JMIR Medical Informatics

Impact Factor (2023): 3.1
Volume 14 (2026) ISSN 2291-9694 Editor in Chief: Christian Lovis, MD, MPH, FACMI

Contents

Reviews

Participatory Design of AI-Based Clinical Decision Support Systems: Scoping Review (e88368)
Tabea Rambach, Patricia Gleim, Carolin Heizmann, Philipp Kellmeyer, Christophe Kunze. 31

Technology-Enhanced Health Care in Smart Homes: Scoping Review of Sensor Technologies, Clinical Applications, Integration Challenges, and Future Directions (e89189)
Yomna El-Saboni, Samira Awwal, Rakesh Mishra, Nityanand Sharma, Anshu Gaur, Leigh Fleming. 52

Prediction Models for In-Hospital Delirium Using Routinely Collected Electronic Health Record Data: Systematic Review (e91618)
Hung-Min Huang, Chun-Shun Lu, Geng-Wei Chang, Ming-Hsu Tien, Yu-Kai Hsu. 84

Natural Language Processing Applied to Psychiatric Clinical Notes: Scoping Review (e91249)
Shuying Rao, Xi'ang Chen, Guifeng Deng, Junyi Xie, Tiecheng Jiang, Tao Li, Yaoyun Zhang, Haiteng Jiang. 113

Unimodal and Multimodal Deep Learning for Pressure Injury Identification: Scoping Review (e91048)
Yingxue Sun, Congcong Liu, Ji-cheng Zhang, Zhengang Wei, Zhenfeng Zhou, Chunmei Fan, Fangyan Yue. 137

Public Reporting Systems in Health Care and the Underconceptualized Technical Substrate, a Core Information Systems Dimension: Scoping Review (e84820)
Elorm Damalie, Reima Suomi, Moustafa Mahmoud. 152

Real-World Barriers to and Facilitators of Implementing AI-Based Clinical Decision Support Systems: Scoping Review (e89834)
Emma Bogner, Abby Thomas, Bishnu Bajgain, Cody van Rassel, Khara Sauro, Joon Lee. 168

Logic Models on Health Information Technology–Related Interventions: Scoping Review Across Disciplines (e87848)
Elske Ammenwerth, Iiris Hörhammer, Michelle Bindel. 184

Digital Public Reporting Systems for Evaluating Health Care Quality: Systematic Review (e80435)
Lanmei Du, Reima Suomi, Elorm Damalie. 208

Influencing Factors of Mobile Health Apps in Kidney Transplant Care: Systematic Review Using the Consolidated Framework for Implementation Research (e84139)
Yingtian Jia, Shaobo Guo, Xinran Yang, Xiaohong Lin, Jiaxin Fang, Lei Dong, Xiangru Li, Haiya Sun, Wanhui Yu, Hongxia Liu. 223

XSL•FO
RenderX

Leveraging MedlinePlus to Improve Health Information Access Among Patients and Caregivers: Systematic Literature Review (e79416)
Fei Yu, Xiaomeng Wang, Jia Liu, Tian Wang, Siobahn Grady, Lixin Song. . . . 239

AI and Internet of Things for Chronic Obstructive Pulmonary Disease Remote Monitoring: Systematic Review of Exacerbation Prediction and Key Physiological Variables (e84814)
Martina Montenegro, Jasper Gielen, Chunzhuo Wang, Bart Vanrumste, David Ruttens, Ruben Knevels, Jean-Marie Aerts. . . . 263

Digital Health Communication for Deaf Individuals: Scoping Review of Technologies, Strategies, and Outcomes (e81358)
Thay Tan, Zi Lim, Uma Palanisamy, Amutha Selvaraj, Jamuna Appalasamy. . . . 288

Machine Learning for Intraoperative Bleeding Prediction in Patients Undergoing Surgery: Scoping Review (e80930)
Shiqiong Yan, Ping Zhang, Wanwan Qiao, Sijia Xie, Huan Hu, Yi Gao, Linli Xie, Jie Jing. . . . 318

Blockchain-Based Dynamic and Revocable Consent for Secondary Health Data Use: Systematic Review (e88536)
Sudip Phuyal, Manila Bhandari, Rabindra Bista, João Ferreira. . . . 335

Machine Learning for Predicting Venous Thromboembolism After Joint Arthroplasty: Systematic Review of Clinical Applicability and Model Performance (e79886)
Junwei Ma, Huifeng Tang, Yunshan Zhang, Xuemei Yi, Tangsheng Zhong, Xinyun Li, Gang Wang. . . . 369

Using Health Information Systems to Support Behavioral Interventions in Local Contexts: Scoping Review (e77296)
Xi Yang, Martin Dijst, Joost Daams, Marc Suhrcke, Haoran Yang, Ronald Cornet. . . . 383

Core Elements, Development, and Implementation Strategies of the Nursing Minimum Data Set: Scoping Review (e84281)
Pascal Müller, Annabell Gangnus, Katrin Gayen, Uta Kirchner-Heklau, Patrick Jahn, Sebastian Hofstetter. . . . 411

Technological Strategies for the Patient Experience in Emergency Departments: Scoping Review (e79782)
Andrés Santafé, Juan Aranda, Wilmer Beltrán, William Guerrero, Maryory Guevara Lozano, Ingrid Bustos. . . . 421

Large Language Model–Based Virtual Patient Systems for History-Taking in Medical Education: Comprehensive Systematic Review (e79039)
Dongliang Li, Syaheerah Lebai Lutfi. . . . 436

Causal Discovery in Observational Medical Research: Scoping Review (e82499)
Zuting Liu, Tian Luo, Hailin Ma, Jiali Mo, Xia Yang, Zhenglong Huang, Jingkun Li, Jie Kuang. . . . 456

Machine Learning–Based Prognostic Models for Functional Outcomes in Spinal Cord Injury: Systematic Review (e84980)
Yuan Liu, Xiangxia Meng, Yi Ding, Ruifa Yao, Shuchang Xu. . . . 475

Blockchain Smart Contracts for Automating Clinical Trials: Systematic Review and Proposed System Architecture (e76980)
Zara Sheikh, Gargi Samarth, Usman Jaffer. . . . 2145

Viewpoints

Beyond Time Saved: A Framework for Comprehensive Evaluation of AI Clinical Documentation (e86091)
Ekstrom Sze Min. . . . 489

Making Genomic Data Actionable in Electronic Health Records: Practical Viewpoint on Standards, Governance, and Implementation (e99130)
Styliana Menelaou, Eirini Schiza, Marios Tomazou, Andreas Neocleous, Anastasis Oulas, Menelaos Pipis, Andreas Menikou, Athina Theodosiou, Maria Papaioannou, Carolina Sismani, Theodoros Kyprianou, George Spyrou, Christos Schizas. . . . 506

The Ethics of AI Scribes as Epistemic Agents (e88235)
Frank Ursin, Sabine Salloch. . . . 523

Dynamic Consent for Secondary Use of Health Data: Challenges and Opportunities Under European Law (e93348)
Sudip Phuyal, Manila Bhandari, Ricardo Correia Bezerra, Rabindra Bista, João Ferreira. . . . 533

Real-World Imaging Data: Opportunities and Challenges (e88202)
Jie Wu, Aline de Araujo, Sean Khozin, Merel Huisman, Domenico Mastrodicasa, Martin Willemink. . . . 547

Medical AI Agents for Clinical Decision Support: Viewpoint Using the Planning, Action, Reflection, and Memory (PARM) Analytical Lens (e92584)
Rasit Dinc, Nurittin Ardic. . . . 562

Toward Drift-Aware Multimodal Early Warning for Acute Exacerbations of Chronic Obstructive Pulmonary Disease (e98345)
Haoran Li, Shuaihua Fan, Xiaojuan Li, Nina Liu, Huaiqing Qi, Jun Guo. . . . 572

From Data Poverty to Data Sovereignty: Operationalizing Gold-Standard Biomedical Datasets in Low- and Middle-Income Countries (e82360)
Shweta Rana, Pranshu Bhagat, Debnath Pal, Sanghamitra Pati, Harpreet Singh. . . . 585

A Conceptual Model for Ambient AI Adoption: Perspectives From Academia and Industry (e91098)
Joshua Biro, Jesse Pines, Sudha Jayaraman, Vamsi Chagari, Raj Ratwani. . . . 593

The Promise of Ambient AI Technology in Medical Education: Opportunities and Guardrails (e88725)
Shirin Shafazand, Umar Bowers, Sudha Jayaraman. . . . 602

Developing Clinical Decision (Support) Systems Combining the Scientific and Regulatory Perspective: European Insights on Challenges, Requirements, and Practical Guidance (e72809)
Sanne Vrijlandt, Sanne Janssen, Annemarie van Rossum, Niek Achten, Rianne Oostenbrink. . . . 607

Dynamic Personalized Optimization: An AI Functionality Framework for Digital Therapeutics (e75256)
Dohyoung Rim. . . . 634

Viewpoint on the Consequences and Mitigation of Cognitive Bias in the Radiological Interpretation of Breast Cancer Imaging Using Artificial Intelligence (e78955)
Lorenzo Conti, Benedetta Capetti, Ottavia Battaglia, Roberto Grasso, Filippo Pesapane, Dario Monzani, Gabriella Pravettoni. . . . 640

Ethical Imperatives for Retrieval-Augmented Generation in Clinical Nursing: Viewpoint on Responsible AI Use (e79922)
Xinyi Tu, Chenghao Shi, Peilin Qian, Lizhu Wang. . . . 655

Improving Clinical Decision-Making in Treating Airway Diseases With an Expert System Built Upon the Free AI Tool Google NotebookLM (e78567)
Cheng-Hao Hsu, Ching-Li Hsu, Chih-Hsiang Tsou, Kuo-Fang Hsu, Hung-Yu Yang. . . . 663

Clinical Model Autophagy: The Risk of Interpretative Drift in Recursive Medical AI (e94813)
Pei Shih. . . . 695

SAFE_DTx: Safety-First Framework for AI-Driven Personalization in Digital Therapeutics (e78202)
Dohyoung Rim. . . . 701

Cybersecurity of Large Language Models Across the Deployment Life Cycle in Health Systems (e101715)
Chun Goh, Haoran Liu, Nethum Devendra, Khoa Cao. . . . 711

Original Papers

Telepathology Development and Stakeholder Perspectives in China: Cross-Sectional Survey (e83514)
Linlin Wang, Fangfang Cui, Xianying He. . . . 616

Experiences With Integrating Medical Terminologies Into User Interfaces for a Decision Support System for Primary Care: Conceptual and Development Study (e74934)
Michaela Neff, Jannik Schaaf, Najia Ahmadi, Michele Zoch, Dania Schütze, Holger Storf. . . . 678

Developing a Suicide Risk Prediction Algorithm Using Electronic Health Record Data in Mental Health Care: Real-World Case Study (e74240)
Linda Hummel, Karin Lorenz-Artz, Joyce Bierbooms, Inge Bongers. . . . 868

Open-Source Anatomical Illustration for Digital Back Pain Documentation: Development and Feasibility Evaluation (e75737)
Yanick Lukic, Sonja Schläpfer, Alessandro Holler, Giovanni Colacicco, Dennis Baumli, Leana Wirth, Steven Häsler, Christoph Laux, Reto Sutter, Georg Kajdi, Benedikt Herzog, Sebastiano Caprara, Claudia Witt, Philipp Ackermann. . . . 911

Stakeholder Perspectives on Affinity Domains in Digital Health Interoperability: Qualitative Study (e83894)
Jan Bruthans, Petra Hospodková, Ilona Fejfarová. . . . 922

Classification of Cochrane Plain Language Summaries by Conclusiveness Using Transformer-Based Models and ChatGPT: Retrospective Observational Study (e72657)
Antonija Mijatovi , Luka Ursi , Nensi Brali , Ružica Bandi , Barbara a i , Ivan Buljan, Ana Maruši 938

Deep Learning Model Using Transfer Learning for Detecting Left Ventricular Systolic Dysfunction: Retrospective Algorithm Development and Validation Study (e83127)
Sungjae Lee, Jung-Woo Son, Sung-Ai Kim, Min-Soo Ahn, Sang Lee, Sang-Jin Han, Taehyun Joo, Yeongyeon Na, Sunghoon Joo, Hyun Ahn, Mineok Chang, Yeha Lee, Young Park. . . . 950

Scalable Identification of Clinically Relevant Chronic Obstructive Pulmonary Disease Documents in Large-Scale Electronic Health Record Datasets With a Lightweight Natural Language Processing Model: Retrospective Cohort Study (e84326)
Mohammed Al-Garadi, Sharon Davis, Michael Matheny, Dax Westerman, Adrienne Conger, Bradley Richmond, Thomas Lasko, Iben Ricket, Laura Paulin, Jeremiah Brown, Ruth Reeves. . . . 969

Interoperable Integration of a National Rare Disease Registry Into a Rare Eye Disease Data Warehouse: Implementation Study (e79378)
Camille Beluffi Marin, Marilyne Oswald, Laura Ratenet, Matthieu Stoll, Kirsley Chennen, Hélène Dollfus. . . . 982

Integrating Clinical Classifications Software Refined, Process Indicators, and Geographic Information System Mapping to Inform Population Health Management: Development of an Interactive Dashboard (e80431)
Joshua Tan, Hao Tan, Gerald Sng, Sing Chia, Su-Yen Goh, Julian Thumboo, Yong Bee. 1000

Clinically Interpretable Deep Learning for Differentiating Vitiligo and Postinflammatory Hypopigmentation: Diagnostic Accuracy Study (e81942)
Amal Alzu'bi, Shadi Al Khateeb, Bassam Elzaghmouri, Diala Alshiyab, Sanaa Abu Alasal, Leming Zhou. 1016

Rectal Cancer Radiotherapy Response Prediction: Retrospective Study of Development of a Deep Learning–Based Radiomics Model (e77313)
Yiqun Li, Hengchang Liu, Qiang Wei, Zhenqi Wang, Zhen Hu. 1032

Comprehensive Pediatric Health Risk Stratification Using an AI-Driven Framework in Children Aged 2 to 8 Years: Design and Validation Study (e80163)
Jundan Chen, Zhihe Mao. 1053

Scalable and Privacy-Conscious End-to-End Processing of Large-Scale Clinical Data for Precision Medicine: Empirical Evaluation Study (e83487)
Jungwoo Lee, Sangwon Hwang, Kyu Lee. 1071

A Bilayer Feature Fusion Framework for Pan-Cancer Survival Prediction Based on Multihead Attention and Adaptive Differential Privacy: Model Development and Validation Study (e83743)
Yun Chen, Zhifang Deng, Lili Wang, Huanhuan Wang, Xiang Wu. 1085

Automatic Kidney Image Segmentation During Robot-Assisted Partial Nephrectomy Using a Deep Learning Model Based on a Multiannotator Dataset: Model Development and Validation Study (e82540)
Gaëlle Margue, Kilian Chandelon, Maxime Pattou, Alice Pitout, Abderrahmane Khaddad, Federico Rubat-Baleuri, Julie Desternes, Laura Richert, Nicolas Bourdel, Adrien Bartoli, Jean-Christophe Bernhard. 1105

Open-Source R Shiny Dashboard (Global Burden of Disease Analysis Suite) for Multimethod Burden of Disease Research: Development and Evaluation Study (e98718)
Belal Hamed, Mohammed Hasan, Omar Abdelwahab, Moaz Abouelmagd, Ramez Odat, Yasar Sattar, Ramy Ghazy. 1119

Trust in AI-Supported Screening in General Practice Among Urban and Rural Citizens: Cross-Sectional Study (e69777)
Larisa Wewetzer, Katja Goetz, Soenke Freischmidt, Jost Steinhauser. 1139

Implementation Readiness and Adoption of AI-Enabled Voice Electronic Medical Records in Resource-Constrained African Health Systems: Multisite Qualitative Study (e100805)
Melika Desalegn, Hocheol Lee, Dawit Tilahun, Alemu Sugi. 1150

Admission Mechanisms for Scalable Federated Health Data Collaboration: Design and Proof-of-Concept Study (e89685)
Enzo Fenoglio, Marzena Nieroda, Graca Carvalho, Malgorzata Smietanka, Dimitrios Kalogeropoulos, Philip Treleaven. 1162

Quantifying the Predictive Power of Social Determinants of Health in Cardiovascular Disease and Type 2 Diabetes Progression Using XGBoost: Retrospective Cohort Study (e80377)
Hielke Muizelaar, Marcel Haas, Maarten van Aken, Rimke Vos, Marco Spruit. 1179

Graph Network Feature Space Fusion for Predicting Irregularly Sampled Medical Time-Series Data: Deep Learning Model Development and Validation Study (e81145)
Tianle Hong, Zedong Ren, Junfei Fang, Shichao Quan, Jingye Pan, Yezhi Lin. 1201

Prediction of Atrial Fibrillation Occurrence With Handheld Mobile Electrocardiogram: Deep Learning Model Development Using Real-World Data (e87142)
Minje Park, Hyun Ahn, Yeongyeon Na, Sunghoon Joo, Young Lee, Seongwoo Han, Myung Park, Dae Cheon, Jeen Lee, Ki Lee. 1233

A Dynamic Graph–Based Multiobjective Optimization Method for Physician Recommendation: Development and Evaluation Study (e88854)
Shuang Geng, Rui Wang, Wenli Zhang, Ben Niu. 1250

R-R Interval Histogram-Based Deep Learning for 3-Class Atrial Fibrillation Screening in Garment-Type Wearable Holter Electrocardiogram Monitoring: Algorithm Development and Validation Study (e91960)
Tomoaki Nakano, Keita Okayama, Masanao Yasuoka, Hironori Shigeta, Akito Kawamura, Takayuki Sekihara, Kentaro Ozu, Takafumi Oka, Shigeto Seno, Yasushi Sakata. 1271

Enhancing Model Generalizability in Medical Artificial Intelligence: Systematic Comparison of Categorical Encoding and Sampling Techniques for Imbalanced Data (e75655)
Chien-wei Chuang, Chung-Kuan Wu, Chao-Hsin Wu, Ben-Chang Shia, Mingchih Chen. 1291

Enterocutaneous Fistula–Associated Sepsis and Mortality: Development and Validation of a Multimodal Artificial Intelligence Prediction Model (e79985)
Hui Li, Jing Chen, Peijun Lin, Youmei Pan, Yawen Cao, Wenfeng Xie. 1314

Novel Online Platform for Trauma Care—Integrating Trauma Phenotypes to Optimize the Trauma and Injury Severity Score Model: Retrospective Cohort Study (e90011)
Jotaro Tachino, Shigeto Seno, Hisatake Matsumoto, Tetsuhisa Kitamura, Shunichiro Nakao, Hiroshi Ogura, Jun Oda. 1336

Bayesian Analysis of AI-Driven Cost Savings in UK and Australian Health Care Systems: Cross-Sector Implementation Study (e89113)
Jayanta Sarkar, Christopher Drovandi, Sandeep Reddy. 1349

Markov Decision Process–Based Personalized Follow-Up Planning for Type 2 Diabetes: Retrospective Cohort Study (e88206)
Silei Chen, Tianyi Liu, Zhonghua Sun, Jian Jia, Dong Hang, Wenhong Zhang. 1363

Design Principles for Interactive Dashboards in Drug Safety Surveillance: Design Science Research (e75936)
Malwina Kotowicz, Mexhid Ferati, Soumitra Chowdhury, Cláudio Martins Pires. 1383

A Data-Centric Approach for Health Care and Research in a Health Knowledge Management Platform: Implementation and Requirement-Based Evaluation Study (e83608)
Björn Schreiweis, Benjamin Kinast, Hannes Ulrich, Tobias Bronsch, Ann-Kristin Kock-Schoppenhauer, Björn Bergh. 1416

Determinants of Acute Kidney Injury After Endoscopic Retrograde Cholangiopancreatography in Patients With Liver Cirrhosis: Retrospective Observational Study (e87551)
Chieh Chang. 1437

Benchmarking Fast Healthcare Interoperability Resources–Based Analytics: Quantitative Study of RESTful Server Queries and Big Data Engines (e82924)
Christian Gulden, Marvin Kampf, Detlef Kraska, John Grimes, Thomas Ganslandt, Hans-Ulrich Prokosch, Susanne Seuchter, Jonathan Mang, Peter Pallaoro, Paul-Christian Volkmer, Jasmin Ziegler. 1449

Deep Learning–Assisted Diagnosis of Middle Ear Diseases in Otoendoscopy Across Clinician Experience Levels: Retrospective Reader Study (e96134)
Se Yi, Jihye Chae, Keunwoo Park, Yeon Choi, Jihoon Kweon, Joong Ahn. 1465

Safety and Performance Evaluation of a Clinical Decision Support System for Imatinib Therapeutic Drug Monitoring: In Silico Study (e93304)
Yuan Pétermann, Roberto Rigamonti, Paul Thoueille, Junrui Chen, Lavinia Alberi, Alexandra Simon, François Veuve, Eva Choong, Bruno Da Rocha Carvalho, Sandro Carrara, François Girardin, Thierry Buclin, Chantal Csajka, Yann Thoma, Monia Guidi. 1477

Machine Learning–Based Risk Prediction of In-Hospital Mortality in Patients With Non–ST-Elevation Acute Coronary Syndrome at Various Stages of the Diagnostic Process: Observational Study (e89242)
Vyacheslav Ryabov, Anastasiia Nesova, Andrey Vishnevskiy, Karina Shakhgeldyan, Boris Geltser. 1492

Patient Stratification for Improving Acute Chest Pain Management and Mitigating Emergency Department Crowding: Machine Learning Model Development and Validation (e83099)
Chih-Chia Hsieh, Shao-Chung Chu, Jung-Ting Lee, Chih-Hao Lin, Chung-Yao Kao. 1516

Prediction of Blood Transfusion Need and Dose in Patients With Upper Gastrointestinal Bleeding: Retrospective Multicenter Prediction Model Study (e83889)
Xiaoyu Li, Yuqin He, Mingyang Hou, Zhi Yu, Shuai Miao, Zhiyong Huang, Min Yang. 1546

GPT-4o–Powered Preanesthetic AI: Development and Validation Study (e83893)
Bo-Han Lin, Cheng-Wei Lu, I-Ching Hou, Tzu-Yu Lin, Chin-E Liu, Chong-Sun Khoi. 1562

Large Language Models for Endodontic Symptom Assessment and Treatment Planning Using Image-Free Clinical Records: Comparative Evaluation Study (e86145)
Dahyun Seo, Jieun Cheong, Yiseul Choi, Yooseok Shin, Wonse Park. 1578

A Hierarchical Machine Learning–Based Framework for Clinical Decision Support in Foot Orthosis Prescription: Algorithm Development and Validation Study (e92831)
Ji-Yong Jung, Wooyeol Yang, Jung-Ja Kim. 1593

Electronic Health Record Workflows in Acute Care Surgery: Ethnographic Study (e89846)
Alex Lee, Devesh Narayanan, Kristan Staudenmayer, Aussama Nassar, Syed Hameed. 1613

Mild Cognitive Impairment Detection System Based on Unstructured Spontaneous Speech: Longitudinal Dual-Modal Framework (e80883)
Yu-Shan Liao, Thiri Wai, Ting-Yun Liao, Ho-Ling Chang, Yu-Ling Chang, Li-Chen Fu. 1625

Enhancing Anesthetic Depth Assessment via Unsupervised Machine Learning in Processed Electroencephalography Analysis: Novel Methodological Study (e77830)
Po-Yu Huang, Wei-Lun Hong, Hui-Zen Hee, Wen-Kuei Chang, Ching-Hung Lee, Chien-Kun Ting. 1649

Machine Learning Prediction of Progression to Dialysis in Patients With Polycystic Kidney Disease: Population-Based Retrospective Cohort Study (e80343)
Cheng-Hao Chang, Mingchih Chen, Ming-Hsien Tsai, Yen-Chun Huang, Hung-Hsiang Liou, Ben-Chang Shia, Chingying Liang, Yu-Wei Fang.
1 6 6 1

Exploring the Role of AI in Managing Treatment Recommendations for Lymphedema: International, Multidisciplinary, Multiprofessional Survey Study of Trust, Reliability, and Impact on Decision-Making (e80553)
Adriano Fabi, Caroline Egli, Séverin Wendelspiess, Sebastian Griewing, Yvonne Haas, Laura De Pellegrin, Dirk Schaefer, Shan Qiu, Yves Harder, Elisabeth Kappos. 1682

Modeling Diabetes Risk and Progression With Public Health Data: Ontology-Guided, Simulation-Capable Digital Twin Study (e87374)
Qingrui Li, Kapileshwor Amat, Eric Johnson, Juan Li. 1694

XSL•FO

Development Process of a Clinical Decision Support System for Empiric Antibiotic Therapies in Patients With Sepsis: Case Study (e79929)
Sophie Schmiegel, Hannah Marchi, Philipp Hege, Svenja Elkenkamp, Juliane Duevel, Christoph Düsing, Wolfgang Greiner, Sean Scholz, Dominic Witzke, Johannes Tebbe, Michael Wehmeier, Olaf Kaup, Rainer Borgstedt, Sebastian Rehberg, Philipp Cimiano, Christiane Fuchs. 1713

Usability and Usefulness of Machine Learning–Based Clinical Decision Support Software in Primary Care: Survey of Users in a Prospective Observational Study (e80527)
Willem Herter, Janine Khuc, Tobias Bonten, Robert Verheij, Mattijs Numans, Niels Chavannes. 1732

Advancing Alzheimer Disease Prediction With Large Language Model–Based Linguistic Feature Analysis: Development and Validation Study (e86965)
Ming-Hsia Hsu, San-Yih Hwang, Yi-Hang Tsai, Yun-Chi Chang, Chih-Kuang Liang, Chiung-Yun Chang. 1747

Prediction of Early Hospital Admission (≤24 Hours) After Stroke Using Machine Learning and Deep Learning: Multicenter Study From China (e90852)
Qingjia Zeng, Jiachen Cui, Xinyu Fan, Dawei Li, Xiao Yang, Menghan Song, Shuangyang Niu, Yuhuan Wang, Yufeng Wang, Fubiao Huang, Yonghui Wang, Qiang Wu, Hongpu Hu. 1763

Exploring the Role of Large Language Models in Primary Care: Qualitative Study of Physicians in the United States and the Netherlands (e91652)
Ilse Super, Harinder Bawa, Onur Asan. 1779

Candidate Passive Sensor Suite Technologies for Tactical Combat Casualty Care Environments: Comparative Assessment Study (e84900)
Ericka Stoor-Burning, James Gaudaen, Holly Pavliscsak, Jeanette Little. 1793

Operationalizing One Digital Health and FAIR Data Principles for Disease Surveillance in a Low-Medium Income Country in Africa: Qualitative Study in the Democratic Republic of the Congo (e93321)
Harvey Basivikidi, Lefilso'o Lambuku, Delphin Kayembe, Arriel Benis, Didier Bompangue. 1812

Network Analysis–Driven Machine Learning Model for Identifying High-Cost Stroke Inpatients Using Hospital Discharge Data: Retrospective Study (e93680)
Haohui Shen, Yilong Yang, Mengge Zhang, Jingyi Xiang, Runan Wang, Pin Yao. 1828

Stress-Symptom Interaction in Inflammatory Bowel Disease: Longitudinal Digital Phenotyping Study (e95854)
Zhihong Li, Yiliminuer Ahemai, Zimei Li, Qianqian Du, Wenwen Zheng, Shaohua Wang, Lazier Halimubai, Yan Wang, Yingbin Cai. 1849

AI-Powered Resting 12-Lead Electrocardiogram Algorithm for Predicting Low Peak Oxygen Consumption: Development and Validation Study (e81105)
Shu-Chun Huang, Tieh-Cheng Fu, Michelle Liou, Yu-Chieh Huang, Sing-Ya Chang, Guan-Yi Huang, Hong-Ren Su. 1867

Predicting Laboratory Test Ordering in Emergency Departments Using Integrated Structured and Unstructured Electronic Health Records: Machine Learning Study (e85255)
Xingyu Zhang, Haipeng Ling, Xin Zhang, Anao Zhang. 1880

Concordance of Death Information Between Two Health Systems Serving the Same Region and the Social Security Administration Death Master File: Retrospective Observational Study (e85136)
Zhan Wang, Mahanaz Syed, Shweta Bansal, Meredith Zozus, Eric Eisenstein, Muayad Hamidi. 1897

Implementation and Evaluation of an Alternative Electronic Health Record Tool for Ordering Blood Products in Pediatric Oncology and Stem Cell Transplantation: Mixed Methods Analysis (e93346)
Ally Sarna, Aya Finkelstein, Caroline Malcolmson, Renee Potashner, Natalie Pitch, Alessia Forestieri, Marilyn Cooper, Yuquing Feng, Aryan Patel, Tal Schechter, Karim Jessa, Lillian Sung, Adam Yan. 1905

Abstract

Background: AI-based clinical decision support systems (CDSS) can improve diagnostics and treatment decisions, but they are rarely implemented in practice. Barriers include limited integration into clinical workflows, lack of transparency, and insufficient involvement of end users in system design. Participatory and user-centered approaches offer ways to address these challenges by aligning development processes with the needs and routines of clinical staff. However, systematic evidence on how such approaches are applied in the development of AI-based CDSS remains limited.

Objective: Our study examined how participatory approaches are used in the development, piloting, and implementation of AI-based CDSS. We analyzed which user perspectives were included, which participatory methods were applied, how they contributed to technical design, and which ethical, legal, and social implications were addressed.

Methods: This scoping review followed the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) guideline, with a protocol published in advance. A systematic search was conducted in MEDLINE, ACM Digital Library, CINAHL, and PsycInfo for studies published from 2012 onward, complemented by snowballing and manual searches. Primary studies in English or German were included if they involved clinical staff in the development, piloting, implementation, or evaluation of AI-based CDSS. Moreover, 3 independent reviewers conducted screening and data extraction, resolving disagreements by consensus. Data analysis followed JBI methodology and focused on the scope of participation, theoretical and methodological foundations, and reported impacts of participatory approaches.

Results: Of 4318 identified records, 37 met the inclusion criteria. The studies showed broad variation in terminology and methods, most often describing user-centered or iterative processes and less frequently co-design. Physicians were involved in nearly all studies, nurses frequently, and other professional groups only occasionally. Participation mainly supported requirements analysis, adaptation of models to clinical workflows, and the design of explainable interfaces. In several projects, it also influenced data selection, annotation, and visualization. Common barriers included time constraints, limited continuity of participation, and uncertainty toward AI. Ethical, legal, and social aspects were addressed implicitly through themes such as autonomy, responsibility, and traceability, while fairness and bias were rarely discussed.

Conclusions: Participatory processes in AI-based CDSS development should extend across all stages of system design and address not only usability but also data quality, bias, and broader ethical, legal, and social issues. Equal inclusion of nursing and therapeutic expertise is essential to reflect the diversity of clinical decision-making. Clear methodological standards are needed to ensure comparability and to strengthen participation as a genuine co-design process shaping data, models, and values in clinical AI.

Introduction

Background

Clinical decision support systems (CDSS) are designed to assist health care professionals in diagnosis, treatment selection, and patient monitoring. These systems aim to improve patient safety and optimize clinical workflows [1-3]. With increasing digitalization and advances in AI, CDSS have increasingly incorporated AI-based technologies to enhance their potential. These systems can access large volumes of digital health data, analyze historical information, continuously learn from new inputs, and provide real-time, personalized recommendations for clinical practice. By identifying patterns in complex datasets, AI enables more precise and individualized decision-making, thereby improving diagnostic accuracy and treatment quality [4,5].

Despite these promises, the implementation of AI-based CDSS in routine clinical care remains limited. Barriers include not only well-known challenges, such as insufficient interoperability, inadequate integration into existing IT infrastructures, and legal uncertainties (eg, data protection and liability), but also a lack of alignment with actual clinical workflows. Many systems fail to reflect the practices, routines, and decision-making logics of their intended users [6,7]. Specific challenges associated with AI-based systems, such as limited data quality, poor model transparency (the "black-box" problem), and ambiguous accountability in AI-supported decisions, further complicate implementation, especially in nursing contexts where documentation is often fragmented and lacks standardization [8,9]. Studies indicate that insufficient user involvement in system development is a key reason for the failure of technological implementations in health care [10].

Participatory approaches offer a promising strategy to address these challenges by involving users early in the development process and systematically integrating experiential knowledge, everyday practice needs, and organizational conditions [11,12]. Such approaches, particularly participatory and user-centered design, aim to develop technologies in close collaboration with future users. Through mutual learning, iterative adaptation, and shared responsibility, these processes aim to produce systems that are not only technically functional but also contextually relevant, acceptable, and usable [13,14]. Participatory and multiperspective methods have proven effective in increasing acceptance and capturing contextual factors in technology design [15-17]. In the field of AI in health care, recent studies show that participatory approaches can enhance data quality, system design, and clinical applicability by incorporating domain knowledge and user expertise [11,12]. Particularly when interpreting complex clinical data, for example, discipline-specific terminology or documentation practices, the user perspective serves as a crucial point of orientation for technical development [11].

At the same time, the literature emphasizes that participatory approaches are not exclusively viewed as beneficial and have also been subject to critical debate. Participation processes may take on a symbolic character ("tokenism") when participants are formally involved but have limited influence on actual decision-making processes [18]. Moreover, research in design and human-computer interaction (HCI) highlights that user involvement can be instrumentalized, for example, when participant feedback is used to retrospectively legitimize design decisions that have already been made [19]. In addition, participatory processes may be selective, allowing certain stakeholder groups to dominate while other relevant perspectives remain underrepresented [20].

The application of participatory methods in the development of AI-based CDSS remains an emerging and dynamic field of research, presenting specific opportunities and challenges. How can collaboration between AI developers, clinicians, and other health care professionals be structured to accommodate the complexity of algorithmic systems? Which participatory methods are most appropriate for integrating clinical expertise and ensuring alignment with real-world decision-making processes? And how can ethical, legal, and social implications, such as algorithmic transparency, bias mitigation, and accountability, be addressed during system development? These questions are central not only to research but also to the responsible implementation of AI in clinical care. Establishing an iterative feedback loop in which developers and users regularly exchange insights may help ensure that systems evolve in tandem with clinical needs and remain contextually grounded over time.

This review aims to address a significant gap in the existing literature by offering a comprehensive summary of the approaches, methods, and practices of participatory research and development in the context of AI-based CDSS for clinical staff. To achieve this, the review systematically examines empirical studies, their theoretical frameworks, and applied methods for the participatory design of AI-based CDSS. By reviewing the current state of user involvement in the development, design, and implementation of these systems, the review will provide valuable insights into how participatory approaches have been used to date and how they can contribute to successful development and implementation.

Objectives and Research Questions

The objective of this review is to provide an overview and systematization of participatory approaches from various disciplines for developing, piloting, implementing, and evaluating AI-based CDSS in clinical settings.

The following research questions were addressed:

1. Inclusion of diverse clinical perspectives: Are the different perspectives on underlying clinical problems (eg, by nurses, physicians, and other health care professionals) addressed by any particular CDSS included in the design of the CDSS?
2. Participation as a process: Which participatory approaches are used to develop, pilot, and evaluate AI-based CDSS in health care?
3. Participation in technical aspects of CDSS design: In which ways are participatory methods specifically supporting the development of AI components of CDSS and their performance?
4. Participation for ethical, legal, and social implications: Which ethical, legal, and social implications have been

XSL•FO
RenderX

identified in existing projects for participatory development, piloting, implementation, and evaluation processes targeting clinical staff?

Methods

Overview

The protocol for this scoping review was previously published in *JMIR Research Protocols* [21]. It outlines the review's parameters and provides justification and explanations of all methodological steps and decisions. To further ensure rigor, we used the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) checklist [22] and reported it in Checklist 1.

Search Strategy and Terms

Information Sources

To identify relevant papers, we selected databases covering publications in biomedical and health sciences, computer science and information technology, psychology, and nursing and allied health. The following electronic databases were included as information sources: MEDLINE via PubMed, ACM Digital Library, CINAHL, and PsycInfo. These information sources were selected for their broad disciplinary scope, which aligns with the objectives of this review. They provide extensive access to studies on the participatory design and development of AI-based technologies in health care, particularly CDSS.

Search Strategy

The databases were searched using combinations of relevant search terms, which were developed and tested for sensitivity before performing the scoping review. We used an iterative approach to develop the search strategy. First, we identified search terms used in previous studies and reviews related to participatory research and AI-based CDSS for clinical staff (particularly relevant are the studies by Kocaballi et al [23], Clar and Wright [24], Kasberg et al [25], Moore et al [26], and Ballard et al [27]). Then, we conducted an initial search in MEDLINE (via PubMed) and CINAHL after analyzing text words (title and abstract) and indexed terms, as suggested by the Joanna Briggs Institute (JBI) methodology for systematic scoping reviews [28,29]. Based on these results, we applied the identified search terms across all databases. Afterward, we checked the references for all included contributions to capture further relevant studies mentioned across the included publications. When necessary, we contacted the corresponding author; this was required only once because the full text was inaccessible.

Multimedia Appendix 1 shows the search strategy for MEDLINE (via PubMed).

To describe the inclusion criteria precisely, we rely on the population, concept, and context scheme [28,29]. The terms were adapted to the basic search particulars (eg, wildcards [*] and truncations) of each electronic database. Textbox 1 shows the most important criteria according to the population, concept, and context scheme.

Textbox 1. Population, concept, and context criteria used in the scoping review.

Population

- Clinical staff (eg, physicians and nurses).

Concept

- Participation, participatory design, cocreation, or co-design.

Context

- Development, piloting, implementation, and evaluation of AI-based clinical decision support systems (hybrid and data-driven AI approaches).

Types of sources

- Primary research: all study types (eg, qualitative, quantitative, and mixed methods) will be included. Systematic reviews and meta-analyses will be used to conduct manual searches of reference lists to identify additional primary studies.

In line with implementation science literature [30], we define implementation as the integration of AI-based CDSS into routine clinical care beyond prototype development, piloting, or controlled testing.

Reporting on stakeholder involvement in the AI-CDSS field was often sparse and inconsistent in terminology. During the initial screening and full-text assessment, it became apparent that only a limited number of studies explicitly referred to their approach as participatory design or participation, even when clinical stakeholders were involved in development-related activities. To avoid restricting the review to self-labeled participatory studies, we adopted a broader concept of involvement in the concept dimension of the PCC framework.

