian at 6% (3246), and Hispanic/Latino at 16% (8199). The mean age for the PC group declined from 72.8 (SD 11.6) years in 2021 to 60.2 (SD 27.1) years and 49.4 (SD 30.5) years in 2022 and 2023, respectively, resulting from the gradual inclusion of the pediatric subgroup. All other measure groups had a mean age range from 56.4 to 66.3 years. The average gaps per participant were below 2 for all measures except DB, which had 2.9 gaps per participant in 2021, 2 in 2022, and 2.2 in 2023. See Multimedia Appendix 2 (Tables S1-S4) for detailed distribution for all 3 years.

Outreach included phone, chat, email, and multichannel approaches. Email was only valid for PC in 2021 and DB in 2023. Multichannel cohort met criteria in PC and CX across all years and DB and BP in 2023. Outreach shifted from phone-dominated in 2021 to greater chatbot and multichannel use by 2023. Multimedia Appendix 2 displays this trend with detailed values for each group.

XSL•FO
RenderX

Compliance Trends and Bivariate Associations

Multimedia Appendix 3 indicates the compliance rate for all 3 years across the measure groups. All measure groups indicate the highest compliance rate in 2021 and a subsequent decrease in 2022. While other measure groups have increased compliance in 2023, possibly indicating a postpandemic stabilization, compliance in the BP group continues to decrease this year. This decrease, however, is relative, as BP continues to be the group with the highest compliance rate each year (1042/1486, 70% to 1440/2550, 56%), while CX is the group with the lowest compliance rate (1698/4264, 40% to 1600/7656, 21%).

Across all measure groups, the outreach method showed a significant association with compliance. The PC group demonstrated the strongest relationship in 2021 with a large effect size (χ^2_3=1767.8; *P*<.001; V=0.57). Though this association persisted for all 3 years, its magnitude decreased, showing a moderate effect size in 2022 (χ^2_2 =220.3; *P*<.001; V=0.16) and 2023 (χ^2_2=409.5; *P*<.001; V=0.21). A significant but weak association was observed for the DB group in 2021 (χ^2_1=10.1; *P*=.001; ϕ=0.08) and a moderate effect size emerged in 2023 (χ^2_3=41.3; *P*<.001; V=0.14). The CX group showed a significant association in 2022 (χ^2_2=14.1; *P*<.001; V=0.10) and 2023 (χ^2_2=70.2; *P*<.001; V=0.10), though effect sizes remained weak throughout. BP had significant but weak associations between intervention and outcome for all 3 years. All significant chi-square test results are listed in Table 1, along with the analytic sample size. A complete report on all variables is available in Multimedia Appendix 4.

[a]PCP: primary care provider.

[b]SVI: social vulnerability index.

The PCP relationship was significantly associated with preventive care gap closure across several measure groups. In the PC group, a moderate association was observed in 2021 (χ^2_1=270.8; *P*<.001; ϕ=0.22), with significance maintained through 2023 (*P*<.001; ϕ=0.17). In the BP group, associations were significant in 2021 (χ^2_1=6.8; *P*=.009; ϕ=0.07) and stronger in 2022 (χ^2_1=135.7; *P*<.001; ϕ=0.27) but not sustained in 2023. The DB group followed a similar pattern, showing small but significant associations in 2021 (χ^2_1=29.9; *P*<.001; ϕ=0.13) and 2022 (χ^2_1=7.2; *P*=.007; ϕ=0.07), which was not sustained in 2023. The CX group showed inconsistent results, with weak associations in 2021 (χ^2_1=8.2; *P*=.004; ϕ=0.03) and 2023 (χ^2_1=4.4; *P*=.04; ϕ=0.02).

The association between SVI and compliance showed dynamic patterns across years. SVI demonstrated a consistent association with compliance in the BP group for all 3 years, peaking in 2022 with the strongest effect size (χ^2_3=21.7; *P*<.001; V=0.11). In contrast, the CX group (χ^2_2=17.0; *P*<.001; V=0.05) and the DB group (χ^2_2=18.6; *P*<.001; V=0.09) showed this association in 2023 only, both with small effect sizes. The same association weakened over time in the PC group, with significant, weak associations observed in 2021 (χ^2_2=25.2; *P*<.001; V=0.07) and 2022 (χ^2_2=10.4; *P*=.006; V=0.04), and no significant association detected in 2023.

Race was significantly associated with compliance in the PC group across all years, but effect sizes were negligible (Cramer V ranged from 0.04 to 0.08). A similar near-zero association was observed for the CX group (V=0.004) in 2022 only. Ethnicity demonstrated small but consistent associations with PC compliance in 2022 (χ^2_1=41.4; *P*<.001; ϕ=0.07) and 2023 (χ^2_1=46.8; *P*<.001; ϕ=0.07). In the CX group, ethnicity was associated in 2022 (χ^2_1=15.4; *P*<.001; ϕ=0.07) with a small effect, and in 2023 with a weaker effect (χ^2_1=6.1; *P*=.01; ϕ=0.03). No significant associations with race or ethnicity were observed in the DB or BP groups.

A significant but small and diminishing association between gender and compliance was noted in the PC group across all 3 years, with effect sizes ranging from 0.02 to 0.04. For the BP and DB groups in 2022 only, gender was significantly associated with compliance with weak effect sizes. Gender associations in the CX group are not reported because most measures in this group specifically targeted women.

Regression Analysis of Compliance Predictors

After adjusting for other significant predictors, the outreach method remained significantly associated with compliance. Compared with phone call outreach, chatbot outreach consistently reduced the odds of gap closure across PC, BP, and CX measures, with a 30%-65% decrease in likelihood, as shown in Figures 2-4. An exception was observed in the DB group in 2023, where chatbot outreach outperformed phone calls (OR 1.81, 95% CI 1.48-2.21; *P*<.001). Multichannel campaigns were generally less effective than phone calls and chatbot outreach, except in the CX group in 2021, where multichannel outreach increased the odds of gap closure compared with phone calls (OR 2.12, 95% CI 1.01-4.44; *P*=.047). This was likely a reflection of the relatively smaller sample size that year, whereas subsequent years had greater representation of multichannel outreach, yielding narrower CIs.

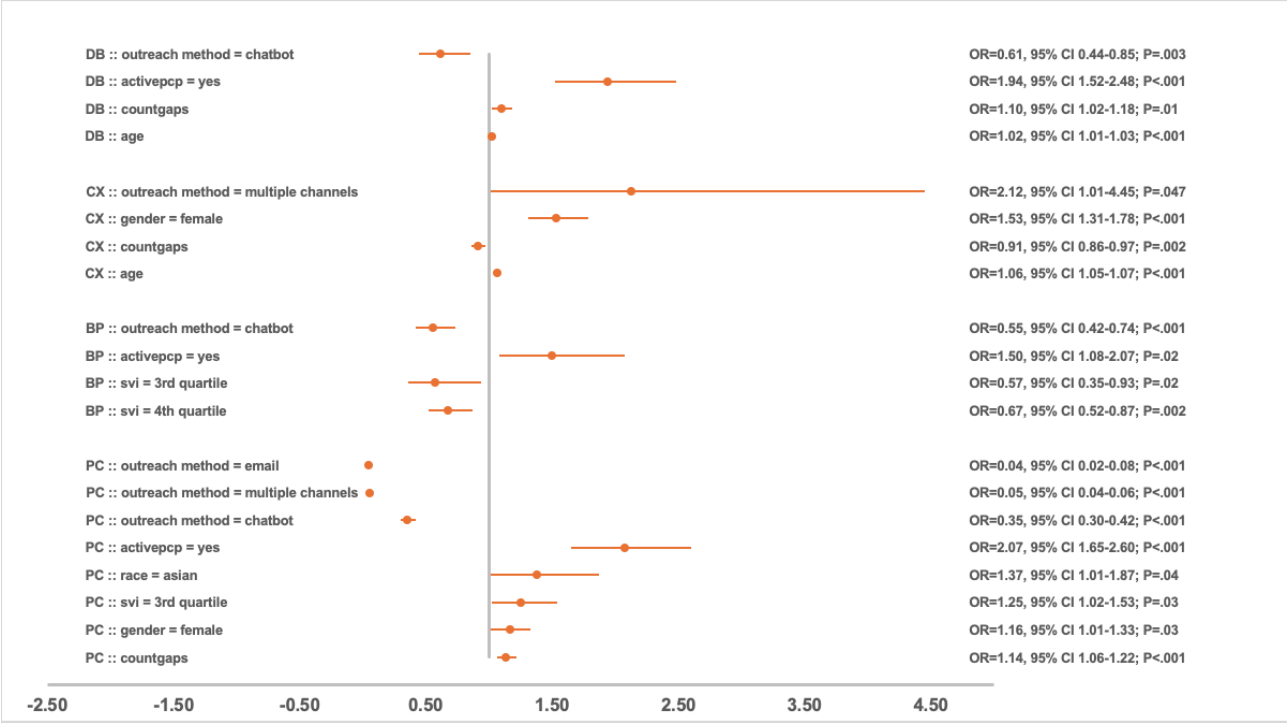
Figure 2. Odds ratio and 95% CI by significant predictors and measure group in 2021. BP: blood pressure; CX: cancer screening; DB: diabetes care; OR: odds ratio; PC: primary care; PCP: primary care provider; SVI: social vulnerability index.



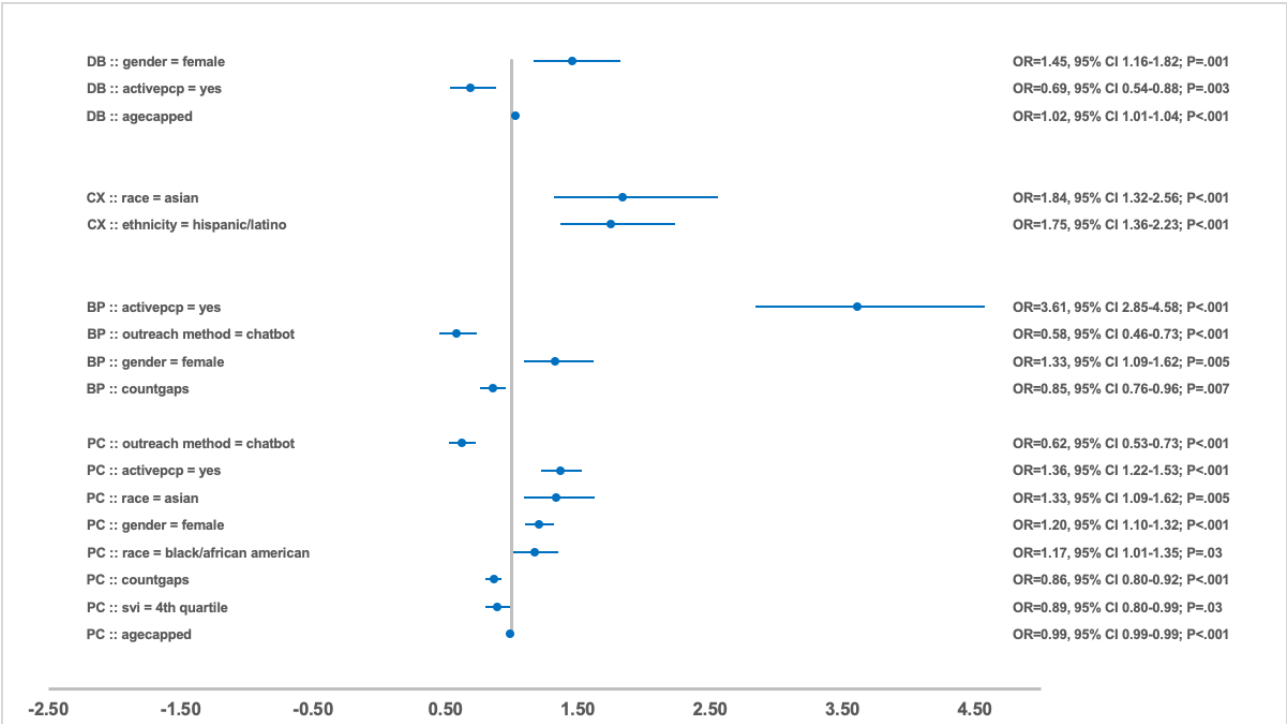


Figure 3. Odds ratio and 95% CI by significant predictors and measure group in 2022. BP: blood pressure; CX: cancer screening; DB: diabetes care; OR: odds ratio; PC: primary care; PCP: primary care provider; SVI: social vulnerability index.

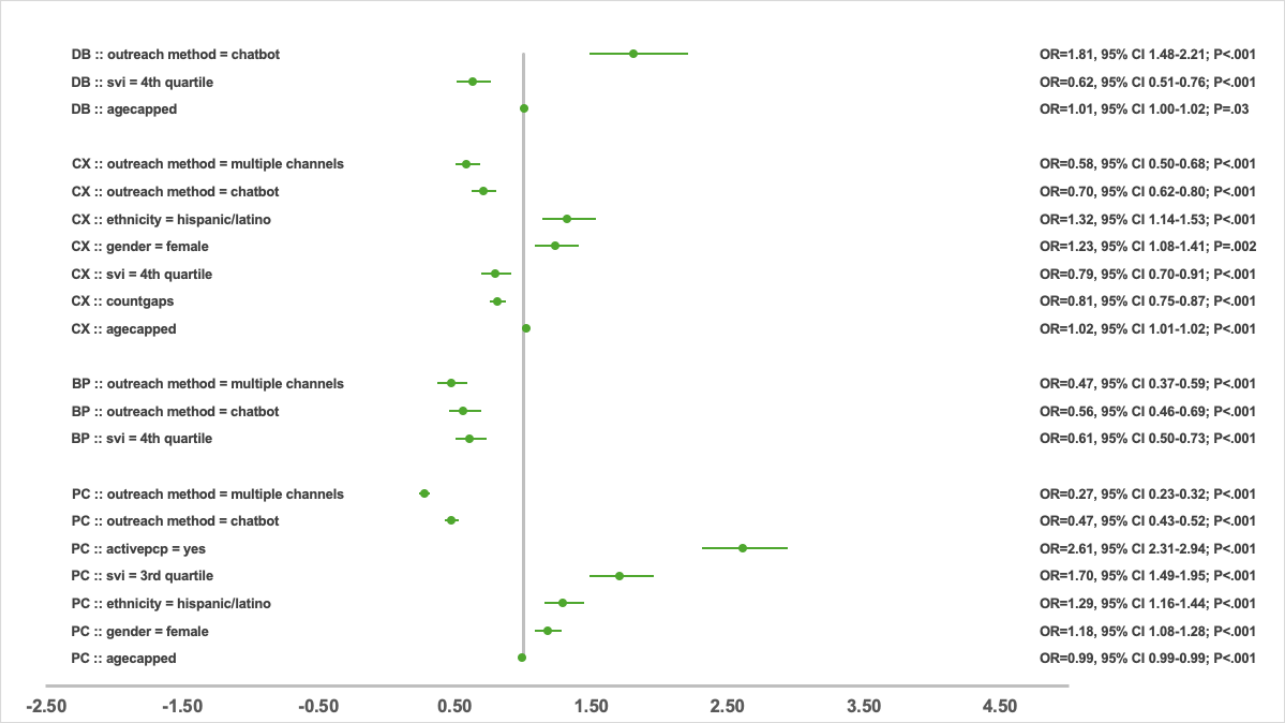
Taking account of other covariates, having a PCP relationship was the strongest predictor (*P*<.001) for care gaps compliance in the PC measure group, with ORs 2.07 (95% CI 1.65-2.60), 1.36 (95% CI 1.22-1.53), and 2.61 (95% CI 2.31-2.94) for 2021, 2022, and 2023 respectively. BP and DB had similarly significant associations in 2021 (BP: OR 1.50, 95% CI 1.08-2.07; *P*=.02; DB: OR 1.94, 95% CI 1.52-2.48; *P*<.001) and 2022 (BP: OR 3.61, 95% CI 2.85-4.58; *P*<.001; DB: OR 0.69, 95% CI 0.54-0.88; *P*=.003), but this association was not sustained in 2023. The final model for the CX group did not surface the PCP relationship as a predictor.

The SVI quartile demonstrated a complex relationship with compliance in the PC group. Participants in the third quartile were more likely to close gaps in 2021 (OR 1.25, 95% CI 1.02-1.53; *P*=.03) and 2023 (OR 1.70, 95% CI 1.49-1.95; *P*<.001) compared with the less vulnerable first quartile. In

XSL•FO
RenderX



contrast, in 2022, participants in the fourth quartile were less likely to close gaps (OR 0.89, 95% CI 0.80-0.99; *P*=.03) relative to the first quartile group. For the BP group, lower odds of gap closure were observed among the third quartile (OR 0.57, 95% CI 0.35-0.93; *P*=.02) and fourth quartile (OR 0.67, 95% CI 0.52-0.87; *P*=.002) in 2021, as well as the fourth quartile in 2023 (OR 0.61, 95% CI 0.50-0.73; *P*<.001). Similar patterns were noted for the CX and DB groups in 2023, where participants in the fourth quartile had reduced odds of closing gaps (CX: OR 0.79, 95% CI 0.70-0.91; *P*<.001; DB: OR 0.62, 95% CI 0.51-0.76; *P*<.001).

Women in the PC group had higher odds of compliance than men across all years, with ORs of 1.16 (95% CI 1.01-1.33; *P*=.03) in 2021, 1.20 (95% CI 1.10-1.32; *P*<.001) in 2022, and 1.18 (95% CI 1.08-1.28; *P*<.001) in 2023. Higher odds of gap closure for women were also observed in 2022 for the BP group (OR 1.33, 95% CI 1.09-1.62; *P*=.005) and DB group (OR 1.45, 95% CI 1.16-1.82; *P*=.001).

Asians were more likely to close gaps in PC group during 2021 (OR 1.37, 95% CI 1.01-1.87; *P*=.04) and 2022 (OR 1.33, 95% CI 1.09-1.62; *P*=.005) compared with White participants. They also showed higher odds of compliance in the CX group in 2022 (OR 1.84, 95% CI 1.32-2.56; *P*<.001). Race and ethnicity were not retained in the final model for BP and DB across all 3 years. However, ethnicity had a positive influence compliance in the CX group in 2022 (OR 1.75, 95% CI 1.36-2.23; *P*<.001) and 2023 (OR 1.32, 95% CI 1.14-1.53; *P*<.001), as well as in the PC group in 2023 (OR 1.29, 95% CI 1.16-1.44; *P*<.001).

Increasing age (capped at 89 years) showed a small, diminishing association with compliance. In the DB group, each additional year of age was associated with 1%-2% higher likelihood of gap closure, while in the CX group, the increased likelihood was 6% in 2021 and 2% in 2023. In contrast, in the PC group, older age was associated with a 1% lower likelihood of closing gaps in 2022 and 2023. Age was not a significant predictor in the final BP models across all 3 years. All percentage values for likelihood are reported based on the OR values in Figures 2-4.

Figure 4. Odds ratio and 95% CI by significant predictors and measure group in 2023. BP: blood pressure; CX: cancer screening; DB: diabetes care; OR: odds ratio; PC: primary care; PCP: primary care provider; SVI: social vulnerability index.

An increase in the number of gaps was associated with a higher likelihood of gap closure in the DB group only in 2021 (OR 1.10, 95% CI 1.02-1.18; *P*=.01), with no significant effects observed in later years. Unlike the DB group, BP and CX groups showed an inverse relationship, where each additional gap decreased the likelihood of compliance (BP 2022: OR 0.85, 95% CI 0.76-0.96; *P*=.007; CX 2021: OR 0.91, 95% CI 0.86-0.97; *P*=.002; CX 2023: OR 0.81, 95% CI 0.75-0.87; *P*<.001). The PC group demonstrated inconsistency, with more gaps increasing the odds of compliance in 2021 (OR 1.14, 95% CI 1.06-1.22; *P*<.001) but decreasing them in 2022 (OR 0.86, 95% CI 0.80-0.92; *P*<.001). ORs, 95% CIs, and *P* values for all variables with significant association in the final regression models are presented in Figures 2-4 across the 3 years. Each point in these figures represents the OR for the listed cohort and variable group on the left, and the line through the point represents the CI. The actual numbers for OR, CI, and *P* value are listed on the right side. Reference values for each category include male, White, non-Hispanic/Latino, SVI first quartile, no active PCP, and phone outreach. Any subgroups excluded due to low volume (<10) for the year are not included in the regression analysis.

Model discrimination, as assessed by the area under the receiver operating characteristic curve (AUC), was highest for the PC measure group in 2021 (AUC=0.82), indicating good

XSL•FO
RenderX

discriminatory ability. Other measure groups demonstrated modest discrimination, with AUCs ranging from 0.59 to 0.68 across years. In 2021, the model also achieved the highest classification accuracy for the PC group (78.6%), while the classification accuracy for other groups varied, ranging from 70.6% (BP) to 63.5% (CX) and 67% (DB).

Across all models, chi-square statistics were significant (P<.001), suggesting that the models were statistically associated with the outcomes. Nagelkerke R^2 values, reflecting the proportion of variance explained, were highest in 2021 for the PC group (R^2=0.41) and lower for other models, ranging from 0.02 to 0.13. Calibration, as assessed by the Hosmer-Lemeshow goodness-of-fit test, showed acceptable fit for some models (eg, CX in 2022 and 2023: P=.85 and P=.98; DB in 2022 and 2023: P=.34), but poorer fit in others (eg, PC in 2023: P<.001), indicating room for improvement in predicted versus observed outcomes alignment. Complete model diagnostics are provided in Table 2.

Table 2. Final regression model metrics for each measure group, 2021-2023.

Year and measure group	Chi-square (*df*)	*P* value	Nagelkerke R^2	*P* value (Hosmer–Lemeshow)	Overall classification accuracy, %	AUC[a]
2021						
PC[b]	1942.15 (9)	<.001	0.41	.02	78.6	0.82

[c]BP: blood pressure.

[d]CX: cancer screening.

[e]DB: diabetes care.

Discussion

Key Findings

Outreach modality remains the key modifiable lever for influencing preventive care gap closure strategies. However, its impact is declining in the PC group across the 3 years, is marginal in the BP and CX group, and needs continued studies in the DB group to establish a trend and sustained evidence of association. In VBC, where outreach for gaps in care is conducted at scale, even smaller effect sizes are worth noting, as they highlight the need for ongoing research to further understand nuances between measure groups and outreach technology preferences for optimizing operational efficiencies.

Among the outreach methods, phone calls demonstrated a stronger positive impact on outcomes compared to chatbots. This may be attributed to the chatbot's deterministic, rule-based design, which lacks the interactivity and adaptability of more advanced artificial intelligence (AI)–powered conversational agents. These results are also in agreement with the recent findings from McDowell et al [20], who presented health communication preferences from their study to show that while the majority of participants preferred SMS text messaging communication in interactions with family and friends, their preference in communicating with health care providers was primarily by use of the phone call. Even though the chatbot design for this study was a web-based chat conversation, it was initiated through an SMS text message seeking consent for further communication. As noted by Fanaroff [21], SMS text messaging–based communication, though universally accessible, may face barriers in health communications due to privacy laws such as the HIPAA (Health Insurance Portability and Accountability Act)–related security constraints imposed during implementation, which can create barriers like requiring multiple clicks to get to the core of the message. This can erode patient trust in digital health technologies, especially as incidences of

XSL•FO
RenderX

SMS text message phishing attacks have increased in the last 5 years [22]. The 2023 diabetes group exception may point to a self-management culture within DB, suggesting potential for enhanced impact through digital engagement. It certainly points to a need for segmentation by measure groups when designing outreach strategies, as well as a need for further exploration of the underlying factors driving these emerging behavioral patterns.

Sustained PCP relationships more than doubled the odds of closing gaps in PC, reinforcing the understanding that it facilitates preventive measures and use in agreement with previous findings [23]. However, the effect reversed for diabetes in 2022, suggesting disease-specific pathways (eg, endocrinology follow-up may supplant the PCP role for glycemic monitoring). The lack of association between PCP relationships and BP, DB, and CX in the 2023 regression models suggests that outreach strategies should be customized by measure and specifically address the distinct impact of PCP relationships within each measure group.

Socioeconomic vulnerability appears to be an emerging barrier. The strengthening association and effect size for this covariate in the BP group over time suggest that an equity-focused resource allocation for hypertension is warranted. The association that emerged in the CX and DB groups in 2023 cannot be ignored. These results are consistent with evidence that shows neighborhood-level disadvantage suppresses screening adherence, with Montgomery et al [24] presenting one recent example of such evidence in a cancer cohort. However, the differential effect between third and fourth quartile participants in the PC group contradicts the usual linear-deprivation narrative. This highlights the need to study community-level resilience factors and changing attitudes toward PC since the 2020 pandemic.

Other demographic predictors had a relatively smaller impact. Race and ethnicity became significant variables for PC and CX outcomes in 2022 and 2023 with small effect sizes. Specifically, the positive direction of the OR for minority groups like Asians and Hispanics is surprising and suggests the need for further targeted research into culture-based practices that promote positive outcomes, so outreach strategies can be culturally tailored for better effectiveness. Gender effects in the PC group are consistently small but show higher odds of compliance among women, agreeing with prior findings [11]. In contrast, gender effects in the BP and DB groups are inconsistent across the 3 years, while interpretation within the CX group is limited due to 2 of its 3 measures being restricted to female participants.

The overall compliance rate difference between the various measure groups does indicate some weight for the burden of completion. For example, the BP measure can be completed with a single PCP visit during the year, whereas CX measures require multiple engagements with health care, which may include imaging appointments or laboratory work in addition to follow-up visits. Complex measures should be complemented with additional support or touchpoints for optimal outreach strategies.

Limitations

This study has several limitations that should be considered when interpreting the findings. First, although the analysis draws from a large sample of individuals with preventive care gaps, the retrospective observational design limits the explanatory power of the findings. Additionally, the outreach method distribution was not uniform across measure groups; for instance, email-only and multichannel outreach cohorts did not consistently meet inclusion thresholds, restricting comparative analyses within certain subgroups. Because outreach assignments followed operational workflows rather than randomization, some selection bias may exist. Exclusions for incomplete or low-volume subgroups were applied to ensure valid statistical testing and consistent data quality. While these steps may modestly limit generalizability, the retained sample remained representative of the health system's attributed population, supporting the internal validity of findings. Generalizability is therefore most applicable to similar real-world VBC settings.

An additional limitation of this study was the presence of unmeasured variables that may account for differences in the efficiency of outreach methods. Factors such as participants' language preference, digital literacy, barriers to completion, comorbidities, and other psychosocial or contextual influences were not consistently captured across all outreach methods, likely contributing to the limited variance explained by several models. Although classification accuracy was acceptable in some cases (eg, 78.6% for PC in 2021), lower performance metrics, including the area under the receiver operating characteristic curve (eg, 0.59 for CX in 2022), indicate potential model under specification. Future research should incorporate more granular clinical, behavioral, and sociodemographic variables to enhance understanding and optimization of outreach effectiveness.

Recommendations for Practice

Even though this is not a randomized trial, the findings from this study apply to a large representative population, therefore several practical recommendations can be made to enhance the design and implementation of outreach strategies for value-based cohorts. Phone calls consistently outperformed chatbots and multichannel campaigns in driving preventive care gap closure across most measure groups and years. Health systems should continue to prioritize phone-based outreach, particularly for high-impact measure groups such as PC, while evaluating digital methods as supplementary rather than primary channels until they are more effective or better personalized. The study highlights meaningful variations in outreach effectiveness by measure group and socioeconomic status. To maximize effectiveness, outreach strategies should be customized according to the specific clinical area and complexity of the care gap, such as differentiating approaches for PC, chronic disease management, and more complex screening measures. For example, the stronger performance of chatbot outreach in the DB group in 2023 suggests that measure-specific digital readiness may guide outreach channel selection.

We also recommend enhancing chatbots for better engagement. Chatbots are an emerging technology that offers better

XSL•FO
RenderX

scalability than phone calls. The rule-based design of the chatbot used in this study likely limited its effectiveness. Transitioning to more advanced, AI-powered conversational agents that support interactive dialogue and user personalization could improve patient engagement and outcomes [25].

Socioeconomic vulnerability was a significant and increasing barrier to care gap closure, particularly in the BP group. Health systems should adopt equity-focused outreach strategies that prioritize high-SVI communities for additional support, such as community health worker involvement or tailored messaging. This is especially important in measure groups with heavier burdens of completion, like CX or chronic disease monitoring.

The relatively low explanatory power of the models underscores the need to expand the range of included variables. Incorporating clinical data (eg, comorbidities and medication adherence), behavioral factors (eg, health beliefs and prior screening history), and social determinants of health (eg, transportation access and housing stability) could significantly enhance the precision of predictive models used to guide outreach prioritization.

Conclusion

In conclusion, this study found that there is variability in the effectiveness of chatbots in outperforming traditional outreach methods for preventive screenings. The findings confirm that outreach modality continues to be a key, modifiable factor in closing preventive care gaps, with phone-based outreach consistently outperforming chatbots and multichannel strategies across most measure groups. However, the effectiveness of each outreach method varied notably by clinical context and patient subgroup, highlighting the need for a segmented outreach design that accounts for differences in patient preferences, health conditions, and burden of gap completion. The limited effectiveness of deterministic, rule-based chatbots points to the potential value of transitioning to more adaptive, AI-enabled engagement tools, particularly those capable of personalized communication and responsiveness to digital literacy. Socioeconomic vulnerability remained a key barrier, with differing trends between the third and fourth SVI quartiles indicating that vulnerability is not a linear predictor of behavior. Incorporating structured data on preferences, barriers, and comorbidities will improve model accuracy. Future research using prospective, randomized designs should further evaluate outreach modality, language, and communication preferences to guide inclusive, high-impact preventive care.

Acknowledgments

The authors would like to recognize the contributions of Mathew Sabu for data cleaning, deidentification, and analysis support during the early stages of this study.

The authors would also like to acknowledge the use of artificial intelligence tools, such as the built-in Microsoft text editor and Grammarly, to refine and clarify text that was primarily written by humans in the preparation of this manuscript.

Funding

This study did not receive external funding. The analysis was conducted as part of an operational quality improvement initiative at Northwell Health and as a component of the author’s doctoral dissertation at Rutgers University, with academic oversight provided by faculty advisors.

Data Availability

The datasets analyzed in this study were derived from health system operational data and accessed under applicable data use agreements that restrict public dissemination, even in deidentified form. Due to such contractual, ethical, and governance constraints, the data are not publicly available. Access may be considered upon reasonable request to the corresponding author and is subject to approval by the data-owning institution and execution of an appropriate data use agreement.

Authors' Contributions

JC led the conceptualization and project administration of the study and was responsible for data curation, formal analysis, visualization, and writing of the original draft. Conceptualization and methodology were jointly contributed by JC, YJ, KS, KM, DK, MD, and LC. Investigation and interpretation of findings were conducted by JC, YJ, KS, and LC. Data curation and resources were supported by KS and DK. Supervision and methodological oversight were provided by YJ, LC, KM, and MD. Writing, review, and editing were performed by all authors. All authors reviewed and approved the final manuscript and agree to be accountable for all aspects of the work in accordance with the International Committee of Medical Journal Editors and CRediT taxonomy guidelines.

Conflicts of Interest

Some authors are employed by Northwell Health, which supported this study as part of internal evaluation and quality improvement activities. Other authors are affiliated with Rutgers University as doctoral student or faculty and contributed to the study

Abstract

Background: Depression affects over 40% of middle-aged and older Chinese adults living with both hypertension and diabetes, amplifying cardiovascular risk, functional decline, and mortality. Existing screening instruments—such as the 10-item Center for Epidemiologic Studies Depression Scale—focus narrowly on mood symptoms and are rarely feasible in busy primary care consultations. They also omit routine functional, cognitive, and social data that may jointly drive depressive states in cardiometabolic populations.

Objective: This study aimed to develop and validate a concise, clinically actionable nomogram that quantifies individual depression risk using readily available information in Chinese adults aged ≥45 years who have diagnosed hypertension and type 2 diabetes.

Methods: We analyzed anonymized wave 5 China Health and Retirement Longitudinal Study data collected between July 2020 and August 2020. Of 1504 eligible participants, 635 (42.2%) met the Center for Epidemiologic Studies Depression Scale cutoff score of >10 for probable depression. A total of 42 candidate predictors spanning demographics, laboratory values, comorbidities, functional status, and socioenvironmental factors were screened. Least absolute shrinkage and selection operator regression with 10-fold cross-validation identified the most parsimonious set. A multivariable logistic model was built on a 70% training set (n=1052) and evaluated on a 30% testing set (n=452). Performance was assessed using the area under the receiver operating characteristic curve (AUC), calibration plots, decision curve analysis, and Shapley additive explanations for interpretability. Multiple imputation was used to handle <20% missingness.

Results: Nine nonredundant predictors entered the final nomogram: activity of daily living score, memory impairment, number of pain sites, sleep duration, life satisfaction score, self-rated health score, social activity engagement score, retirement status, and memory test score. The model achieved excellent discrimination (training AUC=0.819; testing AUC=0.825) and calibration (mean absolute error ≤0.018). Decision curves demonstrated positive net clinical benefit across clinically relevant threshold probabilities. Shapley additive explanations analysis revealed a 3-fold increase in depression odds per 1-point increase in activity of daily living score, whereas retirement conferred substantial protection (prevalence of depression: 103/635, 16.2% in the retired group vs 269/869, 31.0% in the nonretired group; *P*<.001), mediated by greater social participation.

Conclusions: The 9-item nomogram enables <3-minute depression risk stratification in resource-limited primary care settings for adults with hypertension and diabetes. Functional decline, affective-cognitive burden, and socioeconomic disengagement constitute the dominant causal pathway. Prospective trials should examine whether interventions targeting postretirement social engagement and functional rehabilitation can reduce incident depression in this high-risk population.

Introduction

Depression imposes an additional burden on people living with chronic conditions, especially among middle-aged and older adults who are trying to manage both high blood pressure and diabetes [1]. These physical illnesses often appear together with depressive symptoms, making treatment harder and speeding up the loss of daily function [2]. Studies have shown that, in this group, the rate of depression can reach more than 40% in some samples, and it is linked to poorer treatment adherence, higher heart-related risks, and greater chances of early death [3,4]. Even though depression is clearly important, it is still missed in many primary care visits [5]. The screening tools we have are reliable on paper, but they are hard to fit into busy clinics because of limited time and other practical barriers. The 10-item version of the Center for Epidemiologic Studies Depression Scale (CESD-10), widely used in Chinese-speaking populations, is a good example: when used alone, it cannot draw on the wider set of clinical, behavioral, and social clues that would help physicians spot depression earlier [6,7].

Most earlier models for predicting depression were built for people receiving psychiatric care or used general risk factors, so they do not work well for people who also have long-term illnesses [8,9]. A key weakness is that these models rarely include measures of daily function, such as the ability to bathe, dress, cook, and handle money, together with behavioral and social factors [10]. This omission matters because poor physical function can be both an early sign of depression and a result of uncontrolled blood pressure or blood sugar, making it hard to know which came first [11]. For these reasons, we set out to create a simple, practical tool to estimate depression risk in middle-aged and older adults with hypertension and diabetes. Using data from the China Health and Retirement Longitudinal Study (CHARLS), we examined 42 possible predictors covering medical, psychological, and social areas. Using a logistic regression model improved through machine learning and checked through several validation steps, we carried out 3 tasks: choosing the smallest set of predictors that still separates high-risk from low-risk individuals; turning these predictors into a clear, easy-to-use score that can be applied in busy, low-resource clinics; and showing, with numbers, how much heart- and metabolism-related functional problems act as a link between illness and depression. Rather than focusing only on symptoms, our approach places depression risk within the patient's overall health picture. The resulting model can guide clinicians and also point to potentially modifiable risk factors.

Methods

Ethical Considerations

This study used anonymized data from the fifth wave of the CHARLS. The project was approved by the Peking University Biomedical Ethics Committee in June 2008 (approval IRB00001052–11015). All personal identifiers were removed before our analysis. Patients and the public were not involved in the design, conduct, reporting, or dissemination of this research. All participants provided written informed consent, and the study followed the ethical principles set out in the Declaration of Helsinki. No financial or material compensation was offered to study participants.

Study Population

We carried out a retrospective study using data from the fifth wave of the CHARLS collected between July 2020 and August 2020. Participants had to be aged at least 45 years and have both hypertension and diabetes. We excluded anyone who was missing key details such as CESD-10 score, diagnosis of hypertension or diabetes, or age. After these exclusions, 1504 people were left for the analysis. Depression status was based on the CESD-10, a brief questionnaire that mixes positively and negatively worded statements. Each item is scored from 0 to 3, yielding total scores from 0 to 30; higher scores mean more severe depressive symptoms [12,13]. In Chinese older adults, a score above 10 is generally taken to indicate possible depression, and this cutoff has been shown to work well in previous studies and in latent profile analyses [13,14]. Using this cutoff, of the 1504 participants, we labeled 635 (42.2%) as the depression group and 869 (57.8%) as the nondepression group.

Candidate Predictor Variables

Guided by earlier studies and clinical practice, we chose 42 factors that might relate to depression risk [15-17]. These factors cover basic personal details, overall health, daily habits, blood test results, and how well people manage daily tasks. The full list is as follows: sex, age, marital status, smoking status, drinking status, cancer, lung disease, heart disease, stroke, mental illness, arthritis, high blood fat, liver disease, kidney disease, stomach disease, asthma, memory problems, hip fracture, number of painful body sites, exercise level, sleep hours, social activity engagement, whether the patient was retired, medical insurance, pension insurance, years of schooling, household size, number of living children, household income, recent physician visits, memory test score, activity of daily living (ADL) score, instrumental ADL (IADL) score, self-rated health, and satisfaction with life. Regarding "social activity engagement," it was categorized into the following eight types: (1) interacted with friends (visiting friends or socializing with friends); (2) played mahjong, played chess, played cards, or went to community clubs; (3) provided help to family members, friends, or neighbors who do not live with the participant and who did not pay them for the help; (4) went to a sports, social, or other type of club; (5) took part in community-related organization activities; (6) did voluntary or charity work; (7) attended an educational or training course; and (8) other.

Participants completed the questionnaire based on their actual situation: participation in 1 type of the above activities was recorded as "1," participation in 2 types was recorded as "2," and a higher count indicated a higher level of social activity engagement of the participant. For "life satisfaction," the CHARLS survey asked respondents about their overall satisfaction with their lives, with 5 response options: "extremely satisfied," "very satisfied," "relatively satisfied," "not very satisfied," and "not satisfied at all." For the convenience of statistical analysis, we assigned numerical values to these levels: "1" represented "not satisfied at all," "5" represented "extremely

XSL•FO
RenderX

satisfied," and so on, with each level corresponding to a specific number.

Model Construction Methods

We used least absolute shrinkage and selection operator (LASSO) regression to pick out the most useful risk factors while keeping the list short. Ten-fold cross-validation helped us find the best penalty value (λ). We then split the data into a training set (1052 people) and a testing set (452 people) in a 7:3 ratio. The training set was used to find the key factors linked to depression. These factors were entered into a standard logistic regression, and we drew a simple chart (nomogram) to show how each one affected the risk of depression. To keep the model easy to use, we removed predictors with little impact, reran the logistic regression with the remaining ones, and built the final nomogram.

Model Evaluation Methods

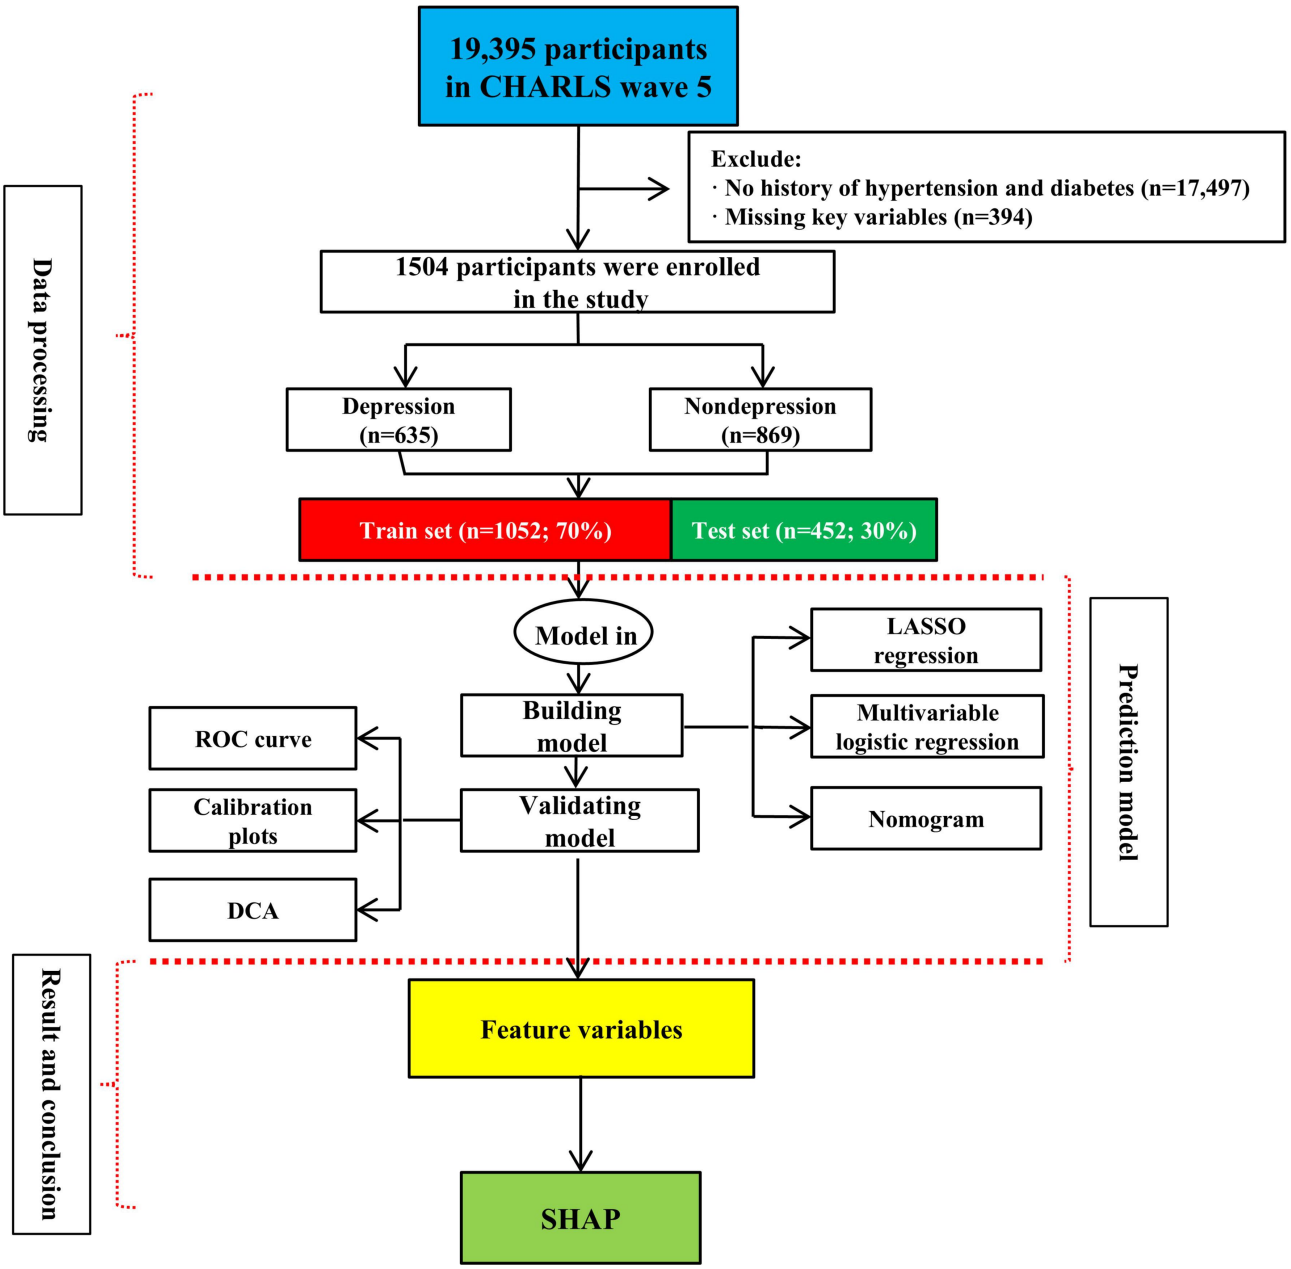
To check how well the model performed, we used receiver operating characteristic curves and the area under these curves (AUC) to measure overall ability to separate people with and without depression, calibration plots to check whether the predicted chances matched what really happened, and decision curve analysis to weigh the benefits of true positive predictions against the harms of false ones, giving a clear picture of both accuracy and clinical value.

Model Interpretation Methods

To make the model easier to understand, we used Shapley additive explanations (SHAP) values to show how much each factor mattered. We drew 4 simple charts (an overall importance plot, a swarm plot, a waterfall plot, and a force plot) that displayed how every factor pushed the risk of depression up or down. These pictures help readers see which factors carry the most weight and how they work together in the model.

Data Processing Methods

All statistical analyses and figure generation were performed using R (R Foundation for Statistical Computing). When less than 20% of the data were missing, we used the *mice* package to run 5 rounds of imputation and kept the set that best matched the overall pattern. We report counts and percentages for categorical variables and means with SDs for continuous variables. We compared groups using 2-tailed *t* tests, chi-square tests, or nonparametric tests as needed; the latter were chosen when the data did not follow the rules for parametric tests. A *P* value <.05 was considered statistically significant.



Results

Flowchart

The study flowchart is presented in Figure 1.

XSL•FO
RenderX

Figure 1. Study flowchart. Analysis of China Health and Retirement Longitudinal Study (CHARLS) wave 5 participants with hypertension and diabetes comorbidity (aged ≥45 years). DCA: decision curve analysis; LASSO: least absolute shrinkage and selection operator; ROC: receiver operating characteristic; SHAP: Shapley additive explanations.

Baseline Characteristics

We included 1504 adults with an average age of 65.99 (SD 8.28) years and 64.93 (SD 8.72) years for those with and without depression, respectively; 678 (45.1%) were men, and 826 (54.9%) were women. Of these 1504 participants, 635 (42.2%) were classed as having possible depression, and 869 (57.8%) were classed as nondepressed. Table 1 shows that the 2 groups differed on many key points. Those with possible depression were more often women, widowed or separated, and less active and reported more illnesses, such as lung disease, heart disease, stroke, arthritis, mental illness, liver disease, kidney disease, stomach disease, asthma, hip fracture, and memory problems. They also had more pain sites; poorer sleep; lower income; fewer years of schooling; smaller households; more physician visits; fewer social activities; and lower scores on memory, daily activities, self-rated health, and life satisfaction (P<.05 in all cases).

Characteristic	Nondepression (n=869)	Depression (n=635)	*P* value
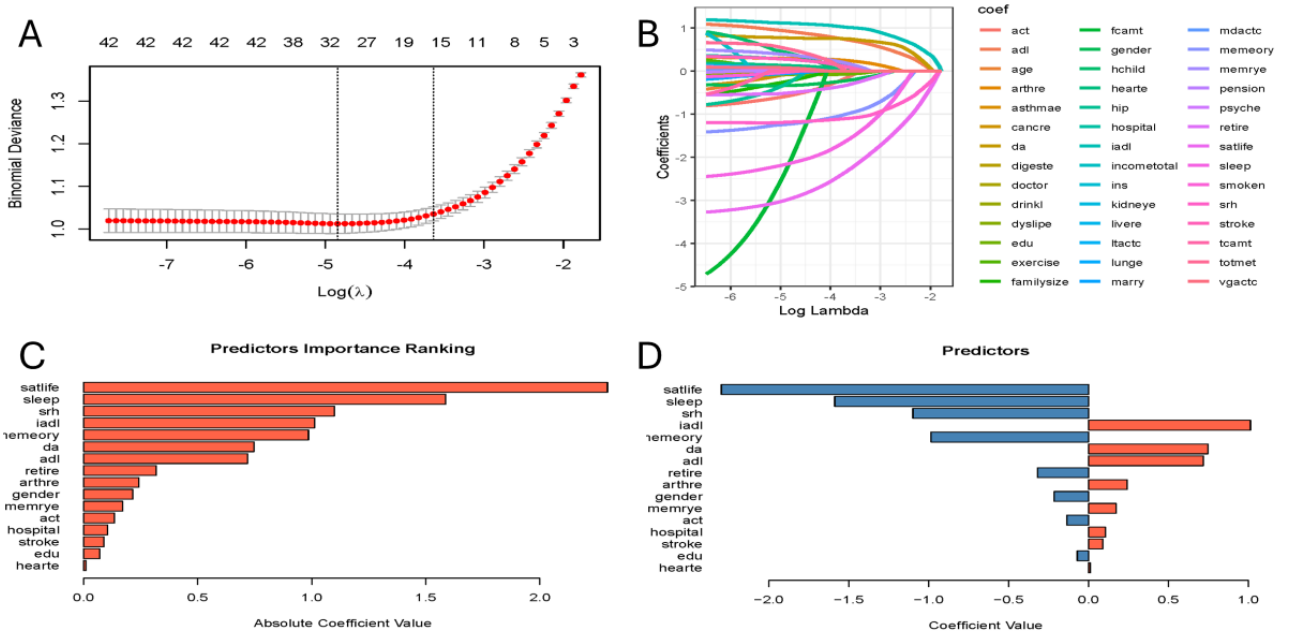
Social activity engagement (number of activities participated in), mean (SD)	0.94 (1.14)	0.65 (0.90)	<.001
Age (y), mean (SD)	64.93 (8.72)	65.99 (8.28)	.02
Educational level[a], mean (SD)	2.26 (1.11)	1.85 (1.02)	<.001
Total MET[b] (min), mean (SD)	4627.13 (4936.56)	4832.40 (5150.61)	.43
Memory score (0-11), mean (SD)	4.51 (1.74)	3.61 (1.84)	<.001
ADL[c] score (0-6), mean (SD)	0.34 (0.85)	1.20 (1.60)	<.001
IADL[d] score (0-5), mean (SD)	0.32 (0.84)	1.18 (1.50)	<.001

[a]Educational level was scored as follows: 1=illiterate; 2=below junior high school; 3=junior high school and above, below university; 4=university and above.

[b]MET: metabolic equivalent of task.



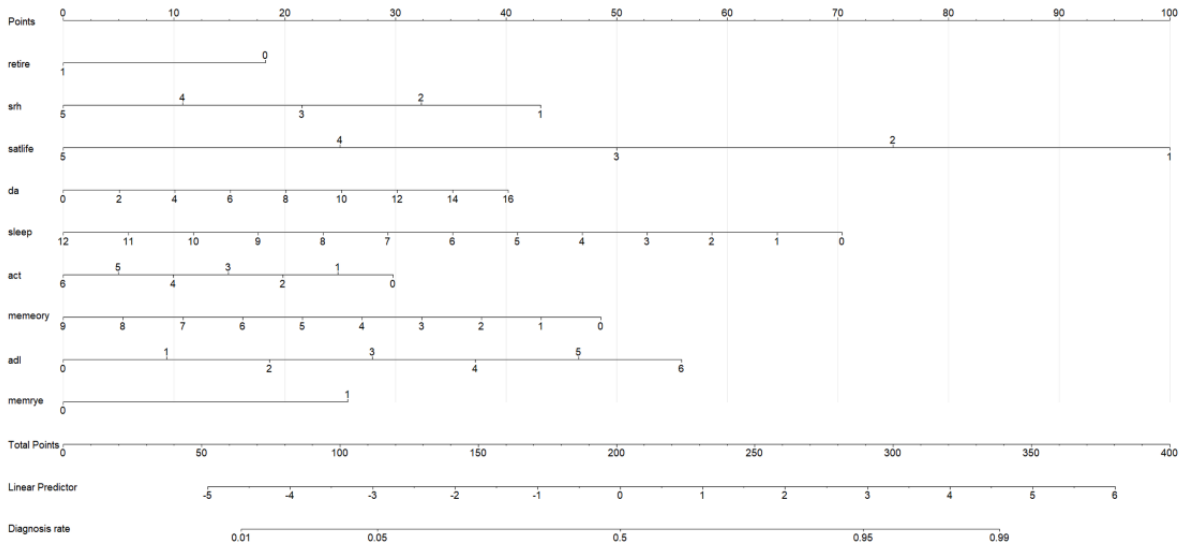
[c]ADL: activity of daily living.

[d]IADL: instrumental ADL.

Results of Model Construction

As the regularization strength (λ) increases, the model error initially decreases and then increases. We chose the simplest model within 1 SE of the minimum error. This left 16 variables whose coefficients stayed above 0 (Figure 2A). Each line in the plot shows one variable's coefficient; as λ grows (moving right), many lines drop to 0 and are removed. In the end, 16 factors remained: life satisfaction score, sleep hours, self-rated health score, IADL score, memory score, pain sites, ADL score, retirement status, arthritis, sex, memory problems, social activity engagement type, recent physician visits, stroke, years of schooling, and heart disease, listed from most to least important (Figure 2C). Figure 2D shows the direction of each factor: red bars mean higher risk, and blue bars mean lower risk.

Figure 2. Predictor selection using least absolute shrinkage and selection operator (LASSO) regression. (A) Cross-validation plot showing the relationship between the regularization parameter (λ) and model deviance. The vertical dashed line indicates the optimal λ value (minimum λ+1 SE). (B) LASSO coefficient path plot showing how variable coefficients shrink toward 0 as λ increases. (C) Ranking of the 16 selected predictors based on their standardized regression coefficients. (D) Coefficient direction plot indicating risk (red=positive coefficient) and protective (blue=negative coefficient) factors for depression. Act: social activity engagement; ADL: activity of daily living; DA: number of pain sites; IADL: instrumental ADL; memrye: memory problems; satlife: life satisfaction score; SRH: self-rated health score.



We took the 16 variables and ran them together in a new regression model and then drew a simple point chart (nomogram). The chart showed which factors mattered the most so that we could drop the weaker ones. After this step, 9 factors remained: retirement status, self-rated health score, life satisfaction score, number of pain sites, sleep hours, social activity engagement type, memory score, ADL score, and memory-related disease. We put these 9 factors into a final regression and built the last nomogram (Figure 3). On the chart, each line shows how many points a person obtains for that

XSL•FO
RenderX

factor; the bottom scale turns the total points into the chance of depression. Higher total points mean higher risk.

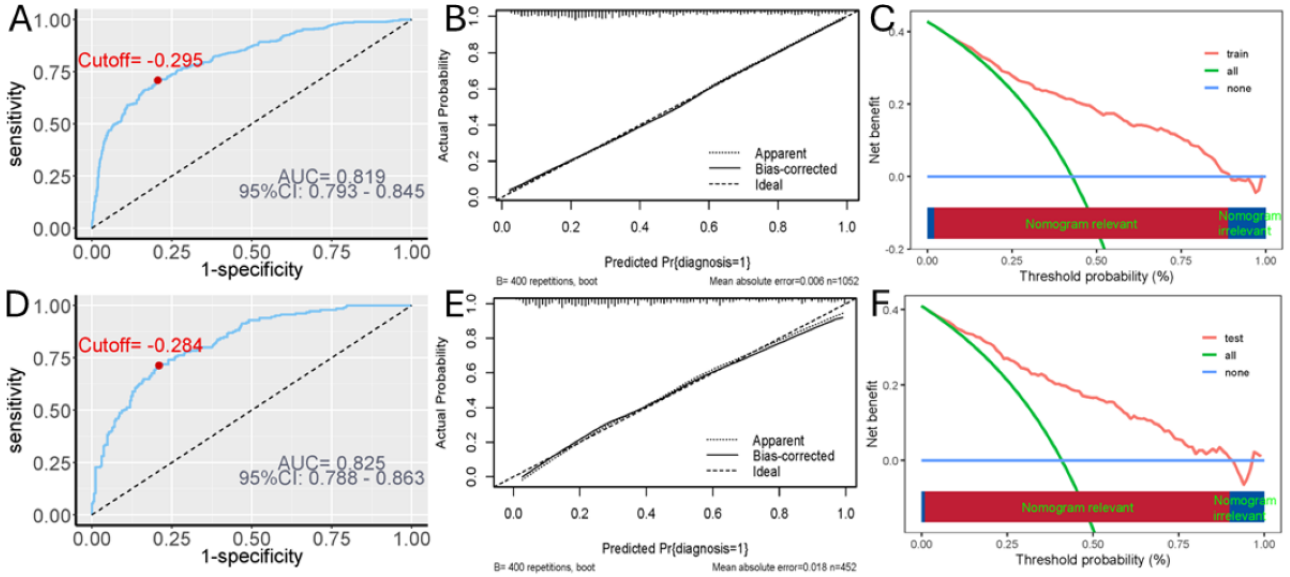


Figure 3. Nomogram for predicting depression risk. The nomogram was constructed using 9 predictors selected from multivariate logistic regression. Each predictor is assigned a point value based on its regression coefficient. The total score corresponds to the predicted probability of depression in the bottom scale. Higher total scores indicate a higher risk of depression. Act: social activity engagement; ADL: activity of daily living; DA: number of pain sites; memrye: memory problems; satlife: life satisfaction score; SRH: self-rated health score.

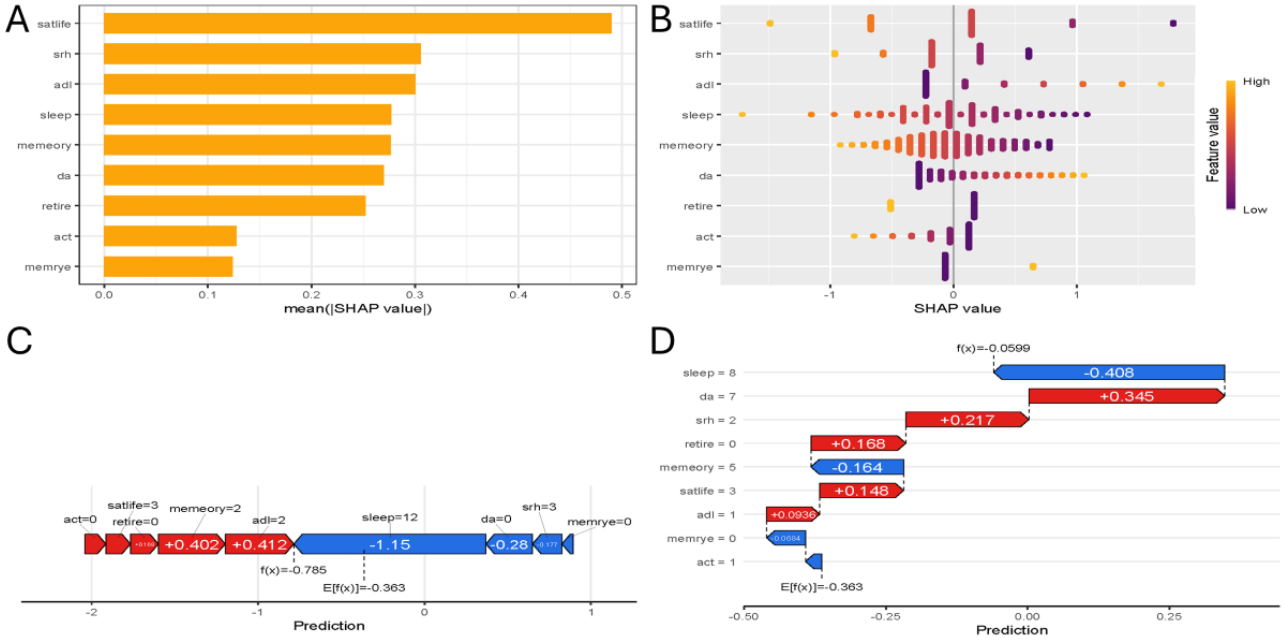
Results of Model Evaluation

We tested how well the model separated people with and without depression using the AUC. In the training data (Figure 4A), the AUC was 0.819, and in the testing data (Figure 4D), it was 0.825, showing good discrimination. The predicted probabilities matched the real outcomes closely in both sets; the average error was only 0.006 in training (Figure 4B) and 0.018 in testing (Figure 4E). Decision curve analysis (Figures 4C and 4F) also showed clear clinical benefit: the model yielded much larger net benefits than the "treat all" or "treat none" approaches. Overall, the nomogram was accurate and clinically useful.

Figure 4. Evaluation of the predictive model. (A) Receiver operating characteristic (ROC) curve and area under the curve (AUC) value in the training set (AUC=0.819). (B) Calibration plot in the training set (mean absolute error=0.006). (C) Decision curve analysis (DCA) in the training set. (D) ROC curve and AUC value in the testing set (AUC=0.825). (E) Calibration plot in the testing set (mean absolute error=0.018). (F) DCA in the testing set. The model demonstrates strong discriminative ability, good calibration, and high clinical utility in both datasets.



Results of Model Interpretation

We used SHAP values to look at the 9 main variables. Global and swarm plots (Figure 5A-B) show how each variable affects the entire sample. ADL score, memory problems, and number of pain sites pushed the risk upward, whereas retirement status, social activity engagement type, sleep hours, life satisfaction score, self-rated health score, and memory score pushed it

XSL•FO
RenderX

downward. To see how these factors worked for individual people, we picked 2 participants at random and used waterfall and force plots (Figure 5C-D) to show each factor's exact contribution.

Figure 5. Shapley additive explanations (SHAP) analysis of the final model. (A) Global SHAP importance plot showing the average impact of each feature on model predictions. (B) SHAP swarm plot illustrating the distribution of SHAP values for each feature across all participants (red=increased risk; blue=decreased risk). (C) Waterfall plot for a randomly selected individual showing the contribution of each feature to the final prediction. (D) Force plot for another individual, highlighting the cumulative effect of features on the predicted probability of depression. Positive SHAP values (red) increase the risk of depression, whereas negative values (blue) decrease it. Act: social activity engagement; ADL: activity of daily living; DA: number of pain sites; memrye: memory problems; satlife: life satisfaction score; SRH: self-rated health score.

Discussion

Principal Findings

This study establishes a clinically operable prediction model for depression risk among middle-aged and older patients with hypertension and diabetes, leveraging multidimensional predictors to achieve robust discrimination (AUC=0.819 - 0.825) and calibration (mean absolute error≤0.018). Nine core variables emerged as significant predictors in the final nomogram: ADL score, memory disorders, number of pain sites, sleep duration, life satisfaction score, self-rated health score, social activity engagement, retirement status, and memory score. The centrality of functional impairment as a mechanistic pathway is underscored by the ADL score's dominant predictive role [18,19], where individuals with depression exhibited markedly elevated scores (mean 1.20, SD 1.60 vs mean 0.34, SD 0.85; *P*<.001). Each unit increase in ADL score corresponded to a 3-fold increase in depression risk, particularly at critical thresholds beyond ADL score ≥2. Retirement status provided substantial protection against depression [19,20], with prevalence rates nearly halved among retirees (103/635, 16.2%) compared to nonretirees (269/869, 31.0%; *P*<.001) mediated by significantly greater social participation (mean activity score 0.94, SD 1.14 vs mean 0.65, SD 0.90; *P*<.001). SHAP value distributions (Figure 5A-B) corroborated a triadic pathogenesis framework. First, functional autonomy erosion (ADL and IADL decline interacting with multisite pain) imposes physical constraints that amplify helplessness [21,22]. Second, affective-cognitive burden manifests through memory disorders (there were memory disorders in 97/635, 15.3% vs 47/869, 5.4% of participants with and without depression, respectively; *P*<.001), and reduced life satisfaction (mean score 2.87, SD 0.87 vs mean score 3.41, SD 0.66 among participants with and without depression; *P*<.001) depletes emotional reserves [23]. Third, socioeconomic disengagement was evidenced by significantly lower household incomes among participants with depression (mean ¥32,470.65 [US $4720.71], SD ¥88,119.77 [US $12,811.20] vs mean ¥54,055.20 [US $7858.73], SD ¥79,512.32 [US $10,687.50], respectively; *P*<.001), constraining access to health-promoting resources [24,25]. The nonlinear inflection point observed in the ADL-depression relationship indicates that moderate functional decline triggers disproportionately severe psychological sequelae, offering an identifiable intercept for targeted interventions [26].

These findings advance beyond prior depression prediction paradigms in several critical dimensions. Traditional screening instruments reliant on mood-based symptomatology such as the Patient Health Questionnaire series demonstrate limited applicability in cardiometabolic populations due to diagnostic circularity: they cannot resolve whether fatigue or anhedonia stems from depression vs underlying chronic disease pathology [27,28]. Our model effectively dissociates these confounds by operationalizing ADLs as an independent construct validated through SHAP's feature dissociation capability. For instance, while arthritis prevalence was markedly higher among participants with depression (389/635, 61.3% vs 324/869, 37.3%; *P*<.001), LASSO selected number of pain sites rather than arthritis diagnosis as the principal pain predictor due to its ability to quantify functional impact severity [29]. When

XSL•FO
RenderX

benchmarked against models with similar AUC values to those of the model evaluated in this study, such as the depressive symptom predictor by Zheng et al [30,31], our algorithm demonstrates superior translational efficiency by using information already captured in routine chronic disease management ADL documentation during nursing assessments, medication review for memory issues, and social history documenting retirement status. This obviates the need for additional screening instruments, reducing assessment time to under 3 minutes. Moreover, we identify novel modifiable pathways absent in prior frameworks. The protective effect of retirement when linked to sustained social activity engagement reveals life transitions as windows for resilience-building interventions [32]. Enhancing life satisfaction emerged as another actionable leverage point given its strong negative association with depression (β=−0.63 via LASSO), suggesting that psychosocial enrichment may disrupt pathogenic cascades more effectively than purely biomedical approaches [33].

Methodologically, the integration of LASSO regression with SHAP value interpretation constitutes a primary strength. LASSO refined the predictor pool from 42 candidates to 9 nonredundant variables, efficiently eliminating noncontributory markers such as cancer or lung disease. SHAP analysis then transformed statistical coefficients—for example, the negative β value for retirement (−0.89)—into clinically interpretable narratives. At an individual level (Figure 5D), retirees maintaining active social roles exhibited an 18-fold depression risk reduction compared to their socially isolated counterparts. The CHARLS cohort's population representativeness further enhances generalizability to China's aging cardiometabolic patient demographic. Four principal limitations warrant acknowledgment. Due to the cross-sectional nature of wave 5 CHARLS data, causal precedence between functional decline and depression could not be definitively established. However, the biological gradient observed in ADL risk proportionality (higher scores predicting depression probability stepwise) lends credibility to functional deterioration as a driver rather than a secondary consequence [34,35]. Second, depression ascertainment using a CESD-10 score >10 may overlook subsyndromal presentations, potentially underestimating risk in highly functional individuals [36]. Third, unmeasured variables influencing both pathways, particularly medication adherence patterns or pharmacodynamic interactions between psychotropics and antihypertensives, were unaccounted for. Finally, sociocultural proxies unique to Chinese aging populations' children's financial support demonstrating borderline significance (*P*=.02-.03) were excluded from the final model despite their potential clinical relevance [37]. Future iterations should address this through culturally adapted predictor sets.

This study was conducted based on statistical data from the CHARLS database. Therefore, the results of this study have limitations in terms of applicability to young and middle-aged populations, as well as populations from different regions and ethnic groups. In future research, we may consider combining data from public databases in the Americas, Europe, and other regions to conduct joint modeling, thereby improving the generalization performance of the model. These findings suggest priority areas for future research and clinical application. Longitudinal analyses using multiwave CHARLS data should test the proposed retirement–social engagement–protection pathway, examining whether weekly social activity sustains resilience to depressive symptoms. A 3-tier risk stratification protocol based on nomogram scores may guide care: individuals scoring ≤150 can continue annual screening; those scoring 150 to 250 should receive functional preservation strategies, including task-oriented exercise and cognitive behavioral approaches to improve ADLs, sleep, and social engagement; and those scoring ≥250 would require multidisciplinary management due to high comorbidity. Embedding this algorithm into electronic health records within China's National Essential Public Health Service Package could enable automated alerts when thresholds are met. Pilot programs should focus on communities where the baseline ADL score is ≥1.5; in this study, 51.2% (325/635) of participants with depression were in this category. Randomized trials are needed to evaluate mediator-targeted interventions, including combined ADL and pain management, structured postretirement social role adaptation, and hemoglobin A_{1c}–stratified memory screening in diabetes. Targeting domain-specific vulnerabilities rather than symptoms alone may reduce depression incidence while optimizing primary care resources.

Conclusions

We developed and validated a depression risk model for middle-aged and older adults with hypertension and diabetes. The nomogram, integrating 9 routinely collected predictors, including ADL score, memory impairment, and pain burden, showed strong discrimination and calibration. Depression risk rose 3-fold for each unit increase in ADL score, whereas retirement was protective. Functional impairment, emotional cognitive burden, and socioeconomic disadvantage formed the dominant risk pathway. LASSO-SHAP integration streamlined predictor selection, enabling screening in under 3 minutes. Prospective trials should test interventions targeting postretirement social engagement and functional rehabilitation, alongside implementing a 3-tier risk stratification protocol in primary care. Targeting these domain-specific risks could reduce depression incidence.

Abstract

Background: Advances in medical imaging have led to massive archives, yet navigating these datasets remains challenging due to the limitations of traditional text-based search engines. While content-based medical image retrieval (CBMIR) offers a visual feature–based solution to enhance clinical workflows and research, its operational integration into picture archiving and communication systems (PACS) remains a significant bottleneck. Despite the progress in deep learning for feature extraction, CBMIR tools are rarely integrated and effectively implemented within existing radiology information systems due to complex protocol barriers.

Objective: To address these challenges, this study develops a CBMIR system meticulously designed to cater to 7 distinct types of brain tumors as seen in brain magnetic resonance images. Our system is tailored to assist radiologists and health care professionals in efficiently retrieving pertinent historical medical images, thereby providing quantitative decision support for radiologists and facilitating evidence-based case comparison, with the potential to improve retrieval efficiency and clinical workflow, rather than directly enhancing diagnostic accuracy.

Methods: The dataset used in this study was collected from a single medical center and is not publicly available. The core innovation is a state-of-the-art deep learning–based feature extraction algorithm specifically engineered for the CBMIR system. We use GoogLeNet as the primary architecture, incorporating generalized mean pooling to capture nuanced local features and an embedding layer for dimension reduction. Crucially, we address the integration gap by harmonizing 2 open-source projects to successfully embed the CBMIR system into a functional PACS environment via standard protocols.

Results: The image dataset contains 658 participants with 15,873 images collected from 2000 to 2017. The empirical findings of our research demonstrate the performance and robustness of the proposed CBMIR system. Our system achieves a remarkable mean average precision score of 89.16% and an equally impressive Precision@10 score of 94.08%. These metrics affirm the system's efficacy in retrieving relevant medical images. Furthermore, we successfully integrate the CBMIR system into a PACS by successfully harmonizing 2 open-source projects.

Conclusions: This study presents the design and implementation of a PACS-integrated CBMIR system for brain magnetic resonance imaging, and the experimental results demonstrate that the system can achieve efficient and accurate image retrieval within a clinical workflow.

Introduction

Background

Advances and rapid growth in medical imaging technology have led to the emergence of massive medical image archives. Effective image retrieval is crucial for both research and clinical applications, yet navigating these large-scale archives remains a time-consuming task, often limited by traditional text-based search engines [1]. Radiologists, in particular, face the challenge of interpreting cross-sectional studies composed of thousands of images retrieved from picture archiving and communication systems (PACS) [2].

PACS is a health care IT system that manages the storage, retrieval, distribution, and presentation of medical digital images within a hospital. It works closely with the DICOM (Digital Imaging and Communications in Medicine) standard, which ensures that medical images and related data are stored and transmitted in a consistent format across different machines and systems. To integrate a third-party system, it must interface directly with the PACS via the DICOM protocol. This integration is critical as it allows health care providers to successfully access and share patient images within their workflows, enabling the content-based medical image retrieval (CBMIR) system to function effectively as a clinical decision support tool.

CBMIR offers a more efficient solution by enabling image searches based on the visual features of source images. CBMIR systems have the potential to significantly enhance clinical imaging workflows, delivering meaningful improvements across multiple areas, including medical education, research, and clinical diagnostics [3].

Röhrich et al [4] found that integrating CBMIR into medical imaging reduced image interpretation time by 31.3% for both junior and senior radiologists, while also helping them access more valuable consultative resources. When combined with an intelligent interactive visual browser, CBMIR could further enhance medical education, research, and clinical care by improving both image navigation and diagnostic outcomes [1]. Müller et al [5] highlighted the usefulness of CBMIR in academic settings, particularly for lecturers and students who can visually explore educational image repositories, facilitating more engaging and insightful learning experiences.

The retrieval principle encompasses several key aspects that collectively contribute to the effective retrieval of information. In particular, intricate processes are involved, such as analyzing and converting user requisites into queries suitable for retrieving data from indexed databases. In the process of CBMIR operation, the features of the images, relying on captions, visual words [6], preannotations [7], and image attributes [8], are first extracted and stored in a database. A distance metric summarizing information about image features measures the similarity between any given pair of images [9,10]. During CBMIR development, the key components are feature extraction and similarity determination [8], with feature extraction being the crucial step. In the past, CBMIR techniques have focused on semantic content matching of images, for example, analyzing and retrieving images based on their color, texture, and layout. Ponciano-Silva and colleagues [11] addressed the limitations of past CBMIR systems that typically used only a single perceptual parameter (ie, feature extraction and distance function), thus restricting such systems to a single search space.

In recent years, the rapid development of artificial intelligence (AI) technology and significant improvements in image processing capabilities have led to the application of AI technology to enhance CBMIR performance. The powerful algorithmic capabilities of deep learning have also been applied to CBMIR systems. Maji et al [12] compared the accuracy of various AI pretrained models, such as DenseNet [13], InceptionResNetV2 [14], InceptionV4 [14], MobileNetV2 [15], ResNet50 [16], and VGG19 (Visual Geometry Group model 19) [17]. They concluded that InceptionResNetV2 exhibited the highest accuracy and chose it as the feature extraction model. They further proposed using principal component analysis and clustering methods to increase retrieval speed by at least a factor of 2.

Rashad et al [18] adopted pretrained deep learning models to extract additional high-level features from medical images to improve the accuracy of the retrieved results in extracting compact, deep, and high-level features. Cheng and colleagues [19] tackled the limited texture representation of brain tumor images in traditional image processing methods. They used the Fisher Vector to aggregate local features into a single vector and used closed-form metric learning to effectively measure similarity between 2 given images. They achieved a mean average precision (mAP) of 94.8%. While this method achieved excellent accuracy, the concatenation of feature vectors from various subregions led to a high dimensionality of up to 24,576, potentially resulting in decreased query speed.