In addition to studies explicitly describing participatory design, co-design, or cocreation, we also included studies reporting consultative forms of user involvement when clinical staff contributed to system development, refinement, piloting, or evaluation. The broader inclusion criteria were already set out in the published review protocol, which also considered related approaches and terms frequently used synonymously with participation or cocreation. It was also based on the staged model of participation by Clar and Wright [24], in which consultation is described as a preliminary stage of participatory influence. At the same time, we are aware that consultative forms of involvement do not necessarily constitute participation in the

XSL•FO
RenderX

strict sense, as joint influence or co-determination may remain limited.

At the same time, the review acknowledges that these concepts are not synonymous. Participatory design refers to a design methodology rooted in democratic design traditions and participatory action research emphasizing iterative co-research and co-design with future users to shape technologies, work practices, and design decisions affecting their work [31]. Co-design can be understood as a specific form of cocreation applied to the design process and involving both designers and people who are not trained in design, whereas cocreation refers more broadly to collective creativity shared by 2 or more contributors [13]. In contrast, user-centered design refers to a broad design philosophy and set of methods in which end users inform and influence how a design takes shape, with a strong focus on users' needs, tasks, and contexts of use, often aiming to improve usability and usefulness [32]. Author-reported terminology was retained descriptively during extraction and not retrospectively harmonized.

To differentiate reported forms of engagement, activities were grouped according to their function within the development process: (1) formative inquiry (eg, interviews, focus groups, and observations), (2) participatory or co-design–oriented activities (eg, co-creation workshops and prototyping), and (3) evaluation-oriented involvement (eg, usability testing, think-aloud procedures, and simulation-based feedback). This analytical distinction was based on the activities reported in the publications. It should not be interpreted as evidence that no earlier or additional involvement had taken place where such processes were not described.

We included studies published from 2012 onward, since this year represents a milestone in the development of deep learning, when the use of deep neural networks in image processing achieved a major breakthrough [33]. The initial database search covered publications published between January 1, 2012, and October 31, 2023. Using the same search strategy, an updated search was conducted for the period from November 1, 2023 to February 18, 2026.

Eligibility Criteria

The inclusion and exclusion criteria that were applied to the studies are shown in Textbox 2.

Textbox 2. Inclusion and exclusion criteria applied in the scoping review.

Inclusion criteria

- Target group: Clinical staff.
- Involvement: Participation in the development, design, piloting, and evaluation of artificial intelligence-based clinical decision support systems.
- Related approaches: Other related approaches, research and design strategies, or concepts, such as co-design, are often used interchangeably with participation and cocreation.
- Type of research: Primary research using different methods (eg, qualitative, quantitative, and mixed methods)
- Language of publications: English or German.

Exclusion criteria

- Participation: No evidence of a participatory research element.
- Target group: No relation to clinical staff.
- Thematic focus: Does not refer to AI-based clinical decision support systems.

Study Selection

We used Zotero (a free and open-source literature management program) [34] as a bibliographic tool. The retrieved references were checked for duplicates and then transmitted to Covidence (software for managing and streamlining reviews, operated by Veritas Health Innovation Ltd) [35] for the screening steps. Moreover, 2 independent reviewers (TR and PG) screened all titles and abstracts separately for inclusion or exclusion. Disagreements were solved by including a third reviewer (CK or PK). The same procedure was then applied to full-text screening, which was carried out by 3 independent reviewers (TR, PG, and CH). Reasons for excluding a study were assessed in each of these steps.

Data Charting Process

Two reviewers (TR and PG) collaboratively developed a data-charting form to determine which variables to extract. The form comprised seven sections: (1) metadata, (2) description of the contribution, (3) conceptual meaning and attribution, (4) theory and methodology, (5) implementation of participatory or cocreative processes, (6) evaluation and outcomes, and (7) miscellaneous. The data were independently charted by 3 reviewers (TR, PG, and CH), who then discussed the results and continually updated the data charting form in an iterative process. To ensure methodological consistency and quality, all reviewers screened 1 initial publication, discussed discrepancies, and jointly revised the data extraction manual before commencing formal screening. Disagreements were resolved by consensus or, when necessary, through consultation with the remaining authors (PK and CK), until full agreement was reached.

If information on specific participatory procedures, process characteristics, or content addressed within participatory activities was not explicitly described in a publication, this was documented as not reported (N/A) rather than coded as absent. This decision reflects the fact that publications often present

XSL•FO
RenderX

only a selective account of the broader development process, and the absence of reporting does not necessarily indicate that a given activity did not take place or that a specific issue was not discussed.

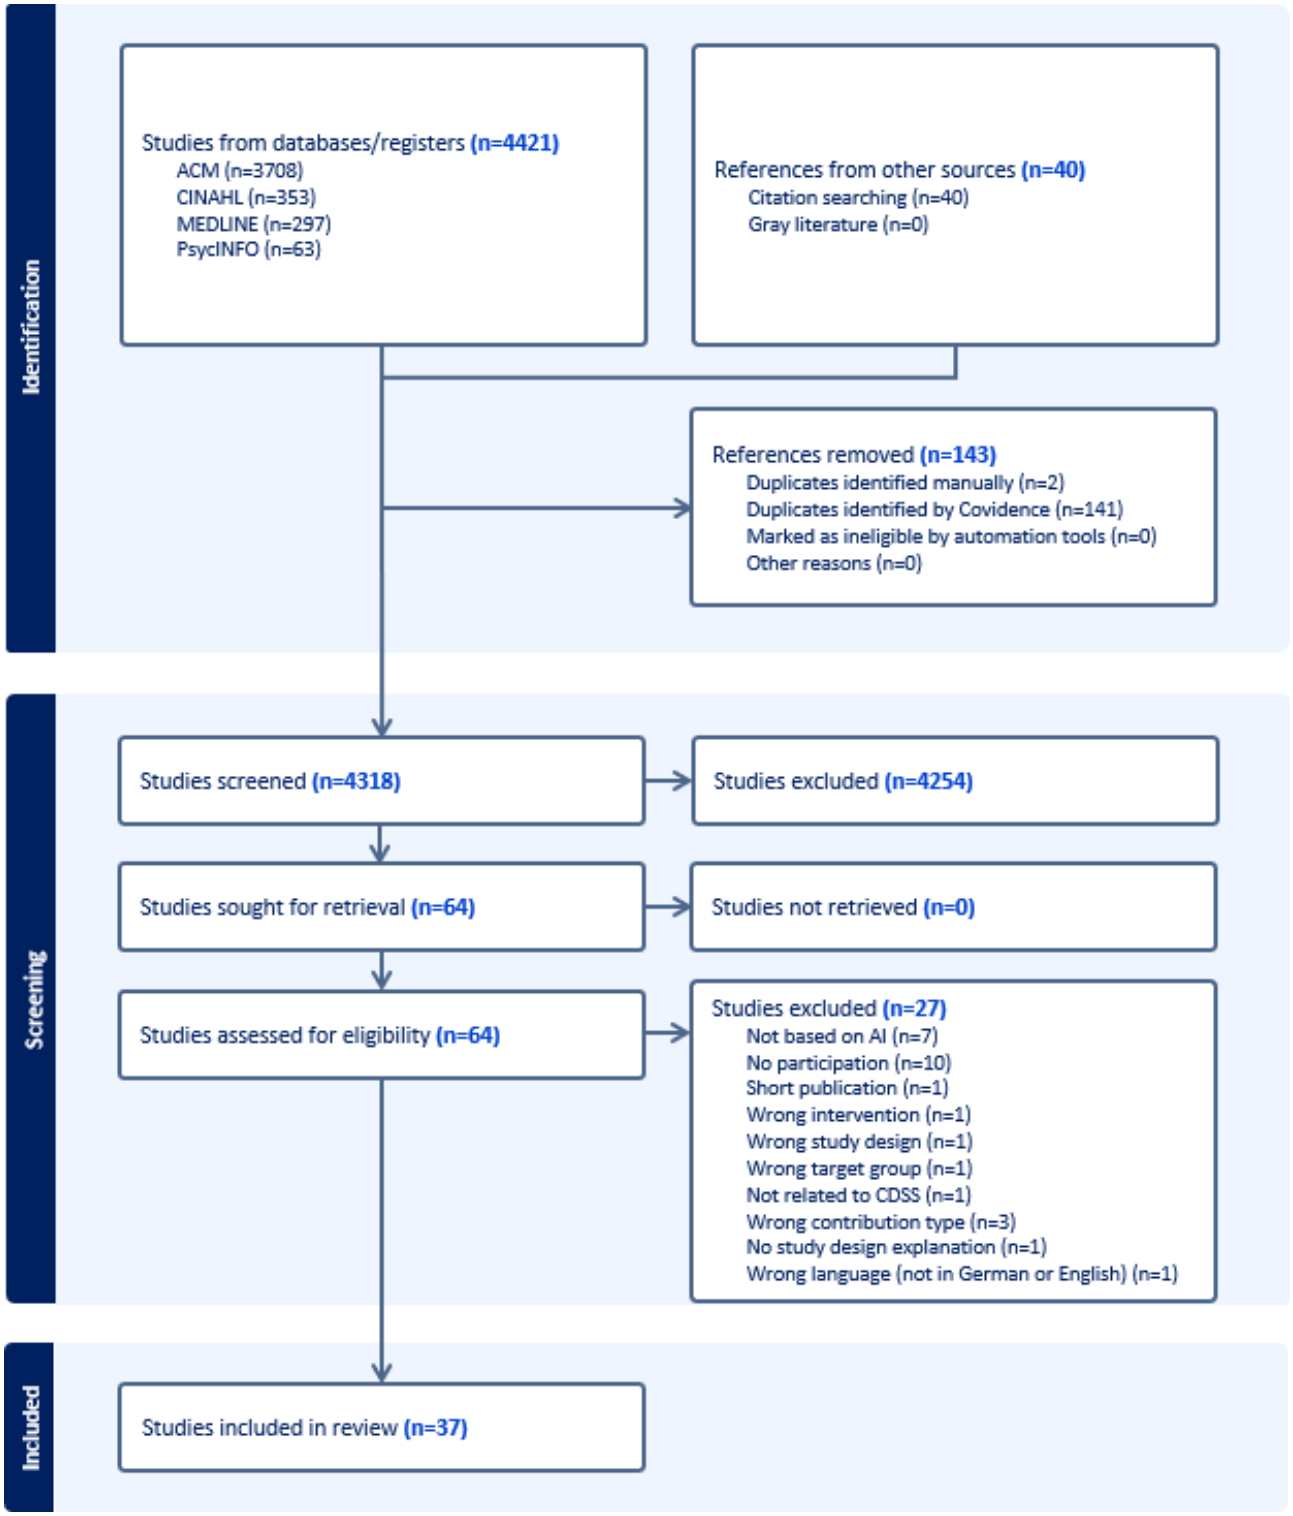
In accordance with JBI guidance, the extraction form was iteratively refined compared with the version published in the review protocol [21,28,29]. Adjustments included expanding metadata categories, providing more detailed documentation of participants, and placing greater emphasis on participatory processes and contextual conditions. Items such as "Generic term for the participatory/co-creative process" and "Degree of participation/Grading" were not retained, as they were either not reported in the studies or would have required substantial interpretation. The final version of the extraction form is available in Multimedia Appendix 2.

Data Items

Data were extracted on publication characteristics (eg, first author, year, journal, and country), study design (eg, clinical setting, target populations, and project phases), as well as key features of stakeholder engagement (eg, involved roles, recruitment procedures, and participatory or cocreative methods applied). Contextual and technical aspects were documented through detailed descriptions of the nature, function, and intended use of the AI-based CDSS. Barriers and facilitators to engagement were identified based on reported structural conditions and study design characteristics. Where applicable, we also extracted reported outcomes and perceived effects of participatory approaches on system development.

The extracted data were synthesized using a descriptive qualitative approach and organized deductively according to the 4 review questions, enabling a structured comparison of findings across studies.

Results



Overview

The systematic search yielded 4421 records from 4 scientific databases, supplemented by 40 additional records identified through citation searching. After removing 143 duplicates, 4318 records were retained for title and abstract screening. Of these, 64 studies were reviewed in full text. Twenty-seven were excluded from the study, primarily due to the lack of participatory elements (n=10) or the absence of an AI component (n=7). A total of 37 studies [36-72] satisfied the inclusion criteria and were thus incorporated into this review (Figure 1).

The 37 included studies represent a diverse range of research projects aimed at developing, testing, or evaluating AI-based CDSS involving clinical staff. Multimedia Appendix 3 provides an overview of key characteristics.

XSL•FO
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram.

Conceptions of Participation, AI, and CDSS

The analysis of the studies reveals considerable conceptual heterogeneity regarding key terms such as participation, AI, and CDSS.

The studies are sometimes not explicitly labeled as "participatory" or "cocreative" [36-47], yet they still report forms of stakeholder involvement in system development. More frequently, they adopt a user-centered design or "iterative or user-engaged" framing [38,39,41,48-59]. Explicit co-design, cocreation, or participatory-design terminology appears in 8 studies [60-67], whereas normative involvement labels such as "participation," "consultation," "collaborative partnership," and "shared leadership" appear in 4 studies [68-71]. Across the included studies, however, explicit reference to participation remained limited, and descriptions of participatory processes were often brief or selective. In many cases, stakeholder involvement was identifiable through reported activities rather than through explicit conceptual framing or detailed methodological reflection. Accordingly, the labels used across

XSL•FO
RenderX

studies did not consistently correspond to comparable forms of stakeholder involvement, and in several studies, interviews, focus groups, or usability procedures constituted the primary reported mode of involvement without being embedded in explicit co-design activities. Several included studies would not necessarily qualify as participatory in a strict definitional sense; rather, they reported more limited or consultative forms of stakeholder involvement. This ambiguity was closely related to the often sparse and selective reporting of involvement processes.

The systems described in the included studies primarily focused on predictive risk assessment in specific clinical contexts, such as stroke rehabilitation [60], heart failure [41], and wound healing [52]. Technological approaches ranged from machine learning [42,43,48,49,58-62,65,68-70] to deep learning [36,44,46,47,50,51,56,63,64,72] and hybrid models [37-39,55,57,66], while several studies did not specify in depth their underlying approach [41,45,53,54,67,71]. The level of technical detail varied considerably; while several studies provided comprehensive descriptions of model architecture and data sources [36,37,44,47,49,51,56,58,60,62,66,69], others remained vague or focused primarily on application aspects [38-40,42,43,45,46,48,52-55,57,59,61,63-65,67,68,70,71]. Similarly, the term “AI” was used inconsistently, ranging from precise model or explainable AI conceptualizations [36,37,39,44,47,50,51,53,54,56,58,60,62,63,65,66] to broad references to automated or learning-based systems [38,40,42,43,45,46,55,57,59,64,67,68,70,71].

Functionally, the systems were consistently described as tools to support clinical staff in making patient-specific decisions. Reported aims included improving decision quality and accuracy, early or more objective detection, prediction, or diagnostic support [40,42,44-47,49-52,55-60,64-66,68-71], facilitating integration into clinical workflows [38,41-48,51,53-57,59,61-66,68-71], and supporting shared decision-making between physicians and patients [36,43,58,59,67,72], as well as across multiple stakeholder groups, including physicians, patients, carers, and health professionals in integrated care settings [39,42].

Diversity of Perspectives on the Underlying Clinical Problem

Several studies examined homogeneous groups of a single profession, such as psychiatrists [36,72], physicians [44,53,55,57,59], technicians [50], or nurses [52]. In contrast, other studies relied on heterogeneous, multiprofessional samples combining physicians, nurses, resident physicians, or therapists [37,39,41-43,45-49,54,56,58,61,63-67,69-71]. In most cases, the participating professionals mirrored the intended users of the system. Overall, the included studies predominantly involved physicians [36,38-41,43-49,51,53,55,57,61-66,68-72], followed by nurses [39-43,46-49,52,54,56,58,61,70,71]. Less frequently, therapists such as physiotherapists, occupational therapists, psychologists, or speech therapists were included [37,39,42,60,61]. In more detail, for example, Aquino [42] involved physiotherapists, occupational therapists, and speech therapists, Lee et al [60] involved occupational and physical therapists, Lee et al [37] mentioned therapists without specifying their discipline, Nemeth et al [61] involved physical, occupational, and respiratory therapists, and Timotijevic et al [39] included physical, occupational, speech therapists, and psychologists. Similarly, the participant groups also included specialized technicians [50] and, in another single instance, social workers and ventricular assist device coordinators [41], while several other studies further broadened the stakeholder spectrum by involving pharmacists, radiographers, managers, AI or HCI experts, patients, and patient or carer representatives [42,43,46,56,58,63-65,67,71].

Sample composition also varied by study phase. Needs assessments ranged from smaller expert groups or profession-specific samples, such as technicians, therapists, or physicians [50,51,60,69], to broader multiprofessional stakeholder constellations, for example, health and social care professionals, intensive care unit (ICU) and imaging staff, or oncology teams [42,45-47,64,66,70,71]. Physicians and nurses dominated design phases, sometimes also involving therapists [36-39,41,48,49,51,53,60-62,69], and, in some studies, being complemented by technical experts, patient and public contributors, or carers [43,56-59,63,65,67,71]. Evaluation phases ranged from profession-specific assessments to larger multiprofessional samples, involving physicians, nurses, residents, therapists, and other stakeholders [36,37,39-41,43-45,47,50-52,54-56,58-61,69,72]. In addition, some studies also involved nonclinical actors, such as designers, engineers, managers, AI or HCI experts, software developers, and nonclinical stakeholder groups including patient and public contributors, carers, and formal patient or carer representatives [43,51,56,63,65,67-69,71,72].

Across the studies, the breadth of stakeholder inclusion varied considerably. While several studies involved multiple professional groups relevant to the clinical workflow, others focused on only 1 professional perspective, even in contexts where broader interprofessional involvement appeared plausible. In most cases, participation remained closely aligned with the intended primary users of the CDSS. In contrast, actors indirectly affected by system use or embedded in adjacent care processes were less frequently included.

Multimedia Appendix 4 provides an overview of the participating groups, their roles, and the respective study phases. The column “participating groups” indicates the stakeholder groups involved in the studies, whereas “description of participants” outlines the actual study samples.

Participation as a Process

The analysis of all included studies shows that user involvement in CDSS development is, in most cases, supported by theoretical, methodological, and empirical foundations. Many studies [36-38,40-42,47-52,54,55,58,60-62,66,68,71] referred broadly to concepts from human-computer interaction or general usability and user-centered design principles to motivate user involvement, typically in a general way and without linking these concepts to concrete participatory procedures. In total, 9 studies [39,56,59,62-65,67,70] explicitly connected theoretical models with the design of participatory processes. Methodological justifications were reported relatively consistently across the studies; however, they primarily referred

XSL•FO
RenderX

to user-centered design activities, such as usability testing, think-aloud protocols, or requirements elicitation, rather than to participatory approaches in a stricter sense. In almost all studies [36-43,46-52,54-68,71,72], these methods were justified in functional terms, for example, to gather requirements, improve usability or explainability, or adapt the system to the clinical context. In contrast, explicit rationales for participatory involvement were rarely provided. However, eleven studies [47,51,56,58,59,61,62,64,66,67,71] included broader methodological reflections on the combination or sequencing of methods. Most included studies were empirically grounded, drawing on primary data or existing evidence to substantiate the value of user involvement.

The implementation of participatory and user-centered approaches varied across the studies. Several studies used interviews, focus groups, or workshops to engage clinical experts [36,38,39,41-47,49-51,53-61,63-72]. Additionally, some studies combined qualitative methods with usability and user experience (UX) techniques such as think-aloud protocols, task-based testing, and standardized questionnaires [37,44,45,47,48,50-53,55,58-60,62,65,66,69,72]. Iterative testing and feedback formats with repeated review cycles were also used [38-41,44,50,51,54,56-59,62,63,66,68,71]. Some studies also incorporated observational methods [40,41,50,51,60,61,72]. Finally, systems were evaluated in simulations or near-clinical scenarios [36,44,45,48,52,55,59,62,66,72]. Taken together, the reported activities ranged from formative inquiry (eg, interviews, focus groups, and observations) to more design-oriented collaborative formats and evaluation-oriented involvement (eg, think-aloud procedures, usability testing, and simulation-based feedback).

Reporting on participatory processes themselves was generally limited across the included publications, and details on power relations, possible biases, participation burdens, or supportive measures were often lacking. However, a few studies documented such aspects in more detail. Grant et al [70] reported introductory activities to support participants' engagement and reflected on the practical burden of aligning participatory activities with clinical work schedules. Jung et al [54] likewise described supportive measures, including adapted session formats and separate walkthroughs for physicians and nurses to reduce hierarchical bias. Samimi et al [58] used structured walkthroughs to help participants engage with interface components step by step, while Fouad et al [63] deliberately balanced expertise across groups. In addition, Jung et al [53] reflected on how different participatory formats shaped participants' ability to engage with future use scenarios. Overall, these remained exceptions, while most studies provided little information on how participation was enabled, how burdens were managed, or how power imbalances were addressed.

Several supportive conditions were identified. Recurrent facilitators included regular feedback loops or iterative refinement [37,39,41,47-51,54,56,59,62,68,71] and the use of real-world clinical cases [37,44,47,48,51,55,59,60], and interdisciplinary collaboration [38,46,49,51,58,59,63,66,68,69,71]. Some studies have also suggested that representations that are visually intuitive or cognitively accessible are beneficial [40,41,46,49,51,54,57,59,61,66,68]. Additional enabling conditions included the involvement of participants with domain-specific expertise [42,47,58,66], skilled facilitation and methodological triangulation [58,70], training, onboarding, and AI literacy support [53,54,56,70], close collaboration between clinical and technical or informatics teams [46,56,66,71], procedural flexibility to accommodate clinical workloads [46,53,54,71], and previous UX with related systems [47]. In addition, several studies reported compensation or protected time for participation, including paid working time or direct financial compensation [45,55,56,58,59].

At the same time, the studies highlighted several recurring challenges. Time and organizational constraints [36,38-41,48,51,53,54,60-62,65,66,69,70] frequently limited the depth of user involvement. Strategies to mitigate this included condensed feedback formats, asynchronous data collection or adjusted study designs to work around clinical schedules [36,38,41,45-47,53,54,56,61,69]. Skepticism and uncertainty toward AI, especially in early development phases, were also reported in the studies [39-42,44,45,47,51,59,62,62,67]. These concerns were addressed through explainability-oriented model or interface design, stakeholder-oriented design processes, and professional training or information adaptations [39-42,44,46,47,51,54,58,59,62,63,67]. Other methodological limitations or concerns included small or single-site samples, artificial test environments, recruitment bias, and prototype-stage evaluation [36,38,40,41,43-48,50,52-55,58-60,64,66,71,72]. These limitations were acknowledged in most cases, with some authors suggesting follow-up studies in real-world or multicenter settings [41,44-47,50,53,55,59,66,72]. In some studies, the inclusion of different disciplinary perspectives also led to coordination challenges and tensions arising from the diversity of stakeholder groups or the incomplete involvement of relevant groups [38,39,45-48,59,61,64,66,67,70,71]. Balancing model performance, explainability, and usability also emerged as a recurring trade-off [40,41,44-47,51,53,59,62,66,67].

Despite these challenges, many studies reported positive experiences with participatory development. User involvement supported the identification of practice-relevant requirements [36,38,41-49,51,53,57-59,61-67,70-72], facilitated contextual adaptation [39,41,42,44,46,47,50-52,55,58-61,63-66,69-71], and helped improve usability and interpretability through iterative testing and feedback [36,37,40,43,44,47,48,51,53-55,58,59,62,63,65,66,72]. In some studies, active cocreation appeared to help foster trust [37,39,40,44,51,56,58,63,65]. Additionally, several studies reported joint prioritization of features [38,39,47,49,51,53,57-59,63,66,67]. Several studies further described participatory processes as useful for surfacing mismatches between technical assumptions and clinical reasoning and for translating these into concrete design revisions, including shifts in system logic or interface structure [45-47,49,50,58,59,66,68].

Overall, the analysis highlights both the potential and the limitations of participatory development in the context of clinical AI. Although some studies offer practical strategies such as adaptive design processes or structured communication,

XSL•FO
RenderX

persistent challenges—limited clinical validation, restricted generalizability, and structural resource constraints—show that important underlying tensions remain unresolved in the development of participatory AI systems in health care.

Participation in the Technical Aspects of CDSS Design

The analysis shows that participatory methods can contribute in multiple ways to the development and refinement of AI components in CDSS. In 6 studies [37,46,50,56,64,69], the structured involvement of clinical professionals supported the identification of practice-relevant variables for model training. This was achieved through interviews, observations, journey mapping, contextual inquiry, workflow analysis, co-design workshops, focus groups, think-aloud procedures, iterative design processes, prototyping, and user studies. Additionally, participatory formats were used to co-develop visual and explanatory components that made AI outputs more transparent, interpretable, and clinically meaningful [37-39,41,44,48-55,58-60,62,63,65,66,72]. Methods used for this purpose included interviews [38,44,50,59,69], focus groups and iterative design sessions [41,49,57,63], think-aloud, observations and user studies [44,48,50,55,66], as well as simulation- or workshop-based formats (eg, using paper prototyping or probing cards [36,38,58,63,65], usability or cognitive walkthroughs [54,66], and heuristic evaluation [66]). Together, these approaches were used to elicit clinical reasoning and information needs, refine explanatory displays and interface elements, and test their comprehensibility and practical fit in more practice-oriented settings. Participatory methods also supported the alignment of AI-based components with clinical workflows and implementation contexts. Illustrative examples include simulation-based testing with standardized patients [36], which informed tool refinement and clinician training materials; focus groups and iterative design sessions [49], which shaped GUI adaptations; interviews and a workshop [38], which informed task models and user requirements; and iterative design activities across phases [41], which supported prototype refinement toward routine care.

A further contribution of participatory processes concerned data quality. Although data quality concerns were addressed in many studies, they were usually not framed as a distinct methodological focus of participation. In several studies [37,39,41-43,46-48,50,51,53,55,56,58,59,64,68,70,71], participants contributed to assessing the relevance, adequacy, and limitations of data used for AI development, for example, by identifying concerns related to clinically meaningful features, incomplete or unreliable routine data, erroneous inputs, limited dataset diversity, and problems of coding, documentation, or labeling. Methodologically, these data-related aspects were elicited through interviews and semistructured interviews [37,39,42,43,46,51,59,63,64], observations, journey mapping, contextual inquiry, and workflow analysis [46,50,64], individual evaluation sessions, user studies, and think-aloud-based testing [37,48,55], as well as iterative design, workshops, and fieldwork-based evaluation formats [41,50,56,58,59,64,70]. Additional contributions included therapist annotation [37], computational modeling and vignette-based assessments [39], and questionnaires and survey-based assessments [53,71].

Interpretability and explainability constituted a third area of participatory impact. In various studies [38,41,44,48-52,54,55,57-59,62,63,65,66,69,72], participants contributed to addressing these aspects within participatory processes. In several studies, explanatory components—such as visualizations, highlight features, or other explanation-oriented displays—were developed or revised with users through think-aloud–based evaluation and individual testing [44,48,55,66], focus groups and iterative design sessions [49,57,63], structured interviews and user observations combined with iterative design [50,59], and co-design sessions [58,62,65]. In the remaining studies [38,41-43,45,51-53,64,69,72], interpretability and explainability were addressed more indirectly by eliciting user requirements regarding transparency, data presentation, algorithmic reasoning, and the need for explanatory support. This was achieved through interviews [42,43,51,69], interviews and workshops [38,64], simulation-based testing and interviews [72], user feedback during prototype testing [52], iterative evaluation formats [41], and surveys or questionnaires combined with workshops or interviews [45,53].

In sum, participatory processes contributed not only to user-friendly interface design but also to the clinical relevance, data integrity, and transparency of AI components, provided that they are methodologically tailored to these aspects. Formats that engage clinical users not only retrospectively but proactively and iteratively in design and development decisions appear particularly effective.

Participation for Ethical, Legal, and Social Implications

The studies included in this review address a variety of ethical, legal, and social implications (ELSI) emerging from the participatory development, testing, and evaluation of AI-based CDSS. While the term ELSI was rarely used explicitly, most studies included theoretical references and empirical insights into relevant aspects. In many cases, however, ELSI-related issues were only indirectly identifiable, as they were embedded in broader discussions rather than explicitly framed as ethical, legal, or social implications.

A recurring ethical principle is that AI systems should support, not replace, clinical decision-making—an aim explicitly stated in several studies [40,41,45,47,50,59,60,65,67,69]. The role of explainable AI is repeatedly emphasized, particularly in relation to transparency, trust, and the interpretability of automated recommendations [37,39,42-44,46,47,49,51,53,54,56,58,59,62,63,65-67,70]. Other common themes include adaptability to clinical workflows [40-42,46,59,60,68,69,71] and the potential of AI systems to enhance the visibility of underrepresented professional roles [40,42,46,56,60]. In addition, several studies highlighted the need for AI-based support to remain clinically meaningful and context-sensitive, for example, by adapting outputs to different users, tasks, and care settings rather than relying on overly generic recommendations [42,46,47,54,59,65]. Closely related to this, some studies also emphasized the importance of preserving clinician autonomy and avoiding overreliance on AI

XSL•FO
RenderX

systems, so that AI was experienced as supportive rather than directive [36,45-48,50,61,66,67,72].

Clinicians voiced diverse expectations, concerns, and requirements. Trust in the technology emerged as a central theme; users demanded validated models, transparent recommendations, and adaptive visualizations, especially in situations of clinical uncertainty [39,40,42-44,47,49,51,53,54,56,58-60,62-67]. Preservation of professional autonomy was emphasized, with AI perceived as a source of reassurance or means of broadening perspectives rather than as an authoritative decision-maker [40,43-47,50,58,60,64,66,67,69]. Some studies reported that AI systems may help reduce subjective variability in clinical assessments [50,60]. Relatedly, participants in several studies described AI more concretely as a form of second opinion, an additional safety layer, or a supportive backup in situations of uncertainty, fatigue, or limited staffing [43,46,49,51,60,64]. Participants also stressed that useful AI support depends on contextual fit; outputs and interfaces needed to be clinically meaningful, interpretable, and adaptable to different users, tasks, and care settings, rather than generic or overly abstract [38,39,42,46,48-50,53,54,58-60,63-65,68,71]. Several studies further highlighted resistance to one-size-fits-all solutions and pointed to the need for role-specific interfaces or explanations tailored to different professional groups [47-50,54,58,61,65].

In most studies, fairness, bias, discrimination, and nondiscrimination were not explicitly discussed with users during participatory activities. Where these aspects were considered, they were mainly implicit, through design choices or technical adaptations. More direct participant-related considerations were evident in 4 studies [37,45,46,58] in which participants raised concerns about consistent, unbiased outputs; anchoring on AI recommendations and over-reliance; overly generic recommendations that may not fit diverse users and contexts; and uneven model performance across patient groups or clinical situations. Several other studies [36,38,40,51,52,60,61,72] showed more indirect consideration, for example, adapting functions to different experience levels [40,51], role-specific customization [38,60], integrating explainability features [52,60], or ensuring broad accessibility [36,61], or through accessibility-oriented design, safeguards against biased interpretation, dataset-related reflections, or broader ethical framing [42,47,56,59,63,67].

Questions of accountability and responsibility in CDSS-supported decision-making were seldom explicitly discussed with users. Where present, they were often addressed indirectly, for example, by emphasizing clinician autonomy or implementing design features to prevent over-reliance on AI [37,38,41,48,72]. More explicit reflections on role delineation, clinician responsibility, and the boundaries of AI support were evident in 9 studies [38,41-43,45,46,54,66,67], for example, through explicit reflections on role delineation, clinician responsibility, and the boundaries of AI support. Several studies [36,40,41,44,47,50,58-61,63] addressed the topic more implicitly, for example, by enabling users to review or reject AI suggestions [36,40], framing the CDSS as a supportive tool [36,47,58-60], or embedding mechanisms for critical review [41,44,61,63]. In Grant et al [70], related concerns focused mainly on clarifying responsibilities, routing documents, and tracking who submitted which data, rather than on accountability for AI-supported decisions in a narrower sense.

In total, 14 studies explicitly reported obtaining approval from a research ethics committee [36,38,46-49,55,56,59,61,64,69,71,72]. Funding sources were predominantly from public research grants [37-39,41,43-45,47-49,51-58,60,61,64-67,69-71]. Some studies additionally drew on philanthropic, foundation-based, or university-internal support [36,40,56,64,66,67,71,72], while Fouad et al [63] reported workshop-specific support from the Alan Turing Institute, although broader project funding was not specified. Moreover, 4 studies combined public funding with contributions from industry partners [36,50,62,72], whereas Staes et al [59] reported direct industry support without a clearly stated combination with public funding.

Of the total, 4 studies reported substantial conflicts of interest, as several authors were directly involved with the company developing the respective CDSS, either as shareholders, employees, directors, or scientific advisors, and some additionally received honoraria, sponsorship, or research funding from pharmaceutical companies [36,59,71,72]. In total, 13 studies explicitly declared that no conflicts of interest existed [38,39,43,45,48-50,54,56,57,64,69,70].

Discussion

Principal Results and Comparison With Previous Work

Conceptual and Semantic Heterogeneity

The analysis highlights the heterogeneity in how key concepts such as participation and AI are used. In most studies, participation was understood primarily in functional terms, for example, in relation to usability testing or user-centered design, and was rarely described in a theoretically grounded manner. One possible explanation for this functional framing is that most studies primarily focused on the technical development or evaluation of a CDSS. In this context, participation often served as a means to design systems for complex sociotechnical environments in a user-oriented way, rather than as an independent research goal or theoretically informed principle. Moreover, in many cases, participation was not a central topic of the publication and was therefore only briefly addressed or conceptually elaborated. However, previous work on co-design and participatory research emphasizes that participation should not be reduced to adapting technical systems to user needs. Still, it should also include the joint definition of goals and responsibilities [15,73].

The term “AI” was used inconsistently across the included studies and, in some cases, was only vaguely described. This inconsistency may also reflect the ambiguous nature of AI as a broad “suitcase” term, as well as the interdisciplinary character of participatory AI development, where technical, clinical, and social science perspectives intersect. Depending on the publication’s aim, the journal’s focus, and the target audience, the level of technical detail varies considerably. At the same time, the underlying computational architecture appears to play

XSL•FO
RenderX

a rather minor role in shaping participatory processes. What seems to matter more is how system outputs are communicated, visualized, and integrated into clinical workflows [74].

Taken together, these observations point to a broader conceptual gap; participatory approaches in AI-CDSS are rarely linked to established theoretical frameworks such as value-sensitive design, participatory action research, or sociotechnical systems theory. Strengthening these foundations could help move participation beyond functional usability improvements toward a more epistemically and ethically informed design practice.

Perspectives of Professional Groups and Interprofessionality

The findings indicate that in most studies, the participating professional groups corresponded to the intended users of the respective system. The fact that physicians were involved far more frequently than nurses thus reflects the focus of many projects, which primarily aimed at supporting medical decision-making. At the same time, this emphasis points to persistent hierarchies in health care, where medical knowledge continues to be systematically valued above nursing and therapeutic expertise [75]. Previous reviews of CDSS also indicate that medical perspectives are primarily included in development processes, while nursing and therapeutic voices remain significantly underrepresented [76]. This not only limits the diversity of expertise but also overlooks the fact that professional groups differ markedly in their clinical responsibilities, information needs, and interaction with CDSS, differences that current designs often fail to address [47]. From a participatory perspective, this imbalance is problematic. Nursing professionals not only provide the majority of direct patient care, but are also largely responsible for continuous observation, documentation, and coordination [77]. Their decision-making reflects a complex process of observation, interpretation, and action that is deeply informed by experience, intuition, and contextual understanding, especially in complex care situations [47,77,78], underscoring the importance of incorporating such experiential expertise into system design. The subordinate role of nurses in the projects examined carries the risk that key routines and data sources essential to the functionality of CDSS will be insufficiently taken into account.

Beyond questions of representation, this imbalance also raises broader issues regarding whose knowledge is considered relevant in the development of clinical AI systems. Such dynamics have been described as forms of epistemic injustice, where certain forms of knowledge receive less recognition in processes of knowledge production [79,80].

In the context of AI-CDSS development, this means that selective involvement may also affect which knowledge enters technical design decisions. If nursing perspectives are less systematically involved, there is a risk that nursing knowledge is less strongly reflected in data selection, annotation, model assumptions, explanations, and visualizations.

This is particularly relevant because medical and nursing perspectives may differ in what they consider clinically meaningful information. Medical perspectives may foreground diagnosis-related parameters, treatment decisions, laboratory values, medication, or other structured clinical data, whereas nursing perspectives often include continuous observation, subtle behavioral changes, relational knowledge, everyday functioning, and contextual assessments developed through ongoing care. If such knowledge is not systematically included, AI-CDSS may reproduce a narrower representation of clinical reality, in which nursing observations, care-related documentation, and contextual information remain less visible. This risk is reinforced by existing digital infrastructures, as nursing knowledge is not always captured in a structured and reusable form in hospital information systems or electronic patient records. Previous work has shown that electronic documentation may limit nursing information exchange and that nurses' clinical judgment may remain only partially visible in electronic records [81,82].

AI-CDSS that build on these data infrastructures may therefore inherit existing omissions in how nursing knowledge is digitally represented. This makes the systematic involvement of nursing perspectives in participatory AI-CDSS development particularly important, as it can help identify clinically relevant observations, documentation gaps, and care-related contextual information that may otherwise remain outside the system's data and design logic. Without such involvement, selective knowledge inclusion may shape which variables are prioritized, how data are interpreted or annotated, which explanations are considered useful, and whether interfaces align with nursing workflows. As a result, AI-CDSS recommendations may be clinically or technically plausible, but still incomplete for concrete care situations if they do not reflect the observations and contextual knowledge of professionals who provide continuous bedside care. This may reduce the usefulness of the system for nursing users, limit its fit with interprofessional workflows, and make it less sensitive to early changes, care needs, or contextual risks observed in everyday nursing practice. At the same time, the reporting of participatory processes in the included studies was often too limited to assess systematically how decision-making power was distributed or whether such hierarchies were actively challenged during development. Further research is needed to better understand how participatory processes in AI development interact with existing knowledge hierarchies in clinical practice.

Multiprofessional approaches were used in some studies, but they remain the exception. Nevertheless, the small number of such approaches shows that interprofessional participation has not yet been systematically implemented. This means that projects run the risk of creating blank spots, for example, in relation to nursing routines, process-related care data, or interdisciplinary coordination.

On a positive note, some studies have also included nonclinical stakeholders such as software developers, data scientists, and experts in HCI. This illustrates that the development of CDSS is necessarily interdisciplinary and that technical and organizational knowledge must be combined with clinical practice. However, combining technical and medical expertise is insufficient if nursing perspectives remain marginalized. For sustainable participatory development, it is crucial that interprofessional and interdisciplinary collaboration is established and that nursing is represented equally [83,84].

Participation as a Process: Opportunities and Limitations

The studies examined used a wide range of methods to involve users, including interviews and focus groups, co-design workshops, usability tests, think-aloud protocols, and simulations. This diversity shows that various formats are available and can be selected based on project objectives, research questions, and the development phase. However, it is striking that participation was usually only documented in individual development phases, primarily in design or evaluation. In most cases, participatory efforts were mainly motivated by usability and acceptance-related goals rather than by ethical or epistemic considerations. Continuous involvement across multiple phases remained the exception. As a result, participation tends to be reduced to selective consultations rather than understood as an iterative, longer-term design process [13]. At the same time, the concrete forms of user involvement often followed a functional development logic rather than an explicitly participatory orientation. Against this background, it becomes necessary to critically question how "participatory" such involvement can be considered when it focuses on activities such as usability testing or data annotation. While these activities provide valuable input for interface design and data quality, they address relatively narrow aspects of system development. When involvement occurs mainly in these later stages, it focuses on components that are already specified; opportunities to influence the AI system's overarching goals or conceptual assumptions are therefore limited. One possible explanation for these patterns is that, particularly when maintained over time, participatory involvement requires substantial time, personnel, and financial resources. Projects must therefore have the capacity to support such engagement, which often restricts their scope in practice [85].

At the same time, the absence of enabling activities or jointly conducted reflections on the participatory process suggests that important processual elements of participatory design were not taken up, even though such components are considered central for negotiating roles, responsibilities, and knowledge relations [31,86].

However, the included studies rarely described participatory processes in sufficient detail to assess how such dynamics were addressed in practice. Information on how participants were prepared for involvement, how possible burdens associated with participation were managed, or whether power asymmetries within groups were actively considered was largely absent. This also suggests that participatory involvement was often reported as inherently beneficial, while potential tensions or limitations of participation itself remained largely unexplored.

These observations also resonate with critical perspectives in participatory design research, which caution that participation can become instrumental or even extractive when stakeholders are primarily involved as sources of feedback rather than having meaningful influence on design decisions [18,19]. In such cases, participatory activities risk legitimizing predefined development trajectories rather than enabling shared decision-making about system goals and assumptions.

A related challenge concerns the limited and inconsistent reporting of participatory processes more broadly. This not only hampered comparability across studies but also made it difficult to trace how specific participatory activities contributed to particular design decisions or technical outputs. Although no reporting guideline currently exists specifically for participatory AI-CDSS development, recent guidance for the participatory development and evaluation of digital health interventions [87] may offer a useful orientation for improving transparency, comparability, and methodological learning in this field.

Beyond the design of individual system components, it would be valuable for participatory activities also to address the joint development of a CDSS's goals, mechanisms of action, and contextual requirements [88]. Participatory methods such as participatory system mapping or theory of change-modeling offer suitable approaches for supporting these collective sense-making processes [89,90].

However, the studies also reported several concrete conditions that facilitated participatory processes in practice. Feedback loops, joint prioritization of features, working with real clinical cases, and interdisciplinary collaboration were described as particularly beneficial. These elements help to align systems more closely with clinical routines and improve usability. In addition, some studies provided protected time or financial compensation for participation. This should not be understood merely as a practical facilitation strategy, but also as a way of recognizing participants' labor and practice-based expertise. Conversely, when participation depends on unpaid contributions in addition to routine clinical work, involvement may become more selective and more difficult to sustain over time [91,92]. At the same time, significant structural barriers emerged: time and organizational constraints, skepticism toward AI, small and poorly generalizable samples, and coordination problems within multiprofessional teams limited the depth and continuity of participation. These structural constraints should not be understood solely as logistical challenges, but as indicators of limited organizational capacity for innovation. In health care institutions, participatory activities usually add to existing clinical responsibilities; without protected time or dedicated resources, they compete with the immediate demands of routine care and are difficult to sustain [93]. Under such conditions, participation may become selectively accessible to professional groups with greater temporal autonomy, stronger institutional support, or more established links to research and development. Such findings are consistent with the literature, which indicates that (clinical) conditions often have a greater impact on participatory research than theoretical models [14,15].

These observations suggest that participatory development processes are closely shaped by their organizational and institutional contexts. While this review primarily focuses on participatory design processes, the findings also highlight the importance of implementation contexts and organizational conditions for the success of these approaches. Frequently reported barriers—such as time constraints, limited resources, and organizational misalignment—remain largely described at a surface level in the included studies. Interpreting these findings through the lens of implementation science may provide a more systematic understanding of why these challenges persist.

XSL•FO
RenderX

Established frameworks such as the Consolidated Framework for Implementation Research (CFIR) [94] and the NASSS (Nonadoption, Abandonment, Scale-up, Spread, and Sustainability) framework [95] highlight the role of factors, including organizational culture, workflow integration, stakeholder incentives, and system complexity, in shaping the adoption of digital health interventions. From this perspective, participatory design cannot be understood in isolation from the institutional environments in which it is embedded.

The limited attention to these dimensions in the reviewed studies suggests a gap in the literature. A similar pattern has been identified in recent research, which shows that real-world implementation of AI systems in health care remains rare and insufficiently documented [96].

Future research should more explicitly integrate participatory design approaches with implementation science frameworks to better understand how participatory practices can be sustained in real-world clinical settings. This includes examining how organizational structures, resource allocation, and policy environments facilitate or constrain meaningful participation. In practical terms, co-design workshops could be extended by an explicit reflection layer on implementation conditions, thereby linking participatory design work more closely to questions of adoption and sustained use. For example, a NASSS-informed implementation canvas could support stakeholders in identifying and reflecting on specific barriers and requirements for introducing digital technologies in clinical practice and in deriving possible solution approaches [97]. In addition, implementation-related reflection questions could be integrated into workshops and other participatory activities and guided by frameworks such as NASSS or CFIR. This would allow implementation considerations to be addressed throughout the participatory process rather than only after system development.

In summary, the findings indicate that participatory design in AI-CDSS remains fragmented and insufficiently theorized, with few studies explicitly connecting participatory methods to established frameworks such as value-sensitive design or sociotechnical systems theory.

Contributions to Technical Design

Participatory contributions focused primarily on peripheral technical levels, variable selection, data annotation, and explainability functions, while developers primarily determined the actual model and algorithm design. This pattern is by no means coincidental, but instead points to the unequal distribution of design power in the development process: clinical expertise is recognized as valuable for “enriching” data and testing interfaces, but not for the basic assumptions of modeling. The findings of Schwartz et al [76] support this observation: their review showed that clinical expertise was primarily involved in feature selection, annotation, and validation, while the core development of machine learning models was carried out almost exclusively by technical developers.

The unequal distribution of influence over design is also evident in how issues of explainability are handled. Although the involvement of clinical users in visualizations or case studies strengthened trust and comprehensibility, it was mostly reactive, focused on feedback on prototypes. Current work on explainable AI in the clinical context, on the other hand, emphasizes that explainability should not be treated as an afterthought but should be developed and negotiated with users as an integral design principle from the outset [98].

A related pattern becomes apparent in how data quality was managed. Data quality issues were only addressed in a participatory manner in a few projects. Where clinical experts were involved, annotations increased terminological precision, and user feedback verified the effectiveness of preprocessing steps (eg, feature selection), yet it is still striking that aspects of data quality were hardly addressed in many projects. This reveals a fundamental tension: while AI-based systems rely on the quality and relevance of their training data, this aspect is often ignored in participatory processes, even though clinical domain knowledge would be crucial for identifying and correcting systematic distortions and biases [85,99]. Such omissions point to deeper epistemic consequences. When data are treated primarily as a technical resource rather than as the outcome of social and clinical practices, their contextual meaning is lost [100-102]. In her analysis of atherosclerosis, Mol [103] demonstrated that the same disease is enacted differently across professional practices. Translated to the context of AI training data, this means that medical and nursing documentation do not merely offer different perspectives on the same “object,” but actively produce distinct versions of clinical reality. If annotations predominantly rely on medical perspectives, only a partial version of this reality is inscribed into the data. Nursing perceptions remain invisible, and this creates conditions under which forms of epistemic injustice may emerge.

Overall, this confirms a pattern observed in previous work: participation improves usability, data integrity, and trust, but remains limited to secondary technical levels [76].

ELSI

The findings suggest that ELSI aspects were addressed selectively across the studies. They can be further contextualized using established dimensions of trustworthy AI, including transparency and explainability, fairness and non-discrimination, accountability and governance, privacy and security, and human agency and oversight. Structuring the results along these dimensions highlights important asymmetries in how ethical, legal, and social implications are addressed in participatory design processes. Most attention was given to issues such as trust, transparency, and the preservation of professional autonomy. Trust itself was rarely addressed as an independent design objective, but rather emerged as a downstream consequence of transparency, explainability, perceived usefulness, and the preservation of professional autonomy. This emphasis is understandable, as it is directly linked to the practical usability of the systems. Without traceable outputs and the ability to retain clinical responsibility, CDSS are hardly compatible with everyday use. However, this focus narrows the ethical debate to trust and transparency, while other dimensions—such as fairness, bias mitigation, and accountability—receive far less attention. Yet these very aspects

XSL•FO
RenderX

are particularly emphasized in international ethical debates on "trustworthy AI" [104]. Privacy and data protection considerations were occasionally mentioned but often remained implicit or underdeveloped. Similarly, aspects related to human agency and meaningful oversight were not systematically discussed. Čartolovni et al [105] show in their scoping review that security and transparency dominate, while fairness, accountability, and governance are considered critical but are often insufficiently addressed in practice.

This thematic narrowing is closely linked to the way ethical questions were negotiated within the development processes. ELSI aspects were rarely discussed with users in a participatory manner; instead, they were mostly addressed implicitly through technical design decisions or organizational frameworks. As a result, the role of clinical actors was often limited to accepting or evaluating transparency and trust functions, while broader ethical principles largely remained in the background. At the same time, the ethical relevance of participatory development depends on which perspectives become influential within these processes. If participation remains limited to certain groups, or if dominant voices prevail in discussions, there is a risk that existing assumptions will be reproduced rather than critically questioned [106].

This tendency becomes particularly evident in the case of responsibility, a central aspect of ethical decision-making. Several studies emphasized that CDSS should support decision-making rather than replace it. However, there was little participatory discussion on how responsibility can be distributed between humans and machines, and which structures can ensure this. This lack of engagement indicates that normative questions were rarely explicitly negotiated, instead being translated into technical or organizational solutions.

Taken together, these findings suggest that participatory AI-CDSS development has so far focused mainly on immediate usability, interpretability, and workflow integration, while broader ethical and governance dimensions remain insufficiently integrated into participatory design processes. As a result, there is a risk that "trustworthy AI" will be reduced to superficial characteristics, while deeper ethical tensions remain unaddressed. Making these dimensions more explicit within participatory processes may support a more comprehensive and transparent approach to AI development in health care.

Strengths and Limitations

To our best knowledge, this is the first review to systematically examine approaches to involving clinical staff in the development, piloting, and evaluation of AI-based CDSS. By analyzing not only *when* involvement occurred across project phases but also *how* it was organized and *who* was engaged, the review provides a differentiated understanding of the forms of involvement. This highlights both the diversity of approaches and existing asymmetries in representation. The review thus offers a comprehensive overview and insights into how involvement can shape data, models, and normative principles, supporting the development of more inclusive and clinically meaningful AI systems.

This review has several limitations that should be considered when interpreting the findings.

A central limitation concerns the inconsistent and often selective reporting of stakeholder involvement, which hampered comparability and frequently obscured the extent, continuity, and influence of participatory processes. Understandings of involvement also varied across disciplines and contexts, underscoring the need for clearer methodological frameworks and standardized reporting practices. Another challenge concerned classification: because only a few studies explicitly described their approach using participatory terminology, inclusion decisions had to rely partly on reviewer interpretation, which carries a risk of subjectivity. Furthermore, most of the included publications were descriptive or conceptual, limiting the ability to draw quantitative inferences about the effectiveness of participatory approaches.

In addition, no formal critical appraisal of study quality was conducted. This approach is consistent with the exploratory purpose of scoping reviews, which aim to map the breadth and characteristics of a research field rather than assess the effectiveness of interventions. However, it implies that studies of varying methodological rigor were considered equally in the synthesis, which may influence the strength and interpretation of the conclusions.

A further limitation relates to the scope of the review. The search was restricted to English- and German-language publications from 2012 to 2026, which may have introduced language bias. Participatory design research has strong traditions in regions such as Scandinavia, and relevant studies published in other languages may therefore not have been captured. Moreover, the relatively small number of included studies compared to the initial search yield reflects the specificity of our review focus on AI-based CDSS with reported stakeholder involvement. While numerous studies address related areas such as digital health, health information systems, or co-design in adjacent technologies, participatory processes are often not explicitly described or are insufficiently reported. This underreporting itself represents an important finding of this review. At the same time, the focused scope of this review may have excluded relevant insights from adjacent domains, including participatory design in non-AI health technologies or broader co-design practices in health care. Future research may benefit from integrating these perspectives to develop a more comprehensive understanding of participatory approaches in the design of AI-based clinical systems.

Although this review covered the full spectrum from development to evaluation, none of the included studies provided systematic evidence on real-world implementation. The findings, therefore, mainly reflect early phases of development, piloting, and testing. The lack of implementation studies is likely related to the fact that AI-based CDSS have so far rarely been integrated into routine care [107], among other reasons due to restricted data access and regulatory hurdles [108], and broader socio-technical barriers that complicate implementation in health care settings [107]. Nonetheless, the review provides a comprehensive overview of existing practices and gaps across multiple disciplines.

Conclusions and Recommendations

The development of AI-based CDSSs should integrate participatory processes continuously throughout all stages of system design and evaluation, rather than restricting them to isolated phases. Participation should address usability, data quality, bias, and ethical, legal, and social considerations. Co-design workshops, iterative prototyping, and shared evaluation dashboards can strengthen communication between developers and clinical users. Moreover, the reporting of participation and co-design remains insufficiently standardized, even though transparent documentation would be essential for contextualizing and critically reflecting on the research process. Although no reporting guideline currently exists specifically for participatory AI-CDSS development, existing guidance may offer useful orientation. This includes the *Best Practices in the Reporting of Participatory Action Research* [109] as well as the reporting guideline for the participatory development and evaluation of digital health interventions (ParDE-DHI) [87]. Such guidance underlines the need for studies to articulate more clearly how participation is conceptually understood, which theoretical assumptions underpin it, and how these assumptions are translated into concrete procedures. In addition, the use of technical reporting standards, such as TRIPOD+AI [110], can enhance transparency in model development and validation. Integrating participatory and technical reporting standards may help to make both user involvement and model transparency systematically visible, comparable, and reproducible. In addition, embedding deliberative and ethical reflection formats (eg, scenario discussions, data ethics cafés) can help translate high-level AI ethics principles into concrete design choices. It is equally important to involve diverse professional groups, particularly those with nursing and therapeutic expertise, to ensure that systems reflect the full spectrum of clinical routines and decision-making logics. As discussed above, participation has largely been framed through an HCI-oriented view of clinicians as "users," yet their expertise would also be valuable for addressing implementation questions.

Future research should develop validated frameworks for participatory AI design that integrate ethical, organizational, and technical perspectives, thereby providing methodological coherence across studies and advancing the field. Longitudinal and comparative research could examine how different levels and forms of participation influence adoption, trust, and patient outcomes. In parallel, implementation studies in real clinical environments are needed to understand how to sustain participatory processes beyond project phases and embed them in institutional governance structures. Creating such frameworks and gathering empirical evidence will be essential to moving participatory design from a methodological aspiration to a practical standard for developing safe, responsible, and context-sensitive AI-CDSS.

Acknowledgments

During manuscript preparation, ChatGPT (OpenAI) was used solely to assist the authors with organizing extracted study information, incorporating findings from newly included studies into the existing results structure, and language editing. All suggestions were critically reviewed, revised, and verified by the authors, who retained full responsibility for the final manuscript.

Funding

This work was partly funded by the Federal Ministry of Research, Technology and Space (Bundesministerium für Forschung, Technologie und Raumfahrt) through the KIDELIR project. The work of T.R. was partly supported by grant 16SV8865 to Furtwangen University. The work of P.G. and C.H. was partly supported by grant 16SV7886K to the University of Freiburg Medical Center. The KIDELIR project aims to develop hybrid AI models to predict delirium in a hospital setting and to support reflective care decisions, with close involvement of care professionals. The funder had no involvement in the study design, data collection, analysis, interpretation, or writing of the manuscript. All data extraction, synthesis, interpretation, and manuscript writing were conducted by the authors.

Data Availability

All data collected and analyzed during our scoping review will be available on the Open Science Framework repository and included as supplementary files with our scoping review publication.

Abstract

Background: Smart home technologies integrated with technology-enhanced health care (TEH) systems are transforming residential care by supporting independent living, continuous health monitoring, and remote clinical interventions. The Internet of Medical Things, wearable biosensors, and AI-driven analytics enable proactive health care delivery and personalized interventions, particularly for older adults and individuals with chronic conditions.

Objective: This review synthesizes literature on TEH integration within smart homes, examining global deployment patterns, technological maturity, biomedical sensor integration, machine learning applications, and health outcomes. It also identifies implementation challenges and disparities to improve digital health care strategies.

Methods: A scoping review was conducted across PubMed, Scopus, Web of Science, ScienceDirect, and IEEE Xplore for peer-reviewed studies published between January 2005 and February 2025. Following screening of 6276 records, 169 studies were included, covering experimental, qualitative, and system design methodologies. Data were extracted on geographic deployment, sensor types, TEH architectures, machine learning algorithms, clinical outcomes, and adoption barriers.

Results: TEH adoption is concentrated in Europe, East and Southeast Asia, and higher-income countries, with potential emerging initiatives in West Asia in lower-income regions. Smart home maturity ranges from foundational systems with basic automation to connected ecosystems with centralized Internet of Things coordination, and intelligent systems with data-driven adaptive monitoring. The literature was synthesized across thematic domains, including sensor technologies, smart home infrastructure, predictive analytics, telehealth integration, and ethical and regulatory considerations, and interpreted through a 3-level maturity taxonomy of foundational, connected, and intelligent smart home systems. Integration of biomedical sensors can enable continuous monitoring of cardiovascular, respiratory, neurological, metabolic, and mobility parameters, while machine learning algorithms can support early disease detection, predictive health analytics, activity recognition, and personalized interventions. Evidence from current literature indicates remote monitoring improves early detection of health issues, chronic disease management, medication adherence, and psychological well-being. Several studies reported that remote monitoring systems improved early detection of health deterioration, chronic disease management, medication adherence, and patient well-being. Adoption barriers include interoperability challenges, data privacy, digital literacy gaps, social and economic disparities, and long-term sustainability concerns.

Conclusions: Unlike previous work, this review emphasizes practical adoption barriers, interoperability challenges, and equity considerations alongside sensor performance and system integration. The key significance in this scoping review is how it highlights technological trends and implementation patterns while mapping global deployments of TEH smart homes through encompassing wearable and environmental systems. It demonstrates realistic integration scenarios and how it enhances independent living, preventive care, and personalized health management while reducing hospitalizations and health care costs. It demonstrates how widespread implementation requires standardized evaluation frameworks, robust interoperability, adaptable design, equitable access, and clinically friendly integration. By addressing technical, social, and regulatory challenges, smart home systems can achieve scalable, sustainable, and effective digital health care delivery.

Introduction

Rationale

The delivery of health care services has undergone a significant transformation in recent years, driven by the growing demand for personalized, preventive, and accessible care [1]. This ongoing transformation was further accelerated by the COVID-19 pandemic, which heightened public awareness of continuous health monitoring and expanded attention beyond older adult populations to include younger individuals, particularly those exposed to occupational stress and long working hours. In both high-income and resource-limited communities, this shift underscores the urgent need for early-stage disease detection and proactive health management. Early intervention not only improves clinical outcomes but also empowers individuals, including those with disabilities, to manage their health through digital platforms and remote care technologies [2,3].

Technology-enhanced health care (TEH) systems integrated within smart home environments offer a promising solution to the growing demand for personalized and proactive care. Smart homes, equipped with high-speed internet and embedded with sensors, smartphones, wearable devices, and intelligent software, provide a robust infrastructure for continuous health monitoring [4]. These environments can seamlessly incorporate a wide range of biomedical sensors such as heart rate monitors, peripheral capillary oxygen saturation (SpO_2) sensors, breath analyzers, skin conductance sensors, glucose monitors, etc, into daily living spaces, enabling real-time data collection and personalized health interventions [5]. TEH systems leverage wearable technologies, mobile apps, and edge computing to facilitate disease prediction, trend analysis, and remote diagnostics, thereby enhancing health care delivery and reducing the burden on clinical professionals [6,7].

Compared to conventional telehealth models and stand-alone digital health interventions such as mHealth (mobile health) applications or remote monitoring devices, TEH integration offers superior data accessibility, contextual awareness, and continuous monitoring. Health data collected within smart homes can trigger physician engagement when early signs of disease progression are detected, while also supporting personalized recommendations for diet, exercise, and lifestyle modifications. Furthermore, the integration of sensor networks and smart devices enables the development of digital twinning (which is a virtual representation of smart homes that simulate residents' behaviors, health status, and environmental conditions). These digital twins allow for predictive modeling of disease progression, early detection of health risks, and optimization of health care resources, thereby supporting proactive and personalized interventions that enhance patient outcomes and system efficiency [8].

The COVID-19 pandemic revealed critical vulnerabilities in global health care systems, including delays in vaccine distribution and overburdening of medical infrastructure [9]. In such a context, TEH integration within residential environments plays a vital role in minimizing the need for physical clinic visits, facilitating remote patient management, and enabling timely medical intervention. TEH systems can assist public health authorities in predicting disease spread and progression based on demographic, behavioral, and environmental factors, thereby supporting targeted containment and mitigation strategies.

At the core of TEH systems are Internet of Things (IoT)–based health sensors, which can be seamlessly integrated into existing smart home networks. Data collected from these sensors is transmitted to smart devices and health care applications, where edge computing platforms perform preliminary processing before forwarding relevant information to cloud servers and health care providers [10]. The deployment of TEH within smart homes requires a multidisciplinary approach to address challenges related to data acquisition, storage, compression, networking, and analytics. Such technologies allow health practitioners to observe parameters such as irregular activities, sleep patterns, high heart rate, or sudden changes in weight remotely and in real time, which can help detect early stages of a health crisis [11].

Given the potential of TEH-smart home integration to improve health outcomes and promote independent living, it is essential to understand the current landscape of TEH technologies, including sensor systems, wearable devices, and smart home infrastructures, and how they are implemented and evaluated. This review presents a systematic investigation into both the integration of TEH systems with smart homes and the use of sensors and monitoring devices, aiming to identify existing gaps and opportunities for improvement. Of 169 peer-reviewed papers analyzed from multiple databases, this study stands out by highlighting the need for a clear framework for assessment and evaluation of TEH interventions. The findings are intended to inform civil, mechanical, electronic, and computing engineers, biosensor engineers, policymakers, and industry stakeholders in developing strategies for effective TEH integration, ultimately contributing to inclusive, scalable, and clinically robust smart health care environments.

Objectives

The main objectives of this paper are summarized in the following points: (1) Synthesize current evidence on TEH integration in smart homes, including global deployment patterns, technological maturity, performance of biosensors, and AI-driven health analytics. (2) Identify adoption barriers and evaluate their impact on user acceptance and long-term efficient adoption; which investigates primarily interoperability, usability, and regulatory frameworks. (3) Highlight technological trends, practical implementation scenarios, and implications for future research in medical smart homes and clinically effective smart home health care solutions.

The remainder of this paper is structured as follows: the methodology section details the systematic review approach, including search strategy, selection criteria, and qualitative analysis methods; this is followed by Results, Discussion, and Conclusions sections, which synthesize current evidence, identify research gaps, and provide recommendations for future TEH-smart home integration initiatives.

Methods

Study Design

This study was conducted as a scoping review to map, examine, and synthesize the breadth of existing literature on the integration of TEH within smart home environments. A scoping review approach is appropriate for this topic due to the heterogeneity of study designs, technologies, clinical applications, and evaluation methods, as well as the rapidly evolving nature of digital health and smart home research.

This review was conducted in accordance with the methodological framework originally proposed by Arksey and O'Malley [12] and subsequently refined by Levac et al and Peters et al [13,14]. Reporting followed the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) guidelines [15] to ensure transparency, reproducibility, and methodological rigor. A PRISMA-ScR flow diagram was used to document the study identification and selection process. The principles of rapid evidence assessment informed the efficiency of the search process, particularly in managing a broad multidisciplinary evidence base [16]. The current review is explicitly positioned as a PRISMA-ScR–compliant scoping review. The objective was to map evidence, identify key concepts, evaluation approaches, and research gaps, rather than to assess intervention effectiveness or conduct formal risk-of-bias appraisal.

This comprehensive review adopts a structured five-stage approach to ensure transparency, reproducibility, and analytical rigor in exploring TEH integration within smart home environments. The first stage involves research objectives and guiding questions formulation to establish scope and relevance. The second stage involves developing a search strategy, including the use of electronic databases, targeted keywords, and Boolean logic to capture relevant literature. Third, eligibility criteria are defined, specifying inclusion and exclusion parameters based on population, intervention type, setting, publication date, and language to ensure consistency in paper selection. Fourth, the screening and selection process is conducted, applying the eligibility criteria systematically. Finally, a qualitative synthesis was conducted to investigate the selected literature in relation to key aspects, including sensor technologies, interoperability frameworks, system performance, user experience, and ethical considerations. This multidimensional evaluation enabled a detailed study of how TEH systems are designed and implemented in independent residential environments, providing insight into both their technical feasibility and measurable health care impact.

Research Questions

The primary objective of this scoping review was to map the scope, characteristics, and evaluation approaches of TEH systems integrated within smart home environments, with regard to technical architectures, clinical applications, sociotechnical factors, and reported health outcomes. The following questions guided this review:

1. To what extent, and through which mechanisms, do TEH sensing systems integrated within smart home environments support health care delivery, preventive care, and healthier living conditions?
2. How are data transfer, system interoperability, resource allocation, and operational efficiency addressed within TEH-enabled smart homes to support scalable and sustainable health care solutions?
3. Which assessment tools and evaluation methodologies are used to measure the performance, usability, and clinical impact of TEH integration, and how do sociotechnical factors such as usability, accessibility, digital literacy, and trust influence their adoption?

These questions were intentionally broad, consistent with scoping review guidance, to capture the full range of technologies, study designs, and evaluation approaches present in the literature.

Search Strategy

A structured electronic literature search was conducted across 6 major academic databases: Web of Science, Scopus, PubMed, IEEE Xplore, ScienceDirect, and Google Scholar. The final search was completed in February 2025. Only peer-reviewed journal papers were considered to ensure academic rigor and methodological transparency.

The search strategy combined fixed keywords using Boolean operators ("AND," "OR") and was designed to capture literature spanning technological, clinical, evaluative, and sociotechnical dimensions of TEH-enabled smart homes. Four thematic clusters were organized for search terms presented in Table 1.

Table . Thematic classification of keywords used for literature search across smart environments, TEH[a], evaluation approaches, and sociotechnical adoption factors.

Theme	Keywords
Theme 1: technology and smart environment terms	Smart home, smart house, smart building, automated home, intelligent home, smart technology, connected device, IoT[b], IoMT[c], wearable devices, digital health technology, health monitoring devices
Theme 2: health care and TEH terms	Technology-enhanced health care, technology-enabled health care, digital health care, mHealth[d], telehealth, telemedicine
Theme 3: evaluation and assessment terms	Evaluation framework, assessment tool, clinical evaluation, usability testing, performance metrics, benchmarking, effectiveness, impact assessment
Theme 4: sociotechnical and adoption terms	Usability, accessibility, digital literacy, trust, adoption, sociotechnical, patient outcomes, care pathways

[a]TEH: technology-enhanced health care.

[b]IoT: Internet of Things.

[c]IoMT: Internet of Medical Things.

[d]mHealth: mobile health.

This strategy ensured comprehensive coverage of the multidisciplinary literature relevant to TEH integration in smart home environments.

Eligibility Criteria

Eligibility criteria were developed iteratively, consistent with scoping review best practices [14], to balance inclusivity with relevance to this review's objectives. The final selection of studies was guided by the eligibility criteria summarized in Textbox 1, ensuring alignment with the objectives of this review. Studies were included if they addressed at least one of the following domains:

Regarding core technology, research on smart home technologies, ambient assisted living, IoT, wearable devices, remote patient monitoring, telehealth or telemedicine, mHealth, medical sensor networks, AI, health informatics, or smart environments; these represent the foundational technologies supporting TEH integration in residential settings.

Regarding clinical and disease-specific management, studies focusing on chronic disease management, cardiovascular or respiratory monitoring, diabetes care, dementia support, tuberculosis surveillance, and other home-based clinical applications, these ensure this review captures personalized outcomes and clinical effectiveness.

Regarding smart framework and infrastructure, papers examining integration frameworks, infrastructure design, interconnected systems, smart health care ecosystems, and health data exchange, these criteria reflect structural, interoperability, and system-level considerations critical for effective TEH deployment.

Regarding implementation barriers, studies evaluating technology acceptance, digital literacy, user resistance, privacy and ethical concerns, cost barriers, accessibility, and trust in technology, these criteria ensure that sociotechnical and adoption challenges are systematically captured.

Exclusion criteria removed studies that were irrelevant to smart and remote health monitoring applications, nonpeer-reviewed, or outdated. By explicitly mapping inclusion and exclusion criteria to core technologies, clinical applications, system infrastructure, and implementation challenges, this review maintains methodological rigor, focus, and relevance while following the rapid evidence assessment approach. This eligibility framework justifies the selection of studies by ensuring that only papers contributing meaningful technical, clinical, or sociotechnical insights are included. It also allows this review to systematically identify gaps in evaluation, interoperability, adoption, and scalability, which underpin the strategic recommendations presented later in this paper.

XSL•FO
RenderX

Textbox 1. Criteria used in the screening process.

Inclusion criteria

- Core technology: smart home technology, ambient assisted living, Internet of Things (IoT), wearable devices, remote patient monitoring, telehealth or telemedicine, mHealth (mobile health), medical sensor networks, AI, health informatics, and smart environments.
- Clinical and disease-specific management: chronic disease management, chronic obstructive pulmonary disease or asthma monitoring, arrhythmia detection, diabetes care, blood pressure monitoring, dementia support systems, tuberculosis surveillance, lung disease diagnostics, and jaundice detection.
- Smart framework and infrastructure: integration framework, infrastructure design, smart health care ecosystem, interconnected systems, and health data exchange.
- Implementation barriers: technology acceptance, digital literacy, user resistance, privacy concerns, cost barriers, demographic challenges, ethical concerns, trust in technology, and accessibility.

Exclusion criteria

- Subjective and not peer-reviewed sources: conference abstracts, comments, gray literature, theses, blog posts, editorials, and opinion papers.
- Irrelevant settings: hospital-based care only, intensive care unit (ICU), emergency department interventions, clinical trials without home-based components, gaming technology, and cryptocurrency and blockchain.
- Irrelevant applications: smart homes for energy efficiency only, home automation unrelated to health, and entertainment systems.
- Outdated or nonscalable technologies: obsolete sensor platforms, single-use or nonrechargeable devices, and nondigital interventions.

Data Charting, Extraction, and Synthesis

Data from the included studies were charted using a structured data extraction framework developed iteratively to ensure consistency and relevance to this review's objectives. The framework was designed to capture key characteristics across technical, clinical, and sociotechnical dimensions of TEH-enabled smart home systems. Extracted data elements included the following: (1) TEH technology types and sensing modalities; (2) smart home infrastructure components and system integration frameworks; (3) clinical application areas and target populations; (4) evaluation tools, performance metrics, and reported outcome measures; (5) user experience, adoption factors, and sociotechnical considerations; and (6) ethical, privacy, security, and scalability considerations.

This synthesis revealed prominent thematic areas including health care delivery, health monitoring, sensing devices, physical activity, mobility, and medication management. The frequent emphasis on concepts such as monitoring, sensors, connectivity, and intelligent systems indicates that existing TEH-enabled smart home research is largely oriented toward continuous health monitoring, disease detection, and data-driven clinical decision support. These themes informed the organization of results and facilitated the identification of gaps related to evaluation practices, system interoperability, and real-world implementation and adoption.

Quality Appraisal and Methodological Limitations

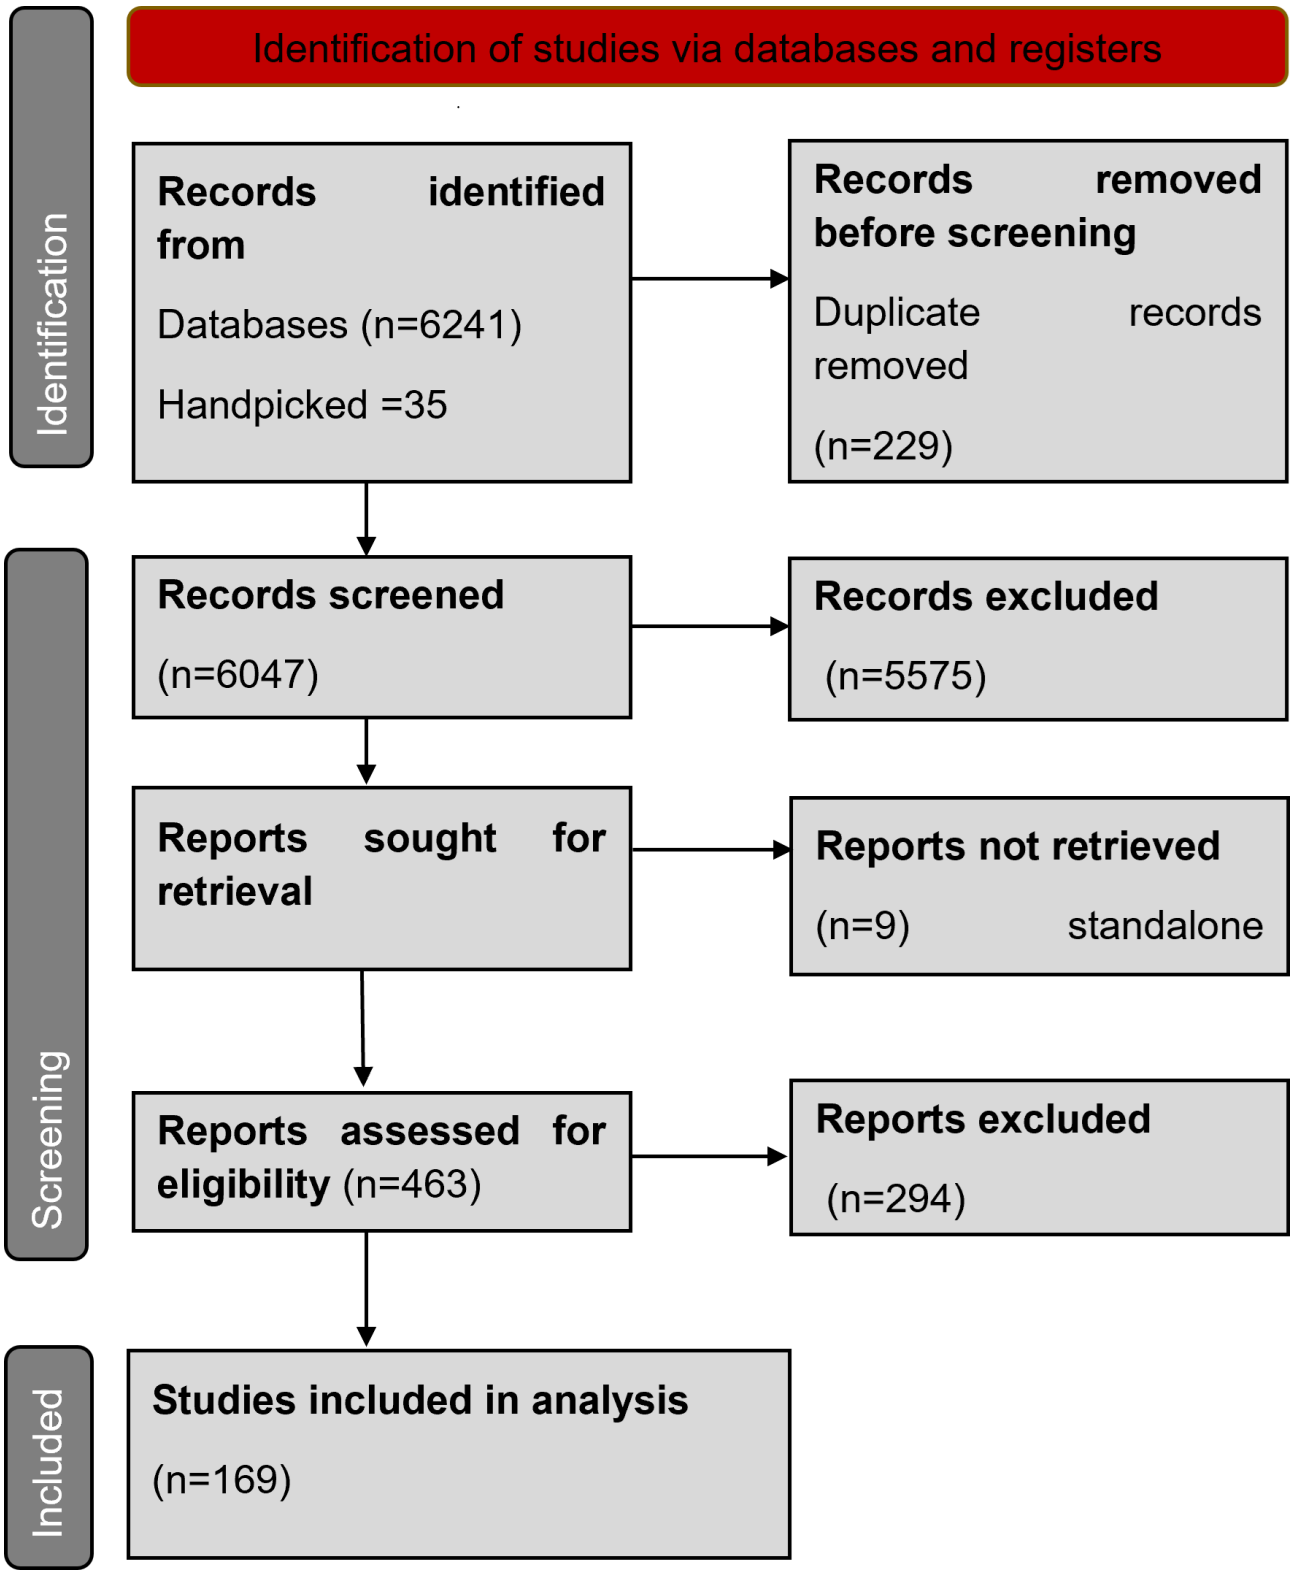
In accordance with PRISMA-ScR guidance, this scoping review did not include a formal risk-of-bias or methodological quality appraisal of individual studies [15]. The primary objective of the current review was to map the extent, nature, and characteristics of existing evidence on TEH integration within smart home environments, rather than to evaluate the effectiveness of specific interventions or to compare outcomes across study designs.