Qayyum et al [20] collected a diverse medical image dataset encompassing 24 anatomical regions and various imaging modalities. They used deep learning to train and build an 8-layer model whose architecture transforms 4096 features into a probability distribution over 24 categories. The average accuracy achieved in classification was 99.76%. They found that without prior classification and querying, mAP reached a mere 53%, while performing classification before querying improved mAP to 69%. Swati et al [21] focused on a contrast-enhanced magnetic resonance imaging brain tumor dataset [22] and used the pretrained VGG19 model (Visual Geometry Group model 19) for fine-tuning transfer learning (TL). Their study applied deep learning by using the last fully connected layer to extract the features, which is the input of the closed-form metric learning for contrast-enhanced magnetic resonance imaging to achieve a mAP of 96.13% [21]. Deepak and Ameer [23] evaluated various pretrained model architectures in terms of classification accuracy, training time, and feature extraction time. They selected GoogLeNet as the basis for their deep learning architecture, requiring a 2-stage training process; the achieved mAP was 97.64%.

Vision Transformer (ViT)–based models have demonstrated significant advantages when dealing with large datasets, enabling them to attend to critical image features, superior capacity for global feature modeling and context awareness,

XSL•FO
RenderX

and thereby improve medical image classification performance [24]. For instance, Anupama and Anitha [25] developed a ViT-based CBMIR system that reliably and precisely extracts pertinent medical images. The predicted results, particularly for magnetic resonance imaging data, confirm the model's capability to manage intricate imaging characteristics and provide precise outcomes [25]. Furthermore, studies by Sunday et al [26] highlight the use of the DINOv2 self-supervised framework to enhance anatomical structure visibility and reduce image noise. This demonstrates the potential of general-purpose self-supervised models in CBMIR, offering high transferability and robustness to varying image quality without requiring extensive domain adaptation [26]. In related work, Sarıateş and Özbay [27] used a TL framework to successfully classify melanoma images and enhance the efficiency of their content-based image retrieval systems.

However, due to technological bottlenecks that have yet to be overcome, CBMIR is rarely used in existing PACS and radiology information systems [1]. CBMIR could greatly benefit researchers and physicians in PACS [28-31]. Valente et al [32] used the open-source PACS software Dicoogle (University of Aveiro) as the development base for CBMIR for clinical applications. Besides general image, they focused on a mammography profile specifying the mammography features, allowing users to access CBMIR features integrated with a PACS to ensure high scalability.

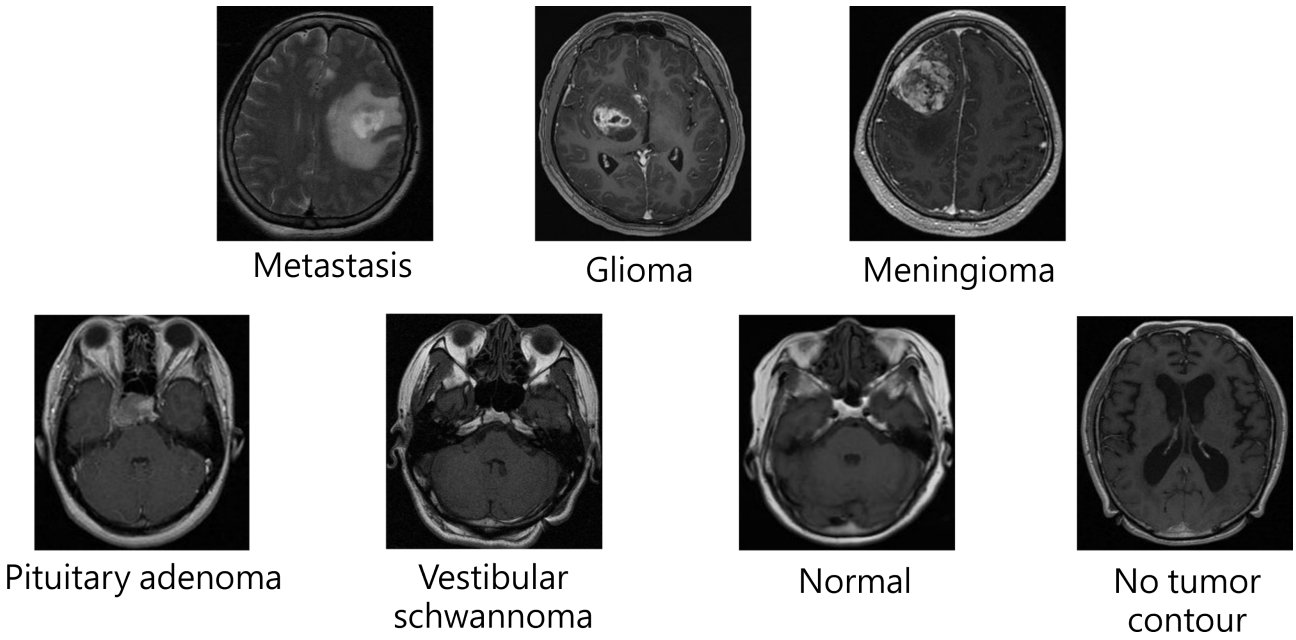
Our Contributions

Our primary contributions are summarized as follows: This study proposes an innovative CBMIR approach using ArcFace Loss [33] to enhance the understanding of image feature similarity and replaces the pooling layer with generalized mean (GeM) pooling. This allows the model to focus on key regions while preserving overall image information. This strategy strengthens the feature space's discriminability, resulting in significantly improved retrieval accuracy (mAP). We developed a robust CBMIR system successfully integrated with open-source DICOM viewer named BlueLight [34], achieving real-time clinical applicability by enabling rapid consultation of structurally similar cases.

Methods

Dataset

We gathered from Taipei Veterans General Hospital (TVGH) a comprehensive collection of brain magnetic resonance (MR) images formatted in DICOM. This image dataset was retrospectively collected and features a wide array of neurological conditions. These conditions have been categorized into 7 distinct groups: metastasis, glioma, meningioma, pituitary adenoma, vestibular schwannoma, and categories for images with no tumor contour and those representing normal brain scans.



All classes of tumors were delineated by neurosurgeons and validated by neuroradiologists from the TVGH, referred to as "ground truth." Table 1 provides statistics regarding the classes of tumors in the dataset. The image dataset, comprising 658 participants, was divided into training (70%, 461 participants, 11,207 images) and test (30%, 197 participants, 4666 images) subsets collected from 2000 to 2017. The median age was 56.4 years. Gender distribution was 57% (375/658) male and 43% (283/658) female. The distribution of image laterality was 52% left and 48% right. The median tumor volume, excluding normal images, was 2.02 mL, calculated from manual segmentation of lesions in MR images. Some patients underwent Gamma Knife radiosurgery that contains both pre–radiation therapy images and follow-up images. No patient overlapped between the training and test sets. Data in the test subset were not augmented. Examples of all classes of tumors are shown in Figure 1.

Table . Classification of tumors in the dataset.

Class	Training set	Test set	Total
Metastasis	1479	651	2130
Glioma	1484	633	2117
Meningioma	1466	632	2098
Pituitary adenoma	1520	629	2149
Vestibular schwannoma	1492	645	2137
No contour	2387	884	3271
Normal brain	1379	592	1971
Overall	11,207	4666	15,873

XSL•FO
RenderX

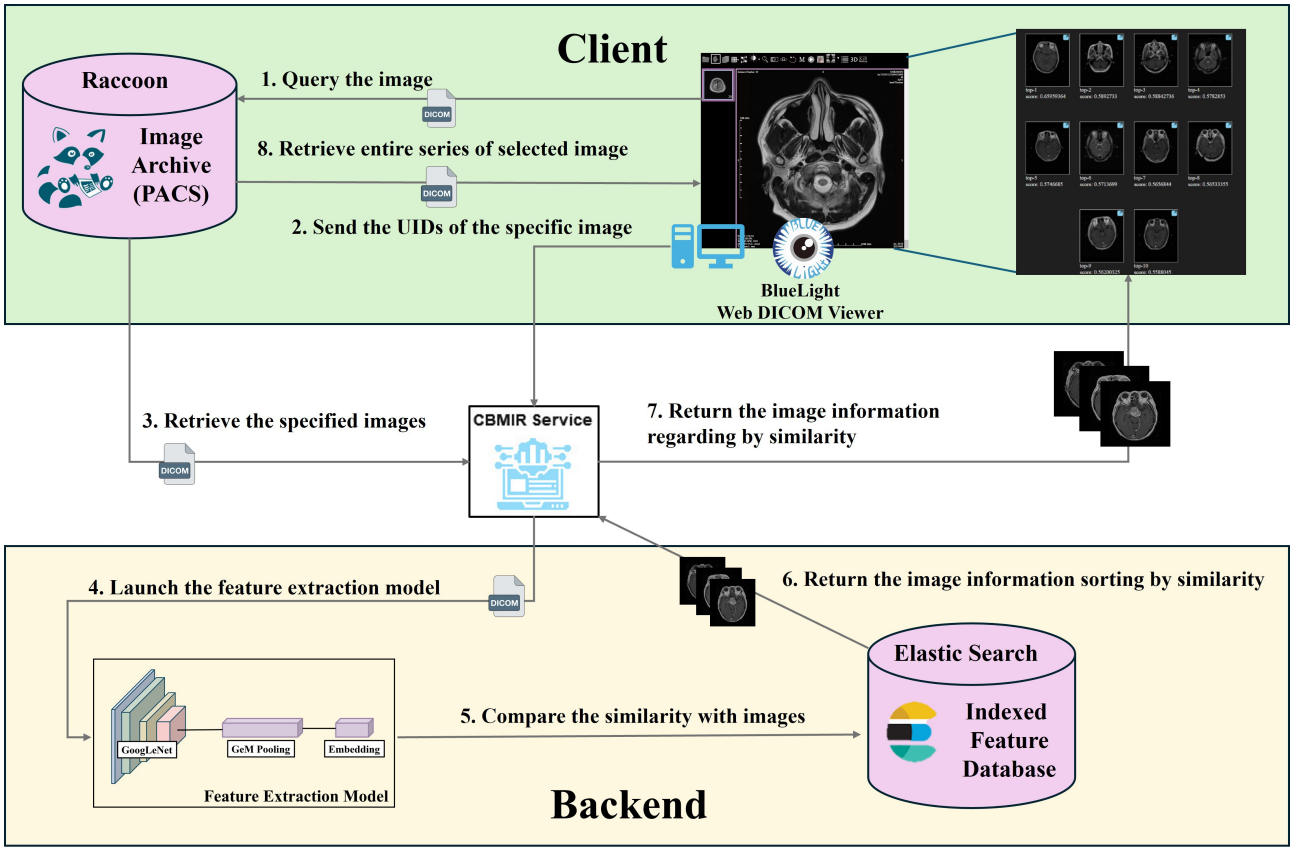
Figure 1. Examples of all tumor classes.

A brain image is inherently composed of a series of image slices, constituting a set that encompasses images both with and without tumor contours. In real-world clinical scenarios, such a dual presence of image types is a common occurrence. Focusing solely on images displaying tumors would inadvertently result in the exclusion of those lacking tumor contours, thereby impeding the accurate extraction of the latter. To mitigate this challenge, we implemented a strategy to segregate such images into a distinct category labeled “no tumor contour.” This deliberate classification enables us to effectively handle and differentiate images without tumor contours, thereby enhancing the comprehensiveness of our dataset and ensuring a more accurate analysis.

Imaging Parameters

All images were acquired using consistent imaging acquisition protocols, detailed as follows. MR scans were obtained using 1.5T parametric MR scanners from manufacturers General Equipment and Philips. Each image had a spatial resolution of 512×512 pixels, with 16-bit depth per pixel, and a slice thickness of 3 mm. The imaging protocols included both T1-weighted (T1W) and T2-weighted (T2W) sequences. These sequences were conducted as follows: (1) T1W+C: acquired using axial 2D spin echo (repetition time = 416 ms, echo time = 9 ms, flip angle = 90°). (2) T2W: acquired using axial 2D spin echo (repetition time = 4050 ms, echo time = 109 ms, flip angle = 90°).

Image Preprocessing and Augmentation



The original 512×512-pixel single-channel DICOM images were resized to 224×224 pixels using bilinear interpolation. Although the GoogLeNet backbone, integrated with GeM pooling, supports variable spatial dimensions, this specific scale was selected to align with the ImageNet pretraining distribution. Such standardization optimizes the balance between representation learning and computational efficiency, significantly reducing graphics processing unit memory footprint and inference latency. To leverage pretrained weights without altering the input layer, the resulting grayscale images were stacked into 3 identical channels (red-green-blue). Finally, while the training set underwent data augmentation (including random rotation, flipping, and scaling) to enhance robustness, the test set remained nonaugmented to ensure an evaluation reflective of clinical practice. This choice represents a practical trade-off between computational efficiency and spatial resolution, which is appropriate for large-scale similarity retrieval rather than pixel-level diagnosis.

System Architecture

The CBMIR system, including the feature extraction model, is illustrated in Figure 2. As seen therein, radiologists can select the images they wish to query for the CBMIR system within the web DICOM viewer. Upon selection, the query image is initially input into a pretrained AI model for feature extraction. Subsequently, CBMIR takes these feature vectors and matches them against the database, retrieving images with similar feature vectors from the database. For each search, the user sends a single query request containing 3 DICOM UIDs: the Study Instance UID, Series Instance UID, and SOP Instance UID. In response, the CBMIR system retrieves the specified image from the PACS and sends it to the feature extraction model. After processing, the retrieved images are then presented in the web DICOM viewer. Finally, the user can select the most closely related image and retrieve the entire study from the PACS server.

Feature Extraction Model

The foundational network of the feature extraction model architecture is based on GoogLeNet, with a modification replacing the original global average pooling with GeM pooling [35] to obtain more generalized features. Finally, an embedding layer is added to reduce the feature dimensions from 1024 to 256, compressing the data for improved computational efficiency. An explanation of each of the components of the model follows in the subsections, including (1) GoogLeNet, (2) GeM pooling, (3) embedding, and (4) the loss function.

1. *GoogLeNet layer*: The primary design core is the inception architecture, which uses 1×1 convolutional layer to reduce dimensionality, thereby lowering computational complexity. The inception architecture also splits the input into various sizes for parallel processing and subsequently aggregates them to extract features at various scales. The choice of GoogLeNet as the network backbone in this study is influenced by a previous study [23]. According to their results, GoogLeNet demonstrates several advantages over other potential network backbones, including lower computational complexity (number of operations), minimal memory consumption (parameter count), higher validation accuracy, shorter training time, and faster feature extraction. Furthermore, although ResNet50 exhibits higher accuracy, its training time is approximately 3 times that of GoogLeNet. Therefore, ResNet50 was not considered for this study due to our preference for efficient computation.

2. *GeM pooling layer*: GeM pooling was proposed by Ponciano-Silva et al [11] as a method that uses a universal formula to replace traditional global max pooling, that is,

$$(1) f(m)=f1(m)\ldots fkm\ldots fK(m)\ ,fkm=\max x\in Xkx,$$

and global average pooling, that is,

$$(2) f(a)=[f1(a)\ldots fk(a)\ldots fK(a)]\ ,fk(a)=1|Xk|\sum x\in Xkx$$

Formula equation (3) shows the process of GeM pooling, which uses a 3D tensor x with dimensions $W \times H \times K$ as input to compute the result, represented as the f vector.

$$(3) f(g)=[f1(g)\ldots fk(g)\ldots fK(g)]\ ,fk(g)=(1|Xk|\sum x\in Xkxpk)1pk$$

In this formula, pk is a parameter that determines the norm level. When $pk\to\infty$, GeM pooling becomes equivalent to max pooling; when $pk=1$, it simplifies to average pooling. Although pk can be treated as a trainable parameter, in this study, it was fixed to $pk = 3$ for all experiments, following prior image retrieval benchmarks [35]. This design choice ensures a stable and reproducible feature embedding space across all evaluations.

By maintaining pk as a constant rather than a trainable parameter, we ensure a stable feature embedding space, particularly when processing domain-specific medical images. This approach contributes to improved accuracy and consistency in image retrieval tasks.

- 3. *Embedding layer*: The embedding layer exists primarily to reduce the dimensionality of the output from the global pooling layer. In this study, we used an embedding structure [33,36] that consists of a sequence of FC (fully connected) − BN (BatchNorm) − PReLU (parametric rectified linear

XSL•FO
RenderX

unit) layers. The FC layer maps the original 1024-dimensional features to 256 dimensions while attempting to preserve the original features as much as possible. The BN layer normalizes the values to mitigate the problem of vanishing gradients, and the PReLU layer adds nonlinearity to the model.

- 4. *Loss function*: This study uses the ArcFace loss function [33], as represented in formula equation 4.

$$(4) L=-1b\log es(\cos(\theta yi+m))es(\cos(\theta yi+m))+\sum j=1,j\neq yines\cos\theta j$$

In this formula, *b* represents the batch size, *s* corresponds to the fixed feature values after L2-normalization,θyi represents the weight and angle between the correct class and feature, and *m* controls the additional angle for separating different classes. The primary objective of this loss function is to ensure that embedding features from different classes are pushed as far apart as possible while keeping embedding features from the same class close together.

Enhanced Feature Discriminability and Aggregation Strategy

In our feature extraction model, 2 key techniques were used to optimize the quality and representativeness of the feature vectors.

ArcFace loss significantly increases the quality and purity of the feature clusters. This robust separation ensures that when the system queries an image, the retrieved results are demonstrably and reliably from the most similar cluster, thus leading to higher retrieval accuracy and confidence.

GeM Pooling allows the network to intelligently decide where to focus its attention for feature extraction. It enables the model to effectively highlight the most relevant regional features (like specific pathological textures) while retaining sufficient global structural context for comprehensive retrieval, making the resulting feature vector more representative of the entire image.

Indexed Features

We use Elasticsearch as the indexing database due to its native support for high-dimensional vector storage that supports a data type for feature vectors and can perform similarity evaluations on vectors that enable retrieval of data results sorted by similarity. The features are 1024-dimensional embeddings extracted from the GoogLeNet backbone. To enhance searching performance, the indexing phase involves the following steps:

For the core similarity calculation between feature vectors (per image), we adopt the Euclidean Distance defined in formula equation 5. This metric calculates the straight-line geometric distance between 2 feature vectors in the high-dimensional space. The retrieval results are then precisely ranked based on this distance, where a smaller distance signifies higher similarity.

To significantly enhance retrieval efficiency, we used a precalculation strategy. During the indexing phase, we precalculate and store the similarity difference values between each image and all other images in the database. Each image record is uniquely identified by 3 UIDs: Study instance UID, Series instance UID, and SOP instance UID. When a new image is queried, the system calculates its distance to the query and uses this preestablished similarity difference lookup table for comparison, which avoids the traditional method of sequentially searching and calculating every single entry.

It should be noted that this precalculation strategy is primarily designed for intradatabase browsing and retrospective analysis and applies only to images that have already been indexed. For new query images not included in the database, similarity computation is performed on the fly using the Hierarchical Navigable Small World (HNSW) algorithm, which is the default vector search method provided by Elasticsearch. Specifically, when a new query image is submitted, its feature vector is extracted and compared against the indexed feature vectors using HNSW-based approximate nearest neighbor search.

Similarity Calculation

The similarity between feature vectors of different samples is typically measured using distance metrics to gauge the closeness or dissimilarity of each sample. In this study, we used the Euclidean distance, as represented in formula equation 5.

$$(5) D(p,q)=(p1-q1)2+(p2-q2)2+\ldots+(pn-qn)2 Similarity sore(p,q)=1D(p,q)$$

Here, *p* represents the feature vector of the image that the user wishes to query, and *q* represents the feature vector of the image stored in the database. The Euclidean distance measures the real distance between any 2 elements in an *n*-dimensional space. While a smaller Euclidean distance mathematically signifies higher feature-level similarity, we transformed these raw distances into "Similarity Scores" via an inverse distance mapping for display within the CBMIR interface. This ensures that higher scores directly reflect closer visual matches, thereby aligning the computational output with standard clinical assessment logic. This design choice aligns with the study's objectives by leveraging the capacity of deep learning models to encode semantic relationships as geometric distances within a high-dimensional feature space, while ensuring that the retrieval outputs are presented in a format intuitive for clinical practitioners.

Evaluation Factors

Once the CBMIR system is developed, objective evaluation metrics are essential to assess its performance. In this context, mAP and Precision@10 are commonly used evaluation measures [19,21,23]. mAP is extended from precision and average precision (AP). Precision is a fundamental metric and is defined as

$$(6) Precision=Relevant images\frown Retrieved images Retrieved images.$$

Precision is often computed as Precision@k for various values of *k*, where *k* is typically set to 10, 20, or 30. This computation helps determine the performance of the retrieval results when a certain number of images are returned. However, precision provides insight into performance only at a specific rank. AP extends precision by considering all ranks of retrieved images. AP is defined as

$$(7) AP=\sum k=1n Precision(k)\times rel(k) Relevant images rel(k)=\{1, if image k is relevant image 0, otherwise$$

Here, *rel*(*k*) is a binary indicator, assuming a value of 1 if the image at rank *k* is relevant and 0 otherwise. AP provides a more comprehensive view of retrieval performance than ordinary precision. However, AP is typically used for a single query; to

XSL•FO
RenderX

assess retrieval performance across multiple queries, mAP is used. mAP is defined as

(8)mAP=∑q=1nAP(q)Q.

Here, *Q* represents the total number of queries, and *q* denotes the current query number. mAP gives an aggregate performance measure across multiple queries, providing a more comprehensive evaluation of the CBMIR system's effectiveness than ordinary precision measures could provide.

Ethical Considerations

This study was conducted according to the guidelines of the Declaration of Helsinki and approved by the Institutional Review Board (1) of TVGH (protocol code 021-05-0005CC; approval date: March 14, 2023). Informed consent was waived because of the retrospective nature of the study and the use of deidentified clinical data.

Results

Overview

In this study, the image dataset contains 658 participants with 15,873 images collected from 2000 to 2017. The experimental environment for this study used the following hardware specifications: an AMD Ryzen 3 PRO 4200G CPU, 24 GB of DDR4 memory, and a dedicated Nvidia GeForce RTX 3060 Ti Graphics Card. The graphics processing unit features 4864 CUDA cores and 8 GB of GDDR6 video memory. The operating system used was Linux Ubuntu (version 22.04; Canonical). For software development, the primary Integrated Development Environment used was PyCharm (JetBrains). The programming language was Python (Python Software Foundation), and the deep learning framework used for code development was PyTorch (PyTorch Foundation).

Evaluation of AI Models for Feature Extraction Model

In evaluating the base feature extraction model for the CBMIR system, our core focus was centered on balancing model performance with clinical use and efficiency. To ensure that the system delivers fast, effective retrieval services within a real-world clinical workflow, we conducted a comprehensive comparative analysis of several state-of-the-art AI models when evaluated on the dataset. This comparison was intended to assess how modern, large-scale ViT architectures perform on the dataset relative to established CNNs (Convolutional Neural Networks).

For consistency and to leverage learned feature representations, TL was applied for all models. Each model was initialized with ImageNet pretrained weights and subsequently fine-tuned on our dataset. To explicitly examine the trade-off between model capacity and dataset size, we evaluated both base-scale ViT architectures (Swin-Base and DinoV2-Base) and their lightweight variants (Swin-Tiny and DinoV2-Small). The comparative results incorporating 95% CIs are shown in Table 2.

The results indicate that, under this TL setting and dataset scale, ViT-based models exhibit higher computational complexity and do not achieve superior retrieval performance compared with the CNN-based approach. In contrast, GoogLeNet demonstrates consistent and robust superiority across accuracy, mAP, F_1-score, and computational efficiency. As evidenced by the clearly separated CIs in Table 2, GoogLeNet (95.9% accuracy) substantially outperforms the second-best architectures (upper bound 87.1%), supporting that its performance advantage is stable and unlikely to result from sampling variability. Therefore, within the context of TL on a specific clinical magnetic resonance imaging dataset, GoogLeNet was selected as the backbone feature extractor for the proposed CBMIR system.

Performance Evaluation for Feature Extraction Model

The feature extraction model underwent training for 150,000 iterations. To evaluate its performance, feature extraction was first applied to all images in both the training and test datasets. Next, the feature vectors from the test dataset were individually compared and ranked against those from the training dataset to measure the similarity between the respective images. Notably, an image was considered relevant (with rel(k)=1 in AP) if its category matched that of the query image.

A summary of the evaluation metrics, including mAP and Precision@10, is shown in Table 3 for each image class. These metrics assess the performance and retrieval quality of the model for each image class as well as overall. The overall mAP for the study was 89.16%, with a Precision@10 of 94.08%. The best performance was observed in the normal brain category, achieving a mAP of 94.95% (95% CI 94.32 - 95.58) and a Precision@10 of 97.57% (95% CI 97.13 - 98.01), indicating high reliability in identifying normal tissues.

The results show that the overall classification performance of this model was excellent, but its mAP for CBMIR was only 89.16%. This disparity highlights the difference between classification and image retrieval in practical terms. In classification, the main training objective of the AI model is to identify the tumor class to which the current image belongs. However, in image retrieval, the training objective must consider the similarity (distance relationship) between the current image and other images to learn the relationships between the features of each image in the pair of images. These are 2 conceptually distinct tasks.

[b]mAP: mean average precision.

Performance Evaluation for Tumor Classification

The main purpose of this study was to use an AI model to extract feature vectors for image retrieval. To realize this purpose, we chose to extend the ArcFace loss function, which is based on the softmax loss function, using a margin of 38 and a scale of 64, as the classification for a model that can theoretically be used for image classification. Therefore, this study also investigated the performance of the AI model for classification tasks. Table 4 shows the precision, recall, and F_1-score for each class, while Figure 3 provides the confusion matrix for each tumor class.

Table . Classification performance evaluation for each tumor class.

Tumor class	Precision, %	Recall, %	F_1-score, %
Metastasis	91.75	94.01	92.87
Glioma	98.17	93.36	95.71
Meningioma	99.02	96.36	97.67
Pituitary adenoma	99.68	97.93	98.80
Vestibular schwannoma	94.62	95.50	95.06
No tumor contour	88.79	89.59	89.19
Normal brain	93.72	98.31	95.96
Overall	95.11	95.01	95.04

Performance Comparison at Various Embedding Dimensions

In our study, ArcFace loss was used not merely for classification but as a feature embedding mechanism to ensure that images belonging to the same tumor class are mapped closer together in the embedding space, while those from different classes are more widely separated. This results in well-clustered and discriminative feature vectors, which form the necessary basis for our similarity-based retrieval. Hence, although these are distinct tasks, they are synergistically integrated within the same CBMIR system: classification helps structure the embedding space, thereby significantly enhancing the discriminative power and ultimately the retrieval performance of the system.

We initially drew inspiration from a study [37] in which the optimal embedding dimension for their specific objective of facial recognition was determined to be 128. However, we recognize that this dimension may not necessarily be optimal for brain tumor classification. Consequently, we undertook a comprehensive comparison of various embedding dimensions, as outlined in Table 5. The findings of this analysis unequivocally indicated that 256 dimensions yielded the highest performance for our retrieval task.

Furthermore, we note that the disparities in performance across dimensions, ranging from 64 to 512, were relatively marginal. This observation is particularly significant when considering the cost-effectiveness of deploying the model on devices with limited computational capabilities. Opting for a dimensionality of 64 can substantially curtail computational overheads while still maintaining respectable performance levels.

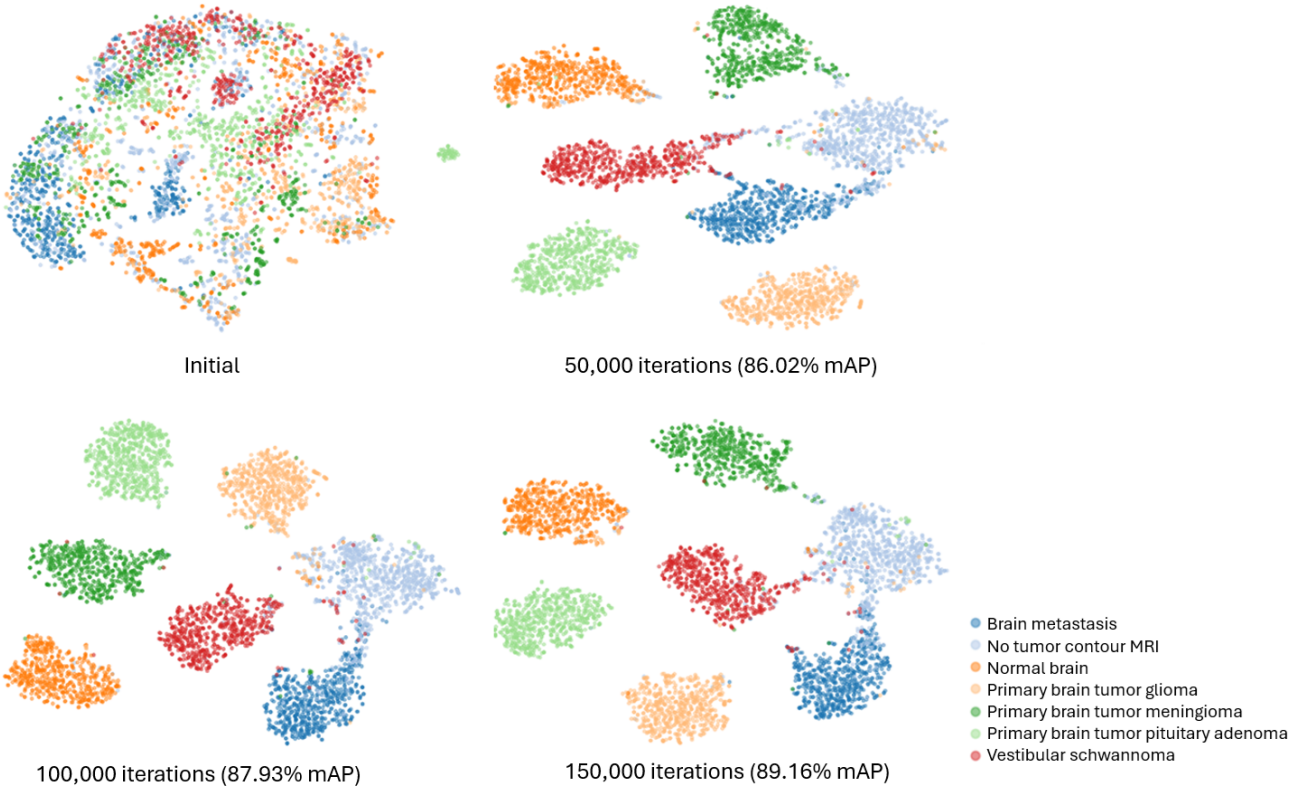
Table . Performance comparison of different embedding dimensions.

Embedding size	Overall mAP, %
64	88.16
128	88.76
256	89.16[a]
512	89.14



[a]Indicates the best performance in different various embedding dimensions.

Feature Vector Projection

Our methodology consolidated similar feature vectors while actively distancing dissimilar ones. While mAP serves as a useful indirect metric for assessing effectiveness, the feature vector coherence can be qualitatively assessed through projection. To qualitatively visualize the evolution of feature representations during training, we used t-distributed Stochastic Neighbor Embedding to project high-dimensional feature vectors into a lower-dimensional space. As a stochastic dimensionality reduction method, t-distributed Stochastic Neighbor Embedding is sensitive to parameter settings and is used here solely for qualitative inspection of learning trends rather than as quantitative evidence of feature space cohesion or class separability. The visual representation of feature vector projection is illustrated in Figure 4.

Figure 4 illustrates that the initially untrained feature vectors, denoted as "Initial," exhibit a scattered pattern with minimal cohesion among different classes. However, as training progresses through 50,000, 100,000, and 150,000 iterations, we observe a gradual convergence of feature vectors within each class, reflecting increasing cohesion. Concurrently, an observable qualitative visual separation implies that feature vectors from different classes become more distantly grouped, highlighting the model's progressive learning and adaptability.

Figure 4. Visual representation of feature vector projection using t-distributed Stochastic Neighbor Embedding across various training iterations. The projection was implemented with 3 components, a perplexity of 30, 1000 iterations, and the Euclidean metric. This visualization is intended to illustrate trends in feature learning rather than to provide quantitative evidence of class separation. mAP, mean average precision; MRI, magnetic resonance imaging.

System Integration With PACS

Our system operates as follows. Users can initiate image queries from the PACS and subsequently retrieve and display these images within BlueLight via the QIDO (query based on ID for DICOM Objects) and WADO (web access to DICOM objects) protocols, respectively. To use the CBMIR functionality, users provide the StudyInstanceUID, SeriesInstanceUID, and SOPInstanceUID for the specific DICOM image they require.

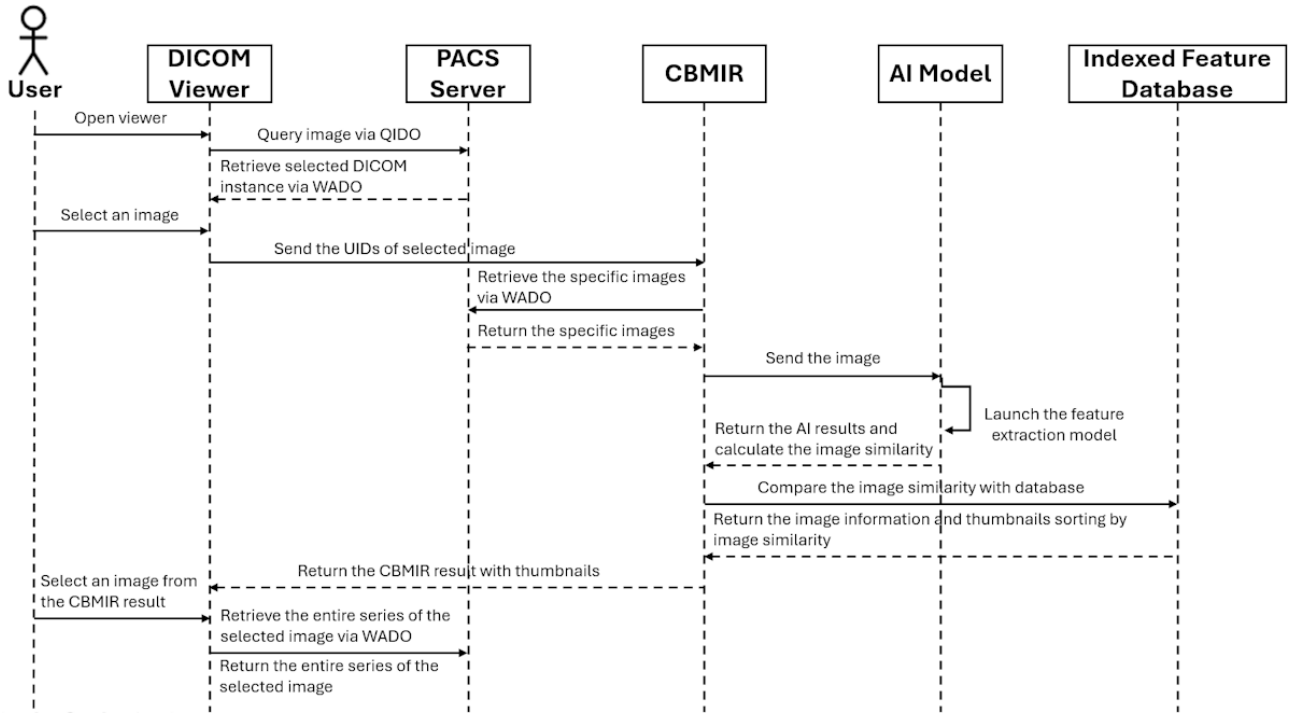
Once these details are specified, the CBMIR system retrieves the corresponding DICOM image from the PACS using WADO and then processes this image to calculate the CBMIR results, returning the top 10 images that bear the highest similarity to

XSL•FO
RenderX

the input image. The operational process and data workflow are depicted in Figure 5.

A demonstration video is provided in Multimedia Appendix 1, and a screenshot of the user interface of the CBMIR client prior to executing a search is shown in Figure 6A. To enhance the successful integration of our CBMIR system into clinical workflows, we integrated it with an open-source DICOM viewer known as BlueLight [34] and the DICOM server Raccoon [38]. This client application communicated with a PACS-supporting DICOMweb, significantly simplifying user access to and interpretation of brain tumor images, including the display of top retrieval results ordered by similarity scores (Figure 6B). Moreover, considering that brain images are inherently 3D, a single image may not always convey the complete information for a whole series of images. The system's workflow ensures that the entire series of images associated with a case is retrieved from the PACS, rather than just a single instance (Figure 6C).

Figure 5. Sequence diagram for the integration of content-based medical image retrieval with a picture archiving and communication system. AI: artificial intelligence; CBMIR: content-based medical image retrieval; DICOM: Digital Imaging and Communications in Medicine; PACS: picture archiving and communication system; UIDs: unique identifiers.



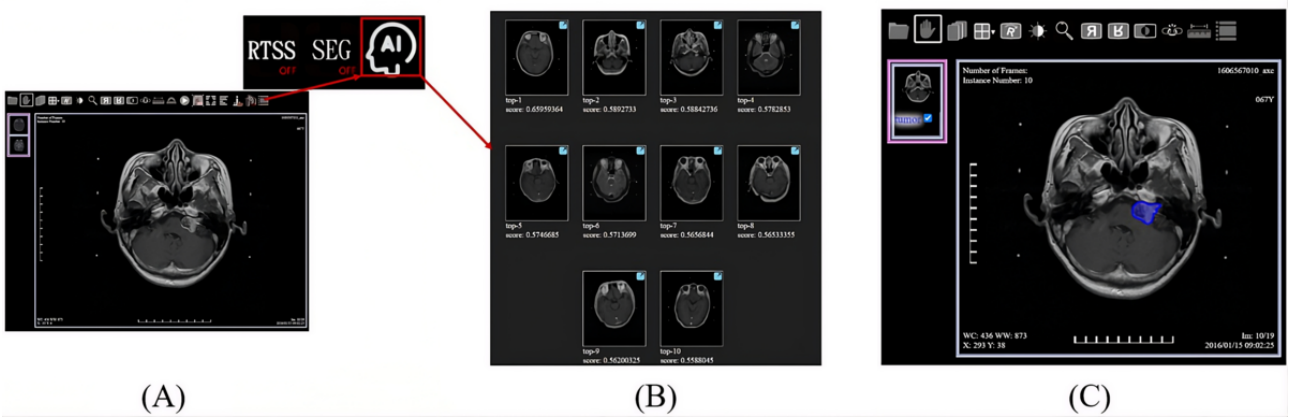


Figure 6. The user interface of the content-based medical image retrieval (CBMIR) services is integrated into a web Digital Imaging and Communications in Medicine viewer. (A) Before performing the CBMIR system; (B) Top 10 retrieval results ordered by descending similarity scores. A higher score denotes greater visual similarity between the query and the retrieved images; (C) Retrieve the selected whole series of images from picture archiving and communication system.

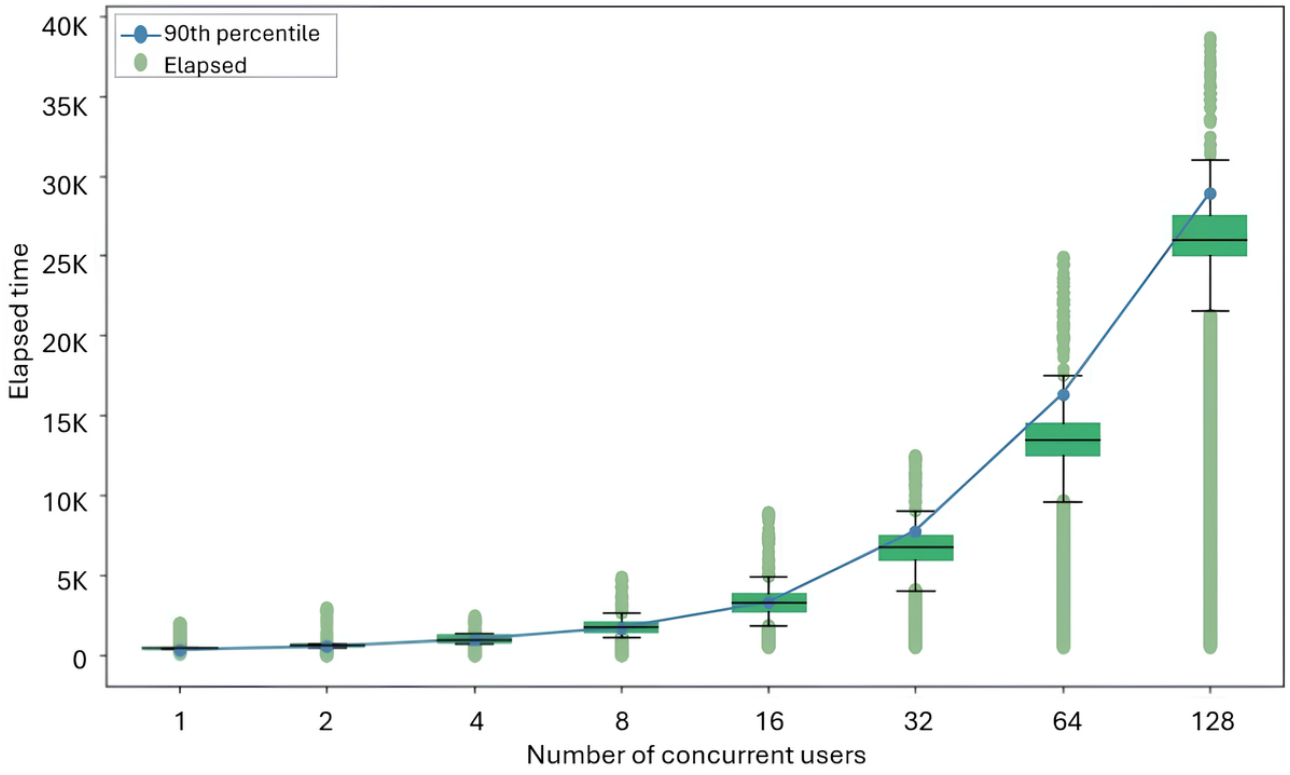
Performance of CBMIR System

During the usage of the CBMIR system, the "time" and "stability" of querying for similar images can significantly impact the overall operational process. Therefore, this study conducted a performance evaluation of the CBMIR system. The response time represents the end-to-end round trip for image retrieval, including WADO communication, database execution, and network transfer latency. The overall response time evaluation involved the following steps: (1) sending image to the CBMIR system, (2) retrieving images from PACS, (3) extracting image feature vectors using the CBMIR AI model,

XSL•FO
RenderX

(4) indexing image feature vectors into the database, (5) querying for similar images within the database, and (6) assessing the response time back to the user.



The stability assessment involved simulations with 2^*n* users, ranging up to 256 concurrent users, using the CBMIR system. The evaluation results are shown in Table 6; a box-and-whisker plot depicting the evaluation results is shown in Figure 7.

Additionally, as no system crashes or errors were observed for user counts ranging from 1 to 128, this study conducted further testing, revealing that when more than 256 users simultaneously used the system, all requests began to experience 30-second time-outs, the default value of request time-out for all web browsers, thereby all requests failed. The results demonstrate that as the number of concurrent users increases, the response time exhibits a nonlinear growth. Specifically, under extreme stress testing conditions (exceeding 64 simultaneous users), the variability in response time expands significantly. When the concurrent load surpasses 256 users, the system reaches its current architectural capacity limit, resulting in request time-outs (exceeding 30 seconds). These findings delineate the operational boundaries of the current implementation, indicating that while the system is stable for routine, low-concurrency clinical usage, high-concurrency scenarios impose a significant load that impacts real-time stability.

Table . Response time results under various user loads.

Users	Response time, ms		
	Average	Maximum	90th percentile
1	273.98	1373	333.00
2	434.48	2696	531.00
4	918.89	2233	1187.00
8	1758.38	4423	2219.00
16	3225.49	8230	3903.10
32	6432.68	12,541	7775.40
64	13629.18	24,391	16337.40
128	25672.47	39,196	28909.10

Figure 7. Relationship between the elapsed response time and the number of concurrent users in the content-based medical image retrieval system evaluation. The green box-and-whisker plots and scatter points display the statistical distribution of the response time (median, quartiles, and extreme values), while the blue line graph indicates the 90th percentile response time.

Discussion

Principal Findings

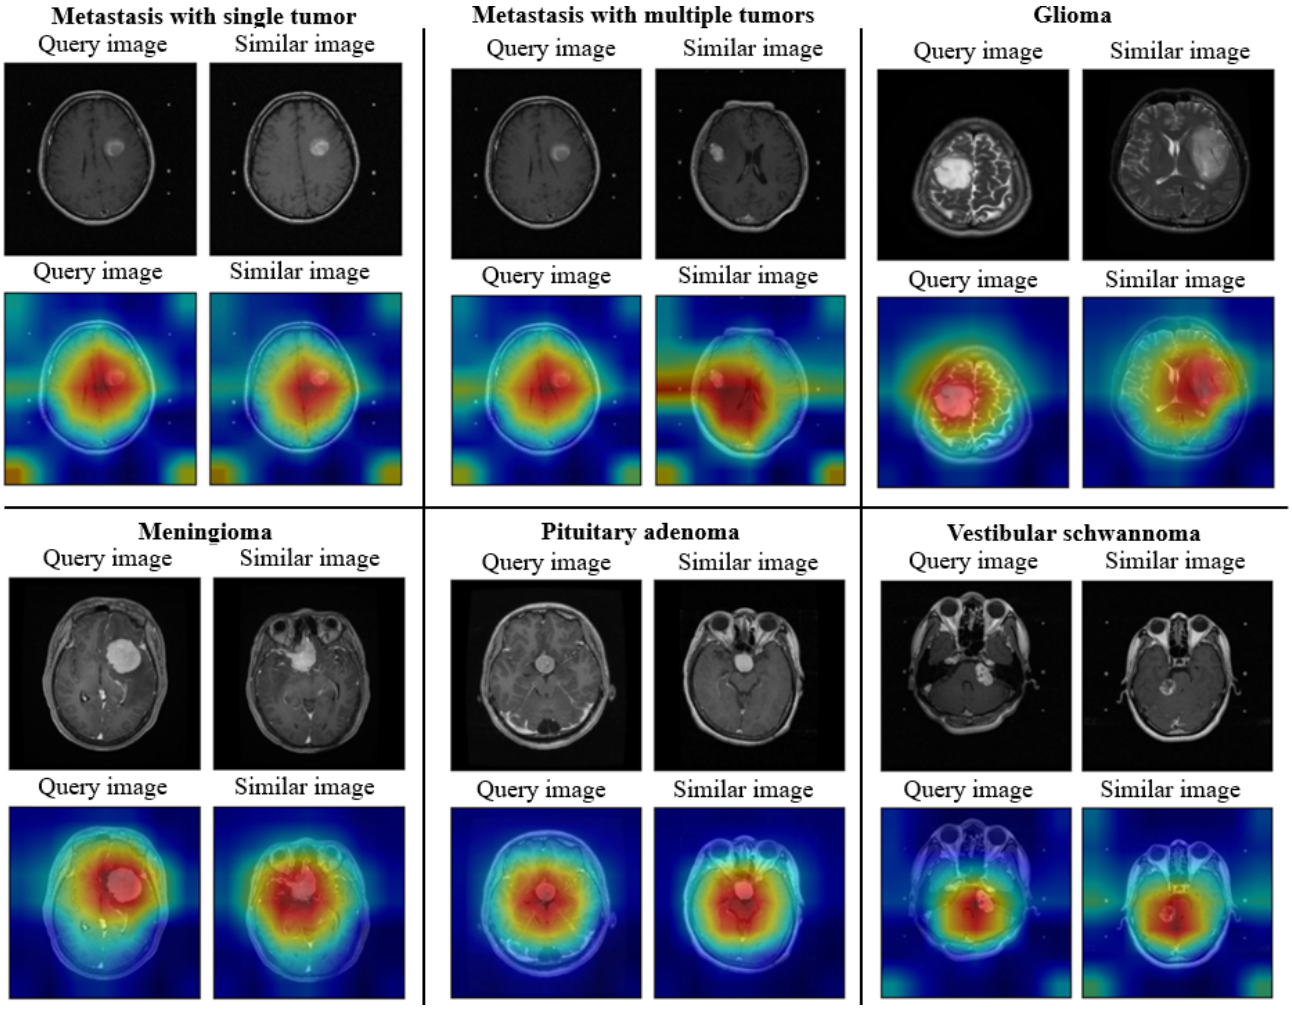
We developed and evaluated a CBMIR system tailored for brain tumor detection within a PACS environment. The results demonstrate a substantial improvement in retrieval accuracy enabled by the innovative deep learning architecture, enhancing feature discriminability. By integrating our AI model with 2 open-source tools—Raccoon for backend DICOM management and BlueLight for frontend web-based image viewing—our CBMIR system provides seamless, real-time decision support directly within the clinician's workflow. This practical integration helps bridge the gap between advanced AI retrieval techniques and routine clinical practice. This achievement represents an important step toward establishing the CBMIR system as a valuable tool for both clinical diagnosis support and medical research.

Rationale for GoogLeNet Selection

We selected GoogLeNet as the backbone feature extractor for our CBMIR system due to its demonstrated optimal balance between clinical use and overall performance.

1. *Performance versus computational cost*: As Table 2 illustrates, while ViT-based and deeper CNN architectures are state of the art in many domains, their performance metrics on our specific medical imaging task are significantly lower than those achieved by GoogLeNet. This discrepancy is likely influenced by the interaction between model complexity and the relatively homogeneous characteristics of the dataset. In contrast, GoogLeNet's moderate depth and multiscale receptive fields appear to facilitate more stable embedding learning and improved generalization in similarity-based retrieval scenarios.
2. *Overwhelming computational advantage*: GoogLeNet demonstrates a massive advantage in efficiency. Its Floating Point Operations are nearly one-tenth that of Swin (1.51 G vs 15.17 G), and its parameter count is approximately one-tenth that of the ViT models (6.8 M vs ≈85 M). Furthermore, its training time is significantly shorter (57 minutes vs ≈500 minutes).
3. *Critical clinical deployment consideration*: Given that a CBMIR system must be lightweight and support low-latency retrieval for real-time clinical use, efficiency is paramount. GoogLeNet provides a high mAP of 89.16% while maintaining minimal computational demands. Therefore, GoogLeNet was chosen as it achieves the best balance among accuracy, model compactness, and deployment efficiency, making it the superior foundation for our CBMIR architecture.

Heatmaps of Image Similarity



To provide interpretability for our CBMIR model's retrieval decisions, we used a visualization technique based on Gradient-weighted Class Activation Mapping, adapted for deep similarity networks following the approach introduced by Stylianou et al [39].

Our heatmaps aim to quantify the degree of feature matching between 2 images. Our methodology integrates Gradient-weighted Class Activation Mapping with the calculation of distances between the final convolutional layer and the pooling layer to gauge the level of attention or similarity across different regions within the images. In the visualization, regions exhibiting high similarity are represented in red, while those with lower similarity are depicted in blue. Figure 8 shows 5 examples of brain tumors, illustrating our primary goal of identifying images of brain tumors that share similarities. The ensuing sections showcase detailed heatmaps for each of the tumor classes.

For all tumor classes presented in Figure 8, except for the case of multiple tumors in metastasis, the examples used contain only a single tumor within the image. This choice was deliberate to ensure that the heatmaps clearly illustrate that retrieval similarity is based on matching the pathological features of the tumor (where the hot spot is located), rather than simply reflecting class probabilities as in a classification task. The high feature consistency observed between the query and retrieved images across these single-lesion cases strongly supports this interpretation. However, it is essential to note that while this analysis explains the underlying mechanism, the study does not draw definitive clinical conclusions regarding these results. It should be emphasized that these heatmaps are presented for qualitative illustration only. Determining whether such activation patterns correspond to meaningful anatomical features or to nonanatomical factors would require systematic image-by-image analysis, which is beyond the scope of this study.

XSL•FO
RenderX

Figure 8. Heatmaps of similar images for various tumor classes: query image and retrieved similar image with corresponding heatmaps.

Single Versus Multiple Tumors (Metastasis Cases)

We included metastasis cases with both single and multiple tumors within a single image. The heatmaps illustrate visually different activation patterns between these 2 scenarios. However, the primary focus of our analysis remains the observed differences in image similarity behavior between metastasis cases with multiple tumors and single-tumor cases, rather than the anatomical interpretation of activation maps.

1. *Single tumor*: In single-tumor cases, the query image heatmap shows a visually concentrated activation region (red or yellow) localized around the dominant lesion. The corresponding retrieved image exhibits a similarly localized activation pattern. This observation reflects a spatially focused activation pattern in both the query and retrieved images.
2. *Multiple tumors*: In multiple-tumor cases, the activation patterns appear more spatially distributed. While high-activation regions remain present near individual lesions, the heatmaps often extend into broader areas of the image. The similarity image heatmap exhibits horizontally distributed activation patterns or band-like structures. These patterns indicate a more dispersed activation distribution in images containing multiple lesions.

Clinical Considerations for Cross-Class Image Similarity

Our heatmap analysis differs from traditional methods, which often focus only on areas of interest within a single image for classification. Our objective is to describe and quantify the similarity between 2 images in terms of mutual focus on specific regions, an understanding pivotal for elucidating the model's retrieval effectiveness. Considering clinical evaluation, 2 radiologists (KHK and WYG) used the hospital's DICOM viewer to cross-validate brain tumor cases and assess the correctness of similarity scores between different tumor classes.

We acknowledge that highly similar images from the query results may not always belong to the same tumor class. Indeed, in some instances, the similarity score may be substantially higher for images assigned to other tumor classes. These cases indicate a significant degree of visual and structural image similarity, even if the retrieved image's classification label may not be totally accurate. The similarity score is calculated for the entire image. While a partial score calculated from the tumor lesion may result in a high score, it is worth noting that when 2 images share a similar location in an axial brain slice, the similarity of surrounding organs and structures may yield a higher final score than that of the tumor lesion alone.

This result shows a clinical potential use in identifying shared characteristics among images across tumor classes. However, it must be emphasized that definitive conclusions regarding

XSL•FO
RenderX

these results were not drawn in this study. To mitigate this potential disparity, the user interface has been thoughtfully crafted to label these images accordingly, providing a clear notification to the user regarding this outcome.

Normal Brain Versus No Tumor Contour

From a clinical perspective, the "Normal Brain" class represents images from patients without a brain tumor diagnosis, whereas the "No Tumor Contour" class consists of image slices acquired from patients with known brain tumors in which no visible lesion is present on the specific slice. Although these 2 classes may appear visually similar at the slice level, they differ fundamentally at the case level, which explains the observed confusion in similarity-based retrieval. Specifically, while the "Normal Brain" class achieves a high mAP of 94.95%, the "No Tumor Contour" class yields a lower mAP of 87.39%, which is below the overall average of 89.16%.

This confusion reflects a realistic diagnostic scenario in routine clinical practice, where individual slices without visible lesions may be indistinguishable from normal brain images. This observation highlights the system's ability to handle visually overlapping categories in routine clinical practice. The inclusion of these classes underscores the system's ability to handle visual overlaps based on deep feature embeddings learned from pixel-level representations, rather than pathology-specific descriptors. Consequently, the reported mAP reflects the global coherence of the learned visual embedding space across diverse clinical categories.

It should be noted that this behavior does not imply a false-negative diagnostic result, as the proposed CBMIR system is designed for similarity-based image retrieval rather than automated diagnosis. Instead, it underscores the necessity of contextual interpretation at the case or series level when reviewing retrieved images. To mitigate potential clinical misunderstanding, the system retrieves the complete image series rather than a single slice, allowing clinicians to examine adjacent slices where lesions may be present. The interface further indicates that tumor annotations exist elsewhere within the retrieved series.

Limitations

While this study successfully developed a high-performing CBMIR system and integrated it into PACS, there are limitations regarding dataset characteristics, system scalability, and model interpretability. First, regarding the dataset characteristics and partitioning, this study used a dataset spanning a long retrospective period (2000 - 2017) from a single medical center, acquired primarily on 1.5T scanners. Although this provided consistency in clinical protocols and image quality, it may limit the model's generalizability. In particular, robustness across different scanner manufacturers, field strengths (eg, 3T), and heterogeneous acquisition protocols remains to be systematically validated. Given the increasing prevalence of 3T scanning in modern neuro-oncology, the model's performance on higher-resolution and advanced acquisition protocols warrants further investigation, especially in multicenter clinical settings.

To ensure balanced class distributions for benchmarking, we used a random split strategy. Unlike a prospective temporal split, this approach introduces a potential for "future leakage" and may not fully simulate clinical deployment timelines. A temporal split, in which earlier data are used for training and later data for testing, may better reflect real-world clinical deployment scenarios and provide a more stringent evaluation of generalization across time. However, such a design requires strict longitudinal harmonization of acquisition protocols, and scanner variations could provide a more stringent assessment of real-world generalization and will be a potential improvement in future studies.

Second, regarding system latency and scalability, although GoogLeNet was selected for its relatively low computational cost, the processes of calculating feature vectors and similarity computation create a computational bottleneck under heavy workloads. Our stress testing demonstrates that response time increases substantially under high concurrency, exceeding 13 seconds for 64 simultaneous users and approaching 26 seconds for 128 users. Such latency is incompatible with real-time clinical workflows and therefore represents a critical limitation of the current implementation.

Third, regarding the analysis of metastasis cases with multiple tumors, we observed distinct horizontal bands of high activation in the heatmaps. While these patterns may suggest distributed feature attention, we cannot definitively rule out the possibility that they represent acquisition or reconstruction artifacts (eg, motion or noise). Consequently, this ambiguity serves as a limitation regarding the model's focus and explainability in complex, multilesion scenarios.

Fourth, to accommodate the input requirements of the pretrained GoogLeNet architecture, the original 512×512 pixels images were resized to 224×224 pixels before feature extraction. This downsampling inevitably reduces spatial resolution and may obscure fine-grained texture details that could be relevant for differentiating certain tumor subtypes. While the loss of fine-grained texture information may affect the representation of subtle local patterns, the system is designed to capture global and midlevel feature similarities that are sufficient for retrieval tasks within the intended clinical workflow. Nonetheless, this resolution reduction is a limitation of the current implementation.

Fifth, similarity in our CBMIR system does not rely on predefined morphological or pathological criteria (eg, tumor size, location, and texture). Instead, it is quantified by computing the Euclidean distance between high-dimensional deep embeddings derived directly from pixel-level representations. Consequently, similarity ranking is fundamentally driven by pixel-derived feature distances, rather than by pathological labels or manually defined structural attributes.

Finally, the retrieval performance metrics reported in this study were computed using Euclidean distance across the full test set to provide standardized and reproducible benchmarking. In contrast, the deployed CBMIR system uses an approximate nearest neighbor search strategy based on HNSW graphs to ensure low-latency, real-time responses and system scalability. The use of HNSW enables efficient similarity search for unseen queries without requiring their prior inclusion in a precalculated distance matrix. While this approximate nature may lead to

XSL•FO
RenderX

minor deviations in retrieval precision or recall compared with an exhaustive search, such a trade-off is essential for practical clinical usability, effectively balancing theoretical accuracy with the demands of real-time medical decision support.

Future Work

Building upon the current findings and addressing the identified limitations, we propose the following three main directions for future research:

1. *Expansion to multicenter dataset validation*: Future work will prioritize incorporating image data from diverse health care institutions to test and fine-tune the model's robustness. Training and validating the system on multicenter datasets will significantly enhance the model's generalizability and practical usefulness.
2. *Exploration of modern AI model*: Although preliminary experiments showed modern AI models, for example, Swin and DinoV2, to be less computationally efficient for our specific task, their inherent strength in capturing long-range dependencies warrants further investigation. Future research may explore methods to optimize or prune these AI models to harness their superior feature learning capabilities without unduly sacrificing computational efficiency.
3. *Integration of multimodal retrieval*: The current system relies solely on visual features. In clinical practice, structured and unstructured radiology reports provide critical contextual information. Future work may explore multimodal deep learning models to combine image features with textual features, enabling more comprehensive and accurate multimodal retrieval functionality.

Conclusions

This study represents the design, implementation, and evaluation of a CBMIR tailored for the classification and retrieval of brain MR images. We successfully developed a CBMIR system focusing on structured tumor classification and incorporating deep learning–based feature extraction, including GoogLeNet combined with ArcFace Loss to enhance the discrimination of image similarities and differences, thereby improving retrieval relevance. In addition, GeM pooling was used as the feature aggregation strategy and evaluated in comparison with conventional average pooling and maximum pooling methods. These results indicate that GeM pooling provides a more refined representative embedding of image features, contributing to improved retrieval accuracy and robustness in the CBMIR system. To facilitate practical deployment, the training workflow was designed as a streamlined, single-stage process, reducing complexity and enabling efficient model preparation. The system was trained using a dataset that includes both tumor-positive and tumor-negative brain MR images, reflecting the diversity of cases encountered in routine clinical practice. Finally, the proposed CBMIR system was successfully integrated with the open-source web DICOM viewer BlueLight with a PACS. The retrieved results were able to be communicated with a PACS to retrieve corresponding medical images for display in a web DICOM viewer, demonstrating the feasibility of integrating CBMIR functionality into existing clinical imaging workflows.

Abstract

Background: Quantitative magnetic resonance imaging (MRI) is an advanced technique that can map the physical properties (T1, T2, and proton density [PD]) of different tissues, offering crucial insights for disease diagnosis. Nonetheless, the practical application of this technology is indeed constrained by several factors, with the most notable being the protracted scanning duration.

Objective: This study aimed to explore whether deep learning (DL)–based superresolution reconstruction of ultrafast whole brain synthetic MRI can obtain quantitative T1/T2/PD maps that are closely approximated to those from routine clinical scans, while substantially shortening scan time and preserving diagnostic image quality.

Methods: A total of 151 healthy adults and 7 individuals with different pathologies were prospectively enrolled. Each individual was examined twice on a 3.0T scanner using routine and fast synthetic MRI protocols. The routine scans (acquisition matrix: 320×256) were interpolated to 512 by 512 for clinical display and served as reference images. The fast scans (acquisition matrix: 192×128) were preprocessed to 256 by 256 and used as inputs to a superresolution generative adversarial network (SRGAN), which reconstructed them to the same 512 by 512 interpolated resolution as the reference. For each quantitative chart, 120 (75.95%) healthy individuals' images were used for training, and 38 (24.05%) individuals' images (healthy individuals: n=31, 19.62%; patients: n=7, 4.43%) were used for testing. Agreement was assessed with a paired *t* test, two 1-sided tests, Bland-Altman analysis, and coefficients of variation.

Results: DL reconstructed and reference T1/T2/PD values were strongly correlated (T1: R^2=0.98; T2: R^2=0.97; and PD: R^2=0.99). The slopes of the linear regression were near 1.0 both for T1 (0.9418) and PD (0.9946), whereas T2 values were moderate, as the slope of the linear regression was 0.8057. Additionally, the average biases of T1, T2, and PD values were small (0.93%, −0.85%, and 0.31%, respectively). The intra- and intergroup coefficient of variation for most of the brain regions stayed below 5%, especially for PD values, and after DL reconstruction, it still has quantitative accuracy for lesions. Quantitative and qualitative analyses of image quality also indicate that SRGAN markedly suppressed noise and artifacts in fast acquisitions, restoring structural fidelity (structural similarity image measure) and signal fidelity (peak signal-to-noise ratio) close to the level of routine scans while substantially improving perceptual naturalness over fast scans (as measured by the naturalness image quality evaluator), although not yet matching that of routine imaging.

Conclusions: SRGAN superresolution applied to ultrafast synthetic MRI yields whole brain T1, T2, and PD maps that show strong correlation with routine synthetic MRI while halving acquisition time and maintaining diagnostic image quality. Although T1 and PD values exhibit near-ideal agreement, and T2 values demonstrate a moderate systematic underestimation, this approach represents a promising step toward accelerating clinical deployment of quantitative brain imaging.

KEYWORDS

magnetic resonance imaging; qMRI; fast MRI; deep learning; brain imaging

Introduction

Quantitative magnetic resonance imaging (qMRI) can reflect the inherent properties of human tissue relaxation times and proton density (PD), providing valuable support for verifying visual assessments of structures and tissues against a normal quantitative standard, thereby holding significant clinical diagnostic value [1]. Nevertheless, the extended scan time of qMRI imposes limitations on its practical use. Synthetic MRI, based on multidynamic, multiecho sequences, can provide multiple quantitative information and multicontrast images in a single scan, enabling fast qMRI scans [2,3]. It has been proven to have comparable diagnostic value to conventional scanning methods, with the generated quantitative data being valuable for disease identification [4-7]. However, the single scan time of this imaging method still typically ranges from 4 to 7 minutes, particularly for brain MRI imaging, which can lead to individual discomfort and potentially impact image quality. Therefore, improving the imaging speed of synthetic MRI is the key to realizing ultrafast qMRI.

It is also crucial to ensure the quality of qMRI and the reliability of quantitative values while accelerating imaging. Usually, fast imaging methods such as parallel acquisition and compressed sensing may result in a loss of image quality [8]. The reconstruction technology based on deep learning (DL) has been applied in various medical image reconstruction tasks, and its development makes it possible to solve the trade-off between image quality and scan time. Generative adversarial networks, renowned for generating high-fidelity superresolution images, have been successfully used in MRI [9]. Many researchers have implemented the concept of generative adversarial networks for MRI image reconstruction, achieving high-quality reconstruction from highly undersampled data [10-14]. In addition, the generative adversarial approach can be used for tasks, such as artifact correction and denoising in MRI [15,16]. In clinical practice, in addition to focusing on image quality, it is more important to determine whether the DL-based reconstruction method can provide less bias and consistent quantitative data [17].

To shorten synthetic MRI quantitative acquisitions and increase clinical throughput, we hypothesized that DL superresolution can generate T1/T2/PD maps that are close to routine long acquisition quantitative values while maintaining image quality, thereby providing faster yet equally reliable neuroimaging and ultimately enhancing diagnostic precision and patient comfort.

Methods

Participants

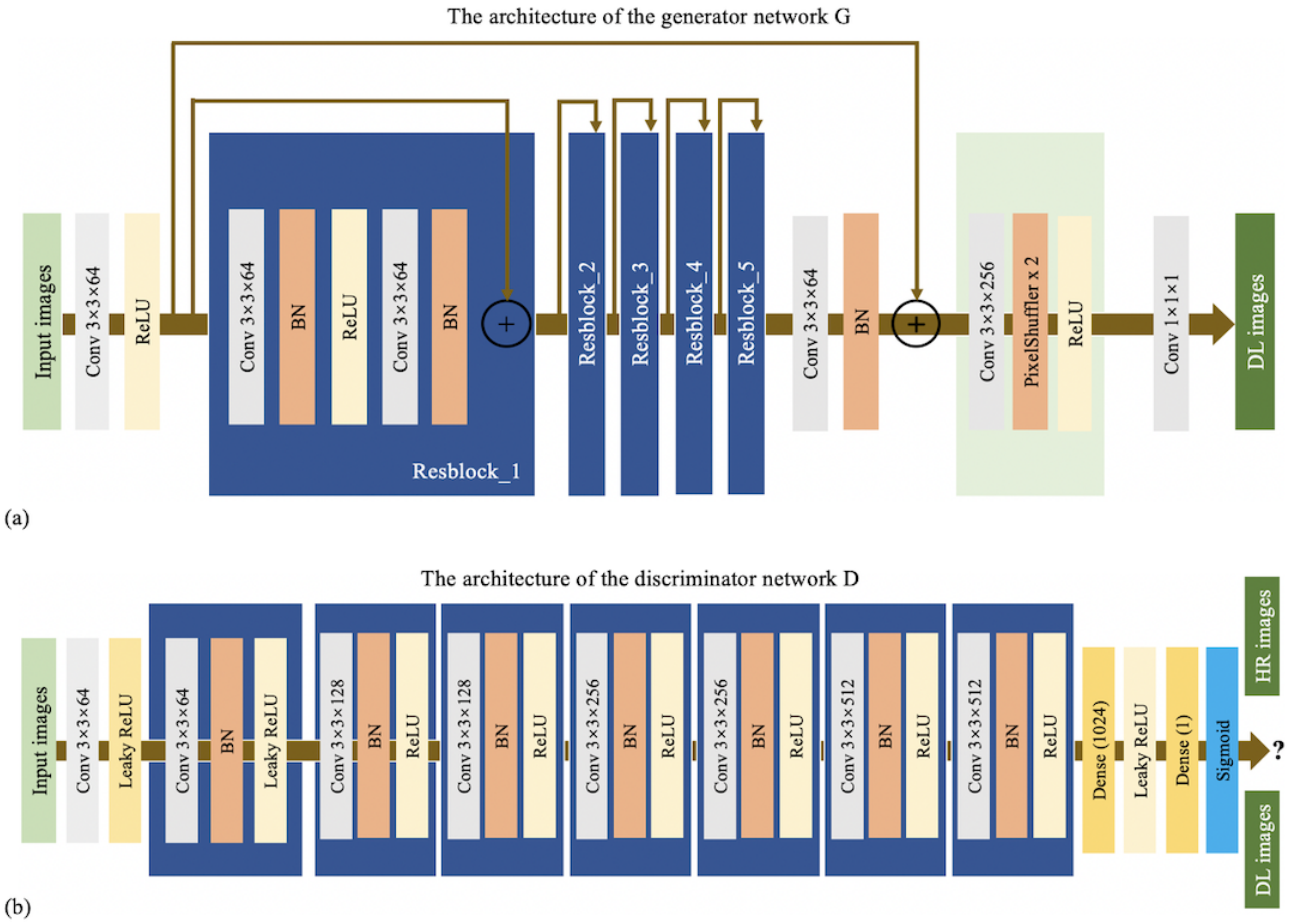
This study was approved by the Medical Research Ethics Committees of the Beijing Friendship Hospital, Capital Medical University (2020-P2-122-02). Written informed consent was obtained from all participants prior to enrollment. A total of 151 healthy individuals were prospectively recruited at 1 institution for this study. The inclusion criteria were as follows: (1) the age of the individual was greater than or equal to 18 years, (2) the individual showed no structural changes or signs of disease in brain MRI, and (3) the individual showed no contraindications or adverse reactions to MRI examination. The exclusion criteria were as follows: (1) there were obvious artifacts in the images, and (2) the individual failed to complete all MRI examinations. In addition, we also collected images from 7 individuals with different pathologies (white matter [WM] hyperintensities, cerebral infarcts, and encephalomalacia) to evaluate the potential for clinical application.

Synthetic MRI Acquisition

All MRI examinations were performed using a SIGNA Pioneer 3.0 T MRI scanner (GE Healthcare). All individuals underwent two synthetic MRI scans using the multidynamic multiecho sequence (MDME sequence, named MAGiC in the GE scanner): a routine scan protocol and a fast scan protocol. The routine scan uses commonly used clinical acquisition parameters: TR=4000 ms; TE1=18.3 ms; TE2=91.4 ms; TI=28.2 ms; thickness=5 mm; FOV=220×220 mm; acquisition matrix=320×256; echo-train length=16; bandwidth=31.25 kHz; delay times=170, 670, 1840, and 3840 ms; and acceleration factors=2, 24 slices, with a pixel size of 0.7×0.8 and an acquisition time of 4 minutes 55 seconds. Fast scan modifies the acquisition matrix and acceleration factor, which affect the acquisition time, by changing the acquisition matrix to 192×128 and the acceleration factor to 3. The remaining parameters remained the same as those of the routine scan, with a pixel size of 1.1×1.7 and an acquisition time of 1 minute 52 seconds.

Data Preprocessing

The same method was used to retrieve the quantitative maps (T1 maps, T2 maps, and PD maps) as mentioned in a previous study [18]. In this study, quantitative maps from the routine scan (reconstruction matrix=512×512, 0.43×0.43 mm² pixel) served as the high-resolution (HR) reference, whereas those from the fast scan (reconstruction matrix=256×256, 0.86×0.86 mm² pixel) were used as low-resolution (LR) inputs. DICOM images were directly read and prepared for network training. It should be noted that the maximum image intensities of T1 maps, T2 maps, and PD maps are 43,000, 20,000, and 1600, respectively, which correspond to 10 times the actual values. This scaling is due to the rescaling slope value of 0.1 specified in the DICOM header file.



Network Architecture

The detailed generator network structure is shown in Figure 1A. It starts with a 9 by 9 convolutional filter and connects to 5 residual blocks, each of which consists of two 3 by 3 convolutional layers alternating with batch normalization layers, and activation is performed using a rectified linear unit (ReLU) function. After the residual network, a 3 by 3 convolution and a 1 by 1 convolution are connected, and a subpixel convolutional

XSL•FO
RenderX

layer is used to upsample the image. In the generator network, except for the last layer that uses tanh as the activation function, all other layers use ReLU as the activation function. The discriminator network structure is shown in Figure 1B. In the discriminator network D, our model first uses an architecture comprising eight 3×3 convolutional layers and Leaky ReLU function activation. All convolutional layers except the first have batch normalization layers. The Sigmoid activation function is applied to the last fully connected layer, which outputs the probability of discriminating whether the input HR image is a real HR image or an image generated by the generator. The network architecture includes a pretrained VGG-19 network, which is used for feature extraction and loss function calculation.

Figure 1. The architecture of the superresolution generative adversarial network. BN: batch normalization; DL: deep learning; HR: high resolution; ReLU: rectified linear unit.

Loss Function

The pixel-by-pixel error method used is the L1 loss function, also known as the mean absolute error, which is calculated using equation 1. Although SRGAN completely discards the pixel-by-pixel error, we still add this error in a certain proportion during the actual training process to amplify the difference and guide the optimization of the model. The cross-entropy loss function of the discriminator is used as the adversarial error of the network, and the calculation method is expressed using equation 2. In addition to using the adversarial error, SRGAN also uses a content error, which is defined as the Euclidean distance between the superresolved image and the feature map of the reference image, and the calculation method is expressed using equation 3. The content error is used to align the content of LR images and HR images, which plays the same role as the mean square error. In this network, the pretrained VGG-19 network is used to extract the feature parameter map. Therefore, the loss function for the generator in this network is described using equation 4.

$$(1) L_{mae} = \frac{1}{CHW}\sum_{i,j,k} |I_{i,j,k}^{DL} - I_{i,j,k}^{GT}|$$

where I^{DL} is the output image of the generator and I^{GT} is the input reference image.

$$(2) L_{gan} = -\sum_{i} \log D(G(I^{DL}))$$

where G and D are the generative network and the discriminative network, respectively.

$$(3) L_{VGG} = \frac{1}{C_j H_j W_j}\sum_{x=1}^{W_j}\sum_{y=1}^{H_j}\sum_{c=1}^{C_j}(\phi_j(G(I^{DL}))_{x,y,c} - \phi_j(G(I^{GT}))_{x,y,c})^2$$

where $(\varnothing j)$ is the feature map obtained from the jth convolutional layer of the VGG-19 network, C_j, H_j, and W_j are the number of channels and height and width of the feature map, respectively, I^{DL} is the output image of the generator, and I^{GT} is the input reference image.

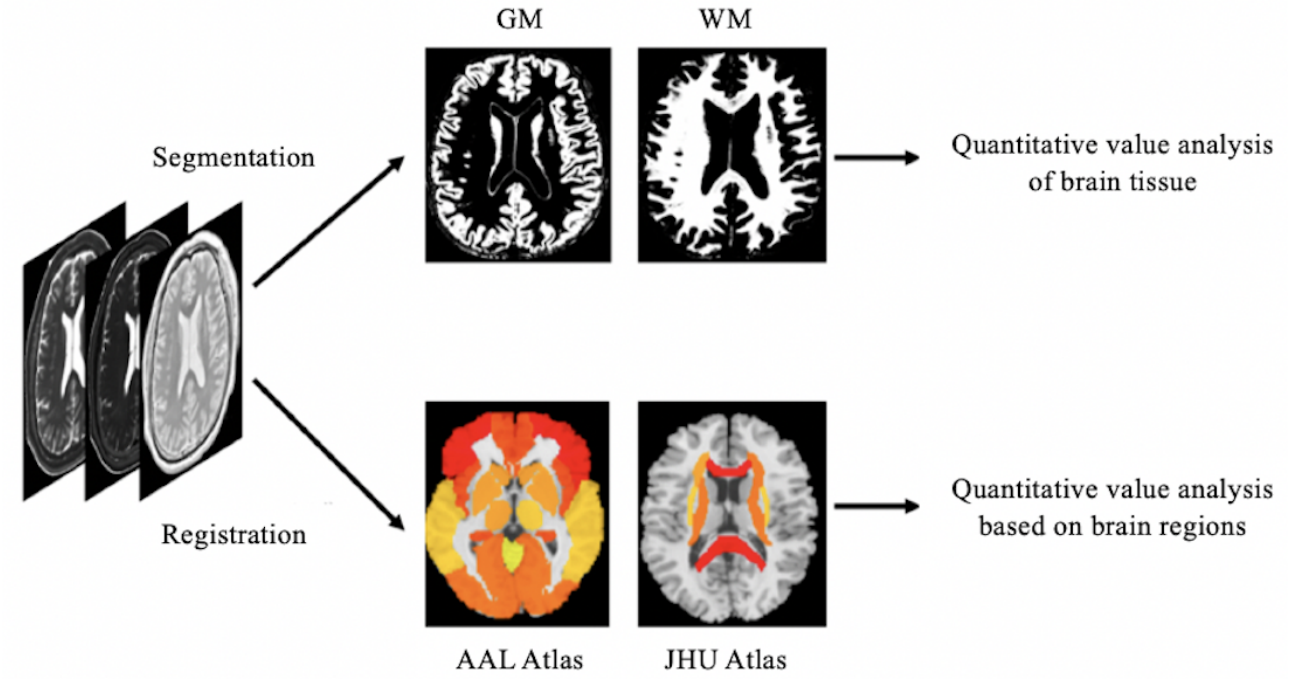
$$(4) L_{total} = L_{mae} + 10^{-3} L_{gan} + 2 \times 10^{-6} L_{VGG}$$

Implementation

Approximately 80% (120 healthy individuals) of the dataset were allocated to training, and the remaining individuals (healthy individuals: 31, 19.62%; and patients: 7, 4.43%) were used for

XSL•FO
RenderX

testing. Slices from each individual were pooled and randomly shuffled within their respective sets to prevent any sequential bias and improve the performance of the model. Before training, all quantitative maps (T1, T2, and PD) underwent intensity normalization to match the output range of the generator network, that is, imagenorm=(pixelvalue/normalizepara)×2−1, where normalize_para is set to 45,000, 22,000, and 1800 for T1, T2, and PD maps, respectively.



The DL models for T1, T2, and PD maps were trained separately but with identical hyperparameters. Each model was implemented using the TensorLayer framework [19] and optimized via the adaptive moment estimation (Adam) optimizer with a learning rate of 1×10^{3} and step-wise decay every 1000 iterations. Training was performed on an NVIDIA Tesla V100 GPU with a batch size of 8 and a total of 200 epochs. All other parameters were kept at their default settings.

Quantitative Value Measurements

The flowchart illustrating the process of quantitative value measurements is presented in Figure 2.

For healthy participants, quantitative value analysis of brain tissue and brain regions was conducted. First, brain tissue segmentation was performed on each individual's quantitative map using the New Segment tool within SPM [20] software. Then, quantitative value extraction of gray matter (GM) and WM was performed using self-written programs in the MATLAB (The MathWorks Inc.) platform.

Figure 2. The process of quantitative value measurements for healthy participants. AAL: anatomical automatic labeling; GM: gray matter; JHU: Johns Hopkins University; WM: white matter.

In addition to analyzing quantitative values for both GM and WM tissue, analysis was also performed by different brain regions for clinical evaluation and application. Using the anatomical automatic labeling atlas of the Montreal Neurological Institute (MNI), 10 GM regions of interest (ROIs) were created on anatomical structures, including frontal cortex, temporal cortex, parietal cortex, occipital cortex, insula, hippocampus, caudate nucleus, putamen, pallidum, and thalamus. Additionally, using the JHU-WhiteMatter-48 atlas, 9 WM ROIs were generated, including the middle cerebellar peduncle, genu of corpus callosum, splenium of corpus callosum, cerebral peduncle, internal capsule, anterior corona radiata, superior corona radiata, posterior corona radiata, and external capsule [21]. In all analyses, right and left quantitative data were averaged. The quantitative value of the corresponding brain region in the quantitative map reconstructed by DL and from routine scans was obtained for each individual for subsequent statistical analysis.

For the images of individuals with pathologies, an experienced radiologist used the ITK-SNAP software (version 3.8.0; [22]) to delineate the ROI of typical lesions manually and acquired the mean value of the signal in the ROI. To ensure paired comparison, identical ROI size and location were replicated on the DL reconstructed and reference routine scan images. A total of 12 ROIs were obtained from 7 (4.43%) patients (individual 3: 3 ROIs, individual 5: 3 ROIs, individual 7: 2 ROIs, and the remaining 4 individuals: 1 ROI each).

Image Quality Evaluation

Two full-reference evaluation indices—peak signal-to-noise ratio (PSNR) and structural similarity image measure (SSIM)—were used in this study for image quality assessment [23]. The larger the value of the 2 indices, the better the image quality. The PSNR was defined by equation 5:

$$MSE=\sum_{m=1}^{M}\sum_{n=1}^{N}[R(m,n)-I(m,n)]^{2}M\times N$$

$$(5)PSNR=20\log L^{2}MSE$$

The calculation method of SSIM is given by equation 6:

$$,$$

$$(6)SSIM(X,Y)=(2\mu X\mu Y+C1)(2\sigma XY+C2)(\mu X^{2}+\mu Y^{2}+C1)(\sigma X^{2}+\sigma Y^{2}+C2)$$

XSL•FO
RenderX

C1=(K1L)2,C2=(K2L)2

where μ and μ , σ and σ , and σ are the local means, SDs, and cross-covariance for the DL quantitative images and routine scans, respectively, and C1 and C2 are 2 quantities used to stabilize the division in the case of a weak denominator, with L=65,535, K1 = 0.01, and K2= 0.03.

In addition, a no-reference image quality assessment method, the naturalness image quality evaluator (NIQE), was used to evaluate the quality of quantitative images reconstructed by DL, with fast scan and with routine scan, respectively [24]. Unlike PSNR and SSIM, the lower the value of NIQE, the less distortion and higher image quality.

Statistical Analysis

For the quantitative analysis of brain tissue in healthy participants, Paired *t*-test was used to compare the differences in quantitative values between DL and routine scans, and equivalence was confirmed using two one-sided tests (TOST). Linear regression analysis and Bland-Altman analysis were used in the study, and we combined GM and WM to comprehensively evaluate overall bias. This method captures the overall trends and variability of different tissue types, which is crucial for evaluating the performance of DL reconstruction in clinically relevant contexts. For the region-based quantitative value analysis in healthy participants, coefficients of variation (CVs) were calculated within each imaging method (intragroup CV) and across each imaging method (intergroup CV). Intergroup CV was calculated using the average of the quantitative values from each method. For the images of individuals with pathologies, Paired *t*-test was used to compare quantitative values in different ROIs between groups. All statistical analyses were performed using SPSS 22.0 and GraphPad Prism 9. A *P* value <.05 was considered statistically significant.

Ethical Considerations

This study was approved by the Medical Research Ethics Committees of Beijing Friendship Hospital, Capital Medical University (2020-P2-122-02). All participants provided informed consent before participating. Participants' privacy and confidentiality were protected, with all data being deidentified during analysis. No compensation was provided for participation. No identifiable information of participants was included in the paper or supplementary materials in Multimedia Appendix 1. All procedures adhered to ethical guidelines for participant autonomy, safety, and confidentiality.

Results

Time Consumption

The average whole brain acquisition time was 4 minutes 55 seconds for routine scans, with an additional 1 minute for vendor postprocessing. Fast scans were completed in 1 minute 52 seconds; applying the SRGAN network trained in this study then reconstructed, the 512 by 512 quantitative T1/T2/PD maps were completed in approximately 1 second. Thus, the combined acquisition and reconstruction time was reduced from 5 minutes 55 seconds to 1 minute 53 seconds, promoting the wider clinical application of quantitative neuroimaging and synthetic MRI.

Quantitative Value Accuracy

A paired *t* test showed significant differences in GM tissue values between DL and fast scans (T1: *P*<.001, PD: *P*=.002), while there was no significant difference in GM tissue values between DL and routine scans at T1 (*P*=.66) and PD (*P*=.18). However, compared with routine scans, T2 values still showed significant differences after DL (*P*<.001). For WM, compared with routine scans, there was no significant difference in T2 after DL (*P*=.11). Although there were still significant differences in T1 and PD, the differences were reduced compared with fast scans (Table 1).

Table . The quantitative value of brain tissue obtained by fast scan, deep learning (DL), and routine scan.

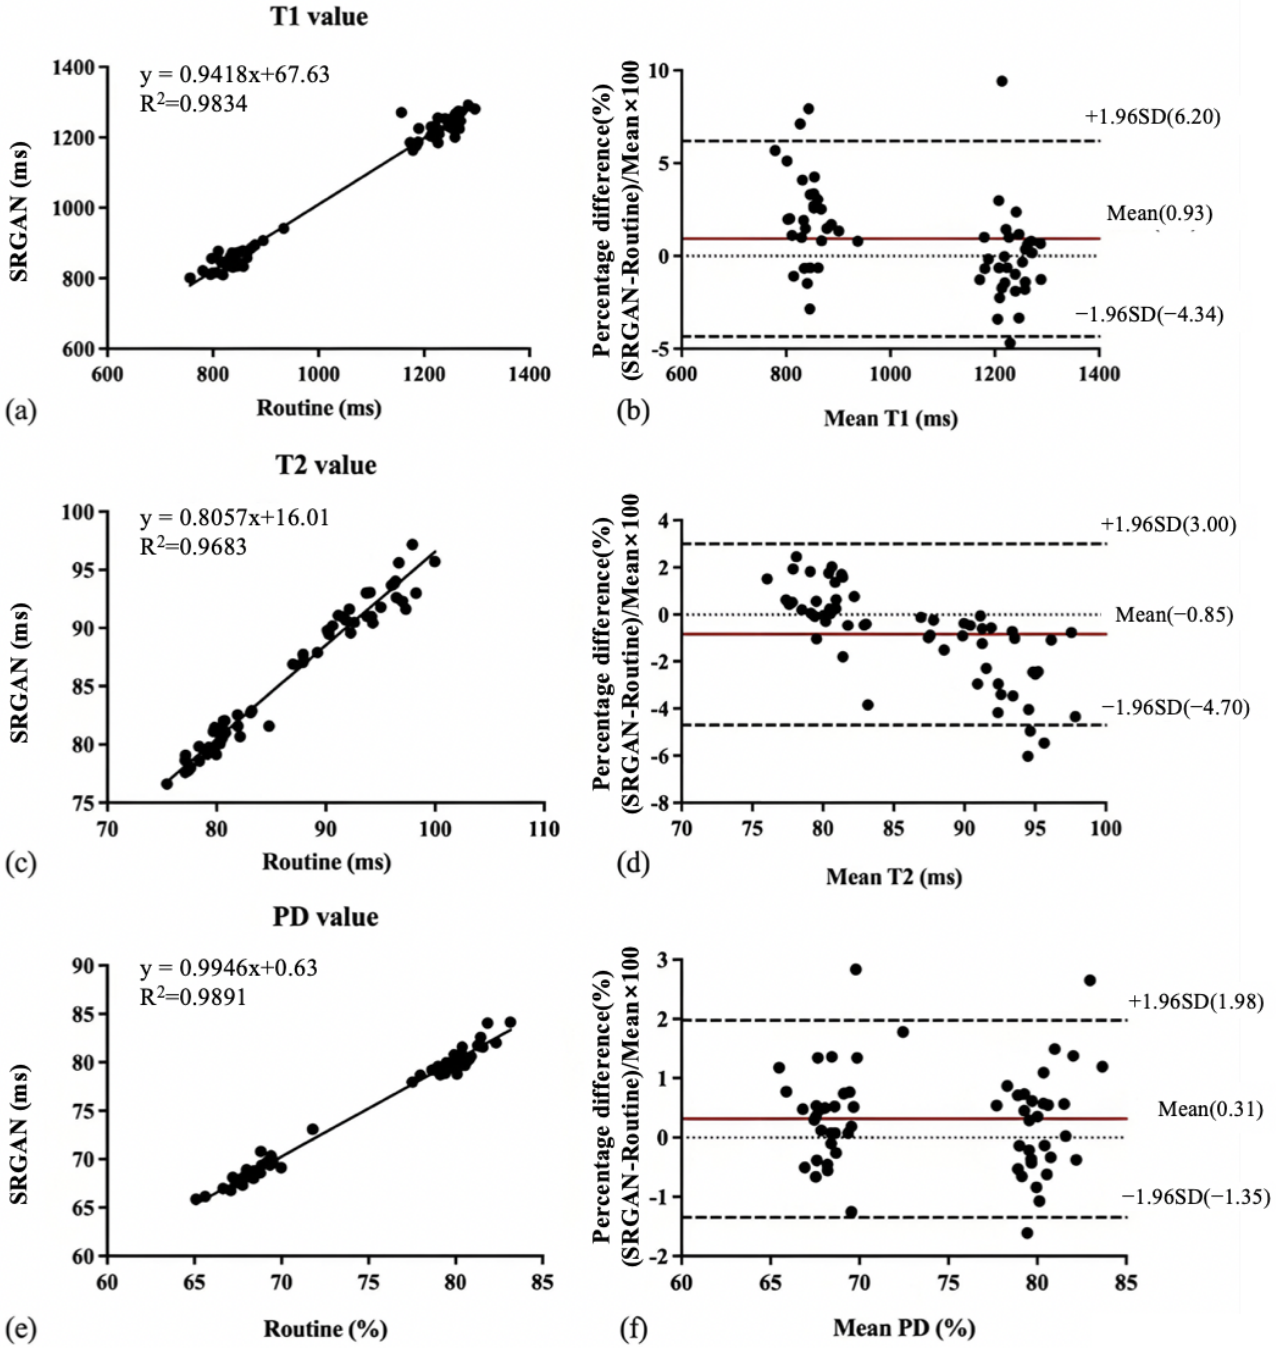
Setting the clinically acceptable brain tissue quantification value limit to ±5% of the mean values from the routine scans (T1_GM epsilon: 61.63 ms, T2_GM epsilon: 4.67 ms, PD_GM epsilon: 4.01%, T1_WM epsilon: 41.89 ms, T2_GM epsilon: 4.00 ms, and PD_WM epsilon: 3.41%), the 90% TOST CI for the brain tissue in 3 quantitative maps (T1_GM: −11.88 to 6.91, T2_GM:



XSL•FO
RenderX

−2.48 to−1.46, PD_GM: −0.04 to 0.41, T1_WM: 10.94 to 23.46, T2_WM: −0.01 to 0.03, and PD_WM: 0.10 to 0.45) were all within the predefined margins (P<.001).

Figure 3 shows the relationship and Bland-Altman plots between the T1, T2, and PD values obtained by DL and routine scans (reference). The correlations to the reference value were excellent, as the R^2 for the T1, T2, and PD values of DL compared to the reference value was 0.98, 0.97, and 0.99, respectively. The slopes of the linear regression were near 1.0 both for T1 (0.9418) and PD (0.9946). In contrast, the T2 values were moderate, as the slope of the linear regression was 0.8057 (Figure 3A,C,E). In addition, the average percentage bias for T1, T2, and PD was 0.93%, −0.85%, and 0.31%, respectively. The 95% limits of agreement were 6.20% to −4.34% for T1, 3.00% to −4.70% for T2, and 1.98% to −1.35% for PD (Figure 3B,D,F). Similarly, Figure 4 shows the relationship and Bland-Altman plots of the T1, T2, and PD acquired by DL and fast scans. The results of linear regression analysis also showed a strong correlation between the 2 methods in T1 and PD (T1: R^2=0.99 and PD: R^2=0.98), with a slightly lower correlation in T2 (R^2=0.80). The slopes of the linear regression were near 1.0 both for T1 (0.9680) and PD (0.9381). In contrast, the T2 values were moderate, as the slope of the linear regression was 0.7755 (Figure 4A,C,E). The results of the bias trend of T1, T2, and PD between these 2 methods also showed similar results, that is, the mean percentage difference for T1 and PD was smaller (3.66% and 1.09%, respectively), whereas the mean percentage difference for T2 was slightly higher (−6.32%) (Figure 4B,D,F).

Figure 4. Scatterplots and Bland-Altman plot results for deep learning versus fast scans. The linear regression lines represent a strong linear relationship with a robust fit between the tissue value measurements of T1, T2, and proton density (PD) obtained from the 2 magnetic resonance imaging methods. Bland-Altman plots show mean percentage differences (solid red line) and the 95% CIs (dashed black line). SRGAN: superresolution generative adversarial network.

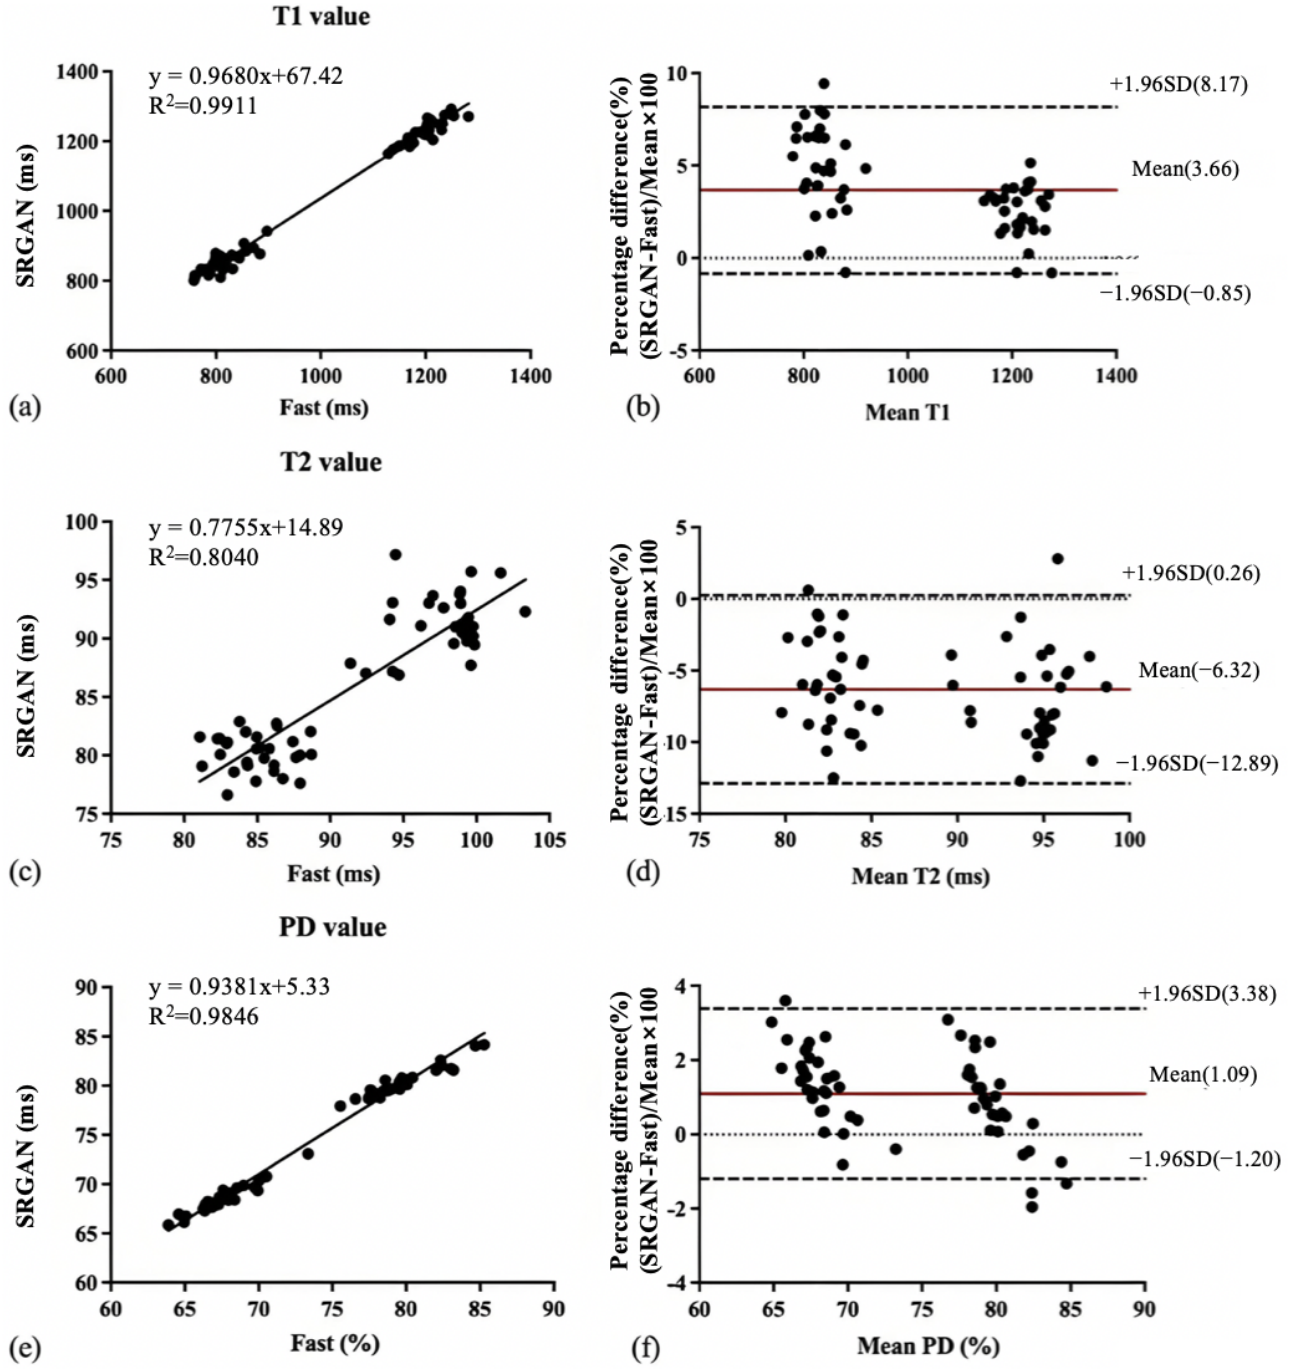

Table 2 presents the intragroup CV and intergroup CV of brain regions' quantitative values acquired by DL and routine scans. The intragroup variability of the quantitative values obtained by these 2 methods is small, as the intragroup CV for the routine scan's PD values ranges from 1.64% to 6.44%, and the PD values for DL range from 1.98% to 5.84%. The highest intragroup CV of T1 and T2 values was noted in the pallidum (T1: 18.77% vs 17.25%; and T2: 17.00% vs 16.33%). The intergroup CV was lower than the intragroup CV for all brain regions. For intergroup CV, there were no significant differences in the quantitative values of T1, T2, and PD for the WM region after DL reconstruction. However, significant differences in T2 values were observed in the GM regions, including the frontal cortex, temporal cortex, parietal cortex, occipital cortex, insula, and hippocampus.

Table 3 presents the quantitative values in ROI of typical lesions acquired by DL and routine scans. Compared with the quantitative values under routine scans, there were no significant differences in the quantitative values reconstructed by deep learning (T1, *P*=.67; T2, *P*=.73; and PD, *P*=.75).

Table . The naturalness image quality evaluator of quantitative maps under fast scan, deep learning (DL), and routine scan.

	Fast scan, mean (SD)	DL, mean (SD)	Routine, mean (SD)
T1 maps	29.46 (6.42)	13.36 (1.88)	10.90 (1.84)
T2 maps	30.56 (5.57)	18.79 (1.46)	15.21 (1.78)
PD[a] maps	34.66 (2.99)	11.74 (2.17)	10.85 (2.53)

[a]PD: proton density.

Discussion

Principal Findings

In this paper, we trained an SRGAN network to reconstruct whole brain T1, T2, and PD maps from accelerated synthetic MRI data. Experimental results show that the application of DL for reconstruction can generate quantitative maps from fast scans with a 50% reduction in acquisition time. The quantitative instability caused by LR acquisition is reduced, with no significant difference between the reconstructed and routine scan values, and intra- and inter-CVs are small in most brain regions. Our study also found that the resulting maps still allow clear visual detection of common pathologies, thereby helping to shorten clinical scanning time.

Comparison With Prior Work

In previous studies, the use of commercial algorithms for fast image reconstruction resulted in a total brain acquisition time exceeding 3 minutes [25]. Our research further reduces the collection time to less than 2 minutes while maintaining accuracy. DICOM raw data were used as input and output for

XSL•FO
RenderX

the network, which conforms to the standard practice of DICOM image processing, where metadata (including rescaled slopes) are crucial for accurate image analysis and quantitative measurement. By adhering to these specifications, the study maintains the integrity of the qMRI data, facilitating a reliable evaluation of the DL reconstruction techniques' impact on the accuracy of quantitative brain tissue values.

The MDME sequence was used to acquire the quantitative maps, and several studies have investigated the repeatability and reproducibility of quantitative values using this sequence. In this study, we applied multiple quantitative metrics and statistical methods to analyze differences among DL reconstructed, fast scan, and routine scan values. The results of our study, as indicated by the paired *t* tests, provide valuable insights into the performance of DL reconstruction and demonstrate that it improves the accuracy of fast quantitative MRI scans, bringing tissue-specific T1, T2, and PD values closer to those of routine clinical acquisitions. In GM, the method achieved no statistically significant difference compared to routine scans. However, a small but statistically significant underestimation in T2 remained. A previous study examining the influence of parameter modifications on MDME-derived quantitative values reported that alterations in acquisition matrix or acceleration factor induced negligible variance in measured constants, with the exception of CSF T2 estimation [26,27]. Notably, this investigation was performed on an isolated, homogeneous phantom; consequently, partial volume effects and other anatomical confounders were absent. The present fast scan protocol, in contrast, simultaneously varies both matrix size and acceleration factor without a commensurate increase in the number of echo times. This divergence in experimental design may compromise the accuracy of T2 mapping—particularly through reduced sampling density in echo space—thereby introducing systematic bias into the fitted relaxation constants. However, TOST analysis further indicates that the 90% CIs of all brain tissue parameters in the 3 quantitative maps are within clinically acceptable ranges, providing the possibility for the clinical applications of DL quantitative reconstruction.

In our quantitative analysis, the linear regression slope for T2 values (DL vs routine) was 0.8057, which deviates from the ideal value of 1.0. Clinically, this may affect the diagnostic accuracy of high T2 lesions, leading to misdiagnosis or delayed intervention. Most of the samples in this study were healthy volunteers, and the accuracy of DL for T2 values under specific pathological manifestations was not validated. Such bias may arise primarily from the L1 loss component, which enforces pixel-wise fidelity at the expense of high-frequency details and can lead to oversmoothing—particularly in regions with high tissue contrast or rapid T2 decay. Consequently, although the average T2 error across healthy tissue may satisfy TOST criteria, it may reduce the accuracy of this method in extreme cases of dynamic range that often occur in pathology. Despite this limitation, the SRGAN model demonstrated good performance in overall image quality metrics, indicating its practicality in routine clinical workflows, although it requires appropriate attention.

Linear regression and Bland-Altman plots also demonstrated that the vast majority of quantitative parameters exhibited high correlation and agreement between the DL and routine scans, with 95% of data points lying within the limits of agreement, which is in line with previous research [28,29]. In contrast, T2 estimates derived from the DL exhibited a marked bias relative to the reference (Figure 3 vs Figure 4). These findings indicate that the DL model successfully compensates for systematic errors introduced by the fast scan, yielding quantitative values that closely approximate those obtained under routine scans. Such error mitigation directly supports the primary objective of this study: to establish the feasibility of using DL for accurate, ultrafast quantitative MR reconstruction.

In addition to measuring the quantitative values of gray and WM, the study also applied classic atlases from brain science analysis: the anatomical automatic labeling and the Johns Hopkins University atlases [30]. These atlases divide the brain into regions based on structure or function, which allows for a more comprehensive characterization of the accuracy and reliability of the quantitative values. Generally, the intragroup CV should ideally be below 10%, and the intergroup CV should remain under 15%, yet a significant intragroup CV was observed in deep GM nucleus regions, such as pallidum. This may be due to the inhomogeneity of B1 and differences in data acquisition parameters or variations in the age and gender of the individuals, which have also been shown and analyzed in previous studies [31-33]. Additionally, these numerical disparities may stem from spatial registration errors between individual quantitative maps and brain region templates, potentially affecting the extraction of quantitative values. Our study also observed significant differences in the T2 CVs between DL and routine scans in some GM brain regions. This difference indicates that although the SRGAN model has good consistency at the overall organizational level, it may introduce variability at the regional scale, which may be due to the model's sensitivity to local texture or noise, potentially limiting its practicality in precise quantitative neuroimaging applications. However, the intra- and inter-group CV for the remaining brain regions remained below 5%, especially for PD values, which show minimal intragroup and intergroup variation across all brain regions. This implies that T2 is relatively sensitive in quantitative analysis and should be a key focus in disease analysis.

The outlined lesion areas in the study are predominantly distributed in the WM. The average T1, T2, and PD quantitative values within these lesion areas exceed 1000 milliseconds, 100 milliseconds, and 80 milliseconds, respectively, which are higher than the ranges observed in the healthy participants' quantitative values. Furthermore, different types of lesions exhibit distinct quantitative values. WM hyperintensities and acute-phase cerebral infarction have similar quantitative values. In contrast, the quantitative values in encephalomalacia are significantly higher than those in the other 2 types of lesions, particularly the T1 values within encephalomalacia (approaching 4000 ms), which are similar to the T1 value of cerebrospinal fluid because the components of encephalomalacia are similar to cerebrospinal fluid. These findings align with clinical knowledge, indicating that lesion areas generally have longer T1 and T2 relaxation

XSL•FO
RenderX

times. Importantly, the quantitative values obtained through DL still maintain diagnostic efficacy. Through careful examination of quantitative values, it was found that with a small amount of lesion data, although the difference in quantitative values between DL and routine scans did not reach statistical significance, 5 reconstructed T2 values were lower than those of the routine scan in 7 WMH and infarct ROIs. Given that these lesions have already exhibited high T2 relaxation times (usually >100 ms), any systematic underestimation may weaken their abnormal manifestations. This may be because superresolution networks are only trained on quantitative images of healthy adults and do not include any pathological cases. Therefore, the model has not yet learned the characteristic diastolic curves of common brain injuries, such as significant prolongation of WM hyperintensities on T2. This lack of exposure may lead to the network interpreting high T2 values in lesions as outliers or reconstruction artifacts, thereby regressing these values to the healthy tissue distribution. Therefore, the sample size will continue to be expanded in the future to verify the quantitative accuracy of DL reconstruction in various neurological diseases.

While the DL maps have basically met the predefined quantitative equivalence margins, the no-reference NIQE metric reveals a residual perceptual gap: compared with fast scanning, the DL image quality has significantly improved (as indicated by a decreased NIQE score), but compared with routine scans, the NIQE scores of the 3-parameter images are slightly higher. This suggests that the current model ensures the accuracy of clinical quantification and significantly improves accuracy on the basis of fast scans, but further improvement is needed to achieve complete perceptual equality with routine HR imaging.

Limitations

This study still has some limitations. First, the study adopted the widely validated SRGAN framework and focused on quantitative agreement and image quality comparison; however, emerging architectures such as ESRGAN or SwinIR were not compared, nor were traditional non-DL upsampling methods used as baselines. Second, the network was trained exclusively on data acquired with a GE 3.0 T scanner and entirely on normal-appearing brain tissue (only 7 patients with 3 common lesion types were used for testing), so the performance of the method on pathological tissue is a preliminary proof of concept rather than evidence of clinical equivalence. The small number of pathology cases limits statistical power and generalizability to diverse or high-contrast lesions, which may pose a barrier to routine clinical deployment. Third, based on the current amount of data, using the training set and testing set with a single subject-level split of 8:2 may prevent data leakage from related slices but may not fully capture the variability between multiple random partitions. Due to limited training data, the model runs on 2D slices instead of 3D volumes, which may result in a loss of spatial continuity between slices. Fourth, acceleration was limited to an R of 3, reconstruction was performed on postprocessed quantitative maps, raw k-space data were not used, and weighted images generated from the quantitative maps were not evaluated. Additionally, the ground truth images have been reconstructed from a matrix of 320 by 256 to a matrix of 512 by 512, and thus, the model learns to reproduce the interpolated image content rather than recovering genuine high-frequency details that would be present in a natively HR acquisition. Finally, evaluation was performed based on quantitative metrics without introducing a qualitative visual assessment by radiologists.

Future Directions

Future research should focus on the following improvements: systematically compare the current SRGAN implementation with newer superresolution networks and quantify the individual contributions of perceptual and adversarial losses to quantitative accuracy, and compare them with non-DL baseline reconstruction methods to better illustrate the benefits of DL. A prospective cohort including demyelinating disease, tumor edema, and microhemorrhages will be enrolled, and the model will be fine-tuned or retrained if necessary before wider clinical deployment. To improve robustness, we will collect both k-space and image-domain data and develop a dual-domain joint reconstruction framework. Future work will explore 3D or slice-aware architectures based on richer training data and computing resources and attempt to use different data partitioning methods to validate generalization further. Finally, the weighted images derived from the superresolved quantitative maps will be generated and assessed for diagnostic quality.

Conclusions

In conclusion, accelerating synthetic MRI is pivotal for its broader clinical adoption in neuroimaging. In this study, we undertook the optimization and enhancement of images acquired through fast synthetic MRI via DL-based reconstruction techniques. Our efforts may result in a remarkable 50% reduction in clinical scan time, all the while achieving better image quality. Importantly, reconstructed T1 and PD maps show excellent agreement with reference scans, supporting their potential for reliable quantification, although T2 values exhibit a consistent underestimation at higher intensities. Despite this limitation, the overall strong correlations and low average biases suggest that using DL methods to mitigate biases in quantitative values is feasible. Furthermore, the shortened scan time not only enhances patient comfort but also reduces the likelihood of motion artifacts. This optimization streamlines the scanning workflow, minimizes redundancy, and maximizes the efficient use of MRI machines.

Abstract

Background: Knee osteoarthritis (KOA) is one of the most prevalent chronic musculoskeletal disorders among the older adult population. Screening populations at risk of rapid progression of osteoarthritis and implementing appropriate early intervention strategies is advantageous for the treatment and prognosis of affected patients.

Objective: This study aimed to construct and validate a nomogram model based on x-ray radiomics to effectively identify individuals experiencing progression of KOA pain.

Methods: The Foundation for the National Institutes of Health Biomarkers Consortium included a total of 600 participants who were classified as pain progressors (n=297, 49.5%) and non–pain progressors (n=303, 50.5%) according to an increase in the Western Ontario and McMaster Universities Osteoarthritis Index pain score of ≥9 points (on a scale from 0 to 100) during the follow-up period of 24 to 48 months. X-rays that lacked defined spacing in the DICOM image were excluded. Fully automatic selection of subchondral bone regions on the inner and outer edges of the tibia and femur as regions of interest and extraction of radiomics features for different combinations of regions of interest were conducted. Least absolute shrinkage and selection operator regression was used to select features and generate a radiomics score using Shapley additive explanations for interpretability. The radiomics score, along with clinical indicators, was incorporated into nomograms using a multivariable logistic regression model. The subgroup analysis focused solely on the progression of pain and cases with no progression at all. The receiver operating characteristic curve, along with calibration and decision curves, was used to assess the discriminative performance.

Results: A total of 450 participants were included in the study. Shapley additive explanations analysis identified Wavelet-HH_gldm_HighGrayLevelEmphasis as the primary radiomics feature. Nomogram 1 and nomogram 2 for predicting KOA pain progression achieved area under the curve values of 0.766 and 0.753, respectively, with mean absolute errors of 0.012 and 0.008, respectively, in the calibration curves. Decision curve analysis showed a positive net benefit across a range of threshold probabilities. In subgroup analyses, nomogram 3 and nomogram 4 yielded areas under the curve of 0.795 and 0.740, respectively.

Conclusions: The nomograms based on x-ray radiomics demonstrated excellent predictive capability and accuracy in forecasting the progression of KOA pain.

KEYWORDS

radiomics; osteoarthritis; knee; nomogram; artificial intelligence

Introduction

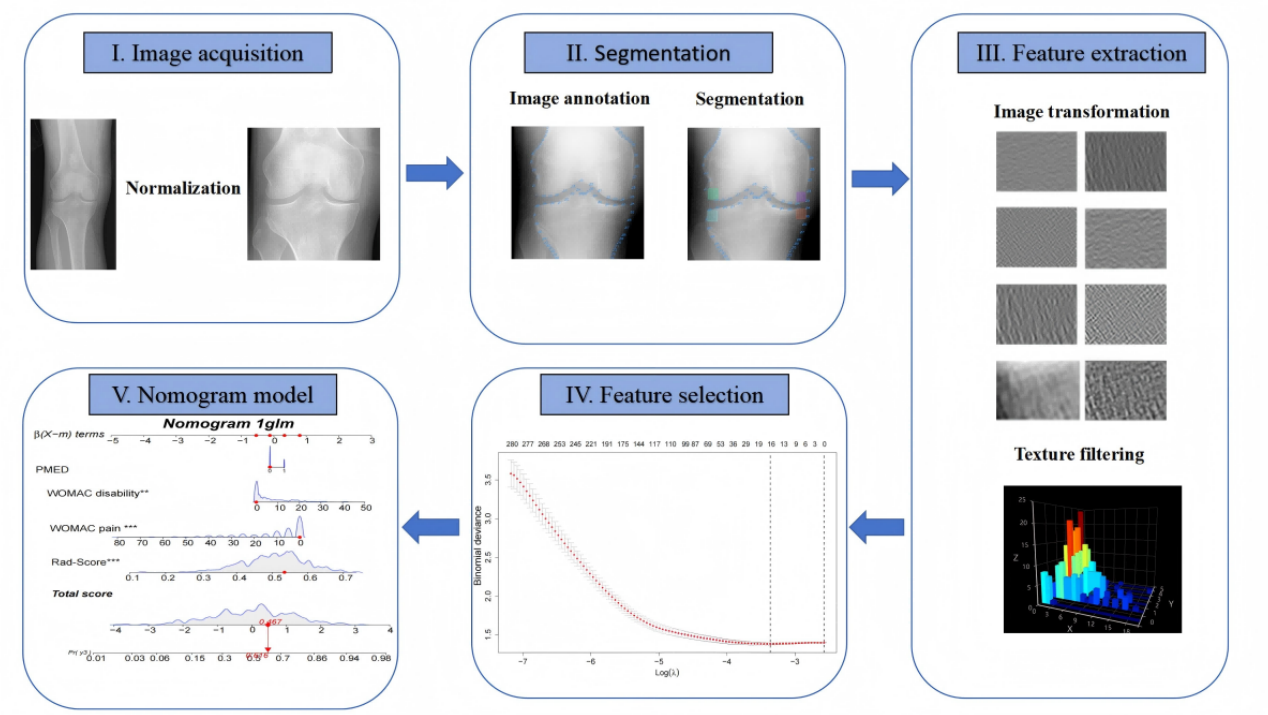
Osteoarthritis (OA) is one of the most common joint disorders affecting the older adult population. With the aging of the population, its incidence has been increasing year by year, imposing a significant burden on both individuals and society [1]. Knee OA (KOA) has the highest incidence among all types of OA. The etiology of KOA is multifactorial, and its pathogenesis remains unclear. KOA can be categorized into various clinical phenotypes and molecular subtypes, including metabolic, inflammatory, mechanical, and genetic [2]. The current treatment guidelines are not suitable for the early diagnosis of KOA and do not distinguish patients who may experience rapid progression [3]. Identifying patients at high risk of rapid progression of KOA will assist in patient education and in the prioritization and allocation of health care resources [4].

The subchondral bone is essential for knee joint structure. Its degeneration disrupts the homeostasis of the intra-articular environment, potentially triggering cartilage degeneration and injury. Furthermore, it is associated with the incidence and progression of OA [5,6]. X-ray imaging continues to be the most prevalent, convenient, and cost-effective modality for evaluating KOA. However, it can only provide a rough estimate of disease severity without quantitative analysis or predicting disease progression [7]. With the application of artificial intelligence in KOA, x-rays can now predict the progression of KOA [3]. Leung et al [8] developed a deep learning predictive model to assess the risk of progression in KOA using knee x-ray images. The findings of their study indicated that this deep learning model surpassed traditional binary outcome models, which are based on standard scoring systems, in predicting the likelihood of total knee arthroplasty among patients with OA [8]. Although deep learning technology is regarded as the most sophisticated image classification technique currently available, its inherent lack of interpretability poses challenges for users in comprehending the model's decision-making outcomes [9].

Radiomics is a novel approach that harnesses advanced image analysis tools and the rapid development of medical imaging data. By integrating artificial intelligence, it enables high-throughput extraction of information from standard medical images and applies the extracted data to clinical decision support systems to enhance the accuracy of diagnosis, prognosis, and prediction [10]. Radiomics has been gradually applied in the field of KOA. Current research primarily focuses on using radiomics to diagnose KOA and predict its radiological progression [11-14]. However, studies on radiomics for predicting the pain progression of KOA are still relatively scarce. A recent study that used magnetic resonance imaging (MRI) radiomics to predict pain progression in KOA demonstrated that the constructed radiomics model achieved an area under the receiver operating characteristic curve (AUC) of 0.79 to 0.86 for KOA pain progression prediction [15]. Nevertheless, the study incorporated 200 radiomics parameters and included omics data from 12- and 24-month follow-ups, resulting in high model complexity and limited practical applicability.

Therefore, this study aimed to develop a nomogram model integrating x-ray subchondral radiomics features and clinical characteristics to predict pain progression in KOA. The Shapley additive explanations (SHAP) method was incorporated to offer a comprehensive explanation and intuitive visualization of the model's predictive mechanisms. This approach allows for the identification of high-risk individuals with rapid pain progression among patients with KOA using cost-effective detection methods, thereby providing clinicians with evidence-based guidance for early intervention strategies.

Methods



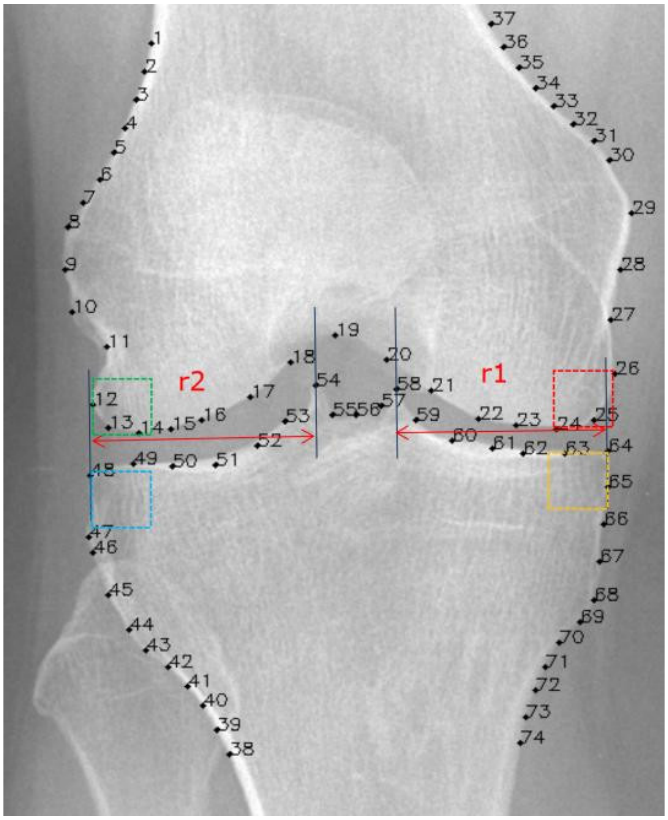
Participants

This study involved participants from the Foundation for the National Institutes of Health (FNIH) Osteoarthritis Biomarkers Project. The design of this research is detailed in previously published literature [16,17]. In brief, the FNIH Osteoarthritis Biomarkers Project includes 600 participants with KOA of Kellgren-Lawrence grades 1 to 3. According to the results of the follow-up, the 600 participants at baseline were categorized into four distinct subgroups: (1) participants exhibiting both radiological and pain progression (n=194, 32.3%), (2) participants with only radiological progression (n=103, 17.2%), (3) participants experiencing only pain progression (n=103, 17.2%), and (4) participants who exhibited neither radiological nor pain progression (n=200, 33.3%). Radiological progression was defined as a loss of minimum joint space width of ≥0.7 mm in the medial femorotibial compartment between baseline and follow-up at 24, 36, or 48 months. Pain progression was characterized by a sustained increase in the Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC) pain subscale (≥9 on a scale from 0 to 100) based on the minimum clinically important difference during the same time frame. In the Digital Imaging and Communications in Medicine (DICOM) standard, pixel spacing is a critical factor for converting image pixels into physical dimensions. Spacing ensures the reliability and reproducibility of medical images in diagnosis, research, and treatment planning [18]. However, some datasets lack or contain erroneous spacing information. They use default values (1.0, 1.0), which result in calculated knee dimensions significantly exceeding normal human anatomical ranges. Such data can be defined as "DICOM data with invalid spacing information." In the standardization process for the Osteoarthritis Initiative (OAI) knee x-ray images, cases with unspecified pixel spacing were excluded. As the pixel spacing of 0.2 mm was predominant in the dataset, all retained images were calibrated to this value to ensure consistent spatial scaling [19]. The specific process of normalization is described in Multimedia Appendix 1 [20-22]. Groups 1 and 3, which

XSL•FO
RenderX

showed pain progression, were combined as the case group, whereas groups 2 and 4, with no pain progression, served as the control group for analysis. Additionally, we conducted subgroup analyses on group 3 (with only pain progression) and group 4 (without both pain and radiological progression). The study flow diagram is shown in Figure 1.

Figure 1. Flowchart of the study. The x-ray images of the knee joint were normalized, and the regions of interest were automatically identified and selected. Subsequently, imaging omics parameters were extracted, followed by a screening process for feature parameters. Imaging omics labels were then constructed to evaluate clinical features, ultimately leading to the generation of a nomogram and an assessment of its performance.



Segmentation and Region of Interest Annotation

BoneFinder (The University of Manchester) is a fully automated software tool designed to outline and segment skeletal structures from 2D radiographs by placing a series of points along bone contours or at key anatomical landmarks. In brief, BoneFinder uses a random forest voting mechanism to precisely determine the optimal placement of model feature points, enabling robust and accurate shape model matching. The system can accurately identify and segment bones not previously present in new images. This method demonstrates exceptional robustness and precision across various skeletal applications, with its generated point data being widely applicable to morphometric analyses, including the construction of statistical morphological models and automatic derivation of standard geometric measurement parameters [23], resulting in 74 markers per image (Figure 2). The fully automatic BoneFinder knee module achieves a mean point-to-curve error of less than 1.0 mm for 99% of 500 images (ie, in 99% of images, the error is less than 1.0 mm) without considering knee size [24].

Four vertical lines are constructed at the marked points 64, 58, 54, and 48 on the knee joint x-ray image, as identified by BoneFinder. These lines are sequentially designated as line 1, line 2, line 3, and line 4. The distance between line 1 and line 2 is denoted as R1, whereas the distance between line 3 and line 4 is referred to as R2. With point 64 designated as the vertex and a side length of R1/4, a square encompassing the medial tibia was defined as the region of interest (ROI). With marker point 64 designated as the vertex and a quarter of R1 as the side length, a square encompassing the medial tibia was defined as the ROI. First, using marker point 48 as the vertex and a quarter of R2 as the side length, a square area on the lateral tibia was selected to define ROI. Second, the selection process for the femur ROI differs from that of the tibia ROI. ROI 3 is defined with the line intersecting marker 24 as its lower boundary, while the line intersecting marker point 26 serves as the side boundary of this ROI. ROI 4 of the lateral femur uses the line indicated at point 14 as the lower boundary of the ROI and the column line marked at point 12 as its vertical boundary. Then, squares with side lengths of a quarter of R1 and a quarter of R2 are constructed. To assess the repeatability of ROI delineation, a total of 40 cases were randomly selected from the collected dataset. Two senior musculoskeletal radiologists (YWS and SNP) conducted manual segmentation of ROIs. Dice similarity coefficients were used to assess manual and automated segmentation agreement. Image annotation was performed using Neusoft Darts [25].

XSL•FO
RenderX

Figure 2. Schematic diagram of the automated region of interest segmentation process.

Radiomics Feature Extraction

The extraction of radiomics features was based on Neusoft Discovery [25]. The features that were extracted can be categorized into 3 distinct groups. First-order features were derived from the gray values of images, reflecting the distribution and heterogeneity of intensity within the ROI, typically including maximum, minimum, mean, median, range, variance, kurtosis, skewness, and entropy. The second-order features refer to the extracted texture characteristics, which include texture feature values derived from the gray-level co-occurrence matrix, gray-level run-length matrix, gray-level connected region size matrix, neighborhood difference matrix, and gray-level correlation matrix. The texture features can quantify the distribution of textures within the ROI that are difficult to perceive visually. Third, features were extracted after log transformation, first-level wavelet decomposition, and gradient transformation were applied to the ROI. All features were normalized using the following formula: $Z=(x–\mu)/\sigma$.

Radiomics Feature Selection and Radiomics Signature Construction

The Spearman correlation was used to remove the redundant features. The feature subset was optimized using the least absolute shrinkage and selection operator (LASSO) method in logistic regression. A 10-fold cross-validation approach was used to identify the optimal model that minimizes the mean squared error, and the correlation coefficients of the features selected by the best LASSO model were calculated. According to the coefficients derived from LASSO regression, a weighted calculation was performed to obtain the radiomics score (rad-score). Radiomics parameters from 4 ROIs (ROIs 1-4) were extracted individually, and rad-score 1 was developed following LASSO screening of the nonzero parameters. The radiomics parameters were applied to ROI 1 and ROI 3, leading to the development of rad-score 2. In subgroup analysis, rad-score 3, obtained from extracted and screened nonzero parameters from ROIs 1 to 4, and rad-score 4, obtained from extracted and screened nonzero parameters from ROI 1 and ROI 3, predicted pain progression only and no progression at all, respectively. SHAP analysis was used to mitigate the “black-box” effect of machine learning, enabling feature prioritization and interpretability of individual radiomics features on the rad-score. Feature maps were used to visualize the results of the rad-score.

Development and Evaluation of Nomograms

The analysis used stepwise backward multivariable logistic regression to identify clinical risk factors at baseline and construct nomograms. The Akaike information criterion likelihood ratio test was used as the stopping rule for the backward stepwise logistic regression analysis. Clinical information from patients at baseline included age, sex, history of injury, BMI, the minimum joint space width of the medial tibial-femoral compartment, Kellgren-Lawrence grade, WOMAC pain score and WOMAC disability score, medicine for pain in the previous 12 months, and race. The nomograms were developed based on the prediction probability value of the optimal radiomics models and clinical independent risk factors. The discriminative ability of the nomogram was evaluated using the AUC and accuracy. Calibration of the nomogram was performed through calibration curves, with optimal calibration indicated by alignment with the diagonal line. Internal validation was conducted using a bootstrap method involving 1000

XSL•FO
RenderX

resampling iterations, and the mean absolute error was used to assess model calibration. Additionally, decision curve analysis (DCA) quantified net benefits at various threshold probabilities to evaluate the clinical effectiveness of the nomograms.

Statistical Analysis

The comparison of categorical variables was conducted using the Pearson chi-square test. Continuous variables were expressed as mean and SD and analyzed using either the 2-tailed *t* test or Mann-Whitney *U* test. The normality of continuous data was assessed using the Kolmogorov-Smirnov test; measurements that followed a normal distribution were subjected to the *t* test, whereas those that did not conform to a normal distribution underwent the Mann-Whitney *U* test. The DeLong test was used for comparing 2 models. *P* values were calculated using a 2-tailed *z* test, with $P<.05$ considered statistically significant. All statistical analyses were performed using the EmpowerStats software (X&Y Solutions, Inc) and the R software (version 4.2.2; R Foundation for Statistical Computing).

Ethical Considerations

This study was conducted in accordance with the Declaration of Helsinki (as revised in 2013). The Institutional Review Board of the University of California, San Francisco (approval 10-00532), and the 4 clinical centers of the OAI project recognized the study as HIPAA (Health Insurance Portability and Accountability Act) compliant. All participants provided written informed consent. Patient-identifiable information (including names and hospital ID numbers) was carefully removed from the x-ray images and reports before analysis. Due to the retrospective design of this study, participants received no compensation.

Results

Baseline Clinical Characteristics

Due to the lack of spacing in DICOM images, a total of 450 participants were ultimately included in the study, with 227 (50.4%) and 223 (49.6%) in the control and case groups, respectively. The baseline characteristics of participants in both the case and control groups were frequency matched for factors including age, BMI, WOMAC functional scores, Kellgren-Lawrence grade, pain medication history, and race. Notably, a statistically significant difference was observed in WOMAC pain scores ($P=.04$) and medication history ($P=.02$) between the 2 groups (Table 1). In subgroup analysis, 18% (n=81) of the individuals demonstrated only pain progression during the follow-up period, whereas 32.9% (n=148) of the individuals exhibited neither pain progression nor radiographic deterioration. The baseline characteristics of participants across both groups were well matched, with no statistically significant differences observed (Table S1 in Multimedia Appendix 2).

Table 1. Baseline characteristics of the study population.

Characteristic	Control group (n=223)	Case group (n=227)	*P* value
Demographics			
Age (years), mean (SD)	62.14 (8.91)	61.48 (8.79)	.38
Female sex, n (%)	131 (58.7)	136 (59.9)	.80
Race, n (%)			.44
Asian	3 (1.3)	2 (0.9)	
Black or African American	21 (9.4)	32 (14.1)	
White	196 (87.9)	191 (84.1)

Segmentation and Feature Extraction

The automated segmentation dataset was used for radiomics feature extraction as the Dice similarity coefficients between automatic and manual segmentation were excellent (0.800; Table S2 in Multimedia Appendix 2). We used 10-fold cross-validation to identify the optimal tuning parameter (alpha). In total, 16 nonzero coefficient features were derived from the optimal tuning parameters in rad-score 1. Rad-score 2 comprised 12 nonzero coefficient features. In subgroup analysis, rad-score 3 included 11 nonzero feature parameters, whereas rad-score 4 consisted of 3 nonzero features (Tables S3-S6 in Multimedia Appendix 2 and Figures S1-S4 in Multimedia Appendix 2). The correlation among features was analyzed using Spearman correlation analysis, and heat maps are presented in Figures S1 to S4 in Multimedia Appendix 2.

Development and Evaluation of Radiomics Signatures

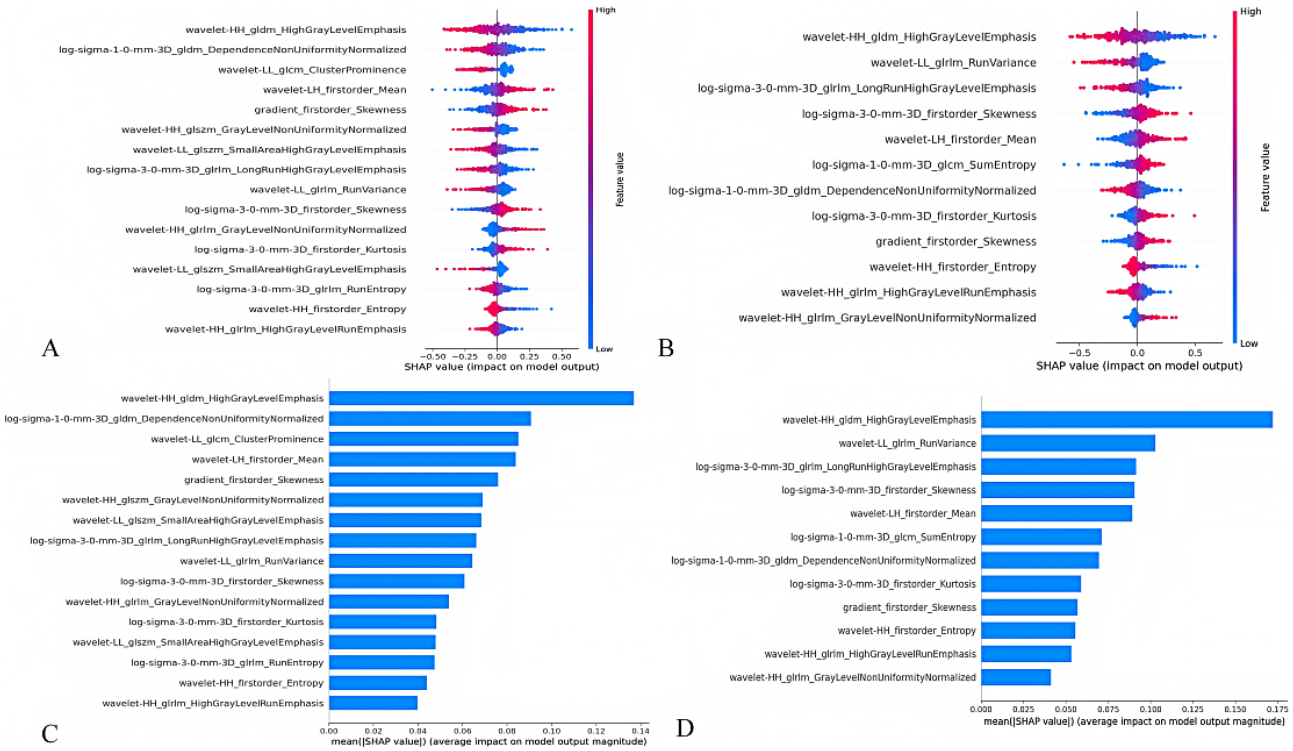

Table 2 shows the diagnostic proficiency of 4 radiomics signatures. The AUC value for rad-score 1 was 0.728 (95% CI 0.681-0.774), the AUC value for rad-score 2 was 0.716 (95% CI 0.635-0.736), the AUC value for rad-score 3 was 0.775 (95% CI 0.714-0.837), and the AUC value for rad-score 4 was 0.679 (95% CI 0.604-0.755; Table 2). The SHAP plot in Figure 3 visually illustrates how radiomics features influenced model predictions in terms of magnitude and direction. Features are sorted vertically by global importance. Each point represents the SHAP value of each feature for a specific patient plotted horizontally and stacked vertically to show density distribution. The color of the point reflects the feature value, from low (blue) to high (red; Figures 3A and C). The bar chart illustrates the impact of various imaging features on the rad-score. Wavelet-HH_gldm_HighGrayLevelEmphasis showed significant effects on both rad-score 1 and rad-score 2 (Figures 3B and D). The SHAP values of each feature in rad-score 3 and rad-score 4 are shown in Figure S5 in Multimedia Appendix 2. Figure 4 shows representative participants with x-ray subchondral bone feature maps from 4 ROIs. The case group participant demonstrated higher ROI heterogeneity than the control group participant, with a higher score (0.58 vs 0.44).

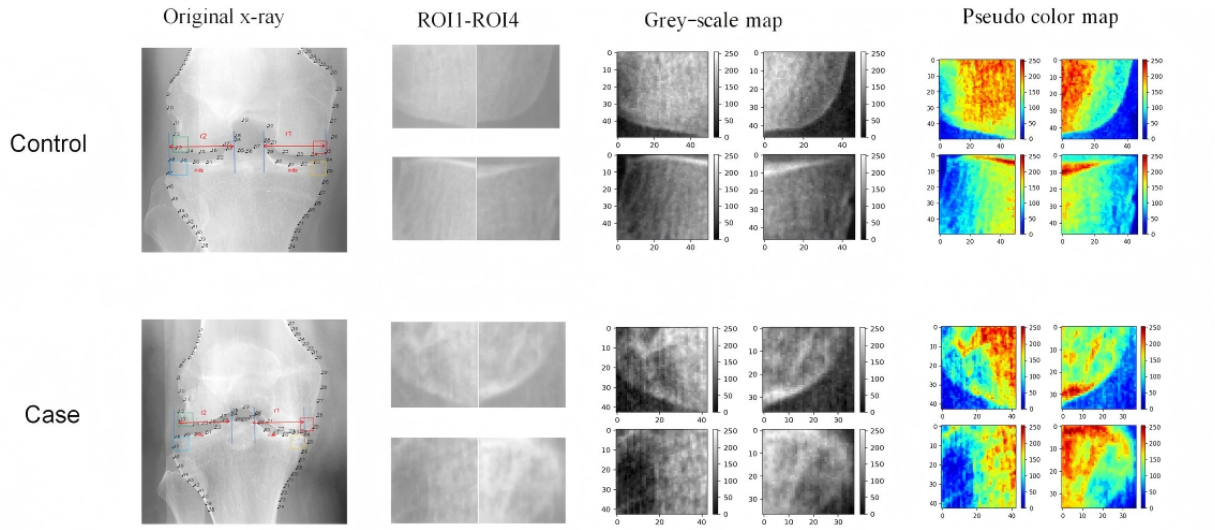
Table 2. Diagnostic efficacy of the 4 radiomics scores.

Radiomics score	AUC[a] (95% CI)	Accuracy	Sensitivity	Specificity
1	0.728 (0.681-0.774)	0.684	0.797	0.570
2	0.716 (0.635-0.736)	0.668	0.683	0.677
3	0.775 (0.714-0.837)	0.742	0.753	0.716
4	0.679 (0.604-0.755)	0.694	0.580	0.757



[a]AUC: area under the receiver operating characteristic curve.

Figure 3. Shapley additive explanations (SHAP) summary plots of the radiomics score. The plot illustrates the feature relevance and attributions of the model's predictive performance: (A) rad-score 1 and (B) rad-score 2. The bar chart illustrates the impact of various imaging features on the rad-score: (C) rad-score 1 and (D) rad-score 2.

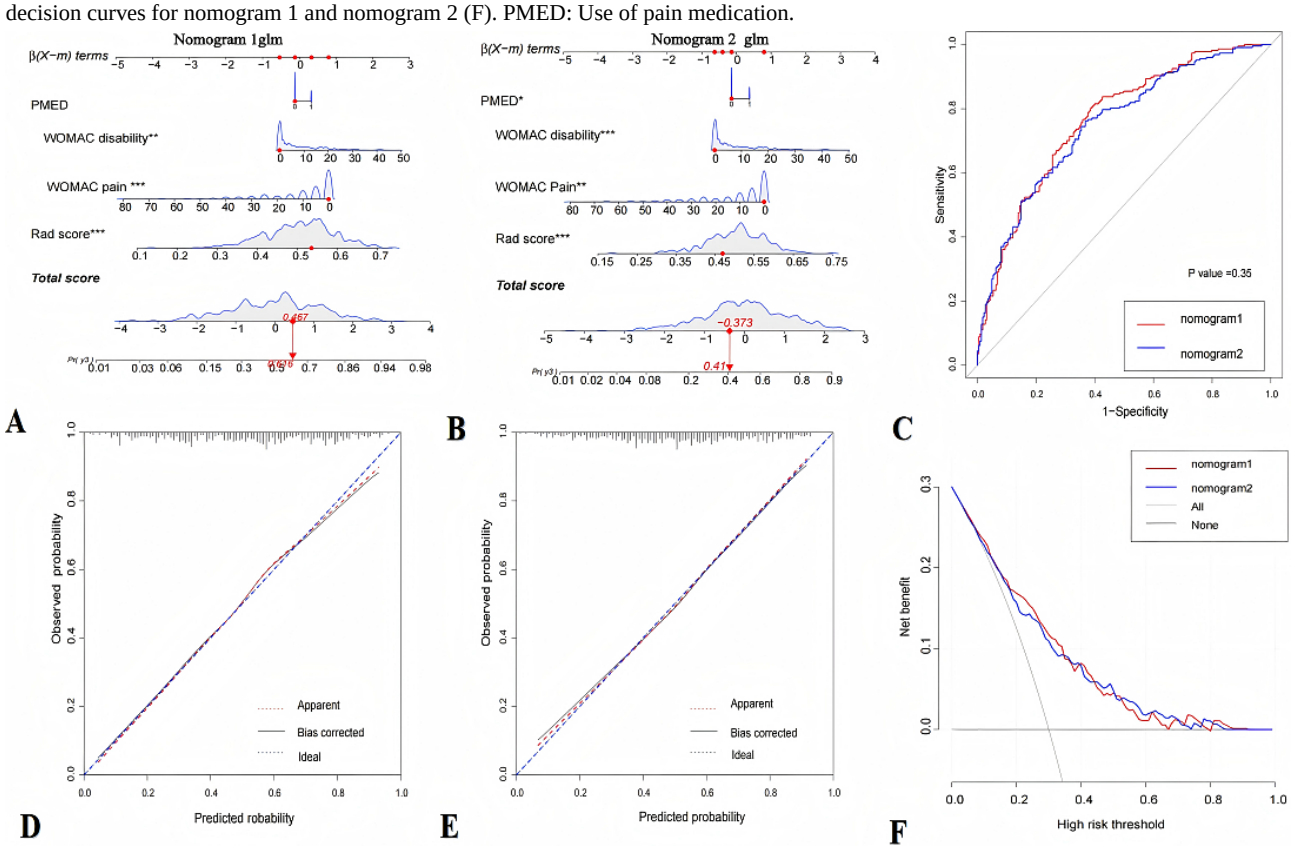

Figure 4. Visualization of radiomics signatures. The case group participant demonstrated higher region of interest heterogeneity than the control group participant, with a higher score.

Construction and Testing of Nomograms

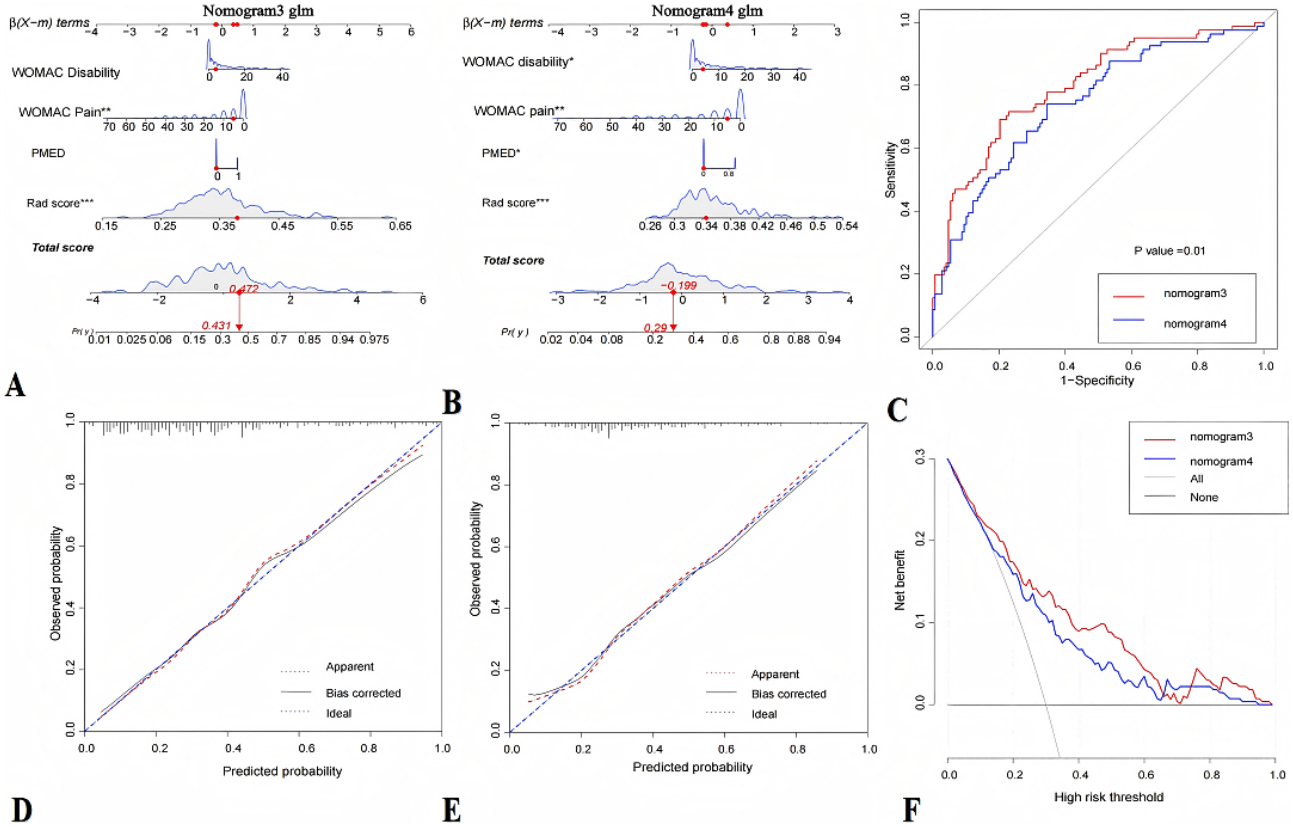
Through multiple regression analysis, the WOMAC disability score, pain medication history, and WOMAC pain score were found to be risk factors for KOA pain progression. We constructed visual nomograms by integrating the score with selected clinical risk factors. The AUC of nomogram 1 was 0.766 (95% CI 0.722-0.809), and the AUC of nomogram 2 was 0.753 (95% CI 0.708-0.797). The comparison of AUC between the 2 models showed no statistically significant difference (DeLong test; *P*>.05; Figure 3). The calibration curve demonstrated that all cohorts were accurately aligned with the actual observations. The internal validation was conducted using the bootstrap method, with a resampling count set to 1000. The mean absolute errors of the calibration curves for the 2 models were found to be 0.012 and 0.008, indicating that the model demonstrated a high level of calibration accuracy (Figure 5 and Table 3). The DCA demonstrated that, if the threshold probability in the clinical decision was in the range of 10% to 70%, both nomogram 1 and nomogram 2 could yield more net benefits compared with either the treat-all-patients strategy or the treat-none strategy.

Figure 5. Development and validation of the nomogram to predict pain progression in knee osteoarthritis (A: nomogram 1; B: nomogram 2), the receiver operating characteristic curves of nomogram 1 and nomogram 2(C), the calibration curves of nomogram 1 and nomogram 2 (D and E, respectively), and decision curves for nomogram 1 and nomogram 2 (F). PMED: Use of pain medication.

XSL•FO
RenderX

Table 3. Diagnostic efficacy of the 4 nomogram models.

Model	AUC[a] (95% CI)	Accuracy	Sensitivity	Specificity	MAE[b]
Nomogram 1	0.766 (0.722-0.809)	0.709	0.692	0.726	0.012
Nomogram 2	0.753 (0.708-0.797)	0.693	0.648	0.740	0.008
Nomogram 3	0.795 (0.734-0.865)	0.760	0.691	0.797	0.011
Nomogram 4	0.740 (0.673-0.808)	0.686	0.740	0.695	0.013



[a]AUC: area under the receiver operating characteristic curve.

[b]MAE: mean absolute error.

Subgroup Analyses

The AUC of nomogram 3 was 0.795 (95% CI 0.734-0.865), and the AUC of nomogram 4 was 0.740 (95% CI 0.673-0.808). The comparison of the AUC between the 2 models showed a statistically significant difference (DeLong test; $P<.05$). The calibration curve demonstrated a robust concordance between the probabilities predicted and the actual observed outcomes. The DCAs demonstrated that, if the threshold probability in the clinical decision was within the range of 10% to 65%, the curve corresponding to nomogram 3 was above nomogram 4, and the AUC that it formed with the "treat none" and "treat all" lines was relatively larger. The net benefit of nomogram 3 was superior to that of nomogram 4, making it the better model (Table 3 and Figure 6).

Figure 6. Development and validation of the nomogram to predict pain progression in knee osteoarthritis (A: nomogram 3; B: nomogram 4), the receiver operating characteristic curves of nomogram 3 and nomogram 4 (C), the calibration curves of nomogram 3 and nomogram 4 (D and E, respectively), and decision curves for nomogram 3 and nomogram 4 (F). PMED: Use of pain medication.

Discussion

Principal Findings

Our study developed a nomogram integrating x-ray radiomics features and clinical variables to predict pain progression in KOA. The resulting baseline-based, cost-effective nomogram demonstrated commendable accuracy and reproducibility in forecasting KOA pain progression, offering significant potential for guiding early intervention strategies in at-risk populations. The application of advanced artificial intelligence to widely available and cost-effective x-ray imaging represents a feasible and promising approach for predicting KOA pain progression. Radiomics models can automatically classify KOA [26], and texture analysis of the subchondral bone, particularly in the tibia, has shown predictive value for radiographic KOA incidence [27,28]. Given the complex etiology of KOA and the frequent discrepancy between clinical symptoms and radiological severity, we focused on subchondral bone remodeling—a process linked to pain pathogenesis through

XSL•FO
RenderX

molecules such as netrin-1 and PEG2, which promote sensory nerve innervation [29,30]. This rationale supported our use of subchondral bone radiomics for predicting symptomatic progression. Radiomics enables high-throughput extraction of quantitative features from medical images, providing data for clinical decision support systems [10]. The selection of key ROIs is critical as different image areas contain varying levels of information relevant to disease progression [31]. While the medial subchondral bone often shows a stronger correlation with OA [32] and the medial tibial margin is recognized as highly informative due to its role in absorbing uneven mechanical loads [33], the optimal ROI selection remains debated. Some deep learning studies for KOA pain progression have also concentrated on the medial joint space and osteophytes [8], whereas other radiomics research suggests that including the entire tibial subchondral bone may yield better outcomes than focusing solely on specific compartments [17].