There are several methodological limitations. The absence of formal quality assessment means that variation in study rigor, reporting quality, and methodological robustness across included studies was not systematically weighted or quantified. As a result, the synthesis reflects the breadth of available evidence rather than the relative strength of individual findings. The inclusion of diverse study designs limits the ability to draw definitive conclusions regarding clinical effectiveness, comparative performance, or causal relationships between TEH-enabled smart home interventions and health outcomes. The findings should therefore be interpreted as indicative of research trends, dominant approaches, and evidence gaps, rather than as confirmatory evidence of impact. The restriction to English-language, peer-reviewed publications may have resulted in the exclusion of relevant studies published in other languages or reported in gray literature, potentially introducing publication bias. This decision was made to ensure methodological transparency and consistency with this review's objectives and reporting standards.

Despite these limitations, the scoping review methodology is well-suited to the aims of this study and provides a comprehensive overview of current research on TEH-enabled smart home systems. The findings offer valuable insights into prevailing technologies, evaluation practices, and sociotechnical considerations, while highlighting areas where more rigorous, theory-driven, and outcome-focused research is needed.

Results

Selection Process



All retrieved citations were imported into the Rayyan web-based screening platform to support systematic screening and duplicate removal. Duplicate records were identified using Rayyan's automated functions and manual verification. Title and abstract screening were conducted independently by multiple reviewers to assess relevance to this review's objectives. Full-text screening was subsequently performed for all potentially eligible

XSL•FO
RenderX

studies. Any disagreements regarding study inclusion were resolved through discussion and consensus, consistent with recommended scoping review practices [13].

The screening process resulted in an initial pool of 6276 records, from which 169 peer-reviewed papers met the inclusion criteria and were retained for data charting and synthesis. The complete screening and selection process is illustrated using a PRISMA-ScR flow diagram in Figure 1.

Figure 1. PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) flowchart for paper selection following rapid evidence assessment protocol.

XSL•FO
RenderX

Selection of Sources

The results of this review reflect the literature search identified as examining the integration of telemedicine, environmental monitoring, and smart home technologies for health care applications. Following the screening process, 169 studies met the inclusion criteria and were included in this scoping review. These studies were published between 2005 and 2024, with a noticeable increase in publications after 2010, reflecting the rapid development of IoT architectures, wearable sensors, and AI in health care applications. This literature spans a wide range of interdisciplinary domains, including sensor technologies, environmental monitoring, machine learning (ML)–based health analytics, smart home infrastructures, and telehealth implementation frameworks. While many studies focus on the technological development of sensing and monitoring systems, fewer investigations examine clinical integration, evaluation frameworks, and regulatory considerations, highlighting important gaps in the current literature.

Most papers focused on wearable and ambient sensor technologies, examining health- and environment-affecting factors such as indoor air quality, temperature, and humidity while demonstrating the development of continuous health tracking systems. Another major discipline considered in this review is the infrastructure involved in the design of smart home systems that enables the integration of these sensors. Few studies investigated health prediction analytics and pattern recognition within smart home environments and how it can have an impact on health outcomes. Finally, this review also looks at ethical, regulatory, and usability considerations, interoperability, and evaluation frameworks essential for the effective and responsible deployment of smart home health care technologies. There is a clear gap in regulatory frameworks in the aspect of TEH integration, as shown in Table 2,2, which requires further development.

Table . Distribution of the 169 included studies across primary research themes.

Primary research theme	Studies, n (%)
Sensor technologies	68 (40.2)
IoT[a] infrastructure	34 (20.1)
Machine learning	27 (16.0)
Telehealth	24 (14.2)
Ethics and usability	16 (9.5)
Total	169 (100.0)

[a]IoT: Internet of Things.

Characteristics of Source Evidence

Demographic Analysis

Smart home technologies have been widely developed and deployed across various European countries, including Germany, Finland, France, Spain, the Netherlands, Sweden, Italy, Ireland, Denmark, Belgium, Greece, Austria, etc. These initiatives predominantly focus on supporting older adult individuals using embedded technologies designed to enhance independent living, safety, and health monitoring [5]. Although the concept of the smart home originated in 1975, the considerable worthwhile transformation in integrated technologies only started within the past 2 decades, with major progress emerging around 2010 in both industry and academic research [17]. Many European nations have since prioritized age-in-place strategies, leveraging TEH systems within residential settings to promote autonomy and reduce dependence on institutionalized care. European institutions have focused on experimental frameworks and pilot studies exploring novel sensing modalities, interoperability standards, and AI-driven data analytics. Examples include research programs funded under the European Union's Horizon 2020 and Horizon Europe initiatives, which investigate smart environments for older adult care, telemedicine, and cognitive monitoring [18,19]. These projects typically assess feasibility, user experience, and system interoperability on a small to medium scale. In contrast, commercial development has concentrated on impact and scalable implementation. Companies such as Siemens, Bosch, and Philips have integrated TEH features into smart home ecosystems through intelligent lighting, fall detection, and remote health management platforms [20]. This integration required emphasis on new aspects such as data reliability, data privacy compliance, and consumer usability over experimental innovation. They invest in better interoperability with IoT home devices, long-term reliability, and secure integration with health care providers.

The quality and maturity of TEH adoption, however, vary significantly across regions. In the United Kingdom, for instance, notable efforts such as Gloucester's Smart House and the Cabernets project demonstrated targeted and personalized innovations in dementia-friendly living environments [21,22]. These projects integrate behavioral analytics, motion sensing, and caregiver alert systems to support autonomy and safety. Yet, nationwide scalability remains hindered by interoperability challenges between smart home platforms and health care networks. In East and Southeast Asia, countries such as Japan, South Korea, and Singapore exhibit some of the most mature TEH infrastructures, supported by government-driven aging policies and integration of IoT-based monitoring within residential architecture [23]. These regions have adopted various forms of ambient assisted living and intelligent home automation to elevate the quality of life for aging and vulnerable populations. Similarly, countries in Western Asia, such as Türkiye, Israel, and Saudi Arabia, are in the early to intermediate stages of TEH smart residential adoption that focuses on the

XSL•FO
RenderX

development of digital health innovation zones [24]. These initiatives show strong potential for accelerated growth as regulatory frameworks and interoperability standards mature.

The diversity observed in these global patterns indicates that TEH adoption is expanding and reflects a shared commitment to addressing demographic challenges and increasing burden of chronic disease management through innovative smart health care solutions. However, the quality of smart home integration remains uneven. Regions with established regulatory infrastructure, health care digitization, and government support demonstrate higher maturity levels, while developing economies continue to explore foundational frameworks for scalability and affordability. The convergence of scalable research innovation and industry implementation is therefore crucial to achieving sustainable, equitable, and clinically validated TEH smart home ecosystems.

Maturity Levels in Smart Home Health Care Ecosystems

Understanding the global variability in TEH adoption provides a contextual foundation for examining how smart home systems evolve in design sophistication. The maturity of health care integration is closely linked to the architectural complexity of smart adaptive ecosystems capable of partial autonomous decision-making. The following section outlines the levels of smart home complexity, illustrating how increasing technological integration enables progressively advanced and personalized health care delivery within residential settings. Smart home environments for health care integration can be conceptualized across 3 progressive levels of complexity: foundational, connected, and intelligent systems [25]. Each level reflects the degree of automation, interoperability, and adaptability embedded within the home infrastructure, which later impacts the scope and sophistication of health care applications that can be supported. Understanding these tiers helps guide the design and deployment of smart home infrastructures aligned with clinical needs, technological capacity, and user readiness.

At the foundational level, smart homes feature basic automation technologies such as smart lighting, thermostats, and motion detectors operating as independent systems. These provide limited yet functional support for simple TEH interventions, including medication reminders, fall prevention lighting, or basic environmental adjustments [26]. Although relatively low cost and easy to implement, foundational systems rely on user activation rather than autonomous health monitoring and thus serve primarily as assistive rather than diagnostic tools. It emphasizes usability and accessibility.

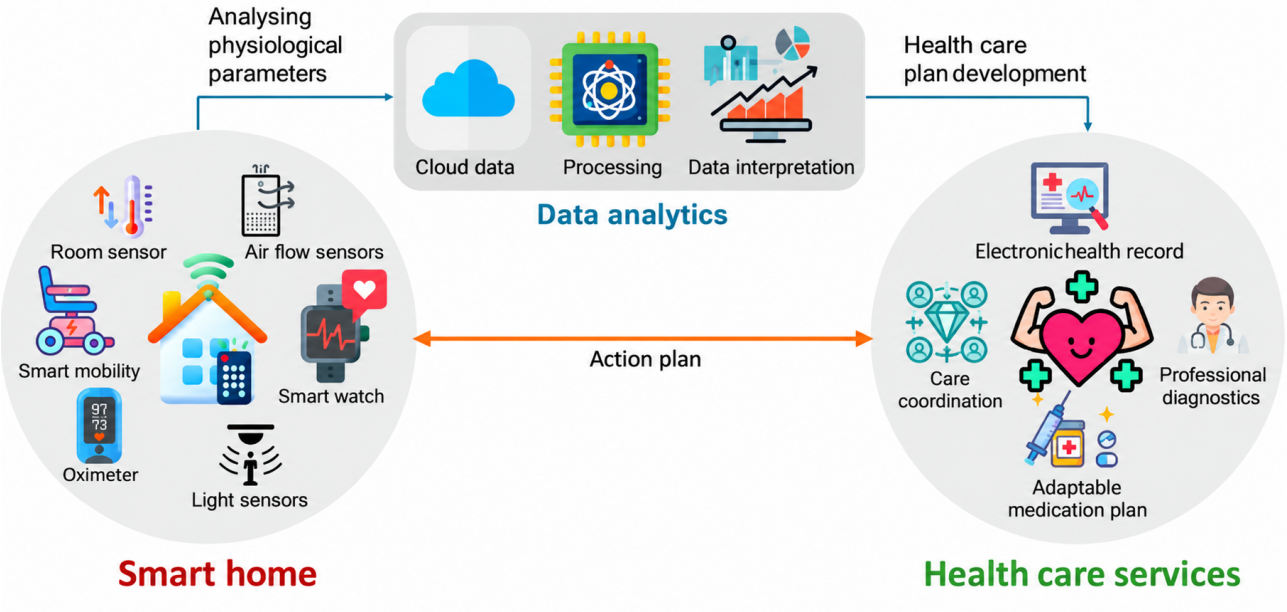
The connected level introduces a wider integrated system through centralized hubs or IoT networks that allow multiple devices to communicate and coordinate actions. This level enables conditional automation and basic data exchange, supporting health workflows such as adjusting air filtration when particulate levels rise, synchronizing temperature controls for patients with chronic respiratory issues, or enabling caregivers to remotely monitor vital signs [27]. Design considerations at this stage emphasize interoperability, reliable data transfer, and secure communication protocols.

Lastly, at the intelligent level, smart homes become adaptive environments that rely heavily on AI, ML, and environmental sensing to autonomously respond to subject needs and physiological cues [28]. These systems interpret biosensor data in real time to optimize environmental conditions, such as adjusting lighting and modifying temperature based on metabolic readings [29]. It can deliver predictive alerts for fall risk, cardiac irregularities, or cognitive decline [30]. Intelligent homes represent the highest maturity in TEH integration, combining predictive analytics, voice and gesture recognition, and automated clinical communication.

Integration of Biomedical Sensors With Smart Home Environments

Biomedical sensors represent a core component of smart home systems, enabling continuous monitoring of individual health status and supporting activity recognition in ambient-assisted living contexts [31]. Within these environments, digital sensors facilitate both personalized health tracking, bridging episodic events and chronic condition management. A relevant model outlining the integration of TEH sensors in smart homes for people with mental health problems categorizes the process into four key steps: (1) establishing a digital platform with a selection of biosensors and personalized responsive screen devices, (2) setting up communication links between health care providers and patients, (3) ensuring that end-user requirements are adequately addressed, and (4) engaging stakeholders and collaborators in the development process [30].

Several studies reported computational capacity challenges faced with TEH implementation within residential ecosystems that presented an association with reduced performance in activity recognition and health monitoring systems. For instance, in most health care applications, as shown in the study by Tang et al [32], single-parameter sensors are insufficient to provide a holistic picture of complex patterns, and environmental uncertainty or its uniformity in data collection affects the credibility of predictive models that depend on singular localized feature sets [33]. Therefore, it is important to integrate both ambient and biomedical sensors together to assist in health monitoring decision-making.



A schematic visualization of this concept is presented in Figure 2, illustrating the TEH architecture integrated within a smart home setting. The main objective of integrating TEH architecture in smart homes is that it improves the quality, efficiency, and accessibility of medical services. At its core, the model shown in the figure aims to connect biomedical sensors, home IoT devices, and data processing platforms to form an intelligent, responsive health care network. For example, wearable biosensors such as ECG (electrocardiography) patches and SpO_2 monitors continuously capture physiological data, while environmental sensors record temperature, humidity, and air quality. These inputs are then transmitted via connected gateways or Wi-Fi routers to edge or cloud computing platforms. The data is then processed in real time using ML algorithms. Initially, the system provides feedback through user interfaces such as smartphone dashboards, smart mirrors, or voice assistants. Next, it will start alerting users or caregivers to abnormal health trends. In practical implementations, such

XSL•FO
RenderX

systems have been used to detect early signs of respiratory distress in patients with chronic obstructive pulmonary disease, identify irregular heart rhythms for arrhythmia prevention, and monitor activity patterns to predict fall risk among older adults.

This architecture represents an interconnected ecosystem that links continuous sensing, intelligent analytics, and clinical communication channels to support proactive, adaptive health care within residential settings.

Figure 2. The architecture of a technology-enhanced health care ecosystem illustrates the interaction between biomedical sensors, ambient devices, and technology-enhanced health care processing platforms.

Smart home applications have used sensors to monitor physical movement, glucose levels in patients with diabetes, and patterns of electronic device usage. However, a significant challenge lies in effectively leveraging biomedical sensor data for reliable disease detection and health risk prediction [31,34]. These sensors often generate high-resolution data in large volumes, transmitting information to cloud servers via home networks. This necessitates advanced computational techniques for real-time data processing and analysis. To address these challenges, ML algorithms that involve both supervised and unsupervised learning have been used to interpret sensor data, predict disease onset, and assess disease progression. Effective health prediction models rely heavily on high-quality, longitudinal datasets for training and validation. The availability and diversity of these training datasets directly impact the accuracy and reliability of algorithmic predictions.

Integrating biomedical sensors with ML tools in smart home environments has demonstrated potential to reduce health care costs and alleviate pressure on clinical services by enabling remote diagnostics and early interventions. Therefore, the strategic incorporation of TEH within smart housing infrastructure remains vital for enhancing health outcomes, ensuring proactive care delivery, and supporting independent living for vulnerable populations. The biosensors examined in this review are broadly categorized into 5 distinct groups, each aligned with a specific physiological domain. Examples of each category are summarized in Textbox 1. It demonstrates the broad functional spectrum of biosensors applied within smart home ecosystems. The reviewed devices encompass respiratory, cardiovascular, neurological, biochemical, and movement monitoring applications, using diverse sensing modalities such as radar, optical, biochemical, and mechanical transduction. Integration formats range from wearable patches and textile-integrated sensors to ambient sensors that enable holistic personalized health monitoring. They facilitate continuous, noninvasive data acquisition, supporting early disease detection, specific condition management, and timely adaptive interventions.

The identified literature was organized into thematic domains reflecting the technological and clinical dimensions of TEH-smart home integration, including environmental monitoring, physiological sensing, predictive analytics, health care system interoperability, and regulatory considerations.

Wearable Medical Sensors

Wearable biosensors play a critical role in real-time monitoring of physiological parameters within smart home environments. Commonly measured vital signs include heart rate, pulse rate, blood pressure, and blood oxygen saturation (SpO_2), which are summarized below in Table 3.

XSL•FO
RenderX

Table . Examples of biosensor applications commonly used in smart homes.

Application and sensor type	Sensing parameters	Clinical applications
Respiratory monitoring		
Respiration rate monitor [35,36]	Breathing rhythm, inhalation cycles	Asthma, COPD[a], sleep disorders
RF[b] sensor [37]	Chest and breathing movement	Lung pulmonary diseases
SpO_2 [c] sensor [38]	Oxygen content in blood	Pulmonary function, COVID-19, hypoxia
Cardiovascular monitoring		
Wearable ECG[d] sensor [39]	Heart rate, electrical signals	Arrhythmia and stroke detection
Blood pressure monitor [40]	Systolic and diastolic pressure	Hypertension, heart disease
Passive radar system [41]	Chest movement, heart-activity proxy	Nocturnal cardiac monitoring
Mental and neurological monitoring		
EEG[e] sensor [42]	Brain activity	Seizure detection
Multiarm bandit system [43]	Sleep patterns	Schizophrenia, insomnia
Electronic pill container [44]	Medication, behavioral patterns	Bipolar disorder, cognitive decline
Biochemical and metabolic sensing		
Skin sensor [45]	Glucose concentration	Diabetes management
Sweat sensor [46,47]	Glucose, sleep markers	Diabetes, hydration, sleep
Color, odor, pH sensor [48]	Urinary profile	UTI[f] detection, hydration analysis
Gas sensor [49]	Air composition (CO[g], VOCs[h])	Air quality monitor
Movement and fall detection		
Floor mat [50]	Motion, pressure changes	Activity and mobility tracking for dementia
Watches [51]	Movement, smoke	Fall detection alerts
Electronic textile [52]	Gait, movement, caloric activity	Obesity and daily monitoring
Camera [53,54]	Visual motion capture	Neurodegenerative tracking
Passive radar system [37]	Movement, respiratory proxy signals	Real-time fall and activity detection
Wearable accelerometer [55,56]	Posture	Fall risk, balance monitoring
Smart RFID[i] sensor [57,58]	Obstacle detection, positional tracking	Fall prevention, assisted navigation

[a]COPD: chronic obstructive pulmonary disease.
[b]RF: radio frequency.
[c]SpO_2 : peripheral capillary oxygen saturation.
[d]ECG: electrocardiography.
[e]EEG: electroencephalography.
[f]UTI: urinary tract infection.
[g]CO: carbon monoxide.
[h]VOC: volatile organic compound.
[i]RFID: radio-frequency identification.

The sensors presented in Table 3 are particularly significant for a patient's lifestyle in living with chronic conditions such as heart failure or kidney disease, within the context of smart home environments [59-62]. Other technologies, such as artificial skin implantation, embed biosensors in the body and monitor health indicators under both static and dynamic conditions present substantial impacts on patient independent living [16-18]. Additionally, many wearable platforms are designed to be integrated into clothing, accessories, or adhesive patches, offering unobtrusive monitoring throughout daily life [63]. This has led to advancements in flexible wound monitoring biosensors embedded in wound dressings that facilitate remote automated assessments and treatment adjustments [63]. Another highly effective TEH smart home solution is the development of thin paper sensing strips that are designed to be paired with smartphone interfaces to provide highly accurate and accessible glucose level monitoring [64]. Furthermore, the table illustrates a diverse class of wearable health devices including but not limited to smartwatches, fitness trackers, flexible patches, and voice-activated systems that can acquire physiological data.

XSL•FO
RenderX

These data streams can be analyzed using ML techniques to support early disease detection, predictive health monitoring, and personalized care [65]. Many of the monitoring devices mentioned in Table 3 rely on mobile apps to transmit health data from wearable sensors to remote servers, supporting disease management in conditions [66] to enhance self-care outcomes and a more responsive and patient-centric health care model [67]. This resolved the challenge of sending data signals to a local substation. That is because in complex sensor networks, gateway interfaces serve as bridges between sensor nodes and access points, streamlining service delivery and regulating data flow within smart home systems [68]. This integration requires seamless coordination between biomedical informatics and health IT to ensure reliable data acquisition, processing, and communication. A brief illustration of how biomedical data is captured by wearable devices and analyzed is demonstrated in Table 4, which lists the different smartphone software applications used for sensing and communicating different forms of health data.

Table . Functional classification of TEH[a] software application in smart home environment.

Category and application	Platform supported	Original health/disease indicator
Voice assistants and smart-home control [69-71]		
Amazon Echo	Bluetooth audio	Diabetes
Google Home	Android (Google LLC)	Glucose levels
OpenHAB	iOS (Apple Inc), Android	Safety for disabled users
Gerikits	iOS, Android	Senior people illness
Health-data platforms [72-76]		
Apple Healthkit	iOS	Diabetes
Samsung Health	Android	Sleep patterns
Fitbit	iOS, Android	Health metrics
Freestyle Libre	iOS	Diabetes
MyFootcare	Android	Foot ulcer
Mental and cognitive health tools [77-81]		
MONARCA	Web-based	Bipolar disorder
FOCUS	iOS, Android	Schizophrenia
CLIN Touch	Mobile	Schizophrenia
Smart FABER	Android	Cognitive impairments
TEH ecosystem [82-84]		
Smart e-Health Gateway	Android	Health monitoring
Care4U	Linux	Health data security
Caregiver App	iOS, Android	Daily activity tracking
Medication management [85]		
iMedBox	Android	Medication management

[a]TEH: technology-enhanced health care.

The table outlines few medical applications and platforms that underpin TEH integration in smart home environments. The reviewed systems encompass a wide spectrum of digital health tools, including voice-activated assistants, mHealth data platforms, cognitive and mental health monitoring applications, and medication management systems. These technologies operate across major operating platforms such as Android, iOS, and Linux, which demonstrates the need for platform compatibility and ecosystem connectivity. The examples mentioned in the table highlight the transition toward interoperable, adaptable, and case-specific health care solutions, where multimodal data from voice interaction, sensor response, and clinical input converge to enable real-time monitoring, disease management, and personalized health support within domestic settings.

The placement and alignment of sensors on the body are prime factors for achieving optimal system performance. It has been found in studies that increased packet losses have occurred because of network difficulties or misalignment of skin-contact sensors. In addition, some of the wearable devices may be forgotten, removed, or disliked by older adult users, reducing their effectiveness and long-term adoption [42]. The challenge in this type of wearable device is the quality of measurement. Additionally, the data acquired must be verified with conventional sensors to ensure accuracy. These devices are often limited to monitoring only a limited set of physiological parameters, and their constrained computing capability limits

XSL•FO
RenderX

the ability to use ML algorithms locally. Furthermore, issues of data latency arise when these devices are used beyond the reliable reach of smart home networks, further complicating real-time health monitoring and timely interventions.

Biosensor Wearability and Mechanical Flexibility

The convergence of flexible electronics and textile engineering has enabled the development of biosensors that are not only functional but also comfortable, discreet, and adaptable to daily life [86]. Wearable technologies and woven smart textiles can be developed to blend unobtrusively into everyday life, providing continuous monitoring while enhancing comfort and adherence [87,88]. These devices are increasingly designed to conform to the human body's contours, leveraging materials such as elastomers, conductive inks, and nanofibers to ensure breathability, biocompatibility, and long-term usability.

A compelling example of this innovation is textile-integrated biosensors, as they offer transformative potential for independent living [89]. By embedding sensors into garments or dressings, patients can continuously monitor vital signs, biochemical markers, and environmental conditions without the need for bulky equipment or frequent clinical visits. These systems enable remote health supervision, reduce the burden on caregivers, and empower individuals to manage their health autonomously. The seamless integration of biosensors into textiles achieved through techniques such as screen printing, knitting, and lamination creates what is known as a "second skin" effect, allowing for unobtrusive and personalized health care.

Moreover, the mechanical strain testing of recently developed textile sensors revealed their ability to bend around diameters as small as 1 mm without compromising conductivity, underscoring their suitability for dynamic and health care applications [90]. This level of flexibility not only enhances comfort but also supports continuous data acquisition in real-world environments, a key requirement for smart home integration and patient-centered care.

Synthesis of Ambient Integrated Sensors

Environmental Sensors

Environmental sensors in smart homes are designed to continuously monitor key indoor parameters such as temperature, humidity, and air quality, all of which have a direct impact on human health [91]. These factors are particularly critical for individuals with respiratory conditions such as asthma, chronic obstructive pulmonary disease, and other pulmonary ailments. Variations in these environmental metrics can exacerbate symptoms or trigger acute episodes, making real-time monitoring essential for preventive care and early intervention.

By integrating environmental sensors into smart home ecosystems, it becomes possible to maintain a health-optimized living environment. These sensors detect fluctuations that may compromise air quality, such as increased particulate matter, volatile organic compounds, or elevated humidity, and can trigger automated responses or alerts to mitigate risk. Furthermore, continuous monitoring allows for long-term analysis of environmental factors and their association with health trends, providing insights that can inform early intervention and individualized care. Recent studies have demonstrated the value of such systems in unobtrusive health monitoring and emphasize the role of ambient sensing in private spaces, noting that smart homes equipped with environmental sensors can significantly enhance the management of chronic respiratory diseases by enabling early detection of symptom-related triggers and supporting adaptive interventions [92].

Motion and Activity Sensors

Motion and activity sensors play a pivotal role in smart home biosensing systems, particularly for monitoring mobility, detecting falls, and assessing behavioral patterns. Technologies such as smart floor sensors, infrared motion detectors, and accelerometers—often integrated with mobile apps—enable continuous tracking of residents' movement and activity levels, which is essential for fall detection, gait analysis, and mobility assessment in older adult care settings [93,94]. These sensors can identify deviations in walking patterns or sudden inactivity, which may signal cognitive decline or acute health events [95,96]. The data collected can be analyzed using ML algorithms to detect anomalies, predict falls, and understand individual habits over time, thereby supporting personalized interventions and early diagnosis [55].

Speech-based IoT interfaces further enhance accessibility for individuals with speech and motor disabilities, enabling voice-activated control of smart devices and health monitoring systems. It was previously demonstrated how adaptive speech recognition systems integrated with IoT platforms can empower users with motor impairments to interact with their environment autonomously [97]. Additionally, sensor edge networks can be deployed to localize movement within the home, reducing latency and improving responsiveness. These networks can be paired with anticollision systems that assist individuals with visual impairment by detecting obstacles and providing real-time feedback through auditory or tactile cues.

A sensor edge network could be deployed to track the movement of residents in a smart home environment, and an anticollision system could be paired that would prevent the accidents and provide information of outdoor environment to individuals with visual impairment [98,99].

Radar Sensors

Radar sensors offer a compelling solution for contactless health monitoring in smart home environments, particularly when integrated with smart speakers or graphical user interface–based health gadgets. These sensors can detect when a person enters a room or approaches a device, automatically waking it from sleep mode and initiating preprocessing for vital sign measurements such as respiration rate and heart rate. This functionality enhances energy efficiency, supports ambient intelligence, and ensures a seamless user experience.

Recent advancements in radar sensing applications have evolved to include a wide spectrum of health care innovations such as human activity recognition, gait analysis, and vital signs monitoring [100]. They emphasize radar's ability to detect respiration and heartbeat unobtrusively, making it ideal for

XSL•FO
RenderX

smart home integration where passive interaction is key to user comfort and system responsiveness.

Previously, interest has been directed toward validating radar's capability to monitor multiple individuals' vital signs in real-world environments [101]. In theory, this system can track movement direction, location, and physiological signals without requiring wearables, reinforcing radar's role in ambient and predictive health care.

Moreover, innovative approaches have emerged, such as microwave radar embedded in smart furniture, which has demonstrated high precision in monitoring cardiac waveforms and heart rate variability [41]. These systems activate based on user presence and movement, aligning with the concept of radar-triggered device wake-up and automated health data acquisition.

Smart Ring Sensing Devices

Smart rings represent a compact and increasingly prominent class of wearable health monitoring devices, designed to track physiological and behavioral parameters comfortably. These rings are equipped with embedded sensors capable of measuring heart rate, heart rate variability, blood oxygen saturation, body temperature, sleep activity and quality, and physical activity levels [102]. By continuously monitoring these biometric indicators, smart rings can support early detection of anomalies, enhance personalized health management, and contribute to improved health outcomes [103].

The device interfaces with a smartphone app that aggregates and analyzes health metrics, enabling users and clinicians to interpret trends in sleep behavior and overall wellness. Advanced sensing techniques within the ring support predictive analytics, offering insights into potential illness onset based on deviations in sleep or activity patterns.

Technically, the smart ring integrates a lithium-ion battery and features enhanced processing capabilities via 6 embedded microcontroller units. These microcontroller units coordinate with multimodal sensors such as accelerometers, PPG (photoplethysmography), and temperature sensors to enable sensor fusion, thereby improving the accuracy and reliability of health data acquisition. This fusion of hardware and software allows the smart ring to function as a powerful tool for continuous, passive health surveillance within smart home ecosystems.

Pressure and Vibration Sensors

When embedded in smart flooring systems or furniture, pressure sensors play a critical role in monitoring gait dynamics, postural transitions, and fall events, which are key indicators of mobility and safety in smart home health care environments. These sensors enable spatially resolved pressure mapping, which supports real-time visualization of movement patterns and biomechanical stress [104]. A recent study demonstrated the development of a self-powered smart insole incorporating 22 pressure sensors capable of detecting 8 distinct motion states, including walking, running, and squatting, with high accuracy [105]. The system demonstrated strong linearity and durability across 180,000 compression cycles, making it suitable for continuous gait monitoring and the early detection of conditions such as Parkinson disease, diabetic foot ulcers, and stroke-related asymmetries.

When combined with vibration sensors, the system's sensitivity to ambient and mechanical cues is significantly enhanced [106]. Vibration sensors can detect oscillatory signals from footsteps, appliance usage, or structural interactions, contributing to a context-aware understanding of the home environment. Vibration sensors are being used in health care for monitoring heartbeats, respiratory movements, and neuromuscular activity, especially when integrated into wearable or ambient systems.

Together, pressure and vibration sensors form a multimodal sensing framework that captures both physical interactions and environmental conditions. These data streams are transmitted via IoT-enabled sensor networks to TEH platforms, where ML algorithms analyze patterns to infer the user's current health status, detect changes in desired patterns, and support predictive interventions. This integration enables continuous, passive, and personalized health monitoring, particularly for populations at risk of mobility decline or cognitive impairment.

Specialized Health Monitoring Tools

Devices such as glucometers, EEG (electroencephalography), and ECG monitors are used for specific health conditions, providing detailed physiological parameters on glucose levels, brain activity, and cardiac function [107,108]. These devices are often part of a broader network of sensors that communicate with a central system to provide a holistic view of the occupant's health. To ensure efficient analysis, fog computing architectures are often used to deploy ML algorithms close to the data source. This enables low-latency processing for real-time health predictions, reducing reliance on distant cloud servers and supporting timely clinical interventions. Among commercial innovations, AliveCor has developed a Bluetooth-enabled ECG device that allows users to visualize cardiac signals directly on their smartphones. With 6 leads, the device can detect atrial fibrillation within 30 seconds, offering rapid diagnostic support in home settings. EcgMove 4 is another device that can provide real-time ECG data along with other parameters such as acceleration, barometric air pressure, and temperature, which enhances the measurement characteristics to compensate for any disturbances. The data collected through Bluetooth could be easily shared with physicians with the assistance of the TEH network, which assists in predicting a stroke in advance.

Wireless Connectivity Approaches in TEH Systems

Robust wireless connectivity underpins the operational framework of smart medical devices, allowing for dynamic data exchange, remote health supervision, and integration with broader smart home networks. Short-range communication technologies such as Bluetooth Low Energy (BLE) are instrumental in enabling wearable biosensors and fitness trackers to transmit data efficiently while conserving power, making them ideal for continuous use [109]. For more expansive connectivity, devices are increasingly using Wi-Fi and specialized IoT protocols to synchronize with cloud platforms, enabling advanced diagnostics and data analytics [110]. The introduction of 5G networks further revolutionizes this space

XSL•FO
RenderX

by enhancing bandwidth and reducing latency, thereby supporting simultaneous, high-volume data transmission across multiple devices in real time.

Beyond technical capabilities, connectivity must also address data privacy and regulatory compliance, requiring devices to adhere to standards such as HIPAA (Health Insurance Portability and Accountability Act) and the General Data Protection Regulation. This is typically achieved through encrypted communication channels, secure firmware updates, and rigorous authentication protocols. In sum, wireless communication is not merely an enabler of convenience, but it is fundamental to delivering responsive, predictive, and personalized health care within smart living environments.

Wireless communication in wearable TEH devices presents significant power and efficiency challenges due to the complex electromagnetic interactions between the device and the human body. As RF signals propagate through biological layers such as skin, fat, and muscle, they encounter media with distinct dielectric properties, resulting in scattering, absorption, and reflection that degrade transmission quality [111]. To compensate for these losses, devices often require elevated transmission power, which strains limited energy sources such as miniature batteries or energy harvesting modules.

Moreover, dielectric mismatches between wearable materials and biological tissues can disrupt antenna impedance matching, leading to frequency shifts and reduced RF efficiency. These effects are exacerbated by dynamic factors such as movement, perspiration, and posture changes, which introduce temporal variability in signal integrity. Maintaining reliable wireless connectivity under such conditions demands advanced design strategies and material innovations.

Internet of Medical Things

The proposed TEH network structure is shown in Figure 2. The diagram highlights the mutual benefits distributed across patients, caregivers, and health care providers using the TEH hub as a control unit based on input from biosensors and adaptive ML tools. The Internet of Medical Things (IoMT) represents a transformative paradigm in health care delivery, characterized by the digital interconnection of medical devices, smart home systems, and clinical systems to enhance patient care outcomes [112]. By facilitating the continuous collection and exchange of physiological and behavioral data, IoMT enables early detection of health risks, timely diagnosis, and proactive intervention while simultaneously reducing the burden on health care providers through automated decision support and remote monitoring capabilities.

At its core, IoMT involves transitioning conventional health care models into a digital landscape by enabling low-cost, low-power, low-energy, and low-data transfer with high efficiency and security [112,113]. This evolution, known as interoperability, relies heavily on real-time monitoring technologies and data integration across interconnected devices, including biosensors, wearable platforms, and smart home infrastructure. These systems perform critical functions such as disease surveillance, therapeutic guidance, and personalized treatment modulation. Central to the IoMT framework is the application of ML algorithms for data interpretation. As datasets become increasingly voluminous and heterogeneous, AI analytics enhance diagnostic precision, risk stratification, and outcome prediction. Advanced models not only facilitate accurate classification of patient conditions but also enable adaptive monitoring and predictive modeling for disease progression.

Detection and Prediction of Disease Within Smart House Through TEH Integration

This section addresses the research objectives 1, 2, and 5 identified in the methodology, focusing on how smart wearable and ambient sensors, combined with ML algorithms, enable early detection and prediction of health conditions. It evaluates the technical performance of predictive models, the quality of input data required, and the potential for personalized monitoring of vulnerable populations within residential environments.

Smart homes enable continuous health monitoring and prediction of potential health problems through the integration of biomedical sensors with computing networks capable of identifying disease progression patterns. It has been shown that using smartphone apps combined with wearables can lead to a positive behavioral outcome in mental illnesses such as bipolar and depressive disorder [114]. Data fusion techniques further enhance the confidence of health trend predictions by integrating multimodal sensor inputs. Disease prediction is achieved through ML algorithms trained on curated datasets, with outcomes heavily dependent on both the type of model and quality of training data. Applications of ML within smart home health care are diverse. For example, dementia can be identified early with the aid of ML models running on remote computing servers [85,115]. The prediction allows early treatment and enhances cognitive well-being for individuals. Support vector machine (SVM) has been used to predict cardiovascular disease using heart sound signals, where estimated heart rate is processed to predict blood pressure and detect disease progression [116,117]. Similarly, SVM-based classifiers support activity recognition for forecasting and preventing chronic diseases [37]. ML models assist in disease classification and prediction from medical images extracted with the assistance of smart closed-circuit television cameras. Monitoring gait is another area where ML models could be deployed for early detection of gait disorders [112]. ML models are capable of estimating ground reaction forces with low error and sensing gait abnormalities that may signal potential neurocognitive disorders. The ML system enables early intervention opportunities for disease progression [118]. Images and facial expressions have been used in the past for patient monitoring for emotion detection, which can indicate diseases such as schizophrenia and depression [119]. Facial expressions are crucial for diagnosing various emotional disorders [120]. TEH systems coupled with ML algorithms can facilitate early intervention and enhance cognitive and physical well-being.

While ML algorithms have shown considerable promise in the early detection and diagnosis of disease within smart home health care systems, several critical limitations persist that affect their reliability and implementation. Foremost among these is the heavy dependence on both the quality and quantity of input

XSL•FO
RenderX

data. The effectiveness of ML models hinges on well-curated training and testing datasets; inaccuracies or insufficiencies in these datasets can significantly undermine prediction outcomes. One method is using deep learning (DL) models, which can be powerful in capturing complex patterns but often present interpretability challenges for health care professionals due to their opaque architectures and computational intricacies. Moreover, the deployment of such models is frequently constrained by insufficient data volume, especially in personalized or longitudinal smart home settings. Similarly, despite the applicability of SVMs in high-dimensional classification tasks, they require extensive and clean datasets to achieve high diagnostic accuracy. Feature extraction for SVM-based models is particularly time-intensive, and performance degradation is common when input data is noisy or artifact-laden.