In this study, we systematically evaluated the impact of ROI selection on model accuracy by constructing radiomics signatures both from 4 ROIs encompassing the entire knee joint and from the 2 medial ROIs alone. Our findings revealed that incorporating lateral ROIs did not improve the overall model AUC compared to using medial ROIs only. However, subgroup analysis indicated that models combining medial and lateral ROIs achieved significantly higher AUC values in specific contexts. The primary cause of this discrepancy may stem from disease heterogeneity. Notably, in the main analysis, both the pain progression group and the nonprogression group included participants with radiological progression. Pathological changes in the lateral subchondral bone may accelerate the radiological progression of the knee joint [34-36]. Therefore, the role of radiomics features in lateral ROIs during pain progression was likely diluted or masked by features from radiologically progressive participants in the control group.

When compared to prior studies, our model demonstrated competitive predictive performance. For instance, Kraus et al [16] applied 3 texture parameters to predict KOA pain progression, achieving AUCs ranging from 0.603 to 0.649. Our rad-score yielded AUCs between 0.679 and 0.775, representing a substantial improvement. This aligns with the understanding that multivariable models integrating multiple risk factors generally provide more reliable estimates than those based on single parameters [37]. The superior performance of our baseline-based model is particularly notable compared to previously reported predictive capabilities relying solely on baseline biomarkers [38]. A recent study using MRI-based radiomics to predict KOA pain progression reported high predictive accuracy, with AUC values ranging from 0.79 to 0.86 [15]. This performance is commendable. However, it is important to note that their model incorporated a substantially larger set of 200 radiomics parameters and, crucially, relied on omics data extracted from 12- and 24-month follow-up MRI scans. While this approach yields high accuracy, the model's complexity and its dependence on longitudinal imaging data significantly limit its practicality and scalability in routine clinical settings. In contrast, our study deliberately pursued a more streamlined and clinically translatable strategy. By using only baseline x-ray images and constructing a parsimonious model using key radiomics features and clinical variables, our baseline-based model eliminates the need for costly follow-up MRI scans and complex feature sets, making it more feasible for immediate clinical application and potential widespread adoption.

Research using deep learning methods to predict KOA pain progression remains scarce. A study using OAI data demonstrated that deep learning models achieved an AUC of 0.77 for predicting KOA pain progression, significantly higher than the 0.692 of traditional models [39]. By integrating demographic, clinical, and imaging risk factors with a deep learning model incorporating baseline knee x-rays, the highest diagnostic efficacy (AUC=0.807) was achieved in predicting pain progression. However, the original study failed to provide specific feature information. In contrast, our study visually presented each feature parameter's impact on the rad-score using Shapley summaries. Wavelet-HH_gldm_HighGrayLevelEmphasis, a gray-level correlation matrix feature derived from high-frequency (HH) subbands of wavelet-transformed images, reflects the concentration of high–gray value regions and emphasizes texture variations in these areas. By quantifying texture changes in knee images, this feature effectively captures tissue degeneration differences caused by pain progression, indirectly reflecting pathological changes and potentially enabling prediction of knee pain progression.

The nomogram was selected for its ability to simplify complex statistical models into user-friendly graphical interfaces that generate individualized risk estimates [40]. While nomograms have been applied in OA contexts such as predicting outcomes after total knee replacement [41,42], their application specifically for predicting KOA pain progression represents a novel contribution. Our nomogram uniquely integrates radiomics signatures with key clinical variables: baseline WOMAC pain scores, WOMAC disability scores, and analgesic use. Interestingly, the baseline WOMAC pain score served as a negative predictor in our model, potentially reflecting the development of tolerance to chronic pain in patients with KOA [43]. The inclusion of WOMAC disability scores and analgesic use is supported by their established roles as risk factors in KOA phenotypic and prognostic models [44,45].

Limitations

This study has several limitations. First, the relatively small sample size may affect statistical power and generalizability. Second, the use of data from previous nested case-control studies could introduce selection bias. Third, our analysis relied solely on internal validation because it was difficult to find an equivalent external cohort. Although the data were sourced from the well-established FNIH Osteoarthritis Biomarkers Project, external validation using independent datasets, such as those from the PROGRESS OA study (phase 2 of the FNIH Biomarkers consortium), was not feasible as these data have not been publicly released [46]. To our knowledge, no other studies have explored the specific pain progression patterns defined by the FNIH [15], and other studies using FNIH data have similarly been unable to perform external validation.

XSL•FO
RenderX

Conclusions

A nomogram based on baseline x-ray radiomics signatures can effectively predict the progression of pain in KOA. This has significant implications for supporting health care professionals in tailoring treatment plans for individuals experiencing rapid pain progression, as well as in reducing health care costs, and these findings need further validation in future trials.

Acknowledgments

The data for this study were obtained and analyzed from the controlled-access datasets distributed from the Osteoarthritis Initiative, a data repository housed within the National Institute of Mental Health Data Archive. The Osteoarthritis Initiative represents a public-private partnership consisting of 5 contracts funded by the National Institutes of Health.

Funding

This study received funding from Liaoning Province Science and Technology Plan Joint Program (2024012243-JH4/4800) and Liaoning Province Science and Technology Plan Joint Technical Breakthrough Plan Project (2024JH2/10 2600325).

Data Availability

The datasets generated or analyzed during this study are available in the Osteoarthritis Initiative repository [47].

Abstract

Background: Data linkage in pharmacoepidemiological research is commonly employed to ascertain exposures and outcomes or to obtain additional information on confounding variables. However, to protect patient confidentiality, unique patient identifiers are not provided, which makes data linkage across multiple sources challenging. The Saudi Real-World Evidence Network (SRWEN) aggregates electronic health records from various hospitals, which may require robust linkage techniques.

Objective: We aimed to evaluate and compare the performance of deterministic, probabilistic, and machine learning (ML) approaches for linking deidentified data of patients with multiple sclerosis (MS) from the SRWEN and Ministry of National Guard Health Affairs electronic health record systems.

Methods: A simulation-based validation framework was applied before linking real-world data sources. Deterministic linkage was based on predefined rules, whereas probabilistic linkage was based on a similarity score–based matching. For ML, both similarity score–based and classification approaches were applied using neural networks, logistic regression, and random forest models. The performance of each approach was assessed using confusion matrices, focusing on sensitivity, positive predictive value, F_1 score, and computational efficiency.

Results: The study included linked data of 2247 patients with MS from 2016 to 2023. The deterministic approach resulted in an average F_1 score of 97.2% in the simulation and demonstrated varying match rates in real-world linkage: 1046/2247 (46.6%) to 1946/2247 (86.6%). This linkage was computationally efficient, with run times of <1 second per rule. The probabilistic approach provided an average F_1 score of 93.9% in the simulation, with real-world match rates ranging from 1472/2247 (65.5%) to 2144/2247 (95.4%) and processing times ranging from approximately 0.1 to 5 seconds per rule. ML approaches achieved high performance (F_1 score reached 99.8%) but were computationally expensive. Processing times ranged from approximately 13 to 16,936 seconds for the classification-based approaches and from approximately 13 to 7467 seconds for the similarity score–based approaches. Real-world match rates from ML models were highly variable depending on the method used; the similarity score–based approach identified 789/2247 (35.1%) matched pairs, whereas the classification-based approach identified 2014/2247 (89.6%).

Conclusions: Probabilistic linkage offers high linkage capacity by recovering matches missed by deterministic methods and proved to be both flexible and efficient, particularly in real-world scenarios where unique identifiers are lacking. This method achieved a great balance between recall and precision, enabling better integration of various data sources that could be useful in MS research.

Introduction

Real-world data (RWD) derived from routine clinical care provide remarkable potential for generating pharmacoepidemiological studies related to medication safety, effectiveness, and utilization [1-4]. The recent emergence of electronic health records (EHRs) in the Kingdom of Saudi Arabia led to the foundation of the Saudi Real-world Evidence Network (SRWEN) by the Saudi Food and Drug Authority [5-8]. This central network plans to integrate and harmonize EHRs from various hospitals, primarily to maximize the efficacy

XSL•FO
RenderX

of RWD in contributing to drug regulatory policymaking and understanding disease dynamics in the Saudi population [6,7].

Common data models (CDMs), such as the observational medical outcomes partnership model, incorporate consolidated formats necessary for data standardization across multiple clinical data sources to perform large-scale observational studies [9-11]. CDMs enable researchers to pool multiple EHR datasets and perform federated data analyses through standardized data architectures, formats, and terminologies [10,11]. The observational medical outcomes partnership CDM, developed as part of the observational health data sciences and informatics, offers a systematic framework of clinical data across diverse subdomains such as demographics, diagnoses, medications, procedures, and laboratory results. It uses standardized terminologies, mitigating inherent variability, customized formats, or inconsistent coding in raw EHR data [9,11].

While CDMs are in place to standardize structures in collecting and evaluating clinical data, many are built on deidentified datasets that may not hold vital contextual information or complete patient histories [9-11]. Thus, restricting the ability to solve such limitations of CDM as incomplete data mapping, the lack of direct mappings for some clinical or medication concepts, laboratory or narrative data gaps, which necessitate going back to the data to retrieve context-specific information that may not be contained in the standardized model [9-11]. Therefore, EHR linkage offers a powerful solution addressing this limitation by enabling researchers to link patient records across various databases and reconstruct comprehensive longitudinal health trajectories [12-14]. Common linkage approaches are deterministic, probabilistic, and machine learning (ML) linkage, each with advantages and challenges [14-16]. For instance, the deterministic linkage is based on an exact matching across predefined variables, achieving high precision; however, sensitivity may be compromised in this case, particularly when matching data that contain errors in a given variable. Probabilistic linkage overcomes this weakness by using weighted matching, enhancing sensitivity at the cost of reduced precision in specific applications [12,13]. ML techniques, such as gradient boosting and neural networks (NNs), can achieve high levels of accuracy [12,13]. These models are particularly successful when integrating a dataset with large volumes of missing and errant data, identifying more links than deterministic and probabilistic approaches [16].

With a growing number of multiple sclerosis (MS) cases among the Saudi population—from 25 per 100,000 in 1998 to 40.4 per 100,000 in 2020—the linkage of data pertaining to MS is of priority, especially given the complexity of MS treatment management, both within Saudi Arabia and globally [17]. SRWEN contains a complex variety of data sources, reference standards, and case definitions, highlighting the intrinsic complexity associated with the reliability of RWD in health care settings [7]. Therefore, accurate linkage of EHRs is paramount for addressing the complexities associated with defining patient outcomes with MS, such as disease progression, relapse rate, and treatment response. This analysis requires frequent validation by clinical expertise and enhancement of the validity and robustness of the SRWEN[17]. To achieve this, we compared different EHR linkage methods, including deterministic, probabilistic, and ML approaches. The findings from this study may have implications for the value and design of future longitudinal studies using linked MS data.

Methods

Ethical Considerations

This study was approved by the institutional review board of Saudi Food and Drug Authority with approval number 2024_17 and by the King Abdullah International Medical Research Center with approval number ROMJ/WE/WS/059/2023. Because the data were extracted from the EHR system as part of routine clinical care, patients are required to provide consent to receive treatment within the institution. Separate study-specific consent was considered waived in accordance with institutional policies. Patient privacy and confidentiality were granted through de-identification of all records prior to data exchange, such that no direct identifiers were available to the research team.

Study Population and Data Sources

In this study, we used 2 datasets from 2 different sources. First, we included SRWEN data of patients with MS between 2016 and 2023. The SRWEN functions as a repository of longitudinal health care information and incorporates diverse EHR data, such as demographics, medical history, medication use, laboratory outcomes, hospitalizations, and clinical outcomes. Information is gathered from diverse EHRs from multiple hospitals in Saudi Arabia, including the Ministry of National Guard Health Affairs (MNGHA). Subsequently, these collected data are standardized through a CDM to ensure consistency and streamline analysis [6]. Furthermore, an anonymization process is implemented prior to exchanging data to ensure patient privacy [6]. For the purposes of this study, we focused exclusively on extracting and analyzing MNGHA data within SRWEN.

Similarly, we collected MNGHA EHR data from King Abdullah International Medical Research Center, identifying patients with MS using the International Classification of Diseases 10th version (*ICD10*: G35) for the same period of (2016 - 2023). MNGHA EHRs contain routinely collected data, including patient characteristics, diagnostic history, medications history, and visit records (ie, admissions, outpatient clinical visits, or emergency visits; Table S1 in Multimedia Appendix 1).

While SRWEN collects data already from the MNGHA, the benefit of the direct link between these 2 entities is advantageous. Data within SRWEN are organized and standardized within a CDM, providing for multi-institutional data analysis at the risk of some loss in source detail. By linking the primary MNGHA EHRs to their corresponding RERN representations, we were able to recover additional clinical granularity from narrative diagnosis notes and reports. This linkage also allowed validation of data consistency between SRWEN and its original source, resulting in a larger and more accurate longitudinal profile of patients with MS.

XSL•FO

Simulation-Based Validation

Overview

We first cloned and deidentified the original dataset to address the challenge of linking deidentified records from the targeted database (ie, SRWEN) with original records (ie, MNGHA EHRs). This process ensured a realistic framework testing and that the dataset resembled the deidentified target dataset. Simulating the conditions of the intended linkage objective, we linked records to themselves using these deidentified cloned records, employing deterministic, probabilistic, and ML approaches. Following this self-linkage phase, we assessed each approach's performance using computational efficiency metrics. Consequently, the best-performing linkage method was used to link the original records to the target dataset, thereby maximizing the accuracy and reliability of the final linkage. This methodology enabled a rigorous, performance-based selection of the optimal linkage approach for secure and accurate record linkage of deidentified datasets [13].

Deterministic Approach

Deterministic EHR linkage is a rule-based approach that relies on exact matches between specific patient identifiers across different EHR systems [12,14,15,18]. Given the lack of patient identifiers in SRWEN, we implemented multiple matching criteria (ie, rules) based on a range of available variables, each considered both independently and in unique combinations (Table S2 in Multimedia Appendix 1). We explored different variable groupings in some detail to determine how various linkage methods perform under conditions with differing degrees of completeness and complexity of data encountered in real-world settings. This approach generates pairs of records classified as match or nonmatches. For each pair, we included multiple linkage variables, including demographic characteristics (eg, gender, date of birth, nationality, eligibility), and health care–related fields (eg, *ICD-10* codes, diagnosis description and date, medication order details, visit type and date, and facility information) [12,14,15,18]. Additional derived variables were generated from these data elements, including coverage, which was derived from eligibility and indicated a patient's treatment eligibility, the first MS diagnosis date, derived from the diagnosis data, and inpatient admission status, derived from visit records.

Probabilistic Approach

In this approach, patient records were grouped into blocks based on shared variables (eg, date of birth, initial MS diagnosis date, received medications, or admission events) to reduce the number of pairwise comparisons required for linkage [12,14,19]. Subsequently, each record pair within a block was compared across diverse fields, including gender, coverage (ie, eligibility), region, nationality, facility name, or diagnostic codes other than MS [12,14,19]. A similarity score was assigned to each record pair corresponding to the level of agreement on predefined variables. Variable weights were estimated as match probabilities (ie, m-probability)—the probability that two field values match, given that the records refer to the same individual—and unmatch probability (ie, u-probability)—the probability that 2 field values match given that the records refer to different individuals. These probabilities were computed using the expectation-maximization algorithm [12-14,19]. An overall similarity score for each pair was computed by summing the weighted scores across all variables [12,14,19].

Pairs were categorized as matches or nonmatches using a one-to-one linkage approach. This method was implemented using the "select_n_to_m" function from the rclin package, which maximizes total similarity score under the constraint that each record is linked only once [20]. This probabilistic approach incorporates imperfect matches caused by inaccuracies or missing data, thereby enhancing the quality and reliability of linked EHR datasets in clinical studies [19].

ML Approach

In the ML approach, record linkage was performed in 2 methods. First, we generated pairs of records using common variables in the cloned data to limit the number of comparisons, creating a grouped set of pairs [20] Similarity scores were computed for each pair across different selected variables 20[]. Pairs were labeled as matches or nonmatches for training using the known true matches. The pairs were then fed into different models for training, and we fitted the model on variables that had the higher impact based on each variable similarity score, allowing the model to learn patterns that accurately identify true matches [20].

Second, a classification-based ML approach was implemented by training models on a labeled training dataset comprising 75% of all possible record pairs derived from the original dataset. Match and nonmatch labels were derived from the reference dataset. The remaining 25% of the record pairs were used for the testing dataset to evaluate the classifier performance [16].

Four ML algorithms—K-nearest neighbor, logistic regression (LR), NN, and random forest (RF)—were used in both methods to evaluate their linkage accuracy [16]. Internal validation was reinforced using a 100-replication bootstrap approach in each method for more robust performance estimates and to ensure stability across repeated sampling iterations [16]

Real-World Record Linkage

In the real-world matching scenario, we linked data from SRWEN and MNGHA to identify patients diagnosed with MS between 2016 and 2023. Because the SRWEN and MNGHA datasets lack a unique common identifier, no reference standard was available to evaluate the performance of each matching algorithm [13]. Therefore, model performance was compared based on the number of matched record pairs identified.

Statistical Analysis

Descriptive analyses of both datasets, including diseases, demographics, and facilities, were tabulated and presented by counts and percentages. Using original identifiers as the reference standard, accurate matches and true nonmatches were defined for the simulation [13]. True matches were record pairs agreeing on identifiers, whereas true nonmatches were record pairs conflicting on identifiers [13]. Sensitivity and positive predictive value (PPV) were calculated along with their corresponding 95% CI. Additionally, the F_1 score was calculated as a measure of balanced accuracy between sensitivity and PPV

XSL•FO
RenderX

(equation 1) [19]. Computational time required by the ML model to complete the record linkage process.

$$F1score=2\times\frac{Sensitivity\times PPV}{Sensitivity+PPV} \quad (1)$$

Results

Descriptive Analysis

The MNGHA dataset contained 2642 patients with MS, whereas 2247 were identified from SRWEN. Because only MNGHA-related dataset within SRWEN was used, 395/2642 (14.9%) patients with MS from the original MNGHA dataset were not captured in the SRWEN data. The distribution of demographic data between the 2 data sources was comparable. For instance, the mean age of patients in the MNGHA dataset was 34.4 (SD 11) years, which was similar to the mean age of 34.6 (SD 11.3) years in SRWEN.

Deterministic Approach

The highest number of pairwise comparisons (3,854,740) was observed in the "sex" variable, compared with a significant precise pairwise comparisons (6212) using the "date of birth (DOB)" or "nationality" variables. Sensitivity was consistent with a perfect score across the variables. However, the specificity rate varied, with the highest (99.9%) observed using "DOB" and the lowest (5%) observed using "nationality." Conversely, precision was considerably low across different variables, with the highest (42.5%) observed using "DOB." Moreover, both "DOB" and "MS Date" had relatively high F_1 scores of 59.7% and 48.8%, respectively (Table 1).

Table . Results of deterministic matching in % based on an individual variable.

Metric	Sex	DOB[a]	Nationality	Coverage	Facility	Region	MS[b] date[c]	Admissions	Other diagnoses	Medications
Accuracy	44.45	99.95	5.09	69	62.92	58.06	99.92	88.15	64.37	99.73
Sensitivity (recall)	100	100	100	100	100	100	100	100	100	100
Specificity	44.43	99.95	5.05	68.99	62.91	58.04	99.92	88.14	64.36	99.73
PPV[d] (precision)	0.07	42.53	0.04	0.12	0.10	0.09	32.28	0.32	0.11	12.45
F_1 score	0.14	59.68	0.08	0.25	0.21	0.18	48.81	0.64	0.21	22.14

[a]DOB: date of birth.

[b]MS: multiple sclerosis.

[c]MS date: first multiple sclerosis diagnosis.

[d]PPV: positive predictive value.

A sequence of deterministic linkage rules was applied to evaluate data matching using a set of variables instead of a single variable (Table 1). The number of correctly matched pairs remained consistent across most rules, with 2642 pairs correctly matched for each rule. Likewise, almost all of the linkage rules resulted in a nearly perfect score across the metrics. The average F_1 score for the deterministic approach was 97.2% (Table S3 in Multimedia Appendix 1). In terms of computing time, deterministic linkage was completed in less than one second for each criterion (Table S3 in Multimedia Appendix 1).

Probabilistic Approach

To ensure a manageable dataset for analysis, we first reduced the number of comparisons by blocking records based on exact matches on DOB (6212 pairs). Precision remained consistently perfect regardless of the variables used across diverse combinations of matching criteria in the probabilistic approach. Both specificity and sensitivity increased with more variables, as the combination of sex, nationality, and coverage was 76%. Further, adding the facility name and the MS diagnosis date led to a perfect score. A similar observation was found for the F_1 score, which began at 69.9% with sex only, increased to 94.6% after adding facility name and region, and reached a perfect score of 100% with the inclusion of MS diagnosis date.

By using a combination of the best-performing variables derived from the deterministic approach to improve match accuracy further, in addition to examining different blocking criteria, precision was constantly at 100%. Sensitivity and specificity rates were high, considerably assisted by combining specific clinical variables. Likewise, the F_1 score ranged from 82% to 99.9% (Table S3 in Multimedia Appendix 1). In terms of computing time, probabilistic linkage required 0.1 to 5 seconds for each criterion (Table S3 in Multimedia Appendix 1).

Using this probabilistic approach with the one-to-one linkage (ie, select_n_to_m from the reclin package) matching criterion, the linkage models achieved perfect performance for all the metrics evaluated. In addition, m-probabilities and u-probabilities were compared across the variables under different matching criteria (Table S4 in Multimedia Appendix 1).

ML Approach

In the similarity-score method, models trained on combinations of DOB, MS diagnosis date, and medications, after being blocked (ie, exact match) on admission, performed best overall. NN, RF, and LR models demonstrated comparable performance, with slightly higher accuracy using NN (99.37% vs 99.36%). However, computational time analysis showed that LR presented a combination of high performance and acceptable processing time (15 - 766 s). In contrast, both RF and NN, while having

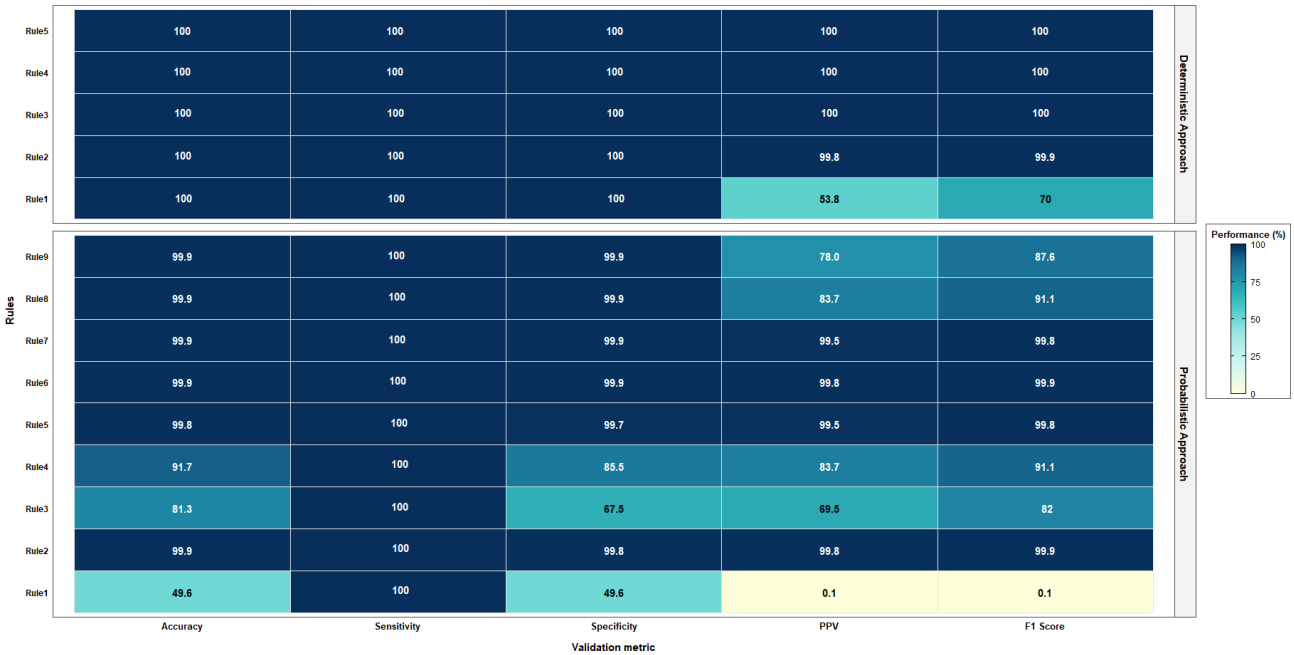
XSL•FO
RenderX

comparable results to LR, were less practical for large-scale linkage tasks due to their longer training times (15 - 7467 s) associated with their complexity (Table S5 in Multimedia Appendix 1).

In the classification approach, despite the blocking variable or combination of matching criteria, performance was constantly high among the three models, ranging from 91.7% to 100%, while computational efficiency varied depending on the blocking strategy and applied comparison criteria. Moreover, the classification is usually more computationally expensive (13 - 16,936 s) compared with the similarity-score approach, affecting scalability for larger datasets. However, K-nearest neighbor demonstrated an excellent trade-off between computational efficiency and linkage performance (Table S5 in Multimedia Appendix 1).

Record Linkage

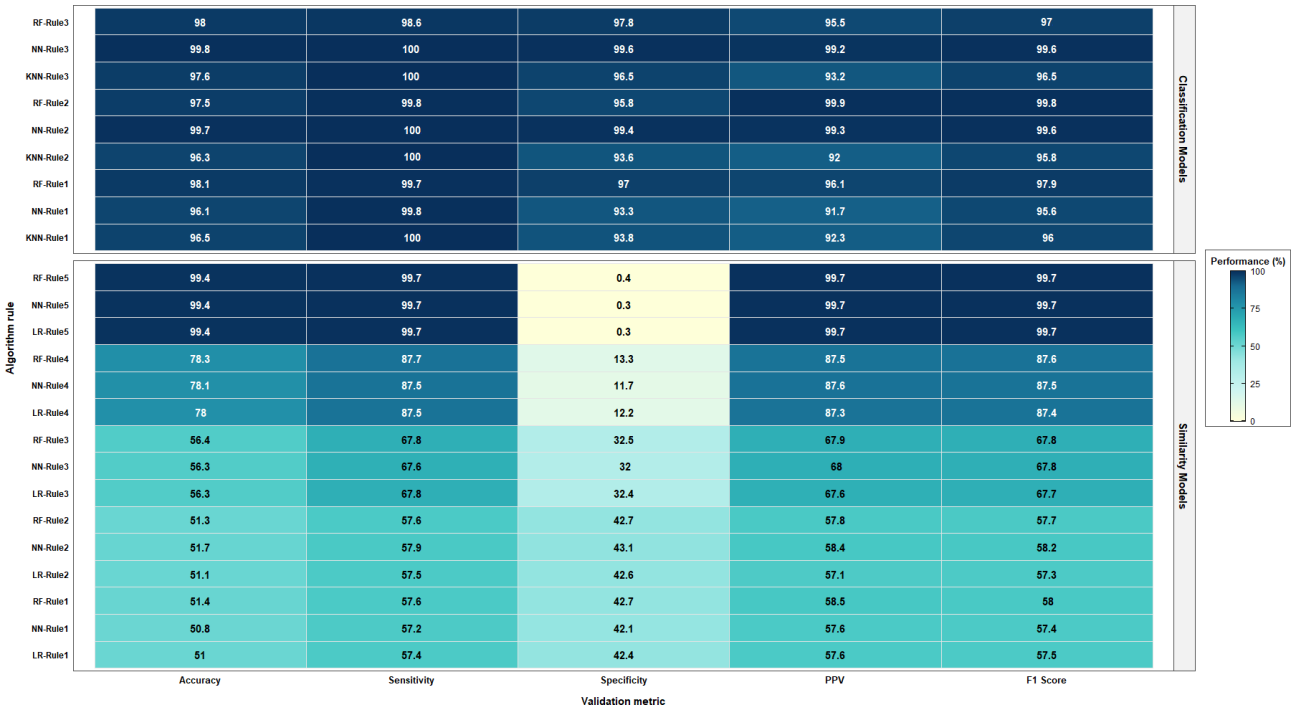
The deterministic approach produced the fewest matched pairs. Increasing the number of variables (eg, adding admissions or medications) made the linkage criteria stricter, resulting in gradually fewer matched pairs, ranging from 1046/2247 (46.6%) to 1946/2247 (86.6%). The probabilistic approach achieved more pairs ranging from 1472/2247 (65.5%) to 2144/2247 (95.4%) based on the combination of variables. The ML approach, using similarity scoring or classification with an NN model, generated 789/2247 (35.1%) pairs and 2014/2247 (89.6%) pairs, respectively (Table S5 in Multimedia Appendix 1).



Discussion

Principal Results

Through the simulated scenario and after using a mixture of variables without identifiers, we determined that the deterministic method was the most efficient data linkage algorithm. Although this approach had limited generality, it accomplished 100% scores across all metrics without incurring high computational times. Therefore, the deterministic approach is practical when we need absolute certainty in matched pairs. In contrast, the probabilistic method also demonstrated efficient performance with a similar mixture of variables. Initially, the recall and specificity metrics exhibited low performances. However, when we applied one-to-one linkages, the performance of the probabilistic method improved significantly, yielding a 100% score. Furthermore, the core benefit of this approach is retrieving a higher number of matched pairs, signifying its advantage when maximum generalization and thorough data retrieval are required. In the case of ML methods like NN models, we attained perfect performance scores at the expense of higher computational costs, limiting their feasibility in real-world scenarios. Among all methods, the probabilistic approach provided the highest number of patients, signifying its flexibility in real-world healthcare scenarios. These outcomes give a reproducible framework for appropriate EHR record linkages, underscoring its efficacy in practical patient care situations.



Considering the average F_1 score for the different models in each approach, the deterministic approach achieved the highest average (97.2%), followed by the probabilistic approach (93.9%). Noteworthy, the probabilistic approach using one-to-one linkage achieved an average of 100%, and in both probabilistic and ML approaches, an initial blocking step based on exact matching was performed. Examining the criteria without applying any blocking led to poor performance in the probabilistic method and was infeasible for ML. Figure 1 shows a comparison between deterministic and probabilistic approaches, while Figure 2 shows a comparison between similarity score and classification ML approaches.

Comparison with Prior Work

Despite the application of a straightforward deterministic algorithm requiring exact matching among all variables of linkage rule, our deterministic solution outperformed the probabilistic method, in contrast to findings from previous studies [21,22]. For instance, Gomatam et al [21] used a forward stepwise deterministic method to evaluate variables independently before constructing matching rules. We used a similar approach and observed high specificity and recall, achieving a perfect score, using this method [21]. The probabilistic linkage was implemented similarly to prior research, and we only allowed for exact matches in the deterministic approach. However, unlike previous studies' findings where probabilistic linkage outperformed deterministic linkage in most scenarios, our results are comparable, with slightly better performance of the deterministic approach when linkage rules (rather than individual variables) were employed [19,21-23]. Implementing a one-to-one linkage method proposed by the reclin package further improved the probabilistic approach to exceed the performance of the deterministic approach when using similar matching rules [20]. Compared with Röchner et al [16], our ML approach exhibited a lower performance than the deterministic approach using a similar combination of rules. Furthermore, even though NN in the classification method achieved a near-perfect score, it required significantly more computational time than the deterministic approach. Nonetheless, we reached a similar finding to Röchner et al [16] in identifying the NN as the highest-performing algorithm in record linkage.

Computational benchmarking was performed on a standard workstation featuring an Intel Core i7 processor, 16 GB of RAM, and 2 GB of GPU (64-bit Windows OS). From a computational perspective, the most efficient method of linkage was the deterministic approach: each run finished in under one second, F_1 scores were between 70% and 100%, and memory requirements were low (<2 GB). The probabilistic approach required 0.1 to 4.88 seconds (F_1 score 82% - 99.9%), while maintaining moderate memory requirements (<8 GB) and achieving excellent accuracy. In contrast, machine-learning-based methodologies were very computationally intensive requiring: 12 to 7467 seconds (~0.2 - 124 min; F_1 score 57.3% - 99.7%, similarity-based models), and 13 to 16,936 seconds (~0.2 - 282 min; F_1 score 95% - 99.8%, classification-based models), both at a maximum memory requirement of 12 to 14 GB. These data demonstrate that the deterministic and probabilistic approaches are ideal for large scale and routine linkage tasks where the computational efficiency of the method is crucial, while ML-based methods, though highly accurate, demand greater resources and are better suited for smaller or high-value analytic linkages where accuracy outweighs runtime considerations.

Clinical and Regulatory Implications

Beyond demonstrating methodological aspects, this study supports the assertion that EHR linkage of original sources with their standardized mapping has clinical importance of linking the fragmented data of MS into a multi-institutional timeline that supports relapse reconstruction, mapping of treatment trajectories, and assessment of long-term outcomes. Importantly, this linkage addresses the challenges of RWD in MS by enabling the validation of deidentified records and matching the structured components (diagnoses, labs, prescriptions, utilization) with unstructured data (notes by physicians and radiology reports) to improve phenotype definition when ICD codes are ineffectively applied. The linked dataset supports earlier case identification (using utilization surrogates as proxies when standard scales are not available), risk stratification and

XSL•FO
RenderX

compliance monitoring across care sites, and provides more frequent and expandable data for pharmacoepidemiologic and safety surveillance that will be more robust than values obtained from trial groups. At the same time, addressing challenges related to the lack of data sufficiency, burdens related to the gaining of patient-reported outcomes data, evolving criteria for diagnosis, and the need for consistent harmonization and resourcing across systems. This linkage produces an analytically reproducible and available dataset for the practical and generalizable studies related to MS and in support of decisions concerning it, changing otherwise unstructured clinical data into actionable knowledge connecting to clinicians, regulators, and health-system leaders.

With the growing availability of large-scale clinical datasets, opportunities to create more comprehensive patient care pathways through data linkage are expanding. The findings of this study suggest that probabilistic linkage of anonymized datasets using indirect identifiers can substantially improve linkage capacity, minimize computational cost, and maintain patient privacy. Probabilistic linkage has demonstrated a greater ability to recover more pairs that may be missed by deterministic methods (1472-2144 vs 1046-1946) due to its flexibility, highlighting its potential as a complementary method to deterministic linkage. Furthermore, to ensure transparency, we examined the contributions of each linkage variable before developing the matching criteria. This approach allowed us to identify the most influential variables for effective linkage. More particularly, the date of birth and first MS diagnosis date achieved F_1 scores of 59.7% and 48.8%, respectively, suggesting strong linkage capabilities with balanced precision and recall. Moreover, incorporating both variables in the matching rules of the deterministic approach resulted in a perfect record linkage across all performance metrics. This improved linkage capability is beneficial for patients with MS by enabling data integration across different providers and supports an even more unified and comprehensive record of each patient's journey. Such a broad linkage helps researchers and clinicians track the progression of diseases over time, evaluate treatment effects on symptoms, and track long-term health outcomes.

The study findings are significant for regulatory requirements, especially when conducting policymaking and postmarketing surveillance. The low computational costs of the deterministic approach enable the regulators to evaluate its treatment outcomes and specify any safety issues, whereas the flexibility and open-ended retrieval of the probabilistic approach is remarkable, especially in the case of comprehensive data retrieval from anonymized records. Therefore, using both deterministic and probabilistic approaches is significant for creating a comprehensive clinical data source for policymaking, postmarketing assessments, and monitoring of the healthcare industry. Ultimately, a combination of these approaches can lead to excellent patient outcomes regarding safety and treatment accuracy.

Limitations

Several limitations must be acknowledged in this study. First, our selection of methods was affected by computational constraints, which highlighted the need for advanced optimization and more powerful hardware for ML models. Discrepancies in patient records count between datasets could also affect generalizability, highlighting the importance of complete data capture in future studies. In our linkage of RWD, we standardized both datasets in terms of variable names and value structure, perhaps influencing the performance of algorithms when linking across different data quality in a real-world application. Furthermore, one patient in SRWEN had an inaccurate date of birth, while 4 patients in both data sets had an unknown nationality. Also, 44 patients in MNGHA and 11 patients in SRWEN had an unknown coverage status. Variables such as other diagnoses, admissions (visits), and medications contain null values (no value), but we believe that these nulls refer to the absence of a clinical event rather than missing entries. Lastly, the lack of an identifier limited our ability to validate the results against a reference standard for the real-world linkage section. Consequently, we could not accurately evaluate the retrieval of matched pairs. Therefore, we used the number of matches solely to describe the linkage performance in real-world linkage.

Conclusion

The findings of this study demonstrate how probabilistic linkage with indirect identifiers can enhance data integration, particularly for MS research and patient care. In real-world situations where we lack unique identifiers, probabilistic linkage proved to be both flexible and efficient as a complement to traditional approaches. These results provide a more holistic overview of patients with MS care and afford researchers access to an inclusive dataset for studying disease progression, treatment outcomes, and monitoring medication safety. In conclusion, applying probabilistic linkage techniques can be expected to facilitate more informed, data-driven clinical and research practices in managing MS.

Abstract

Background: Cancer risk prediction models are vital for precision prevention, enabling individualized assessment of cancer susceptibility based on genetic, clinical, environmental, and lifestyle factors. However, the practical use of these models is hindered by fragmented resources, heterogeneous reporting, and the absence of transparent, structured systems for systematic discovery and comparison.

Objective: This study aimed to develop a retrieval-augmented, knowledge-guided system that provides accurate recommendations for cancer risk prediction models.

Methods: We developed CanRisk-RAG, a recommendation platform underpinned by a precisely constructed knowledge base comprising more than 800 peer-reviewed cancer risk prediction models spanning diverse cancer types, modeling approaches, and predictive variables. The system integrates (1) large language model (LLM)–based semantic tag extraction, (2) embedding vectorization of structured metadata and abstracts, (3) a multifactor ranking algorithm combining semantic similarity with multiple quality indicators, and (4) LLM-generated literature summarization to support rapid user interpretation. Performance was evaluated across 4 types of representative queries. Eight domain experts independently assessed retrieval quality. CanRisk-RAG was benchmarked against PubMed, ChatGPT-4o, ScholarAI, and Gemini 1.5 Flash.

Results: On the independent validation set, CanRisk-RAG consistently outperformed all 4 baseline applications, achieving the highest overall relevance (8.30 [SD 0.59]) and reliability (7.62 [SD 0.76]) scores on a 10-point scale (P<.05). It also demonstrated high authenticity, data completeness, and consistency. Baseline applications frequently returned incomplete, inconsistent, or fabricated results, especially for complex, multifactorial queries, whereas CanRisk-RAG delivered accurate and structured recommendations grounded in validated evidence.

Conclusions: CanRisk-RAG presents a transparent, domain-specific, and semantically enriched framework for discovering cancer risk prediction models, addressing several limitations of existing keyword-based search tools and general-purpose LLMs. By integrating structured knowledge, multifactor ranking, and LLM-based reasoning, the system aims to improve the precision, reproducibility, and usability of model selection in cancer risk prediction. While our evaluation demonstrates encouraging performance compared with baseline systems, further validation in broader clinical contexts and real-world applications is warranted. The framework's general design may also be adaptable to other clinical model domains, providing a potential foundation for advancing evidence-based model discovery in precision medicine.

Introduction

Cancer risk prediction models are increasingly recognized as essential components of precision medicine, offering clinicians and researchers the ability to estimate an individual's likelihood of developing cancer based on diverse risk factors. These models integrate genetic markers, clinical data, environmental exposures, and lifestyle behaviors, thereby enabling more personalized approaches to prevention and screening [1-4]. These heterogeneous factors are not independent but often interact in complex and nonlinear ways. For example, genetic susceptibility may amplify the carcinogenic effects of smoking or obesity, while lifestyle interventions can partially mitigate inherited risk [5,6]. Understanding and modeling these interdependencies is therefore crucial for accurate cancer risk prediction.

Statistical approaches such as logistic regression, Cox proportional hazards models, and Bayesian networks have traditionally been used to analyze correlations and interactions among these predictors. More recently, advanced machine learning techniques, including random forests, gradient boosting, and deep neural networks, have enabled the modeling of higher-order, nonlinear, and cross-domain relationships between genetic, clinical, and environmental factors [7-10]. These methods can capture subtle patterns that traditional regression frameworks may overlook, thus improving predictive accuracy and interpretability when properly validated.

By identifying individuals at elevated risk, cancer risk prediction models facilitate earlier interventions, targeted monitoring, and ultimately reductions in cancer incidence and mortality [11,12]. Recent advances have demonstrated that combining heterogeneous risk determinants can substantially improve predictive accuracy. For instance, multivariate models that combine germline mutations (eg, BRCA1/2), hormonal and reproductive history, and lifestyle exposures have achieved strong discriminative power in breast cancer risk prediction [13,14], while integrative models linking smoking intensity, air pollution exposure, and genomic markers have improved lung cancer risk stratification [15,16]. Together, these developments highlight both the promise and the complexity of synthesizing genetic, clinical, environmental, and behavioral information into actionable tools for precision prevention.

Despite the promise of cancer risk prediction models, their practical impact is limited by barriers related to accessibility and adoption. A fundamental problem lies in the fragmentation of available models, which vary widely in methodological approach, target population, and predictive variables. Clinicians and researchers often struggle to identify the most appropriate model for a given use case, a challenge compounded by the lack of centralized, structured resources for systematic discovery. General medical retrieval systems are ill-suited to this task, as they are designed primarily to locate literature rather than extract or recommend specialized prediction tools. As a result, existing models are underutilized, research efforts are frequently duplicated, and the translational pathway from model development to clinical implementation remains inefficient. Indeed, it has been observed that most published prediction models are never adopted in clinical practice, highlighting a persistent gap between academic research and implementation [17]. Reviews further emphasize that although many models have been developed, only a small fraction have been successfully translated into clinical or public health practice, largely due to limitations in validation, usability, and acceptability [18,19].

To date, most users seeking cancer risk prediction models have relied on mainstream biomedical databases such as PubMed [20]. While PubMed provides broad access to scientific publications, its keyword-based search mechanisms often generate an overwhelming number of results, many of which are irrelevant for model identification. Moreover, critical details regarding model structure, predictive variables, validation cohorts, or performance metrics are typically buried in unstructured text, making systematic retrieval difficult.

In parallel, institutional platforms have been developed to provide more direct access to specific risk prediction tools. The US National Cancer Institute's Division of Cancer Epidemiology and Genetics offers a set of statistical macros and online calculators covering selected cancer types [21], while the Memorial Sloan Kettering Cancer Center provides nomograms tailored to particular clinical scenarios [22]. Although these resources represent valuable contributions, their scope remains restricted to only several (typically fewer than a dozen) tools, employ relatively narrow modeling methodologies, and lack detailed metadata regarding model characteristics or generalizability.

Large language models (LLMs) have recently been explored as potential solutions to improve medical information access. Their ability to integrate knowledge and process complex clinical text holds significant promise for bridging gaps between scattered information and practical decision-making [23-26]. However, empirical studies highlight critical weaknesses in LLMs, including limited precision, the generation of fabricated or irrelevant outputs, and the opacity of reasoning processes [23,27,28]. Retrieval-augmented generation (RAG) has been proposed as a mechanism to mitigate these shortcomings by grounding model outputs in external knowledge sources [29,30]. Several initiatives illustrate the potential of this approach. RefAI [31], for instance, combines PubMed retrieval with a GPT-4–based summarization system, enabling more effective access to recent biomedical publications. Similarly, WeiseEule [32] integrates keyword-driven retrieval from PubMed with LLM-based responses to improve query precision. However, these systems largely depend on user-defined search terms and ad hoc knowledge construction, leading to inconsistent coverage and limited reproducibility. Moreover, they are not designed to handle structured, model-specific metadata, such as predictive variables, validation cohorts, or performance metrics, that are critical for evidence-based model selection.

To address these challenges, the present study introduces CanRisk-RAG, a knowledge-guided and LLM-enhanced recommendation system designed to systematically retrieve, rank, and summarize cancer risk prediction models. Built on a knowledge base that we systematically constructed to consolidate validated cancer risk prediction models across

XSL•FO
RenderX

multiple cancer types, predictive variables, and methodological frameworks, CanRisk-RAG provides a structured foundation for model discovery and reuse. By combining domain-curated knowledge with LLM-driven semantic reasoning, the system bridges the gap between unstructured user queries and structured model metadata. Furthermore, a multi-factor ranking algorithm integrates semantic similarity with evidence-based indicators, such as publication quality, model performance, and timeliness, ensuring that recommended models are both relevant and scientifically robust. To enhance interpretability and usability, CanRisk-RAG also generates concise LLM-based summaries that highlight key model characteristics.

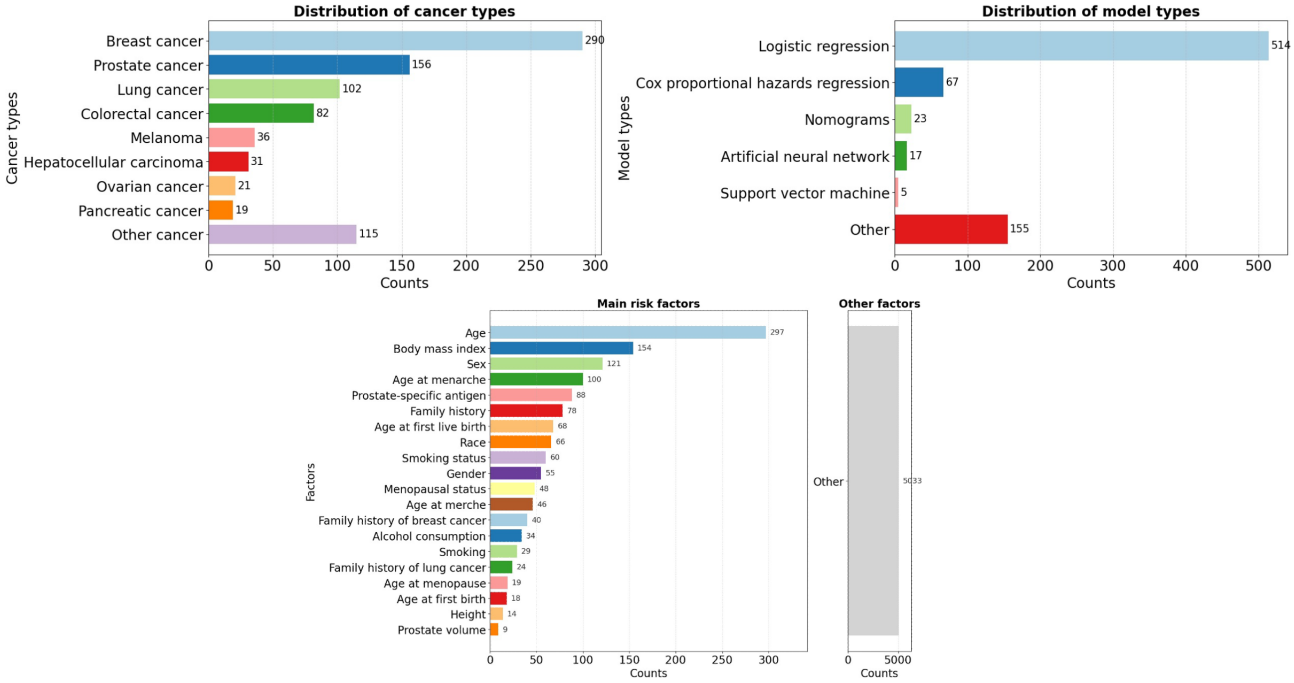
In essence, CanRisk-RAG aims to provide a scalable, transparent, and domain-aware retrieval framework that supports both research and clinical decision-making in cancer risk assessment. By facilitating the efficient reuse of existing models and improving accessibility for diverse user needs, including population-level screening and high-risk cohorts defined by genetic predisposition or family history, it represents a step toward operationalizing precision prevention in oncology.

This paper is organized as follows: We first introduce the data sources and system development workflow. Next, we describe the design of the evaluation tasks and the specific evaluation metrics used. We then present the performance results of CanRisk-RAG in terms of model recommendation and tool usability, along with comparative analyses against four baseline applications. Finally, we discuss the implications of the findings and explore potential directions for extending the system to other cancer research or medical domains.

Methods

Overview

The Methods section outlines the construction of CanRisk-RAG, covering data preparation, semantic vectorization, tag extraction via LLM, hybrid ranking with multiple quality indicators, literature summarization, and comparative evaluation. For more implementation details and technical specifications, please refer to Supplemental Information 1.1 in Multimedia Appendix 1.



Dataset

Data Preparation

We constructed a knowledge base containing peer-reviewed cancer risk prediction models, consolidating clinically developed and validated cancer risk prediction models extracted from PubMed. The detailed search criteria and the inclusion and exclusion standards used for model collection are provided in Supplemental Information 1.2 and 1.3 in Multimedia Appendix 1.

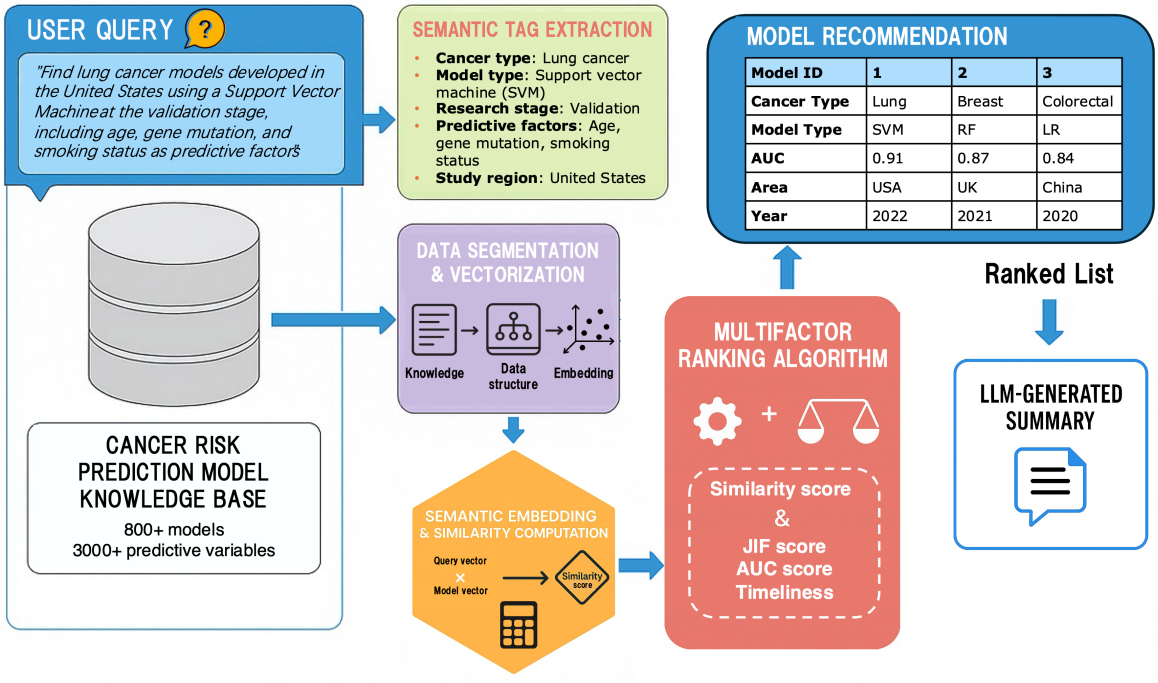
Following this procedure, a total of 808 cancer risk prediction models were included. Each model is uniquely identified by a model ID (MID). Each model was comprehensively described using metadata covering 3 major categories, namely basic information, sample information, and model information, across a total of 36 fields. To facilitate structured storage and interpretation, an Entity–Relationship (ER) diagram was constructed (see Supplemental Information 1.4 in Multimedia Appendix 1). In addition, as illustrated in Figure 1, the knowledge base organizes data across more than 10 cancer types (see Supplemental Information 2.1 in Multimedia Appendix 2 for the full distribution), over 13 methodological frameworks (eg, logistic regression, Cox regression, nomograms), and 3095 predictive factors, including age, body mass index, sex, and family history.

Figure 1. Distribution of cancer types, model types, and predictive factors in the CanRisk-RAG.

XSL•FO
RenderX

Data Segmentation and Vectorization

To enable semantic retrieval, data from the knowledge base were transformed into structured vector representations. Key attributes of each model, including cancer type, methodological approach, research stage, predictive factors, and geographic context were integrated to form composite descriptors that reflect the essential semantic characteristics of the models. These descriptors were then encoded using advanced sentence embedding techniques to generate dense vector representations, ensuring that key semantic meaning was preserved.



In parallel, the textual abstracts of the model research were independently embedded to capture complementary contextual details not fully represented by structured metadata. The combination of structured semantic vectors and unstructured textual embeddings provided a comprehensive representation of each model (see Supplemental Information 1.1 in Multimedia Appendix 1 for details). This dual encoding strategy established the basis for subsequent similarity search and model ranking, allowing the system to align user queries with the most relevant prediction models in a context-aware and interpretable manner.

Workflow of CanRisk-RAG

System Architecture

The overall workflow of CanRisk-RAG comprises a multistage pipeline that transforms unstructured model resources into structured model recommendations (Figure 2). The system integrates several key components: (1) semantic tag extraction, in which user queries are parsed by a LLM into predefined biomedical fields; (2) semantic embedding and vectorization, which encode both structured metadata and unstructured abstracts into dense representations for similarity computation; (3) multifactor ranking, combining semantic similarity with quality indicators such as the journal impact factor (JIF), the area under the curve (AUC), and publication recency to ensure reliable prioritization; and (4) LLM-based summarization, which synthesizes retrieved content into concise and readable outputs. Together, these stages enable CanRisk-RAG to perform context-aware retrieval, interpret complex user intents, and deliver transparent, evidence-based model recommendations supported by structured domain knowledge.

Figure 2. Pipeline of CanRisk-RAG construction. This figure presents the full pipeline of CanRisk-RAG, a retrieval-augmented framework designed to identify and summarize validated cancer risk prediction models from peer-reviewed resources. The workflow proceeds from user query interpretation to model recommendation: (1) users enter a natural language query describing desired model features; (2) a large language model (LLM)–based semantic tag extractor converts the query into structured fields (eg, cancer type, model type, predictive factors, study region); (3) the query is matched against a knowledge base constructed from PubMed containing over 800 cancer risk models and 3000 predictive variables; (4) structured metadata and text are vectorized using optimized sentence embeddings; (5) semantic similarity between query and models is computed; (6) a multifactor ranking algorithm integrates similarity, journal impact factor (JIF), model area under the curve (AUC), and publication recency into a composite score; and (7) top-ranked models are presented with metadata and an LLM-generated summary.

Tag Extraction for Enhanced Semantic Matching

To support efficient retrieval, user queries were first transformed from free text into structured semantic representations. This process was facilitated by a LLM (DeepSeek-V3) [33], chosen for its open-source nature and ability to support scalable deployment. Rather than directly matching raw text against the database, the model extracted predefined semantic fields, including cancer type, model type, research stage, predictive factors, and study region, thereby aligning user intent with structured knowledge (see Supplemental Information 1.5 in Multimedia Appendix 1 for the prompt contents).

XSL•FO
RenderX

An evaluation set of 40 queries (Supplemental Information 1.6 in Multimedia Appendix 1) was constructed to evaluate the tag extraction process. The queries were designed to cover diverse cancer types, model types, predictive factor combinations, geographic contexts, and noisy inputs (eg, typos and incomplete descriptions). Two independent annotators created gold labels following the predefined schema (Cancer_Type, Model_Type, Research_Type, Involved_Factors, Country), and disagreements were adjudicated by a third expert. Precision, recall, and F_1-score were calculated per category and additionally provided uncertainty estimates using Wilson 95% CIs for precision (Supplemental Information 1.7 in Multimedia Appendix 1).

Embedding Model Selection

To prioritize relevant models, CanRisk-RAG employs a ranking strategy primarily driven by semantic similarity. User queries are semantically aligned with database entries through embedding-based similarity, which captures both structured tags and contextual meaning. The similarity score serves as the main determinant, reflecting the degree of correspondence between user intent and model characteristics.

Before performing multifactor ranking, to determine which embedding model achieved the best semantic representation performance, we evaluated four widely used sentence-embedding architectures [34-36], including all-MiniLM-L6-v2, all-MiniLM-L12-v2, all-mpnet-base-v2, and all-distilroberta-v1. Each model's output was assessed by 2 independent evaluators across 12 predefined recommendation queries derived from 4 thematic categories (Textbox 1). For each model, average relevance and reliability scores were calculated. All-distilroberta-v1 achieved the highest overall performance, with statistically significant advantages in both relevance and reliability metrics (see Supplemental Information 2.2 in Multimedia Appendix 2). Therefore, all-distilroberta-v1 was selected as the optimal embedding model for subsequent tool development and deployment.

Textbox 1. Evaluation themes and representative queries used for CanRisk-RAG development.

Model recommendation tasks based on cancer type

- Breast cancer
- Lung cancer
- Prostate cancer

Model recommendation tasks based on model type

- Logistic regression
- Support vector machine
- Neural network

Model recommendation tasks based on predictive factors

- Age, gene mutation, and family history
- PSA level, digital rectal examination, and prior biopsy
- Sex, smoking status, emphysema, and pulmonary nodule

Comprehensive model recommendation tasks

- Gastric cancer; logistic regression; predictive factors: age, family history, and BMI
- Colorectal cancer; Cox proportional hazards regression; predictive factors: prior biopsy, alcohol intake, and height
- Bladder cancer; nomogram models; predictive factors: race, gene mutation, smoking status, and education

Multifactor Ranking Algorithm

To enhance credibility and practical utility, 3 additional factors were integrated into the ranking: the JIF as an indicator of publication quality [31], the AUC as a measure of model performance, and publication recency to emphasize timely contributions. The AUC was treated as a continuous metric using a smoothed compression function, while JIF values were normalized through a log-smoothing transformation to mitigate right-skewed distributions [37]. The publication year was linearly normalized to yield a continuous timeliness score. These components were then combined into a unified weighted scoring function (Equation 1).

(1)Total score=α×similarity score+β×journal impact factor score+γ×AUC score+δ×timeliness score

LLM-Based Literature Summarization

To support user interpretation, CanRisk-RAG incorporates an automated summarization component that synthesizes the content of retrieved studies into concise, coherent overviews. By integrating information across multiple abstracts, the system highlights key findings and methodological features, enabling users to rapidly grasp the essential contributions of relevant models.

RenderX

Assessment Experiments

Benchmarking and Evaluation Design

To optimize the performance of CanRisk-RAG, we conducted a comprehensive comparative evaluation using 12 representative queries spanning 4 thematic areas, including cancer types, modeling approaches, predictive factors, and integrated multicomponent queries. Each theme was further divided into subthemes to reflect major research directions in cancer risk prediction [38-47] (see Textbox 1). Eight domain experts, including 3 clinical cancer researchers and 5 biomedical informatics specialists, independently assessed the outputs for all themes, with each query evaluated by 2 experts. In parallel, multiple ablation experiments on the training dataset (Table 1) examining alternative weighting schemes enabled the optimization of the final ranking configuration, ensuring balanced and robust system performance.

Table . Weight configurations for multifactor ranking algorithm used in ablation experiments.

Group	α (Similarity)	β (JIF)[a]	γ (AUC)[b]	δ (Timeliness)
G1 (Proposed)	0.85	0.05	0.05	0.05
G2 (Similarity only)	1	0	0	0
G3 (AUC+)	0.7	0.05	0.2	0.05
G4 (Recency+)	0.7	0.05	0.05	0.2
G5 (JIF+)	0.7	0.2	0.05	0.05
G6 (Similarity + Recency)	0.85	0	0	0.15
G7 (Similarity + AUC)	0.85	0	0.15	0
G8 (Similarity + JIF)	0.85	0.15	0	0
G9 (Similarity + Recency + AUC)	0.8	0	0.1	0.1
G10 (Similarity + Recency + JIF)	0.8	0.1	0	0.1
G11 (Similarity + AUC + JIF)	0.8	0.1	0.1	0

[a]JIF: journal impact factor.

[b]AUC: area under the curve.

At the application level, CanRisk-RAG was benchmarked against PubMed, ChatGPT-4o [48], ScholarAI [49], and Gemini 1.5 Flash [50], each accessed through their respective application programming interfaces under standardized query conditions. Prompts were standardized across systems to maintain fairness in comparison (see Supplemental Information 1.8 in Multimedia Appendix 1).

This stage was evaluated by domain experts. Performance was scored on 5 key dimensions: relevance, reliability, authenticity, data completeness, and consistency (0 - 10 scale). Table 2 summarizes the evaluation types, metrics, and definitions used to assess the 5 applications, including CanRisk-RAG (see Supplemental Information 1.9 in Multimedia Appendix 1 for the scoring criteria of the 5 evaluation metrics).

XSL•FO
RenderX

Table . Evaluation metrics and definitions used for model recommendation and tool usability assessment.

Evaluation metrics type and metric names		Definition
Model recommendation performance evaluation		
	Relevance	The purpose of the relevance assessment is to determine the extent to which the recommended models match the user's specified criteria.
	Reliability	The reliability assessment examines the authority of the sources where the models were published and evaluates the performance of the models themselves.
	Authenticity	Authenticity checks whether the sources of the models are genuine and can be verified in various journal databases.
	Data completeness	Data completeness evaluates the thoroughness of the model information provided by each application, including metadata, cancer type, modeling type, model performance, predictive factors, and more.
	Consistency	Consistency evaluation measures how consistently the model recommendation results align when the same search conditions or prompts are used in 2 separate instances.
Tool usability evaluation		
	User goal achievement	This metric evaluates whether the tool meets users' specific needs and expectations under open-ended, self-defined query scenarios. Participants independently formulated queries based on their own research or clinical information needs. The score reflects the extent to which users were able to successfully locate relevant cancer risk prediction models that satisfied their personalized model recommendation requirements.
	Operative accessibility	Operative accessibility refers to the overall ease of using the tool and encompasses aspects such as deployment complexity, interface design, navigation intuitiveness, and loading speed. A user-friendly tool should minimize operational complexity and cognitive load while offering clearly structured content, intuitive workflows, and comprehensive help pages.

Validation and Usability

To prevent data leakage between hyperparameter tuning and final performance assessment, we strictly separated the datasets used for weight optimization and for comparative evaluation. Weight optimization and ablation analyses were conducted solely on the development dataset, whereas the final benchmarking against baseline applications (PubMed, ChatGPT-4o, ScholarAI, and Gemini 1.5 Flash) was performed on an independent, held-out evaluation set. This evaluation set consisted of 20 carefully designed queries (Supplemental Information 1.10 in Multimedia Appendix 1) covering previously unseen cancer types, modeling approaches, and multifactorial scenarios that jointly specified cancer type, model type, and predictive factors. Recommendation outputs were independently assessed by eight domain experts using the predefined five evaluation dimensions.

In addition, usability was assessed by 10 potential end users, including clinicians and biomedical informatics researchers, based on 2 criteria: goal achievement and operative accessibility (see Supplemental Information 1.11 in Multimedia Appendix 1 for the scoring criteria). Inclusion criteria of potential end users required participants to be able to independently complete retrieval tasks. To mitigate potential conflict-of-interest bias, individuals involved in system development or dataset curation were excluded from usability scoring. None of the evaluators were members of the development team.

This multiperspective evaluation enabled a systematic assessment of CanRisk-RAG's retrieval quality and practical applicability in comparison to existing systems. Table 2 summarizes the evaluation types, metrics, and definitions used for the assessment of CanRisk-RAG.

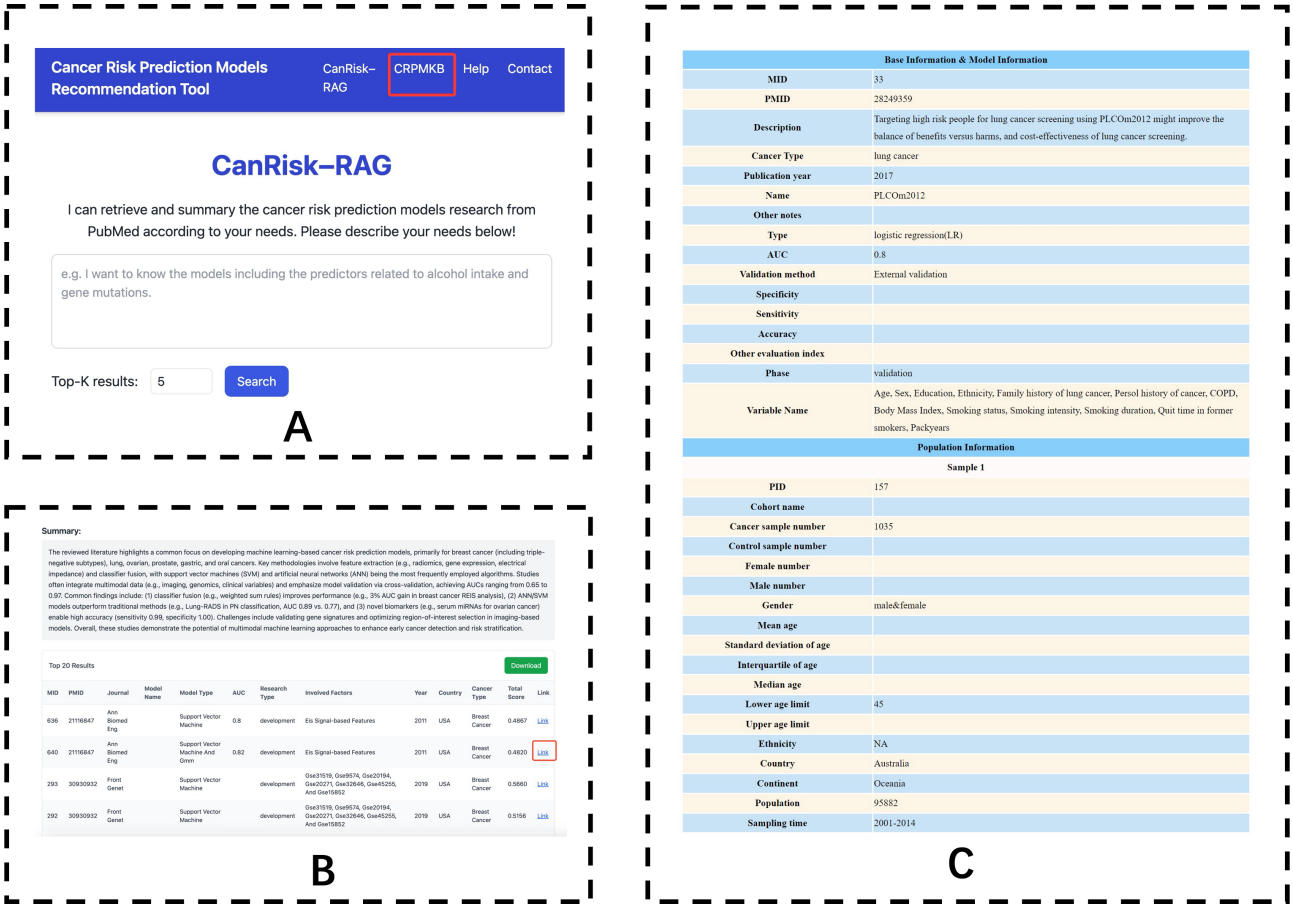
XSL•FO
RenderX

Statistical Analysis

The evaluation was conducted in 2 phases: first, the embedding models were assessed, then the 5 applications were evaluated. Descriptive statistics on the scores were given by the evaluators, including the mean and SD. To determine the consistency among evaluators for every metric assessed, we conducted a 2-way intraclass correlation coefficient analysis.

For the evaluation of different applications, the Shapiro-Wilk test was employed to determine whether the scores assigned by different evaluators for a specific metric followed a normal distribution. Due to the departure of the scores from normality, the Mann-Whitney *U* test was selected to compare the overall performance scores. To explore variations in performance across the five applications and various subthemes, the Kruskal-Wallis rank-sum test was employed. When significant differences were identified by the Kruskal-Wallis test, Dunn post hoc multiple comparisons test was used to evaluate the performance of the different baselines in relation to CanRisk-RAG. Cliff delta was reported for all pairwise comparisons. Multiplicity control across post hoc tests was handled using Benjamini–Hochberg adjustments (α=.05). A significance level of P<.05 was applied to all statistical tests. All statistical tests were performed using Python (version 3.12).

Ethical Considerations



This study did not involve human or animal subjects; therefore, an ethics review board assessment was not required in accordance with institutional and national guidelines of Sichuan University. All analyses were conducted on publicly available, nonidentifiable data, consistent with regional research ethics policies [51].

Results

Tool Interface

As shown in Figure 3, the homepage of CanRisk-RAG features an interactive input form (Figure 3A) that allows users to specify any retrieval criteria related to cancer risk prediction models. Users may define the desired number of recommended results through a customizable selection option. Additionally, users can directly access the data source associated with the homepage by clicking the “CRPMKB” link in the main navigation bar. After entering the desired model criteria in the input field and clicking the “Search” button, the system displays the results page (Figure 3B), which presents a list of recommended models retrieved based on the user’s specified conditions. In the table result, each recommended model is presented with detailed information, including attributes such as MID, PMID, Journal, Model Name, Model Type, AUC, Research Type, Involved Factors, Year, Country, Cancer Type, Total Score. Each model entry is hyperlinked to its corresponding detailed record (Figure 3C). Furthermore, for all recommended models, the tool automatically generates a summary of the corresponding research abstract (Figure 3B), providing a concise overview of these studies to support rapid understanding and comparison.

Figure 3. CanRisk-RAG tool interfaces. (A) Homepage query form. (B) Recommendation results page. (C) Detailed model information page.

Model Recommendation Evaluation Results

Weight Configuration

We systematically evaluated eleven alternative weighting configurations (G1-G11) that varied the relative contributions of similarity (α), JIF (β), model AUC (γ), and publication timeliness (δ) (Table 3). Each configuration was tested on the same dataset of representative queries, and the average scores for relevance, reliability, and total performance were calculated.

A nonparametric Kruskal–Wallis *H* test revealed a statistically significant overall difference among the eleven configurations (H=47.916, P<6.430 × 10 , see Supplemental Information 2.3 in Multimedia Appendix 2).

The proposed configuration (G1: α=.85, β=.05, γ=0.05, δ=0.05) achieved the highest overall score, significantly outperforming variants such as SimOnly and Recency+ (P_{Holm}<.01). G1 consistently yielded higher scores across all configurations, demonstrating a robust performance on relevance and reliability.

Table . Performance comparison of different weighting configurations (mean [SD] for relevance, reliability, and total scores).

Group	Avg_Relevance, mean (SD)	Avg_Reliability, mean (D)	Avg_Total, mean (SD)
G1 (Proposed)	9.50 (0.78)	8.88 (0.85)	18.38 (1.44)
G8 (Similarity + JIF[a])	8.50 (0.66)	9.21 (0.78)	17.71 (1.16)
G7 (Similarity + AUC[b])	8.92 (0.97)	8.75 (0.85)	17.67 (1.55)
G6 (Similarity + Recency)	9.25 (0.74)	8.04 (0.81)	17.29 (1.12)
G3 (AUC+)	7.96 (0.96)	9.25 (0.90)	17.21 (1.59)
G5 (JIF+)	8.17 (0.92)	8.67 (0.96)	16.83 (1.37)
G10 (Similarity + Recency + JIF)	8.08 (0.78)	8.25 (0.79)	16.33 (0.87)
G9 (Similarity + Recency + AUC)	8.17 (1.05)	8.08 (0.93)	16.25 (1.51)
G11 (Similarity + AUC + JIF)	7.83 (0.64)	7.92 (0.72)	15.75 (0.79)
G2 (Similarity only)	9.42 (0.65)	5.46 (0.72)	14.88 (1.08)
G4 (Recency+)	7.33 (0.96)	7.08 (0.72)	14.42 (1.06)

[a]JIF: journal impact factor.

[b]AUC: area under the curve.

Performance Comparison of Applications

In the comparative evaluation across 5 applications, CanRisk-RAG consistently achieved the highest relevance and reliability across all 4 themes of the validation set (Table 4, see Supplemental Information 2.4 and 2.5 in Multimedia Appendix 2 for detailed statistics), delivering markedly superior retrieval precision compared with existing applications. For relevance, the average score was 8.30 (SD 0.59; 95% CI 8.02-8.58), indicating that the retrieved models closely matched the intended cancer types, modeling approaches, and predictive factors specified in the queries. In terms of reliability, the average score reached 7.62 (SD 0.76; 95% CI 7.27-7.98), reflecting strong consistency with authoritative and well-validated literature sources. These results confirm that, when applied to independent validation themes, CanRisk-RAG maintains robust generalization and stable interpretability, effectively extending to unseen data while preserving retrieval accuracy and quality consistency, thereby underscoring its scalability and real-world applicability. PubMed showed reasonable accuracy for straightforward cancer-type queries but struggled when tasks involved modeling approaches or specific predictive factors, often returning incomplete or no usable results. Scholar AI performed moderately in simpler recommendation tasks, but its accuracy dropped sharply for more complex, integrative queries. ChatGPT-4o occasionally retrieved relevant cancer-type models but frequently missed methodological or variable-level details. Gemini 1.5 Flash repeatedly failed to interpret user intent or generate sufficient recommendations, underscoring its limited capability for structured retrieval.

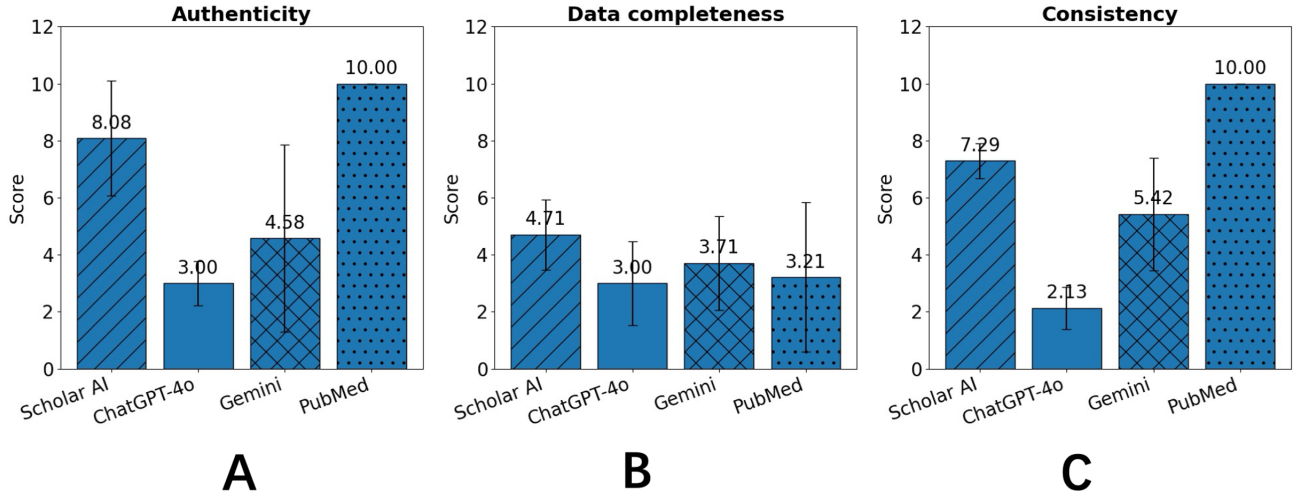
[a]P_{bh}: Benjamini–Hochberg adjusted significance levels, representing statistical comparisons against the corresponding CanRisk-RAG scores within the same topic or in the overall average.



[b]Not applicable.

[c]Not significant.

As a structured and knowledge-grounded recommendation system, CanRisk-RAG achieved high performance in authenticity, data completeness, and consistency, and was therefore used as the benchmark for evaluating other applications (Figure 4). PubMed, while fully reliable in authenticity and consistency due to its literature-based retrieval, showed only moderate data completeness, particularly failing in the comprehensive recommendation task. The 3 LLM-based tools, Scholar AI, ChatGPT-4o, and Gemini 1.5 Flash, performed less reliably overall and often generated incomplete or inconsistent metadata (see Supplemental Information 2.6 in Multimedia Appendix 2). Scholar AI displayed partial strength across themes but still suffered from missing model details, while Gemini 1.5 Flash showed some consistency in recommending models based on cancer types and modeling approaches yet frequently fabricated or cited nonscientific sources such as blogs or online news (see relevant examples in Supplemental Informations 1.12 and 1.13 in Multimedia Appendix 1).

XSL•FO
RenderX

Figure 4. Comparative evaluation of authenticity, data completeness, and consistency among 4 baseline applications in cancer risk prediction model recommendation tasks.

Overall, these findings demonstrate that CanRisk-RAG effectively bridges structured domain knowledge with LLM-driven semantic reasoning, achieving both high retrieval precision and reproducibility. Across all evaluation metrics, CanRisk-RAG consistently outperformed PubMed, Scholar AI, ChatGPT-4o, and Gemini 1.5 Flash, attaining markedly higher relevance and reliability alongside near-perfect scores in authenticity, data completeness, and consistency. In contrast, the baseline systems frequently struggled with complex, multifactorial queries, often returning incomplete, inconsistent, or fabricated information.

Usability Evaluation Results

The usability scores are summarized in Supplemental Information 14 in Multimedia Appendix 1. On a 3-point scale, CanRisk-RAG achieved a mean score of 2.7 (SD 0.48) for user goal achievement, indicating that the system was generally effective in meeting users' personalized retrieval needs. In addition, the tool demonstrated good operative accessibility, with an average score of 2.5 (SD 0.53), suggesting that users found the interface and overall operation intuitive and easy to use. Taken together, these results indicate that CanRisk-RAG is user-friendly, enabling most users to accomplish their intended tasks efficiently with minimal operational burden.

Discussion

Principal Findings

The results highlight CanRisk-RAG's clear advantages in recommending cancer risk prediction models, outperforming general-purpose LLM tools and traditional systems like PubMed. By combining an organized knowledge base, which provides rich metadata including cancer types, modeling methods, and performance metrics with a RAG framework, CanRisk-RAG enables high-quality personalized recommendations and advances beyond keyword-based retrieval toward expert-level semantic recommendation. Unlike ChatGPT-4o, Scholar AI, and Gemini 1.5 Flash, which often hallucinate content or misinterpret domain-specific queries, CanRisk-RAG delivers accurate recommendations with structured information grounded in validated literature. It should be noted that as a peer-reviewed, specialized biomedical literature database, PubMed achieved near-perfect scores in authenticity and consistency, which should be interpreted as a reference baseline rather than an algorithmic achievement. While PubMed inherently ensures authenticity through direct literature indexing, it lacks the semantic parsing capabilities required for complex, multifactorial queries, thereby underscoring the value of domain-specific systems that integrate structured knowledge with semantic understanding. It should also be acknowledged that a degree of circularity exists between the system design of CanRisk-RAG and the reliability evaluation. Specifically, JIF is incorporated as a low-weight auxiliary signal in the ranking algorithm, while the reliability metric used in expert evaluation partially reflects publication in authoritative journals. Consequently, the high reliability scores achieved by CanRisk-RAG should be partly interpreted as evidence that the system adheres to its predefined design principles, namely prioritizing models supported by established, higher-reputation peer-reviewed sources, rather than being overinterpreted as direct indicators of clinical effectiveness.

The system adopts a dual-embedding strategy that fuses tag-level semantic representations with embeddings of the original user query, allowing it to jointly capture structured domain constraints and broader user intent. This design enables effective semantic matching even in the absence of exact keyword overlap. Building on this representation, a multi-factor ranking algorithm integrates semantic similarity with complementary quality indicators—including JIF, model AUC, and publication recency—to enhance the credibility and practical usefulness of the recommended models. This is particularly beneficial for model comparison and systematic review scenarios, where both relevance and evidential strength are critical. In addition, our tag-extraction evaluation demonstrates that DeepSeek-V3 achieves high overall accuracy (micro-F_1=0.994), with only two omission cases observed in the 40-query test set. These rare errors were primarily attributable to implicit semantic descriptors or typographical issues rather than systematic extraction failures. Importantly, the fused embedding framework provides partial robustness to such upstream imperfections, as the original-query embedding channel can still encode missing concepts even when a structured tag is not completely extracted.

XSL•FO
RenderX

With respect to the comparative evaluation strategy, baseline LLM systems, namely ChatGPT-4o, ScholarAI, and Gemini 1.5 Flash, were evaluated using static zero-shot prompts to ensure standardized and reproducible conditions across tools. Although this design choice reduces prompt engineering bias and enhances fairness, it may underestimate the upper bound performance of general purpose LLMs, which can benefit from chain of thought prompting, multiround clarification, or interactive refinement. However, incorporating adaptive and tool-specific prompt optimization would compromise reproducibility and comparability, as performance would then depend on prompt engineering expertise rather than intrinsic system capability. Importantly, CanRisk-RAG does not rely on iterative user clarification. Instead, it embeds domain knowledge and semantic constraints directly into the retrieval pipeline, reflecting a distinct design philosophy that shifts cognitive and procedural burden from the user to the system. This property is particularly important in clinical and translational research settings. Moreover, unlike interactive LLM-based tools, CanRisk-RAG produces deterministic and reproducible outputs for identical inputs, which is essential for evidence-based model discovery and systematic research workflows.

Although the superior performance of CanRisk-RAG highlights the advantage of integrating structured domain knowledge with retrieval-augmented generation, its effectiveness largely depends on the built-in knowledge base, which supplies high-quality, expert-verified model information. Consequently, the "extensibility" of the framework depends on the sustainable expansion of such constructed resources. To address this scalability challenge, we developed a semiautomated update pipeline that combines automated literature retrieval, rule-based metadata extraction, and LLM-assisted knowledge extraction in a workflow [52]. This tool substantially improves data update efficiency while reducing manual workload. Nevertheless, essential human review and expert supplementation are retained to ensure the accuracy of curated content. The knowledge base is planned to be updated every six months to maintain both recency and reliability.

In addition, although currently focused on cancer risk prediction models, the CanRisk-RAG framework is adaptable to other disease domains and scenarios, including prognosis and treatment response models, underscoring its potential as a universal platform for the discovery and application of clinical prediction models.

Limitations

Despite the encouraging performance of CanRisk-RAG, several limitations should be acknowledged.

First, although CanRisk-RAG offers enhanced flexibility and effective retrieval, its performance is inevitably shaped by multiple structured layers of uncertainty spanning internal (algorithmic) and external (evidence-base) factors. Internally, reliance on semantic similarity may reduce field-level specificity; LLM-based tag extraction can over-generalize factors (eg, interpreting "family history of breast cancer" as "family history" or generalizing a specific genetic factor such as BRCA1/2 mutation into a broad category like "genetic risks") and changes in multi-factor weights (eg, raising "Recency" weight from 0.05 to 0.15) can alter rankings. These factors introduce algorithmic uncertainty, which we partially mitigated through ablation experiments and iterative weighting optimization. Externally, heterogeneity in study design, sample size, population, and reporting limits comparability and generalizability. For instance, lung cancer survival models from small regional cohorts may not generalize to multi-institutional datasets, and models trained on East Asian populations may underperform in Western populations due to demographic and healthcare-system differences. Even established models (eg, Gail) exhibit cohort-dependent AUC and calibration, highlighting cross-dataset variability as an important uncertainty layer. Future work will incorporate domain adaptation and uncertainty quantification methods to reduce these effects.

Second, the current ranking strategy relies on a limited set of quality-related indicators. JIF is included as a low-weight auxiliary signal and is normalized to mitigate its influence; however, it remains a coarse, venue-level metric that does not directly reflect study-level methodological rigor. Important indicators such as sample size, calibration reporting, and the extent of external validation are not yet uniformly available across the curated literature and therefore could not be systematically incorporated as first-class ranking features in the present version. As a result, residual bias may be introduced when finer-grained quality signals are missing or inconsistently reported, even though JIF is used only to refine the ordering among semantically similar candidates. In addition, the ranking strategy incorporates reported AUC values as a quantitative indicator of model performance without explicitly differentiating or weighting AUCs derived from model development versus external validation stages. This design choice may inadvertently favor development studies that report optimistic performance over rigorously validated models with stronger generalizability. Future versions of CanRisk-RAG will aim to integrate validation-aware performance stratification and explicit study-level quality indicators, such as cohort size, validation design, and calibration metrics, to better balance apparent accuracy with real-world applicability and progressively reduce reliance on venue-level signals.

Third, the present study relied on a single LLM (DeepSeek-V3) for semantic tag extraction and literature summarization. While this design choice ensured internal consistency and reproducibility across experiments, it inevitably limited robustness to model-specific variability and potential biases inherent to a single LLM. In addition, baseline comparisons with general-purpose LLMs were conducted under a static zero-shot prompting setting without access to external retrieval, web browsing, or tool invocation capabilities. As a result, these baselines were constrained to parametric-only knowledge, which may underestimate their performance in more interactive or retrieval-augmented configurations. In this context, the evaluation primarily highlights the hallucination risks and structural limitations of ungrounded LLM responses when external knowledge is unavailable, rather than serving as an exhaustive benchmark of the full capabilities of modern LLM ecosystems. Future work will extend this evaluation framework by incorporating multi-model ensemble strategies for tag extraction and summarization to enhance robustness and

XSL•FO
RenderX

stability. In parallel, more comprehensive comparisons will be conducted against LLM-based systems equipped with web browsing, tool use, or fully integrated RAG workflows, including multi-turn and interactive prompting strategies.

Fourth, expert scoring was performed manually, introducing subjectivity despite inter-rater consistency checks. Future studies will incorporate automated evaluation methods, such as rule-based matching and semantic alignment metrics, to improve reproducibility and reduce dependence on manual assessments.

Fifth, although CanRisk-RAG includes an LLM-based literature summarization module, the current evaluation is primarily centered on retrieval and recommendation performance. The adopted metrics assess the relevance and reliability of retrieved models and metadata but do not explicitly quantify the factual accuracy or hallucination rate of the generated summaries. The summarization component is intended to serve as an assistive tool for facilitating user comprehension and synthesizing key information from retrieved literature, rather than to provide precise quantitative data; future work will incorporate dedicated evaluation protocols to systematically assess the quality and faithfulness of the generative component.

Finally, a key limitation of the present study is that the CanRisk-RAG knowledge base was constructed using literature retrieved prior to December 2022, and therefore does not include cancer risk prediction models published from 2023 onward. This temporal constraint may temporarily place CanRisk-RAG at a relative disadvantage when compared with contemporary LLMs that potentially have access to more recent biomedical literature. Beyond general concerns regarding data currency, this cutoff has specific implications for users seeking state-of-the-art computational or deep learning–based cancer risk prediction models, as recent years have witnessed a rapid proliferation of AI-driven approaches incorporating deep neural networks and multimodal data integration. As a result, the current version of CanRisk-RAG may be less suitable for users whose primary objective is to identify the most recent model architectures. To address this limitation and enhance temporal coverage, we have developed a semiautomated update pipeline that integrates automated literature retrieval, rule-based metadata extraction, and LLM-assisted curation, while retaining expert review to ensure data quality. The knowledge base is planned to be updated on a semiannual basis. Future evaluations will incorporate newly published models to assess how expanded temporal coverage influences retrieval performance, and to enable more temporally aligned comparisons with evolving LLM-based systems, particularly in the context of rapidly advancing AI-driven cancer risk modeling.

Conclusion

This study introduced CanRisk-RAG, a knowledge-driven retrieval framework for cancer risk prediction models that integrates structured knowledge with semantic reasoning. Through systematic evaluation, CanRisk-RAG demonstrated superior performance in relevance, reliability, and data consistency compared with existing retrieval systems. These results indicate that combining structured knowledge representation with LLM-based reasoning can substantially improve the precision and transparency of model discovery in biomedical research, supporting reproducible and evidence-based applications in precision oncology.

Abstract

Background: Minimally invasive posterior lumbar interbody fusion (MIS-PLIF) is commonly performed to treat degenerative lumbar spinal conditions. Patients of advanced age often present with multiple comorbidities and reduced physiological reserves, influencing surgical risks and recovery. The growing aging population has led to a rising demand for care for older adults, posing significant challenges for health care systems worldwide.

Objective: This study aimed to identify the associations between different age groups and MIS-PLIF outcomes.

Methods: This study retrospectively analyzed data from the United States Nationwide Inpatient Sample collected between 2016 and 2020. Patients aged ≥60 years who underwent MIS-PLIF were eligible for inclusion in this study. Patients were categorized into age groups (60-69, 70-79, and ≥80 y). Logistic and linear regressions were used to determine the associations between the study variables and outcomes, including in-hospital mortality, complications, nonroutine discharge, and length of stay.

Results: A total of 785 patients aged ≥60 (mean age 69.4, SD 0.2) years who underwent MIS-PLIF were included in the analysis, and 18.7% (147/785) experienced at least one complication. After adjustment, compared with patients aged 60 to 69 years, the risk of nonroutine discharge was significantly increased in patients aged 70 to 79 years (adjusted odds ratio 2.33, 95% CI 1.57-3.46; *P*<.001) and ≥80 years (adjusted odds ratio 4.79, 95% CI 2.64-8.67; *P*<.001). No significant differences in the risk of complications or length of hospital stay were observed across the age groups.

Conclusions: In older patients undergoing MIS-PLIF, advanced age is an independent predictor of nonroutine discharge. Furthermore, our findings suggest that age alone is not an independent risk factor for complications or extended hospital stays among older patients. These findings underscore that MIS-PLIF is a viable option for older patients, for whom extra attention may still be needed for postoperative care. Implementing age-stratified management for older patients undergoing MIS-PLIF may have important clinical policy implications.

Introduction

Minimally invasive posterior lumbar interbody fusion (MIS-PLIF) represents a surgical cornerstone in addressing lumbar spine pathology [1,2]. This innovative procedure accesses the lumbar spine through a posterior approach to treat damaged intervertebral discs and fuse adjacent vertebrae [3]. The procedure can achieve results similar to those of open procedures while minimizing disruption to the surrounding tissues.

With the increase in population age, the incidence of degenerative spine disorders has also increased, leading to an increased demand for surgical treatments. Conditions such as osteoarthritis, spinal stenosis, and degenerative disc disease are more common in older individuals, resulting in a growing need for procedures such as spinal fusion, laminectomy, and discectomy to manage pain and improve mobility [4]. The relationship between advancing age and spinal health is paramount, given the potential implications of age-related changes in bone density [5,6]. These changes may not only influence the procedural success of MIS-PLIF but also impact the overall safety and effectiveness of the procedure.

Surgery for degenerative spinal conditions presents specific challenges in the older population seeking relief from symptoms [7,8]. Beyond the structural considerations of bone density, older patients often have additional health concerns and comorbidities, adding increased risk to the surgical procedure and the subsequent recovery process [9]. Understanding the relationship between age and surgical outcomes is important for tailoring surgical approaches to ensure optimal outcomes and postoperative recovery in the older population.

Despite MIS-PLIF being a common and generally well-tolerated procedure, limited research has specifically focused on the impact of age on postoperative outcomes [10,11]. The increasing prevalence of degenerative spinal diseases in older individuals makes it important to understand how age may influence the success and safety of MIS-PLIF. Furthermore, age-stratified management is becoming increasingly important due to the rapidly growing older population worldwide. This study aimed to deepen the understanding of the effect of age on outcomes by analyzing the relationship between advancing age and postoperative outcomes of MIS-PLIF using a large, nationally representative dataset from the United States [12]. Using a large, nationally representative dataset, this study provides the statistical power necessary to detect clinically meaningful differences across age groups that smaller studies may have missed. This study may offer valuable implications for both clinical practice and policy development.

Methods

Ethical Considerations

This study was conducted in accordance with the principles of the Declaration of Helsinki (1975) and its amendments. The protocol for this study was submitted for review to the Institutional Review Board of Chang Gung Medical Foundation (202301168B0), which granted an exemption from formal Institutional Review Board oversight. This study complies with the terms of the Nationwide Inpatient Sample (NIS) data-use agreement. The data used in this study were obtained through the Online Health Care Cost and Utilization Project (HCUP) Central Distributor. Given the anonymized nature of the data, the requirement for informed consent was consequently waived. No compensation was provided to participants.

Data Source

This investigation drew upon data extracted from the NIS for the period of 2016 to 2020. The NIS, an initiative of the HCUP under the aegis of the Agency for Healthcare Research and Quality [13], encompasses a 20% stratified sample of inpatient admissions across 45 states and 1051 participating hospitals. The database meticulously records a wealth of patient information at the time of discharge, including primary and secondary diagnoses and procedures, dates of admission and discharge, discharge status, demographic details, and duration of hospital stay. Moreover, the NIS is equipped with statistical weights designed to facilitate the extrapolation of these findings to national patient volumes.

Study Design

This study was designed as a population-based, retrospective analysis. All data were sourced through a request to the Online HCUP Central Distributor, which manages the database [14] (certificate HCUP-4T28I74JW). This research strictly adhered to the data-use protocols stipulated by the NIS under the HCUP. The investigation used deidentified secondary data from the NIS database; hence, there was no direct involvement of patients or the public.

Study Population

The NIS database was searched for patients aged ≥60 years who underwent MIS-PLIF during the study period. The exclusion criteria were (1) traumatic injury; (2) injury in traffic accidents; and (3) missing values for weight, outcomes of interest, and covariates. All diagnoses and procedures were identified by the *International Classification of Diseases, Ninth Revision and Tenth Revision, Clinical Modification* (*ICD-9-CM* and *ICD-10-CM*) codes, as detailed in Table S1 in Multimedia Appendix 1. Following previous literature, we stratified age into 3 groups (ie, 60-69 y, 70-79 y, and ≥80 y) to perform comparative analyses across these categories [15,16].

Main Outcomes and Variables

The primary outcomes included in-hospital mortality, nonroutine discharge (ie, discharged to long-term care facilities), prolonged length of stay (LOS; defined as ≥75th percentile of LOS in the study population), and complications. Complications assessed included surgical (eg, infection, dural tear, hemorrhage, hematoma or seroma, and postoperative anemia) and medical complications (eg, pneumonia, pulmonary embolism, acute kidney injury, acute myocardial infarction, and urinary retention) based on insights from our literature review and clinical experience.

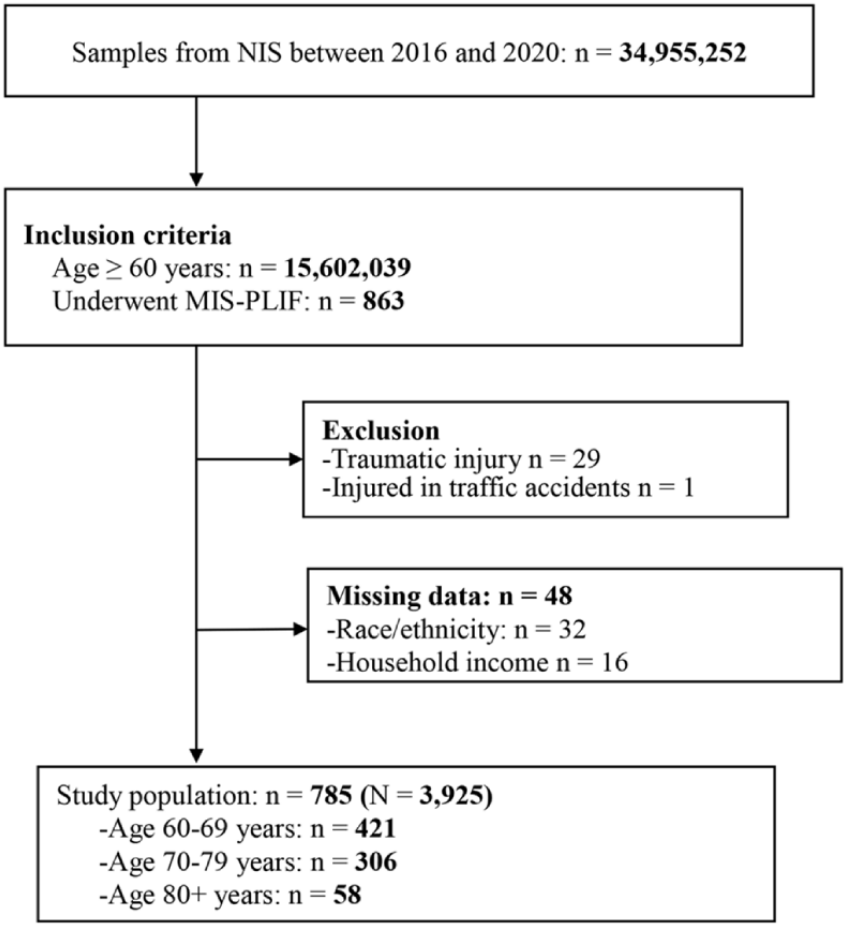
Demographic variables analyzed in this study encompassed patient age, sex, race or ethnicity (categorized as White, Black, Hispanic, and other), household income, insurance status

XSL•FO
RenderX

(identified by the primary payer), and whether admission occurred over a weekend. Household income quartiles were derived from the NIS, which estimates income based on the ZIP code of each patient's residence [17]. Comorbidities were identified using *ICD-9* and *ICD-10* codes and included diabetes mellitus, osteoporosis, obesity (defined as a BMI ≥30 kg/m²), chronic obstructive pulmonary disease, renal disease, hypertension, coronary artery disease, and heart failure. Relevant codes for each comorbidity are provided in Table S1 in Multimedia Appendix 1. Charlson Comorbidity Index was calculated from individual comorbidities to represent patients' overall severity of comorbid conditions.

Additionally, characteristics related to the hospital, such as bed size, location and teaching status, and regional location, were also collected as part of the extensive dataset available for all patients.

Statistical Analysis



The NIS database comprises a 20% stratified sample of US annual inpatient admissions, using weighted samples, strata, and clusters to facilitate national estimates in all analyses. Data analysis was conducted using the SURVEY procedure in SAS, which is optimized for sample survey data. Descriptive statistics for patients are presented as counts (n) and weighted percentages (%) or as means with SEs. Group comparisons for categorical variables were conducted using the Rao-Scott chi-square test, whereas weighted mean differences for continuous variables were analyzed using survey methods that account for stratification, clustering, and sampling weights, ensuring valid and robust statistical inferences within the context of complex survey designs. Logistic regression analyses were performed to assess the associations between study variables and binary outcomes, with results presented as odds ratios (ORs) and 95% CI. Linear regression was performed to assess the associations between the study variables and LOS. Multivariable regression was adjusted for variables that were significant (P<.05) in the univariate analysis. All statistical tests were 2-sided, with P<.05, deemed to indicate statistical significance. The analyses were conducted using SAS (version 9.4; SAS Institute Inc).

Results

Patient Selection

The patient selection process is illustrated in Figure 1. Between 2016 and 2020, 863 patients aged ≥60 years who underwent MIS-PLIF were identified from the NIS database. After excluding 29 patients with traumatic injuries, 1 patient with a traffic accident injury, and 48 patients with missing information on race, ethnicity, and household income, 785 patients were included in the study. Using the sample weight from the NIS database, this cohort corresponds to a total of 3925 hospitalized patients across the United States, as illustrated in Figure 1.

Characteristics of the Study Population

In the study population, the mean age was 69.4 (SD 0.2) years, 60.9% (478/785) were female individuals, 79.2% (622/785) were White, and 72.9% (572/785) had insurance covered by Medicare or Medicaid. A total of 66% (518/785) of the patients were diagnosed with spondylolisthesis. Patients aged 60 to 69 years had a significantly higher percentage of obesity, patients aged 70 to 79 years had a significantly higher frequency of diabetes mellitus and heart failure than the other age groups, and patients aged ≥80 years had the highest frequency of renal disease and hypertension (Table 1).

[b]Quartiles (Q1-Q4) were derived by dividing the distribution of the variable into four equal parts, with Q1 representing the lowest and Q4 the highest range.

In-Hospital Outcomes

Only 0.1% (1/785) of the study population died in the hospital, whereas 18.7% (147/785) had at least one complication, of which 13.8% (108/785) had a least one surgical complication, and 7.3% (57/785) had at least one medical complication. Among the 3 age groups, patients aged ≥80 years had a significantly higher frequency of nonroutine discharge (20/58, 35% in the ≥80 y age group vs 52/421, 12.4% in the 60-69 y age group and 76/306, 24.9% in the 70-79 y age group; *P*<.001). There were no significant differences in complications (*P*=.68) and LOS (*P*=.11) between the 3 age groups (Table 2).

Associations Between Age and Inpatient Outcomes

Table 3 shows the univariate and multivariable analyses of the associations between patient and in-hospital outcomes. After adjustment, the multivariable analysis showed that compared with patients aged 60 to 69 years, those aged 70 to 79 years (adjusted OR 2.33, 95% CI 1.57-3.46; *P*<.001) and those aged ≥80 years (adjusted OR 4.79, 95% CI 2.64-8.67; *P*<.001) had a significantly higher risk of nonroutine discharge (Table 3).

Table 3. Associations between any surgical or medical complication, nonroutine discharge, and age.

Outcomes	Age (y)							
	70-79 vs 60-69				≥80 vs 60-69

In addition, compared to patients aged 60 to 69 years, the LOS was not significantly different in the other 2 age groups after adjustment for confounders in the multivariable analysis (70-79 vs 60-69, adjusted β=0.33, *P*=.14; ≥80 vs 60-69, adjusted β=0.14, *P*=.61). Similar findings were observed when the LOS analysis was restricted to home-discharge patients (Table S2 and S3 in Multimedia Appendix 1). Similar outcome patterns were observed when age was modeled as a continuous variable (Tables S4 and S5 in Multimedia Appendix 1).

Discussion

Principal Findings

This study used the NIS data to determine the impact of age on outcomes following MIS-PLIF in patients aged ≥60 years. The results revealed a low in-hospital mortality rate (only 0.1%) and a complication rate of 18.7%, with no significant differences across age groups and a similar LOS between the 3 age groups. Nonroutine discharge is a binary variable that indicates a deviation from the standard discharge pathway, such as transfer to another hospital with better medical resources, and is often associated with greater clinical severity. Notably, older age was associated with an increased risk of nonroutine discharge, with a 2.3-fold increase in patients aged 70 to 79 years and a 4.8-fold increase in those aged ≥80 years. However, older age did not significantly influence LOS or complication risk. These findings offer valuable insights into the relationship between age and postoperative outcomes after MIS-PLIF, suggesting that while MIS-PLIF is a viable and generally safe option for older patients, extra attention should be given to postoperative care, especially for those aged >70 years.

Minimally invasive procedures have become the method of choice due to decreased surgical trauma and faster recovery. Studies have compared the outcomes of MIS-PLIF with those of open procedures. For example, Mimura et al [18] compared adjacent segment pathology in patients who received a minimally invasive procedure and those who received an open approach for degenerative spondylolisthesis. The results showed that compared to conventional open PLIF, MIS-PLIF was associated with a higher disease-free survival rate and a lower incidence of adjacent segment pathology. Goldstein et al [19] performed a systematic review and meta-analysis examining adverse events of minimally invasive versus open posterior lumbar fusion. All outcomes of interest were similar between the 2 groups, although patients who underwent the minimally invasive procedures had a slightly lower rate of postoperative medical complications. However, the authors noted that the overall quality of the evidence was low.

Among the various outcomes assessed in our study, only nonroutine discharge was significantly associated with older age. Other studies have also reported that increasing age is associated with higher rates of nonroutine discharge in patients undergoing lumbar fusion; however, these studies did not further stratify older patients by age [20,21]. While there can be many reasons for this association, a possible reason is that older patients are in general more likely to be transferred to specialized care facilities after discharge because they have greater needs than their younger counterparts [22]. In addition, patients with a more advanced age may need more care than family members can provide at home or specialized rehabilitation services that are available in such facilities.

While advanced age is associated with adverse events for many surgical procedures [12,23], our results clearly showed that increased age did not significantly affect LOS or complication rate following MIS-PLIF. Luo et al [24] compared the surgical outcome of multilevel anterior cervical discectomy and fusion in older and younger patients with myelopathy. Overall, outcomes were similar between different age groups, although the older patients tended to have a lower recovery rate and higher short-term complication rate. Liu et al [25] reported that in patients undergoing PLIF, factors associated with the need for a perioperative blood transfusion were 3 or more fusion segments, low hemoglobin preoperatively, hypertension, lower BMI, and more advanced age. Our results challenge common perceptions about the risks associated with surgical procedures in older populations and highlight the potential viability of MIS-PLIF for patients of advanced age, even for those aged >80 years.

Clinical Implications

The findings of this study have important clinical implications for the management of older patients undergoing MIS-PLIF. Notably, while MIS-PLIF is generally safe for older adults, the increased likelihood of nonroutine discharges in patients aged ≥70 years underscores the need for tailored postoperative care plans. Clinicians should consider enhanced recovery protocols and more comprehensive discharge planning to address the specific needs of older patients. This could involve early involvement of multidisciplinary teams, including geriatric specialists, physical therapists, and social workers, to facilitate smoother transitions to either home or rehabilitative settings.

Strengths and Limitations

The primary strength of this study lies in its analysis of a large and nationally representative patient database, which enhances the generalizability of the conclusions to the broader population in the United States. This extensive scope ensures that the findings reflect a wide demographic profile, providing valuable insights applicable to the general population. The study's relatively large sample size enabled the assessment of various complications, including infrequent complications.

Nevertheless, this study has several limitations. This was a retrospective study, which may have introduced selection bias. As with other studies relying on *ICD* coding systems, this study may have been affected by potential coding inaccuracies. Additionally, it lacks long-term postdischarge follow-up data and preadmission status information, which are essential for a comprehensive assessment of outcomes. Furthermore, comorbidities may vary in severity; however, the NIS database lacks detailed clinical parameters, such as glomerular filtration rate, glycated hemoglobin levels, and precise BMI values, limiting our ability to assess severity or perform precise staging for conditions such as diabetes, chronic kidney disease, and obesity. Complications were identified throughout the hospitalization period, without the ability to distinguish between intraoperative and postoperative events. Preoperative physical

XSL•FO
RenderX

performance status, such as the American Society of Anesthesiologists Physical Status Classification, was not available. We could not confirm the timing of postoperative infections due to the absence of time-stamped data. Certain outcomes, such as changes in neurological function, altered mental status, or pain, are not captured in this administrative database, as it lacks such granular clinical and laboratory details. Minor complications, such as intolerance to pain medication, are also difficult to accurately identify, as they may not be consistently coded in electronic medical records. Although this study provides a broad overview of the outcomes using a large cohort, these limitations warrant cautious interpretation of the findings and highlight the need for future clinical studies to address more detailed outcome measures.

Conclusions

In conclusion, this study on the impact of age on MIS-PLIF outcomes demonstrated that the procedure is relatively safe for patients aged ≥60 years, as evidenced by the low in-hospital mortality rate and low complication rate, regardless of age. However, patients aged ≥70 years had a higher risk of nonroutine discharge. Although age alone did not significantly affect LOS and complications, targeted postoperative care for older patients, particularly those aged ≥70 years, is still recommended.

These findings support the notion that MIS-PLIF is a viable surgical option for older adults, including those aged ≥80 years. Importantly, age alone should be viewed as a factor that necessitates tailored postoperative strategies. Implementing age-stratified management pathways—including early engagement of geriatric care teams, customized rehabilitation plans, and structured discharge protocols—may optimize recovery, reduce health care burden, and enhance patient outcomes.

Abstract

Background: Pulmonary dysfunctions are common and frequently co-occur with depressive symptoms, worsening outcomes, and increasing health care burden. Clinically usable models for identifying pulmonary dysfunction–depression comorbidity remain limited by suboptimal interpretability, inconsistent validation, and uncertain generalizability.

Objective: This study developed and compared logistic regression (LR), Bayesian network (BN), and Extreme Gradient Boosting (XGBoost) models for identifying factors associated with pulmonary dysfunction–depression comorbidity and evaluated their clinical usefulness across different decision thresholds.

Methods: Data were drawn from the 2011 and 2015 waves of the China Health and Retirement Longitudinal Study. The analytical sample comprised 1146 adults with confirmed pulmonary dysfunction, of whom 514 (44.9%) exhibited clinically significant depressive symptoms (10-item Center for Epidemiologic Studies Depression Scale [CESD-10] score of ≥10). Models incorporated demographic, biomarker, comorbidity, and behavioral variables. Performance was assessed via discrimination (area under the receiver operating characteristic curve [AUROC]), calibration (Hosmer-Lemeshow test), and decision curve analysis. Sensitivity analyses excluding psychiatric history addressed potential conceptual overlap with the outcome.

Results: LR and BN showed similar discrimination across cohorts (AUROC≈0.73), exceeding XGBoost (0.690 training; 0.650 validation). LR had the most balanced validation performance (specificity 0.721; sensitivity 0.647), whereas BN favored sensitivity (0.884) over specificity (0.401). Training calibration was good for LR or BN, but only LR remained acceptable in validation; XGBoost was miscalibrated. XGBoost's training net benefit did not generalize. Psychiatric history was the strongest factor (odds ratio 3.46 - 7.63), followed by nephropathy, arthritis, and gastropathy; BMI and household registration were inversely associated. Excluding psychiatric history modestly reduced AUROC. With 20 shared predictors, AUROCs converged (0.658 - 0.665), BN calibrated best, LR or BN remained sensitivity-forward, and XGBoost remained specificity-forward.

Conclusions: Using routinely available clinical and sociodemographic variables, LR and BN matched or exceeded XGBoost in externally validated performance and produced more reliable probability estimates. Model choice should align with intended use: BN (or LR) is preferable for sensitivity-forward screening, whereas XGBoost may be reserved for high-threshold confirmatory decisions only after recalibration. Across methods, psychiatric history, nephropathy, arthritis, gastropathy, household registration status, and BMI emerged as stable markers of vulnerability to depressive symptoms in pulmonary dysfunction.

Introduction

Pulmonary dysfunctions (PDs) are defined as a pathological state characterized by impaired ventilation (obstructive or restrictive patterns) and/or gas exchange abnormalities (diffusion limitation and ventilation-perfusion mismatch), leading to hypoxemia and/or hypercapnia [1,2]. Common etiologies include chronic obstructive pulmonary disease (COPD), asthma, interstitial lung disease, pulmonary fibrosis, and pulmonary embolism [1,2]. Pulmonary dysfunction–depression comorbidity (PDDC) constitutes a clinically significant syndemic, jointly contributing to accelerated morbidity, mortality, and increased health care burdens globally [3]. PDs affect more than 500 million individuals worldwide and are frequently complicated by depressive disorders, a comorbidity associated with 23% - 40% reductions in treatment adherence and a 1.8-fold increase in hospitalization rates [4-6]. The bidirectional relationship between PDs and depression has been extensively documented, with accumulating evidence demonstrating their synergistic impact on clinical outcomes. For instance, individuals with PDs, particularly pulmonary tuberculosis, COPD, and cystic fibrosis, exhibit a 1.5 - to 2.5-fold higher risk of developing depressive symptoms than the general population [7]. While the prevalence of depression in the general Chinese population is approximately 10.6% [8], it reaches up to 39.5% among patients with particularly pulmonary tuberculosis [9]. A matched cohort study further reported that the incidence of depression was 11.4 per 1000 person-years among patients with COPD, compared with 5.7 per 1000 person-years in non-COPD controls [10].

Longitudinal analyses confirm the progressive influence of depressive symptomatology on pulmonary deterioration [11,12]. Multivariable models further demonstrated that depression severity independently predicted reduced forced expiratory volume in 1 second as a percentage of the predicted value (FEV1%) at 2-year follow-up [11]. Conversely, impaired lung function has also been found to independently predict the onset of depression, potentially mediated by hypoxemia, systemic inflammation, and glucocorticoid dysregulation [12]. The underlying pathophysiological mechanisms involve neuroendocrine-immune cross talk, including proinflammatory cytokine release (eg,interleukin-6 and tumor necrosis factor–α) induced by chronic hypoxia and hypercapnia, which disrupt monoamine neurotransmission and hippocampal neurogenesis—hallmarks of depression [13,14]. Socioeconomic disparities further exacerbate these effects, with stronger associations observed between lung function decline and subsequent depression in populations of lower socioeconomic status [15]. Despite growing understanding of this bidirectional relationship, several critical gaps remain. First, most studies use cross-sectional designs, limiting causal inference regarding temporal dynamics. Second, although pulmonary rehabilitation and selective serotonin reuptake inhibitors have demonstrated efficacy in improving both psychological and pulmonary outcomes (eg, FEV1), the biological pathways mediating these dual benefits remain poorly characterized [16]. Third, standardized screening protocols for PDDC are inconsistently applied, resulting in underdiagnosis and undertreatment.

Clinically, the prognostic implications of this comorbidity are substantial. A German cohort study of patients with cystic fibrosis revealed that depressive symptoms interacted with baseline FEV1% to predict disease trajectories: individuals with preserved lung function (FEV1>70%) but comorbid depression experienced significantly steeper declines (ΔFEV1=–5.2% vs –1.3% in nondepressed counterparts over 2 years) [11]. These findings emphasize the importance of early psychological screening within pulmonary care frameworks. However, current predictive models remain insufficiently integrated and fail to capture the full complexity of this syndemic.

Traditional statistical methods, such as logistic regression (LR), have been widely used in early research due to their transparency and interpretability. Nevertheless, these approaches have notable limitations: univariate selection strategies may overlook important interaction effects (eg, the combined influence of biomarkers and psychosocial stress), and linear assumptions may be inadequate for modeling threshold phenomena in disease progression (eg, a sharp decline in lung function triggering psychological decompensation) [17,18]. In parallel, machine learning techniques—such as random forests, Bayesian networks (BNs), and Extreme Gradient Boosting (XGBoost)—have gained increasing traction in medical prediction [19]. These algorithms offer theoretical advantages in identifying complex patterns through automated feature engineering and nonparametric modeling. However, existing applications often neglect 3 key challenges: limited clinical interpretability (black box models hinder mechanistic understanding), sample size dependency (complex algorithms may perform suboptimally in small datasets), and insufficient validation strategies (lack of robust assessment across time and geographic regions).

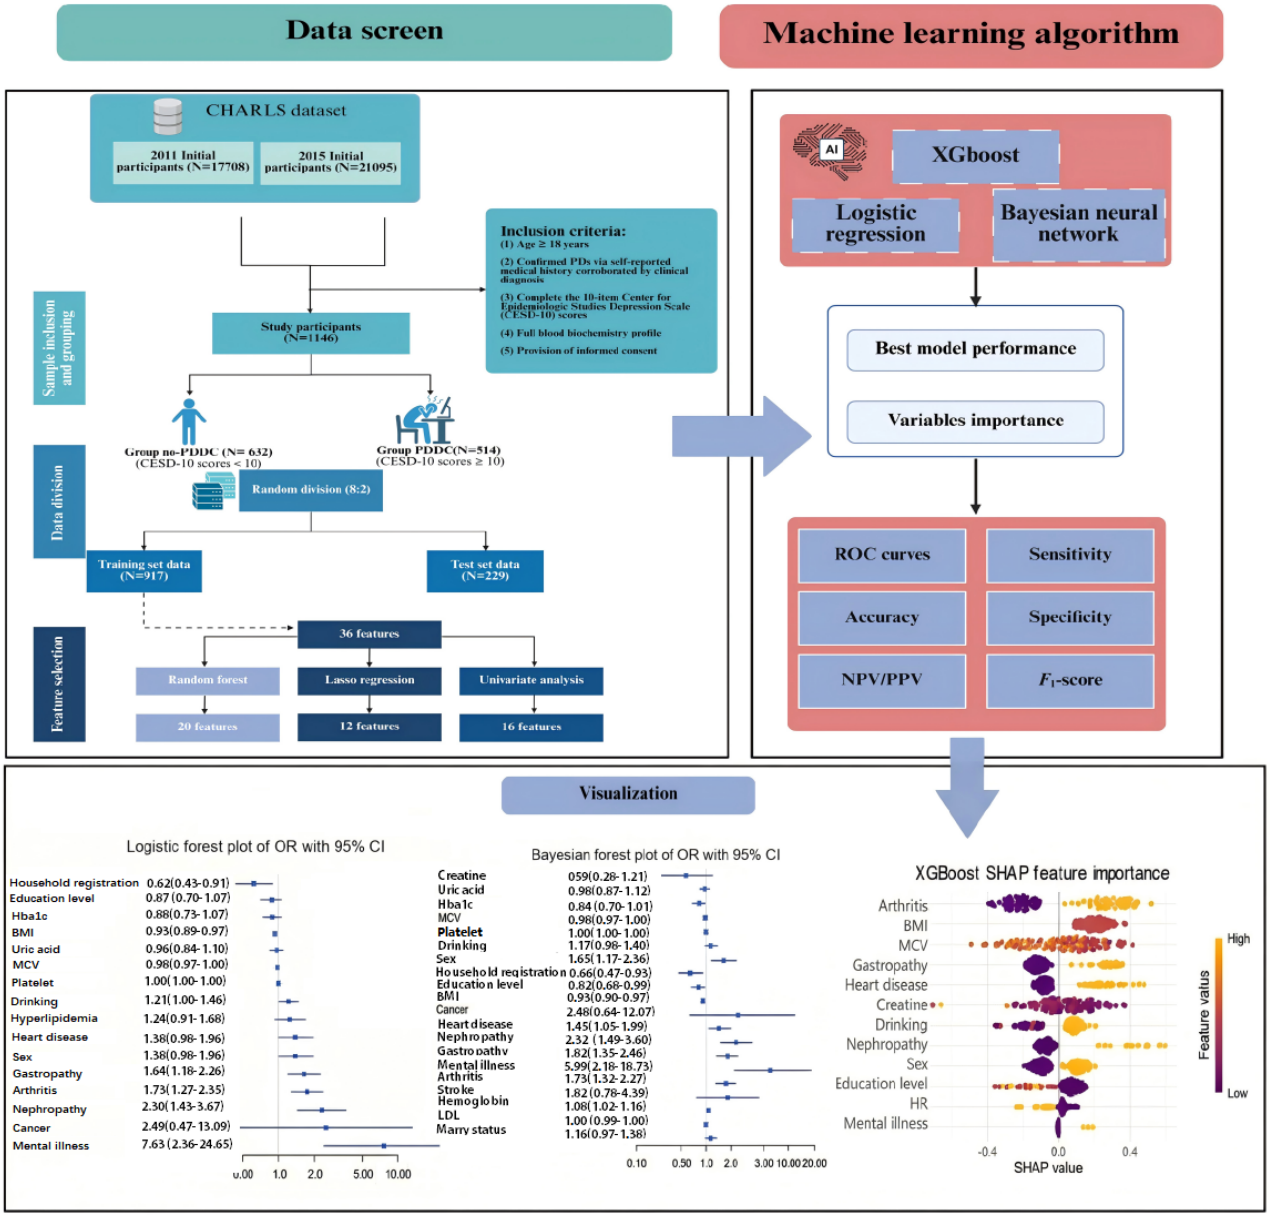
Despite expanding literature, 3 unresolved issues persist. First, methodological constraints remain: current models prioritize predictive accuracy over clinical interpretability, thereby limiting their use in guiding mechanistic insights or informing therapeutic decisions. Second, generalizability remains questionable, as many studies rely on single-center or region-specific data, undermining external validity across diverse populations. Third, nonlinear relationships and synergistic interactions—such as FEV1 thresholds precipitating depression onset or the combined influence of biological and psychosocial factors—are inadequately addressed.

To address these limitations, the study pursues 3 objectives. First, model development: we propose a hybrid analytical framework that integrates traditional statistical methods (eg, LR), explainable machine learning (eg, BNs), and advanced machine learning algorithms (eg, XGBoost). This framework is designed to balance predictive performance with clinical interpretability, thereby supporting actionable decision-making. Second, framework exploration: BN analysis will be used to identify key mediators—such as biomarkers, sociodemographic characteristics, and comorbidity indicators—and to clarify their conditional dependencies within PDDC. Third, validation strategy: model performance will be rigorously assessed using bootstrap resampling and DeLong tests to evaluate discrimination across spatial and temporal dimensions while addressing sample size constraints.

XSL•FO
RenderX

Through these aims, the study seeks to develop a clinically actionable model for PDDC that can inform personalized screening and targeted interventions, with the potential to reduce the burden of this syndemic. Specifically, we aim to (1) compare the discriminative performance and clinical operating characteristics of LR, BN, and XGBoost models; (2) identify core factors consistently associated with PDDC across analytical approaches; and (3) assess the clinical usefulness of each model for screening versus confirmatory diagnostic applications. We hypothesize that although machine learning models may better capture complex nonlinear relationships, traditional statistical methods will achieve comparable discrimination with greater interpretability, and that chronic multimorbidity patterns and sociodemographic factors will emerge as dominant correlates across all modeling frameworks.

Methods



Data Source and Inclusion Criteria

The study used data from the 2011 and 2015 waves of the China Health and Retirement Longitudinal Study (CHARLS) [20], a nationally representative, longitudinal cohort study organized by the National School of Development at Peking University. The CHARLS database uses a multistage, stratified probability sampling design, spanning 28 provinces, municipalities, and autonomous regions, and encompasses 150 counties. It contains comprehensive health-related data for more than 20,000 individuals aged 45 years and older, including standardized assessments of demographic characteristics, health status and functional capacity, health care utilization and insurance coverage, and socioeconomic status, collected via structured questionnaires, clinical examinations, and laboratory assays.

Participants were selected through a rigorous multistage process. This study workflow was summarized in Figure 1. In the initial screening phase, all individuals with self-reported lung disease diagnoses or respiratory symptoms were identified from the database. From 38,803 CHARLS participants in the 2011 and 2015 waves, we applied sequential inclusion criteria: (1) age ≥18 years, (2) confirmed PD, (3) complete depression assessment, and (4) <20% missing predictor data. PD was defined using a composite criterion incorporating both self-reported physician diagnosis of chronic lung diseases (chronic bronchitis, emphysema, asthma, or pulmonary heart disease; corresponding to ICD-10 [*International Statistical Classification of Diseases, Tenth Revision*] codes J40-J47) and, where available, spirometry-confirmed airflow limitation (postbronchodilator FEV_1 /FVC <0.70 per Global Initiative for Chronic Obstructive Lung Disease criteria) [21]. This dual approach minimizes misclassification bias inherent in single-source definitions [22]. Exclusions included severe cognitive impairment (Mini-Mental State Examination <18) and terminal malignancies. The final analytical sample comprised 1146 participants.

Figure 1. This flowchart outlines the machine learning analysis pipeline based on the CHARLS dataset. AI: artificial intelligence; CESD-10: Center for Epidemiologic Studies Depression Scale-10; CHARLS: China Health and Retirement Longitudinal Study; HbA_{1c}: hemoglobin A_{1c}; HR: household registration; LDL: low-density lipoprotein; MCV: mean corpuscular volume; NPV/PPV: negative/positive predictive value; OR: odds ratios; PDs: pulmonary dysfunctions; PDDC: pulmonary dysfunction–depression comorbidity; ROC: receiver operating characteristic; SHAP: Shapley Additive Explanations; XGBoost: Extreme Gradient Boosting.

Variables and Data Collection

This analytical framework used multidimensional variables systematically categorized into four distinct domains: (1) Demographic parameters including age, sex, BMI, education level, household registration, and marital status. (2) Blood-based biomarkers comprising glucose, cholesterol, high-density lipoprotein, low-density lipoprotein, triglycerides, blood urea nitrogen, creatine, uric acid, high-sensitivity C-reactive protein, hemoglobin A_{1c} (HbA_{1c}), hematocrit, hemoglobin, white blood cell, mean corpuscular volume (MCV), and platelet. (3) Chronic disease comorbidity quantified through binary classification (yes/no) of 13 clinically significant noncommunicable conditions: hypertension, diabetes, cancer, hyperlipidemia, hepatopathy, heart disease, stroke, nephropathy, gastropathy, mental illness (defined as physician-diagnosed depression, anxiety, or other psychiatric conditions documented in medical history, distinct from current depressive symptoms assessed by 10-item Center for Epidemiologic Studies Depression Scale [CESD-10]), memory-associated disorders, arthritis, and asthma. Notably, while "mental illness" as a predictor and CESD-10–defined depression as an outcome are related constructs, they capture different dimensions: the former reflects historical clinical diagnosis, whereas the latter measures current symptom severity. (4) Behavioral determinants encompassing smoking and drinking. More details are reported in Table S1 in Multimedia Appendix 1.

Outcome Specification

Depressive symptomatology was assessed using the CESD-10 [23], a psychometrically validated screening instrument in population-based studies. Participants rated symptom frequency

XSL•FO
RenderX

over the preceding week (eg, depressed mood, loneliness, and fear) on a 4-point Likert scale (total score range: 0‐30). Consistent with established epidemiological thresholds, scores ≥10 were classified as clinically significant depressive symptoms, demonstrating robust sensitivity (91.93%) and specificity (92.76%) in prior validation studies [23].

Statistical Analysis

This study used a cross-sectional design using pooled data from 2 CHARLS waves (2011 and 2015) to develop and validate an analytical framework for identifying factors associated with prevalent depressive symptoms in patients with PDs. These waves were selected because they contain the most complete blood biomarker panels, which were essential for our multidimensional analytical approach. More recent CHARLS waves (2018 and 2020) have incomplete biomarker data due to changes in data collection protocols and COVID-19 pandemic disruptions. The pooled analytical sample comprised 1146 participants. The dataset was partitioned through random allocation, with 80% (917) of participants constituting the derivation cohort for model development, while the remaining 20% (229) served as an independent validation cohort to assess model generalizability.

Model Construction

Data Preprocessing

Systematic preprocessing was performed prior to model development. Missing values for continuous variables were imputed using multiple imputation techniques, while missing categorical variables were coded as a distinct category to retain maximal information.

LR Model Construction

We constructed a conventional LR model as a reference comparator, adopting a hierarchical analytical approach to variable selection. The methodology proceeded through two sequential phases: (1) Bonferroni-adjusted univariate screening ($\alpha \leq .05$) to identify candidate associated factors exhibiting preliminary associations with incident PDDC, followed by (2) an iterative refinement process using forward stepwise regression (entry threshold: $\alpha < .05$) to achieve optimal model parsimony while preserving discriminative capacity. The final LR model took the form:

$$\log (p1-p)=\beta 0+\sum i=1k\beta iXi$$

where p denotes the probability of depressive symptoms, β the intercept, and β the coefficients for predictors X.

BNs Model Construction

We implemented a BN model using the R package brms (BN Models using Stan, version 2.18.0). The modeling procedure comprised three principal components: (1) Associated-factor selection: twenty clinically relevant variables were identified through random forest–based feature importance analysis, spanning demographic parameters, blood-based biomarkers, chronic disease comorbidity, and behavioral determinants. (2) Prior distribution specification: weakly informative normal priors (N(0, 1)) were assigned to all regression coefficients, providing sufficient regularization while maintaining theoretical flexibility [24]. (3) Markov Chain Monte Carlo sampling configuration: the model used 4 parallel Markov Chain Monte Carlo chains, each executing 2000 iterations (1000 warm-up and 1000 sampling iterations) [25]. Convergence was optimized by setting the adaptation parameter (adapt_delta) to 0.95, effectively reducing divergent transitions while maintaining sampling efficiency.

XGBoost Model Construction

The XGBoost model construction used a 2-stage pipeline integrating Least Absolute Shrinkage and Selection Operator (LASSO) regularization for feature selection followed by gradient boosting for classification [26].

Feature Selection via LASSO

LASSO regression with L1 penalty was applied to all candidate variables. The optimal regularization coefficient (λ) was determined via 10-fold cross-validation, selecting the λ value within 1 standard error of the minimum cross-validated deviance (λ=0.023). This procedure yielded 12 variables with nonzero coefficients: mental illness, nephropathy, arthritis, gastropathy, household registration, BMI, sex, heart disease, drinking, education level, creatinine, and MCV. The relatively stringent feature selection reflects LASSO's tendency to select 1 representative variable among correlated predictors, which may have excluded potentially informative features.

Hyperparameter Optimization

XGBoost hyperparameters were optimized via grid search with 5-fold cross-validation on the training set. The parameter grid included max_depth (3, 4, 5, and 6), learning rate η (0.01, 0.05, 0.1, and 0.2), n_estimators (100, 200, and 300), subsample (0.7, 0.8, and 0.9), and colsample_bytree (0.7, 0.8, and 0.9). The optimal configuration maximizing cross-validated area under the receiver operating characteristic curve (AUROC) was max_depth=6, η=0.1, n_estimators=200, subsample=0.8, and colsample_bytree=0.8. Early stopping was implemented with a patience of 20 rounds to prevent overfitting. The objective function minimized:

$$L(\theta)=\sum i=1nl\ (yi,y\hat{}i) + \lambda\sum j=1m|wj|$$

where $l(y, \hat{y})$ denotes the logistic loss, w the feature weights, and λ the regularization strength.

Model Validation

All models were validated using a comprehensive set of metrics: (1) Primary metric: AUROC, with 95% CIs computed via the DeLong method. (2) Secondary metrics: accuracy, sensitivity, specificity, positive predictive value, and negative predictive value, each reported with point estimates and 95% CI. (3) Calibration: model calibration was assessed using calibration curves plotting observed versus predicted probabilities across deciles of predicted risk, with Hosmer-Lemeshow goodness-of-fit test statistics. (4) Clinical usefulness: decision curve analysis (DCA) was performed to evaluate net benefit across a range of clinically relevant threshold probabilities (0.1‐0.6), comparing each model with "treat all" and "treat none" strategies [27].

XSL•FO
RenderX

To facilitate fair model comparison, we additionally conducted a unified feature set analysis in which all 3 models were fit using the same prespecified predictor set (defined a priori based on clinical relevance and data availability). We reconstructed all 3 models using an identical 20-feature (ie, household registration, sex, education level, BMI, marital status, creatine, HbA_{1c}, MCV, platelet, LDL, uric acid, hemoglobin, cancer, nephropathy, heart disease, gastropathy, arthritis, mental illness, stroke, and drinking) input set. Performance metrics (discrimination, calibration, and decision-curve net benefit) were then compared under identical inputs. All analyses were conducted in R (version 4.4.3) using validated computational libraries (brms, rstan, dplyr, pROC, caret, xgboost, rmda, ggplot2, and forestplot), with complete reproducibility scripts archived in Table S2 in Multimedia Appendix 1.

Ethical Considerations

This study adhered to the principles of the Declaration of Helsinki and received ethical approval from the Biomedical Ethics Committee of Peking University (approval no. IRB00001052-11015). The requirement for informed consent was waived by the ethics committee because the study was based on a secondary analysis of routinely collected administrative data and did not involve any direct contact with individual participants. Both the original data collection and the current secondary analysis were approved without the need for additional informed consent. All data from the CHARLS were anonymized before analysis. Identifiable information had been removed by the data custodian, and the authors had no access to any personal information that could enable the identification of individual participants. Data access and analytical procedures were carried out in accordance with applicable data protection requirements. No financial or other incentives were provided to participants, as the study did not involve direct enrollment of or interaction with human subjects. Neither the manuscript nor the supplementary materials contains any images or other information that could reveal the identity of individual participants.

Results

Baseline Characteristics

The study cohort comprised 1146 participants (non-PDDC: n=632; PDDC: n=514), with baseline characteristics detailed in Table S3 in Multimedia Appendix 1. Demographic comparisons revealed no significant age difference between groups (mean 62.48, SD 9.93 vs mean 62.16, SD 9.67 years; *P*=.58), although marked disparities emerged in BMI (mean 23.20, SD 4.22 vs mean 22.54, SD 3.71 kg/m²; *P*=.01), sex distribution (male: 372/632, 58.9% vs 232/514, 45.1%; *P*<.001), educational attainment (high school or above: 169/632, 26.7% vs 65/514, 12.6%; *P*<.001), and urban household registration (215/632, 34.0% vs 100/514, 19.5%; *P*<.001). Marital status showed no statistical significance (*P*=.08). Hematologic profiling identified elevated uric acid (mean 4.81, SD 1.37 vs mean 4.43, SD 1.20 mg/dL; *P*<.001) and HbA_{1c} (mean 5.3, SD 1% vs mean 5.2, SD 1%; *P*=.002) in the non-PDDC group, alongside increased MCV (mean 91.59, SD 8.47 vs mean 90.25, SD 8.91 fL; *P*=.01) and reduced platelet counts (mean 194, SD 95 vs mean 202, SD 93×10 /L; *P*=.05). No significant differences were observed in glucose, lipid profiles, renal markers, or inflammatory indices. Chronic comorbidity analysis demonstrated substantially lower prevalence rates in the non-PDDC group for cancer (3/632, 0.5% vs 10/514, 1.9%; *P*=.02), hyperlipidemia (281/632, 44.5% vs 281/514, 54.7%; *P*=.001), heart disease (107/632, 16.9% vs 150/514, 29.2%; *P*<.001), and organ-specific pathologies (nephropathy: 46/632, 7.3% vs 88/514, 17.1%, *P*<.001; gastropathy: 130/632, 20.6% vs 211/514, 41.1%, *P*<.001). Behavioral assessments revealed differential alcohol consumption patterns (*P*<.001), with increased drinking frequency (≥ monthly: 171/632, 27.1% vs 98/514, 19.1%) and reduced nondrinkers (404/32, 64.0% vs 386/514, 75.1%) among patients with non-PDDC.

Nonunified Feature Set Analysis

Modeling Construction

LR Analysis

Sixteen significant associated factors (*P*<.05) were identified through univariate analysis, encompassing sociodemographic factors (BMI, sex, education level, and household registration), blood-based biomarkers (uric acid, HbA_{1c}, MCV, and platelet), chronic disease comorbidity (cancer, hyperlipidemia, heart disease, nephropathy, arthritis, gastropathy, and mental illness), and behavioral determinant (drinking) in the training dataset (Table 1). Multivariable LR analyses identified mental illness as the most robust associated factors of PDDC (odds ratios [ORs] 7.63, 95% CI 2.36 - 24.65), with subsequent clinical correlates demonstrating descending effect magnitudes: nephropathy (OR 2.30, 95% CI 1.43 - 3.67), arthritis (OR 1.73, 95% CI 1.27 - 2.35), gastropathy (OR 1.64, 95% CI 1.18 - 2.26), and drinking (OR 1.21, 95% CI 1.00 - 1.46). Notably, inverse associations emerged for household registration status (OR 0.62, 95% CI 0.43 - 0.91) and BMI (OR 0.93, 95% CI 0.89 - 0.97), suggesting potential protective effects (Figure 2A).

[a]Continuous variables are presented as mean (SD). Normality was assessed using the Shapiro-Wilk test. Variables meeting normality assumptions (BMI, glucose, HDL, LDL, MCV, and hemoglobin) were compared using Student *t* test. Nonnormally distributed variables (TG, BUN, creatinine, uric acid, hsCRP, HbA_{1c}, hematocrit, WBC, and platelet) were compared using the Mann-Whitney *U* test.

[b]Categorical variables are presented as n (%) and compared using Pearson chi-square test or Fisher exact test (for expected cell counts <5).

[c]PDDC: pulmonary dysfunction–depression comorbidity.

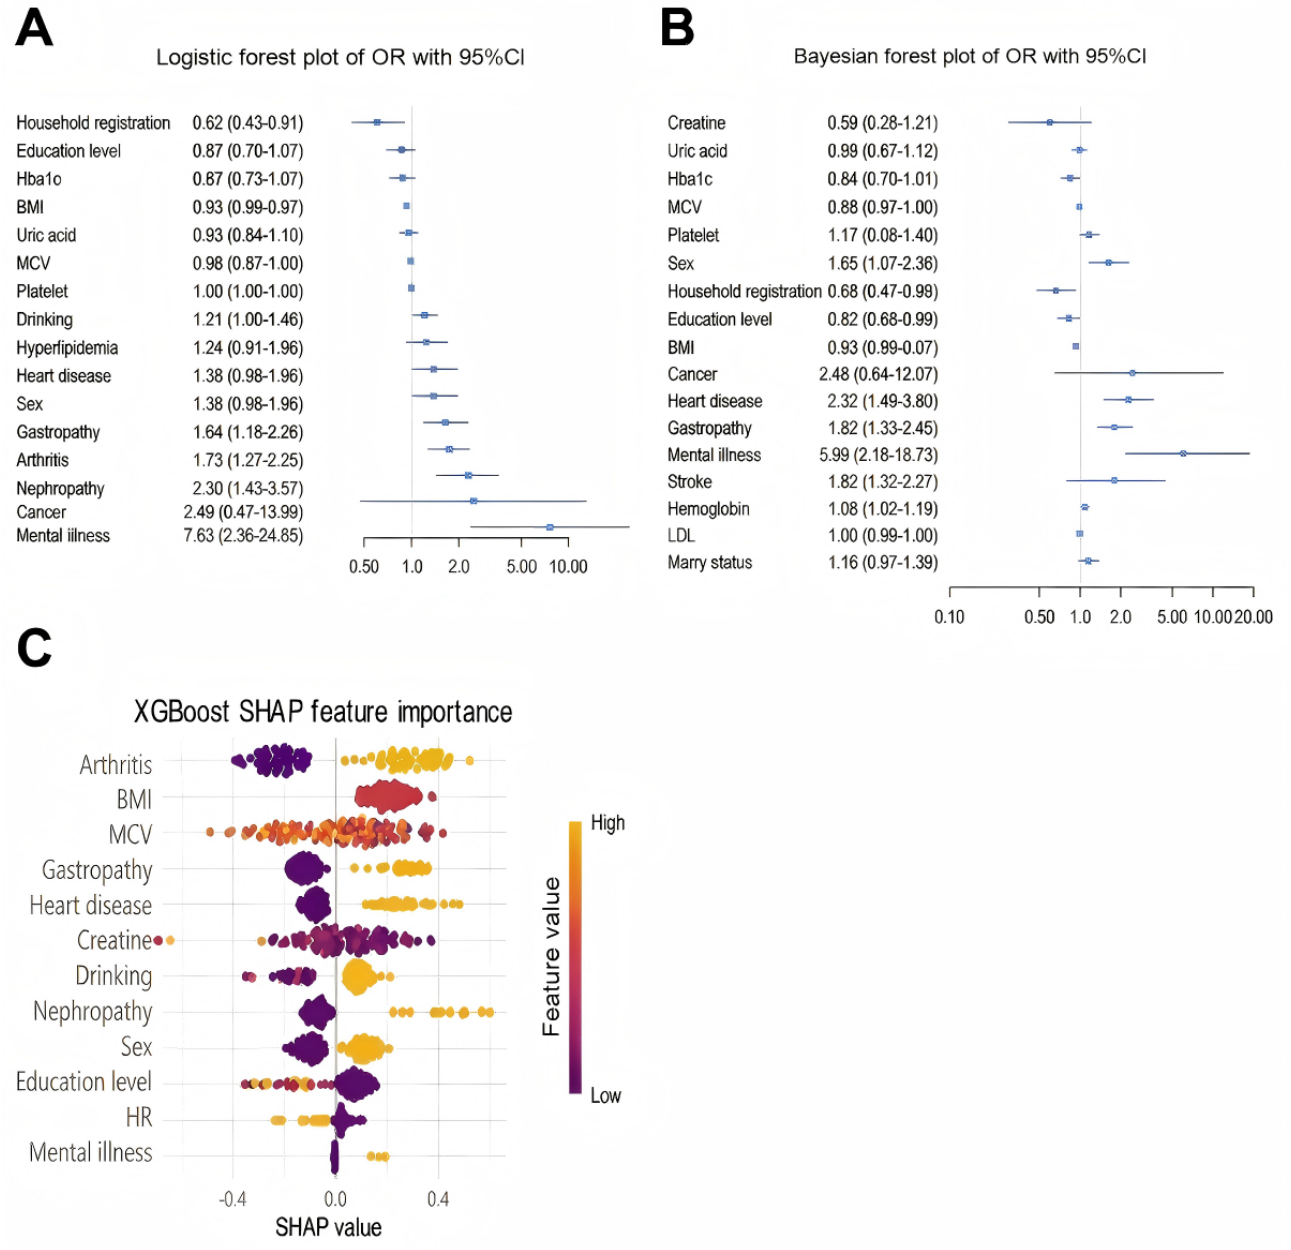
[d]HDL: high-density lipoprotein.

[e]LDL: low-density lipoprotein.

[f]TG: triglycerides.

[g]BUN: blood urea nitrogen.

[h]hsCRP: high-sensitivity C-reactive protein.



[i]HbA_{1c}: hemoglobin A_{1c}.

[j]WBC: white blood cell.

[k]MCV: mean corpuscular volume.

HbA_{1c}: hemoglobin A_{1c}; HR: household registration; LDL: low-density lipoprotein; MCV: mean corpuscular volume; OR: odds ratios; SHAP: Shapley Additive Explanations.

BN Analysis

The BN model was constructed through 2 methodologically integrated phases. First, variable selection was conducted via random forest feature importance analysis, which identified 20 clinically significant associated factors across four domains: (1) demographic characteristics (household registration, sex, education level, BMI, and marital status), (2) hematologic biomarkers (creatine, HbA_{1c}, MCV, platelet, LDL, uric acid, and hemoglobin), (3) chronic comorbidities (cancer, nephropathy, heart disease, gastropathy, arthritis, mental illness, and stroke), and (4) behavioral determinants (drinking; Figure S1 in Multimedia Appendix 1). These variables demonstrated substantial analytical capacity. Second, the final model with Bayesian forest plot verification demonstrated mental illness as the strongest associated factor (OR 5.99, 95% CI 2.18 - 18.73), followed by nephropathy (OR 2.32, 95% CI 1.49 - 3.60), gastropathy (OR 1.82, 95% CI 1.35 - 2.46), arthritis (OR 1.73, 95% CI 1.32 - 2.27), sex (OR 1.65, 95% CI 1.17 - 2.36), heart disease (OR 1.45, 95% CI 1.05 - 1.99), and hemoglobin (OR 1.08, 95% CI 1.02 - 1.16). Protective associations were identified for household registration status (OR 0.66, 95% CI 0.47 - 0.93), education level (OR 0.82, 95% CI 0.68 - 0.99), and BMI (OR 0.93, 95% CI 0.90 - 0.97) (Figure 2B).

XGBoost Model Analysis

LASSO regression selected 12 robust associated factors, with 6 variables (mental illness, nephropathy, arthritis, gastropathy, household registration, and BMI; 50%) overlapping across all models. Arthritis, mental illness, gastropathy, sex, heart disease,

XSL•FO
RenderX

nephropathy, and drinking were consistently identified as positive associated factors, whereas BMI, household registration status, education level, creatine, and MCV demonstrated inverse associations (Figure S2 in Multimedia Appendix 1). Feature importance analysis via Shapley Additive Explanations (SHAP) values identified arthritis (mean |SHAP|=0.409), BMI (mean |SHAP|=0.376), and MCV (mean |SHAP|=0.350) as the 3 most salient associated factors of PDDC, with hierarchical dominance persisting across all model configurations (Figure 2C).

Sensitivity Analysis Excluding Mental Illness

To mitigate conceptual overlap between physician-diagnosed psychiatric history ("mental illness") and the CESD-10 outcome, we repeated the analyses after removing this covariate from all 3 models. In the LR model, nephropathy (OR 1.94, 95% CI 1.20 - 3.14), arthritis (OR 1.85, 95% CI 1.35 - 2.53), gastropathy (OR 1.93, 95% CI 1.38 - 2.70), household registration status (OR 0.67, 95% CI 0.46 - 0.98), and BMI (OR 0.92, 95% CI 0.88 - 0.96) remained significantly associated with the outcome. Similar associations were observed in the BN model: nephropathy (OR 2.10, 95% CI 1.30 - 3.54), arthritis (OR 1.95, 95% CI 1.40 - 2.74), gastropathy (OR 1.84, 95% CI 1.33 - 2.54), household registration status (OR 0.62, 95% CI 0.43 - 0.84), and BMI (OR 0.92, 95% CI 0.87 - 0.94). In the XGBoost model, the following features were identified as important contributors based on their SHAP values: arthritis (SHAP=0.260), gastropathy (SHAP=0.202), education level (SHAP=0.144), sex (SHAP=0.108), BMI (SHAP=0.106), household registration status (SHAP=0.079), MCV (SHAP=0.073), and creatine (SHAP=0.073). Model discrimination declined modestly (BN AUROC: 0.735-0.698, LR AUROC: 0.734-0.698, and XGBoost AUROC: 0.690-0.677) but remained acceptable, indicating that predictive performance was not primarily driven by the psychiatric history variable. The consistent, limited attenuation across models supports the independent predictive contribution of the remaining factors.

Discrimination, Calibration, and Classification Performance

To evaluate the discriminative capacity of analytical models in analyzing PDDC, receiver operating characteristic analysis was performed on both training and validation cohorts (Table 2 and Figure 3). In the training dataset, the LR model achieved an AUROC of 0.734 (95% CI 0.708 - 0.752) with balanced performance metrics (sensitivity 0.633 and specificity 0.735). The BN demonstrated comparable discrimination (AUROC 0.735, 95% CI 0.709 - 0.760) but showed distinct operational characteristics (sensitivity 0.894 vs specificity 0.389). The XGBoost algorithm yielded relatively lower predictive accuracy (AUROC 0.690, 95% CI 0.638 - 0.731) with moderate sensitivity (0.558) and specificity (0.444; Figure 3A). This performance pattern persisted in the test set, where LR maintained robust discrimination (AUROC 0.731, 95% CI 0.700 - 0.759) with preserved sensitivity (0.647) and specificity (0.721). BN showed similar AUROC performance (AUROC 0.733, 95% CI 0.709 - 0.770) but continued to exhibit high sensitivity (0.884) at the expense of specificity (0.401). XGBoost demonstrated reduced generalizability (AUROC 0.650, 95% CI 0.603 - 0.688) with suboptimal operational characteristics (Figure 3B; Table S4 in Multimedia Appendix 1).