These limitations underscore the need for robust data preprocessing pipelines, the development of explainable AI frameworks, and integration of clinician-oriented decision support tools to ensure safe, reliable, and trustworthy deployment of ML algorithms within TEH systems.

The Use of Big Data Methods in Smart Home Environments

ML algorithms constitute the computational foundation of any smart home environment, enabling continuous health monitoring, activity recognition, autonomous decision support, and early disease prediction. Supervised learning approaches remain central to TEH analytics, where algorithms such as decision trees, logistic regression models, and k-nearest neighbor classifiers are commonly trained on structured physiological and behavioral datasets to perform diagnostic categorization and generate timely alerting mechanisms for potential health risks [121,122]. To recognize and capture the correct features of locomotion, gait dynamics, and mobility patterns are analyzed using specialized ML models such as SVMs are analyzed to develop fall detection, gait deviation identification, and rehabilitation monitoring systems [123]. These models typically rely on labeled datasets derived from wearable sensors or environmental monitoring devices and are often evaluated using validation strategies such as cross-validation, hold-out testing, or benchmark dataset comparisons to assess classification accuracy and model stability. These models are trained using motion data collected from accelerometers, gyroscopes, or pressure sensors embedded in wearable devices [124-127]. Several studies report promising performance metrics in controlled experimental environments; however, many datasets used for model development remain relatively limited in scale, often consisting of tens to hundreds of participants. Consequently, although these systems demonstrate high classification accuracy under laboratory conditions, their performance in long-term real-world home environments remains an active area of investigation [128,129]. Another developed model known as context-aware methods (CAMs) extends these capabilities by developing a multiplexed sensor system that can consider inputs from physiological, environmental, and behavioral data to improve contextual accuracy. Fog-assisted IoT architectures represent a prominent implementation of CAMs, as they enable distributed analysis of high-priority health signals such as EEG, ECG, and EMG (electromyography) data directly at the network edge. By performing data processing at intermediate network nodes closer to the sensing devices, fog computing enables distributed analysis of high-priority health signals at the network edge. This reduces latency while supporting dynamic, real-time clinical decision-making processes [130]. CAM models can also incorporate environmental and patient-specific historical data to compute personalized health indices, thereby offering a more robust representation of an individual's physiological status. Furthermore, the layered topology further facilitates simultaneous acquisition and analysis of multiple monitoring elements such as EEG, ECG, and EMG, enhancing the sensitivity and responsiveness of TEH monitoring systems [68].

Another relevant approach used for long-term sleep analysis and anomaly detection using continuous monitoring datasets is known as the multiarmed bandit model [131]. Similarly, patient-state determination algorithms support predictive alert generation by analyzing multiplexed biosensor data to infer deviations from normal physiological states and send indicators with risk levels for further interventions or early-stage disease progression [42]. Big data infrastructures contribute to scalable and efficient processing of the heterogeneous and large volume of health data captured within TEH ecosystems. Distributed computing platforms enable real-time analytics for clinical decision support and behavioral modeling while enabling responsive care solutions [132]. As highlighted in recent public health applications, big data frameworks have been instrumental in infection surveillance, pandemic transmission modeling, and patient triage optimization [133]. They also play a growing role in logistics, such as predictive modeling for vaccine distribution and deployment planning, where analytics can assist in equitable allocation strategies. Within TEH-specific implementations, big data platforms support the integration of ML algorithms capable of detecting disease signatures and performing physiological assessments using distributed computational architectures [134-138]. These architectures enable simultaneous usage of physiological and environmental variables to generate context-aware predictions and early detection outputs.

However, it is important to recognize the challenges faced with the current big data tools and how they are being compensated for. Certain ML techniques such as k-nearest neighbor–based classifiers often present computational burdens that exceed on-device processing capacities within residential IoT ecosystems, limiting their applicability for real-time TEH inference tasks [66]. Furthermore, model robustness is heavily dependent on the fidelity of input data. Sensor noise, missing data, and measurement artifacts can significantly degrade model performance and compromise diagnostic reliability. In response, comparative studies of classification algorithms such as random forestsradio frequency, multilayer perceptrons, SVMs, and Naive Bayes classifiers have demonstrated the potential for high accuracy, including reports of neural network models achieving up to 99% accuracy when classifying key bio signals [139]. Nonetheless, suboptimal feature extraction processes remain a limiting factor for activity recognition, often reducing classification accuracy in less controlled ambient settings. Alternative approaches such as clustering models and

XSL•FO
RenderX

probabilistic frameworks, including hidden Markov models, have shown strong performance in modeling heterogeneous health datasets for disease prediction. DL architectures further expand the analytic capabilities of TEH environments. Convolutional neural networks are particularly effective for identity recognition and activity modeling when trained on gait signals from wearable sensors [140,141]. In parallel, recurrent neural networks, including long short-term memory–based variants, have been used for temporal modeling of movement patterns and for detecting sleep changes using audio signals [142]. Recent enhancements in recurrent neural network frameworks have demonstrated improved energy efficiency at the IoT edge, reducing power consumption through optimized data transmission and localized inference pipelines.

The translation of many ML-based monitoring systems from experimental prototypes to clinically validated health care solutions remains limited [143-145]. Many published models rely on datasets that lack demographic diversity, particularly underrepresenting older adults, individuals with chronic health conditions, and populations from low-resource environments [146-148]. This imbalance may introduce bias in model predictions and reduce generalizability across diverse user groups. Furthermore, only a small subset of proposed algorithms has undergone longitudinal validation in real-world smart home deployments or clinical evaluation studies. Consequently, while ML techniques demonstrate substantial potential for enhancing predictive health care capabilities in TEH ecosystems, further large-scale validation, diverse dataset development, and clinical benchmarking are required to ensure reliability, fairness, and real-world applicability.

Disparities Related to Smart Home TEH Integration

Sociodemographic Disparities

A significant concern in the current smart environment landscape is the sociodemographic bias present in existing research. Most studies and technological deployments have been conducted in high-income, predominantly Western nations, resulting in limited representation of low-income countries. This disparity not only marginalizes diverse cultural, economic, and infrastructural contexts but also contributes to a critical knowledge gap regarding the applicability, usability, and scalability of TEH systems across varied global settings [30]. Without inclusive research and development frameworks, the transformative potential of smart home health care technologies risks being inaccessible or ineffective for underserved populations. Addressing these disparities requires participatory design, equitable funding strategies, and localized innovation models to ensure global relevance and impact.

Access to Technology

Another profound barrier to equitable TEH integration is the disparity in access to enabling technologies, most notably broadband internet connectivity [149,150]. Individuals residing in rural or underserved regions frequently encounter infrastructural limitations that restrict high-speed internet connectivity, a foundational requirement for deploying telehealth platforms and accessing digital health resources. This persistent digital divide deepens preexisting health disparities by excluding populations that may benefit most from remote monitoring and continuous support systems [151]. Bridging this technological gap necessitates coordinated policy interventions, sustained investments in digital infrastructure, and equitable deployment strategies. Furthermore, inclusive design approaches that consider connectivity constraints during development and deployment are essential to ensure that TEH systems remain accessible, resilient, and scalable across diverse socioeconomic contexts.

Resource Allocation

Resource allocation plays a decisive role in shaping the feasibility and deployment of smart home environments. In many low- and middle-income countries, health care budgets are predominantly directed toward combating infectious diseases and addressing immediate public health crises [136]. This prioritization, though contextually justified, inadvertently sidelines the evolving needs of aging populations, whose care could be significantly augmented through smart home technologies. The lack of investment in aging-related infrastructure curtails the implementation of TEH solutions that use mobile networks, sensor-based monitoring, and behavioral analytics, which are key components in supporting independent living and chronic disease management among older generations [152]. As demographic transitions accelerate in low- and middle-income countries, the absence of such infrastructure widens disparities between acute care provision and the sustainable management of chronic, age-related health challenges. Closing this gap demands a strategic recalibration of health policies and funding frameworks, promoting balanced resource distribution that considers long-term population health trends alongside acute disease burdens.

Digital Literacy

To ensure effective adoption and usage of TEH systems, digital literacy is a prerequisite. Older adults, as well as frontline health care providers, often face challenges in understanding and navigating the digital interfaces, interconnected sensor networks, and data-driven functionalities that form the backbone of smart health care ecosystems [153-155]. Without adequate training and tailored support mechanisms, the implementation of TEH solutions may falter, resulting in underuse, user frustration, and widening disparities in health outcomes. People with low income and vulnerable racial and gender minority groups will be at a disadvantage [156]. Furthermore, smart health care devices frequently raise complex ethical and safety considerations from data privacy to autonomous decision-making, which must be fully comprehended by end users to foster trust and responsible engagement [157]. Addressing digital literacy gaps requires inclusive educational strategies, user-centric design, and ongoing engagement to empower all stakeholders in the smart health ecosystem.

Digital literacy also extends to health care professionals, not just end users, because it requires the interpretation and management of continuously generated health data within clinical workflows [158]. If not used properly, TEH integration might produce frequent, unfavorable false alerts and will produce urgent overloads from excessive or poorly prioritized alerts and will not support the decision-making structures.

XSL•FO
RenderX

Improving digital literacy should be accompanied by structured training in signal interpretation and defined triage processes to ensure that the integration process enhances and develops traditional clinical decision-making and health outcomes.

Cultural Acceptance

The perception, usage, and integration of health care technologies are deeply influenced by cultural norms, beliefs, and values, which can vary markedly across communities and regions. These disparities affect not only the willingness of individuals to engage with TEH solutions but also how these technologies are interpreted and applied in daily life. In situations where digital health tools conflict with cultural expectations around privacy, caregiving, or autonomy, their implementation may be met with fear or resistance, limiting their potential benefits. Consequently, cultural misalignment can exacerbate inequities in access and health outcomes, reinforcing structural barriers to widespread TEH uptake [159,160]. To address this, the development of culturally responsive frameworks grounded in participatory design, cross-cultural research, and inclusive policy remains essential for ensuring equitable integration of TEH innovations.

Enhancements in Health Outcomes With TEH Integration

Overview

TEH systems support a shift from reactive to preventive health care, empowering individuals to engage proactively with their health while enabling clinicians to deliver quicker, informed, and relevant interventions. This section explores the measurable benefits of TEH integration that span across health trajectories, functional independence, and overall quality of life. The included studies reported health, usage, and economic outcomes using heterogeneous nonrandomized study designs, including observational analyses, matched-control evaluations, and statistical modeling. The approaches presented in this section are not intended to quantify definite effectiveness or establish causal inference but to categorize and characterize the analytical approaches of outcome evidence.

Early Detection of Health Issues

The deployment of IoT sensors within smart homes allows for continuous passive monitoring of residents' physiological and behavioral data. Subtle deviations such as irregular gait patterns, sleep disturbances, or temperature anomalies can be flagged in real time, enabling early identification of emerging health conditions. This predictive insight facilitates prompt medical intervention, potentially averting critical incidents and improving prognosis.

The integration of TEH systems within smart homes has significantly advanced the early detection of health issues through continuous, passive monitoring of subjects' physiological data [161,162]. The fusion of multiple sensing devices, including simple parameters such as heart rate, blood oxygen levels, and body temperature, which can be easily measured, enables identification of clear deviations such as irregular gait patterns, sleep abnormalities, or body temperature shifts. Recent studies have demonstrated that combining smartphone applications with wearable devices can lead to better outcomes in many mental health conditions such as bipolar and depressive disorders [163]. Additionally, DL IoT systems have been developed for the remote monitoring and early detection of health problems in home clinical settings [164]. These predictive insights facilitate prompt medical intervention, potentially averting critical incidents and improving prognosis. A particularly valuable approach is the continuous monitoring of health parameters, especially among older adults, whose physiological changes may be subtle yet clinically significant [165,166]. Sustained observation not only improves temporal granularity in data collection but also helps detect fluctuations and early markers of decline, supporting timely interventions [167].

Improved Monitoring of Health Indicators

TEH care systems enable granular, ongoing observation of vital parameters, including mobility, heart rate, and medication compliance. Integrating these data streams into a responsive graphical user interface supports caregivers in analyzing trends, comparing baselines, and detecting deterioration patterns [168,169]. Such systems enhance chronic disease management by transforming episodic care into continuous oversight.

Enhanced Patient Lifestyle

TEH-enabled smart homes foster psychological well-being by enhancing comfort, autonomy, and social connectedness. Ambient intelligence such as adaptive lighting, mood-sensitive music, and virtual companionship can reduce feelings of isolation, particularly among older adults [170]. These emotionally intelligent environments serve as therapeutic ecosystems, bolstering mental health and elevating the lived experience.

Personalized Health Management

By harnessing AI algorithms and individualized health data, TEH platforms deliver personalized interventions aligned with each resident's condition and preferences. Whether it is monitoring and adjusting medication schedules, recommending tailored physical activity, or adjusting environmental controls, a patient-focused approach ensures care is not only clinically relevant but also contextually meaningful [171]. New studies, as presented in the study by Mora et al [172], show how home-based health monitoring platforms can support better clinical assessment and more efficient personalized intervention planning. This study shows how to initially capture behavioral patterns before a clinician identifies deviations from expected routines in daily activities. This adaptability drives more precise and effective health outcomes while allowing more independent living.

Enhanced and Secure Caregiver Accessibility

IoT systems enable seamless communication between residents and caregivers, ensuring that any health concerns are promptly addressed. As many caregivers are challenged in balancing the needs of their loved ones and carrying their own jobs and financial responsibilities, TEH integration offers a supportive environment that can lead to better health outcomes and more independent living [96,173,174]. However, privacy and trust concerns persist, especially with the absence of standardized

XSL•FO
RenderX

data formats and the vulnerability of personal health data traversing multiple platforms [112,175-179]. One study investigated the best approach to implement a privacy-aware home care assistance system specifically for older adults living alone that used multiple biosensors and ML tools to support informal caregivers [180]. The platform developed continuously captures daily patterns and feeds them to the model developed to make it adaptable and then can automatically issue alerts when extreme changes have been detected. This enhances the process by which the caregivers are being informed and provides a more secure approach while reducing the need for direct observation.

Reduction in Hospital Readmissions

Through anticipatory monitoring and automated escalation protocols, TEH systems help manage acute episodes before they necessitate hospitalization. Data-driven alerts for abnormal activity or vitals support early intervention strategies, reducing unnecessary admissions [86]. This proactive infrastructure contributes to sustained recovery trajectories, easing strain on health care resources while optimizing resident health outcomes. A recent example is a study conducted 2 years ago that illustrates how the use of home digital monitoring devices was able to significantly lower hospitalizations just after 3 months of implementation and emergency department visits at 6 months after implementation [181]. Moreover, another review on telemedicine interventions using telemonitoring instruments has shown a decrease in readmission rates [182].

However, other issues have recently started to arise, such as user acceptance and economic sustainability in the long term, which reduces the effectiveness of TEH systems [183]. That is because patient compliance is by no doubt a critical factor in the success of IoT-based health care technologies, and high costs associated with technology deployment and maintenance also pose barriers to the widespread adoption of TEH systems. Therefore, an evaluation framework should be developed to investigate the risks associated with these issues.

Case Study Example

A recent Australian study conducted a home environment that implemented a before-and-after control intervention experiment design to examine health care usage and evaluate outcomes [184]. The observational study included 100 test patients receiving telemonitoring intervention and 137 matched control patients receiving traditional usual care and were followed for 276 days. Outcomes were assessed using observational comparisons and regression-based modeling rather than randomized assignment. The analysis relied on statistical modeling to estimate changes in medical and pharmaceutical expenditure, hospital admissions, and hospital length of stay before and after the start of telemonitoring. Based on projected expenditure trajectories, the study reported modeled reductions in predicted medical expenditure (46.3%), predicted hospital admissions (53.2%), predicted length of stay (67.9%), and reductions in mortality (between approximately 41% and 48%) relative to controls [184]. These estimates are derived from a combination of observed usage data and statistical prediction models rather than from a randomized controlled design. This example demonstrates the analytical approaches being implemented and how matched control groups are considered to objectively obtain realistic estimates of the impact of TEH interventions on potential health and economic outcomes rather than relying on generalization assessments.

Discussion

Summary

This review investigates methods of integrating TEH systems in smart homes by looking at the patterns in technological maturity deployed worldwide and how it is reflected in the performance of both ambient and wearable biosensors that rely on AI-driven health analytics. Our findings show that TEH adoption is concentrated in higher-income regions such as Europe and East and Southeast Asia, with emerging initiatives in lower-resource settings. Smart home systems range from foundational automation to fully interconnected intelligent ecosystems, demonstrating varying levels of clinical functionality and predictive capability. Adoption is limited because of interoperability challenges, usability limitations, and gaps in regulatory frameworks, as these key factors influence user acceptance and the long-term sustainability of TEH systems. Additionally, inconsistent reporting on ethical, usability, and regulatory considerations, coupled with limited long-term clinical validation, is restricting future improvements that could enhance effectiveness and wider deployment. This review highlights technological trends, practical implementation scenarios, and research implications for the development of more clinically effective, socially inclusive, and sustainable smart home health care solutions.

Infrastructure Implementation

Overview

Building upon the disparities described previously, this section presents analyzed perspectives on the conceptual, technological, and infrastructure factors that influence the integration of TEH into residential environments. In this section, a wide range of challenges will be systematically addressed to ensure successful implementation, allow scalability, and consider long-term viability.

Conceptual Implementation

Despite the promising benefits of TEH within smart environments, achieving full integration remains a complex challenge. Limited computing capacity in residential environments will most likely reduce the efficiency of objectively recognizing and classifying human activities, especially with isolated single sensors that cannot capture complex patterns; yet, evidence suggested that deploying multiple sensors may increase system complexity and intrusiveness [32]. Environmental uniformity in data collection restricts model generalization, making predictive algorithms overly dependent on localized feature sets [33].

System reliability is heavily influenced by infrastructure variables such as Wi-Fi coverage, device upkeep, and the quality of internet services, factors that directly impact data transmission fidelity and monitoring effectiveness [42,134,135,172,180]. Privacy and trust concerns persist, especially with the absence

XSL•FO
RenderX

of standardized data formats and the vulnerability of personal health data traversing multiple platforms [112,175-179]. Additionally, the large volume of data generated by diverse sensors can overwhelm communication protocols and resource-constrained hardware, while a lack of interoperability across IoT devices poses a significant barrier to streamlined TEH deployment [168].

Although edge computing enhances real-time processing, its limited storage and computational capacity necessitate reliance on cloud infrastructures, introducing latency and security risks [102,169]. Validation remains a bottleneck for noninvasive and semi-invasive sensors, many of which lack clinical approval for broad deployment [173]. Moreover, disparities in digital infrastructure, especially in rural areas, widen gaps in access, underscoring the digital divide's role in perpetuating health inequities [159].

Smart environments struggle with long-term activity recognition due to the demand for extensive training datasets, frequent recalibration, and platform dependency, which is particularly challenging for older residents [42,47,174]. Sensor design limitations, such as poor skin compatibility and sensitivity to environmental factors, further compromise data quality [36,91,174]. The absence of clinically validated parameters hampers the translation of wearable data into meaningful health outcomes [122], while gaps in eHealth literacy and technology adoption among marginalized populations constrain inclusivity [36].

Security vulnerabilities from smartphone app integration to sensor network breaches call for robust encryption and energy-efficient security protocols [58,151,160]. Addressing these multifaceted challenges requires interdisciplinary collaboration, rigorous validation cycles, and standardized frameworks to ensure the scalable, ethical, and effective implementation of TEH in smart residential spaces. While these conceptual challenges limit the functionality and inclusivity of TEH systems, their practical implementation is further constrained by technological and infrastructural limitations, as discussed next.

Technological and Infrastructure Implementation

Foremost among the obstacles is the heterogeneity of devices and platforms. Variations in OSs, sensor types, manufacturers, and communication protocols create severe interoperability bottlenecks. These discrepancies often result in inefficient data exchange, inconsistent performance, and resource allocation conflicts across devices. While frameworks have been proposed to unify operations, the absence of universally standardized communication protocols remains a persistent issue, impeding seamless integration and real-time data synchronization.

Limited battery capacity of wearable and embedded sensing devices poses another challenge, especially due to continuous data acquisition and computation. Sustainable operation necessitates low-power hardware architectures, adaptive duty-cycling strategies, and energy-aware communication protocols. Although protocols such as BLE offer promise for restricted-power wearable devices, ensuring longer runtime while maintaining adequate data transmission, their efficacy is often challenged by variable user activity, multisensor environments, and the need for uninterrupted monitoring.

The disaggregated nature of IoT ecosystems results in fragmentation, reducing compatibility between devices from different manufacturers and complicating data harmonization. This lack of interoperability and standardization hampers holistic system performance, inflates development costs, and undermines user confidence in TEH solutions [113]. Protocols such as Zigbee (ideal for battery-powered sensor networks) and LoRaWAN (for long-range motion monitoring), BLE (for real-time wearable communication), and Matter offer partial solutions, but require coordinated adoption across the ecosystem. A recent standard established, called the Matter standard developed by the Connectivity Standards Alliance as a unified IP-based smart home connectivity protocol, provides a common framework that enables devices from different manufacturers to operate together and reduces the need for multiple gateways in a way to simplify user integration [150]. It improves interoperability and helps overcome many of the connectivity challenges identified in this review.

Ethical, Usability, and Evaluation

The successful implementation of TEH systems in smart homes depends not only on technical feasibility but also on adherence to ethical principles, universal design, and rigorous evaluation standards. These 3 dimensions are deeply interconnected and together determine the reliability, acceptance, and sustainability of smart health care technologies. Initially, the implementation of TEH technologies raises important ethical questions, particularly around privacy and autonomy. For individuals with cognitive impairments, excessive monitoring may compromise personal freedom and psychological well-being. Ethical design frameworks and transparent user consent protocols are fundamental to building trust in these systems.

These ethical issues are amplified by the technical challenge of data management in smart home systems, where personal sensor data creates new vulnerabilities and performance constraints. The transmission and storage of sensitive physiological and behavioral data raise privacy and security risks. Robust encryption schemes and secure communication frameworks are imperative to protect personal information and uphold patient confidentiality [168]. Emerging technologies such as blockchain have shown potential for enhancing data integrity and security within smart home architectures [82], although their integration remains limited and largely experimental. The vast volume of measured data generated by multiple sensors and IoT devices threatens to overwhelm existing communication protocols, leading to latency, packet loss, and bandwidth saturation. Optical fiber-based networks may alleviate bandwidth constraints, yet infrastructure limitations persist. Introducing middleware layers can facilitate data preprocessing, adaptive bandwidth allocation, and selective transmission, thereby enhancing data exchange efficiency and reducing system load.

Furthermore, the everyday usability of TEH systems plays an equally important role in determining user trust and sustainable adoption. Usability remains a critical determinant of TEH-smart home adoption, particularly among older adults who may struggle with system complexity. Designing accessible, intuitive,

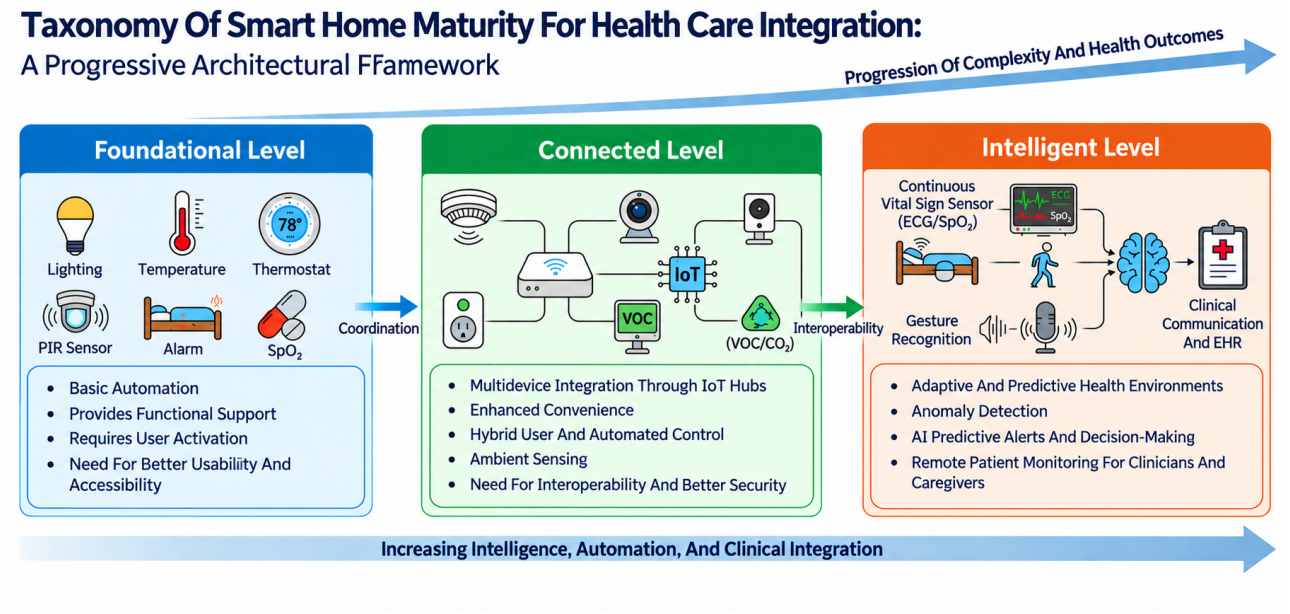
XSL•FO
RenderX

user-friendly interfaces with inclusive features such as simplified navigation, voice-based controls, and adaptive personalization is essential to foster user acceptance and long-term use. TEH systems must accommodate diverse cognitive and physical capabilities to ensure equitable access and functionality [115]. To do so, technologies with a user-centered design must be supported by robust evaluation frameworks that ensure TEH systems are effective, interoperable, and aligned with international standards.

Evaluating TEH integration within smart homes demands not only clear performance indices but also alignment with internationally recognized standards to ensure consistency, interoperability, and scalability. Key metrics include data exchange efficiency, compatibility rate across sensing devices, response time, error rate, and resource usage. These metrics need to reflect core system capabilities such as responsiveness, reliability, and integration flexibility. However, without a universally agreed framework, comparing performance across heterogeneous TEH architectures remains challenging. There are standards such as IEEE 2951‐2025 that provide structured evaluation methods for smart home devices, assessing intelligence levels across dimensions such as perception, cognition, coordination, and security. Similarly, ISO/TS 37151:2015 outlines performance indicators for smart community infrastructures emphasizing sustainability, resilience, and user-centric design.

Incorporating IEEE and ISO standards provides a range of strategic advantages that support system development and deployment. First, benchmarking consistency becomes achievable, allowing for reproducible and comparable assessments across diverse platforms and architectures. This consistency lays the groundwork for meaningful performance analysis and longitudinal validation. Standards also foster interoperability, enabling seamless integration of heterogeneous devices, sensors, and middleware—a crucial factor in multimodal smart home environments. Furthermore, they inform scalability and optimization efforts by guiding system upgrades and middleware configuration to meet evolving health care demands. Adherence to these standards supports regulatory alignment, ensuring systems comply with international norms for health care delivery and smart infrastructure, which is vital for global deployment and clinical adoption. Together, these benefits underscore the necessity of standards and metrics for evaluation in advancing robust, reliable, and future TEH-smart home technologies. Practical implementations may include adopting IEEE 802.15.4-based protocols for low-power, high-reliability communication, or leveraging edge computing to reduce latency and optimize bandwidth allocation. Looking ahead, future research and development should prioritize the adoption of harmonized metric frameworks grounded in IEEE and ISO guidelines, ensuring that TEH smart home systems mature toward clinically robust, scalable, and globally deployable solutions. Despite growing efforts to standardize performance evaluation in a universal manner, a comprehensive operational framework that integrates technical performance, interoperability, and human-machine interaction (HMI) remains weak. Once developed, this framework is needed to align usability, patient engagement, and system reliability to optimize both adoption and patient health outcomes.

In addition to all the technical challenges mentioned above, structural barriers impact long-term usability and global adoption of TEH integration. Variations in digital infrastructure, literacy, and regulatory maturity levels across regions significantly influence the feasibility of deploying these systems at a larger scale [156]. This is because in more advanced, wealthy settings, there are usually more developed broadband networks, digital health reimbursement pathways, and established regulatory frameworks that facilitate the integration of remote monitoring and assisted health care services, while in lower-income regions, people often face infrastructural limitations, fragmented policy environments, and constrained health care budgets that restrict the deployment of advanced TEH systems. If not deployed efficiently, TEH integration would amplify existing health disparities by disproportionately benefiting populations with greater technological access and digital literacy. While investing in infrastructure and smart personalized system design, TEH solutions have the potential to reduce geographic and socioeconomic barriers by enabling remote monitoring, expanding access to specialist care, and supporting preventive health care delivery in underserved communities.



Developing Regulatory Integration Maturity Framework

Earlier in the Results section, the 3 levels of TEH integration maturity were classified and identified as foundational, connected, and intelligent systems. This classification is useful in demonstrating how the integration process progresses simultaneously with the available architectural complexity. However, currently, in most cases, inconsistent assessment and heterogenous criteria are applied when evaluating or categorizing any form of TEH integration without a standardized form of assessment that examines the sophistication and efficiency of a smart system. Current evaluation approaches primarily assess discrete performance metrics such as response time, compatibility rates, accuracy, and energy efficiency, which quantify a form of effectiveness but not in a comparable fashion as part of a unified model that can be used in system development. This was while 1 recent published framework emphasized the need for a responsible deployment of digital health technologies to ensure that system development aligns with clinical effectiveness, accessibility, and sustainability [156]. However, the study lacks quantitative mechanisms for assessing the maturity and integration readiness of smart home health care systems. This variation in assessment tools used to evaluate TEH integration highlights the need for a maturity framework standard with elements capable of assessing readiness across technical performance, interoperability, clinical validation, usability, and scalability. This framework will allow the translation of potential pilot implementations into sustainable, scalable, and efficient TEH integrations. Most importantly, a structured maturity framework can enable the evolution of TEH systems across the different stages from foundational to multimodal clinically intelligent systems. This framework would serve as a regulatory-aligned standard for telemedicine deployment and remote digital therapeutics in smart homes. This is essential when establishing a compliance assessment that considers both system safety and efficiency based on evident

XSL•FO
RenderX

improvements in clinical outcomes and quality of life benefits. To visualize the proposed framework, Figure 3 presents a conceptual diagram that illustrates the three layers of TEH integration maturity and how they differ in complexity and functionality. This diagram illustrates guidelines for the system developers or regulatory parties involved to assess and guide implementation strategies.

Figure 3. Smart maturity taxonomy of technology-enhanced health care integration: progressive nature of system development, highlighting that as smart home health care technologies evolve, they move from basic operational capabilities into connected systems and then toward more sophisticated, interoperable, and clinically intelligent systems. AI: artificial intelligence; CO_2 : carbon dioxide; ECG: electrocardiography; EHR: electronic health record; IoT: Internet of Things; PIR: passive infrared; SpO_2 : peripheral capillary oxygen saturation; VOC: volatile organic compounds.

Future Directions

Foundation for TEH Assessments

As ensuring efficient data capture is critical for achieving reliable health insights and predictive outcomes in smart residential environments, it is important to increase participant diversity in empirical studies and address current limitations in sample size and sociodemographic representation. At this stage, it is important to distinguish between near future priorities that will have a direct impact on current TEH systems, including but not limited to improving sensor reliability, data integrity, and its harmony with the different systems involved while there are priorities for the more distant future which will lead the path to scalability and long-term continuous use such as the development of a regulatory-based integration framework, clinical validation, and sustainable widespread expansion. A broader and more representative participant group enhances the generalizability and relevance of findings, ensuring that health monitoring systems remain relevant across diverse populations and cultural contexts. Effective systems must be capable of managing large volumes of heterogeneous data from diverse sensors distributed throughout the smart environment [140]. This includes handling real-time inputs, minimizing latency, and maintaining synchronization across devices.

However, to avoid data redundancy, technical methods are used, such as implementing sliding window-based feature representation, which allows continuous sensor data to be segmented into short intervals, improving temporal precision and reducing redundancy in physiological signal monitoring [185]. Similarly, skeleton extraction techniques translate visual or depth data into simplified human body models, enabling nonintrusive monitoring of mobility, posture, and gait while reducing data volume and privacy risks. These strategies strengthen the accuracy, interpretability, and inclusivity of TEH assessments, forming a critical foundation for future frameworks that integrate sensor reliability, user diversity, and adaptive analytics. Such strategies support the development of comprehensive, resilient, predictive, personalized, and adaptive health care within intelligent living spaces.

Potential for TEH Home Integration Frameworks

When approaching long-term needs, more investigative research should be conducted to develop a harmonized regulatory model that factors clinical validation and elements of global-scale integration in health care infrastructures in economically disadvantaged environments. An evaluation metric that looks at and quantifies the level of integration of a TEH device or system is essential to justify its cost of deployment. The next generation of TEH home development should avoid isolated technological innovations and focus on 3 main aspects: sustainable, interoperable, and socially affordable ecosystems. Future research should investigate frameworks that integrate technical scalability, environmental adaptability, policy compliance, and sustainable clinical value.

Additionally, future systems must be evaluated based on their energy consumption to reduce the environmental footprint of continuous sensing. The concept of lifecycle sustainability should extend to software development by adopting modular architectures and open-source frameworks, which can ensure that systems remain adaptable and maintainable across decades of technological evolution. Such an approach supports both

XSL•FO
RenderX

environmental sustainability and economic viability, particularly for large-scale deployment in public health infrastructures. Future work should prioritize defining regulatory criteria within integration framework standards that can align and evolve the maturity of TEH systems with tested and validated clinical, social, and economic outcomes.

As TEH systems become increasingly integrated into daily life, HMI must be a central component of future frameworks. Assessing HMI ensures that devices are intuitive, accessible, and adaptable to the diverse needs of users, including older adults and individuals with physical or cognitive impairments. Frameworks should prioritize device flexibility, allowing sensors and wearables to accommodate different body types, living arrangements, and user preferences without compromising accuracy or continuity of monitoring. Equally important is wearability and comfort; continuous monitoring devices, including smart textiles and embedded sensors, must be unobtrusive to encourage long-term adherence. Usability and cognitive load are critical, and interfaces should minimize technical complexity while supporting users with varying levels of digital literacy. Adaptive systems that respond to user routines, updated health parameters, and environmental context can further enhance engagement and reduce burden. For example, a system can look at adjusting sampling frequency in response to detected fatigue or activity levels. Systematic evaluation of HMI within TEH frameworks ensures that devices are not only reliable but also personalized for each case separately. This strategy promotes sustained engagement and effective integration into daily life.

Sustainable TEH frameworks must also integrate a rigorous assessment of ethical, legal, and social implications to ensure alignment with societal norms, patient rights, and regulatory standards. Privacy and data security are foundational, requiring robust encryption, access control, and compliance with internationally recognized regulations and regional standards. Frameworks should also assess autonomy and consent, particularly for vulnerable populations, ensuring that continuous monitoring respects individual choice and maintains user control over data collection and sharing. Equity and accessibility are essential; TEH systems must be evaluated for usability across diverse socioeconomic, cultural, and demographic groups, with attention to adoption patterns and engagement barriers. Transparency and algorithmic accountability are critical for measured biosensor data, as it requires predictive models to be interpretable, auditable, and free from systemic bias. Finally, the social and psychological impact of monitoring technologies, including perceived intrusiveness, trust, and potential effects on mental well-being, should be evaluated. Embedding operational assessment into TEH frameworks will ensure that smart home health care systems are not only technically robust but also ethically sound, socially responsible, and legally compliant, supporting long-term adoption and personalized care. Such frameworks will guide the development of intelligent living spaces capable of delivering predictive, personalized, and equitable health care while remaining scalable, maintainable, and socially acceptable across diverse populations and contexts.

Enhancing Adoption in Future TEH Systems

As a near-future target, improving usability, interoperability, and clinical use of TEH systems is essential to improve user engagement and global trust in digital therapeutics and address the challenges faced by clinicians during the integration process. The incorporation of smart sensor data with clinical workflow will require a structured process in prioritizing alerts while assigning clinical responsibility and minimizing excessive or nonactionable notifications. To achieve this, it is critical to evaluate false positive rates, signal specificity, and escalation protocols to prevent unnecessary interventions or patient anxiety. In the long term, this will enable access across diverse deprived populations. Effective integration of TEH in smart homes relies on the seamless and secure transmission of health data from wearable devices and remote monitoring systems into clinical workflows. However, concerns about data privacy and cybersecurity remain significant barriers to adoption. Implementing multilevel encryption strategies alongside robust data governance frameworks is essential to maintaining user trust and ensuring regulatory compliance.

Personalization and usability play a critical role in patient satisfaction. Unfortunately, many wearable devices and smart home sensors lack intuitive interfaces or adaptive features, limiting accessibility for users with diverse health needs, living situations, and levels of digital literacy. Enhancing usability and tailoring system interactions to individual preferences and clinical contexts are therefore crucial for encouraging engagement and sustainable adoption. TEH solutions with intuitive interfaces and personalized features can produce clinical benefits and achieve higher satisfaction ratings. This can be assessed using a multidimensional approach by combining quantitative and qualitative methods. For instance, the general evaluation of medical services questionnaire captures core dimensions including convenience of use, perceived value, efficiency, and overall satisfaction, reflecting both operational improvements and user experience factors. Complementary qualitative approaches, including structured surveys and detailed interviews, provide insights into user perceptions, motivations, and barriers, enabling developers to tailor future iterations of TEH systems. By integrating these quantitative and qualitative evaluations, smart home health care solutions can be refined to maximize usability, trust, and positive outcomes, which lead to more effective and sustained engagement.