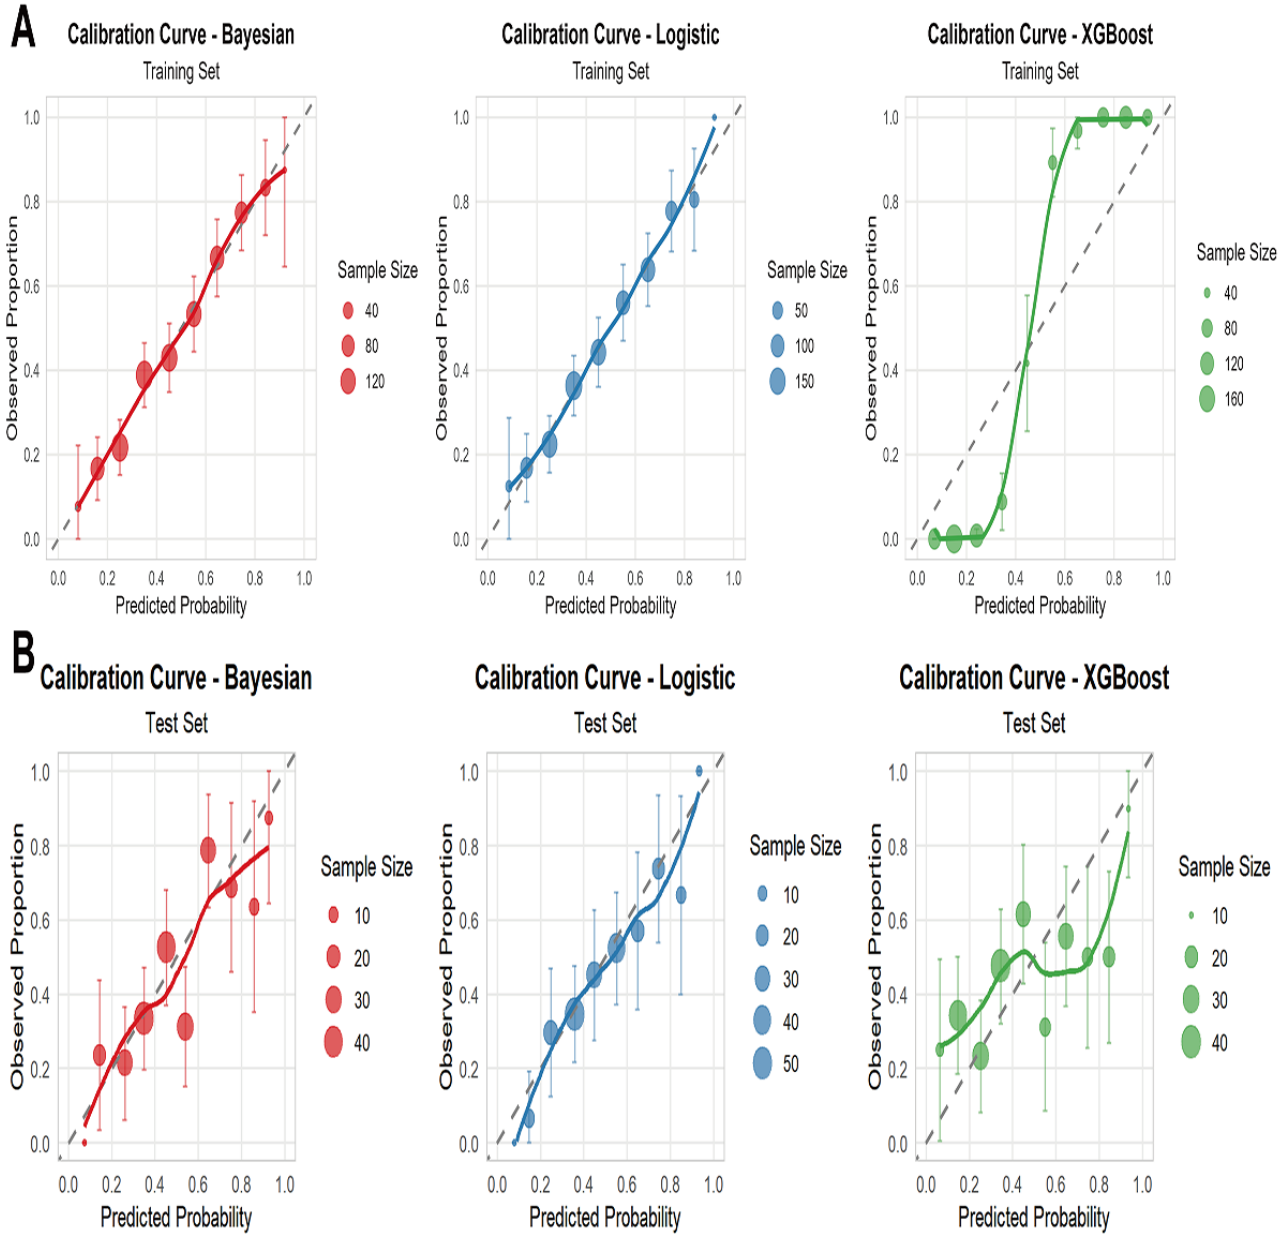
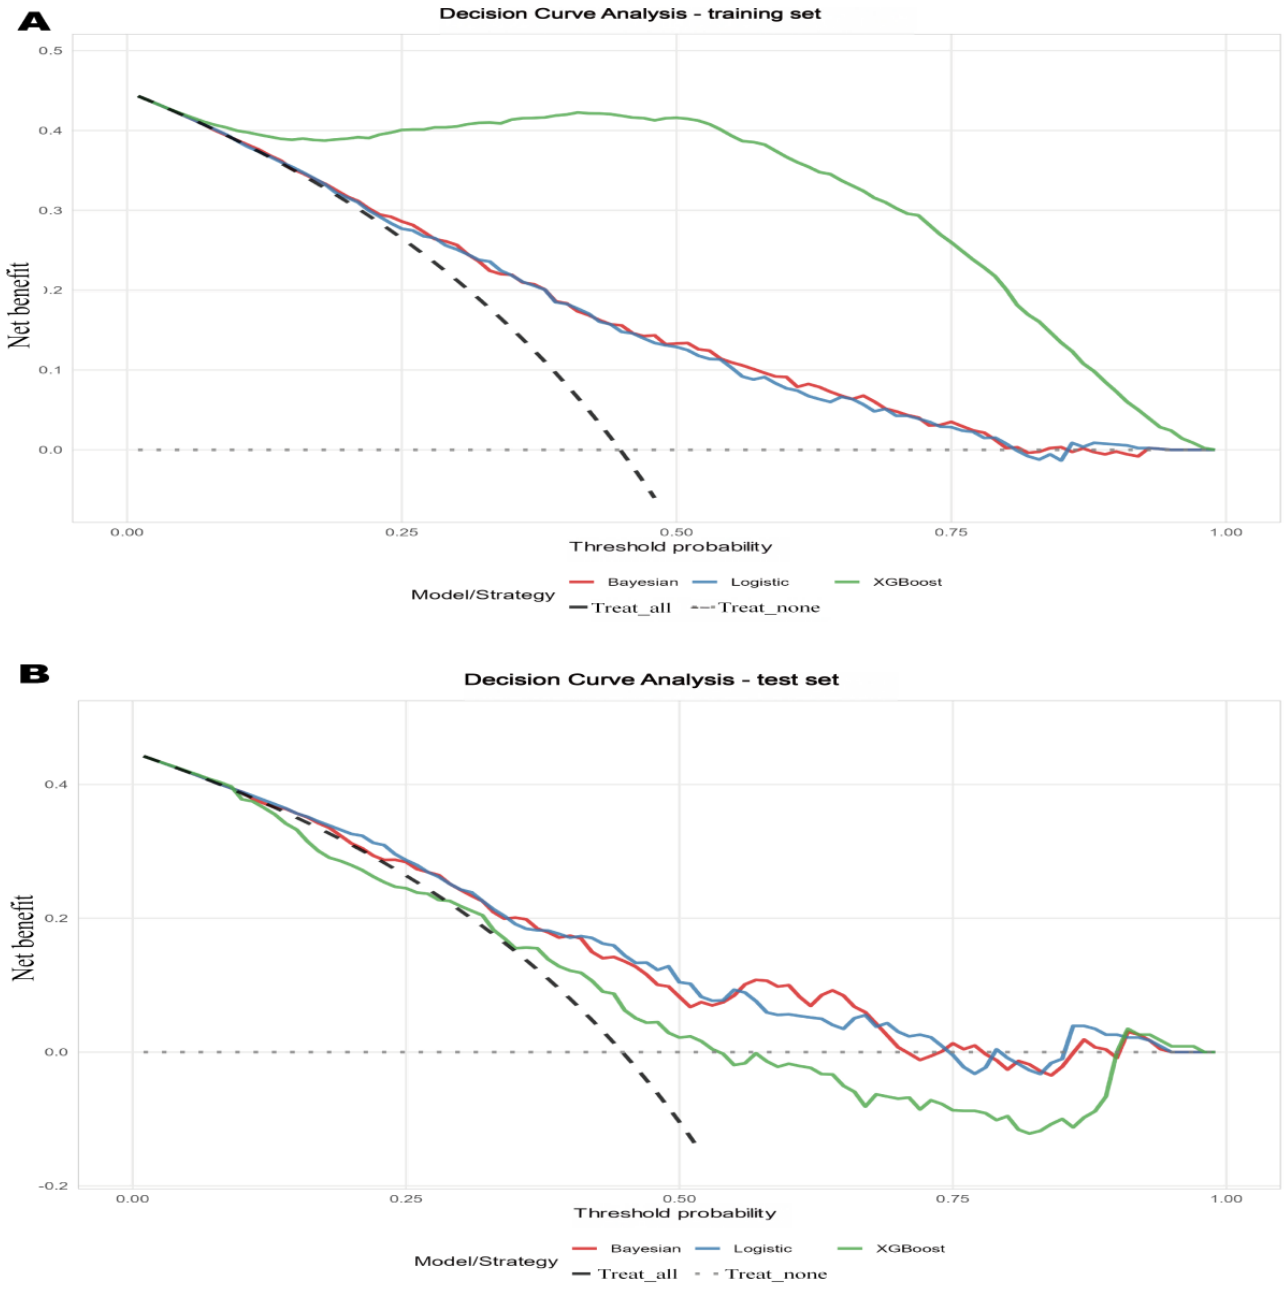
Figure 3. Comparative performance of the 3 models in analyzing pulmonary dysfunction–depression comorbidity through receiver operating characteristic analysis in the nonunified feature set. (**A**) Discriminative capacity of logistic regression, Bayesian network, and Extreme Gradient Boosting models in the training dataset. (**B**) External validation of model generalizability in a test dataset. ROC: receiver operating characteristic; XGBoost: Extreme Gradient Boosting.



Calibration analyses for all 3 models are shown in Figure 4. In the training set, both LR and BN models demonstrated excellent calibration, with predicted probabilities closely aligned with observed outcomes (Hosmer-Lemeshow test: P=.98 and P=.99, respectively). In contrast, the XGBoost model exhibited significant miscalibration (P<.001), indicating overfitting (Figure 4A). In the test set, only the LR model maintained acceptable calibration (Hosmer-Lemeshow χ^2_8=10.71; P=.22), although moderate underestimation was observed in lower probability ranges (calibration slope=0.918). The BN model showed significant miscalibration (χ^2_8=21.18, P=.01; calibration slope=0.858), suggesting limited generalizability. The XGBoost model demonstrated the poorest calibration, with severe deviation across the probability spectrum (calibration slope=0.374; χ^2_8=48.93; P<.001; Figure 4B). Brier scores in the test set were 0.211 for LR, 0.213 for BN, and 0.256 for XGBoost, indicating comparable overall prediction accuracy between LR and BN. These findings suggest that while XGBoost achieves superior discrimination in the training set, its probability estimates require recalibration before clinical application. The LR model provides more reliable probability estimates with better preserved calibration upon external validation.

DCA revealed distinct threshold-dependent patterns between the training and test sets (Figure 5). In the training set, XGBoost demonstrated the highest net benefit across all threshold probabilities, outperforming both BN and LR models (Figure 5A). This pattern reversed in the test set, where XGBoost

XSL•FO
RenderX



yielded lower net benefit than BN and LR across the entire threshold range, indicating limited generalizability (Figure 5B). Within the test set, BN and LR models provided more consistent clinical usefulness. At moderate-to-high thresholds (55% - 60%), the BN model showed marginally higher net benefit than LR. Overall, while XGBoost exhibited superior training set performance, and BN and LR achieved more stable net benefit upon external validation, consistent with overfitting by XGBoost.

Unified Feature Set Analysis

Modeling Construction

LR Analysis

In multivariable LR, physician-diagnosed mental illness showed the strongest association with the outcome (OR 4.70, 95% CI 1.51 - 14.62). Other significant correlates, in descending magnitude, were nephropathy (OR 2.12, 95% CI 1.31 - 3.42), arthritis (OR 1.94, 95% CI 1.42 - 2.65), gastropathy (OR 1.84, 95% CI 1.32 - 2.58), male sex (OR 1.71, 95% CI 1.17 - 2.51), heart disease (OR 1.55, 95% CI 1.07 - 2.22), and hemoglobin (OR 1.10, 95% CI 1.02 - 1.20). Household registration status (OR 0.61, 95% CI 0.42 - 0.90) and BMI (OR 0.93, 95% CI 0.89 - 0.96) were inversely associated with the outcome.

BN Analysis

The BN model yielded a similar pattern. Mental illness remained the strongest predictor (OR 3.46, 95% CI 1.38 - 8.94), followed by nephropathy (OR 2.14, 95% CI 1.32 - 3.56), arthritis (OR 1.95, 95% CI 1.42 - 2.72), gastropathy (OR 1.86, 95% CI 1.35 - 2.56), male sex (OR 1.72, 95% CI 1.19 - 2.46), heart disease (OR 1.54, 95% CI 1.05 - 2.25), and hemoglobin (OR 1.11, 95% CI 1.02 - 1.20). Household registration status (OR 0.61, 95% CI 0.42 - 0.86) and BMI (OR 0.92, 95% CI 0.89 - 0.96) again showed inverse associations.

XGBoost Model Analysis

SHAP analyses from the XGBoost model ranked arthritis as the most influential feature (mean |SHAP| 0.260), followed by gastropathy (0.202), education level (0.144), sex (0.108), and BMI (0.106). These features contributed the largest marginal

XSL•FO
RenderX

effects on predictions and accounted for most of the model's explanatory signal (Figure S3 in Multimedia Appendix 1).

Sensitivity Analysis Excluding Mental Illness

To reduce potential conceptual overlap between physician-diagnosed psychiatric history ("mental illness") and the CESD-10 outcome, we repeated the unified feature set analyses after removing this covariate from all 3 models. Model discrimination remained largely unchanged, indicating that predictive performance was robust to this specification. The modest, consistent attenuation observed across models suggests that the remaining multimorbidity and sociodemographic predictors contribute independent prognostic information. Although mental illness was strongly associated with the outcome, the retained covariates continued to provide substantial predictive value (Table S5 in Multimedia Appendix 1).

Discrimination, Calibration, and Classification Performance

In the training set, LR achieved an AUROC of 0.753, with specificity of 0.763 and sensitivity of 0.597. The BN showed a similar AUROC (0.749) but a distinct operating profile, with higher specificity (0.814) and lower sensitivity (0.548). XGBoost demonstrated superior discrimination (AUROC 0.844), with sensitivity of 0.697 and specificity of 0.792. In the independent test cohort, discriminative performance was comparable across models: LR yielded an AUROC of 0.665 (95% CI 0.595 - 0.736), BN 0.661 (95% CI 0.590 - 0.731), and XGBoost of 0.658 (95% CI 0.585 - 0.731), with no significant pairwise differences (all P>.37). Despite similar AUROCs, threshold-dependent performance differed substantially. At their respective optimal thresholds, BN and LR favored sensitivity (0.755 for both), whereas XGBoost prioritized specificity (0.833; Table 2; Figure S4 and Table S4 in Multimedia Appendix 1).

Calibration results are shown in Figure S5 in Multimedia Appendix 1. In the training set, LR and BN exhibited near-perfect calibration (Hosmer-Lemeshow P=.84 and P=.93, respectively), whereas XGBoost was significantly miscalibrated (P<.001), consistent with overfitting. In the test set, only BN retained acceptable calibration (Hosmer-Lemeshow χ^2_8=14.23; P=.12), despite mild underestimation at lower probabilities (calibration slope=0.645). LR showed moderate miscalibration (P=.01; slope=0.613), and XGBoost performed worst, with systematic deviation across the probability range (slope=0.680) and unreliable Hosmer–Lemeshow statistics owing to sparse bins. Brier scores in the test set were 0.227 for XGBoost, 0.229 for LR, and 0.229 for BN, indicating marginally superior point prediction accuracy for XGBoost despite its calibration shortcomings. A composite calibration score integrating Brier score, calibration slope, and Hosmer-Lemeshow results ranked BN highest (0.493), followed by LR (0.182); XGBoost could not be fully scored owing to unreliable statistics. DCA revealed threshold-dependent net benefit (Figure S6 Multimedia Appendix 1). Between 0% and −40% risk threshold, LR and BN outperformed XGBoost, reflecting their higher sensitivity for ruling out disease in screening settings. Above −40%, XGBoost delivered the greatest net benefit, consistent with its high-specificity profile for confirmatory testing (except a narrow range near 60%, where LR was marginally superior). In summary, with identical features, the simpler LR and BN models matched XGBoost's discriminative performance while offering substantially better-calibrated probabilities. BN provided the most reliable risk estimates overall. For low-risk-threshold (screening) applications, BN or LR is preferred; for high-risk-threshold (confirmatory) decisions, XGBoost can be considered if its probabilities are recalibrated.

Discussion

Principal Findings

In a cohort of 1146 participants, PDDC was characterized by a higher burden of chronic comorbidities and less favorable sociodemographic profiles, while most routine laboratory markers showed limited separation between groups. Across modeling strategies, discrimination for PDDC risk was modest and broadly comparable, whereas calibration and threshold-specific operating behavior differed meaningfully. A small set of recurrent factors—psychiatric history, nephropathy, arthritis, gastropathy, household registration status, and BMI—emerged consistently across models and remained informative when psychiatric history was excluded to reduce conceptual overlap with the CESD-10 outcome.

Impact of Feature Selection

Different feature selection strategies (univariate screening for LR, random forest importance for BN, and LASSO- or SHAP-guided selection for XGBoost) yielded overlapping predictors, suggesting a stable signal rather than method-specific artifacts [28]. Notably, the unified feature set analysis narrowed performance differences and highlighted that model behavior was driven less by discrimination than by calibration and operating thresholds. This finding is practically important: when models are restricted to the same routinely available inputs, simpler approaches can match the discrimination of more complex learners, while often offering more interpretable structure and, in some evaluations, more reliable probabilities.

Comparative Performance of Analytical Models

Discriminative Capacity

In the development data, LR and BN achieved similar discrimination (AUROC=0.73) and consistently outperformed XGBoost (AUROC 0.69 in training, declining to 0.65 in validation), suggesting weaker generalizability for the more complex learner under the original specification. When evaluated in an independent test cohort with identical predictors, all 3 models converged to nearly identical AUROCs (0.66) and did not differ statistically. This convergence indicates that, with the available feature set, algorithmic complexity alone did not translate into improved discrimination; instead, the attainable signal for separating PDDC from non-PDDC appears constrained by the information content of routinely collected variables [29].

Clinical Operational Characteristics

Despite similar AUROCs, the models adopted distinct operating points at their optimized thresholds. LR tended to preserve a more balanced sensitivity-specificity trade-off in the development or validation evaluation, whereas BN consistently

XSL•FO
RenderX

favored sensitivity at the expense of specificity. This high-sensitivity profile may be advantageous in screening contexts where the primary objective is to minimize missed cases [30]. In contrast, XGBoost favored specificity in the independent test cohort, aligning better with confirmatory strategies where avoiding false positives is prioritized.

DCA underscored that clinical usefulness was threshold dependent and cohort sensitive [31]. In the development set, XGBoost showed higher net benefit across thresholds, but this advantage did not generalize; in the test set, LR and BN provided more stable net benefit. In the independent test cohort, LR or BN was preferred at lower risk thresholds, whereas XGBoost offered greater net benefit at higher thresholds, consistent with their sensitivity- versus specificity-forward profiles. These results argue against selecting a model solely on discrimination and support aligning model choice with the intended decision threshold range [32].

Limitations of Model Reliability

Calibration differentiated model reliability more clearly than discrimination [33]. In the development set, LR and BN were well calibrated, while XGBoost showed clear miscalibration consistent with overfitting. Calibration in held-out data was less stable and varied by evaluation cohort: in 1 test evaluation, LR retained acceptable calibration with mild underestimation at low predicted risks, whereas BN showed significant miscalibration; in the independent test cohort analysis with identical predictors, BN achieved the strongest overall calibration profile (despite underestimation at lower probabilities), LR was moderately miscalibrated, and XGBoost exhibited systematic deviation and unstable goodness-of-fit diagnostics due to sparse bins. Across these analyses, two points are consistent: (1) calibration is more fragile than discrimination and sensitive to dataset shift, and (2) XGBoost produced the least reliable probability estimates without recalibration, even when its point prediction error (Brier score) was competitive. Because risk stratification in practice relies on accurate probabilities rather than rankings alone, calibration performance should be a primary determinant of clinical readiness [34].

Clinical Significance of Key Associated Factors

Core Associated Factors Identified Across Models

Across analytic approaches, psychiatric history was the strongest associated factor, with nephropathy, arthritis, and gastropathy consistently ranking among the most influential clinical correlates. Heart disease and hemoglobin also emerged as contributors in multivariable models, reinforcing the relevance of broader multimorbidity and systemic health in PDDC risk profiles [35]. The repeated identification of these conditions across LR, BN, and XGBoost interpretability analyses (OR/credible intervals and SHAP rankings) supports their robustness as markers of vulnerability.

Crucially, removing psychiatric history to address conceptual overlap with CESD-10 produced only modest declines in discrimination and preserved the associations for nephropathy, arthritis, gastropathy, household registration status, and BMI. This pattern indicates that the predictive framework was not dominated by psychiatric history alone and that the remaining variables contributed independent prognostic information. By contrast, several laboratory biomarkers that differed between groups at baseline (eg, uric acid, HbA_{1c}, and platelet count) played a less consistent role in multivariable models, suggesting that their crude differences may be confounded or clinically modest in magnitude [36].

Impact of Sociodemographic Factors

Sociodemographic factors were consistently retained in the final models and were generally associated with lower PDDC risk. At baseline, rural household registration status and lower educational attainment were more common in the PDDC group; in adjusted analyses, both household registration status and education level were inversely associated with subsequent PDDC risk [37,38]. This pattern aligns with the influence of structural determinants—access to services, continuity of care, health literacy, and material constraints—on susceptibility to depressive symptoms among individuals with impaired pulmonary function [39,40].

The inverse association between BMI and PDDC risk contrasts with much of the Western literature, where obesity is often linked to higher depression risk. Several cohort- and context-specific considerations may account for this difference. In older Chinese adults, lower BMI more frequently reflects malnutrition, sarcopenia, or frailty, all of which are strongly associated with depressive symptoms. Moreover, an “obesity paradox” has been reported in Asian populations, whereby modestly higher BMI is associated with better outcomes in later life. In our cohort, BMI was relatively low overall (mean 22.9 kg/m²), and obesity was uncommon (BMI≥30 kg/m², approximately 4%), limiting power to detect nonlinear (U- or J-shaped) associations. Cultural norms may also shape the BMI-depression relationship by altering the social meaning of body weight and the extent of weight-related stigma [41,42]. Notably, BMI showed an inverse association across multiple models, consistent with the lower mean BMI observed in the PDDC group [43]; this likely captures vulnerability phenotypes—frailty, sarcopenia, or higher chronic disease burden—rather than a protective effect of lower weight per se [44]. Sex differences remained evident after adjustment in the unified analyses, suggesting heterogeneity in symptom reporting, comorbidity profiles, or access to care that merits further investigation.

Methodological Contributions and Innovations

This study contributes methodologically by evaluating 3 distinct modeling paradigms—linear (LR), probabilistic graphical (BN), and gradient-boosted trees (XGBoost)—under both model-specific and unified predictor settings. The evaluation emphasized not only discrimination but also calibration and DCA, aligning performance assessment with clinical decision-making rather than rank-based metrics alone. Interpretability was addressed through complementary tools (effect estimates for LR or BN and SHAP for XGBoost), enabling triangulation of core factors that remained consistent across methods. Finally, the sensitivity analysis excluding psychiatric history directly addressed a common concern in depression prediction and strengthened confidence that

XSL•FO
RenderX

multimorbidity and sociodemographic variables provide independent predictive signal.

Study Limitations

Several limitations should be considered. First, overall discrimination in external testing was modest, indicating that key determinants of PDDC risk remain unmeasured. Second, calibration was cohort dependent, and goodness-of-fit testing was unstable for XGBoost in the independent test cohort due to sparse bins, limiting inferential confidence from Hosmer-Lemeshow statistics. Third, CESD-10 is a screening tool rather than a diagnostic interview; outcome misclassification is possible. Fourth, comorbidity histories and behavioral measures may be subject to reporting or recording bias, and the cross-sectional design precludes causal interpretation. Fifth, our reliance on 2011 and 2015 CHARLS data, while necessary to obtain complete biomarker profiles, limits the temporal relevance of our findings. Health care accessibility, diagnostic practices, and population health characteristics may have evolved over the past decade. Finally, the feature set lacked clinically rich markers such as pulmonary function severity, symptom burden, medication exposure, and psychosocial stressors, which likely mediate or modify PDDC risk. Although the core biological and sociodemographic relationships we identified are likely to remain stable, validation with more recent cohort data is warranted when comprehensive biomarker panels become available.

Future Research Directions

Future work should focus on (1) prospective, multisite external validation to quantify calibration drift and transportability; (2) formal recalibration and model updating, particularly for tree-based learners, before clinical use; (3) incorporation of disease severity measures and longitudinal trajectories to distinguish incident from persistent depressive symptoms; and (4) evaluation of clinically actionable thresholds in workflow-based impact studies to determine whether model-guided screening or referral improves outcomes. Given the contribution of sociodemographic factors, fairness and subgroup performance analyses should also be prioritized.

Conclusions

Using routinely available clinical and sociodemographic data, LR and BN achieved discrimination comparable with XGBoost and, in several evaluations, provided more reliable probability estimates. Model selection should be driven by the intended clinical application: LR offers a balanced operating profile, BN is attractive when sensitivity is prioritized, and XGBoost may be considered for high-threshold decisions only with careful recalibration. Across modeling strategies, psychiatric history, nephropathy, arthritis, gastropathy, household registration status, and BMI emerged as stable associated factors, and the predictive signal persisted after excluding psychiatric history, underscoring the independent contribution of multimorbidity and social determinants to PDDC risk.

Acknowledgments

No generative artificial intelligence tools were used to generate the manuscript text, analyses, figures, tables, or multimedia appendices. All study design decisions, analyses, interpretations, and final wording were produced and verified by the authors. The authors would like to express their gratitude to the participants who kindly took part in this study.

Abstract

Background: Visual identification and verification of medications during dispensing and administration are prone to human error, particularly in high-pressure and high-volume clinical settings. Misidentification can lead to medication errors, posing risks to patient safety and placing a burden on health care systems. Recent advances in computer vision and object detection offer promising solutions for automated solid oral dosage form (pill) recognition. However, comprehensive studies comparing code-based and no-code (automated machine learning [AutoML]) approaches for pill recognition are lacking.

Objective: This study aimed to evaluate and compare the performance, cost, usability, and deployment feasibility of pill recognition models developed with Ultralytics YOLO11 and 3 cloud-based AutoML platforms (Amazon Rekognition Custom Labels, Google Vertex artificial intelligence [AI] AutoML Vision, and Microsoft Azure Custom Vision) using multiple datasets, including real-world clinical images.

Methods: Five training subsets of increasing size (1230, 3450, 7380, 14,400, and 26,880 images) from 30 commonly dispensed medications were used to train models on YOLO11 and 3 AutoML platforms. Models were evaluated on 6 datasets from different environments: clinical images from 3 hospitals, a verification dataset, a laboratory dataset, and an exhaustive testing set. Performance metrics, including accuracy, precision, recall, and mean average precision, were calculated. We evaluated the impact of training data size on performance and benchmarked training time, platform costs, and limitations.

Results: No single platform dominated across all test environments. On the verification dataset (optimal conditions), accuracy ranged from 80.83% (YOLO11) to 91.60% (Google Vertex AI) when trained with the full training dataset. YOLO11 showed consistent performance improvement with increasing training data (accuracy: 63.06%-80.83%) and achieved near-perfect precision and mean average precision scores (0.95 - 1.00). Google Vertex AI reached above 90% accuracy on 3 training subsets but showed unpredictable declines. Amazon Rekognition maintained near-perfect precision (0.92 - 1.00) but had the highest false negative rates (up to 0.74), missing many pills. Custom Vision demonstrated steady performance improvements (77.08%-85.62% accuracy) but lagged behind other AutoML platforms, probably due to its older YOLOv2-based architecture. On clinical datasets, accuracy fluctuated (20.62%-90%) depending on the dataset and platform. Training costs and time varied: YOLO11 (open-source), Microsoft Azure (US $9.50-US $28.60, allowed user-predefined training duration), Google Vertex AI (US $69.30 with consistent 2.5 - 3-hour training times), and Amazon Rekognition (US $5.43-US $43.89 with size-dependent training time scaling, reaching nearly 40 hours on the full 26,880-image dataset).

Conclusions: Each platform offers distinct advantages and trade-offs: YOLO11 provides the highest flexibility and lowest platform costs but requires technical expertise, while AutoML platforms can offer high performance at a higher cost but with limited user control, introducing unpredictability. The performance variations demonstrate that successful clinical deployment requires careful platform selection based on specific performance requirements, budget constraints, and available technical resources, followed by rigorous validation using real-world, representative data to ensure patient safety in clinical workflows.

Introduction

Background

Medication errors are preventable failures in medical care that can potentially lead to patient harm and increased health care costs, with a global financial burden estimated at US $42 billion annually [1]. These errors are responsible for an estimated 7000 - 9000 deaths per year in the United States [1] and contribute to 1708 deaths in England [2], highlighting the urgent need for improved medication safety strategies. Medication errors can occur at various stages of therapy, from prescribing to dispensing and administration of medications [3], and are among the most common causes of death [4]. Medication therapy management in hospitals, clinics, and inpatient health care settings is often managed under the supervision of a clinical pharmacist, who is responsible for monitoring patients' treatment process and identifying any discrepancies [5]. During inpatient care, medication reconciliation, that is, the process in which pharmacists compare the medications a patient is currently taking or should be taking with newly ordered therapies, often requires visually distinguishing between numerous solid oral dosage forms (eg, pills, tablets, and capsules, often referred to collectively as "pills") based on the patient's therapy regimen. This process can be challenging because these products often show only subtle differences in their physical characteristics [6]. Therefore, even the most experienced professionals could occasionally make mistakes, as visual identification and verification are prone to human error, especially in high-pressure and high-volume environments such as hospitals and clinics [7]. These challenges and limitations have led to investments in automation technologies for unit-dose dispensing to improve hospital pharmacy services [8,9] and the exploration of leveraging novel techniques, such as object detection, to assist pharmacists with verification tasks and ultimately reduce dispensing errors [6]. However, it is important to note the specific clinical context for such tools. Unlike medication reconciliation at admission, where a patient may present a disorganized collection of loose pills for identification, during hospital pharmacy manual dispensing processes, staff typically use organized unit doses and dosette boxes. In this context, the primary challenge is usually not identifying a mystery pill but verifying that the pill in a specific compartment matches the prescribed therapy. Automated pill recognition systems could support this verification process, as well as additional workflows, including detection of dispensing errors before medications reach patients and identification of medications returned to the hospital pharmacy unit.

Recent advances in computer vision and object detection offer promising solutions for image analysis, including high-performance object detection models based on the You Only Look Once (YOLO) architecture, which allows fast and accurate localization and classification in a single step [10,11]. YOLO has proven to be an attractive choice for a variety of medical applications [11], including pill recognition [12]. YOLO has demonstrated strong performance in code-based pill recognition systems, particularly for preprocessing segmented images within multistream, 2-phase neural models using metric embedding [13]. One of the latest iterations in the Ultralytics YOLO series is YOLO11, released in September 2024. This version improved upon previous models by implementing a new backbone architecture that enhances feature extraction (identifying key patterns such as edges, textures, or shapes from raw image data) with improved accuracy and processing speed, making it suitable for complex visual recognition tasks [14]. These advancements create new opportunities for developing clinical decision support systems that assist health care professionals in the visual identification of pills.

In parallel with the evolution of code-based models, which provide flexibility and customization but require strong programming skills and longer development time, low-code or code-free automated machine learning (AutoML) platforms have emerged. These platforms enable relatively simple development and testing of specialized object detection models using easy-to-use cloud-based platforms [15,16].

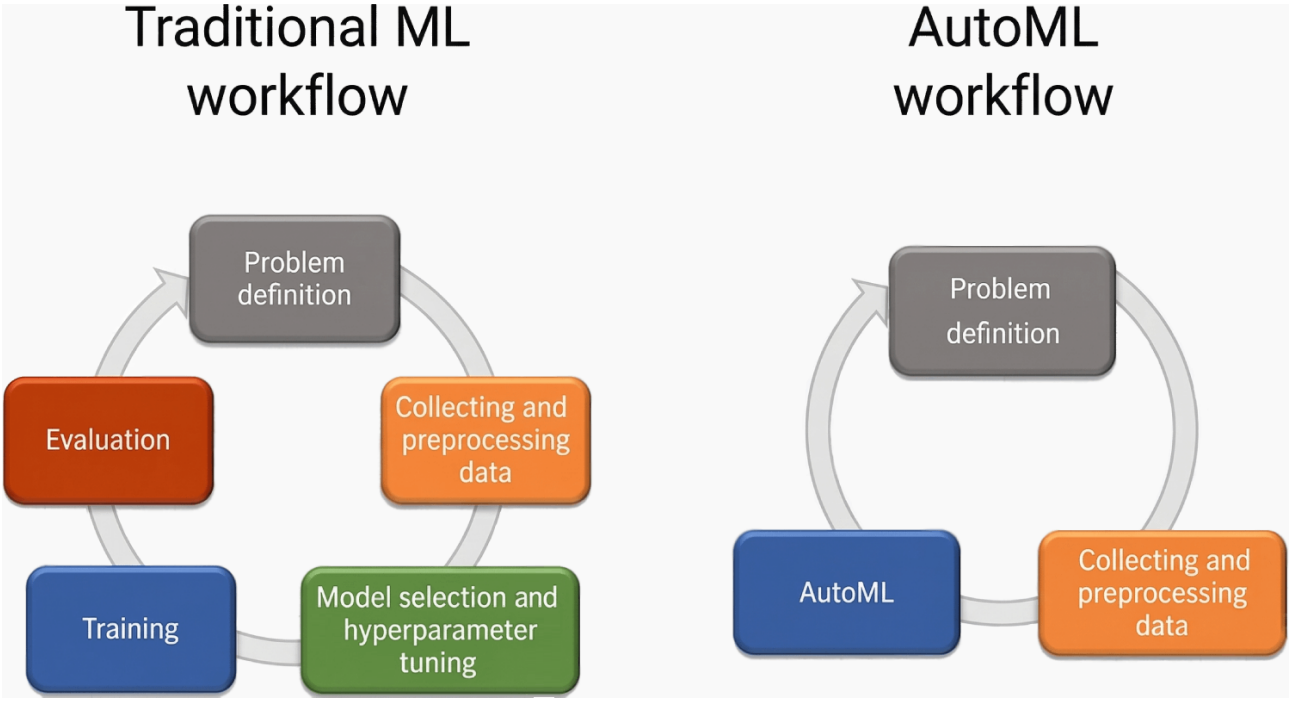
Rationale

Although both traditional code-based models and cloud-based AutoML platforms have shown promise in medical image analysis [17], there is a lack of comprehensive, direct comparative studies evaluating the performance of these approaches in the context of pill recognition. Previous studies have commonly focused on controlled environments that do not reflect typical usage scenarios and conditions. The open-source, code-based deep learning object detection YOLO model and code-free, cloud-based AutoML platforms represent fundamentally different development concepts, each with its own associated advantages and limitations. This justifies a comprehensive comparison of these solutions to determine robustness, scalability, and implementation complexity in practical environments. Limited published, peer-reviewed studies compare the performance of traditional code-based and code-free pill recognition models using images captured in real-world clinical environments, which often differ substantially from standardized reference images. To our knowledge, this is the first study to directly compare these approaches using clinical data under such specific conditions.

Objectives

This study aimed to evaluate and compare the effectiveness of pill recognition models developed using YOLO11 with cloud-based AutoML platforms provided by Amazon Rekognition Custom Labels, Google Vertex artificial intelligence (AI) AutoML Vision, and Microsoft Azure Custom Vision. Factors, such as cost, ease of use, and deployment feasibility, as well as key performance metrics including accuracy, precision, recall, F_1-score, mean average precision (mAP), overall error rates (OERs), and false negative rates (FNRs), were evaluated on different test sets, including real-world images captured by clinical pharmacists.

Code-Based and Code-Free Object Detection



Traditional code-based deep learning frameworks, such as YOLO11, require programming and machine learning (ML) expertise but offer full control over model architecture and training parameters, whereas code-free development and training using cloud-based AutoML platforms provide simplified workflows with limited customization options. The YOLO

XSL•FO
RenderX

family of deep-learning–based object detectors uses a single-stage approach, which means that the entire input image is processed in a single forward pass, predicting bounding boxes and class probabilities simultaneously [18]. This allows YOLO models to balance inference speed and detection accuracy, making them one of the most widely used object detection algorithms. In our experiments, we used the YOLO11 real-time object detection model, which was designed to address a wide spectrum of application requirements and supports a wide range of computer vision tasks, including object detection [14,18]. A detailed description of the YOLO11 model structure is provided in Multimedia Appendix 1.

In a traditional deep learning ecosystem, model development involves several manual and iterative processes, such as data collection and preprocessing, feature engineering, model selection, hyperparameter tuning, training, and validation, as shown in Figure 1. This approach requires a high level of expertise and intensive experimentation to fine-tune the model's performance.

Figure 1. Traditional machine learning (ML) vs automated machine learning (AutoML) workflows.

Cloud-based, no-code AutoML platforms have emerged as suitable alternatives to traditional, often code-intensive model development approaches. These platforms automate most of the workflows involved in managing ML pipelines, thereby lowering the barrier to entry and making model development accessible even to those without programming skills or data science expertise [19]. In addition to enhancing accessibility, these platforms accelerate the model development lifecycle by automating repetitive and time-consuming tasks, allowing rapid prototyping, while reducing complexity by handling the underlying tasks associated with managing the computational infrastructure and ecosystem required for model development [19]. However, AutoML has inherent disadvantages. While AutoML democratizes model development by minimizing human effort, it requires significant computational resources, which can lead to expensive cloud service costs, particularly when developing models iteratively using large datasets. AutoML users typically have very limited control over the choice of base models, underlying training algorithms, and hyperparameter adjustments. In addition, AutoML platforms lack transparency in model architecture and hyperparameters and may raise privacy concerns [20]. Therefore, the choice of the optimal platform depends on a variety of factors.

This study aimed to provide empirical evidence to guide such platform selection decisions for pill recognition model development intended for deployment in clinical and hospital pharmacy settings, where accuracy and reliability are of utmost importance. We evaluated AutoML solutions offered by Amazon Web Services (AWS), Google Cloud, and Microsoft Azure, 3 of the most popular cloud-based providers for object detection, alongside code-based models trained with a traditional workflow using YOLO11.

Microsoft offers a wide range of AI and ML services on its Azure platform, including Custom Vision, a more specialized service focused on building, training, and deploying custom image classification and object detection models using a no-code or low-code approach [21]. It is accessible through a dedicated, code-free web interface and software development kits (SDKs) requiring minimal coding experience. Vertex AI AutoML Vision is part of Google Cloud's unified Vertex AI platform. Vertex AI allows users to train, deploy, and fine-tune a wide range of models with supervised learning, data- and application-specific training strategies, and tools to manage the entire lifecycle of ML [22]. Vertex AI offers choices for a manual approach that provides full control over the training pipeline using traditional coding development, as well as AutoML for code-free model development, which is accessible via the Google Cloud Console web interface and through SDKs compatible with popular open-source libraries such as TensorFlow (Google) and PyTorch (Meta AI) [23]. Amazon Rekognition Custom Labels is a feature

XSL•FO
RenderX

within AWS's broader Rekognition service that allows users to train custom object detection models using AutoML [24]. Although Amazon Rekognition follows a similar workflow to other platforms, including the option of manual labeling, it imposes stricter restrictions on the ML workflow.

Methods

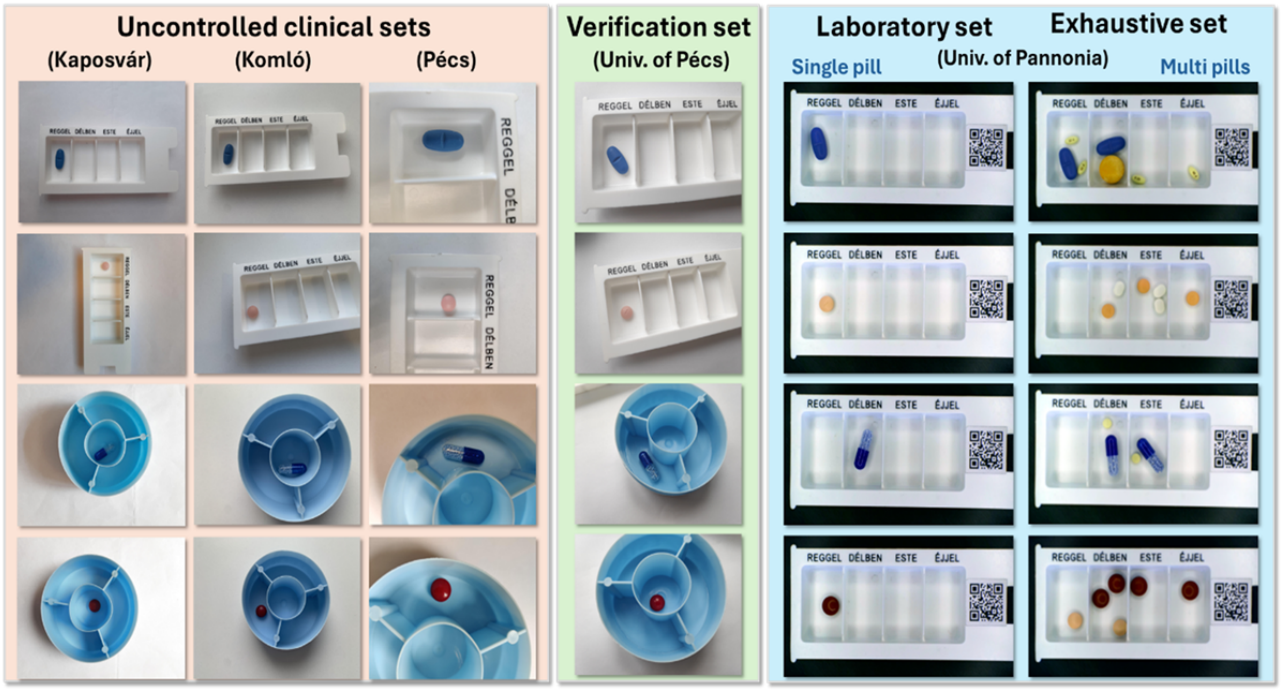
Overview

This section details the methodologies used for data collection, preprocessing, and coded model development. We compared 2 fundamentally different approaches to model development and training: traditional code-based deep learning using YOLO11, and code-free development using 3 major cloud-based AutoML platforms (Amazon Rekognition Custom Labels, Vertex AI AutoML Vision, and Custom Vision). We performed 5 training runs per platform using 5 progressively larger subsets of our training images. The evaluation metrics used for benchmarking and comparative analysis are explained in detail in Multimedia Appendix 2.

Data Collection and Preprocessing

For model training and evaluation, we used a tailor-made proprietary dataset focusing on 30 commonly dispensed solid oral dosage forms in Hungary (Figure 2). Selection of medications and curation of the dataset followed a strict protocol described in our previous publication [15].

For testing datasets, images were captured with a single pill placed in blue-and-white dosette boxes routinely used for manual dispensing in Hungarian clinical settings, except for one dataset prepared for exhaustive performance evaluation, which contained multiple pills per image (refer to Figure 3).



XSL•FO
RenderX

Figure 2. The 30 medications selected for this study.

XSL•FO
RenderX

Figure 3. Illustration of testing datasets.

Training images had a resolution of 1200×900 pixels, while test images were at native device resolution (4032×3024 and 4000×3000 pixels) to better simulate real-world conditions where input images vary in size. All images were captured in JPEG format with consistent quality settings.

The study's datasets were organized as follows:

- The "full training dataset" comprised 26,880 images in total, provided by the University of Pécs, with 896 images per class for the 30 selected medications. To evaluate the impact of training data size on the model performance, 5 subsets were created from these images using a logarithmic binning strategy, each with a progressively increasing number of images:
  - Subset 1: 1230 images (41 images/class)
  - Subset 2: 3450 images (115 images/class)
  - Subset 3: 7380 images (246 images/class)
  - Subset 4: 14,400 images (480 images/class)
  - Subset 5: 26,880 images (full training dataset, 896 images/class)
- A "verification dataset" containing 1440 images (48/class) was created at the University of Pécs using the same location, conditions, and procedures as the training dataset images.
- Three "uncontrolled clinical test sets (UCTSs)" of 480 images each (16/class) were captured by clinical pharmacists at Kaposvár, Komló, and Pécs hospitals under authentic clinical conditions to assess model performance in uncontrolled health care environments. UCTS images were collected using purposive sampling to ensure balanced representation across all medication classes (16 images/class at each hospital site). This design enables fair per-class comparison of model performance, avoiding bias toward majority classes seen with imbalanced test sets. Similar balanced sampling approaches are used in established pill recognition benchmarks, such as the CURE dataset [25] and the National Library of Medicine Pill Image Recognition Challenge [26]. To create the dataset, clinical pharmacists photographed medications within their routine workspaces using the dosette boxes and imaging equipment available in their daily practice. Class identity recorded during image acquisition served as the ground truth label during subsequent evaluations. This protocol preserved authentic environmental and human variables affecting input image quality, including camera variability, lighting conditions, and operator technique, while maintaining balanced class representation for fair platform comparison. No image quality filtering or manipulation was applied; all captured images were included regardless of quality to ensure the dataset accurately reflected authentic real-world variability in clinical settings.
- Two additional test datasets were created in a controlled laboratory environment at the Image Processing Laboratory, University of Pannonia. The first dataset, referred to as "laboratory test set," contained 120 images with single pills per image, while the second dataset included 120 multipill images called "exhaustive test set" intended for exhaustive model testing. Medications were arranged in a white dosette box, and controllable top-mounted lighting was used to evenly illuminate the pills. Images were captured with a fixed camera position at 3840×2160 resolution, with a slight reduction in resolution following image undistortion.

YOLO11 Implementation

For our experiments, we selected the medium-sized pretrained model (YOLO11-m), which balances speed, accuracy, and training time. All hyperparameters remained at their default values, except for the early stopping patience parameter, which was set to 15 epochs to terminate training if the validation loss did not improve within 15 consecutive epochs. Standard data augmentation techniques (eg, rotation, brightness adjustment,

XSL•FO
RenderX

and so on) were not applied during training to ensure uniform conditions across platforms, as cloud-based AutoML platforms typically apply such augmentations automatically, with limited or no user control. All experiments ran for 100 epochs with a batch size of 20, using an NVIDIA Quadro RTX 5000 graphics processing unit (GPU) with 16 GB video random-access memory for both training and evaluation.

Cloud-Based AutoML Platform Implementation

Microsoft Azure Custom Vision

Custom Vision offers a streamlined workflow for training object detection models. Users must create Custom Vision training and prediction resources in their Azure subscription via the Azure portal. New object detection projects can be created through the Custom Vision portal or via SDK, which offers a choice of predefined domains optimized for specific scenarios and edge or mobile deployment. Training images can be uploaded directly via the web portal or SDK, with an integrated tagging interface for drawing bounding boxes and assigning labels. Custom Vision requires a minimum of 15 images per label for training, but recommends 50 or more images per label for better performance. Users can select either Quick training (completed in minutes) or Advanced training (with extended computation budget) [27]. The platform automatically selects the optimal base model, training, tuning, and augmentation settings based on uploaded data and the selected project domain. Each training run generates a new model iteration that can be published to a prediction endpoint accessible via Representational State Transfer application programming interfaces (APIs) or SDKs.

Google Vertex AI AutoML

Vertex AI requires an active Google Cloud project with images stored in Google Cloud Storage. The platform accepts various image formats, with data imported either from local machines or directly from Google Cloud. Annotations must be provided in comma-separated values or JSON Lines (JSONL) formats containing bounding box coordinates and corresponding labels. Vertex AI requires at least 10 annotated images per label for training and recommends providing 1000 or more for optimal model performance [28]. For unannotated datasets, users can apply annotations through the Google Cloud Console interface. Without user-specified splitting, Vertex AI automatically partitions datasets using an 80% - 10% - 10% split for training, validation, and testing [29]. Since our original XML annotations were incompatible with Vertex AI's input requirements, we converted them to a single JSONL file, with each line representing an annotated instance. We created the dataset by selecting object detection as the project objective and linking the JSONL file from a cloud storage bucket. Vertex AI's custom dataset splitting functionality was used to create appropriate training, validation, and testing sets. For optimization, we used the high-accuracy training option within Vertex AI. After performing initial experiments, we opted for a specific high-accuracy training configuration that significantly outperformed other available options.

Amazon Rekognition Custom Labels

Rekognition requires prelabeled data in Amazon SageMaker Ground Truth manifest format, a JSONL structure with pixel-based bounding box coordinates [30]. This format has a different internal structure compared to Vertex AI's requirements, necessitating the conversion of our annotations using Python scripts. Data management in Rekognition offers moderate flexibility; however, Amazon S3 is the mandatory cloud solution for image storage. If no test dataset is provided, Rekognition automatically splits the training data to create a test dataset using an 80% - 20% split [31].

Model training can be initiated through the AWS Console or the CreateProjectVersion API. However, Rekognition provides no hyperparameter control, limiting customization during training. Each successful training run generates a new project version with an associated Amazon Resource Name. Performance metrics, including F_1-score, precision, recall, and mAP, are available through the API and Rekognition.

Evaluation Metrics

Object detection evaluation differs from standard classification because it requires assessment of localization and classification, meaning models must simultaneously locate objects within an image and correctly identify each object. Therefore, metrics that ignore spatial accuracy of predictions, such as simple classification accuracy, precision, and recall without intersection over union (IoU) thresholds, or classification-only F_1-scores, are insufficient for rigorous model evaluation.

To comprehensively assess our pill recognition models for both localization precision and classification accuracy, we used metrics incorporating IoU to enable fair comparison across fundamentally different model architectures and development approaches.

IoU quantifies the spatial accuracy of object detection by measuring the overlap between predicted and ground-truth bounding boxes, calculated as the ratio of overlap area to union area between boxes. Higher values indicate better localization accuracy, with a threshold (typically 0.5) determining whether a detection is considered correct.

In object detection, the accuracy metric is adapted to account for both classification and localization performance. A prediction is considered correct only if it has the correct class label and the IoU with the ground-truth bounding box exceeds a specified threshold.

Precision and recall incorporate IoU thresholds for object detection. Precision measures the percentage of correct detections among all predictions, indicating how reliable the model's positive predictions are. Recall measures the percentage of ground-truth objects correctly detected, reflecting the model's ability to identify all relevant instances.

Average precision represents the area under the precision-recall curve, providing a comprehensive performance measure across different confidence thresholds for each class. mAP averages average precision values across all classes, providing an overall performance measure. Common variants include mAP@0.50 (using an IoU threshold of 0.5) and mAP@0.50 - 0.95

XSL•FO
RenderX

(averaging across multiple IoU thresholds from 0.5 to 0.95 in 0.05 increments), which provides a more rigorous evaluation.

Beyond standard performance metrics, a critical evaluation of model suitability for clinical deployment necessitates an analysis of error profiles. To understand the failures impacting patient safety, we analyzed OERs and FNRs for each model. OER and accuracy are inversely related; they measure the model's overall tendency to misidentify medications through missed detections or incorrect classifications. FNR specifically quantifies the proportion of pills that models fail to detect, a critical safety metric in clinical settings. A detailed description of evaluation metrics, mathematical definitions, and computational procedures is provided in Multimedia Appendix 2.

Analytical Approach

This study used a comparative benchmarking design to characterize platform performance across diverse deployment scenarios rather than hypothesis testing. We selected standard object detection metrics following established conventions in computer vision and pill recognition research to enable direct comparison with other published literature. We additionally reported OER and FNR due to their clinical relevance for patient safety. CIs and formal statistical comparisons across hospital sites were not performed, as the evaluated cloud-based AutoML platforms have major inherent limitations and do not consistently provide the data needed for these calculations.

Used Medicines

Our datasets included the 30 most commonly dispensed medications from 3 participating clinical centers [15]. The medications represent various therapeutic areas, including cardiovascular agents (eg, bisoprolol and perindopril), antibiotics (amoxicillin/clavulanic acid), analgesics (naproxen and tramadol), psychiatric medications (alprazolam and quetiapine), and essential vitamins and supplements.

These medications cover a diverse range of solid oral dosage forms, including film-coated and uncoated tablets (the most prevalent forms), enteric-coated tablets, hard and soft gelatin capsules, and one chewable tablet. A complete medication list with active pharmaceutical ingredients, dosage forms, distinctive features, colors, and shapes is provided in Multimedia Appendix 3.

Ethical Considerations

This study did not involve human participants, and ethics approval was therefore not required. No personally identifiable information was collected or processed. No informed consent was required, as no human participants were involved in this study.

Results

Overall Detection Performance

Our evaluation of pill recognition models across multiple test datasets revealed notable performance differences, with no single platform consistently dominating all test scenarios. We trained models using 5 progressively larger training subsets (from 1230 to 26,880 images) and evaluated them using standard metrics: accuracy, precision, recall, OER, FNR, F_1-score, mAP@0.50, and mAP@0.50 - 0.95 to comprehensively assess platform performance, strengths, and limitations. Table 1 presents the results of models trained on the full dataset of 26,880 images, with comprehensive results of all training runs and subsequent evaluations provided in Multimedia Appendix 4.

XSL•FO

[a]OER: overall error rate.

[b]FNR: false negative rate.

[c]mAP: mean average precision.

[d]AI: artificial intelligence.

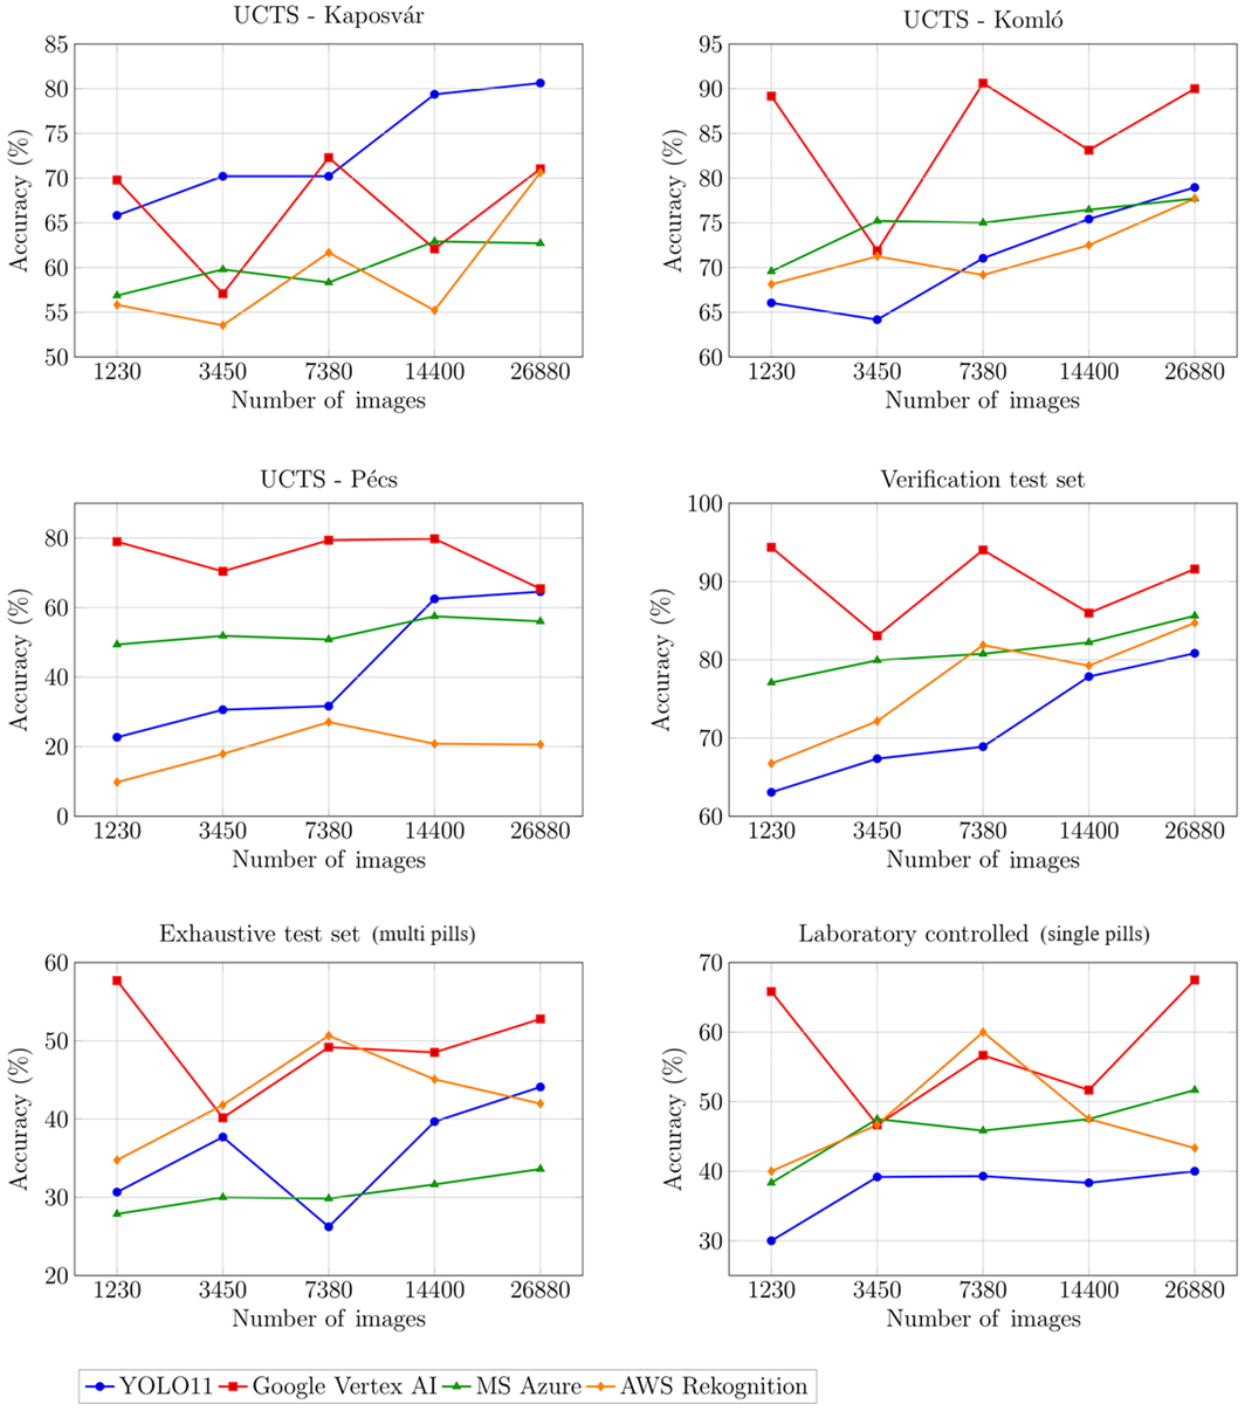
Results are organized into 3 categories: UCTS (representing real-world hospital conditions), verification dataset (optimal imaging conditions replicating training images), and laboratory-controlled datasets (standardized research settings).

On the UCTS images from Kaposvár hospital, models trained with the full training dataset of 26,880 images exhibited varied performance (Table 1). YOLO11 demonstrated superiority, achieving the highest scores in accuracy (80.63%), recall (0.92), F_1-score (0.95), and mAP metrics. Amazon Rekognition achieved the highest precision (1) but also showed the highest FNR, indicating its conservative detection strategy. Vertex AI ranked second with 71.04% accuracy. Microsoft Azure did not achieve top results in any instance on this dataset, but it maintained consistent performance, with accuracy ranging from 56.87% to 62.92% across training set sizes (Multimedia Appendix 4).

On the UCTS images from Komló hospital, competition was balanced between YOLO11, Custom Vision, and Amazon Rekognition, while Vertex AI showed considerably higher performance compared to the others. Across all training configurations, YOLO11 dominated mAP metrics, achieving a perfect 1.0 mAP@0.50 with 14,400 and 26,880 training images. Vertex AI excelled in accuracy, reaching 90.62% with 7380 images and 90% with the full training subset of 26,880 images.

XSL•FO
RenderX

Custom Vision improved steadily from 69.58% to 77.71% accuracy with increasing training data, while Amazon Rekognition maintained perfect precision (1.0) across all 5 training scenarios while achieving 77.71% accuracy.



On the UCTS images from Pécs hospital, Vertex AI outperformed other platforms despite varying results, achieving 79.79% accuracy with the training subset of 14,400 images but 65.42% with the full dataset. The other AutoML solutions performed poorly: Microsoft Azure achieved 57.5% accuracy with the training subset of 14,400 images and 56.04% with the full training dataset, while Amazon Rekognition reached only as high as 27.08% accuracy with the training subset of 7380 images on this dataset, which fell to 20.62% when trained with the full training dataset (Multimedia Appendix 4). YOLO11 also showed strong results, particularly for the more challenging mAP@0.50‐0.95 threshold metric (0.76). This dataset demonstrated the challenging nature of certain clinical environments, where lighting conditions, camera positioning, and other external factors significantly impact model performance.

On the verification dataset from the University of Pécs, Vertex AI excelled across all metrics, achieving 91.60% accuracy, perfect 1.0 precision and mAP@0.50, and 0.98 recall with the full training dataset. It only slightly underperformed YOLO11 in the mAP@0.50‐0.95 metric (0.79 vs 0.89). Microsoft Azure achieved 85.62% accuracy, 1.0 precision, and 1.0 mAP@0.50, while Amazon Rekognition reached 84.72% accuracy with perfect precision (1.0) but lower recall (0.85). YOLO11 showed linear performance improvement with increasing training dataset size, reaching 80.83% accuracy with perfect precision (1.0) and a high recall of 0.96. This dataset demonstrated the potential upper bound on performance when testing conditions are well-matched to training data.

The laboratory-controlled (single pills) and the exhaustive (multipills) test sets from the University of Pannonia showed varying performance across different platforms under optimal imaging conditions in a fully controlled environment. When analyzing the exhaustive dataset, Vertex AI achieved the highest accuracy on the full training dataset (52.79%) with excellent mAP@0.50 (0.99), followed by YOLO11 (44.10%, 0.95), Amazon Rekognition (41.97%, 0.98), and Microsoft Azure (33.61%, 0.77). The lower accuracy scores in the exhaustive dataset reflect the increased complexity of detecting multiple objects within an image, with potential occlusions and varying orientations. On the laboratory dataset, Vertex AI achieved 67.50% accuracy with perfect 1.0 precision and mAP@0.50, followed by Amazon Rekognition, mainly due to its robust mAP metrics, which maintained good performance across other metrics, although still falling short of Vertex AI's performance. Figure 4 visualizes these trends across all datasets and training set sizes, illustrating nonlinear performance patterns and platform-specific variations.

Influence of Training Dataset Size on Model Performance

Increasing training images generally improved model performance across all metrics, although improvements were nonlinear with platform-specific patterns. Table 2 illustrates these effects using the verification dataset, which, despite being captured under optimal conditions similar to training data, serves as a neutral baseline for comparing platform responses to increased training data because all models were trained and tested using the same datasets. Overall, YOLO11 and Custom Vision showed predictable linear improvement, with YOLO11's accuracy increasing from 63.06% to 80.83% and Microsoft Azure's from 77.08% to 85.62% as training data increased from 1230 to 26,880 images. Conversely, Amazon Rekognition and Vertex AI showed variable patterns with several fluctuations, suggesting dynamic model selection based on dataset characteristics, resulting in performance variations that do not follow the expected logarithmic improvement pattern with an eventual plateau typically seen in ML models. Notably, Vertex AI achieved near-optimal performance (94.37% accuracy, 1.0 precision, and 1.0 recall) with the smallest training subset at just 1230 images, though challenging clinical datasets required the full training set for acceptable performance.

Cost, Usability, and Limitations of AutoML Platforms

Several important pricing and usability differences exist between platforms. Vertex AI and Amazon Rekognition Custom Labels charge continuously for endpoint availability, accumulating costs in minute increments even during idle periods. In contrast, Custom Vision charges only per request, eliminating costs during idle periods. Vertex AI maintains consistent flat-rate pricing regardless of the dataset size, charging US $3.465 per hour for training and US $2.002 per hour for deployment and online prediction [32]. Amazon Rekognition Custom Labels charges US $1 per hour for training and US $4 per hour for inference, but scales training time and resources with dataset size, resulting in proportionally higher costs for larger datasets [33]. Custom Vision charges US $10 per hour for training, but allows users to specify computation time budgets, providing better cost control. Inference costs US $2 per 1000 individual requests [34]. While Google and Amazon have regional pricing variations, Azure maintains uniform US dollar pricing that is directly converted to local currencies. Each platform offers limited free tiers: Azure provides 1 hour of free training per month plus 10,000 predictions; Google provides US $300 in free credit for new customers and includes 30 minutes of free online predictions; Amazon offers 1 free inference hour per month during its 12-month free tier. YOLO11, being open-source, has no platform costs but requires local computational resources.

Training times varied considerably. YOLO11 training times scaled linearly with dataset size, from 38 minutes for the 1230-image training subset to nearly 13 hours for the full dataset. Microsoft Azure completed all training within 3 hours, even when allocated 4 - 5 hours, indicating that the cloud-based AutoML platform determined that additional training was unnecessary. Amazon Rekognition required the longest time, reaching nearly 40 hours for the full dataset. Vertex AI

XSL•FO
RenderX

maintained consistent 2.5 - 3-hour training times regardless of dataset size. Table 3 provides an overview of training times and associated costs for each platform.

Table . Training time and cost comparison across platforms.

Platform and training subset	Training time (hour:minute)	Training cost (US $)
Ultralytics YOLO11		
1230 images	00:38	<1

Performance on Edge Device

We evaluated Microsoft Azure and YOLO11 on a Raspberry Pi 5 using the exhaustive test set. Only these platforms were tested since Microsoft Azure alone provided downloadable Open Neural Network Exchange (ONNX) models for edge deployment. Table 4 shows a significant performance trade-off between edge and cloud-based inference.

Microsoft Azure's performance decreased on-device (25.83% accuracy) compared to cloud inference (33.61% accuracy). YOLO11 maintained better consistency, achieving 43.33% accuracy with ONNX and 44.10% with the native .pt format. Inference times differed substantially: Microsoft Azure ONNX achieved 0.19 seconds per prediction, while YOLO11 required 1.38 seconds per prediction in ONNX format on the Raspberry Pi 5.

Discussion

Principal Findings

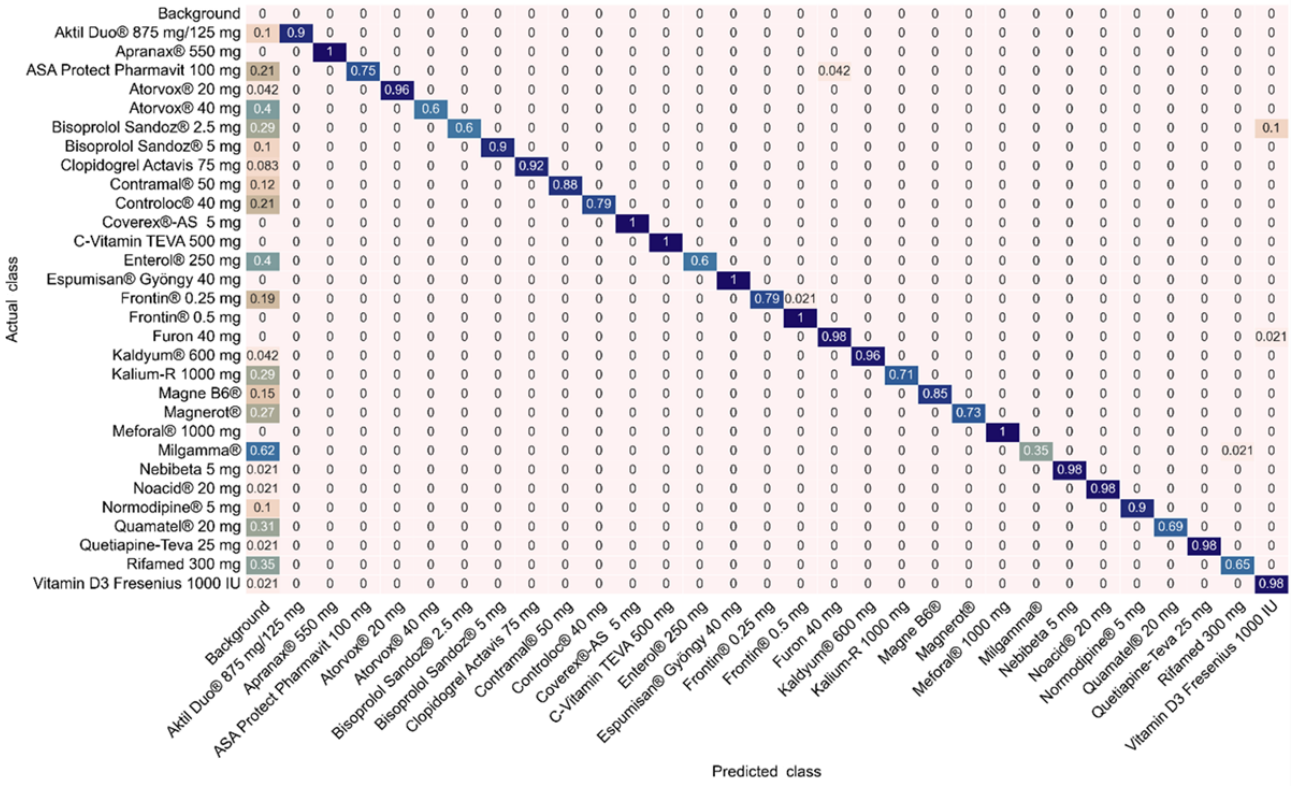
Our comprehensive evaluation of pill recognition models using code-based YOLO11 vs major code-free cloud-based AutoML platforms revealed that no single platform consistently outperforms others across all test scenarios, highlighting the importance of matching platform selection to specific deployment conditions and available training resources. The dramatic performance variations observed across clinical sites—for example, ranging from 20.62% accuracy (Amazon Rekognition) to 65.42% accuracy (Vertex AI) on the same clinical hospital dataset when both were trained on the full 26,880-image training dataset—demonstrate that imaging hardware, environmental, and personnel factors have a more tangible impact on model performance than platform choice alone.

Our results indicate that increasing the number of training images generally improves model performance across all metrics, although improvement patterns were not strictly linear and varied by platform, likely due to different underlying architectures and optimization strategies. Fair comparisons are challenging, especially for AutoML frameworks, which dynamically select the most suitable model architecture for each specific dataset and task. Consequently, different model types may be chosen (eg, a convolutional neural network in one instance and a vision transformer in another), even when trained on the same dataset.

Another critical finding is the substantial variation in how platforms balance the precision-recall trade-off across real-world clinical datasets. Amazon Rekognition's high precision across multiple clinical datasets often came at the cost of low recall, with values as low as 0.26 in one clinical dataset. This conservative approach resulted in the platform missing up to 74% of pills in the most challenging clinical dataset. Conversely, YOLO11's balanced precision-recall trade-off suggests suitability for scenarios where both false positives and false negatives carry clinical risk.

YOLO11 demonstrated the most consistent and predictable improvement trajectory with larger training datasets, achieving excellent mAP scores on most datasets, making it ideal for applications requiring precise object localization. The most dramatic improvement was observed on the most challenging clinical dataset, where accuracy increased from 22.71% to 64.58% and recall improved from 0.49 to 0.91. Consistently positive mAP trends across all datasets confirmed YOLO11's ability to effectively use additional training data.

Vertex AI presented more complex patterns. While generally improving with larger training datasets, performance fluctuations, including degradations, occurred in multiple instances with larger subsets. For instance, on the same clinical dataset, its accuracy dropped from 69.79% (1230-image training subset) to 57.08% (3450-image training subset), then recovered to 72.29% (7380-image training subset), dropped again to 62.08% (14,400-image training subset), and finally reached 71.04% (26,880-image full training dataset). This pattern likely reflects dynamic model architecture selection, where different model types are chosen for different dataset sizes. While resource-efficient, this behavior introduces unpredictability that could complicate training and deployment.



Custom Vision showed the most consistent behavior among cloud-based AutoML platforms, maintaining stable performance without degradation risks from model changes. Although Microsoft does not publicly disclose the model architecture used by Custom Vision, analyses of exported ONNX models suggest that the structure appears to be an older YOLOv2-based architecture, which would explain this consistency and the absence of architectural uncertainty we observed in other cloud-based AutoML platforms. Performance improvement trends paralleled YOLO11; however, the older architecture resulted in lower overall metrics.

Amazon Rekognition improved consistently with training data volume despite performing dynamic model selection during training. It demonstrated particularly strong performance on fully controlled datasets, especially in mAP values, with remarkable stability across IoU thresholds. Unlike other

XSL•FO
RenderX

platforms, it showed minimal degradation at the 0.50 IoU threshold and maintained strong performance on the challenging mAP@0.50 - 0.95 metric. It follows a conservative object detection strategy that prioritizes avoiding false positives, maintaining perfect precision (1.0) across multiple tests but with considerable false negative values indicative of missed detections, illustrated in the confusion matrix (Figure 5) with values listed in the background column. Analysis of confusion patterns revealed that the primary source of misclassification across all platforms was visual similarity among medications. Small, round, oblong, and oval white or off-white pills were most frequently confused with each other. Notably, these visually similar medications often represent therapeutically distinct drug classes (eg, beta-blockers, antiplatelet agents, and anxiolytics), where misidentification could have significant clinical consequences. Medications with distinctive visual characteristics, such as unique colors, shapes, or prominent surface markings, showed substantially lower misclassification rates across all platforms. The confusion matrices in Figure 5 and Multimedia Appendix 5 illustrate these visual and platform-specific confusion patterns in detail.

Figure 5. Confusion matrix showing Amazon Rekognition performance on the verification dataset (trained on the full training dataset of 26,880 images).

The cost-performance evaluation showed that although cloud-based AutoML platforms offer high accessibility, they also incur high platform costs, whereas traditional approaches, such as YOLO11, may provide comparable or better performance without platform costs. However, this does not account for the technical expertise required for YOLO11 implementation, which could offset the savings from platform costs. The primary cost consideration for YOLO11 implementation is human expertise rather than computational resources. Deployment requires proficiency in Linux system administration, Compute Unified Device Architecture, and CUDA Deep Neural Network library GPU driver configuration, Python programming, and deep learning frameworks such as PyTorch, typically representing senior AI and ML engineering expertise that substantially increases total implementation cost compared to the accessible web interfaces of cloud-based AutoML platforms. Our experiments used a workstation equipped with an NVIDIA Quadro RTX 5000 GPU, acquired for approximately US $3650 in 2021. The system consumes approximately 0.38 kW during training; consequently, the longest training run (approximately 13 hours) consumed an estimated 5 kWh of electricity, representing a negligible operational cost of less than US $1 at typical regional commercial electricity rates.

Among the cloud-based AutoML platforms, Vertex AI showed robustness with numerous comparative advantages, including high accuracy and F_1 performance values across various datasets, with relatively fast training time and good results on different training subsets, albeit with unpredictable fluctuations and significant cost barriers (higher flat-rate pricing and continued billing even when the endpoint is idle and the object detection model is not in use), which may limit its adoption in resource-constrained health care settings.

Limitations

The broader context of AI deployment in health care encompasses critical considerations beyond the scope of this study, including data security, privacy, and interoperability with existing hospital systems and protocols. Several limitations should be considered when interpreting our results. The dynamic model selection by cloud-based AutoML platforms prevented direct architectural comparisons, as different underlying models

XSL•FO
RenderX

were selected for different dataset sizes. Edge device testing was limited to Microsoft Azure and YOLO11, as other cloud-based AutoML platforms do not support ONNX model export. Performance metrics were evaluated at a conventional confidence threshold of 0.5, which may not be optimal for all platforms or deployment scenarios. The absence of CIs and formal statistical testing across hospital sites may be viewed as a limitation. However, the cloud-based AutoML platforms evaluated do not support the cross-validation procedures necessary for consistent variance estimation, and our study design prioritized assessment of the effects of real-world human and environmental factors on model performance. Several potential sources of bias should be considered when interpreting our results. The study was limited to 30 medications representing commonly dispensed products in Hungarian clinical settings, which does not encompass all possible visual characteristics encountered across different health care contexts or geographic regions. Performance may vary on larger medication databases, different medication types, and on medications with visual characteristics underrepresented in our dataset. While our clinical dataset was designed to assess real-world deployment challenges, it may confound interpretation of site-specific performance differences, as observed performance variations reflect the combined effects of platform capabilities and local imaging conditions rather than either factor in isolation. Collection of patient-based prescription images would face substantial ethical, regulatory, and practical barriers; therefore, in the creation of our clinical dataset, we used purposive sampling with balanced class representation to enable fair cross-platform comparison. While this approach is a standard methodology for ML benchmark studies and aligns with established datasets, it does not reflect natural prescription prevalence patterns. Future implementation studies should use representative sampling within appropriate ethical frameworks to validate model performance under authentic clinical workflow conditions.