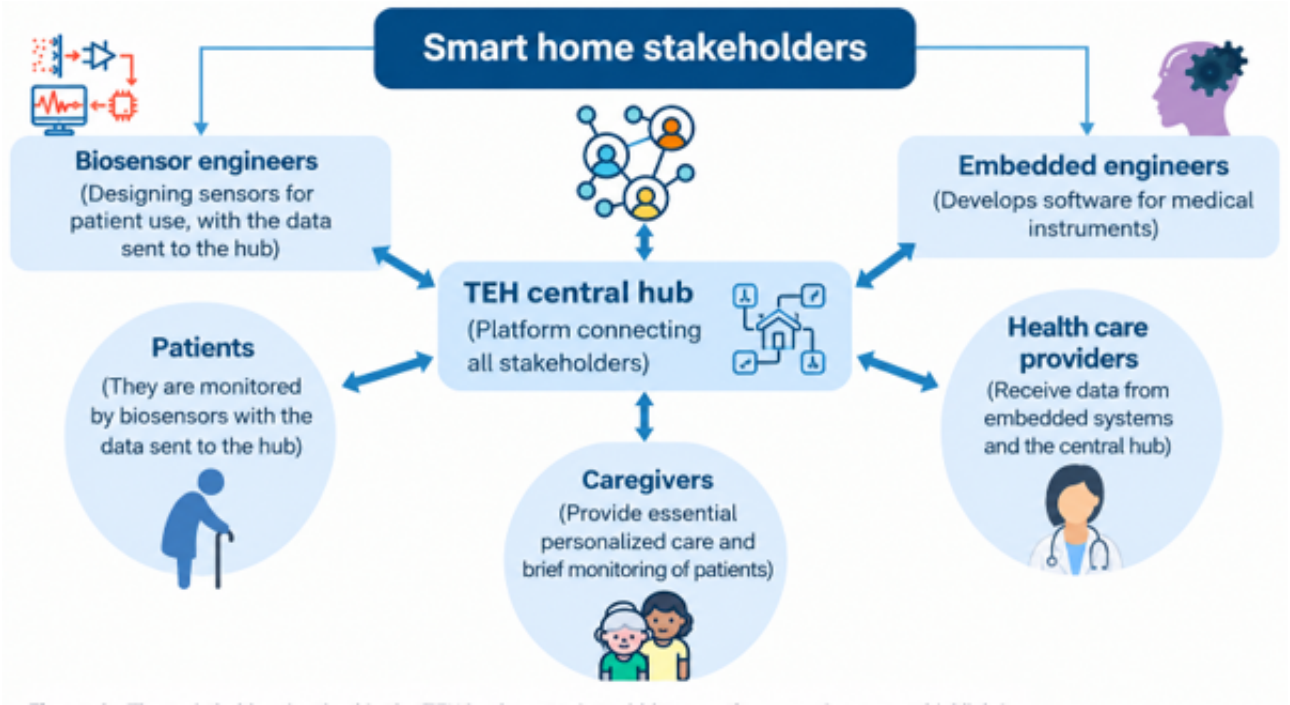
Implications for Research and Practice

Building on the challenges discussed and the perspectives outlined in this section, the work done in this review provides a detailed layout for the process of TEH integration in smart homes, highlighting conceptual, technological, ethical, and infrastructural elements. Unlike previous research reviews published, this work primarily focuses on both technological and clinical outcomes while presenting a holistic picture of how wearable and ambient sensors are linked with health care data analytics, interoperability challenges, and HMI.

Furthermore, another main contribution of this work is that by connecting technical performance with usability, ethical considerations, and scalable deployment strategies, it demonstrates a realistic potential of TEH integrated homes. Its

XSL•FO
RenderX

findings guide researchers, developers, and policymakers in designing clinically robust, socially responsible, and accessible smart home health care solutions. Additionally, it supports personalized health management and enhances caregiver accessibility while promoting equitable adoption. This aids in the development of TEH frameworks that are sustainable, inclusive, and capable of improving health outcomes across diverse populations.



Limitations

Unfortunately, most research on TEH-smart home systems is concentrated in higher-income regions because that is where they can afford to investigate the effectiveness of advanced technologies, which limits generalizability in under-resourced or rural settings where digital infrastructure, regulatory maturity, and health care resources differ significantly and would be more expensive to deploy. The conclusions of this review about deployment feasibility may not extend to low-resource settings.

Another limiting factor for this review is that sample sizes in many studies are small, and again participant sociodemographic diversity is limited, which constrains the applicability of findings across different age groups, cultural contexts, and health conditions. That explains why currently many TEH systems included in the literature lack long-term clinical validation, standardized evaluation metrics, and interoperability across devices, which restricts the robust assessment of effectiveness, scalability, and real-world implementation.

Another limitation faced when presenting this review is how ethical, usability, and regulatory considerations are inconsistently reported across the TEH literature, which significantly limits understanding of how these systems are perceived and adopted by users. Without clear reporting on these issues, it is difficult to assess whether TEH systems respect user rights and maintain trust, which are critical factors for long-term engagement, particularly among vulnerable populations such as older adults or individuals with cognitive impairments. It limits stakeholders' understanding and confidence in the practical feasibility, scalability, and sustainable adoption of TEH systems in health residential settings (Figure 4).

Figure 4. The stakeholders involved in the TEH implementation within smart home environments, highlighting bidirectional communication, interoperability among heterogeneous sensors, and the central role of the TEH hub in coordinating monitoring, decision support, and feedback delivery, as discussed in the literature [25,92]. TEH: technology-enhanced health care.

Conclusions

Integrating TEH systems into smart home environments is reshaping how health services are delivered, offering continuous monitoring, early detection of risk, and support for independent living. This review demonstrates that multimodal sensor systems that include wearable biosensors, ambient environmental sensors, and specialized medical devices can collectively strengthen chronic disease management and improve clinical outcomes. Studies across Europe, Asia, and the Middle East provide evidence of reduced hospital readmissions, decreased emergency visits, enhanced caregiver accessibility, and improved patient engagement when these systems are properly implemented. The progression from foundational automation to connected and fully intelligent smart home ecosystems reflects increasing maturity in TEH integration and highlights the growing feasibility of personalized, adaptive health care within residential settings.

Despite this progress, this review identifies persistent fragmentation in system design, data governance, interoperability, and clinical validation. Adoption remains uneven across global regions, influenced by variations in digital infrastructure, regulatory readiness, economic capacity, and worldwide cultural acceptance. Although ML applications show great impact in activity recognition, disease prediction, and

XSL•FO
RenderX

signal analysis, they will remain limited by data quality, model interpretability, and computational constraints. Wearable devices and ambient sensors also face challenges related to measurement accuracy, sensor placement, packet loss, network reliability, and long-term user adherence. Therefore, technical, infrastructural, and personalization barriers need to be addressed to enable scalability and allow the implementation of TEH smart home systems from pilot studies to sustainable real-world deployments.

Building on the discussion of unified TEH evaluation tools and the interoperability challenges, this review demonstrates the absence of a quantified objective framework model that can assess the TEH integration maturity of any potential system implemented or projected. Current implementations range from simple monitoring elements to highly adaptive environments driven by AI and multimodal sensing platforms, yet there is no consistent method to evaluate readiness, interoperability, clinical reliability, or sustainability. Establishing a structured operational framework that can weigh environmental constraints, technical performance, data quality, privacy safeguards, and long-term scalability is essential for guiding potential implementation. This framework will provide a regulatory standard and a compliance assessment model for telemedicine and digital therapeutics that improves safety standards and health care value. Such a maturity model would enable researchers, policymakers, and health care providers to benchmark and quantify systems, identify gaps, support regulatory approval, and align implementations with measured clinical outcomes and ethical standards.

Addressing broader disparities is equally crucial, as unequal access to broadband connectivity, limited digital literacy, affordability challenges, and sociocultural concerns continue to restrict equitable adoption. Ensuring that TEH home integration reduces rather than deepens existing health inequities requires policies that promote inclusion, accessible design, and personalized training, alongside data governance models that preserve trust and privacy. This review establishes the need for coordinated, quantifiable, and recognized frameworks that can guide the responsible and scalable integration of TEH within smart homes. By addressing existing technical, environmental, and policy challenges and by systematically evaluating implementation outcomes, future TEH ecosystems can support personalized, ethical, and resilient health care delivery.

Acknowledgments

We acknowledge the contributions of researchers whose work formed the foundation of the studies discussed in this paper. The authors declare the use of generative AI (GenAI) in the research and writing process. According to the GAIDeT (2025; Generative Artificial Intelligence Delegation Taxonomy), the following tasks were delegated to GenAI tools under full human supervision: literature search and systematization, visualization, and proofreading and editing. The GenAI tools used were Grammarly (Superhuman Platform), ChatGPT (OpenAI), Gemini (Google LLC), and Copilot (Microsoft Corp). Responsibility for this paper lies entirely with the authors. GenAI tools are not listed as authors and do not bear responsibility for the outcomes. Declaration submitted by YE-S.

Funding

The authors would like to thank the University of Huddersfield for funding this research and the development of this review. This work was supported by the University Research Fund (URF) at the University of Huddersfield. The funder had no involvement in the study design, data collection, analysis, interpretation of the results, or the writing of this paper.

Conflicts of Interest

None declared.

Abstract

Background: Delirium is a common and clinically important form of acute in-hospital mental status deterioration. Electronic health record (EHR)–based prediction models may support early identification and targeted prevention, but their methodological quality, validation rigor, and clinical readiness remain uncertain.

Objective: This systematic review aimed to synthesize and critically evaluate prediction models for in-hospital delirium developed using routinely collected EHR data, focusing on model characteristics, validation strategies, performance, risk of bias, and clinical applicability.

Methods: We searched PubMed, MEDLINE, Embase, PsycINFO, and Web of Science from inception to November 11, 2025. Eligible studies developed, validated, or evaluated multivariable prediction models using routinely collected EHR or administrative data to predict acute mental status deterioration during adult hospital admissions. Although eligibility criteria were broad, all included studies operationalized deterioration as delirium. Data extraction was informed by CHARMS (Checklist for Critical Appraisal and Data Extraction for Systematic Reviews of Prediction Modeling Studies) and TRIPOD (Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis) or TRIPOD–artificial intelligence guidance. Model performance, validation, calibration, and implementation features were synthesized narratively. Risk of bias and applicability were assessed using PROBAST (Prediction Model Risk of Bias Assessment Tool).

Results: Twenty-nine studies met the inclusion criteria. The evidence clustered into 4 overlapping prediction tasks: admission or early-stay risk stratification, perioperative or postoperative prediction, dynamic intensive care unit prediction, and external validation or workflow evaluation of existing tools. Most studies were retrospective cohorts (20/29, 69%) and were conducted in general ward, mixed ward–intensive care unit, intensive care unit, or emergency department settings. Machine learning or hybrid approaches were common (18/29, 62%), but more complex models did not consistently outperform statistical or rule-based approaches. Of 29 studies, internal discrimination was reported in 24 (83%; area under the receiver operating characteristic curve range 0.77-0.97) studies, whereas external discrimination was reported in 12 studies and calibration in 15 studies. Decision curve analysis was reported in 3 studies, and prospective evaluation or workflow integration remained limited. Overall risk of bias was low in 8 studies, unclear in 10 studies, and high in 11 studies, mainly because of analysis-domain limitations.

Conclusions: Routinely collected EHR data can support delirium risk prediction across hospital settings, and many models show moderate to high discrimination. However, no single algorithm is ready for routine adoption. The field remains limited by heterogeneous prediction tasks, inconsistent outcome ascertainment, weak calibration and decision-analytic reporting, and insufficient external or prospective evaluation. Future studies should define the intended clinical use case before model development, evaluate calibration and clinical usefulness alongside discrimination, and test models across institutions, time periods, and workflows before deployment.

Introduction

Acute in-hospital mental status deterioration is a clinically important manifestation of acute brain dysfunction, encompassing disturbances such as confusion, inattention, agitation, and reduced consciousness. In current hospital-based prediction modeling research using routinely collected electronic health record (EHR) data, however, this construct has been operationalized almost exclusively as delirium. Delirium is common across hospital settings and is associated with increased morbidity, mortality, prolonged hospitalization, institutionalization, and persistent cognitive impairment following discharge [1,2].

Delirium is the most clinically and methodologically established target in this literature. Its prominence reflects both its prognostic significance and the availability of validated bedside assessment tools, most notably the Confusion Assessment Method (CAM) and its intensive care unit (ICU) adaptations [3].

Prediction modeling for in-hospital delirium is motivated by the need to support early identification and prevention in resource-constrained clinical environments. Universal application of intensive preventive strategies is rarely feasible, and risk stratification tools that identify patients at elevated risk early in the hospital course offer a pragmatic approach to targeting preventive interventions [4]. Advances in EHR-based modeling, including machine learning and natural language processing (NLP), have enabled scalable development of delirium prediction models using routinely collected clinical data [5].

However, recent systematic reviews have highlighted important limitations in the existing evidence base. Although many delirium prediction models report moderate to high discrimination, substantial heterogeneity exists in outcome definitions, predictor handling, validation strategies, and reporting quality. External validation, calibration assessment, and prospective evaluation remain inconsistently performed, limiting confidence in clinical generalizability and real-world usefulness [6-8].

Against this background, the present systematic review aims to synthesize and critically evaluate prediction models for in-hospital delirium using routinely collected EHR data. Although the search strategy was intentionally broad to capture a range of acute mental status outcomes, all eligible studies identified at full-text review operationalized deterioration as delirium. This finding underscores the central role of delirium as the dominant and currently most clinically actionable manifestation of acute in-hospital mental status change within the prediction modeling literature. Accordingly, this review focuses on delirium prediction models, with particular emphasis on methodological quality, validation practices, risk of bias, and implications for the development of clinically actionable decision support tools.

Methods

Study Design and Reporting Standards

This systematic review was conducted and reported in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [9]. Given the focus on prediction model development and validation, data extraction and synthesis were additionally informed by relevant items from the TRIPOD (Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis) and TRIPOD–Artificial Intelligence (TRIPOD-AI) reporting frameworks to support structured evaluation of model characteristics, validation strategies, and reporting quality [10,11]. This review was not prospectively registered in PROSPERO because protocol registration was not completed before screening had begun; this is acknowledged as a limitation.

Eligibility Criteria

Studies were eligible for inclusion if they met the following criteria: (1) involved adult patients (aged ≥18 years) admitted to hospital settings, including ICUs, general medical or surgical wards, or mixed ICU–ward cohorts; (2) developed, validated, or updated multivariable prediction models using routinely collected EHR or administrative data; (3) predicted delirium occurring during the index hospital admission; and (4) reported sufficient methodological or performance information to allow data extraction.

Eligible outcomes included delirium occurring during the index hospital admission, identified using validated clinical assessment tools (eg, CAM and CAM-ICU), diagnostic codes, or structured chart review. Although the search strategy was designed to capture a broader range of acute mental status deterioration outcomes, all studies meeting inclusion criteria at full-text review predicted delirium. Therefore, delirium was treated as the primary outcome for this review.

Studies using any statistical or machine learning–based modeling approach were eligible, including traditional regression-based models and advanced machine learning methods. Both retrospective and prospective study designs were included. Studies were excluded if they (1) focused exclusively on pediatric populations; (2) were conducted in outpatient, community, or psychiatric clinic settings without hospital admission; (3) relied solely on nonroutine data sources such as imaging, genomics, or specialized psychometric instruments not typically available in EHR systems; (4) predicted outcomes defined at the population level or occurring outside the index hospital admission (eg, long-term suicide risk or postdischarge psychiatric readmission); or (5) did not report delirium or an equivalent acute in-hospital mental status outcome.

Information Sources and Search Strategy

A comprehensive literature search was conducted to identify studies developing or validating prediction models for delirium and related acute mental status outcomes occurring during hospitalization. The search strategy was designed a priori to be intentionally broad to maximize sensitivity and capture models targeting a range of clinically relevant mental status changes. However, all studies meeting inclusion criteria at full-text review

XSL•FO
RenderX

focused exclusively on delirium. This reflects the predominance of delirium as the most consistently defined and operationalized outcome in this field, and the present review therefore focuses specifically on delirium prediction models.

The following electronic databases were searched from inception to November 11, 2025: PubMed or MEDLINE, Embase, PsycINFO, and Web of Science. The search combined terms related to prediction modeling and machine learning (eg, prediction, risk model, machine learning, and AI), routinely collected health care data (eg, EHRs, administrative data, and claims data), acute mental status outcomes (eg, delirium, acute confusion, agitation, mental status change, and psychotropic medication use), and hospital settings (eg, inpatient, ward, and ICU).

Database-specific search strategies were developed using a combination of controlled vocabulary (eg, MeSH) and free-text terms. Full search strategies for each database are provided in Multimedia Appendix 1. No restrictions were placed on geographic location or health care setting. Only studies published in English were included. Reference lists of included studies and relevant review papers were manually screened to identify additional eligible studies. All retrieved records were imported into reference management software, and duplicate records were removed before screening.

Study Selection

After removal of duplicate records, titles and abstracts were screened to identify potentially eligible studies. Full-text papers were retrieved for all records deemed potentially relevant and assessed against the predefined eligibility criteria. Study selection was performed independently by 2 reviewers (CSL and GWC). Discrepancies at either the title or abstract or full-text screening stage were resolved through discussion and consensus, with consultation of a third reviewer (MHT) when necessary. The overall study selection process is summarized using a PRISMA flow diagram.

Data Extraction

Data were extracted independently by 2 reviewers (CSL and GWC) using a standardized data extraction form developed a priori. The extraction framework was informed by established guidance for prediction model studies, including the CHARMS (Checklist for Critical Appraisal and Data Extraction for Systematic Reviews of Prediction Modelling Studies), and reporting domains from the TRIPOD and TRIPOD-AI statements [10-12].

For each included study, extracted information included study metadata (first author, year, country, clinical setting, and study design), population characteristics (sample size and cohort definition), outcome definition and ascertainment method (eg, CAM-based assessment, *ICD* [*International Classification of Diseases*] codes, and chart review), prediction time horizon, modeling approach, predictor variables, feature selection methods, and model presentation.

Model development and validation characteristics were extracted in detail, including type of validation (internal, temporal, or external), validation datasets, and reported performance measures. Extracted performance metrics included measures of discrimination (eg, area under the receiver operating characteristic curve [AUROC]), sensitivity, specificity, and predictive values where available. Calibration measures and decision-analytic measures (eg, decision curve analysis) were recorded when reported. Information on missing data handling was extracted for each study, including use of complete-case analysis, single or multiple imputation, or algorithm-intrinsic handling of missingness. Where missing data handling was not explicitly described, this was recorded as not reported.

Risk of Bias and Quality Assessment

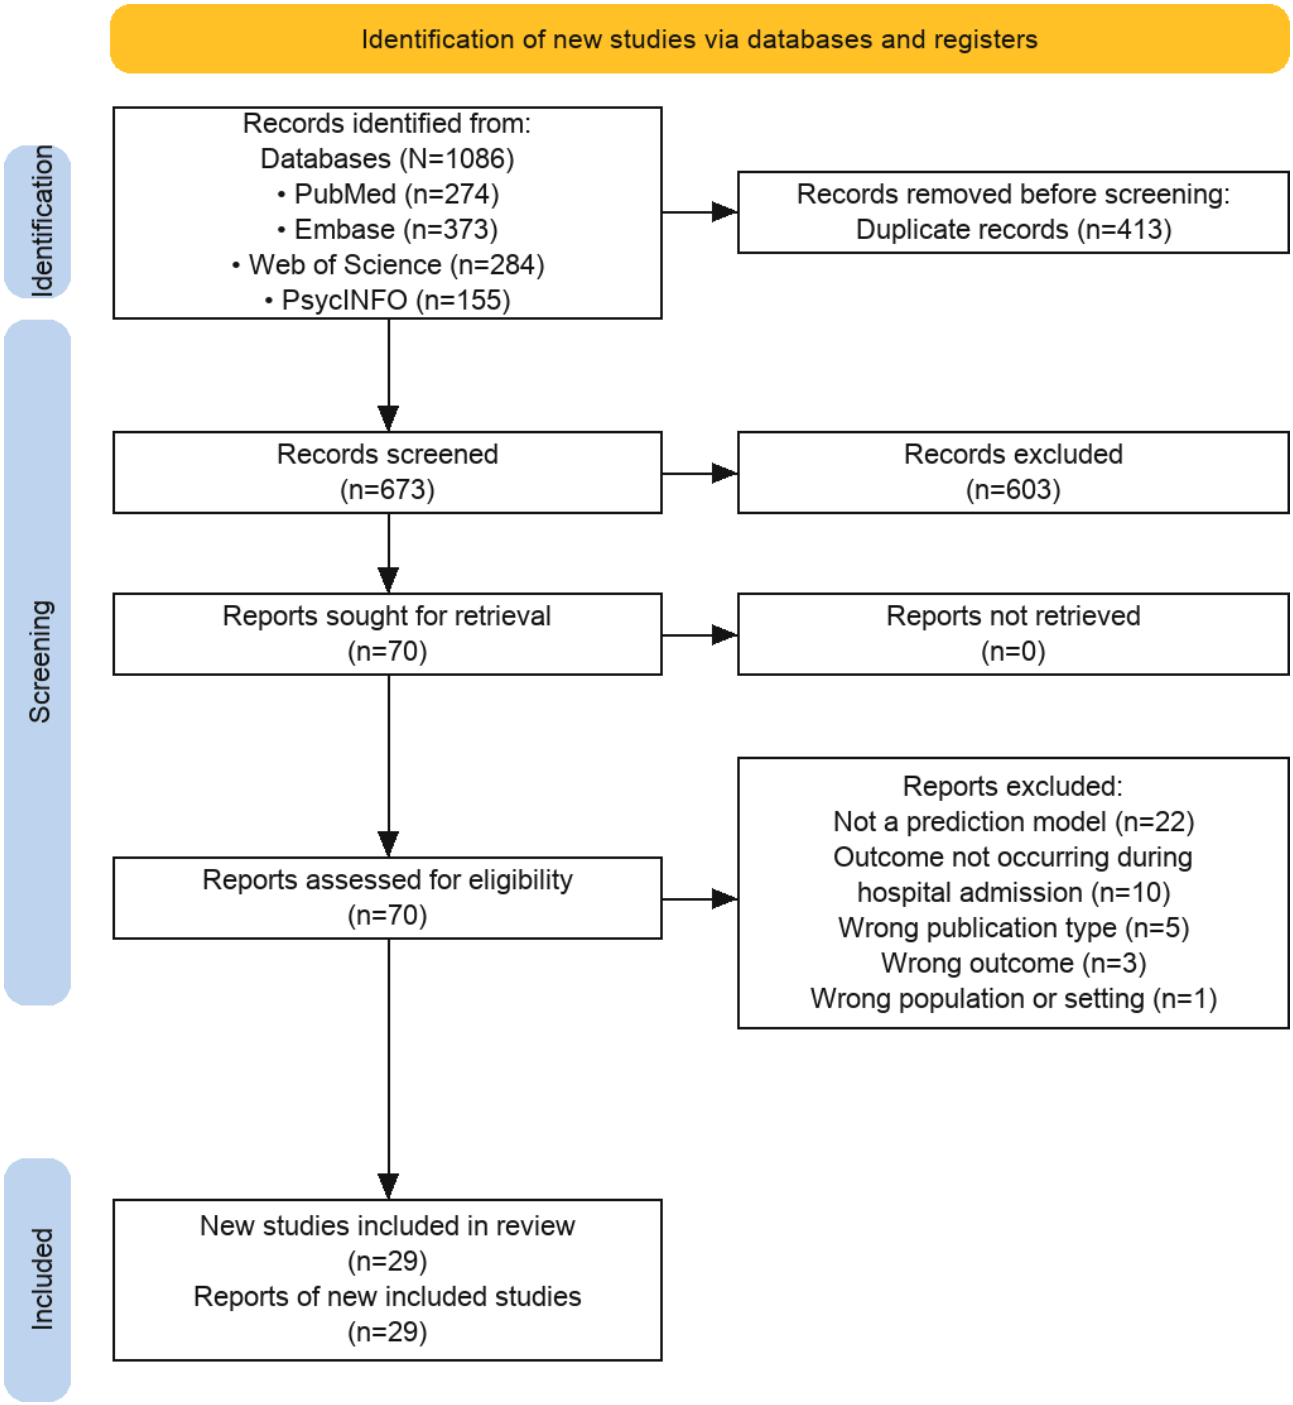
Risk of bias and applicability of included studies were assessed using the PROBAST (Prediction Model Risk of Bias Assessment Tool), which evaluates 4 domains: participants, predictors, outcomes, and analysis [13]. Two reviewers (CSL and GWC) independently completed PROBAST assessments using the tool's signaling questions. Each domain was rated as low, high, or unclear risk of bias. Discrepancies were resolved through discussion and consensus, with involvement of a third reviewer (MHT) when necessary. PROBAST assessments were used to support qualitative interpretation of methodological strengths and limitations rather than to exclude studies or weight quantitative comparisons.

Data Synthesis and Analysis

Given substantial heterogeneity across studies with respect to clinical setting, population characteristics, outcome definitions, prediction horizons, modeling approaches, and validation strategies, a quantitative meta-analysis of model performance was not performed. Findings were therefore synthesized narratively using a structured framework focused on 4 questions: What clinical prediction task was being addressed? What routinely collected data were used? How well models performed under internal and external validation? How close the models were to clinically reliable implementation.

Prediction model characteristics and performance metrics were summarized descriptively. Performance differences were interpreted in relation to clinical setting, prediction horizon, outcome ascertainment, validation strategy, calibration reporting, and risk of bias rather than by algorithm type alone. This approach was chosen to distinguish technical feasibility from clinical readiness.

Results



Study Selection

The database search identified a total of 1086 records, including 274 from PubMed, 373 from Embase, 284 from Web of Science, and 155 from PsycINFO. After removal of duplicate and overlapping records, 673 unique records remained for title and abstract screening, of which 603 were excluded. Seventy reports were retrieved for full-text assessment. Following full-text review, 41 reports were excluded. The most common reasons for exclusion were the absence of a multivariable prediction model, outcomes not occurring during the index hospital admission, wrong publication type, wrong outcome definition, or an ineligible study population. A total of 29 studies met the inclusion criteria and were included in the final qualitative

XSL•FO
RenderX

synthesis. The study selection process is summarized in Figure 1.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram of study selection [9].

Study Characteristics

The 29 included studies did not represent a single uniform prediction problem. Instead, they formed a heterogeneous evidence base spanning early admission screening, perioperative risk prediction, short-term ICU warning systems, and external validation or prospective evaluation of existing tools. Country, center structure, and study design are summarized in Table 1. The narrative synthesis highlights the patterns most relevant to interpretation.

Sun et al (2022) [41]	Germany	Multicenter	Mixed retrospective–prospective
Wong et al (2018) [42]	United States	Single-center	Retrospective cohort

Most studies used retrospective cohort designs (20/29, 69%) [14-23,25,29-33,35,39,40,42]. Of 29 studies, prospective cohorts were less common (4/29, 14%) [26,28,36,37], 4 (14%) studies combined retrospective development with prospective validation or evaluation [27,34,38,41], and 1 (3%) study used a retrospective case-control design [24].

This design profile is important because much of the literature remains closer to model development than to implementation science. The strongest clinical evidence generally came from studies that moved beyond internal validation into external, temporal, or prospective evaluation.

Clinical setting, population focus, and sample size are summarized in Table 2. Clinical settings were unevenly represented. Of 29 studies, general ward populations accounted for 13 (45%) studies, mixed ward-ICU cohorts accounted for 8 (28%), ICU-only cohorts accounted for 7 (24%), and the emergency department accounted for 1 (3%). Fifteen (52%) studies were single-center, while 14 (48%) studies used

XSL•FO

Wong et al (2018) [42]	General ward	Adult general inpatients	18,223

[a]ICU: intensive care unit.

[b]ED: emergency department.

[c]NR: not reported.

Across all studies, adult inpatients constituted the primary population of interest, but the intended use cases differed. Some models were designed for broad hospital screening, some for older adult or surgical pathways, and others for high-frequency monitoring in intensive care. Sample sizes ranged from fewer than 100 patients in a small prospective deployment cohort [27] to more than 100,000 patients in large multidatabase studies [19], making direct comparison of performance estimates difficult.

Outcome definitions, assessment methods, and prevalence are summarized in Table 3. Delirium was the outcome across all included studies, but the clinical meaning of the outcome varied.

XSL•FO
RenderX

Of the 29 studies, 27 (93%) modeled incident delirium, 1 (3%) modeled prevalent delirium in the emergency department [15], and 1 (3%) considered any delirium regardless of timing [38]. Outcome labels included in-hospital delirium, postoperative delirium, ICU delirium, and recurrent or short-term delirium risk.

[g]DOS: Delirium Observation Screening Scale.

[h]DSM: Diagnostic and Statistical Manual of Mental Disorders.

[i]ICDSC: Intensive Care Delirium Screening Checklist.

Outcome ascertainment was a major source of heterogeneity. Studies used structured tools such as CAM, CAM-ICU, the Delirium Observation Screening Scale, or the Intensive Care Delirium Screening Checklist, as well as *ICD* codes, EHR-derived definitions, NLP-enhanced ascertainment, and manual chart review or adjudication. These approaches identify overlapping but not identical clinical events, which limits the interpretability of pooled performance comparisons.

Outcome prevalence also varied substantially. Among the 20 studies with clearly extractable prevalence percentages, 6 (30%) reported prevalence below 5%, 10 (50%) reported prevalence between 5% and 20%, and 4 (20%) reported prevalence above 20%. Low prevalence was typical in general ward and broad inpatient cohorts, whereas higher prevalence was more common in ICU, surgical, and selected high-risk cohorts.

This variation has direct implications for clinical interpretation. In low-prevalence settings, even a model with good AUROC may have low positive predictive value (PPV) and may generate many false-positive alerts. In higher-prevalence settings, the same threshold can produce a very different balance between missed cases and unnecessary intervention.

Prediction horizon and TRIPOD classification are summarized in Table 4. Prediction horizons further separated the studies into different clinical tasks. Some models estimated risk at admission or during the first 24 - 72 hours, some predicted postoperative delirium over a fixed perioperative period, and others updated risk dynamically using rolling ICU or hospital windows. These are not interchangeable tasks: short-term dynamic prediction benefits from more proximal clinical signals, whereas admission-time models must support earlier but less certain prevention decisions.

XSL•FO

Wong et al (2018) [42]	During hospitalization	TRIPOD 2a

[a]TRIPOD: Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis.

[b]ED: emergency department.

[c]ICU: intensive care unit.

Accordingly, apparent differences in discrimination should not be interpreted as simple evidence that one model family is superior. They may instead reflect differences in timing, population acuity, outcome prevalence, and availability of predictors close to delirium onset.

TRIPOD classifications also reflected a field still weighted toward development and validation rather than deployment. Type 1b and 2b studies predominated, while fewer studies focused on external validation, model updating, temporal validation, or prospective implementation.

Taken together, the study characteristics show that the literature is clinically broad but methodologically fragmented. The central synthesis question is therefore not only whether EHR-based delirium prediction is feasible but which models have been tested under conditions close enough to their intended clinical use.

Model Development and Predictors

Model categories are summarized in Table 5, with detailed model development and predictor characteristics provided in Multimedia Appendix 2 [14-42]. Machine learning models were the largest single group (10/29, 34%), followed by statistical or rule-based approaches (8/29, 28%), deep learning models (5/29,

XSL•FO
RenderX

17%), and hybrid approaches combining statistical, machine learning, or deep learning components (6/29, 21%). Tree-based ensemble methods such as random forests and gradient boosting were common, while deep learning was concentrated in ICU or large-scale EHR datasets.

Table . Model category across included studies.

Study ID	Model category
Ali et al (2023) [14]	Existing rule-based statistical model (external validation only)

Sheikhalishahi et al (2023) [39]	Deep learning with attention mechanisms
Sun et al (2021) [40]	Transformer-based deep learning
Sun et al (2022) [41]	Transformer-based deep learning
Wong et al (2018) [42]	Classical machine learning and statistical models

Several studies compared multiple modeling paradigms within the same dataset [16,17,20,22,24,25,31,33,42]. These comparisons did not show a consistent advantage for increasing model complexity. In some cohorts, tree-based or penalized regression models performed similarly to neural network approaches, and apparent internal advantages were not always preserved during external validation.

Predictor sets were built mainly from structured EHR data. Of 29 studies, demographics were included in 28 (97%), comorbidities or diagnostic history in 25 (86%) , laboratory values in 22 (76%), medications in 20 (69%), vital signs in 17 (59%), and nursing or care process variables in 7 (24%). This pattern indicates that most models relied on broadly available routine data rather than specialized research measurements.

Temporal handling of predictors was a key distinction between models (Table 6). Of 29 studies, 15 (52%) used static single-time snapshots, most often at admission, preoperatively, or within an early fixed window. Of 29 studies, 14 (48%) incorporated time-varying information through repeated recalculation, aggregated temporal summaries, rolling windows, or sequential time series modeling.

XSL•FO

[a]ED: emergency department.

[b]ICU: intensive care unit.

Of 29 studies, only 8 (28%) used NLP or unstructured free-text data [17,18,23,26,29,38,40,41]. In several of these, NLP supported outcome ascertainment rather than contributing predictor features. Thus, despite the clinical importance of narrative documentation for cognitive and behavioral change, most models remained dependent on structured EHR fields.

Reporting of missing data handling, class imbalance, and interpretability was uneven (Table 7). Missing data handling was not reported in 24% (7/29) of the studies, and class imbalance handling was absent or not reported in 55% (16/29) of the studies. Interpretability was addressed most often through post hoc feature attribution (14/29, 48%) or intrinsically interpretable models (7/29, 24%), but these explanations were rarely linked to clinical workflow decisions.

[a]DL: deep learning.

[b]ML: machine learning.

Overall, model development methods show that EHR-based delirium prediction is technically feasible, but the clinical value of additional data complexity remains uncertain without stronger validation, calibration, and implementation testing.

Model Performance

Model discrimination is summarized in Table 8, with additional model performance metrics, including sensitivity, specificity, PPV, negative predictive value (NPV), and threshold definitions provided in Multimedia Appendix 3 [14-42]. Reported discrimination suggested promising technical performance but should be interpreted cautiously. Of 29 studies, internal AUROC was reported in 24 (83%) studies, with values ranging from 0.77 [24] to 0.97 [23]. Confidence intervals were inconsistently reported, and the internal estimates came from heterogeneous designs, including split-sample validation, cross-validation, temporal evaluation, and prospective cohorts.

Of 29 studies, external AUROC was reported in 12 (41%) studies [15,17,19,24,25,27,29,33,34,37,38,40]. Values ranged from 0.69 in prospective validation [38] to approximately 0.95 in large multisite evaluations [40]. However, external validation datasets differed substantially in clinical setting, prevalence, and outcome definition, limiting direct ranking of models.

Precision-recall performance and threshold reporting are summarized in Table 9. Precision-recall performance was much less frequently reported than AUROC. Of 29 studies, internal precision–recall area under the curve (PR-AUC) was reported in 6 (21%) studies [19-21,30,32,39], and external PR-AUC in 2 (7%) [19,33] studies. This is an important gap because many delirium prediction settings are low-prevalence tasks where AUROC can appear favorable despite limited PPV.

[b]NR: not reported.

[c]MCC: Matthews Correlation Coefficient.

[d]AUPRC: Area under the precision-recall curve.

[e]PIPRA: Pre-Interventional Preventive Risk Assessment.

Threshold-based metrics were difficult to compare. Although sensitivity, specificity, PPV, and NPV were often reported, thresholds were selected using different strategies, including data-driven optimization, fixed probability thresholds, and percentile-based risk strata. Few studies justified thresholds in relation to clinical resources, alert burden, or the intended intervention.

The performance synthesis therefore supports a cautious conclusion: routinely collected EHR data can discriminate delirium risk, but discrimination alone does not establish clinical usefulness. For deployment, external calibration, threshold consequences, and decision-analytic benefit are as important as AUROC.

Validation, Calibration, and Implementation Characteristics

Validation strategies are summarized in Table 10 and show a clear gap between model development and transportability testing. Of 29 studies, 9 (31%) reported internal validation only, 8 (28%) combined internal and external validation, 2 (7%) focused on external validation only, and 2 (7%) reported temporal validation only. Of 29 studies, 3 (10%) were prospective evaluations without a distinct internal or external validation phase; 2 (7%) combined external validation with prospective evaluation; 2 (7%) combined internal, external, and prospective evaluation; and 1 (3%) reported apparent performance only.

[a]ED: emergency department.

Overall, 16 studies reported some form of external or prospective validation [14,15,17,19,23-25,27-29,33,34,37,38,40,41]. Most external validation tested transfer across hospitals, health systems, time periods, or critical care databases. Cross-setting validation, such as applying an ICU-derived model to ward patients or vice versa, was uncommon.

Among the 7 studies with directly comparable internal and external AUROC values, 5 (71%) showed lower discrimination after external validation (Figure 2). The magnitude of decline varied, indicating that performance transportability was influenced by differences in population, data capture, outcome ascertainment, and workflow context.

XSL•FO
RenderX

Figure 2. Comparison of internal and external AUROC values among studies reporting directly comparable discrimination results. AUROC: area under the receiver operating characteristic curve [19,24,25,29,33,34,38].

In this subset, mean internal AUROC was 0.845 and mean external AUROC was 0.772, corresponding to a mean change of −0.073. This descriptive comparison should not be interpreted as a pooled effect estimate, but it illustrates the risk of relying on internal performance when judging deployment readiness.

The external validation evidence was therefore mixed: several models remained discriminative outside their development data, but validation was often conducted in settings similar to the development environment. Evidence for robust transport across substantially different institutions, care pathways, and outcome assessment practices remains limited.

Calibration methods and decision curve analysis are summarized in Table 11. Of 29 studies, calibration was assessed in 15 (52%) studies [15-17,21,24-28,30,32,33,36,37,41]. Methods included calibration plots, Brier scores, Hosmer-Lemeshow tests, calibration slope or calibration-in-the-large, Platt scaling, isotonic regression, and expected calibration error. The diversity of methods, combined with incomplete reporting, made calibration difficult to compare across studies.

Sun et al (2021) [40]	Not reported	No
Sun et al (2022) [41]	Isotonic regression; calibration plots	Yes
Wong et al (2018) [42]	Platt scaling; calibration plots	No

Calibration reporting was often less mature than discrimination reporting. Several studies relied mainly on visual assessment, and recalibration after external validation was rare. Of 29 studies, decision curve analysis was reported in only 3 (10%) [17,25,41], leaving limited evidence about whether model-guided decisions would improve net clinical benefit.

Prospective evaluation and implementation characteristics are summarized in Table 12. Of 29 studies, 8 (28%) included prospective evaluation [26-28,34,36-38,41], and 9 (31%) reported some form of workflow integration or implementation testing [26-28,34,36-38,40,41]. These ranged from silent prospective validation to live EHR alerts, but few assessed downstream effects on clinician behavior, prevention delivery, alert burden, or patient outcomes.

[d]EMR: electronic medical record.

Risk of Bias and Applicability

Risk of bias was assessed using PROBAST, with domain-level judgments summarized in Multimedia Appendix 4 [14-42] and overall proportions illustrated in Figure 3. Of 29 studies, overall risk of bias was judged low in 8 (28%), unclear in 10 (34%), and high in 11 (38%). The main pattern was not a lack of clinical relevance but limited methodological assurance.

XSL•FO
RenderX

Figure 3. PROBAST (Prediction Model Risk of Bias Assessment Tool) stacked bar. ROB: risk of bias.

Low-risk studies generally had clearer participant selection, predictor timing, outcome ascertainment, and model evaluation [15,16,21,25,32,33,36,39]. These studies provide the most reliable evidence that routinely collected data can support delirium prediction.

Studies with unclear risk of bias were usually limited by incomplete reporting rather than obvious methodological failure [17,20,22,23,29-31,35,37,42]. Common sources of uncertainty included missing data handling, calibration assessment, feature selection, and validation procedures.

High risk of bias was identified in 11 studies, most often because of analysis-domain limitations [14,18,19,24,26-28,34,38,40,41]. Recurrent issues included apparent-only performance reporting, case-control designs, inadequate handling or reporting of missing data, limited calibration assessment, and incomplete reporting of feature selection.

Within the 11 high-risk studies, inadequate handling or reporting of missing data was identified in 6 studies [26-28,34,38,41], limited or absent calibration assessment in 4 studies [14,19,34,38], apparent-only performance without validation in 1 study [18], case-control design in 2 studies [24,40], and incomplete feature selection reporting in 2 studies [14,19]. Several studies had more than 1 limitation.

These risk-of-bias findings help explain why high AUROC values should not be interpreted as readiness for practice. Models can appear accurate in development datasets while still being vulnerable to overfitting, miscalibration, missing data artifacts, or poor transportability.

Applicability concerns were more limited than risk-of-bias concerns. Most studies evaluated adult inpatient populations and used routinely collected EHR predictors, supporting broad relevance to hospital practice. However, applicability was still context-dependent for ICU-only, perioperative, emergency department, rehabilitation, COVID-19, and single health system models.

The overall quality assessment therefore supports a nuanced interpretation: the field is clinically relevant and technically active, but the evidence base is not yet consistently strong enough to support unqualified clinical deployment. No study was excluded on the basis of PROBAST assessment. Instead, risk-of-bias judgments were used to interpret how much confidence should be placed in the reported performance and implementation claims.

Discussion

Principal Findings

This systematic review included 29 studies developing, validating, or evaluating prediction models for in-hospital delirium using routinely collected EHR data. The principal finding is that EHR-based delirium prediction is feasible across several hospital settings, but the current evidence is fragmented across different clinical prediction tasks. The literature supports the existence of measurable risk signals in routine data; it does not yet establish that any model class is consistently ready for routine clinical deployment.

Four findings are especially important for readers. First, most models were developed retrospectively, and only a minority underwent prospective evaluation or workflow testing. Second, model performance was commonly summarized by AUROC, while calibration, precision-recall metrics, and decision-analytic evaluation were less consistently reported. Third, increased algorithmic complexity did not consistently translate into better or more transportable performance. Fourth, risk of bias was

XSL•FO
RenderX

mainly driven by analysis-domain limitations rather than by lack of clinical relevance.

These findings indicate that the next stage of the field should be less focused on producing additional internally validated models and more focused on defining clinical use cases, testing transportability, calibrating models for local populations, and evaluating whether model-guided care changes decisions or outcomes.

Interpretation in Context of Existing Literature

The heterogeneity observed in this review is consistent with previous systematic reviews of delirium prediction and broader clinical prediction modeling research [6-8]. Models differed not only in algorithm type but also in clinical setting, prediction timing, outcome ascertainment, and validation design. These differences mean that a single pooled estimate of performance would be difficult to interpret and could obscure clinically meaningful distinctions between prediction tasks.

The predominance of machine learning approaches also mirrors wider trends in hospital and critical care prediction research [43]. However, this review suggests that algorithmic sophistication is not the main bottleneck. In several studies, simpler statistical or tree-based approaches performed similarly to deep learning models, especially when evaluated under comparable conditions. Data quality, predictor timing, outcome definition, and validation context appeared at least as important as model family.

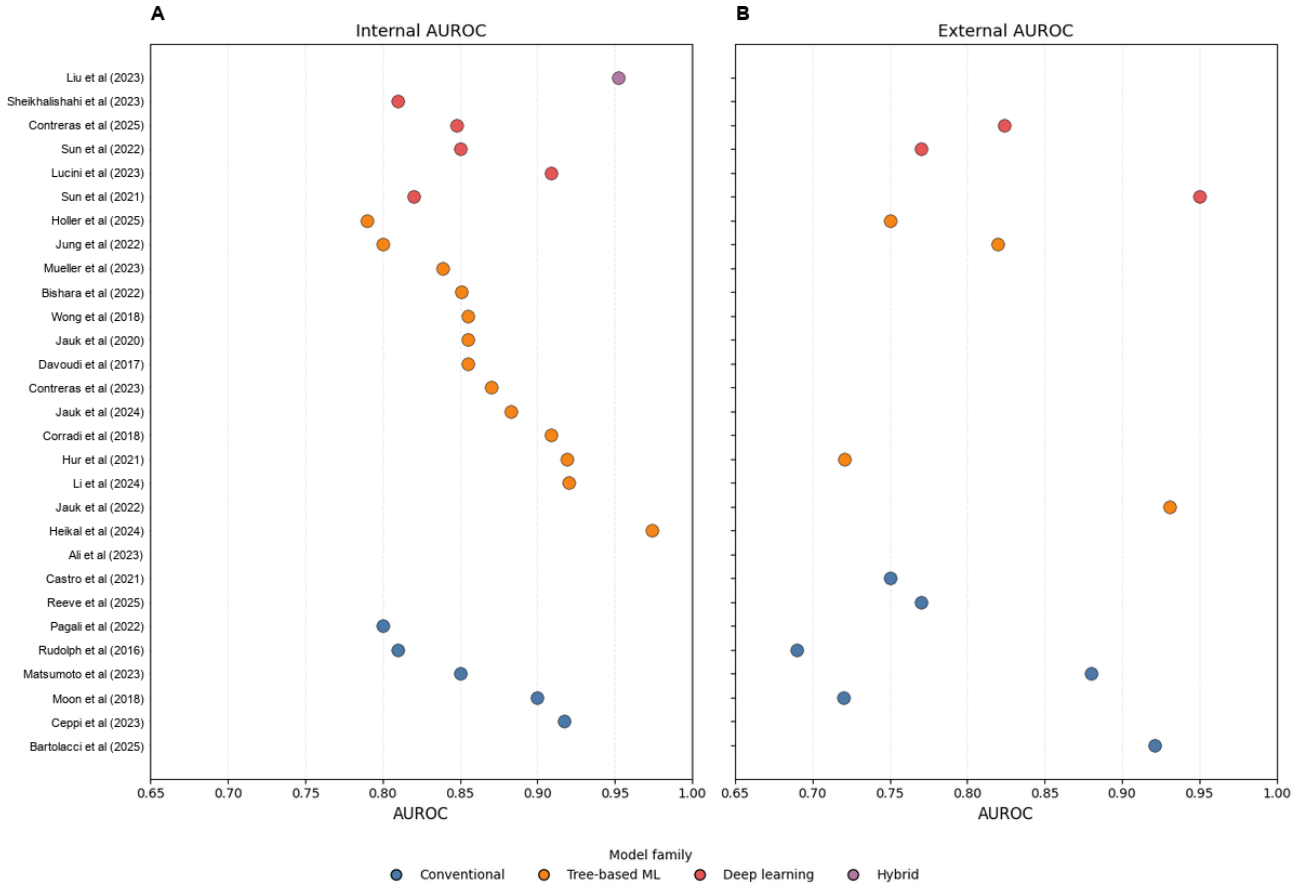
The risk-of-bias patterns also align with metaresearch showing that many published prediction models have limitations in the analysis domain, including missing data handling, overfitting, and incomplete calibration assessment [44]. Evidence that high-risk models often perform less well in external validation [45] is directly relevant here, because several delirium models showed lower discrimination when tested beyond their development data.

Clinical Implications

Clinically, delirium prediction models are attractive because they could help target prevention, screening, and staffing resources to patients most likely to benefit. The reviewed studies show that routine EHR data contain useful risk information in ward, ICU, perioperative, and emergency care contexts. This supports continued development of delirium prediction as a component of clinical decision support.

The implementation evidence, however, remains incomplete. Few studies assessed whether predictions changed clinician behavior, reduced delirium incidence, improved patient outcomes, or avoided alert fatigue. Without these evaluations, models with favorable discrimination may still have limited value in practice, particularly if thresholds are poorly calibrated to local prevalence and available resources.

Methodological Implications



Model Complexity and Performance

Across studies that directly compared modeling approaches, there was no consistent evidence that more complex models outperformed simpler alternatives. Tree-based machine learning, penalized regression, rule-based tools, and neural network approaches all achieved overlapping discrimination ranges. In several cases, models with favorable internal performance did not retain a clear advantage during external validation.

This finding does not imply that complex models are unnecessary, particularly for dynamic ICU prediction or high-dimensional time series data. Rather, it suggests that model choice should follow the clinical task, data structure, interpretability requirements, and implementation constraints. For many hospital use cases, a well-calibrated and externally validated simpler model may be more useful than a complex model with opaque behavior and limited transportability evidence. The relationship between model family and reported AUROC is shown descriptively for internal and external performance in Figures 4A and 4B, respectively.

XSL•FO
RenderX

Figure 4. Reported AUROC by final model family across included studies: (A) internal AUROC; (B) external AUROC. AUROC: area under the receiver operating characteristic curve; ML: machine learning [14-42].

Prediction Horizon and Task Comparability

Prediction horizon was one of the most important sources of heterogeneity. Admission-time models, perioperative models, rolling ICU models, and full-stay prediction models answer different clinical questions. They differ in how early an intervention can be triggered, how close predictors are to delirium onset, and how much uncertainty remains at the time of prediction.

Consequently, comparing AUROC values across prediction horizons can be misleading. A dynamic model predicting delirium in the next 12 hours may appear stronger partly because it uses proximal physiological information, whereas an admission-time model may be clinically valuable precisely because it operates before deterioration is obvious. Future studies should therefore define the intended prediction moment and intervention pathway before evaluating performance.

Validation and Generalizability

External validation remains the key step separating promising models from generalizable tools. Although some studies tested models outside the development dataset, validation often occurred in similar clinical settings or related health systems. Cross-setting validation and temporal validation were less common, despite being highly relevant for EHR models whose predictors and labels can change with local documentation practices.

The observed decline from internal to external AUROC in most directly comparable studies reinforces the need for conservative interpretation. Models intended for deployment should be tested across institutions, time periods, and patient groups that reflect their proposed use, and they should be recalibrated when transported to new settings.

Calibration and Reliability

Calibration is central to clinical reliability but was inconsistently assessed. Good discrimination indicates that a model can rank patients by risk; it does not show that predicted probabilities are accurate. For delirium prevention, inaccurate probabilities may lead to undertreatment of truly high-risk patients or excessive alerts for patients unlikely to develop delirium.

The limited use of recalibration and decision curve analysis is therefore a major evidence gap. Before deployment, models should report calibration-in-the-large, calibration slope, calibration plots, and clinically meaningful threshold analyses. Decision curve analysis or equivalent usefulness-based evaluation can help determine whether the model adds value beyond usual care or simpler screening rules.

Class Imbalance and Performance Metrics

Outcome prevalence varied widely, and several cohorts had low delirium prevalence. In such settings, AUROC can overstate practical usefulness because it is insensitive to the number of false positives generated at a chosen threshold. PPV and PR-AUC are especially important when the intended

XSL•FO
RenderX

intervention is resource-intensive or when repeated alerts could reduce clinician trust.

The limited reporting of PR-AUC and threshold rationale therefore weakens the clinical interpretability of many studies. Future work should present threshold-specific consequences, including the number of patients flagged, false positives, false negatives, and expected resource implications at clinically plausible operating points.

Threshold Selection and Implementation

Threshold selection should be treated as a clinical design decision rather than a statistical afterthought. Data-driven thresholds such as Youden index may maximize a performance statistic in a development dataset, but they may not match local prevention capacity or acceptable alert burden. Fixed thresholds and percentile-based risk groups can be easier to implement, but they also require calibration to local prevalence and workflow.

For clinical deployment, threshold selection should be linked to the intended action: enhanced screening, multicomponent prevention, geriatric consultation, medication review, or ICU-specific intervention. The acceptable balance between sensitivity and specificity will differ across these use cases.

Use of Unstructured Data and NLP

The limited use of unstructured data is notable because delirium symptoms are often documented in narrative nursing, medical, and allied health notes. NLP may therefore improve both outcome ascertainment and predictor representation. However, free-text models raise additional challenges, including annotation burden, governance, changing documentation practices, and transportability across institutions. Future NLP-enhanced models should distinguish clearly between using language data to define the outcome and using language data as predictors. These uses have different risks for information leakage, temporal validity, and clinical implementation.

Implementation Considerations

Several findings have direct implications for deployment. A model should not be implemented solely because it has a high AUROC. It should have an explicitly defined clinical role, evidence of calibration in the target population, threshold analyses tied to available resources, and prospective evaluation showing that predictions can be acted on without excessive alert burden.

Implementation studies should therefore evaluate not only model performance but also workflow fit, clinician response, alert fatigue, equity, prevention delivery, and patient outcomes. This is particularly important for delirium, where prediction is useful only if it leads to timely and feasible prevention or treatment.

Limitations

Several limitations should be considered when interpreting the findings of this review. First, the quality of the included evidence base was variable, with a substantial proportion of studies judged to be at high risk of bias, primarily due to analytical limitations. Second, external validation and prospective evaluation were inconsistently performed, limiting confidence in the generalizability of reported performance.

This review also has inherent limitations. Only English-language studies were included, which may introduce language bias. The review was not prospectively registered before screening began, which may increase the risk of reporting bias. In addition, substantial heterogeneity in study design, outcome definitions, and reporting precluded formal meta-analysis. Finally, risk-of-bias assessment relied on the completeness of reporting in the original studies, which may have resulted in conservative or unclear judgments in some cases.

Future Research Directions

Future research should move from model development toward clinically anchored validation and evaluation. The immediate priority is external and temporal validation across heterogeneous populations, with calibration assessed in ways that can support local recalibration rather than only discrimination ranking.

Implementation research should then test whether predictions change care in practice. Studies should specify the intended intervention pathway, alert threshold, resource assumptions, and monitoring plan before deployment, and should measure clinician response, alert burden, prevention delivery, equity, resource use, and patient outcomes.

Reporting should make threshold consequences easy to interpret. Future studies should present the number of patients flagged, false positives, false negatives, and expected workload at clinically plausible operating points so that health systems can judge whether a model is compatible with local capacity.

Future models may benefit from combining structured EHR variables with unstructured clinical notes, because cognitive and behavioral changes are often documented narratively. NLP-enhanced models should distinguish outcome ascertainment from predictor use, and maintain temporal separation between predictors and outcomes to avoid information leakage.

Expansion beyond delirium to broader acute mental status deterioration may be valuable only when outcomes are clearly defined, temporally valid, and clinically actionable. Across all future work, transparent reporting and alignment with TRIPOD, TRIPOD-AI, CHARMS, and PROBAST will be essential to move from technically promising models toward reliable decision-support tools.

Conclusions

Routinely collected EHR data can support delirium prediction across hospital settings, but favorable discrimination alone does not establish clinical readiness. The evidence remains heterogeneous in outcome definition, prediction timing, prevalence, validation strategy, calibration reporting, and implementation maturity; risk of bias, particularly in the analysis domain, also remains common. More complex algorithms did not consistently improve performance. Future work should prioritize externally validated, well-calibrated, and clinically interpretable models evaluated prospectively within real workflows, with explicit attention to threshold consequences, alert burden, and patient benefit.

Abstract

Background: Psychiatric clinical notes in electronic health records (EHRs) provide rich longitudinal information that can support clinical decision-making. Using historical medical data can enable earlier identification of mental illness, better characterization of disease trajectories, and more personalized treatment planning. Natural language processing (NLP) transforms these unstructured notes into analyzable representations for research and care.

Objective: This study aims to systematically summarize NLP methodologies for psychiatric clinical notes, compare major modeling paradigms and application areas, and highlight emerging large language model (LLM) trends, key challenges, and future research directions.

Methods: Following the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) guidelines, a literature search was conducted for articles on NLP methods based on psychiatric clinical notes published from January 2021 to December 2025 in Ovid MEDLINE, Ovid EMBASE, PubMed, Scopus, Web of Science, the ACM Digital Library, and ScienceDirect. This scoping review analyzed NLP methods applied to psychiatric clinical notes, focusing on major trends, identifying suitable features for traditional machine learning (ML)–based models, applications of pretrained language models (PLMs), and key challenges. Approaches were categorized as rule-based, traditional ML, hybrid, deep learning (DL), and LLM-based methods across information extraction and text classification tasks.

Results: In total, 101 studies were eligible for inclusion. Rule-based methods (n=36) and hybrid approaches (n=34) remained the most widely used techniques, largely favored for their interpretability in handling nuanced, subjective clinical notes. These were followed by DL (n=15), traditional ML (n=10), and LLM-based approaches (n=6). Traditional ML studies relied heavily on engineered features, which could be grouped into 5 broad categories: domain knowledge features, lexical and statistical features, vector-based semantic features, emotion-related features, and temporal features. PLMs improved performance mainly through domain adaptation and task-specific fine-tuning, enhancing the handling of psychiatric language, medical terminology, and clinical note structure. LLM-based studies, although still limited in number, indicated a growing shift toward generative and reasoning-based applications.

Conclusions: Hybrid NLP approaches remain dominant, combining domain rules with ML for extraction and classification. DL approaches continue to advance, with domain adaptation supporting medical terminology and clinical semantics. LLMs may further automate complex workflows via zero-shot capabilities and reasoning, alongside growing interest in temporal modeling and multimodal integration. Key future needs include improved generalizability across institutions, privacy protection, and careful attention to ethical implications in clinical deployment.

KEYWORDS

psychiatric clinical notes; electronic health records; natural language processing; large language models; information extraction

Introduction

Mental illness, also known as psychiatric disorders, is a prevalent problem worldwide and continues to be one of the most serious public health issues [1]. There are many different types of mental illness, including depression, suicidal ideation, bipolar disorder, autism spectrum disorder (ASD), anxiety disorders, schizophrenia, etc. All kinds of mental illness negatively affect an individual's physical health and well-being, and the COVID-19 epidemic has further exacerbated this problem [2]. According to recent statistics, millions of people worldwide experience one or more psychological disorders [1]. Therefore, it is of great significance to study the development trajectory and potential mechanisms of mental illness based on scientific and objective measurement methods, and to promote the development of early diagnosis, personalized medicine, and precision treatment strategies for mental illness.

Language plays a central role in mental health, serving as a medium for expressing symptoms, delivering therapy, and assessing clinical conditions. Traditionally, language analysis in psychiatry has relied on expert opinions, clinical ratings, and manual methods, which are often subjective, incomplete, or prone to inaccuracies. Automated language analysis offers a transformative opportunity to shift from subjective clinical judgment to "measurement-based care" [3], enabling robust, quantitative, and scalable tracking of language variables. This advancement has the potential to revolutionize psychiatric practice and research.

Electronic health records (EHRs) are a rich source of health care data and have been widely used to record patient medical histories [4]. Psychiatric EHRs often include narrative clinical notes that contain valuable information for advancing clinical research and health care [5]. However, much of this clinical information remains locked in unstructured text [6], posing challenges for systematic analysis. In the field of psychiatry, standardized measures of patients are used inconsistently and infrequently in clinical practice. Due to the heterogeneity and complexity of clinical notes, along with its diverse application scopes, the application of natural language processing (NLP) in clinical notes still needs to be further explored.

The rise of statistical NLP in the 1990s [7] and recent advances in deep learning (DL) technology [8,9] have influenced the methods used in clinical notes analysis. A pivotal turning point in this trajectory was the introduction of the Transformer architecture, which enabled a new modeling paradigm: pretrained language models (PLMs), such as Bidirectional Encoder Representations from Transformers (BERT) [10]. PLMs are first trained on large, general-purpose text corpora via self-supervised objectives, then adapted to specific downstream tasks through fine-tuning — substantially reducing dependence on large manually annotated datasets. With the rapid expansion of computational resources, PLMs were subsequently scaled to billions of parameters, giving rise to large language models (LLMs), such as GPT and Gemini, which demonstrate superior performance across a wide range of NLP tasks, including text classification, entity recognition, summarization, sentiment analysis, and text generation [11]. Clinical applications for clinical notes, such as summarization and information extraction [12,13], have been widely used to assist in disease diagnosis, including suicide screening [14], depression identification [15], and mental state prediction [16].

Several recent reviews have explored various aspects of NLP in mental health, each with distinct focuses. Some reviews are highly specialized, concentrating on specific aspects such as mental illness detection [17] or intervention tools [18]. Other reviews do not incorporate the recent breakthroughs, such as the development and application of attention mechanisms, transformers, and pretrained LLMs. Reviews such as Le Glaz et al [19] primarily focus on traditional NLP and machine learning (ML) techniques applied across mental health domains. Meanwhile, Jin et al [20] provide a high-level overview of LLM applications and performance metrics without diving into the specific methodological challenges of working with clinical notes. Given these gaps, this scoping review aims to provide a comprehensive and methodologically detailed examination of NLP methods applied specifically to psychiatric clinical notes. We focus on the latest trends, tools, and challenges in using NLP for mental illness research based on clinical notes.

This scoping review aimed to address the following research questions:

1. What are the major NLP trends and methods for clinical notes analysis in psychiatric disorders?
2. In traditional ML-based models, which features of clinical notes are suitable for extraction for downstream research on mental illness?
3. How to apply PLMs to improve the performance of text-based models in the field of mental illness?
4. What are the main challenges and future directions for NLP in clinical notes of psychiatric disorders?

Methods

Design and Protocol Registration

This scoping review was conducted in accordance with the Joanna Briggs Institute guidance for scoping reviews and reported in compliance with the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) [21-23]. A formal protocol was not prospectively registered. The review protocol was retrospectively registered in the Open Science Framework [24]. The completed PRISMA-ScR checklist can be found in Checklist 1.

Our search included any document published from January 2021 to December 2025. We selected 2021 as the starting year to position this review as an update to prior broad mental health NLP reviews and to focus on the most recent methodological phase of the field.

XSL•FO
RenderX

Information Sources and Search Strategy

A systematic electronic search was developed with an experienced librarian and implemented across 7 databases: Ovid MEDLINE, Ovid EMBASE, PubMed, Scopus, Web of Science, the ACM Digital Library, and ScienceDirect. The search was first performed on January 16, 2024, and then updated with a second search on December 15, 2025.

The search strategy combined controlled vocabulary terms, where available, and free-text terms covering 3 core concepts: (1) psychiatric or mental disorders, (2) clinical notes or electronic health records, and (3) NLP or text mining. Database-specific syntax, subject headings, field tags, and adjacency operators were adapted for each source while preserving the same conceptual structure across databases. The full search strategies for all databases are reported in Multimedia Appendix 1.

All retrieved citations were exported to Zotero. Duplicate records were removed in 2 stages: (1) automated deduplication using bibliographic fields such as title, author, year, journal, and DOI or PMID, followed by (2) manual review of potential duplicate pairs.

Inclusion and Exclusion Criteria

We included English-language full-text journal articles and full conference or workshop papers that reported completed studies using NLP methods applied to English psychiatric clinical notes, and that made a methodological contribution. Studies using quantitative, qualitative, or mixed-method designs were eligible if they described completed research.

We excluded abstract-only publications, study protocols, review articles, editorials, and papers without sufficient full-text methodological detail. We also excluded studies in which the primary text source was not psychiatric clinical notes; examples included interviews, speech or voice data, social media posts, or general clinical text unrelated to mental health. Studies were also excluded if they did not apply NLP methods or if their application was not specific to psychiatry or mental illness (eg, deidentification or redundancy removal).

Study Selection and Screening Process

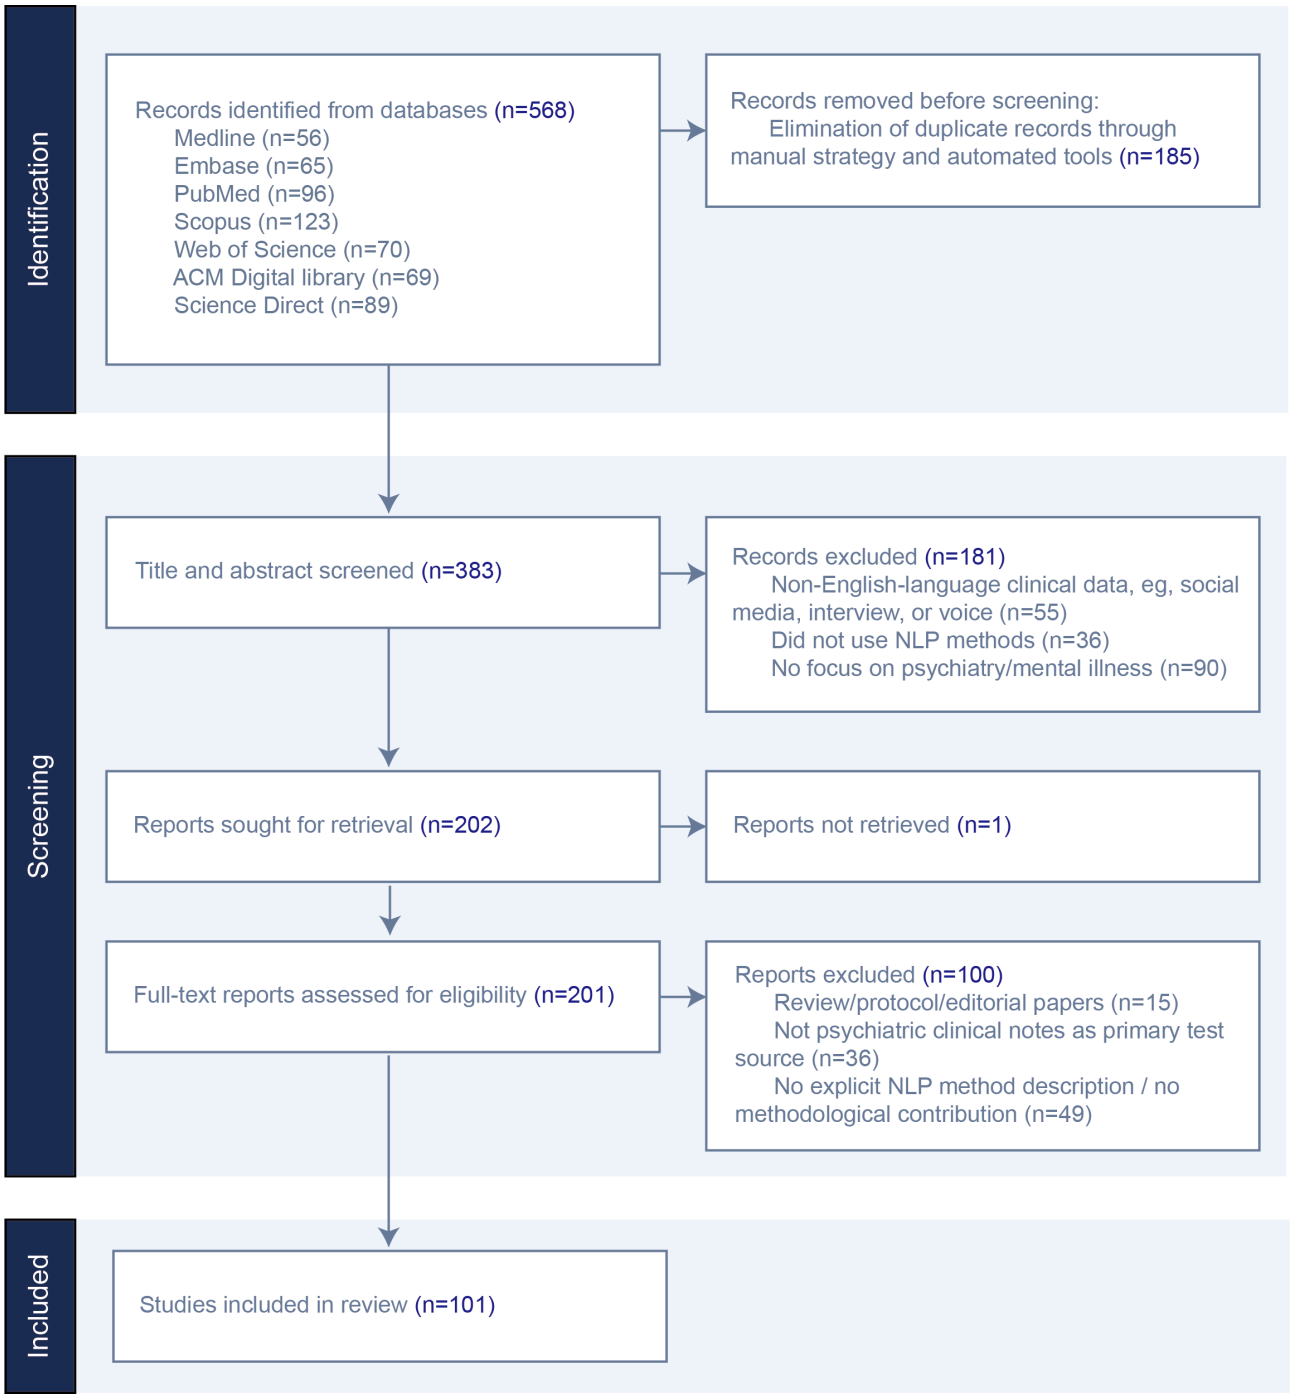
Initial screening of the titles and abstracts was conducted independently by 2 reviewers either (SR and TJ) or (GD and JX). The records were divided between 2 reviewer pairs (SR with TJ, and GD with JX), and each record was assessed by 1 reviewer pair. At this stage, each article was categorized into one of the following groups: (1) fully met the inclusion criteria, (2) did not analyze clinical data, (3) did not use NLP methods, (4) did not focus on mental illness, and (5) had unclear eligibility for inclusion. To maximize sensitivity, records were advanced to full-text review whenever eligibility could not be determined from the title and abstract alone.

Full-text eligibility assessment followed the same procedure, with each report independently assessed by 2 reviewers within 1 reviewer pair. At this stage, all inclusion criteria had to be met for a study to be retained in the review. Disagreements at either stage were first resolved through discussion within the reviewer pair; if consensus could not be reached, a third reviewer (XC) adjudicated the final decision.

Data Collection

The final data collection form used for peer-reviewed articles is shown in Table S1 in Multimedia Appendix 2. The information for each study included data sources, sample information, regions, NLP tasks, applied NLP methods, application domain, and psychiatric categories. These articles were divided into 5 parts (each part included 20 or 21 papers). A total of 5 researchers (SR, XC, GD, JX, and TJ) independently extracted data from each part of the papers. To ensure the accuracy of data extraction, we conducted a double-check process. The researchers cross-checked each other's work, reviewing the data extraction process.

For this scoping review, we developed a categorization framework based on NLP methodology approach applied for psychiatric clinical notes: rule-based, traditional ML, hybrid, DL, and LLM-based methods. Definitions of the key terms used throughout this review are provided in Multimedia Appendix 3.



Results

Overview

The initial search yielded 383 records after deduplication. Following title and abstract screening, 181 records were excluded, leaving 202 reports for full-text retrieval. Of these, 1 report could not be retrieved, and the remaining 201 were assessed for eligibility. Full-text screening resulted in the exclusion of a further 100 articles, with reasons detailed in Figure 1. Ultimately, 101 studies [25-125] were included in the scoping review, as shown in Multimedia Appendix 4. The results of the search and the study inclusion process are presented in the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart in Figure 1 [126].

XSL•FO
RenderX

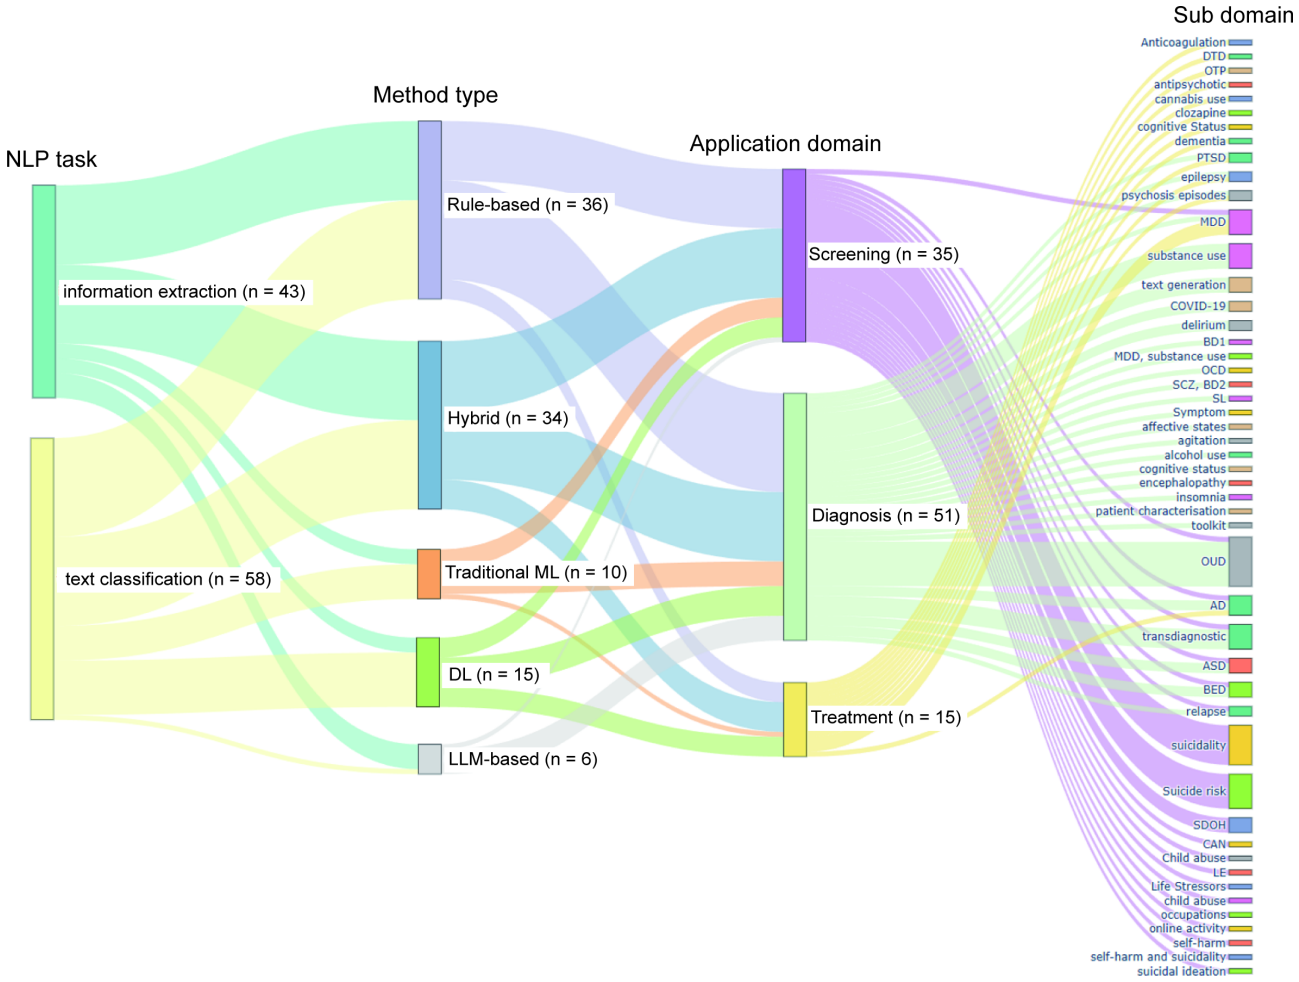


Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart of search history. EHR: electronic health records; NLP: natural language processing.

Across the 101 included studies [25-125], the identified tasks were broadly grouped into information extraction (IE) and text classification (TC), implemented using rule-based, traditional ML, hybrid, DL, and LLM-based approaches. Figure 2 presents a Sankey diagram [127] illustrating the relationships among NLP tasks, methods, and application domains in mental health. Specifically, the included studies were organized into three major application domains: screening, diagnosis, and treatment. Screening-related studies mainly focused on suicidal ideation, suicide risk, crisis prediction, and related risk detection; diagnostic applications involved symptom identification, disease classification, phenotype characterization, and comorbidity recognition; and treatment-related studies addressed drug information extraction, treatment quality assessment, and outcome prediction. Together, these pathways highlight the interdisciplinary nature of applying NLP to psychological assessment and intervention by demonstrating how various computational techniques interconnect across different domains.

XSL•FO
RenderX

Figure 2. Sankey diagram of natural language processing (NLP) tasks, methods, and clinical applications across the 101 included studies. The diagram is read from left to right, linking NLP task categories (information extraction and text classification) to method types (rule-based, hybrid, traditional machine learning (ML), deep learning (DL), and large language model [LLM]–based approaches), then to the 3 main clinical application domains (screening, diagnosis, and treatment), and finally to specific psychiatric subdomains. The width of each flow is proportional to the number of studies following that pathway, thereby showing how specific NLP tasks and methods connect to downstream clinical applications. AD: Alzheimer disease; ASD: autism spectrum disorder; BD1: behavioral disturbance; BD2: bipolar disorders; BED: binge-eating disorder; CAN: child abuse and neglect; CVD: cardiovascular disease; DTD: difficult-to-treat depression; LE: life events; MDD: major depressive disorder; OCD: obsessive-compulsive disorder; OTP: opioid treatment program; OUD: opioid use disorder; PTSD: posttraumatic stress disorder; SCZ: schizophrenia; SDOH: social determinants of health; SL: stigmatizing language.

The following subsections detail the resources (including data sources and knowledge bases) and a systematic review of modeling approaches ranging from rule-based and traditional ML to hybrid, DL, and the latest LLM-based approaches. Finally, we address model evaluation metrics and performance. Although many techniques overlap with general clinical NLP, the distinctive characteristics of psychiatric notes and mental health care challenges require specialized resources, methods, and considerations.