Practical Implications

The substantial variation in performance observed across different clinical settings highlights the importance of environmental factors in model performance. The marked performance degradation observed in certain clinical settings indicates that local validation is essential before deployment.

When selecting platforms, users should consider each platform's unique characteristics, especially when working with smaller training datasets. YOLO11 offers competitive performance without platform costs and provides superior edge device compatibility for cost-sensitive applications requiring local processing. However, larger training datasets may be necessary for optimal performance. When evaluating the total cost of ownership, YOLO11's zero platform cost must be weighed against both hardware investment and the human capital required for implementation and ongoing maintenance after deployment. Consequently, cloud-based AutoML platforms, despite higher per-use costs, may prove more economical for some organizations and deployment scenarios. Vertex AI offers strong performance and ease of use despite higher costs, making it suitable for scenarios in which access to technical expertise is limited. Its fixed pricing model can be advantageous for situations requiring frequent processing of large volumes of images. Custom Vision and Amazon Rekognition are more economical for smaller-scale deployments, given their pricing structures. Custom Vision delivers predictable performance improvements, while Rekognition provides high-precision detection. Platform selection ultimately requires balancing technical requirements, budget constraints, and deployment scale to achieve optimal clinical pill recognition performance. For real-time point-of-care verification, response times below 2‐3 seconds generally integrate well into verification workflows without causing perceptible delays that could reduce productivity, introduce operator fatigue, or disrupt routine workflow rhythm. All prediction times observed in our study fall within this acceptable range, suggesting that computational speed is unlikely to be a limiting factor for any of the evaluated platforms.

The clinical implications of different error types warrant careful consideration for deployment planning. Missed detections and misidentifications pose a significant risk if undetected, potentially leading to missed therapeutic effects, unexpected adverse events, or dangerous drug interactions. Our findings reinforce the necessity of manual verification during clinical workflows for maintaining safety. Automated dispensing and verification systems should augment rather than replace pharmacist verification, with particular vigilance required for medications exhibiting high visual similarity to other products in the hospital formulary.

Conclusions

This study provides the first comprehensive comparison of a traditional code-based model and cloud-based AutoML approaches for pill recognition model training intended to be used in clinical settings. While no single platform dominated across all test scenarios, each demonstrated distinct advantages for specific use cases. YOLO11 proved reliable for model development and training due to its flexibility, cost-effectiveness, and edge deployment capabilities. Vertex AI delivered a strong overall performance with minimal technical expertise required. The substantial performance differences (20.62%-91.60% difference in accuracy) observed across UCTS underscore the critical importance of imaging conditions and the value of rigorous validation for real-world applications.

Platform selection for pill recognition should consider (1) available technical expertise and resources, (2) deployment environment characteristics, (3) budget constraints, and (4) edge deployment requirements. Future research should explore performance on larger medication databases and develop standardized imaging protocols to achieve consistent results for training pill recognition systems. As both traditional deep learning frameworks and cloud-based AutoML platforms continue to evolve, periodic systematic evaluation of these technologies using existing pill image datasets could provide valuable insights into how these technologies can be used to improve medication safety through automated verification systems.

Abstract

Background: Multimorbidity has become a major global public health challenge. However, existing research primarily emphasizes the identification of disease patterns at the population level and lacks the capacity to provide predictive insights into individual future pattern membership. Bridging this gap is crucial for personalized prevention and management.

Objective: This study aims to propose an innovative framework that integrates population-level multimorbidity pattern recognition with individual-level predictive modeling, thus advancing multimorbidity research from descriptive analysis to prospective multimorbidity pattern prediction.

Methods: Using longitudinal health follow-up data, we first applied latent transition analysis (LTA) to identify temporally stable multimorbidity patterns. These patterns were subsequently transformed into predictive labels to construct a novel deep learning model, CLA-Net (Cross-Lag Attention Network). CLA-Net is designed to predict individual future multimorbidity patterns by leveraging the complementary strengths of Gated Recurrent Units (GRU) and transformer architectures. It introduces a bitemporal directed cross-attention mechanism to simultaneously capture temporal dependencies and complex feature interactions. We compared CLA-Net against several advanced baselines and conducted ablation studies to validate its architectural components.

Results: In terms of pattern recognition, the LTA identified 5 clinically meaningful multimorbidity patterns: Cardiometabolic-Multisystem, Hypertension-Arthritis, Respiratory-Musculoskeletal, Metabolic Syndrome, and Gastritis-Arthritis. In terms of prediction, experimental results demonstrated that CLA-Net significantly outperformed all baseline models. CLA-Net achieved an accuracy of 0.8352 (SD 0.0048), a precision of 0.8326 (SD 0.0053), a recall of 0.8312 (SD 0.0056), and an F_1-score of 0.8319 (SD 0.0051). Notably, it achieved an area under the curve of 0.9293, surpassing baseline models. Ablation studies confirmed the necessity of the dual-branch architecture and the directed cross-attention mechanism, as removing these components resulted in performance declines ranging from 0.93% to 2.50%.

Conclusions: This study extends the scope of LTA beyond descriptive statistical modeling and establishes the scientific value of multimorbidity pattern prediction as an independent research task. By bridging population-level insights with individual-level prediction, the proposed framework provides a data-driven tool for the prospective prediction of future multimorbidity pattern membership conditional on survival, thereby supporting stratified disease management and care planning, rather than general risk stratification for acute or end-stage deterioration. This offers new methodological and practical value for precision medicine and public health policymaking.

KEYWORDS

multimorbidity; latent transition analysis; LTA; deep learning; population-level patterns; personalized medicine

Introduction

Multimorbidity, commonly defined as the coexistence of 2 or more chronic conditions within a single individual [1], has emerged as one of the most pressing public health challenges of the 21st century amid the accelerating global trend of population aging [2]. Worldwide, approximately one-third of adults have 2 or more chronic diseases, and the proportion exceeds 50% among individuals aged 60 years and older [3]. Multimorbidity not only substantially increases health care resource consumption and imposes a heavy burden on health systems, but also severely compromises patients' quality of life, leading to a markedly higher risk of functional disability and

XSL•FO
RenderX

premature mortality, thereby greatly increasing the complexity of chronic disease management and clinical decision-making [4,5]. Previous studies have demonstrated that the co-occurrence of chronic diseases is not a random phenomenon but tends to manifest as distinct multimorbidity patterns, in which specific combinations of diseases frequently occur in particular populations [6,7]. This suggests the potential existence of shared pathophysiological mechanisms, risk factors, or lifestyle determinants underlying these patterns [8]. Therefore, systematically identifying, understanding, and predicting these multimorbidity patterns holds strategic importance for the early detection of high-risk individuals, the advancement of precision medicine, and the optimization of health care resource allocation [9,10].

Although various methods for identifying multimorbidity patterns have been proposed, such as factor analysis, cluster analysis, latent class analysis (LCA), and network analysis [11-15], they share significant limitations and fall short of meeting the clinical demand for personalized and prospective management. First, most approaches group populations primarily based on disease prevalence or epidemiological characteristics, assuming homogeneity within groups while overlooking the inherent heterogeneity among individuals [14,16]. Such population-level stratification can facilitate the identification of common multimorbidity patterns at a macrolevel but fails to uncover microlevel differences within patterns, which is particularly inadequate for supporting fine-grained individualized management in clinical practice. In reality, even among patients belonging to the same multimorbidity pattern, disease trajectories may differ substantially. For example, some patients experience slow progression and remain stable over a long period, whereas others may rapidly develop multisystem dysfunction [17]. Neglecting such heterogeneity may directly result in biased risk assessments and inefficient resource allocation, thereby severely constraining the practical implementation of precision medicine. In addition, existing studies have mainly focused on static multimorbidity pattern mining [16,18], and the methods used often struggle to maintain consistency of pattern meanings in longitudinal data. This instability not only reduces the comparability of research findings but also weakens the ability to capture disease progression, thereby limiting the clinical interpretability and practical value of the conclusions.

To address the above challenges, latent transition analysis (LTA), a longitudinal latent variable model, has been introduced into health research. LTA can identify stable latent health states across multiple time points and ensure their consistency and comparability over time [19]. Compared to other longitudinal modeling approaches, LTA offers distinct advantages for identifying multimorbidity evolution. Unlike growth mixed models or latent growth curve models, which primarily characterize continuous trajectories of a single variable (eg, functional decline over time), LTA is specifically designed to model transitions between discrete, qualitative latent statuses, aligning perfectly with the categorical nature of multimorbidity patterns. Furthermore, in contrast to standard Markov chain models that rely on observed states, LTA separates measurement error from true structural transitions by inferring latent classes from multiple observed indicators, thereby ensuring more robust and clinically meaningful pattern identification. By modeling follow-up data, LTA can effectively capture heterogeneity within populations and provide new perspectives for understanding the dynamic evolution of multimorbidity patterns [20,21]. However, LTA is essentially a descriptive statistical method, with its primary focus on identifying and summarizing patterns from historical or current data, while lacking the capacity to predict individual future health states. This limitation hinders its ability to meet urgent clinical needs, such as providing precise early warnings for high-risk individuals, developing timely intervention strategies, and guiding personalized treatment planning. Therefore, constructing predictive models that can accurately forecast individuals' future multimorbidity patterns carries substantial clinical value and practical significance.

Predicting individual future multimorbidity patterns requires accounting for both the temporal evolution of health states and the complex interactions among multidimensional health features. On the one hand, the progression of chronic diseases exhibits marked and highly nonlinear temporal dependencies. A patient's current health status not only reflects their immediate physiological condition but also embodies the evolution from the previous health state, reflecting the staged characteristics of disease progression [22]. Ignoring such sequential state transitions weakens a model's ability to capture disease progression trends, thereby limiting its capacity to deliver reliable forward-looking predictions. On the other hand, multidimensional health features, including lifestyle factors, preexisting conditions, and functional indicators, are interconnected through intricate nonlinear couplings and synergistic effects. These dynamic interactions drive the formation and evolution of multimorbidity patterns [23]. Many conventional statistical methods, such as logistic regression, support vector machines, random forests, gradient boosting trees, and k-nearest neighbors (KNN), perform well in modeling static feature associations [24,25]. However, when confronted with high-dimensional, nonlinear, and temporally dependent medical data, their modeling capacity is limited, making it difficult to simultaneously capture nonlinear state transitions and deep couplings among features. Therefore, there is an urgent need to develop a model that overcomes these limitations by effectively integrating sequential health state changes and feature coupling effects in longitudinal data, thus enabling precise and prospective prediction of individual future multimorbidity patterns and providing robust data support for clinical decision-making.

Based on the above discussion, this study proposes an innovative framework that integrates population-level multimorbidity pattern recognition with precise prediction of individual future states, thereby advancing multimorbidity research from macrolevel description to prospective application. Specifically, the framework first uses LTA to identify population-level multimorbidity patterns with temporal consistency and clinical stability from longitudinal follow-up data, and then transforms these patterns into individual predictive labels. On this basis, we designed the Cross-Lag Attention Network (CLA-Net), which leverages immediate longitudinal context to model

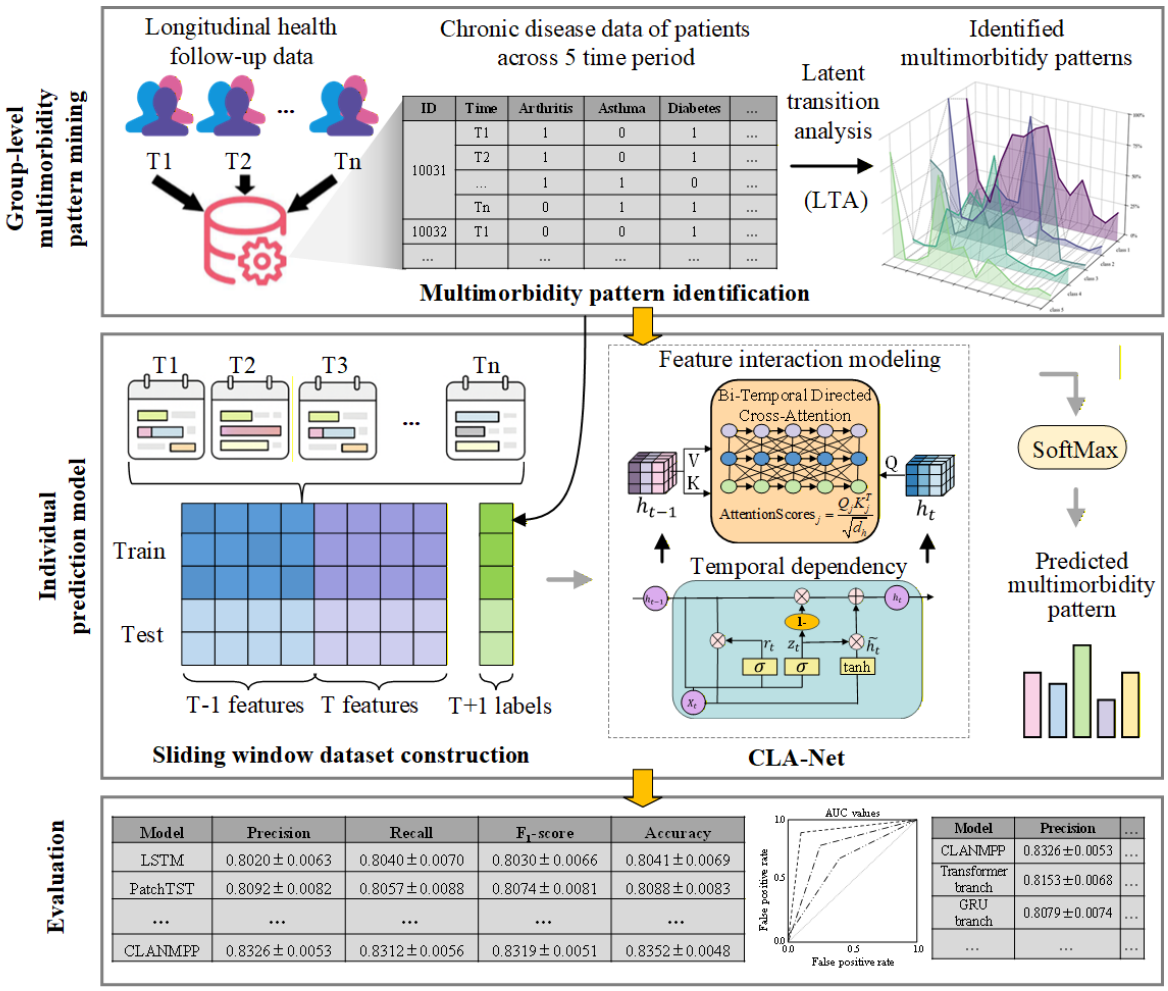
XSL•FO
RenderX

short-term, nonlinear state transitions and complex feature interactions among health variables, thereby enabling accurate prediction of individual future multimorbidity patterns.

The contributions of this study can be summarized in 3 aspects. First, we propose a novel cross-paradigm framework that bridges a statistical latent-variable modeling approach with deep representation learning for longitudinal multimorbidity research. Specifically, population-level multimorbidity patterns identified through LTA are leveraged as clinically interpretable supervisory signals for individual-level prediction. By integrating latent structure discovery with prospective modeling, this framework overcomes the limitation of traditional multimorbidity studies that are largely restricted to retrospective pattern characterization and establishes multimorbidity pattern prediction as a distinct and clinically meaningful research task.

Second, we propose a novel hybrid neural network architecture, CLA-Net, for multimorbidity pattern prediction. CLA-Net integrates the inherent strength of Gated Recurrent Units (GRU) in efficiently modeling short-term, nonlinear state transitions with the powerful representational capacity of the transformer architecture in capturing complex feature interactions. This design surpasses the capacity of traditional linear models, enabling deep modeling of the intricate couplings within medical data. Furthermore, CLA-Net incorporates a bitemporal directed cross-attention mechanism, which establishes directional information channels between the preceding and current health states. This mechanism facilitates feature extraction across time steps and dynamic association modeling, allowing the network to simultaneously perceive and effectively integrate dynamic state changes and feature coupling effects within complex longitudinal medical data.

Third, the experimental results demonstrate that the proposed CLA-Net model significantly outperforms other mainstream baseline models. Further ablation studies confirm that the synergistic integration of GRU and transformer, together with the bitemporal directed cross-attention mechanism, is the key factor driving the performance improvement. These findings not only provide strong evidence for the superiority of CLA-Net and the soundness of its design but also offer new insights and paradigms for model development in the field of multimorbidity pattern prediction.



Methods

Overview

We designed a novel research framework that integrates multimorbidity pattern recognition with individualized prediction. The overarching idea is to first identify population-level latent multimorbidity patterns with temporal consistency from longitudinal health data, and then build a deep learning model to predict each individual's future pattern membership, thereby establishing a unified framework that bridges population-level recognition and individual-level prediction. As illustrated in Figure 1, the proposed framework consists of 3 stages. In the first stage, LTA is applied to longitudinal health records to identify latent multimorbidity patterns at the population level, ensuring that these patterns maintain consistent clinical meaning and comparability across different time points, thus providing a stable and reliable label basis for subsequent individual prediction tasks. In the second stage, based on the LTA-derived pattern labels, we design and construct the CLA-Net, which integrates temporal dependencies and complex feature interactions to enable accurate prediction of individual future pattern membership. In the third stage, we conduct a comprehensive performance evaluation and validation of the prediction model.

Multimorbidity Pattern Identification

This study used SAS 9.4 (SAS Institute) to apply LTA for identifying the latent class structures of population-level multimorbidity patterns across 5 waves of China Health and Retirement Longitudinal Study (CHARLS) data. LTA is a longitudinal analytic method based on finite mixture models, which can detect unobserved health subgroups (latent statuses) within the sample across multiple time points. By imposing measurement invariance constraints, LTA ensures temporal consistency and stability of the latent classes [20], thereby guaranteeing that the identified classes maintain comparable and clinically meaningful interpretations across different time points. This provides stable and reliable classification labels for subsequent individual prediction modeling tasks. To control classification error and enhance model stability, we adopted a 2-step analytic strategy [26]. The detailed procedure is as follows: in step 1, we first conducted LCA separately at each time point to explore the optimal number of latent class partitions. In the model specification process, we considered different numbers of latent classes (ranging from 2 to 6) [26]. Model fit was evaluated using the Akaike Information Criterion (AIC), Bayesian Information Criterion (BIC), sample-size adjusted BIC (SaBIC), and entropy, to determine the optimal class solution.

Specifically, the AIC balances model fit and complexity, with smaller values indicating better fit [27]. The BIC adds a penalty for sample size, favoring more parsimonious models and thus being more conservative in class determination, particularly in large samples [28]. The SaBIC further adjusts BIC for sample size, offering greater robustness in large-sample contexts [29]. Entropy (ranging from 0 to 1) measures the certainty of individual classification, with values above 0.80 generally indicating high classification accuracy [30]. In addition, we used the Bootstrap Likelihood Ratio Test (BLRT) to compare log-likelihood differences between adjacent class models, in order to assess whether adding an extra class significantly improves model fit [31,32].

In step 2, after determining the optimal number of classes, we conducted chi-square tests on the log-likelihood values of each model [31] and performed invariance testing of class structures across different measurement time points, in order to verify whether the meanings of multimorbidity classes remained consistent over time [31]. This step is a critical prerequisite for ensuring that classes retain the same interpretive meaning across time points, thereby enhancing the interpretability and stability of the model [33].

In this study, LTA is used as a population-level structure discovery tool to identify clinically stable multimorbidity phenotypes, rather than as a component optimized for

XSL•FO
RenderX

downstream predictive performance. The primary objective of LTA in our framework is to define a consistent and interpretable latent outcome space that reflects the underlying disease co-occurrence structure at the population level. Accordingly, LTA was estimated using the full longitudinal dataset across all available survey waves to maximize phenotype stability and clinical interpretability by leveraging the complete temporal information within the observed follow-up window. Within this 5-wave longitudinal design, the use of all waves enables the identified latent classes and transition patterns to reflect the evolution of multimorbidity structures across the entire observed period, rather than being driven by partial or wave-specific information. This design choice allows the latent class definitions to be less sensitive to sampling variability across individual waves and ensures that the resulting multimorbidity patterns are representative of the population dynamics observed within the study timeframe, rather than tailored to a specific subsample.

Proposed CLA-Net Framework

Multimorbidity Pattern Prediction Dataset

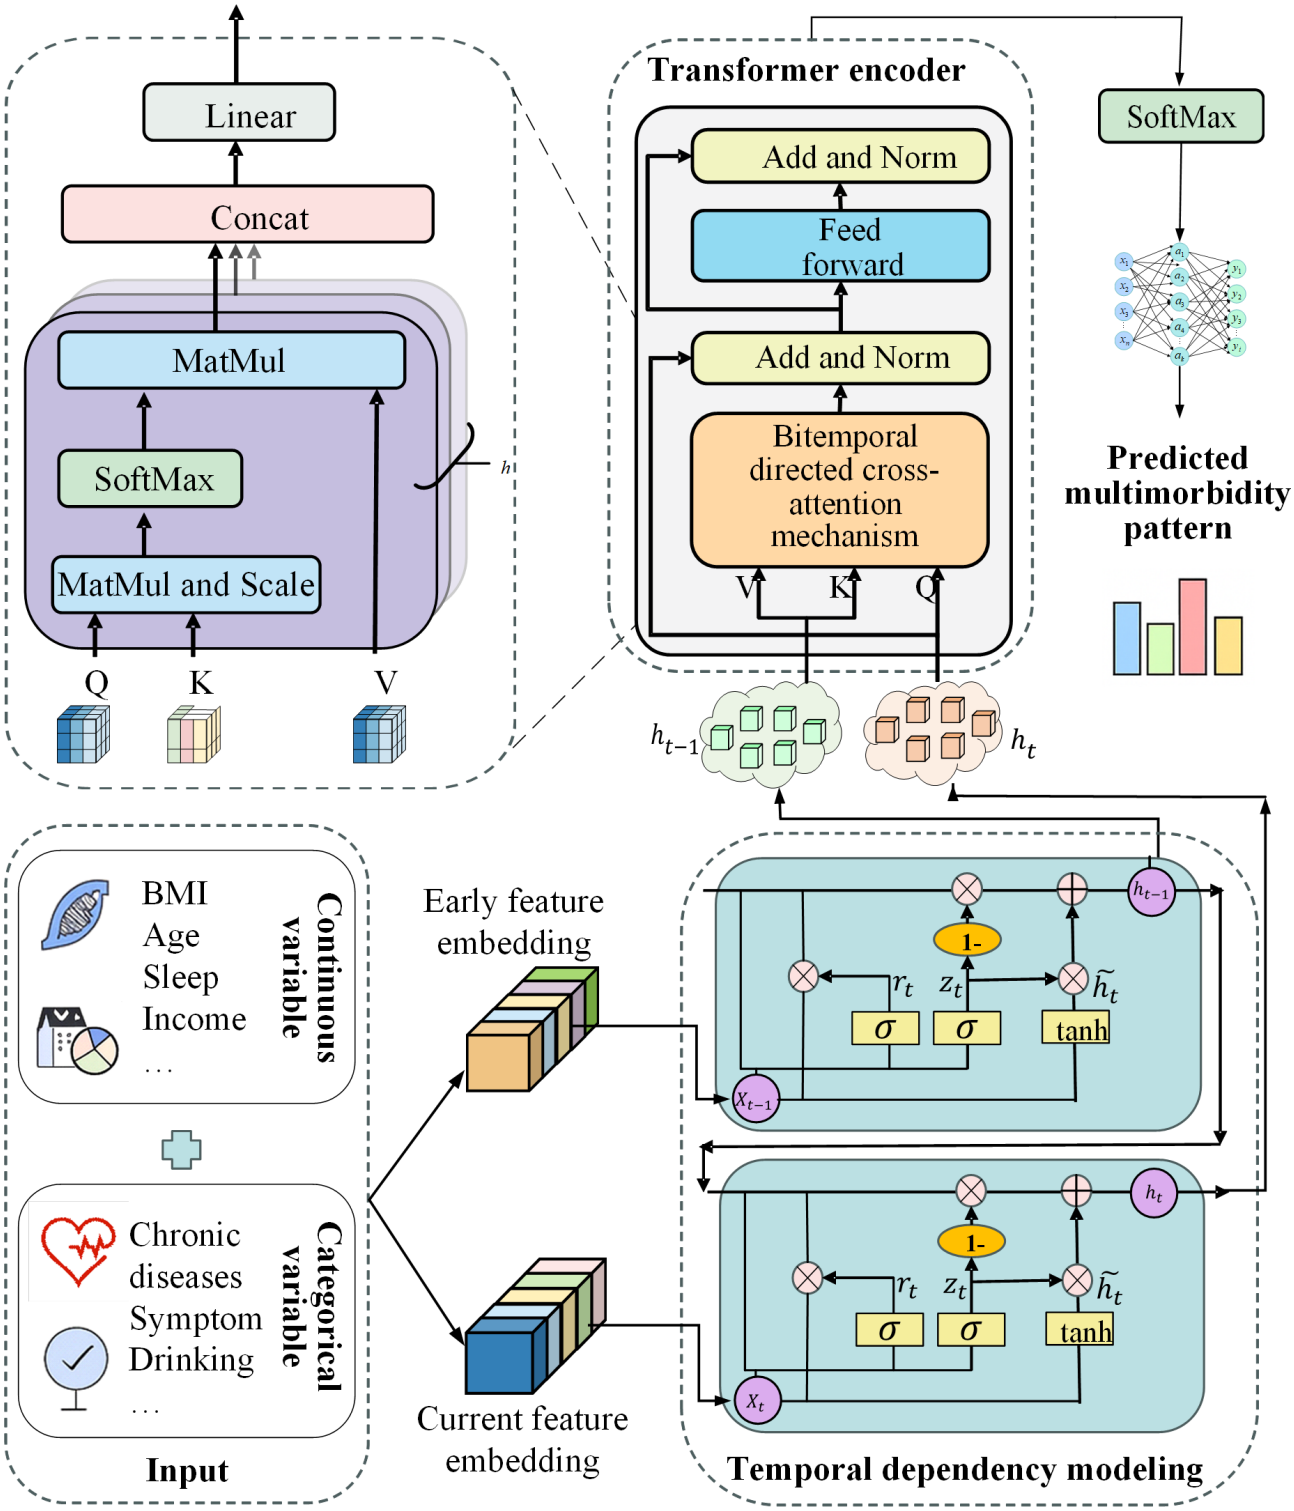
This study constructed a task-oriented dataset for prospective prediction of multimorbidity patterns based on the CHARLS, a nationally representative longitudinal survey in China. To bridge the gap between population-level pattern discovery and individual-level prediction, we constructed a supervised learning task using LTA-derived latent classes as predictive targets. Since LTA is a probabilistic model, it outputs the posterior probability of an individual belonging to each latent class rather than a deterministic category. To transform these probabilistic outputs into deterministic prediction labels for CLA-Net, we used a maximum posterior probability assignment strategy. Specifically, for each individual n at time step t, the LTA model calculates a posterior probability vector $\boldsymbol{P}_{n,t} = [p_1, p_2,\ldots, p_K]$, where K is the number of latent patterns. The ground truth label $y_{n,t}$ is assigned to the class with the highest probability:

$$(1)\text{yn,t=arg maxk}\in\{1,...,\text{K}\}(\text{Pn,t(k)})$$

These deterministic labels ($y_{n,t}$) serve as the supervisory signals (ground truth) for training the CLA-Net.

We used 2 consecutive follow-up waves as the input window to predict the multimorbidity pattern at the subsequent wave. In CHARLS, the intervals between survey waves are 2‐3 years, which align with the slow evolution and long-term accumulation process of chronic diseases. Although the intervals vary slightly, the progression of chronic conditions is characterized by slow variables (ie, gradual progression, stable trends, and limited abrupt changes), making 2‐3 years sufficient to capture substantial changes in individual health status while reducing noise from short-term fluctuations. This temporal span is clinically reasonable for modeling chronic disease progression. According to the study objectives, we reorganized the raw data using a sliding-window approach to construct 3 temporally progressive subdatasets, each corresponding to a "past–current → future" window structure:

- Subdataset 1: 2011 features as early input ($\mathbf{x}_{t-1}$), 2013 features as current input ($\mathbf{x}_t$), and 2015 LTA-derived multimorbidity patterns as prediction labels (y_{t+1})
- Subdataset 2: 2013 features as ($\mathbf{x}_{t-1}$), 2015 features as ($\mathbf{x}_t$), and 2018 multimorbidity patterns as (y_{t+1})
- Subdataset 3: 2015 features as ($\mathbf{x}_{t-1}$), 2018 features as ($\mathbf{x}_t$), and 2020 multimorbidity patterns as (y_{t+1})



The 3 subdatasets were concatenated by rows to form a unified prediction dataset, structured as triplets ($\mathbf{x}_{t-1}$,$\mathbf{x}_t$, y_{t+1}), where $\mathbf{x}_{t-1}$ and $\mathbf{x}_t$ represent feature vectors from 2 consecutive time points, and y_{t+1} denotes the LTA-identified future multimorbidity pattern label. This construction preserves the natural temporal evolution of disease states without relying on long-sequence assumptions, while effectively augmenting the training data. It enables the model to learn multistage health state transitions within the same population, thereby providing a robust data foundation for subsequent individual-level prospective prediction.

Overview of the Model Architecture

This study proposes an innovative deep learning model, named the CLA-Net. CLA-Net integrates the sequential state encoding capability of GRU with the global feature interaction advantages of an improved transformer architecture, enabling fine-grained cross-time feature interactions through a bitemporal directed cross-attention mechanism. The model is composed of 4 core modules: an input embedding layer, a temporal GRU encoder, a transformer encoding layer based on the bitemporal directed cross-attention mechanism, and a classifier layer. An overview of the model architecture is shown in Figure 2.

XSL•FO
RenderX

Figure 2. The architecture of the Cross-Lag Attention Network.

Components of CLA-Net

Feature Embedding Layer

The input features include continuous variables (eg, biomarkers and cognitive scores) and binary indicator variables (eg, disease diagnoses and medication use). Socioeconomic variables, including total household income and per capita household consumption, were inspected for extreme values prior to normalization. Given the heavy-tailed distributions of these variables, a percentile-based outlier handling strategy was applied to mitigate the undue influence of extreme observations while preserving the original scale of the data. Min-max normalization was then used to rescale these variables to a common range, ensuring numerical stability and consistency with the scaling of other continuous inputs used in the model. Binary features were kept unchanged. Subsequently, heterogeneous features are mapped into a unified representation space through learnable linear transformations:

(2)Xt−1Wext−1+be∈ Rd

(3)Xt=WeXt+be∈ Rd

XSL•FO
RenderX

where xt∈ RD denotes the raw input features, Xt∈ Rddenotes the embedded representation, We∈ Rd×Dand be∈ Rdare shared parameters, *D* denotes the input dimension, and *d* represents the hidden space dimension.

Temporal GRU Encoder

After feature embedding, the representations of features from the earlier time point ($\mathbf{X}_{t-1}$) and the current time point ($\mathbf{X}_t$) are concatenated into a 2-step sequence, which is then fed into a GRU for temporal modeling. Through the update mechanism of its hidden states, the GRU efficiently captures the sequential evolution of the disease process, ensuring that the nonlinear dynamics of health state transitions are explicitly modeled. This design enables the network to capture the critical short-term progression from *t*–1 to *t* and to explicitly model the nonlinear dynamics underlying near-term health state transitions.

(4)ht−1=GRU(Xt−1,hinit)

(5)ht=GRU(Xt,ht−1)

where $\mathbf{h}_{init}$ denotes the initial hidden state, and $\mathbf{h}_{t-1}$ and $\mathbf{h}_t$ represent the hidden state outputs at the 2 time steps. The internal computational mechanism of the GRU is defined as follows:

(6)rt=σ(WrXt+Urht−1+br)

(7)zt=σ(WzXt+Uzht−1+bz)

(8)h~t=tanh (WhXt+Uh(rt⊙ht−1)+bh)

(9)ht=(1−zt)⊙ht−1+zt⊙h~t

Here, $\mathbf{X}_t$ denotes the input at time step *t*. $\mathbf{r}_t$ is the reset gate, which controls how much information from the previous time step is retained. $\mathbf{z}_t$ is the update gate, which determines the proportion of information to be updated at the current time step. ht~ represents the candidate's hidden state. σis the sigmoid activation function, and ⊙ denotes elementwise multiplication. $\mathbf{W}_*$ and $\mathbf{U}_*$ are learnable weight matrices, and $\mathbf{b}_*$ is the bias vector.

Transformer Encoding Layer

Bitemporal Directed Cross-Attention Mechanism

Although GRUs are effective at encoding immediate longitudinal context via gated state updates, they have limited capacity to explicitly characterize fine-grained interactions among heterogeneous features, especially when the predictive signal arises from short-term, nonlinear state transitions rather than long-range history. In our setting, an individual's future multimorbidity pattern is shaped not only by the recent state representation but also by complex cross-feature influences that operate across adjacent time points. To address this, we adopt an asymmetric attention paradigm, in which features from the current time point are used as the query vector **Q**, while features from the earlier time point serve as the keys (**K**) and values (**V**) in the attention computation, enabling the model to attend to historical representations when updating the current state. This design reflects the directional interactions between features across time. For each attention head $j \in \{1,...,H\}$, the GRU outputs are first projected into the **Q**, **K**, and **V** spaces:

(10){Qj=htWQ(j)Kj=ht−1WK(j)Vj=ht−1WV(j)

where Q_j, K_j, and V_j denote the query, key, and value representations of the *j*th attention head, which are vector-valued representations derived from the input hidden states. WQ(j), WK(j), WV(j)∈ Rd×dh denotes the projection matrix of the *j*th head, *d* is the input dimension, and $d_h=d/H$ is the dimension of each attention head. The attention scores are computed using scaled dot-product attention:

(11)Attention scoresj=QjKjTdh

The scaling factor 1/dh is critical for maintaining gradient stability. Without scaling, the dot-product values increase with feature dimensionality, which may push the SoftMax function into regions with extremely small gradients. The computation for each attention head is defined as

(12)headj=Attention(Qj,Kj,Vj)=SoftMax (QjKjTdh)Vj

After concatenating the outputs of all attention heads, a linear transformation is applied to obtain the multi-head cross-attention output:

(13)MultiHeadCrossAttn(ht−1,ht)=Concat(head1,…,headH)Wo

where $\mathbf{W}_O$ denotes the output projection matrix. Through the multihead mechanism, the model can learn distinct attention patterns in different representation subspaces, allowing it to attend to diverse types of feature relationships simultaneously and thereby enhancing its expressive capacity.

Stacked Transformer Encoder Architecture

To capture the hierarchical patterns of disease progression, we use a stack of *L* transformer encoder layers. Each layer builds upon the representations from the previous one, thereby progressively modeling more complex temporal dependencies. Each layer, $l \in \{1,..,L\}$ consists of 2 sublayers with residual connections. Specifically, Equation 14 corresponds to the bitemporal directed cross-attention mechanism sublayer, while Equation 15 represents the positionwise feed-forward network (FFN) sublayer:

(14)z^(l′)=LayerNorm(z(l−1)+Dropout(MultiHeadCrossAttn(ht−1,z(l−1))))

(15)z(l)=LayerNorm (z^(l)+Dropout(FFN(z^(l))))

Here, the positionwise FFN uses the ReLU activation function and incorporates dropout to prevent overfitting, defined as

(16)FFN(x)=ReLU(xW1+b1)W2+b2

where $\mathbf{W}_1$ is the weight matrix of the first feed-forward layer, which expands the feature dimension by a factor of 4 to enhance nonlinear representational capacity. $\mathbf{W}_2$ is the weight matrix of the second feed-forward layer, which projects the expanded dimension back to the original size *d*. $\mathbf{b}_1$ and $\mathbf{b}_2$ denote the bias vectors for the first and second layers, respectively. After passing through *L* stacked layers, we obtain the final fused representation $\mathbf{z}^{(L)}$, which simultaneously encodes early and later temporal information of patients and is further enriched through direct cross-time feature interactions.

Classifier Layer

The fused features $\mathbf{z}^{(L)}$ output by the transformer encoder are fed into a 2-layer fully connected neural network as the classifier. This classifier consists of a linear layer, a ReLU

XSL•FO
RenderX

activation function, a dropout layer, and a final linear output layer, which maps the fused features into probability distributions over multimorbidity patterns.

First Layer: Linear Mapping and Nonlinear Activation

The first layer of the classifier consists of a linear mapping followed by a nonlinear activation function. This step is crucial for transforming the fused features into a more complex representation. The output of this layer is computed as follows:

(17)o=ReLU (z(L)W1(c)+b1(c))

where W1(c)∈ Rd×d and b1(c)∈ Rd are the weight matrix and bias vector of the first layer, respectively, and ReLU denotes the activation function. A dropout regularization is applied after this layer to reduce the risk of overfitting.

Second Layer: Output Mapping

The second layer of the classifier maps the transformed features to output logits, representing the class scores. This layer computes the logits as follows:

(18)ylogits=o W2(c)+b2(c)

where W2(c)∈ Rd×C and b2(c)∈ RC represent the weight matrix and bias vector of the second layer, respectively, and *C* denotes the number of output classes. The final prediction $\mathbf{y}_{\text{logits}}$ is obtained by applying the SoftMax function to transform the outputs into probabilities:

(19)y^=SoftMax(ylogits)=exp (ylogits, c)∑c′=1Cexp (ylogits, c′)

Loss Function

We trained the model using the standard cross-entropy loss function for multiclass, single-label classification. Based on the predicted probability distribution y^ output by the classifier, the cross-entropy loss is defined as

(20)L=−1N∑i=1N∑c=1Cyi(c)log (y^i(c))

where *C* denotes the number of classes, yi(c)is the one-hot encoded true label of the *i*th sample for class *c*, and yi(c)represents the predicted probability that the *i*th sample belongs to class *c*. The objective is to minimize the average loss across all training samples. Cross-entropy is particularly suitable for our multiclass single-label task because it encourages the network to assign high probability to the correct class while penalizing confident but incorrect predictions. Since the dataset has a relatively balanced class distribution, no class weighting was applied in the loss function. The use of SoftMax outputs with cross-entropy is equivalent to maximizing the likelihood of the correct class and is a standard choice for neural network classifiers.

Training Configuration and Implementation Details

All experiments were conducted using PyTorch v1.7.0 (Facebook AI Research, Meta Platforms) and Python 3.8 (Python Software Foundation) on Ubuntu 18.04 (Canonical Ltd), with an NVIDIA RTX 4090 GPU (24 GB memory) and 32 GB RAM (CUDA 11.0). The proposed model and all baselines were trained under identical configurations and hyperparameters (Table 1). The main settings were 60 training epochs, mini-batch size of 64, embedding and GRU hidden dimensions set to 128, Adam optimizer with a learning rate of 0.0001 (determined via grid search), cross-entropy loss, and a dropout rate of 0.3 applied to both transformer layers and the classifier. Model weights were initialized using PyTorch defaults. During data preprocessing, feature normalization was fitted only on the training set and then applied to the validation and test sets. The dataset was partitioned into 80% training and 20% testing sets using a subject-wise splitting strategy based on unique individual identifiers. This approach ensures that all

XSL•FO
RenderX

longitudinal observations from the same participant were assigned exclusively to a single subset, thereby preventing potential data leakage. From the training set, 20% (n/N) of the individuals were further held out as a validation set. During training, the macro-F_1-score on the validation set was used as the criterion for early stopping and model selection. Only the best-performing model on the validation set was retained, and a final evaluation was conducted on the independent test set.

Table . Training hyperparameters.

Parameters or hyperparameters	Value
Epoch	60
Learning rate	0.0001
Dropout	0.3
Random seed	42
Batch size	64
Hidden dimension	128

Evaluation Metrics

To evaluate the performance of the model in the multiclass classification task, we used commonly used metrics, including accuracy, precision, recall, and F_1-score, and reported their macroaveraged values. Macroaveraging assigns equal weight to each class, thereby avoiding the bias of microaveraging, which tends to favor majority classes in imbalanced datasets. This provides a more comprehensive and balanced assessment of the model's ability to identify all 5 multimorbidity patterns. The formulas for these evaluation metrics are as follows:

$$\text{Accuracy}=\sum_{c=1}^{C}TP_c\Big/\sum_{c=1}^{C}(TP_c+FP_c+FN_c+TN_c) \quad (21)$$

$$\text{Precision}_c=TP_c/(TP_c+FP_c) \quad (22)$$

$$\text{Recall}_c=TP_c/(TP_c+FN_c) \quad (23)$$

$$F1=2\times\text{Precision}_c\times\text{Recall}_c/(\text{Precision}_c+\text{Recall}_c) \quad (24)$$

where TP_c, FP_c, FN_c, and TN_c denote the true positives, false positives, false negatives, and true negatives for class c, respectively. Accuracy represents the proportion of correctly predicted samples to the total number of samples. Precision measures the proportion of samples predicted as a given class that actually belong to that class. Recall indicates the proportion of samples that are correctly identified among those that truly belong to a given class. The F_1-score, defined as the harmonic mean of precision and recall, provides a balanced measure of the model's classification performance for a given class. Macroaveraging is obtained by taking the arithmetic mean of the metric values across all classes. The formulas are defined as follows:

$$\text{Macro-Precision}=\frac{1}{C}\sum_{c=1}^{C}\text{Precision}_c,\ \text{Macro-Recall}=\frac{1}{C}\sum_{c=1}^{C}\text{Recall}_c,\ \text{Macro-F1}=\frac{1}{C}\sum_{c=1}^{C}F1_c \quad (25)$$

In addition, we further introduced the receiver operating characteristic (ROC) curve and the area under the curve (AUC) as complementary evaluation metrics. While accuracy focuses on the correctness of class predictions, AUC assesses the ranking quality of predicted probabilities. Particularly in multiclass problems, a higher macroaveraged AUC together with higher accuracy provides stronger evidence that the model can achieve good discrimination across all classes, rather than merely benefiting from class size distributions. The ROC curve is plotted with the false positive rate (FPR) on the x-axis and the true positive rate (TPR) on the y-axis and is mathematically defined as:

$$\text{FPR}=FP/(FP+TN),\ \text{TPR}=TP/(TP+FN) \quad (26)$$

AUC measures the overall discriminative ability of a model, with values ranging from 0 to 1, where values closer to 1 indicate stronger separation between positive and negative classes. Commonly, AUC >0.9 is considered excellent, 0.8‐0.9 good, 0.7‐0.8 acceptable, and <0.7 poor. For multiclass prediction, we adopted a one-vs-rest strategy, treating each class as positive against all others to compute class-specific ROC curves and AUC values. To validate the effectiveness of the proposed model, we compared it with multiple baselines under identical test conditions and reported AUC as a key performance metric. The evaluation procedures followed recommended practices for multiclass classification to ensure reliable assessment of predictive performance.

In addition to AUC-ROC, we also reported AU-PRC (area under the precision-recall curve), which provides a complementary evaluation of model performance by emphasizing the trade-off between precision and recall. AU-PRC is particularly informative in settings with class imbalance, as it focuses on the model's ability to correctly identify positive instances without being overly influenced by true negatives. Similar to the ROC-based evaluation, AU-PRC was computed using a one-vs-rest strategy for multiclass prediction, and class-specific precision-recall (PR) curves were aggregated to assess overall performance.

Baseline Models

Logistic Regression

A linear classification model that estimates class probabilities through a logistic function, serving as a simple and interpretable baseline to assess the benefit of nonlinear feature interactions [34].

Support Vector Machine

A margin-based classifier that constructs an optimal separating hyperplane in the feature space, enabling the evaluation of nonlinear decision boundaries through kernel-based learning [34].

XSL•FO
RenderX

Random Forest

An ensemble learning method that aggregates multiple decision trees trained on bootstrapped samples, capturing nonlinear feature relationships and improving robustness against overfitting [35].

XGBoost

A gradient boosting framework that builds additive tree-based models in a stagewise manner, designed to optimize predictive performance by modeling complex nonlinear interactions among features [36].

Convolutional Neural Network

Extracts local temporal features via convolutional kernels without explicitly modeling temporal order, serving to test the importance of temporal structure [37].

Long Short-Term Memory

Captures long-term dependencies through gating mechanisms, used to compare different recurrent units for short-sequence modeling [38].

Transformer

Models relationships across time steps using self-attention, with concatenated features fed into a standard transformer encoder [39].

PatchTST

Reduces computational complexity through a "patching" strategy, improving efficiency for long-sequence prediction [40].

iTransformer

Applies attention along the feature dimension rather than the temporal dimension, better capturing inter-variable relationships in multivariate time series [41].

Mamba

Mamba uses a selective state space mechanism to model long-term dependencies with linear complexity [42].

MambaTS

An enhanced variant of Mamba that incorporates improved state space mechanisms to further boost long-sequence prediction performance [43].

Long Short-Term Memory+Transformer

A variant of CLA-Net that replaces the GRU encoder with a long short-term memory (LSTM), used to compare the effects of different recurrent units.

To ensure a fair comparison with the deep learning models, the input configuration for all traditional machine learning baselines (logistic regression, support vector machine, random forest, and XGBoost) was aligned with the dual-time-point setup of CLA-Net. Specifically, the feature vectors from the historical time point (Xt-1) and the current time point (Xt) were concatenated to form a single flattened input vector [Xt-1, Xt]. This ensures that all models use the exact same longitudinal information, preventing any performance bias due to information asymmetry.

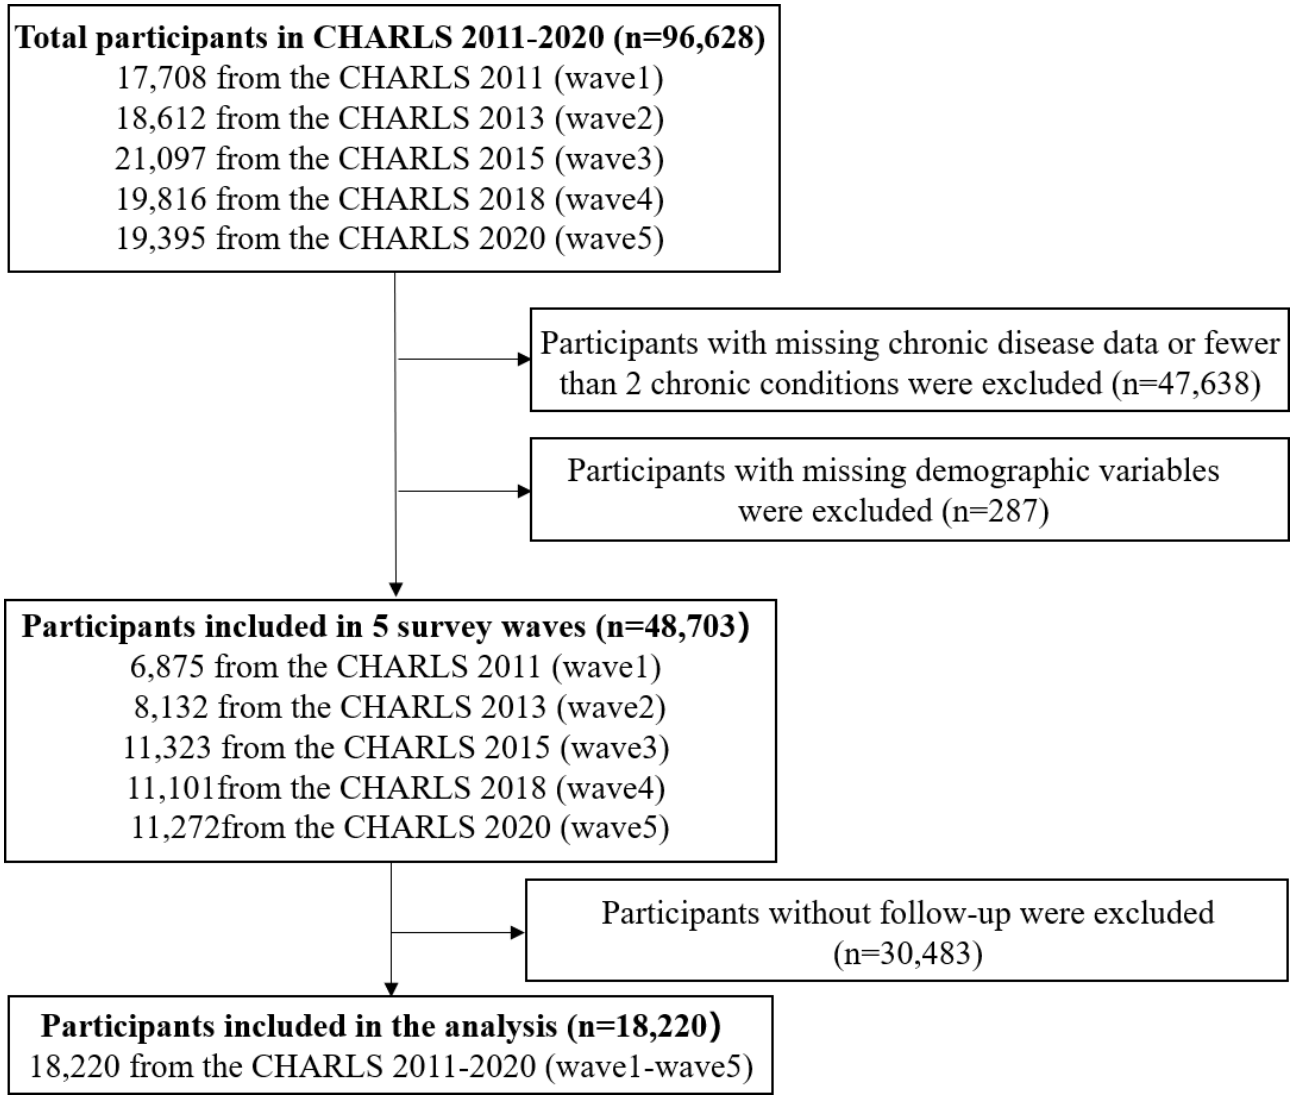
Ethical Considerations

Ethical approval for the original data collection in the CHARLS project was granted by the Biomedical Ethics Review Committee of Peking University (approval number: IRB00001052-11015). All participants provided written informed consent at the time of enrollment. As this study involves a secondary analysis of publicly available, deidentified data, the requirement for additional informed consent was waived. To ensure privacy and confidentiality, all direct identifiers were removed from the dataset by the CHARLS team prior to public release. Furthermore, this paper and its supplementary materials do not contain any images or information that could identify individual participants.

Results

Dataset

This study adopted a longitudinal cohort design using publicly available data from the CHARLS. CHARLS is a nationally representative longitudinal survey covering 28 provinces, 150 counties and districts, and 450 communities, and provides extensive demographic, chronic disease, and other health-related information. Using 2011 as the baseline, we included respondents with at least 2 chronic conditions and complete demographic data who participated in all 5 waves, yielding 3644 individuals and 18,220 person-wave observations. The sample selection process is shown in Figure 3. Attrition during follow-up occurred due to both mortality and nonmortality loss to follow-up. Specifically, the without-follow-up observations (30,483 person-wave observations) corresponded to 1617 person-wave observations attributable to death and 28,866 person-wave observations attributable to other reasons for nonparticipation.



Data preprocessing included logical error correction and outlier removal. Regarding missing value treatment, to strictly prevent data leakage, we adhered to a rigorous "split-then-impute" strategy. The dataset was first partitioned into training and independent test sets. Subsequently, missing values were handled using the MiceForest method for multiple imputation [44]. Crucially, the imputation model was fitted exclusively on the training set. The MiceForest method is based on random forests and predictive mean matching, allowing it to capture nonlinear relationships and improve imputation accuracy [45,46]. To ensure data quality, variables with more than 50% missingness were excluded, and only those with relatively low missingness were retained [45].

The final dataset variables are summarized in Table S1 in Multimedia Appendix 1 and include (1) individual identifiers and survey time (ID and year); (2) 14 chronic disease variables used for LTA-based identification and transition modeling of multimorbidity patterns, which also served as target variables in the prediction task; and (3) symptom variables along with demographic, behavioral, psychological, socioeconomic, and macropolicy features, which were used as input features for the prediction model. A final cohort of 3644 individuals with multimorbidity who maintained participation across all 5 survey waves was included in the analysis. Table 2 presents the baseline sociodemographic characteristics of the participants (recorded

XSL•FO
RenderX

in 2011). The cohort was predominantly female (n=2132, 58.51%) and comprised mainly middle-aged and older adults, with 93.33% (n=3401) of participants aged between 45 and 74 years. In terms of socioeconomic status, the sample was characterized by relatively low educational attainment, as 90.12% (n=3284) of participants had an education level below junior high school. The majority were married (n=3283, 90.09%) and resided in rural areas (n=2306, 63.28%), while less than half (n=1550, 42.54%) were covered by pension insurance.

LTA-Based Identification of Multimorbidity Patterns

To clarify the consistency and heterogeneity of multimorbidity pattern structures across different time points, we first conducted LCA at each wave to provide the basis for subsequent LTA. The model fit results (Table 3) indicated that the 5-class solution performed best across multiple criteria: at T1, T2, T3, and T5, it achieved the lowest AIC and SaBIC values with good classification quality (entropy=0.838 - 0.926); at T4, although the 4-class and 5-class solutions showed comparable entropy, the 5-class model outperformed in AIC, BIC, and SaBIC. The BLRT consistently supported the 5-class solution across all time points (all P<.001). Moreover, the class distributions of the 5-class solution were relatively stable and clinically plausible across waves. Taken together, the 5-class model was selected as the optimal solution for the LTA.

After establishing the 5-class structure at each time point, we tested measurement invariance to ensure the validity of cross-time comparisons. As shown in Table 4, constraining item-response probabilities to be equal across time did not significantly worsen model fit compared to the freely estimated model ($\Delta\chi^2_{75}$=88.7; P=.14). This nonsignificant likelihood ratio test confirmed measurement invariance, indicating that the latent classes maintained consistent meanings across all 5 waves.

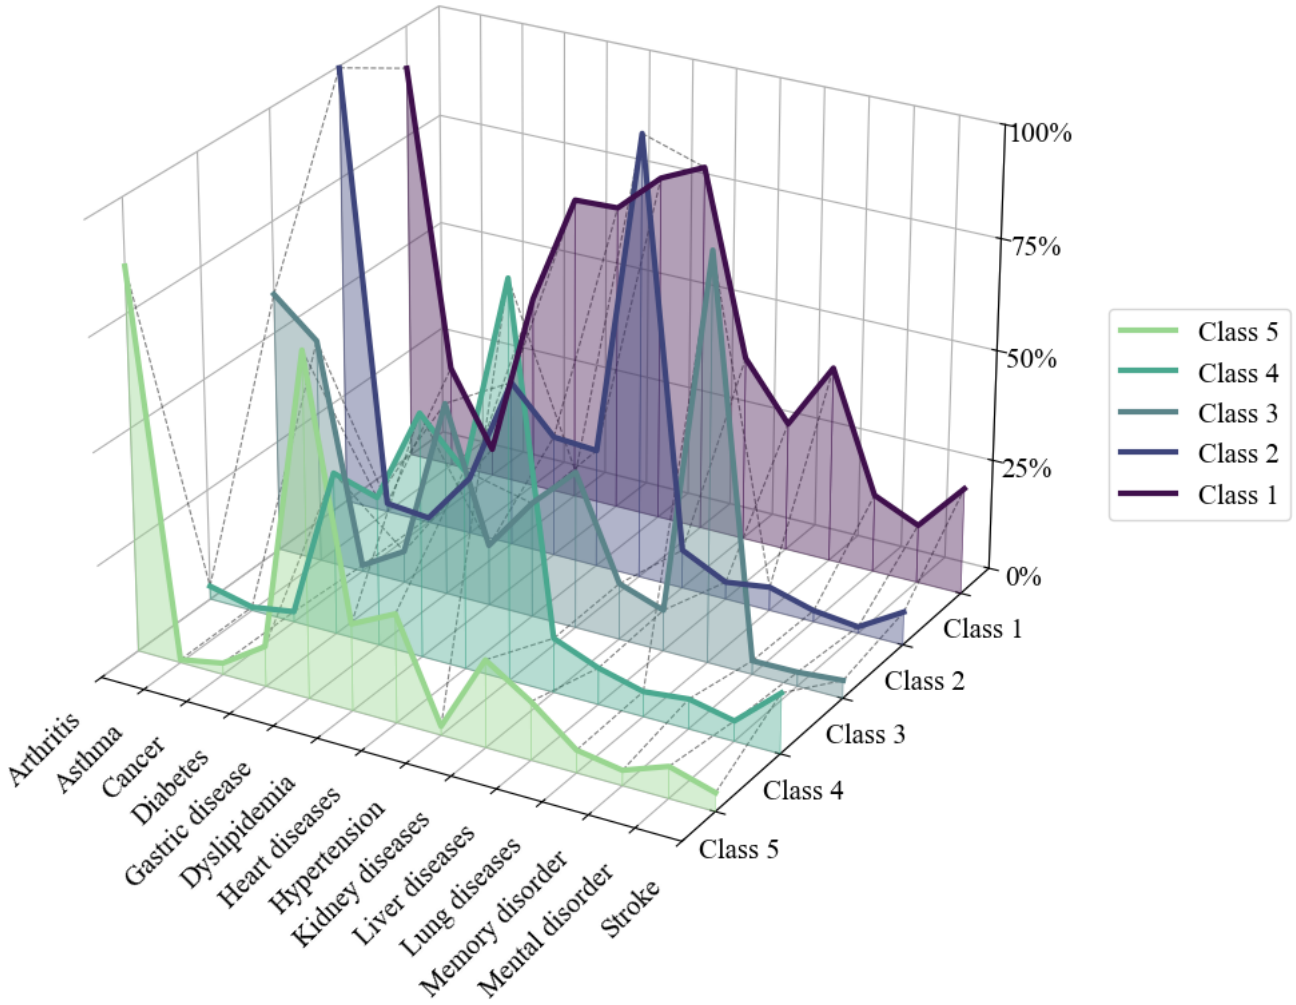
The LTA clustering results for the 5-class model are shown in Figure 4. Class 1 (19.8%) had the highest overall disease burden, with nearly universal hypertension (82.7%), accompanied by high prevalence of heart disease (78.1%), dyslipidemia (69.3%), gastritis (68.9%), diabetes (43.9%), arthritis (90.4%), lung disease (44.3%), and stroke (24.1%). This class represented severe multisystem involvement [47] and was labeled the "Severe Cardiometabolic-Multisystem Pattern."

Class 2 (22.3%) was characterized by extremely high probabilities of hypertension (99.7%) and arthritis (99.6%). Gastritis showed a moderate prevalence (37.5%), while dyslipidemia (27.3%) and heart disease (26.6%) were present in about one-quarter of individuals. Other conditions were rare (<13%), indicating a pattern primarily dominated by hypertension and joint disease. This class was labeled the "Hypertension-Arthritis Pattern."



Class 3 (15.6%) was dominated by lung disease (90.8%), with co-occurrence of arthritis (58.7%), asthma (50.4%), gastritis (43.4%), and hypertension (35.3%). This class was labeled the "Respiratory-Musculoskeletal Pattern."

Class 4 (24.1%) exhibited typical metabolic syndrome features, including high prevalence of hypertension (88.3%), dyslipidemia (54.5%), and heart disease (44.4%), with moderate diabetes (36.3%) and gastritis (33.4%). Other diseases were less common (<14%), indicating a primarily cardiometabolic profile without extensive multisystem involvement. This class was labeled the "Metabolic Syndrome Pattern."

Class 5 (18.2%) had the lowest overall disease burden, dominated by arthritis (85.2%) and gastritis (76.4%), with all other diseases below 25%. This class was labeled the "Gastritis-Arthritis Pattern." The naming of latent multimorbidity patterns was guided by the dominant disease combinations and their clinical interpretation, following conventions widely used in epidemiologic and multimorbidity-cluster studies [19,48-52].

Performance Evaluation Results of CLA-Net

In the experiments, the proposed method was trained on the training set and evaluated on an independent test set. To ensure robustness, the entire process was repeated 50 times, and the mean and SD of all evaluation metrics across these runs were reported as the final performance results. The comparative performance of all models on the multimorbidity pattern prediction task is summarized in Table 5, the ROC curves are presented in Figures 5 and 6, and the detailed results of the ablation study are shown in Table 6.

As shown in Table 5, CLA-Net consistently outperformed all baseline models in multimorbidity pattern prediction. Traditional machine learning approaches perform relatively poorly, while deep learning models designed for temporal modeling yield substantial improvements. Among the baselines, Mamba performed best overall, while convolutional neural network (CNN) performed the worst, underscoring the importance of temporal feature modeling in longitudinal health data. The hybrid LSTM+transformer model achieved relatively high accuracy, highlighting the benefits of combining sequential modeling with attention mechanisms. Nevertheless, CLA-Net surpassed all baselines across accuracy, precision, recall, and F_1-score, with low SDs confirming its stability and robustness.

We further conducted formal statistical significance testing to assess whether the observed performance gains of CLA-Net over baseline models were statistically robust. Specifically, 2-sided Wilcoxon signed-rank tests were applied to paired performance scores obtained from 50 repeated experimental runs for each evaluation metric. To account for multiple comparisons across baseline models and metrics, *P* values were adjusted using the Holm step-down procedure. The Wilcoxon signed-rank test results are given in Table 7. The results indicate that CLA-Net achieves statistically significant performance improvements over all baseline models. The consistent significance across repeated experiments confirms that the observed gains are robust rather than driven by random fluctuations.

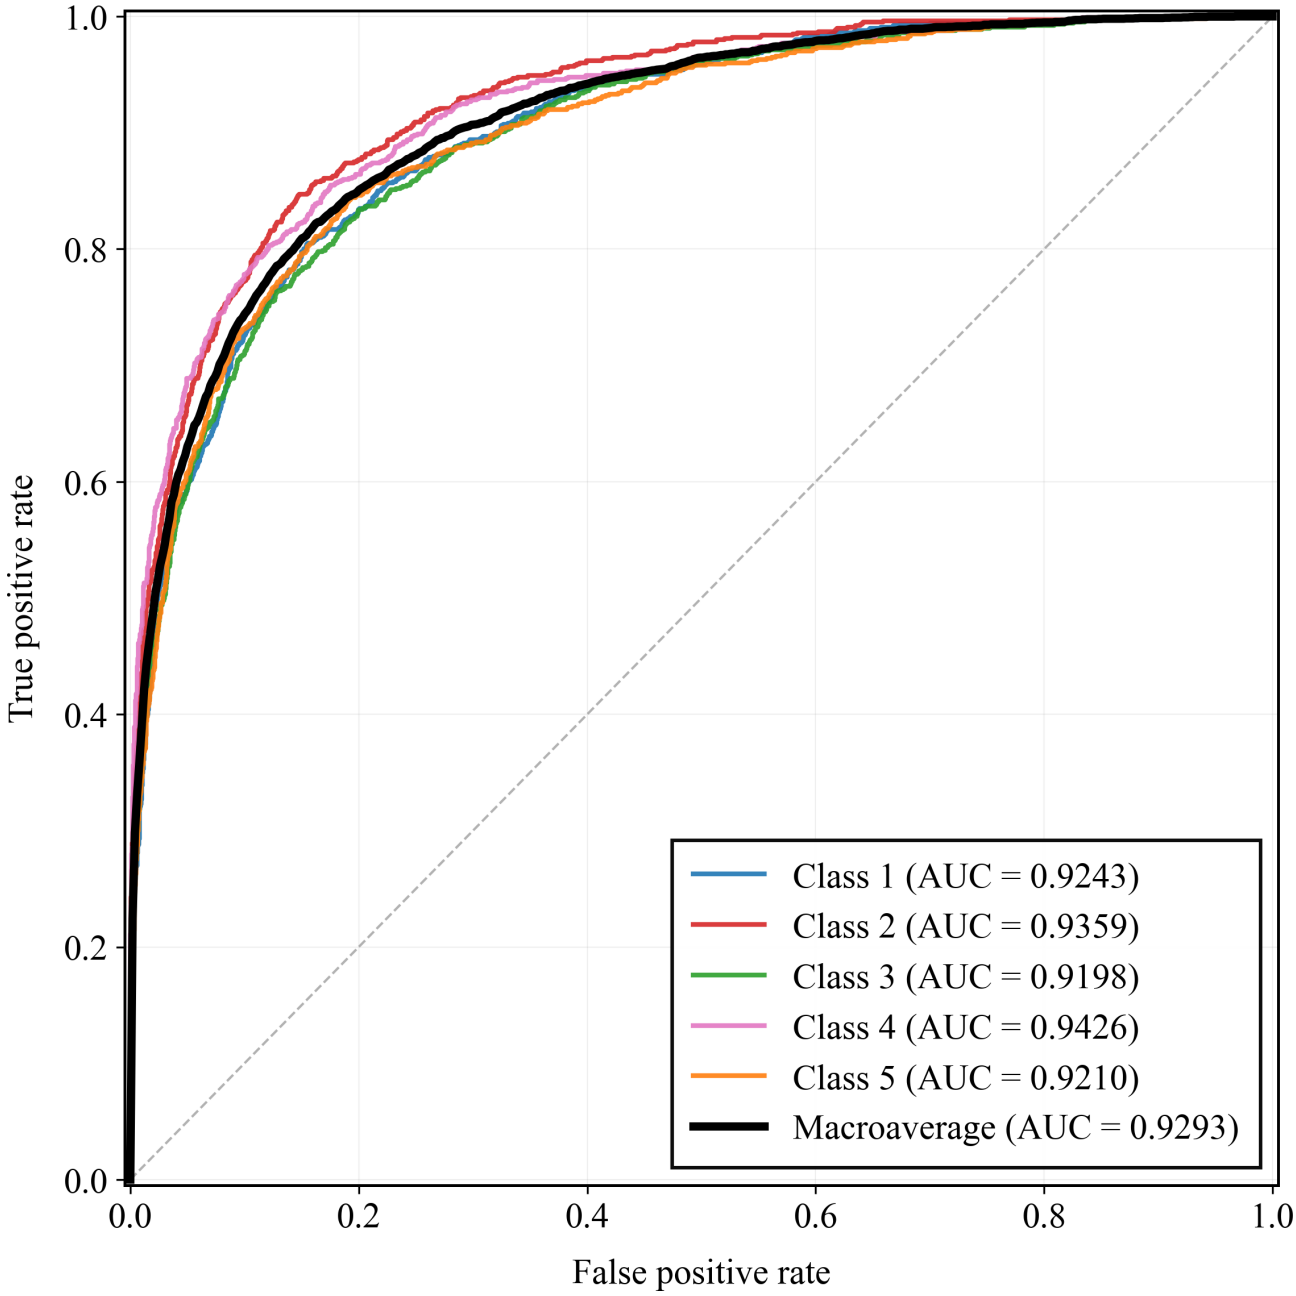
Figure 5 presents the AUC-ROC curves comparing CLA-Net with a range of baseline models. As shown in Figure 5A, among deep learning approaches, CLA-Net achieves the highest AUC of 0.9293, demonstrating superior discriminative ability in multimorbidity pattern prediction. Models explicitly designed for temporal modeling, such as Mamba (AUC=0.9187), MambaTS (AUC=0.9142), PatchTST (AUC=0.9017), and iTransformer (AUC=0.9016), outperform conventional CNN-based architectures, highlighting the importance of capturing long-range temporal dependencies in longitudinal health data. The hybrid LSTM+transformer model attains an AUC of 0.9106, ranking among the strongest deep learning baselines, while CNN yields the lowest AUC (0.8746) within this group.

To further assess performance under class imbalance, Figure 6 reports the PR curves and corresponding AUC-PRC values. As shown in Figure 6, CLA-Net achieves the highest AUC-PRC among deep learning models (0.8885), indicating a superior PR trade-off across recall levels. Temporal models such as Mamba, iTransformer, and LSTM+transformer also perform competitively, whereas CNN shows relatively weaker performance. Figure 6 demonstrates that CLA-Net substantially outperforms traditional machine learning baselines, including logistic regression, support vector machine, random forest, and XGBoost. Overall, the PRC results complement the ROC analysis and further confirm the robustness of CLA-Net in identifying future multimorbidity patterns under imbalanced conditions.

As summarized in Table 6, the full CLA-Net consistently outperformed all ablation variants, underscoring the importance of integrating both GRU and the bitemporal directed cross-attention mechanism. Removing either component or replacing cross-attention with self-attention led to clear performance drops, confirming the effectiveness of the original design.

Regarding input configurations, single-time-point input resulted in the largest decline, while 3-time-point and 4-time-point settings provided only marginal gains but reduced overall accuracy, indicating that the 2-time-point design achieves the optimal balance, efficiently capturing the most relevant temporal signals without introducing the complexity or noise associated with longer historical windows. These results indicate that, under the current architecture, incorporating immediate temporal context is critical for prediction, whereas extending the input window beyond 2 time points yields diminishing or even negative returns. In addition, reversing the order of transformer and GRU also impaired performance, supporting the strategy of “temporal encoding before interaction.”



Figures 7 and 8 show the class-specific ROC and PR curves for the 5 multimorbidity patterns. All classes achieved consistently high ROC performance, with AUCs ranging from 0.9198 to 0.9426 and a macroaverage of 0.9293. The PRC analysis yielded AUC-PRC values between 0.8310 and 0.8620 (macroaverage=0.8429), indicating stable precision-recall trade-offs across classes. Overall, CLA-Net demonstrates robust and balanced predictive performance for all multimorbidity patterns.

To complement this threshold-free evaluation, Table 8 reports classwise precision, recall, and F_1-scores, indicating consistently good predictive performance across patterns, with F_1-scores ranging from 0.7906 to 0.8508. As further illustrated by the confusion matrix in Figure 9, classification errors are primarily

XSL•FO
RenderX

concentrated among clinically related multimorbidity patterns, suggesting that residual misclassifications arise from intrinsic overlap between multimorbidity profiles rather than systematic model failure.

Sensitivity Analysis: Robustness of Class Stability

To address concerns regarding potential information leakage and the temporal robustness of latent class definitions, we conducted a comprehensive sensitivity analysis in which the LTA was reestimated using only the training-period waves (2011 - 2015), thereby excluding all future observations used as prediction targets in the main analysis. This analysis was designed to evaluate whether the multimorbidity pattern structure identified in the full longitudinal dataset was inherently stable, rather than being driven by information from later waves.

We first reassessed the optimal number of latent classes by fitting LTA models with 2 to 6 classes under a free-parameter specification using the training-period data only. As shown in Table 9, information criteria (AIC, BIC, and SaBIC) consistently improved as the number of classes increased from 2 to 5, while a marginal deterioration in fit was observed when moving from 5 to 6 classes. The BLRT strongly supported the 5-class solution over the 4-class solution (P<.001), whereas the improvement from 5 to 6 classes was only marginal (P=.03), suggesting diminishing returns with increased model complexity.

[f]Not applicable.

In addition, classification quality, as reflected by entropy, reached its highest value under the 5-class solution (entropy=0.87), indicating satisfactory class separation despite the reduced number of waves and observations compared with the full-sample model. Taken together, these results demonstrate that the 5-class structure remained the optimal and most parsimonious representation of multimorbidity patterns even when the analysis was restricted to the training-period data.

To ensure consistency of class interpretation across time, measurement invariance constraints were imposed on the selected 5-class model. Although imposing invariance resulted in a modest increase in information criteria and a slight reduction in entropy (from 0.87 to 0.86), the overall classification quality remained high, indicating that the core latent structure was robust to parameter constraints and not dependent on future observations.

Beyond overall model fit, we directly examined the stability of class definitions by comparing disease-specific item-response probabilities between the full-sample LTA model and the training-period-only LTA model. For each latent class, the top 4 representative chronic conditions were retained, and their conditional probabilities were contrasted across the 2 modeling strategies (Table 10).

[b]Derived from the complete dataset, including Waves 1 through 5 (2011 - 2020).

[c]Derived exclusively from the training dataset (Waves 1 through 3, 2011 - 2015), blinding the model to future test data.

[d]Pearson correlation coefficient calculated based on the probability vectors of all 14 chronic conditions for the corresponding class.

[e]Mean absolute deviation value.

[f]Mean value.

[g]Not applicable.

Across all 5 classes, the composition and relative ordering of dominant conditions remained highly consistent. The cardiometabolic-multisystem class continued to be characterized by a high prevalence of arthritis, hypertension, heart disease, and dyslipidemia; the hypertension-arthritis class preserved its defining dual dominance of hypertension and arthritis; the respiratory-musculoskeletal class remained anchored by lung disease and asthma; the metabolic syndrome class retained its core metabolic features; and the gastritis-arthritis class continued to reflect co-occurring gastrointestinal and musculoskeletal conditions. Importantly, no class exhibited a change in its defining disease constellation when future waves were excluded from model estimation.

Quantitatively, the similarity between item-response probability profiles was high across all classes, with Pearson correlation coefficients ranging from 0.954 to 0.983 and a mean correlation

XSL•FO
RenderX

of 0.969. These correlations were computed using the full set of disease-specific probabilities, indicating strong structural concordance rather than superficial agreement limited to a subset of conditions [53]. Differences in absolute probabilities were generally modest, with a mean absolute deviation of 0.048 across classes, reflecting only minor shifts in disease prevalence rather than substantive changes in class meaning.

Taken together, these findings provide strong evidence that the multimorbidity class structure identified in the main analysis is stable and not driven by information from future observations. Even when latent classes were defined exclusively using training-period data, both the optimal number of classes and their clinical interpretations remained highly consistent with those derived from the full-sample model. The observed differences were limited to modest shifts in absolute disease probabilities, while the underlying pattern structure and relative disease importance were preserved.

We acknowledge that, under a strictly unbiased evaluation framework, latent class definitions could alternatively be derived exclusively from training-period data and then applied to the test set, for example, by projecting test observations onto a training-derived latent space. In this study, however, we adopted a population-level LTA fitted on all available waves to define stable multimorbidity patterns, which were subsequently treated as fixed targets for prediction. Importantly, as demonstrated in Table 9, the latent class structures derived from training-period data and from the full dataset exhibited a high degree of concordance (mean r=0.969), indicating that the class definitions were not driven by any single wave or subset of the data. Therefore, the use of the full-sample LTA model to generate predictive targets does not introduce meaningful bias into the evaluation. The “ground truth” labels for the test set would remain virtually unchanged even if they were generated by projecting test data onto a latent space fitted strictly to training parameters. The reported predictive performance of CLA-Net reflects a genuine ability to forecast future multimorbidity states rather than an artifact of information leakage in the target generation process.

To explicitly assess whether the use of full-sample LTA targets introduces any optimistic bias in predictive evaluation, we conducted an additional experiment in which the LTA model was estimated exclusively on training-period data, with all model parameters fixed thereafter. The downstream prediction pipeline was then fully repeated using these training-only LTA-derived targets, and the CLA-Net model was retrained and reevaluated accordingly.

As summarized in Table 11, the predictive performance obtained under training-only LTA targets remains highly consistent with the original results based on full-sample LTA targets. Specifically, the differences in accuracy, precision, recall, and F_1-score are all below 0.3%, and all metrics remain well within 1 SD of the original estimates. The slight performance reductions observed are expected and can be attributed to minor numerical variations in latent class assignment, rather than to any systematic bias arising from information leakage.

Table . Comparison of predictive performance under full-sample and training-only LTA[a] targets.

Metric	Full-sample LTA targets, mean (SD)	Training-only LTA targets, mean (SD)	Difference
Accuracy	0.8352 (0.0048)	0.8338 (0.0050)	−0.0014 (−0.17%)
Precision	0.8326 (0.0053)	0.8315 (0.0055)	−0.0011 (−0.13%)
Recall	0.8312 (0.0056)	0.8290 (0.0060)	−0.0022 (−0.26%)
F_1-score	0.8319 (0.0051)	0.8302 (0.0054)	−0.0017 (−0.20%)

[a]LTA: latent transition analysis.

Transition-Focused Evaluation of Multimorbidity Class Prediction

To disentangle the prediction of genuine multimorbidity progression from trivial class persistence, we conducted a stratified evaluation by separating individuals into those whose multimorbidity class remained unchanged between consecutive waves (stayer-only) and those who experienced a true class transition (transition-only). Performance was assessed using macroaveraged precision, recall, F_1-score, and overall accuracy for each subset.

To further account for chance agreement and the high prevalence of class persistence, we additionally report chance-adjusted performance metrics. Across the full sample, CLA-Net achieved a Cohen κ of 0.7935 (SD 0.0055) and a Matthews correlation coefficient of 0.7968 (SD 0.0058), reflecting substantial chance-adjusted concordance between predicted and observed class labels. These values are consistent with the maintained performance on the transition-only subset, confirming that CLA-Net possesses robust discriminative power to identify genuine multimorbidity evolution rather than merely replicating static baselines.

As shown in Table 12, the model retained substantial discriminative ability on the transition-only subset, where individuals experienced a true change in multimorbidity class between tand t+1. On this subset, macroaveraged precision, recall, and F_1-score reached 0.7615 (SD 0.0106), 0.7632 (SD 0.0112), and 0.7623 (SD 0.0102), respectively, with an overall accuracy of 0.7654 (SD 0.0096). Although performance on the transition-only subset was lower than that observed in the full-sample and stayer-only evaluations, this reduction is expected given the increased complexity of predicting off-diagonal class transitions. Because multimorbidity patterns tend to remain relatively stable across adjacent waves in populations with largely irreversible chronic conditions, the transition-only subset represents a smaller and more

XSL•FO
RenderX

heterogeneous group, which inherently increases prediction difficulty and performance variability, as reflected by the larger SDs observed.

Table . Performance evaluation on different dynamic subsets.

Evaluation subset	Precision, mean (SD)	Recall, mean (SD)	F_1-score, mean (SD)	Accuracy, mean (SD)
Full sample	0.8326 (0.0053)	0.8312 (0.0056)	0.8319 (0.0051)	0.8352 (0.0048)
Transition-only ($Y_t \neq Y_{t+1}$; 23.47%)	0.7615 (0.0106)	0.7632 (0.0112)	0.7623 (0.0102)	0.7654 (0.0096)
Stayer-only ($Y_t = Y_{t+1}$; 76.53%)	0.8544 (0.0049)	0.8521 (0.0052)	0.8533 (0.0047)	0.8566 (0.0044)

As an important clinical benchmark, we further evaluated a naive persistence model that simply predicts class($t+1$)=class(t). On the test set, the naive model obtained an overall accuracy of 0.7653, substantially below CLA-Net (0.8352, SD 0.0048). Notably, on the transition-only subset, the naive model achieves 0% accuracy by definition, whereas CLA-Net maintains 0.7654 accuracy, demonstrating its added value in identifying genuine transitions rather than merely reproducing stable states. Together, these results indicate that the overall performance gain is not driven by trivial persistence, but by the model's capacity to capture progression-related signals associated with changes in multimorbidity structure.

To further account for chance agreement and the high prevalence of class persistence, we additionally report chance-adjusted performance metrics. Across the full sample, CLA-Net achieved a Cohen κ of 0.7935 (SD 0.0055) and a Matthews correlation coefficient of 0.7968 (SD 0.0058), reflecting substantial chance-adjusted concordance between predicted and observed class labels. These values are consistent with the maintained performance on the transition-only subset, confirming that CLA-Net possesses robust discriminative power to identify genuine multimorbidity evolution rather than merely replicating static baselines.

Sensitivity Analysis of Data Imputation Methods

To strictly verify the validity and robustness of the imputation strategy used in this study (ie, MiceForest), we conducted a comparative experiment to assess how different missing data handling methods affect the final predictive performance of CLA-Net. In this experiment, the standard MiceForest algorithm was replaced by 4 alternative strategies: complete case analysis (CCA; directly discarding samples with missing values), random imputation (filling missing values with randomly selected observed values), mean imputation (filling with the variable mean), and KNN imputation. The comparative results are presented in Table 13.

Table . Performance comparison of Cross-Lag Attention Network using different missing data handling strategies.[a]

Imputation strategy	Precision, mean (SD)	Recall, mean (SD)	F_1-score, mean (SD)	Accuracy, mean (SD)
Complete case analysis	0.8015 (0.0072)	0.7980 (0.0078)	0.7995 (0.0075)	0.8050 (0.0070)
Random imputation	0.8080 (0.0085)	0.8050 (0.0090)	0.8065 (0.0088)	0.8110 (0.0082)
Mean imputation	0.8150 (0.0065)	0.8120 (0.0069)	0.8135 (0.0066)	0.8180 (0.0062)
KNN[b] imputation	0.8265 (0.0058)	0.8240 (0.0062)	0.8252 (0.0060)	0.8290 (0.0055)
MiceForest (ours)	*0.8326 (0.0053)*	*0.8312 (0.0056)*	*0.8319 (0.0051)*	*0.8352 (0.0048)*

[a]The italicized values represent the best performance of each data handling strategy on the evaluation metrics. These italicized values are used to highlight the most outstanding results among the different strategies.

[b]KNN: k-nearest neighbors.

As shown in Table 13, the model using MiceForest for data imputation achieved the best performance across all metrics (accuracy=0.8352, F_1-score=0.8319). In contrast, CCA resulted in the lowest performance (accuracy=0.8050). It is important to note that the CCA metrics were evaluated on a reduced test set (subset of individuals with complete data only), whereas imputation methods were evaluated on the full test set. Despite being tested on this potentially "cleaner" subset, CCA still underperformed. This confirms that the substantial reduction in training sample size caused by discarding data severely compromises the model's ability to learn robust patterns, thereby limiting its generalizability. Random imputation also performed poorly (accuracy=0.8110), primarily because randomly assigned values introduce significant noise and disrupt the true correlation structure between variables. While mean imputation (accuracy=0.8180) and KNN imputation (accuracy=0.8290) showed improvements over random methods, they still lagged behind MiceForest.

These results indicate that MiceForest, which leverages iterative random forests to model non-linear interactions, effectively preserves the underlying data structure better than stochastic (random) or distance-based (KNN) methods, confirming it as the optimal choice for our framework.

Discussion

Principal Results

This study proposes an innovative research framework that integrates population-level multimorbidity pattern recognition with individual-level future prediction, achieving a key transition in multimorbidity research from descriptive statistics to prospective prediction.

In terms of multimorbidity pattern recognition, this study identified 5 clinically meaningful classes using LTA: Cardiometabolic-Multisystem, Hypertension-Arthritis, Respiratory-Musculoskeletal, Metabolic Syndrome, and Gastritis-Arthritis. Patients in the Cardiometabolic-Multisystem pattern bore the heaviest overall disease burden, with widespread hypertension, heart disease, dyslipidemia, diabetes, gastritis, arthritis, lung disease, and kidney disease, while the coexistence of stroke further indicated advanced vascular damage. The interactions and cascading effects among these chronic conditions have been confirmed in multiple studies. For instance, cardiometabolic diseases such as hypertension, diabetes, dyslipidemia, and heart disease frequently co-occur and significantly increase the risk of cardiovascular events and mortality [50]. Inflammatory arthritis (eg, rheumatoid arthritis) has also been associated with elevated cardiovascular risk [54]. This multisystem involvement highlights the importance of comprehensive and integrated management for such patients. The Hypertension-Arthritis pattern was characterized by the strong co-occurrence of hypertension and arthritis. This pattern is well supported by prior studies showing that hypertension is a common multimorbidity of osteoarthritis, potentially linked through shared mechanisms such as inflammation, oxidative stress, and vascular dysfunction, with arthritis treatments possibly influencing blood pressure [51,55]. The Respiratory-Musculoskeletal pattern was defined by a high prevalence of lung disease, arthritis, and asthma, often accompanied by gastritis and hypertension. This finding is consistent with previous clinical evidence [52,56]. The Metabolic Syndrome class exhibited high rates of hypertension, dyslipidemia, heart disease, and diabetes, without significant multisystem involvement. This aligns with the classical definition of metabolic syndrome and its strong association with increased risks of cardiovascular disease and type 2 diabetes [57]. Finally, the Gastritis-Arthritis pattern showed the lowest overall disease burden, primarily involving arthritis and gastritis. This finding is supported by prior medical studies reporting comorbidities such as enteropathic arthritis in patients with inflammatory bowel disease or gastrointestinal complications related to arthritis medications [58].

In multimorbidity pattern prediction, this study introduces CLA-Net, a novel deep learning framework specifically designed to forecast multimorbidity patterns from longitudinal health data with short temporal lags. Our comprehensive evaluation demonstrated that CLA-Net consistently outperformed all baseline methods, achieving an accuracy of 0.8352 and an AUC of 0.9293. Several strong deep learning baselines included in the comparison, such as Mamba, PatchTST, and iTransformer, were originally developed for long-sequence time series forecasting and are optimized to exploit long-range temporal dependencies through mechanisms such as selective state-space modeling or patch-based representations. In the present task, the input sequence consists of 2 adjacent time points $t-1$ and t, which may limit the extent to which these architectures can fully leverage their design strengths. In contrast, CLA-Net explicitly focuses on modeling short-lag transitions through a dual-branch architecture and a bitemporal directed cross-attention mechanism, enabling more effective capture of immediate disease-state dependencies. Compared with the best-performing baseline Mamba model, CLA-Net improved accuracy by 1.10% (0.8352 vs 0.8242) and by 1.05% over the hybrid LSTM+transformer architecture (0.8352 vs 0.8247). More notably, CLA-Net increased AUC by 1.87% relative to LSTM+transformer (0.9293 vs 0.9106), indicating superior discriminative ability across decision thresholds, which is particularly important for clinical applications requiring flexible risk stratification strategies.

Our ablation experiments revealed the critical contributions of individual components and validated the soundness of the architectural design. Only the transformer branch reduced accuracy to 0.8166 (−1.86%), highlighting its essential role in capturing global cross-temporal dependencies. Retaining only the GRU branch further decreased accuracy to 0.8102 (−2.50%), indicating that while GRU effectively models temporal dynamics, the absence of global feature interactions severely limits its ability to capture complex multimorbidity patterns. The performance gap between the 2 branches (0.8166 vs 0.8102) also suggests that global interactions are slightly more important than local temporal dependencies, yet their integration is necessary to achieve optimal performance. Replacing the bitemporal directed cross-attention with standard self-attention reduced accuracy to 0.8244 (−0.93%), with precision and F_1-scores declining by 1.08% and 1.12%, respectively. This underscores the importance of the directed mechanism in maintaining predictive stability and balance. Unlike standard self-attention, which may cause “future information leakage,” the dual-window design enforces a “history-to-current” information flow that better aligns with the clinical logic of predicting future risk based on historical data.

In terms of input configuration, single-time-point input resulted in a sharp drop in accuracy to 0.7985 (−3.67%) and recall to 0.7964 (−3.48%), indicating that the absence of historical information causes the model to miss many true multimorbidity cases, likely because early signals of certain patterns can only be detected through temporal evolution. Interestingly, adding more historical time points (3 or 4) did not improve overall performance: with 3 time points, precision slightly increased (0.8355 vs 0.8334) but accuracy dropped to 0.8228 and recall to 0.8185; with 4 time points, recall reached its highest (0.8360), but accuracy (0.8268) and F_1-score (0.8262) fell below the 2-time-point configuration. This empirical finding suggests that for this specific multimorbidity prediction task, immediate history is significantly more predictive than long-term history. Including more distant waves (eg, from 6‐8 years prior) appears to introduce noise or weaker relevance that obscures the strong signals from the most recent health state transition. Therefore, the 2-time-point configuration effectively captures

XSL•FO
RenderX

the critical "immediate" evolution while minimizing interference from outdated information, thus striking the best balance between information richness and model complexity. Importantly, this temporal design also has clear implications for practical clinical use. By leveraging a "past–current" window spanning approximately 2 - 3 years to predict multimorbidity patterns 2 - 3 years into the future, CLA-Net is not intended for short-term clinical decision-making (eg, acute care), but rather for midterm risk stratification and early intervention planning. In real-world settings, such predictions could be used to identify individuals who are likely to transition into more complex or higher-burden multimorbidity patterns within the next few years, thereby providing a clinically meaningful window for intervention. Finally, reversing the order of GRU and transformer (GRU-transformer) lowered accuracy to 0.8235 (−1.17%), confirming the effectiveness of the "temporal encoding before interaction" design. GRU provides temporally aware representations that serve as more suitable inputs for subsequent attention mechanisms, enabling more effective cross-temporal interactions, whereas applying attention without temporal context may lead to suboptimal feature modeling.

Considering the chronic and partially irreversible nature of many included conditions, class persistence is expected to be high. Consistent with this, approximately 76.53% of test instances were stayers. While the naive model achieves high accuracy on stable patients, it has zero clinical utility for risk warning, as it fails to identify any patient whose health state is deteriorating or changing (0% accuracy on the transition subset). In contrast, CLA-Net successfully identifies 76.54% of the patients who undergo pattern transitions. From a clinical perspective, the primary value of a predictive model lies in its ability to provide early warnings for high-risk transitions rather than merely confirming stability. Therefore, the complexity of the deep learning approach is justified by its ability to capture these critical, nonlinear disease progressions that a simple persistence rule completely misses.

Regarding generalizability, the proposed framework is designed to be transferable to other longitudinal electronic health record (EHR) datasets. The LTA component relies on routinely collected chronic disease diagnoses, which are widely available across EHR systems, allowing population-level pattern structures to be reestimated or adapted to different health care contexts. Meanwhile, the CLA-Net architecture operates on generic temporal feature representations and does not depend on dataset-specific coding schemes. This modular design facilitates scalability to larger cohorts and longer observation periods and enables potential transfer learning scenarios in which a pretrained representation model can be fine-tuned using locally derived multimorbidity structures. These properties suggest that the framework has the potential for broader application beyond the present dataset. However, due to the inherent survivorship bias of longitudinal follow-up cohorts, the current model is primarily applicable to chronic disease management in surviving, community-dwelling populations. Importantly, it should not be applied to high-acuity clinical settings (eg, emergency or Intensive Care Unit populations) where mortality risk is a competing outcome and may dominate near-term trajectories. In such contexts, mortality-aware endpoints and competing-risk modeling would be required prior to any clinical deployment.

Practical Implications

The ability of CLA-Net to anticipate future multimorbidity pattern membership offers important implications for the longitudinal management of patients with established chronic conditions. Rather than responding to isolated disease events, clinicians can leverage pattern-based forecasts to organize care around expected configurations of coexisting conditions, thereby supporting a more coordinated and forward-looking approach to chronic disease management.

First, knowledge of an individual's likely future multimorbidity pattern can inform proactive care planning within patients with multimorbidity. For example, individuals predicted to enter the metabolic syndrome pattern may benefit from earlier emphasis on lifestyle modification, metabolic regulation, and adherence support, with the aim of slowing progression toward more complex cardiometabolic profiles. Similarly, those expected to belong to the cardiometabolic-multisystem pattern can be prioritized for closer surveillance and integrated management across cardiovascular, metabolic, and musculoskeletal domains, helping to mitigate cumulative disease burden over time.

Second, pattern-level prediction provides a practical framework for structuring multidisciplinary collaboration. Instead of relying on uniform or reactive referral pathways, health care providers may tailor multidisciplinary team composition according to the anticipated constellation of conditions. For instance, the respiratory-musculoskeletal pattern underscores the value of coordinated input from pulmonology, rheumatology, and rehabilitation services to jointly address respiratory impairment and functional limitation. Likewise, the gastritis-arthritis pattern highlights the need for alignment between gastroenterology and pain management to balance long-term anti-inflammatory therapy with gastrointestinal protection.

At the organizational level, pattern-based predictions can facilitate more efficient allocation of follow-up intensity, monitoring priorities, and supportive services for patients with multimorbidity within long-term chronic care systems. Consistent with its design scope, the proposed framework does not seek to model acute deterioration, end-stage progression, or mortality-related outcomes. Rather, it functions as a scalable decision-support layer to identify patients who may benefit from anticipatory, pattern-oriented management strategies in settings focused on sustained multimorbidity care.

Limitations and Future Direction

Although this study has made significant progress in multimorbidity pattern prediction, several areas remain for improvement. First, although CLA-Net demonstrated strong predictive performance on a longitudinal cohort, the current evaluation was conducted using a single data source. Differences in population characteristics, disease coding systems, and follow-up structures across EHR datasets may affect model behavior and warrant further investigation. Future work will focus on validating the framework across diverse EHR datasets, exploring transfer learning strategies, and extending the model to other chronic disease domains and health care systems.

XSL•FO
RenderX

Second, this study does not explicitly incorporate medication-related information into the modeling framework. Chronic conditions were therefore represented as binary indicators of presence or absence, without distinguishing between actively treated and untreated disease states. This abstraction is appropriate for predicting future multimorbidity pattern membership at the population level, but it may obscure clinically relevant differences in disease control achieved through pharmacological management. Consequently, the predicted pattern assignments should be interpreted as reflecting disease co-occurrence status rather than treatment-adjusted clinical responses. Future work integrating longitudinal medication data may further enhance the clinical granularity of multimorbidity pattern prediction.

Third, the model's predictive performance reflects a combined but functionally distinct reliance on objective disease history and subjective self-assessment measures, such as self-rated health and self-rated memory. While objective disease variables anchor predictions to diagnosed multimorbidity status, subjective assessments provide higher-level summaries of perceived health and functional burden and may contribute more strongly for individuals with borderline or heterogeneous disease profiles. Although the proposed framework demonstrates strong overall predictive performance, the relative contributions of subjective versus objective inputs cannot be fully disentangled within the current framework without dedicated interpretability analyses, such as feature attribution or attention visualization. Addressing this limitation and providing greater transparency regarding the sources of predictive power will be a key focus of future work.

Fourth, although the proposed framework demonstrates strong predictive performance, incorporating detailed interpretability analyses, such as SHAP (Shapley Additive Explanations) values or attention weight visualizations, may further enhance its practical utility. Owing to the complexity of the model architecture, such analyses are beyond the scope of this study. Future research will focus on developing tailored interpretability strategies to better elucidate the learned multimorbidity representations and support clinical interpretation.

Fifth, regarding temporal granularity, the survey waves in the CHARLS dataset are separated by nonuniform intervals, ranging from approximately 2 to 3 years. In the current CLA-Net architecture, transitions between adjacent waves are modeled as equidistant steps, without explicitly encoding the varying time intervals. This simplification may introduce temporal noise into the estimation of transition dynamics, particularly when interpreting changes across waves with heterogeneous follow-up durations. Future work could address this limitation by incorporating time-aware representations or modeling strategies explicitly designed for irregular temporal intervals.

Another methodological consideration concerns the transformation of probabilistic latent class assignments into deterministic labels for supervised prediction. In this study, posterior class probabilities obtained from the LTA were converted into hard labels using a maximum posterior probability assignment strategy. While this approach provides a clear and stable supervisory signal for training the prediction model, it inevitably discards information regarding classification uncertainty. In particular, individuals with ambiguous or borderline posterior distributions are treated as belonging entirely to a single class, which may encourage overconfident predictions. Future work could address this limitation by leveraging soft targets, such as full posterior probability vectors, within the learning objective. Incorporating probabilistic supervision through distribution-based loss functions or uncertainty-aware architectures may enable a more nuanced representation of multimorbidity structure and further improve predictive robustness.

Finally, to ensure the integrity of longitudinal trajectory modeling and the stability of LTA patterns, this study included participants present in all 5 waves (2011‐2020). We acknowledge that excluding individuals who died or dropped out due to severe illness may introduce survivorship bias, potentially skewing the dataset toward a "healthier survivor" cohort. However, this inclusion criterion was a necessary methodological trade-off to accurately capture the continuous evolution of multimorbidity patterns. It is worth noting that the primary goal of this framework is to support chronic disease management and secondary prevention in the general population, rather than predicting acute mortality risk in end-stage patients. To address this limitation, future research could incorporate advanced strategies such as joint longitudinal-survival modeling, inverse probability-of-censoring weighting, or competing-risk frameworks to explicitly account for nonrandom attrition and mortality, thereby extending the model's generalizability to high-risk clinical populations.

Conclusion

This study addresses the complex challenges of multimorbidity management in the context of population aging by proposing an innovative framework that bridges population-level pattern recognition and individual risk prediction. Using LTA, we identified multimorbidity patterns with temporal consistency and clinical stability (ie, Cardiometabolic-Multisystem, Hypertension-Arthritis, Respiratory-Musculoskeletal, Metabolic Syndrome, and Gastritis-Arthritis), which were then transformed into predictive labels to develop the CLA-Net deep learning model. CLA-Net integrates the sequential modeling capacity of GRU with the feature interaction advantages of a bitemporal directed cross-attention mechanism, achieving superior performance in capturing both temporal dependencies and complex feature interactions in chronic disease progression. Experimental results demonstrated that CLA-Net significantly outperformed existing methods across accuracy, recall, precision, F_1-score, and AUC.

Abstract

Background: Stroke remains one of the leading causes of mortality and long-term disability worldwide. Atrial fibrillation (AF) is a major and often underdiagnosed risk factor for ischemic stroke as it is frequently asymptomatic and may remain undetected until a catastrophic cerebrovascular event occurs. The lack of timely identification and preventive treatment for AF substantially increases stroke risk. Although previous studies have proposed various predictive models for AF detection, many rely primarily on structured clinical variables and are developed using data from a single institution, which limits their generalizability and real-world applicability across different health care settings.

Objective: The objective of this study was to develop a robust and generalizable AF risk prediction model for patients with stroke using electronic medical records. By integrating structured clinical variables with features derived from unstructured clinical text, this study aimed to construct a more comprehensive representation of patient health status. Furthermore, this study emphasized systematic internal and external validation, along with calibration assessment, to evaluate model stability and generalizability across multiple hospital datasets, thereby supporting its potential use in routine clinical practice.

Methods: This study analyzed datasets from 2 hospitals in Taiwan: Landseed International Hospital (LIH), with 3988 patients, and Chia-Yi Christian Hospital (CYCH), with 5821 patients. We applied 5 feature engineering techniques to extract features from unstructured electronic medical record data, addressed data imbalance using 6 distinct resampling methods, and used 9 classification algorithms to compare model performance across both internal and external validation sets. This study identified the top 20 most important features from the best-performing models for both the LIH and CYCH datasets.

Results: The optimal predictive model for LIH was based solely on structured variables, whereas the model for CYCH achieved superior results by integrating structured variables with text-derived variables obtained from unstructured clinical notes using term frequency–inverse document frequency. Notably, feature importance analysis consistently identified the ratio of E- to A-wave velocities, left atrial size, and age as the top 3 predictive factors across both datasets, underscoring their critical role in AF risk assessment among patients with stroke.

Conclusions: This study demonstrated the development of predictive models for AF in patients with ischemic stroke. Notably, the integration of structured variables with variables derived from unstructured clinical text improved predictive performance in selected model configurations. Rigorous internal and external validation processes confirmed the superior performance of ensemble learning–based machine learning models compared with alternative algorithms, underscoring the potential of this approach for AF risk prediction.

Introduction

Stroke ranks as the second leading cause of death and the third leading cause of disability worldwide, with both related mortality rates and the global disease burden continuing to rise [1,2]. The most common types of recurrent stroke are acute ischemic stroke (AIS) and transient ischemic attack (TIA) [3]. Within 1 year following an ischemic stroke, the risk of recurrence exceeds 7% [4-6]. Moreover, patients who experience a recurrent stroke within 10 years face more than twice the risk of death or disability compared with those who experience a first stroke [7].

Atrial fibrillation (AF) is a common sustained or paroxysmal cardiac arrhythmia [8,9]. Treatment may often be delayed as AF can be asymptomatic or episodic, making it challenging to detect [10]. AF is closely associated with cerebrovascular disease: irregular heartbeats over time can impair efficient blood contraction and clearance, potentially leading to blood clot formation. These clots may then travel to the brain and cause a stroke if AF remains untreated, increasing the risk of acute complications [11,12]. Patients with AF have twice the risk of dying from cardiovascular disease and up to a 5-fold increased risk of stroke [13]. Consequently, AF impacts patients with stroke significantly in terms of risk, treatment, and daily care requirements [14-17]. Regarding medication, for patients with stroke and AF, oral anticoagulants (eg, factor IIa and Xa inhibitors and warfarin) have been shown to reduce mortality by one-quarter and the risk of recurrent stroke by two-thirds [12]. Comparatively, antiplatelet drugs can reduce the risk of recurrent stroke by three-fifths [18]. Newer direct oral anticoagulants such as apixaban, rivaroxaban, edoxaban, and dabigatran are considered relatively safer and more effective, with a reduced risk of major bleeding compared with warfarin [19,20]. Physicians should find more underdiagnosed patients with AF, mostly paroxysmal AF, among those with AIS and TIA to administer appropriate safe and effective treatment for stroke prevention [21].

Risk assessment scales such as CHA2DS2-VASc [22] and its 2024 updated CHA2DS2-VA version [23] are widely used as clinical tools for evaluating AF risk based on variables collected from patient data. However, these assessments often require additional time or supplementary screening items to thoroughly identify associated risks. Long-term screening studies reveal that the diagnosis rate of AF, particularly paroxysmal AF, tends to increase with extended electrocardiographic (electrocardiogram; ECG) monitoring, although this also raises costs. Furthermore, collecting ECG data is time-intensive and can be cumbersome. Some researchers advocate for the use of continuous ECG monitoring (eg, Holter monitors) for AF detection, noting that recordings exceeding 24 hours may improve detection rates. However, given limited medical resources [7], the presence or absence of AF in patients with stroke significantly influences both treatment outcomes and subsequent risk levels. Thus, it is crucial to develop an efficient screening method that enables physicians to more accurately identify high-risk patients [10].

Electronic medical records (EMRs) contain rich structured and unstructured information that can be leveraged to support risk stratification and early detection of AF among patients with ischemic stroke [24]. While prior studies have demonstrated the potential of machine learning models for AF prediction, many have relied primarily on structured variables and data from a single institution, which may limit model generalizability and real-world applicability across different clinical settings [25-27]. In addition, the incremental value of incorporating unstructured clinical text into predictive models has not been systematically evaluated using rigorous external validation.

The aim of this study was to develop and validate a robust and generalizable machine learning model for predicting AF during hospitalization among patients with ischemic stroke using EMRs. Specifically, we sought to (1) integrate structured clinical variables with features derived from unstructured clinical text; (2) systematically evaluate multiple feature extraction methods, resampling strategies, and classification algorithms; and (3) assess model performance and calibration through rigorous internal and external validation across 2 independent hospital datasets. By emphasizing generalizability and real-world applicability, this study aimed to provide an effective decision support tool to facilitate early identification of high-risk patients and support clinical screening strategies for AF after stroke.

Methods

Study Population

This retrospective study was conducted using EMR datasets from 2 hospitals in Taiwan. The study population included all inpatients who were diagnosed with or suspected of having ischemic stroke by a physician during hospitalization, as well as those who presented with stroke-related symptoms. The dataset from Landseed International Hospital (LIH) covered the period from 2018 to 2022 and included a total of 3988 patients, while the dataset from Chia-Yi Christian Hospital (CYCH) spanned 2007 to 2020 and comprised 5821 patients. In total, 9809 patients were initially identified across the 2 hospitals.

Because the objective of this study was to develop predictive models for AF among patients with ischemic stroke without a prior history of AF, several exclusion criteria were applied. Consistent with prior studies, patients with documented AF prior to the index stroke were classified as having known AF before stroke and were excluded from model development. Known AF before stroke was defined as an AF diagnosis recorded in the medical history at the time of admission, indicating that AF had been identified through outpatient visits or cardiac monitoring before the current hospitalization. In addition, patients with AF detected on admission were excluded. AF detected on admission was identified based on the initial ECG, admission records, or documentation in the present illness or past medical history.

After applying the inclusion and exclusion criteria, the LIH dataset consisted of 1969 inpatients with unstructured clinical records, 2032 inpatients with structured clinical data, and 1226 inpatients with both structured and unstructured data. Similarly, the CYCH dataset included 3319 inpatients with unstructured

XSL•FO
RenderX

data, 1441 inpatients with structured data, and 1072 inpatients with both data types.

Patients with both structured and unstructured data were defined as the intersecting cohort, representing overlapping patients across the 2 data sources. This intersecting cohort constituted the final analytic population used for model development and evaluation to ensure consistent feature availability across all included patients. Patients with data available in only 1 data source were not included in the final modeling analyses.

In the LIH intersecting cohort, 7% (86/1226) of the patients were identified as having AF during hospitalization following ischemic stroke. In contrast, in the CYCH intersecting cohort, 32.6% (350/1072) of the patients met the criteria for AF. Therefore, both cohorts exhibited class imbalance with notably different proportions of AF cases, which motivated the use of resampling strategies in subsequent model development.

Ethical Considerations

The study protocol was approved by the institutional review boards of LIH (IRB-22-049) and Ditmanson Medical Foundation Chia-Yi Christian Hospital (IRB2022071). As this was a retrospective study using de-identified medical records, the requirement for informed consent was waived by both institutional review boards. To ensure patient confidentiality, all personal identifiers were removed and replaced with unique study identification numbers prior to analysis. No participants received any financial compensation, as no direct contact or intervention was involved.

Outcome Variable

The primary outcome variable in this study was the occurrence of AF during hospitalization following ischemic stroke among patients in the intersecting cohort. AF status was determined using a predefined set of criteria that integrated multiple data sources from the EMRs, as summarized in Table 1. Specifically, AF was ascertained based on evidence from structured diagnostic information, unstructured clinical text, and medication records. Structured data included *International Classification of Diseases* diagnosis codes indicative of AF, whereas unstructured sources comprised textual mentions of AF in clinical narratives and examination reports, such as Holter monitoring reports; cardiac ultrasound reports; ECG reports, excluding the first ECG on admission; and general medical records, including discharge summaries. Keyword-based text searches were conducted using commonly used terms referring to AF. In addition, prescriptions of antiarrhythmic agents and oral anticoagulants were incorporated as supportive evidence for AF identification [28]. A patient was classified as having AF if any one of the criteria listed in Table 1 was satisfied.

Table . Criteria used to ascertain atrial fibrillation (AF) status in the intersecting cohort.

Criterion	Conditions
AF-1	AF documented in the stroke registry during hospitalization
AF-2	AF-related keywords identified in Holter monitoring report text
AF-3	AF-related keywords identified in cardiac ultrasound report text
AF-4	AF-related keywords identified in ECG[a] report text, excluding the first ECG on admission
AF-5	AF-related keywords identified in clinical narratives, including hospital discharge summaries
AF-6	Presence of an AF-related *ICD*[b] diagnosis code (*ICD-9-CM*[c] 427.31 or *ICD-10-CM*[d] I48.91)
AF-7	Prescription of antiarrhythmic medications, including amiodarone, propafenone, or dronedarone
AF-8	Prescription of oral anticoagulants, including warfarin, apixaban, edoxaban, rivaroxaban, or dabigatran

[a]ECG: electrocardiogram.

[c]*ICD-9-CM*: *ICD, Ninth Revision, Clinical Modification.*

[d]*ICD-10-CM*: *ICD, 10th Revision, Clinical Modification.*

Predictor Variables and Text Preprocessing

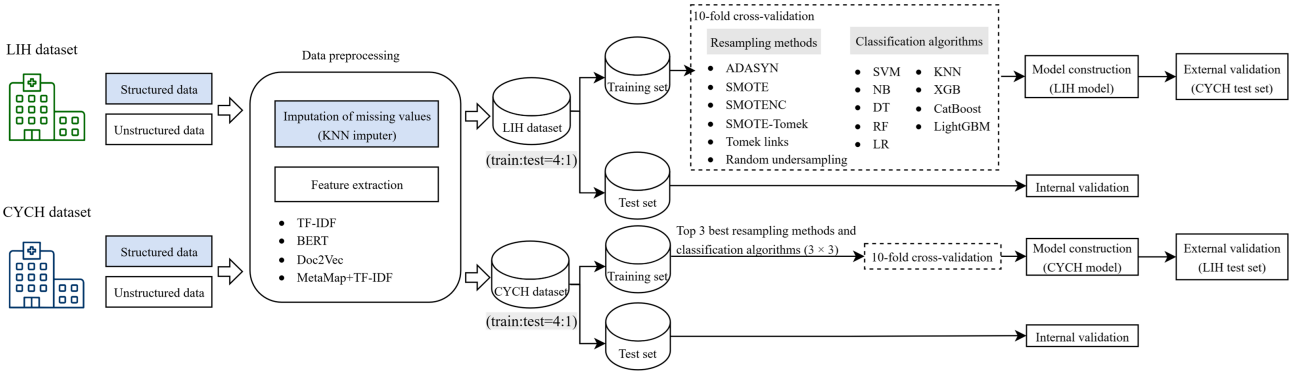
Predictor variables comprised data obtained within 72 hours of admission. After excluding patients with a history of AF or diagnosed with AF upon admission, all variables were standardized across both hospitals.

The structured variables, detailed in Multimedia Appendix 1, comprised a comprehensive set of clinical predictors that are routinely available at hospital admission and during early hospitalization. These structured predictors included demographic characteristics (sex, age, height, and weight); vascular imaging findings derived from carotid duplex sonography; echocardiographic parameters reflecting cardiac structure and function (eg, aortic diameter, left atrial size, ventricular dimensions, ejection fraction, and diastolic function indexes); vital signs (body temperature, heart rate, respiratory rate, and blood pressure); and laboratory measurements covering hepatic function, renal function, coagulation profiles, inflammatory markers, lipid profiles, and hematological indexes. In addition, neurological severity was captured using individual

XSL•FO
RenderX

National Institutes of Health Stroke Scale (NIHSS) subitems, as well as the overall NIHSS score, enabling fine-grained representation of stroke-related neurological deficits. Family medical history variables related to hypertension, diabetes mellitus, stroke, and ischemic heart disease were also included as nominal predictors. Together, these structured variables provided a multidimensional characterization of patients' demographic profiles, cardiovascular status, metabolic conditions, neurological severity, and familial risk factors.

Unstructured data encompassed magnetic resonance imaging results, chief concerns, and present illness. Text preprocessing of variables derived from unstructured clinical text involved Chinese-English translation, spell-checking, abbreviation expansion, nonword symbol removal, AF-suggestive word deletion, lowercase conversion, word form reduction, negation marking as "_NEG" using additional negation words [29,30] and the Natural Language Toolkit's (Team NLTK) *mark_negation* function, and stop word removal.



For text feature extraction, we used bidirectional encoder representations from transformers (BERT) [31,32], Doc2Vec [33,34], term frequency–inverse document frequency (TF-IDF) [35,36], and MetaMap [37,38]. These 4 methods were selected to represent complementary paradigms in clinical natural language processing, ranging from deep contextualized language models to traditional statistical and knowledge-based approaches. BERT has demonstrated strong performance in modeling contextual semantics and capturing complex linguistic patterns in clinical narratives and has been widely adopted in biomedical and clinical natural language processing tasks. Doc2Vec was included as a representative neural embedding method that captures document-level semantics with lower computational complexity, making it suitable for large-scale clinical text analysis. TF-IDF remains a widely used and robust baseline in clinical text mining due to its interpretability and effectiveness in high-dimensional sparse representations. MetaMap was incorporated to leverage domain-specific medical knowledge by mapping clinical text to standardized concepts in the Unified Medical Language System, which has been shown to enhance semantic normalization and downstream clinical prediction tasks.

Medical concepts (concept unique identifiers) were identified via MetaMap and subsequently transformed into feature vectors using TF-IDF applying a term frequency threshold with maximum and minimum values set to 0.9 and 0.1, respectively. In addition, Chinese text translation and spell-checking were conducted using *googletrans* (version 3.1.0a0) and *pyspellchecker* (version 0.8.1) to improve text consistency prior to feature extraction.

Prediction Model Development and Evaluation

Figure 1 delineates a comprehensive machine learning model validation workflow encompassing both internal and external validation phases. The internal validation phase uses the LIH dataset and a 10-fold cross-validation strategy. During this process, various combinations of resampling methods and modeling techniques are evaluated, with the top 3 best-performing combinations (totaling 9 configurations) selected for further analysis. This step is crucial for identifying the most appropriate models and parameter settings for the given data.

Figure 1. The process of machine learning model construction. ADASYN: adaptive synthetic sampling; BERT: bidirectional encoder representations from transformers; CatBoost: categorical boosting; CYCH: Chia-Yi Christian Hospital; DT: decision tree; KNN: k-nearest neighbor; LightGBM: light gradient-boosting machine; LIH: Landseed International Hospital; LR: logistic regression; NB: naive Bayes; RF: random forest; SMOTE: synthetic minority oversampling technique; SMOTENC: SMOTE for nominal and continuous features; SVM: support vector machine; TF-IDF: term frequency–inverse document frequency; XGB: extreme gradient boosting.

The external validation phase leverages an independent dataset from CYCH. In this stage, the optimal model and resampling method combinations identified during internal validation are used to train models, which are subsequently evaluated on the external dataset. This phase is essential for assessing the models' generalizability, ensuring their robustness and efficacy when applied to novel, unseen data. This rigorous 2-stage validation approach enhances the reliability and external validity of the developed predictive models, providing a robust framework for clinical application in AF risk assessment among patients with stroke. For both the internal and external validation phases, we used k-nearest neighbor imputation to address missing values within structured data. Additionally, we applied multiple feature extraction techniques to the unstructured text, including TF-IDF, BERT, Doc2Vec, and MetaMap combined with TF-IDF, followed by subsequent evaluations to compare model performance. To comprehensively evaluate the predictive power of different data types, we constructed and compared three distinct model configurations: (1) models using only structured variables, (2) models using only variables derived from unstructured clinical text (ie, text-derived variables), and (3) models combining both structured and text-derived variables.

XSL•FO
RenderX

To address the class imbalance present in the datasets from both hospitals, we implemented various resampling techniques during the model training phase, including adaptive synthetic sampling, synthetic minority oversampling technique (SMOTE), SMOTE for nominal and continuous features, SMOTE-Tomek, Tomek links, and random undersampling. We stratified and split the data into training and test sets with a 4:1 ratio using the parameter *stratify=df[['AF']]* to maintain consistent class ratios across sets.

We evaluated multiple classifiers, including support vector machine, Gaussian naïve Bayes, k-nearest neighbor, decision tree, random forest, logistic regression, Extreme Gradient Boosting (XGBoost), categorical boosting (CatBoost), and light gradient-boosting machine (LightGBM). The training process incorporated 10-fold cross-validation with stratification (*stratify=df[['AF']]*) to obtain robust performance estimates. We assessed model performance using multiple evaluation metrics, including the area under the receiver operating characteristic curve (AUC), sensitivity, specificity, and expected calibration error. Following the identification of optimal model combinations, we conducted both internal and external validation. The final results reflected the outcomes of the test set.

To enhance model interpretability, we used Shapley values (using *shap* version 0.45.0) to explain the best-performing models in both the LIH and CYCH datasets. This approach provides insights into the relative importance of different features in the prediction task.

Baseline Models

The baseline model was compared with machine learning models using traditional risk-scoring models (AS5F [age, stroke severity NIHSS>5 to find atrial fibrillation] [39-41] and CHASE-LESS [coronary, heart failure, age, stroke severity–lipidemia, sugar, and prior stroke] [15,42,43]). CHASE-LESS was developed using data derived from a Taiwanese population, which is consistent with the population of this study, and its variables include age, NIHSS score, coronary heart disease, congestive heart failure, hyperlipidemia, diabetes mellitus, and prior stroke or TIA. The threshold value of CHASE-LESS was set to 6, and the scoring items were based on the variables in the EMR at the time of admission. The AS5F score is designed to determine the need for long-term ECG monitoring in patients with AIS or TIA.

Results

We conducted modeling and prediction using both structured and text-derived variables from the two hospitals. In the internal validation for LIH (Table 2), the combination of structured variables with logistic regression yielded the best performance, achieving an AUC of 0.896. For text-derived variables, the model using Doc2Vec, random undersampling, and LightGBM achieved an AUC of 0.674. When integrating both structured and text-derived variables, the model incorporating Doc2Vec, SMOTE, and CatBoost performed well, with an AUC of 0.885. Some models showed enhanced performance when integrating both types of variables. For instance, in the LightGBM model implementation, the integration of structured and text-derived variables, coupled with the adaptive synthetic sampling technique, demonstrated superior performance, with an AUC of 0.876. This feature-integrated approach substantially outperformed both models using only structured variables (AUC=0.850) and those using only text-derived variables (AUC=0.468). However, not all combined approaches demonstrated such improvement.

In the external validation of the LIH model using the CYCH dataset (Table 3), the best performance was achieved using a combination of BERT and SMOTE, with an AUC of 0.795, which exceeded the AUC for models using only structured variables (AUC=0.781) and those using only text-derived variables. In the internal validation for CYCH (Table 4), the best-performing model was a combination of BERT with undersampling and XGBoost, achieving an AUC of 0.861. In the external validation, the optimal combination involved an imbalanced technique with CatBoost, resulting in an AUC of

XSL•FO
RenderX

0.832. These findings suggest that combining structured and text-derived variables can improve predictive performance in some models, highlighting the importance of selecting appropriate models and resampling techniques to enhance model outcomes.

Figure 2 presents the external validation results from the 2 hospitals, indicating that the combination of CatBoost and SMOTE ranked third in both cases as determined by the AUC metric. Overall, ensemble learning demonstrated superior performance throughout the validation process. While the incorporation of text-derived variables did not consistently yield the highest AUC values in both internal and external validation, it is noteworthy that their inclusion generally resulted in improved outcomes based on the expected calibration error during external validation.

Discussion

Summary of Main Findings

This study developed and validated machine learning–based prediction models for identifying AF during hospitalization among patients with ischemic stroke by leveraging EMRs from 2 independent hospitals. The main findings can be summarized in 3 points. First, models trained on structured clinical variables achieved strong predictive performance, and the integration of unstructured clinical text further improved discrimination and calibration in selected model configurations, particularly in the external validation setting. Second, ensemble learning methods, including CatBoost, XGBoost, and LightGBM, consistently outperformed traditional risk scores and conventional classifiers across internal and external validation. Third, feature importance analysis using SHAP revealed that echocardiographic parameters, including the ratio of E- to A-wave velocities, left atrial size, and age, were among the most influential predictors across both datasets. Together, these findings demonstrate the feasibility and generalizability of incorporating structured and unstructured EMR data to support early risk stratification for AF after ischemic stroke.

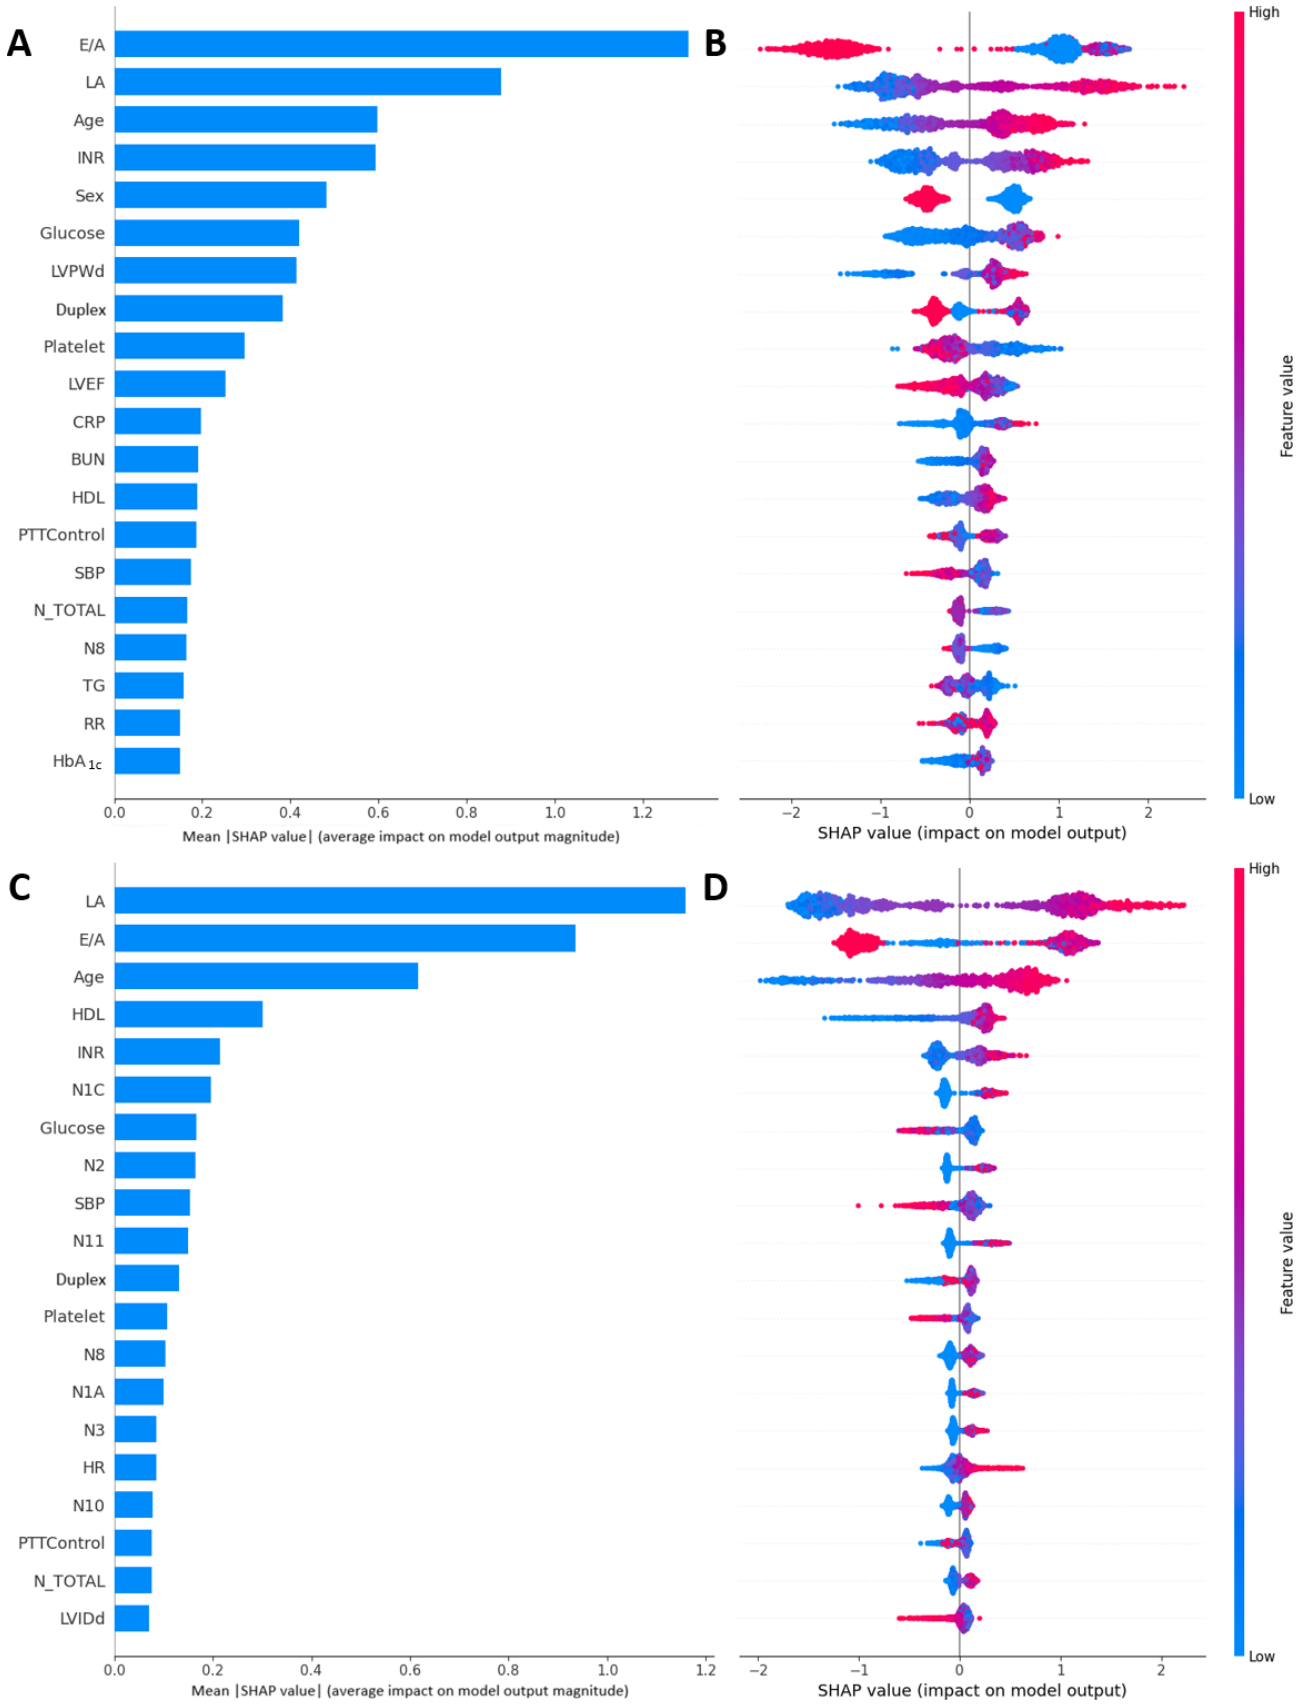
Implications of Integrating Structured and Text-Derived Variables

Although the integration of structured variables with variables derived from unstructured clinical text improved predictive performance in several model configurations, the results in Table 2 indicate that such integration did not uniformly outperform models based solely on structured variables. This finding warrants careful interpretation rather than being viewed as a limitation of the proposed framework. In this study, structured clinical variables already encompassed well-established and highly discriminative predictors of AF, including echocardiographic parameters such as the ratio of E- to A-wave velocities, left atrial size, and age. When such strong predictors are present, models trained exclusively on structured variables may achieve near-optimal performance, leaving limited room for additional gains from text-derived variables.

Moreover, variables derived from unstructured clinical text are inherently high-dimensional and potentially noisy, particularly when generated using representation techniques such as TF-IDF or Doc2Vec. For certain classifiers that are sensitive to feature dimensionality or redundancy, the inclusion of text-derived variables may dilute the contribution of strong structured predictors, resulting in marginal or inconsistent performance gains. This phenomenon is consistent with prior observations in studies integrating clinical text with structured EMR data.

Importantly, our results suggest that the benefit of feature-level integration is highly model dependent. Ensemble learning–based algorithms, including LightGBM, XGBoost, and CatBoost, demonstrated a greater capacity to exploit complementary information from heterogeneous feature sources, particularly when combined with appropriate resampling strategies. In contrast, simpler or less flexible classifiers did not consistently benefit from the inclusion of text-derived variables. These findings indicate that integrating unstructured clinical text should be viewed as a complementary strategy whose effectiveness depends on the interaction among feature representation, classifier architecture, and imbalance-handling methods.

In addition, Table 2 indicates that resampling did not consistently improve performance for all classifiers as some models achieved comparable results when trained on the original imbalanced data. This finding suggests that the necessity of resampling is model dependent. Ensemble learning–based classifiers may inherently mitigate class imbalance effects, whereas other models benefit more substantially from resampling techniques. Therefore, resampling should be considered a robustness-oriented strategy rather than a mandatory preprocessing step.



Significant Features

Figure 3 illustrates the 20 most significant features identified for the LIH and CYCH datasets using shap (version 0.45.0). In Figure 3, features are ranked according to their mean absolute Shapley values, which quantify the global importance of each feature in relation to the model's output. Figure 3A presents the feature ordering for LIH, whereas Figure 3C depicts the ordering for CYCH. Figure 3 shows beeswarm plots that visualize the Shapley values for each patient concerning these features. The beeswarm plots convey the contribution of each feature to the model's output based on the magnitude and direction of the Shapley values. Figure 3B represents the contributions of LIH patients, whereas Figure 3D illustrates those of CYCH patients. Notably, the graphs reveal that the top 3 features consistently identified across both datasets were ratio of E- to A-wave velocities, left atrial size, and age.

XSL•FO
RenderX

Figure 3. The top 20 most important features identified by the model based on structured variables. Panels A and C display bar charts representing the mean absolute Shapley values, which indicate the average contribution of each feature to the model's output. Panels B and D present beeswarm plots of individual Shapley values for each feature across patients, where the position of each dot on the x-axis reflects that feature's contribution to the prediction for a given patient. The color of each dot corresponds to the relative value of the associated feature. BUN: blood urea nitrogen; CRP: C-reactive protein; E/A: ratio of E- to A-wave velocities; HbA_{1c}: hemoglobin A_{1c}; HDL: high-density lipoprotein; HR: heart rate; INR: international normalized ratio; LA: left atrial size; LVEF: left ventricular ejection fraction; LVIDd: left ventricular internal dimension in diastole; LVPWd: left ventricular posterior wall in diastole; N1A: level of consciousness responsiveness; N1C: level of consciousness commands; N2: best gaze; N3: visual fields; N8: sensory; N10: dysarthria; N11: extinction and inattention; PTTControl: partial thromboplastin time control; RR: respiratory rate; SBP: systolic blood pressure; SHAP: Shapley additive explanations; TG: triglyceride.

Clinical Applications and Significance

Predicting AF following a stroke is critical for effective secondary stroke prevention as it directly influences medical decision-making and patient outcomes. Given the constraints of health care resources, it is essential to optimize their use by incorporating efficient screening protocols. In this context, machine learning offers a highly effective approach. This study identified the optimal combination of variables derived from unstructured clinical text through rigorous external validation

XSL•FO
RenderX

supplemented by internal validation using the LIH dataset and further validated using EMR data from CYCH. Although models built on internal data are often preferred for clinical applications, our experiments revealed that models developed using the CYCH data occasionally outperformed those based on LIH data. This discrepancy may be attributed to missing information and the relatively small sample size of the LIH dataset. The models developed in this study aim to support clinicians by identifying high-risk patients who would benefit from additional screening measures, such as ECG, ultimately reducing the risk of missed diagnoses and ensuring timely and appropriate treatment.

Limitations

This study has several limitations that should be acknowledged. First, the data source poses a potential issue as the data were derived from EMRs within the hospitals. It is possible that patients were diagnosed with AF outside these institutions, introducing bias, particularly given the older age demographic of the hospital population. Second, regarding the data themselves, while generalizability was tested across 2 different hospitals, the variability in clerical styles between the hospitals may affect the consistency of the variables derived from unstructured clinical text. For structured variables, a high proportion of missing values in factors known to be associated with stroke or AF (eg, smoking history), uncertainties about the accuracy of the records, and the small and variable sample size could all impact the overall efficacy of the model. Finally, it should be noted that the predictors contributing to the model in this study do not imply causality.

Conclusions

This study demonstrates the feasibility of developing machine learning–based predictive models to identify AF in patients with ischemic stroke using EMR data. The integration of structured variables with variables derived from unstructured clinical text, including medical history and magnetic resonance imaging findings extracted from free-text sources, showed potential to improve predictive performance in selected model configurations. Internal and external validation results indicate that ensemble learning–based models performed favorably compared with other algorithmic approaches, supporting their potential utility for AF risk prediction in clinical settings.

Funding

This research was supported in part by the National Central University–Landseed Hospital Research and Development Office (NCU-LSH-111-B-008) and the Ministry of Science and Technology of the People's Republic of China (grant MOST 111-2410-H-008-026-MY2).

Abstract

Background: Hyperhomocysteinemia (HHcy) is recognized as an independent risk factor for coronary heart disease (CHD), yet accurately predicting CHD risk in patients with HHcy remains a challenge. This study aimed to develop and validate multiple machine learning models for predicting CHD risk in patients with HHcy and elucidate key predictors using Shapley Additive Explanation (SHAP) algorithms.

Objective: This study aims to develop and validate machine learning models for predicting the risk of coronary heart disease in individuals with normal homocysteine levels, aiming to improve early risk stratification and clinical decision-making.

Methods: This single-center retrospective study collected data from patients who were diagnosed with HHcy through electronic medical records, which were randomly divided into training (n=364, 70%), validation (n=78, 15%), and test (n=78, 15%) sets. Seven machine learning models were constructed, including logistic regression, k-nearest neighbor, decision tree, random forest, extreme gradient boost, light gradient boosting machine (LightGBM), and stacking. Six core variables (age, weight, hypertension, continuous drinking history, activated partial thromboplastin time, and carotid plaque) were utilized as inputs, with performance evaluation metrics encompassing area under the receiver operating characteristic curve, accuracy, F_1-score, calibration curve, Brier score, and decision curve analysis. Additionally, SHAP interpretation was conducted on the optimal LightGBM model.

Results: The LightGBM model exhibited superior performance in the test set (area under the receiver operating characteristic curve=0.807, F_1-score=0.606), demonstrated good calibration (Brier score=0.2415), and yielded high clinical net benefit. SHAP analysis revealed age and activated partial thromboplastin time as the most influential predictors, followed by hypertension, weight, carotid plaque, and continuous drinking history. The correlation heat map illustrated low collinearity among variables, ensuring model stability.

Conclusions: The LightGBM model demonstrated high accuracy and interpretability in forecasting CHD risk among patients with HHcy. The integration of machine learning and interpretable artificial intelligence methods holds promise for delivering personalized early risk assessment and intervention strategies in clinical settings.

KEYWORDS

retrospective study; hyperhomocysteinemia; coronary heart disease; machine learning; predictive model

Introduction

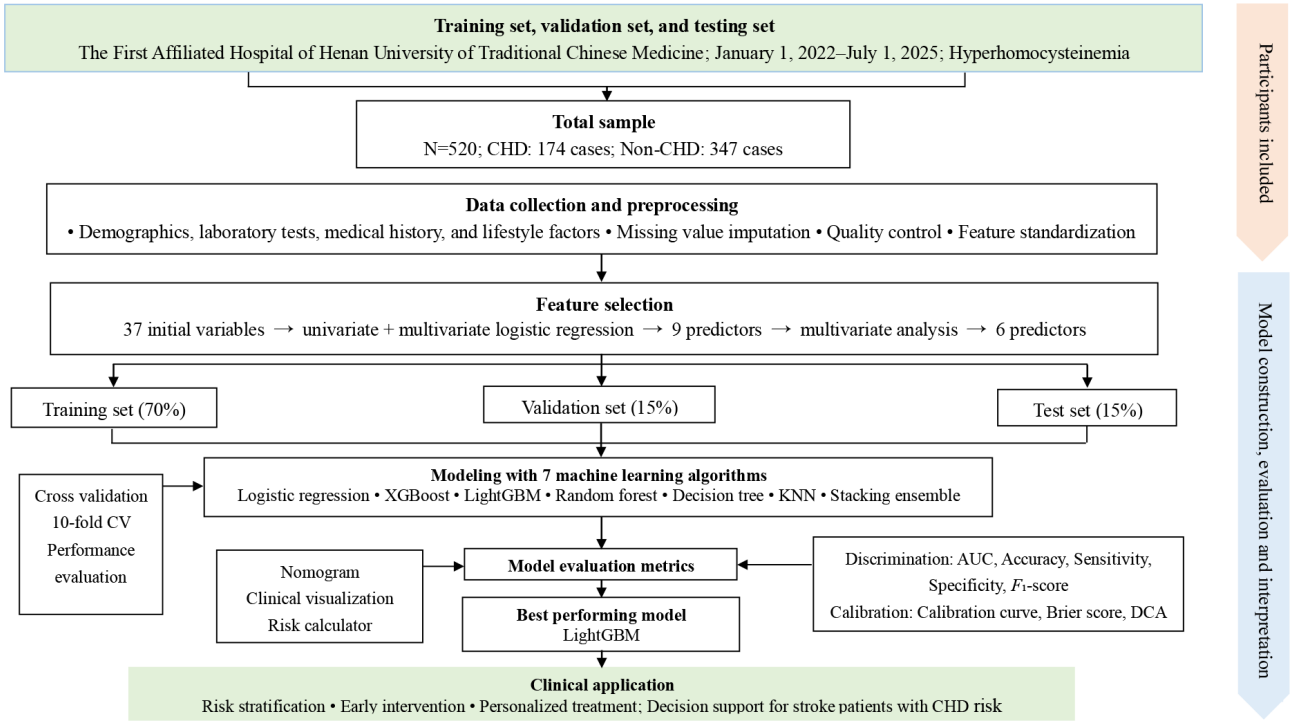
Hyperhomocysteinemia (HHcy) predisposes individuals to heightened and premature susceptibility to coronary heart disease (CHD) [1,2]. Existing research has substantiated that HHcy expedites atherosclerosis progression via various mechanisms, including vascular endothelial impairment, pro-oxidative stress, and disrupted coagulation pathways, establishing it as a stand-alone CHD risk factor [3-5]. Nevertheless, the CHD risk profile in HHcy cohorts is heterogeneous, potentially modulated by a confluence of factors

XSL•FO
RenderX

encompassing age, biochemical milieu, lifestyle choices, and vascular morphology.

The current assessment tools for CHD risk in patients with HHcy are limited [6]. Traditional models, such as Cox or logistic regression, are typically based on a small number of variables and struggle to capture the intricate nonlinear interactions among variables in real clinical settings. Furthermore, these models often rely on predictors that necessitate specialized knowledge or image interpretation, hindering their widespread adoption among noncardiovascular specialist clinicians [7]. Given that HHcy is a common condition and many patients are initially diagnosed in primary or nonspecialist clinics, there is a pressing need for a predictive tool that offers predictability, universality, and interpretability to facilitate early risk assessment and intervention in clinical practice.

Machine learning technology holds potential for predicting the likelihood of diabetes, arrhythmia, and various cardiovascular diseases by effectively capturing intricate multidimensional patterns [8]. Ensemble models, such as light gradient boosting machine (LightGBM) and extreme gradient boosting (XGBoost), excel in automatically discerning key features and enhancing predictive accuracy [9]. Nevertheless, there is a scarcity of dedicated modeling research on CHD risk among individuals with HHcy. Moreover, the clinical interpretability of numerous machine learning models remains inadequate, constraining their reliability and utility in medical settings [10,11].



This study seeks to develop CHD risk prediction models for individuals with HHcy using real-world electronic health record data from a single center [12]. The study aims to compare the performance of 7 mainstream machine learning algorithms in terms of discriminative power, calibration, and clinical net benefit. To improve clinical interpretability, the Shapley Additive Explanation (SHAP) method was used to assess model decision-making and identify key variables. Emphasis was placed on the generalizability of variable selection and form, prioritizing standardized biochemical and lifestyle indicators that are routinely accessible to avoid reliance on specific specialties or complex imaging techniques. The objective is to create a practical model that can be easily implemented across various clinical settings, balancing predictability and interpretability. This model aims to serve as an early risk assessment tool for high-risk HHcy populations and establish a basis for future multicenter external validation studies.

Methods

Research Materials

A comprehensive workflow of the study, including data collection, feature selection, model development, evaluation, and interpretation, is illustrated in Figure 1.

Figure 1. Flowchart of developing and validating machine learning–based models for predicting coronary heart disease (CHD) risk in patients with hyperhomocysteinemia. This flowchart outlines the entire process of constructing and evaluating risk prediction models for CHD in patients with hyperhomocysteinemia. AUC: area under the receiver operating characteristic curve; CV: cross-validation, DCA: decision curve analysis; KNN: k-nearest neighbor; LightGBM: light gradient boosting machine; XGBoost: extreme gradient boosting.

General Information

This retrospective registry study examines patients with HHcy treated at the First Affiliated Hospital of Henan University of Traditional Chinese Medicine between January 1, 2022, and July 1, 2025.

Patients were categorized into either the CHD group or the non-CHD group based on clinical diagnoses. Subsequent to

XSL•FO
RenderX

admission, demographic features, laboratory values, medical history, familial history, and additional indicators were gathered for statistical assessment.

Ethical Considerations

Ethical approval was obtained from the Ethics Committee of the First Affiliated Hospital of Henan University of Chinese Medicine (approval number: 2025HL-202‐01). The data used were fully deidentified, and no personally identifiable information was accessible to the researchers. The requirement for informed consent was waived by the ethics committee in accordance with national regulations, citing the retrospective nature of the study. No compensation was provided to participants.

Diagnostic Criteria

The patient was diagnosed with stable CHD in accordance with the 2025 American College of Cardiology/American Heart Association (ACC/AHA) guideline for chronic coronary syndromes [13]. Acute coronary syndromes were identified following the criteria outlined in the 2023 ESC and 2021 ACC/AHA guidelines for non–ST-elevation acute coronary syndrome [14,15].

Inclusion and Exclusion Criteria

Inclusion Criteria

Participants were required to meet the diagnostic criteria for HHcy, be aged between 18 and 80 years, and have complete baseline clinical data available for analysis.

Exclusion Criteria

Participants excluded from the study encompass those with comorbid severe organic conditions (eg, advanced tumors, hepatorenal insufficiency), nonatherosclerotic heart ailments (eg, congenital heart disease, myocarditis), individuals with mental illness or cognitive deficits hindering study cooperation, pregnant or lactating women, and those engaged in other clinical trials within the preceding 3 months.

Observation Indicators

This study utilized data collected through a standardized case report form, encompassing five key categories of core indicators: (1) demographics and basic information, such as age, gender, height, weight, BMI, educational level, and marital status; (2) medical history and lifestyle factors, including a history of diseases, such as hypertension, diabetes, transient ischemic attack, as well as lifestyle habits, such as persistent smoking and alcohol consumption; (3) laboratory examination indicators, comprising blood routine parameters (red blood cell, white blood cell, and platelet counts), biochemical markers (total cholesterol, triglycerides, and creatinine), and coagulation function tests (activated partial thromboplastin time [APTT], prothrombin time, and fibrinogen); (4) imaging examination indicators, specifically the presence or absence of carotid plaques as determined by ultrasound or computed tomography angiography; and (5) quality control measures involving the uniform extraction of all data by trained researchers through the electronic medical record system and laboratory information system. A double-person review system was implemented to ensure data accuracy. Following the integrity assessment, no missing values were identified in the variables included, thus obviating the need for imputation or data elimination procedures. The detailed data extraction workflow and quality control procedures are provided in Multimedia Appendix 1.

Machine Learning Modeling and Related Statistical Methods

Statistical analysis was performed using SPSS Statistics 27. Machine learning modeling utilized R 4.5 (caret package) and Python 3.13 (scikit-learn, xgboost, lightgbm) libraries. Quantitative data were reported as mean (SD). Group differences were assessed using independent-sample 2-tailed *t* tests (for normal distribution) or Mann-Whitney *U* tests (for nonnormal distribution), based on data distribution. Categorical data were presented as n (%), with group differences analyzed using the chi-square test or Fisher exact probability method.

Variable Screening and Dataset Division

Variable screening involved a 2-step dimensionality reduction approach utilizing “univariate+multivariate logistic regression.” Initially, 9 variables exhibiting significant differences ($P<.05$) between the CHD and non-CHD groups were selected for the candidate pool. Subsequently, multivariate analysis was conducted using stepwise regression (backward method, inclusion criterion $\alpha=.05$, exclusion criterion $\alpha=.10$), resulting in the retention of 6 independent predictors: age, body weight, hypertension, history of continuous alcohol consumption, APTT, and carotid artery plaque. The variance inflation factors for all variables were less than 5, indicating the absence of significant multicollinearity.

The data were stratified based on the presence of CHD comorbidity, resulting in division into a training set (n=364), a validation set (n=78), and a test set (n=78) at a ratio of 7:1.5:1.5. To ensure result reproducibility, a random seed (random_state=2024) was set. The training set was used for model training and initial parameter optimization, the validation set for fine-tuning model parameters and classification threshold optimization, and the test set as an independent dataset for the final model performance assessment.

Machine Learning Model Construction

Seven classification models were developed to forecast the risk of CHD, categorized into traditional models (logistic regression, decision tree, and k-nearest neighbors [KNNs]) and ensemble models (random forest, XGBoost, LightGBM, and stacking). Hyperparameter optimization was performed on all models using grid search (GridSearchCV) on the training set to enhance the area under the receiver operating characteristic curve (AUC) on the validation set.

Logistic regression employs L2 regularization and class weight balancing (class_weight='balanced') with a regularization strength of C=0.1. The decision tree and random forest models optimize the max_depth, which is ultimately determined to be 7, with min_samples_split set to 2 for the decision tree and n_estimators set to 50 for the random forest. KNN utilizes the Euclidean distance metric, with the number of neighbors ultimately set to 9.

XSL•FO
RenderX

In the context of boosting models, both XGBoost and LightGBM were configured with a scale_pos_weight of 2 to address class imbalance. Parameter optimization yielded the following settings: XGBoost (max_depth=3 and learning_rate=0.3) and LightGBM (max_depth=3 and learning_rate=0.01). The stacking model used the aforementioned 6 models as base learners, with logistic regression serving as the meta-learner. The integration of outputs was achieved through 5-fold cross-validation.

All parameter tuning details are listed in Table S2 in Multimedia Appendix 2 to enhance reproducibility.

Model Evaluation and Validation

A multidimensional index is used to thoroughly assess the model's performance, with the subsequent metrics computed on the training, validation, and test sets, respectively:

Discrimination is primarily assessed using the AUC, computed through "sklearn.metrics.roc_auc_score." Additionally, metrics, such as accuracy, recall, specificity, and F_1-score, are documented. To provide a comprehensive evaluation of classification performance, the precision-recall (PR) curve is generated, and the PR-AUC is determined.

Calibration is assessed through a calibration curve generated using the sklearn.calibration.calibration_curve function. An optimal calibration curve closely aligns with the diagonal line. The Brier score quantifies the accuracy of predicted probabilities by measuring the mean squared error between predicted probabilities and true labels. A lower Brier score signifies more precise predicted probabilities.

We used a 10-fold cross-validation method on the training set to assess model stability, recording the mean AUC and standard deviation. To evaluate generalization capability, we considered the metrics of the test set as the reference standard. A significant decrease in the test set's AUC compared to the training set (eg, ΔAUC<0.1) suggested potential overfitting.

Sample Imbalance Processing and Threshold Optimization

To address the 1:2 sample imbalance between the CHD and non-CHD groups, the following strategies were implemented to enhance the model's ability to identify the minority class (CHD group):

For models supporting weight parameters (eg, logistic regression, XGBoost, LightGBM, and random forest), class_weight='balanced' or scale_pos_weight=2 was set. Specifically, class_weight='balanced' automatically calculates class weights inversely proportional to class frequencies, amplifying the contribution of CHD samples in the loss function. Meanwhile, scale_pos_weight=2 directly sets the weight of positive samples (CHD group) to twice that of negative samples (non-CHD group), aligning with the 1:2 sample ratio and mitigating the model's bias toward the majority class caused by imbalance.

Although class weight adjustment balances class importance during training, the default classification threshold (0.5) may not meet the clinical demand for high sensitivity in CHD screening. Therefore, further threshold optimization was performed on the best-performing LightGBM model. Based on predicted probabilities from the validation set, candidate thresholds ranging from 0.1 to 0.6 (stepping at 0.05) were evaluated, with sensitivity, specificity, and F_1-score calculated for each threshold. The optimal threshold was determined by balancing these metrics—prioritizing high sensitivity (to identify as many true CHD patients as possible) while maintaining acceptable specificity. This approach breaks the limitation of a fixed threshold, enabling the model to better align with the practical goal of "reducing missed diagnoses" in imbalanced scenarios (see Figure S1 in Multimedia Appendix 3).

Analysis of Model Interpretability

The LightGBM model's optimal performance was assessed using the SHAP algorithm for both global and local interpretability analyses. Globally, the SHAP summary plot illustrated the average contribution of each variable to the model prediction, identifying key factors influencing the risk of CHD. Locally, the SHAP dependence plot depicted the functional relationship between each feature and the model output, highlighting the positive and negative effects of variables, such as age and APTT, on the predicted value. Additionally, a Pearson correlation heatmap was generated to assess collinearity among features, confirming that no strong correlations (r<0.5) existed among the model variables. This analysis ensured the model's stability and bolstered the credibility of its interpretation.

Sample Size Estimation

Based on the recommendations by van Smeden et al [16,17] and Riley et al [18,19], we estimated the minimum sample size required to develop a reliable multivariable prediction model using 5 candidate predictors. Assuming an outcome prevalence of approximately 30%, a shrinkage factor of 0.9, and an expected Cox-Snell R^2 of 0.15, the minimum required sample size was calculated to be approximately 218. This study developed models with a larger sample size, thus mitigating the potential for major overestimation bias based on these parameters.

External Benchmark Models

For comparative purposes, Framingham risk score [20] and the ACC/AHA pooled cohort equations (ASCVD score) [21] were calculated for all patients using baseline clinical parameters. These scores were included as benchmark models to evaluate the incremental value of the model.

Results

Comparison of Clinical Data Between the 2 Groups

This study comprised 520 patients with HHcy, with 174 in the CHD group and 347 in the non-CHD group, resulting in a CHD detection rate of 33.46%. The analysis of baseline data revealed significant differences in 9 variables between the 2 groups, all with P<.05, as detailed in Table 1.

Univariate Regression Analysis of Risk Factors for CHD in HHcy Patients

Nine statistically significant factors were selected as independent variables for logistic regression analysis to predict the occurrence of CHD. The results revealed that 6 variables—age, weight, hypertension, continuous drinking history, APTT, and carotid plaque—significantly influenced the occurrence of CHD (all *P*<.05), as shown in Table 2.

Table . Logistic regression analysis of risk factors for coronary heart disease (CHD) in patients with hyperhomocysteinemia.[a]