Resources

Clinical notes in the reviewed studies were primarily sourced from medical institutions, with access typically requiring data use applications and institutional review board approval due to privacy concerns. Among the 101 included studies, data were drawn from 42 medical institutions and only one public database, the MIMIC-III dataset [128], underscoring the limited availability of openly accessible psychiatric EHR resources. Specialized psychiatric data sources, particularly the South London and Maudsley NHS Foundation Trust [129] and the US Department of Veterans Affairs (VA) [130], were among the most frequently used, appearing in 24 and 9 studies, respectively. In addition, Rush University Medical Center's Substance Use Intervention Team (SUIT) [131] program contributed data to five studies on opioid addiction. Overall, the heavy reliance on institution-specific proprietary databases indicates substantial fragmentation in the current resource landscape, which may hinder reproducibility, external validation, and cross-institutional collaboration. A detailed distribution of data sources is provided in Multimedia Appendix 5.

The Observational Medical Outcomes Partnership (OMOP) common data model is an open standard designed to standardize observational data, enabling efficient and reliable analyses [132]. In [25,26], the OMOP common data model was used to harmonize clinical data, including diagnostic codes, demographics, and clinical notes. Similarly, the Health Level 7 (HL7) Fast Healthcare Interoperability Resources (FHIR) standard facilitates health care data exchange using modern web technologies, organizing data into modular "resources" accessible via RESTful APIs [133]. Afshar et al [27] used HL7

XSL•FO
RenderX

data standards to transfer EHR data to the cloud, supporting the deployment of a real-time NLP CDS tool for opioid misuse screening. However, the adoption of these standards in mental health remains limited due to challenges such as customization requirements, integration complexity, and privacy concerns. Future advancements in data-sharing frameworks and public dataset availability may enhance research in this field.

Standard terminology sets are foundational for NLP in psychiatric clinical notes by providing unified concepts and formats that support interoperability across institutions and systems. Commonly used terminologies include the Unified Medical Language System (UMLS) [134], Systematized Nomenclature of Medicine–Clinical Terms (SNOMED-CT) [135], *International Classification of Diseases, Ninth Revision* (*ICD-9*) and *International Classification of Diseases, Tenth Revision* (*ICD-10*) [136], and RxNorm [137] for drug information. Psychiatric clinical notes analysis also faces distinct needs—complex diagnostic criteria, behavioral assessments, subjective language, strict confidentiality, and longitudinal monitoring—so domain-specific resources are often essential. The *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (*DSM-V*) provides standardized diagnostic criteria for mental disorders [138], while the Addiction Behaviors Checklist (ABC) supports structured assessment of addictive behaviors [139]. Links to these terminology sets are provided in Table 1.

Table . An overview of the dictionaries and knowledge bases used for extracting information (data) from clinical notes.

Dictionary or knowledge base	Description	Examples
UMLS[a] [134]	Biomedical thesaurus organized by concept and it links similar names for the same concept	[28]
SNOMED-CT[b] [135]	A globally accepted medical terminology system	[29]
ICD[c] [136]	Knowledge on the extent, causes, and consequences of human disease and death worldwide	[30]
DSM[d] [138]	Standardized classification and criteria for diagnosing mental disorders	[31]
RxNorm [137]	A standardized nomenclature for clinical drugs	[32]
ABC[e] [139]	A scale commonly used to assess an individual's addictive behavior	[33]

[a]UMLS: Unified Medical Language System.

[b]SNOMED-CT: Systematized Nomenclature of Medicine–Clinical Terms.

[c]*ICD*: *International Classification of Diseases.*

[d]*DSM*: *Diagnostic and Statistical Manual of Mental Disorders*.

[e]ABC: Addiction Behaviors Checklist.

Rule-Based Approaches

Rule-based approaches use predefined rules and keyword-based features to identify patterns in text [140], offering transparency, traceability, and cost-effectiveness by leveraging domain-specific knowledge without requiring large annotated datasets [141]. These methods often rely on clinical standards, guidelines, curated dictionaries, and knowledge bases, which can be easily updated and adapted [142]. Initial keyword lists are typically derived from expert domain knowledge or standard terminologies like UMLS, SNOMED-CT, and *ICD-9* and *ICD-10*, enabling comprehensive coverage of medical concepts. Rule-based NLP pipelines map free-text clinical notes to standardized ontologies (eg, UMLS) through medical concept normalization, identifying terms related to drugs, diagnoses, symptoms, and clinical measurements while expanding searches to related concept groups.

Clinical notes often contain nonstandard language, abbreviations, misspellings, and diverse expressions for the same symptom. Rule-based approaches refine terminology dictionaries using regular expression (RegEx) patterns and iterative feedback from domain experts [34,35]. They also identify modifiers—such as emotions (negation, affirmation), descriptive attributes (severity, duration), and annotation sections (medical history, assessment)—to contextualize concepts and exclude irrelevant mentions [32,36]. Negation detection, often using the NegEx algorithm [143], is a key application. Rule-based methods can also track symptom trajectories, as demonstrated by Young et al [37], who classified and monitored dynamic behavioral phenotypes in ICU patients over time.

However, relying solely on dictionary-based concept recognition cannot capture all essential information in clinical texts. To capture comprehensive information, custom rule sets are often developed, as detailed in [144]. Several NLP systems facilitate rule-based development, including MedLEE [145], MetaMap [146], clinical text analysis and knowledge extraction system (cTAKES) [147], Clinical Language Annotation, Modeling, and Processing Toolkit (CLAMP) [148], and Biomedical Information Collection and Understanding System (BioMedICUS) [149], which are widely used for named entity recognition (NER) and IE in clinical and biomedical research [150].

Traditional Machine Learning Approaches

Traditional ML refers to a family of statistical and mathematical algorithms that learn patterns from data to make predictions or decisions, but typically require human-guided feature

XSL•FO
RenderX

engineering rather than automatically extracting hierarchical representations through multilayered neural networks. In TC tasks, traditional ML models such as Conditional Random Fields, support vector machines, structured support vector machines, logistic regression, Bayesian models, and random forests are commonly used. These models learn patterns from input data and labeled outputs without explicit programming [151], with their development process involving data preprocessing, feature extraction, modeling, optimization, and evaluation. Unlike DL, traditional ML requires significant human intervention for feature engineering. As summarized in Table 2, the most suitable features fall into five broad categories: domain knowledge features, lexical and statistical features, vector-based semantic features, emotion-related features, and temporal features. These features capture different aspects of psychiatric clinical notes that are relevant to downstream research. Domain knowledge and lexicon-based features are useful for identifying explicit symptom descriptions and clinically salient terminology; semantic vector representations help normalize variation in narrative expression; emotion-related features, extracted using tools like ABSApp [152], are particularly relevant for affective states and suicide risk [38]; and temporal features are important for modeling symptom progression [39], instability, and longitudinal risk. Together, these findings suggest that traditional ML is especially suited to settings where clinically interpretable features can be engineered from notes to support tasks such as phenotyping, subgroup discovery, outcome prediction, and risk stratification.

Table . An overview of features used in traditional machine learning-based models.

Features	Description	Examples
Domain knowledge features		
UMLS[a]	UMLS is a set of key terminology, coding standards, and associated resources related to biomedical information.	[28,29]
Lexical and statistical features		
BoW[b]	The simplest form of text representation using numbers of vocabularies.	[40]
n-gram	N-gram is a contiguous sequence of n words.	[41]
TF-IDF[c]	TF-IDF reflects the importance of the word in the document.	[31,42]
Vector-based semantic features		
Word embedding	The vector-based representation of words. Examples: word2vec, GloVe.	[43]
Emotion-related features		
Sentiment scores	Determining the sentiment polarity of texts (positive, negative, or neutral)	[38,44]
Temporal features		
Time features	Focusing on the time-related features, like time interval.	[39]

[a]UMLS: unified medical language system

[b]BoW: Bag of Words

[c]TF-IDF: term frequency–inverse document frequency

Most ML research in this field relies on supervised learning, which requires high-quality labeled data for effective model training. However, data labeling is time-consuming and challenging. Unsupervised learning methods, such as clustering [153] and latent Dirichlet allocation (LDA) topic modeling [45], can extract useful patterns without labeled data and may complement supervised classifiers [46]. Clustering methods, such as non-negative matrix factorization (NMF), can differentiate patient subgroups based on text features. Zhao et al [31] used TF-IDF to normalize ASD terms in clinical texts, revealing distinct ASD subgroups through clustering. Topic modeling, an unsupervised technique for identifying thematic patterns in text [154], represents topics as probability distributions over words. LDA topic modeling has successfully identified insomnia factors within military health systems [45] and transformed unstructured “chief complaints” into quantitative symptom clusters (eg, somatic or cognitive distress) [47]. Additionally, dynamic topic modeling (LDASeq) models how word distributions evolve over time by inducing conditional dependence between sequential intervals. By tracing the longitudinal prominence of themes such as “Suicide” or “Medication,” Levis et al [48] provide a mechanism for monitoring clinical “lability” and time-sensitive risk fluctuations in high-risk populations, offering insights into the dynamic nature of suicide risk that traditional static variables cannot capture.

Hybrid Approaches

The hybrid approach integrates rule-based and ML methods within a single system. In terminal hybrid models, rule-based systems perform feature extraction, producing structured outputs

XSL•FO
RenderX

that serve as inputs for ML models. Rule-based methods, leveraging dictionary lookup and pattern recognition, facilitate medical concept normalization. Feature engineering then vectorizes extracted data for ML applications. Ontologies further enhance NLP by capturing related concepts and contextual nuances, such as negation and speculation in clinical notes. For instance, phrases like “patient denies memory loss” or “possible onset of dementia” are accurately processed. IY Oh et al [49] applied this approach to extract clinical phenotypes from unstructured data, which was then used to train ML models for predicting Alzheimer disease progression and identifying modifiable risk factors.

Hybrid approaches also enhance ML-driven lexicon expansion and disambiguation. Developed open-source NLP software such as NimbleMiner [155] allows users to mine clinical texts to quickly discover large synonym vocabularies containing abbreviations and spelling errors based on word embedding models. For concept normalization, the Medical Concept Annotation Toolkit (MedCAT) [156] uses self-supervised embeddings to disambiguate candidates detected via dictionaries, accurately mapping mentions to the SNOMED-CT ontology even amidst linguistic noise.

Foundational infrastructures like the General Architecture for Text Engineering [157] facilitate hybrid NLP by enabling the integration of rule-based transducers, such as Java Annotation Patterns Engine, with diverse ML resources. A key application is TextHunter [158], which powers the CRIS-CODE project [159] by combining SVM for sentence classification with the rule-based ConText algorithm. By automating the detection of negation, temporality, and subject, TextHunter has successfully extracted over 40 mental health symptoms with a 90% median precision, supporting transdiagnostic research [50,51] and dynamic psychosis risk prediction [52]. Moreover, the CLARK [160] toolkit democratizes these hybrid methods for non-experts by allowing users to define clinical features through RegEx, which are then transformed into feature vectors for downstream ML classifiers. CLARK has demonstrated robust performance in identifying depression and substance use disorder diagnoses within medically complex populations [53]. Lately, VIEWER [54] enhanced mental health care by integrating hybrid NLP into visual analytics, providing a longitudinal, data-driven perspective of patient journeys. An overview of several prominent clinical NLP toolkits in psychiatry based on these hybrid approaches is provided in Table 3.

Table . An overview of clinical natural language processing toolkits in psychiatry based on hybrid approaches.

Toolkit	Description	Rule-based method	ML[a] method	Examples
GATE[b] [157]	A modular infrastructure for the full lifecycle of text analytics	JAPE[c] grammars for pattern matching and gazetteers	Pluggable models (SVM[d], Weka, DL)[e]	[55]
TextHunter [158]	A suite designed for psychiatric concept extraction and model building	ConText algorithm for negation and subject detection	SVM for high-precision sentence classification	[51,52]
CLARK [160]	A graphical interface for computable phenotyping by clinical researchers	User-defined RegEx for feature selection	Standard ML classifiers (RF[f], SVM, Naïve Bayes)	[53]
NimbleMiner [155]	A system for rapid lexicon discovery and mining through word similarity	High-precision regex search using enriched lexicons	Skip-gram word embeddings for finding semantic synonyms	[56]
MedCAT [156]	A toolkit for automated concept linking and disambiguation in clinical notes	Dictionary-based concept candidate detection	Self-supervised embeddings (Word2Vec) for disambiguation	[57]
VIEWER [54]	An interactive visual analytics tool for point-of-care decision support	Pattern matching for symptom and intervention detection	Distributed pipelines for automated clinical data extraction	Not available.

[a]ML: machine learning.

[b]GATE: General Architecture for Text Engineering.

[c]JAPE: Java Annotation Patterns Engine.

[d]SVM: support vector machine.

[e]DL: deep learning.

[f]RF: random forest.

Deep Learning Approaches

Traditional ML models rely on feature engineering, whereas DL frameworks automatically capture meaningful features without manual intervention [161]. DL, a subfield of ML, learns hierarchical representations through neural networks such as recurrent neural networks (RNNs), convolutional neural networks (CNNs), and transformers.

DL frameworks typically consist of an embedding layer and a classification layer [162]. Embedding techniques range from word embeddings to contextual encoders (eg, BERT [10] and ALBERT [163]). In classification layers, CNNs use convolutional filters to capture spatial relationships and pooling

XSL•FO
RenderX

layers to reduce computational complexity. In [58], a CNN-based multilabel classifier was developed to predict alcohol abuse, opioid abuse, and non-opioid substance abuse. This model demonstrated higher sensitivity than single-label classifiers, suggesting that integrating multiple substance abuse screenings into a single model can enhance clinical decision support and reduce alarm fatigue.

Beyond custom architectures, researchers have leveraged modular NLP frameworks to address specific psychiatric tasks with high data efficiency. By fine-tuning ScispaCy [164] to extract "health status" keywords from outpatient notes, Verter et al [59] achieved high precision (>92%) using minimal manual annotations. In addition, Med7 was a DL model originally trained on general physical health data [128], and in [165], it was further fine-tuned on the UK-CRIS database to extract granular pharmacological details (including dosages and titration schedules), thus enabling the comprehensive characterization of treatment resistance in a cohort of over 28,000 patients.

Recent advances in NLP have introduced PLMs — a class of deep neural models pretrained on large text corpora and adapted to specific tasks through fine-tuning. These PLMs, predominantly built on the Transformer architecture, demonstrate strong generalization across tasks and domains [10]. For instance, Ford et al [60] fine-tuned the BERT model for NER to identify 5 key concepts (diagnosis, medication, dosage, signs or symptoms, and substance use), coupled with a contextual classification model to determine the "Status" (eg, has, had, and does not have) and "Experiencer" (eg, patient vs. family member) of the extracted entities. This methodology was integrated into the Akrivia Health database [61] framework to process millions of patient records. Domain-specific adaptations such as BioBERT [166], MentalBERT [167], and Bio_ClinicalBERT [168] have also proven highly effective in clinical settings [62,169]. Building on these discriminative strengths, Xie et al [63] further integrated the generative capabilities of the text-to-text transfer transformer (T5) model [170] to capture complex epilepsy outcomes. T5 was used to transform unstructured notes into precise, structured data regarding seizure frequency and dates, effectively revealing the remitting-relapsing dynamics of epilepsy across large-scale EHRs.

LLM-Based Approaches

While PLMs transformed the field by facilitating the fine-tuning of broad representations for targeted clinical tasks, the emergence of generative LLMs marks a distinct evolutionary leap [171]. In this review, LLMs refer specifically to PLMs scaled to billions of parameters and built predominantly on decoder-only Transformer architectures. This massive scaling unlocks "emergent" abilities, most notably zero-shot chain-of-thought (CoT) reasoning [172] and in-context learning [173], allowing them to simulate complex clinical decision-making and generate coherent patient narratives without weight updates or extensive task-specific training data [174]. For example, Leng et al [64] demonstrated that GPT-4o, using a "summary of summaries" hierarchical approach, could identify stages of cognitive impairment with an expert concordance rate (Kappa=0.95) that far surpassed BERT-based benchmarks. Moreover, iterative prompt refinement has enabled models like GPT-4 to produce discharge summaries that blinded psychiatry specialists rated as superior to those written by residents [65]. This reasoning capability also facilitates the generation of high-fidelity synthetic data, a crucial development for fields constrained by stringent privacy regulations. Warner et al [66] leveraged 2 local instances of Llama 3.3 (70B) to act as "Interviewer" and "Patient" through CoT-driven interaction; they generated complex synthetic patient profiles that provide a viable alternative to sensitive psychiatric clinical notes for model training.

To bridge the gap between general reasoning and domain-specific precision, researchers have increasingly focused on fine-tuning. Techniques such as low-rank adaptation (LoRA) [175] allow models to master the nuanced lexicon of psychiatry while operating within computational and privacy constraints. Notably, Shukla et al [67] illustrated that smaller, open-source models (eg, Llama-3-8B) fine-tuned via LoRA can outperform massive proprietary models like GPT-4o in specialized tasks, including note proofreading and substance use identification. This trend toward localized optimization is further exemplified by the work of Krishnamoorthy et al [68], who used a fine-tuned Llama 3.3 (70B) to translate complex discharge summaries into patient-friendly language, thereby enhancing health literacy and engagement.

To situate these recent developments within the broader language-model landscape of psychiatric NLP, Table 4 provides a comparative overview of the major language model families applied to psychiatric clinical notes, including both earlier encoder-based PLMs and recent generative LLMs. It demonstrates how foundational open-source encoders are typically fine-tuned for granular extraction, whereas modern scalable models leverage advanced prompting and parameter-efficient tuning to tackle complex reasoning, summarization, and synthetic generation. It also suggests a degree of functional differentiation across model types: general-purpose proprietary LLMs showed their clearest advantages in longitudinal summarization, reasoning-oriented staging, and patient profile generation, whereas domain-adapted or locally fine-tuned open models were often more competitive for tightly bounded extraction, standardization, and institution-specific workflows.

Table . Overview of language model families applied to psychiatric clinical notes.

Studies	Model family	Representative models	Adaptation strategy
Open-source			
[5,10,60,69]	BERT series	• BERT[a] • ClinicalBERT • BlueBERT, • BioClinicalBERT • MentalBERT • DementiaBERT	• Continued pretraining on clinical or psychiatric corpora • Supervised fine-tuning (eg, for Named Entity Recognition) • Embedding regularization (eg, triplet-loss)
[7,11,66,68]	LLaMa series	• Llama 3.1 • Llama 3.2 • Llama 3.3	• Parameter-efficient tuning (eg, low-rank adaptation) • Local instruction tuning (with institution-specific note corpora), • Locally deployed multiagent prompting
[70]	FLAN-T5 series	• FLAN-T5-XL	• Zero-shot instruction followed by category-specific fine-tuning • Synthetic-example augmentation • Question-answering style prompting for note-level extraction
Closed-source			
[4,11,64]	GPT series	• ChatGPT-4 • GPT-4o	• Prompt-based inference (multistep, confidence-aware) • Integration with retrieval system • Clinician-in-the-loop review

[a]BERT: Bidirectional Encoder Representations from Transformers.

Model Evaluation

In IE and TC tasks, performance is typically evaluated using a confusion matrix (contingency table) to derive error rates from true positives, false positives, false negatives, and true negatives. Common metrics include sensitivity, recall, specificity, precision (PPV), NPV, and F_1-score. For probabilistic outputs, threshold-independent measures such as AUC and PRAUC are also reported. Most ML studies adopt a hold-out design (training, validation, and test), while cross-validation (CV) estimates predictive error by repeatedly training on subsets and testing on the remainder.

LLM evaluation often follows a multidimensional framework that combines quantitative metrics with expert review. Human assessment—eg, blinded preference tests, distinguishability studies, and Likert-scale rubrics—focuses on clinical utility, coherence, and correction effort. Automated metrics (eg, BERTScore [176], METEOR [177], readability indices [178]) complement human judgment by quantifying semantic fidelity and text quality. Safety and reliability are commonly examined through hallucination and prompt-adherence error analysis, and, when generating synthetic data, statistical comparisons with real-world demographic distributions. Interannotator consistency is frequently measured using Cohen kappa, reflecting variability due to fatigue, interpretation differences, and annotator expertise.

Table 5 summarizes representative model evaluation results across typical IE and TC tasks, including domain-specific evaluation strategies: (1) temporal evaluation, reflecting symptom progression over time (eg, Garriga et al [39], area under the receiver operating characteristic curve=0.865 for mental health crisis prediction); (2) multilabel evaluation, addressing comorbidity (eg, Afshar et al [58], area under the receiver operating characteristic curve=0.88 for alcohol misuse and 0.94 for opioid misuse); (3) severity-aware metrics, particularly relevant for suicide risk where false negatives are high-cost; (4) clinician agreement, benchmarking model outputs against clinician judgments (eg, Leng et al [44], 95% consistency for CI stages classification); (5) cross-domain generalization, comparing performance across conditions or health care systems (eg, Cliffe et al [71]); and (6) unsupervised evaluation, using clinical interpretability of discovered patterns when labels are limited (eg, Andrew et al [46] applying topic modeling and clustering to opioid-related cohorts).

XSL•FO
RenderX

Table . Results of model evaluation on information extraction and text classification tasks.

Categories and study	Primary aim	Subjects or dataset	Performance or main findings
Rule-based			
[72]	Identify neuropsychiatric symptom domains following COVID-19 hospitalization	6619 patients from 6 Eastern Massachusetts hospitals	The most commonly-documented symptom domains were fatigue (13.4%), mood and anxiety symptoms (11.2%), and impaired cognition (8.0%)
[71]	Characterize each eating disorder patient's suicidality profile	1126 and 420 patients at WCM[a] and SLaM[b]	SLaM approach: F_1-score 0.85 versus 0.68; WCM approach: F_1-score 0.87 versus 0.72
Traditional machine learning			
[30]	Predict postdischarge suicides	448,788 VA[c] patients	AUROC[d]: 0.747 - 0.780
[46]	Develop computational phenotypes for patients with opioid-related disorders	82,577 patients from 10 sites within a regional health care network	Reveal 9 distinct opioid-related cohorts
Hybrid			
[57]	Design a data extraction strategy for 21 common physical comorbidities	17,500 individuals at SLaM	Precision rates (F_1-score) above 0.90 for all conditions
[73]	Detect delirium episodes	1,565,678 clinical notes from 10,516 patients from 9 hospitals	Micro F_1-score=0.978; macro F_1-score=0.918
Deep learning			
[39]	Predict mental health crises	59,750 patients from NHS[e]	AUROC: 0.865
[58]	Screen for substance misuse	54,915 and 1991 patients at RUMC and LUMC	AUROCs: 0.88 for alcohol misuse; 0.94 for opioid misuse
Large language models-based			
[65]	Evaluate if AI[f]-generated psychiatric discharge summaries match the quality of those written by residents	20 cases at the Psychiatric University Hospital Zurich	Humans scored significantly higher (3.78 vs 3.12, P<.05); Found hallucinations in 40% of AI summaries (37.5% clinically relevant)
[64]	Develop and evaluate a framework to classify CI stages	1002 & 769 patients at MGB	GPT-4o achieved high accuracy (Weighted Kappa 0.95), outperforming BERT and USE models

Discussion

Principal Results

The application of NLP to psychiatric clinical notes presents unique challenges and opportunities, distinct from other medical domains. This stems from the inherently narrative and subjective nature of mental health documentation, where nuanced descriptions of patients' experiences and clinicians' interpretations take precedence over objective measurements. Psychiatric data is often dense, nuanced, and sensitive. Consequently, psychiatric clinical notes demand specialized NLP approaches capable of maintaining context over extensive narratives and extracting meaningful insights from highly subjective content. Parsing these nuanced expressions is crucial for capturing the complexity of a patient's mental state, which often defies straightforward quantification.

Rule-based methods have long been dominant in psychiatric NLP for IE and TC. Their interpretability, customizability, and efficacy with smaller datasets make them suitable for evolving clinical guidelines. However, a significant drawback of such systems lies in their inability to grasp context, particularly when it comes to negations and expressions of uncertainty. As the complexity of mental health data grows, the field has shifted toward hybrid systems that combine the strengths of rule-based methods and ML approaches. Hybrid systems offer enhanced scalability while retaining transparency and adaptability to clinical needs. Despite this, DL has seen limited adoption in

XSL•FO
RenderX

psychiatric clinical notes processing due to challenges such as data scarcity and the demand for model interpretability in clinical decision-making.

In recent years, PLMs based on transformers, such as BERT, have become the cornerstone of psychiatric NLP. By learning linguistic representations directly from large corpora, these models capture semantic nuances far better than previous NLP methods. Their value in mental health applications appears to lie particularly in domain adaptation and task-specific fine-tuning. Domain-adapted variants, including MentalBERT and Bio_ClinicalBERT, extend the utility of general PLMs by continued pretraining on biomedical and clinical corpora, thereby improving the handling of medical terminology, note structure, and psychiatric narrative style. When further fine-tuned for downstream tasks, these models have achieved state-of-the-art performance in tasks such as phenotyping [69], outcome prediction [63], and extracting features [62] from psychiatric clinical notes. However, these advances come with challenges when applied to long longitudinal records, including difficulty handling the exponentially increasing computing requirements in response to the input length.

LLMs offer promising advancements for psychiatric NLP, marking a significant paradigm shift from traditional discriminative tasks to generative and reasoning-based applications. With their flexibility and zero-shot capabilities, LLMs can transform clinical workflows by automating routine tasks, such as generating expert-level discharge summaries [65]. Furthermore, CoT prompting enables the simulation of complex clinical reasoning. Recent studies suggest that LLMs' use in mental health is expanding beyond summarization to broader forms of clinical assistance [179], including automated coding of clinical encounters, real-time clinical decision support, and the generation of synthetic high-fidelity patient profiles [66]. However, in psychiatric contexts, the risk of hallucination is particularly consequential: models may generate plausible but incorrect interpretations of symptoms, suicidality, psychosis, or treatment adherence, thereby introducing errors into clinical documentation or downstream decision-making. More broadly, the high output variability and limited inherent explainability of LLMs remain major barriers to safe clinical deployment [180]. For this reason, future psychiatric LLM systems will likely require not only retrieval-augmented generation [181], but also stronger human oversight, structured validation, and privacy-preserving deployment strategies [182]. In addition, the increasing reliance on proprietary closed-source models raises important ethical concerns in psychiatry, where clinical notes often contain highly sensitive and stigmatizing information. This consideration has strengthened interest in more transparent and locally deployable alternatives. In particular, parameter-efficient techniques such as LoRA make it possible for smaller fine-tuned models to achieve performance comparable to large proprietary models at a fraction of the cost [67].

Our review reveals a clear evolutionary trajectory in psychiatric NLP methods: from rule-based systems to ML, then to hybrid and DL, and most recently to LLM-based approaches. Each paradigm shift has expanded the capabilities of the field while introducing new trade-offs, as summarized in Table 6. Whereas rule-based methods and traditional ML prioritize interpretability and work well with limited labeled data, DL offers superior contextual understanding at the cost of transparency and data requirements. Hybrid methods help bridge this gap by domain knowledge integration, although they often increase system complexity and maintenance burden. LLMs extend this further by enabling generative applications and few-shot learning, but introduce new concerns around factual reliability and clinical safety. The choice of approach should therefore be guided by the specific clinical task, available resources, data characteristics, and the acceptable trade-off between model performance and interpretability.

Table . Comparative advantages and disadvantages of natural language processing approaches for psychiatric clinical notes.

NLP[a] approaches	Advantages	Disadvantages
Rule-based	• High interpretability • No training data needed • Easy to audit • Effective with expert curation	• Labor-intensive rule creation • Poor scalability • Brittle to linguistic variation • Cannot capture implicit semantics
Traditional ML[b]	• Learn patterns from data • Rich feature representations • Interpretable feature importance • Effective on smaller datasets	• Requires feature engineering • Performance depends on feature quality • Limited long-range context modeling
Hybrid	• Combine rule interpretability with ML adaptability • Balance precision and recall • Modular and extensible	• Increased system complexity • Requires both domain expertise and ML skills • Maintenance overhead
Deep learning	• Automatic feature learning • Capture contextual semantics • Domain-adapted BERT[c] available • Strong generalization ability	• "Black-box" nature • Higher computational cost • Performance suffers with limited data • Difficulty with long documents
LLMs[d]-based	• Zero and few-shot capability • Chain-of-thought reasoning • High computational efficiency • Versatile across tasks • Synthetic data generation	• Hallucination risk • Prompt sensitivity • High computational demands • Privacy concerns • Regulatory uncertainty

[a]NLP: natural language processing.

[b]ML: machine learning.

[c]BERT: Bidirectional Encoder Representations from Transformers.

[d]LLM: large language model.

The temporal dynamics of mental health conditions further complicate NLP applications in psychiatry. Many psychiatric disorders follow nonlinear progressions, necessitating sophisticated temporal modeling techniques that can track both rapid behavioral changes and long-term symptom trajectories [37,49]. This temporal aspect is vital in psychiatry, where the course of illness can be as informative as the symptoms themselves [183]. Notably, recent NLP research has expanded beyond single-disorder tracking to transdiagnostic approaches. For instance, dynamic temporal network analysis has been successfully applied to model the prodrome of severe mental disorders [51]. By mapping causal pathways among NLP-derived features, researchers identified distinct behavioral communities that consistently precede the onset of full-threshold disorders.

Multimodal integration is another hallmark of psychiatric NLP. Mental health is influenced by a complex interplay of biological, psychological, and social factors, necessitating NLP approaches that can synthesize information from diverse sources, including clinical notes [31,45], genetic studies [184], neuroimaging results [185,186], and even social media interactions [187]. This holistic approach represents a significant departure from traditional, siloed methods of medical data analysis. Integrating NLP-derived clinical features with brain MRI has proven effective in predicting complex conditions like treatment-resistant depression [74]; combining text-based symptom extraction with brain network analysis yields superior predictive performance compared to unimodal methods, validating the additive value of integration.

Public datasets like MIMIC-III are scarce in mental health, meaning most research relies on proprietary institutional data. Research in this domain is distributed across a wide range of institutions, particularly in the US and UK, with key contributors such as major medical centers like SLaM, the VA, and Rush University Medical Center focusing on substance use. However, limited data access is only part of the challenge. Psychiatric clinical notes also reflect important institutional and population-specific differences that may affect model development and generalizability. Clinical notes can vary across institutions in charting style, documentation granularity, terminology, and local diagnostic practice, which may influence the linguistic patterns captured by NLP models. In addition, datasets from individual hospitals or health systems often reflect the demographic, socioeconomic, and clinical characteristics of their local patient populations, introducing potential biases that may reduce the portability of findings across settings. These factors complicate cross-institutional collaboration and create technical barriers to external validation, transfer learning, and domain adaptation. While general health care standards such as OMOP and HL7 FHIR could support improved interoperability, their adoption in psychiatry remains limited, and structural harmonization alone may be insufficient to address variation in narrative documentation. To address these challenges, data-sharing initiatives, privacy-preserving methods

XSL•FO
RenderX

such as federated learning, and more systematic cross-site evaluation will be important.

Subjectivity in psychiatric assessments introduces a level of variability that profoundly impacts NLP model development and evaluation. Unlike other medical fields with objective biomarker-based standards, psychiatric NLP must contend with inter-rater variability among clinicians. This challenge has spurred the development of novel evaluation metrics, such as clinician agreement rates and severity-aware measures, particularly crucial in high-stakes scenarios like suicide risk assessment [55].

Limitations

Although this scoping review was conducted according to the PRISMA-ScR guidelines and a rigorous search strategy, there were some limitations that are worth noting. First, consistent with scoping review methodology, we did not perform a formal risk-of-bias assessment because the aim of this review was to map the scope and methodological landscape of the field rather than to synthesize effect estimates. Second, the requirement for terms specifically related to “psychiatry” or “psychiatric disorder” in the title or abstract means it is possible that some relevant articles focusing on specific conditions without using the broader umbrella terms were not included in this review. Third, the exclusion of non-English text limits the scope of this review to Anglophone clinical settings, potentially overlooking valuable methodological developments in other languages. Finally, this review was conducted in an area of research that is constantly growing and developing and therefore only provides a time-stamped representation of the field.

Conclusions

Psychiatric NLP is shaped by the distinctive characteristics of mental health documentation: subjective narrative language, longitudinal complexity, and heightened privacy and ethical stakes. The field is progressing from interpretable rule-based systems toward hybrid methods and Transformer-based PLMs, with LLMs enabling new generative and reasoning-based workflows. As these tools evolve, they hold the potential to significantly improve patient care, advance our understanding of mental illness, and ultimately alleviate the burden of those living with mental health conditions. The path forward requires collaborative efforts across health care systems, development of adaptive learning models, and careful ethical implementation. In addressing these challenges, psychiatric NLP not only promises to transform mental health care but also to expand the frontiers of clinical NLP more broadly.

Abstract

Background: Pressure injury (PI) can cause severe infections or death, and has a high global prevalence. Accurate staging is vital for effective intervention. Deep learning streamlines PI assessment; enhances efficiency; and yields practical, accurate results.

Objective: The primary objective of this scoping review was to map the landscape of deep learning applications for PI identification and categorize the existing body of evidence into distinct technological trajectories: unimodal imaging and multimodal integration.

Methods: We searched the following databases and sources: PubMed, the Cochrane Library, IEEE Xplore, and Web of Science. This scoping review was conducted in accordance with the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) guidelines.

Results: A total of 15 articles were included: 40% (n=6) studies applied multimodal integration, whereas 60% (n=9) applied unimodal imaging. In total, 26 models were involved. Different models exhibited varying accuracy rates in staging PI, with overall accuracy fluctuating between 54.8% and 93.7%. The same model demonstrated significant variations in recognition accuracy across different studies. Multimodal integration appeared to be a distinguishing characteristic of the studies that will progress toward clinical validation.

Conclusions: The current landscape of deep learning in PI identification is heavily skewed toward unimodal imaging, creating a modality gap that hinders clinical translation. While unimodal models demonstrate high accuracy in controlled settings, future research must prioritize bridging the gap from unimodal imaging to true multimodal integration to achieve clinical-grade reliability.

Introduction

Pressure injury (PI) refers to localized damage to the skin and/or underlying tissues resulting from intense and/or prolonged pressure or pressure combined with shear forces [1]. The affected areas typically occur over bony prominences or at points of contact between the skin and medical devices. The prevalence of PI has consistently remained at a high level across different countries and regions [2]. A meta-analysis revealed that the prevalence of PI among hospitalized adults worldwide between 2008 and 2018 was 12.8% [3]. Advanced-stage PI typically proves difficult to heal within a short time frame. This prolongs hospital stays by 3 to 5 times and increases mortality risk by 2 to 3 times [4]. PI may lead to severe infections or even death, posing significant challenges to both patients and health care systems.

Accurate diagnosis of PI staging is a prerequisite for medical intervention, and nurses' assessment of PI staging directly influences treatment outcomes. In PI nursing, junior nurses may misdiagnose staging accuracy due to insufficient expertise, assessment skills, and systematic training, compounded by constraints in resources and psychological support [5]. Research indicates that the accuracy of PI staging diagnosis ranges from merely 30% to 70%. This may be attributable to several factors: PI staging relies on evaluators' subjective descriptions of wound tissue appearance, with considerable variation in diagnostic interpretation between assessors; achieving accurate staging requires extensive accumulated experience; and the unclear

XSL•FO
RenderX

demarcation between the injured area's coloration and normal skin may also contribute [6]. Therefore, advanced technology is required to assist medical personnel in PI staging diagnosis, thereby enhancing the accuracy and efficiency of PI classification.

The vast majority of existing deep learning research has focused on unimodal imaging. While architectural evolutions, from convolutional neural networks (CNNs) to vision transformers, have achieved high accuracy in laboratory settings, these models remain fundamentally constrained by the limitations of visible light [7]. To overcome these limitations, the field is gradually shifting toward multimodal integration. A research problem or machine learning model is described as multimodal when it needs to incorporate and process at least 2 distinct modalities (such as visual data, audio data, tactile data, and text) simultaneously. Multimodal fusion inherently encompasses not only data-level integration but also feature-level fusion, where heterogeneous representations derived from the same or different sources are combined to provide complementary information [8]. Current research is beginning to explore the multimodal fusion of wound images and clinical signs to assess the depth of damage to the underlying tissue [9]. The existing literature remains insufficient in terms of verifying the generalization ability, adaptability to small sample sizes, and multicenter consistency of multimodal models in real-world clinical settings; model performance is prone to significant fluctuations [10]. Several reviews have examined the use of intelligent recognition models for wound assessment, including the comprehensive diagnosis of diabetic foot ulcers, arterial ulcers, venous leg ulcers, PIs, and surgical wounds [11]. Some studies have also focused on the use of AI in monomodal image analysis for wound assessment [12]. This raises several questions: what is the current distribution of deep learning studies on PI identification? Specifically, how many studies fall into the category of unimodal vs true multimodal approaches? What are the models for intelligent PI identification, what are the training methods, and how effective are they? The primary objective of this scoping review was to map the landscape of deep learning applications for PI identification, categorize the existing body of evidence into distinct technological trajectories (unimodal imaging and multimodal integration), evaluate the translational readiness of these studies, and assess their validation strategies and clinical implementation stages.

Methods

Protocol and Registration

This review was based on the recommendations of the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) guidelines [13] and used the methodological framework developed by Peters et al [14]. The completed PRISMA-ScR checklist is provided in Checklist 1. This study was registered with PROSPERO on December 12, 2025 (registration number CRD420251251573).

Eligibility Criteria

The inclusion criteria were defined using the population, concept, and context framework. Detailed inclusion and exclusion criteria can be found in Multimedia Appendix 1.

Information Sources

To identify potentially relevant studies, the following bibliographic databases were searched up to December 10, 2025: PubMed, Cochrane Library, IEEE Xplore, and Web of Science. We limited the search to English-language publications and included specific article types (journal articles and conference proceedings), explicitly excluding preprints. The search strategies were drafted by an experienced librarian and further refined through team discussion. We supplemented our search with forward and backward citation chasing to minimize the risk of missing key studies.

Search

This review was conducted by combining the terms "deep learning," "multi-modal," "artificial intelligence," "convolutional neural networks," and "pressure injury." The search was conducted on April 15, 2026 (see Multimedia Appendix 2 for the complete database search strategies).

Selection of Sources of Evidence

Two researchers conducted the literature search using the above-mentioned search terms. The final search results were exported into EndNote (Clarivate Analytics), and duplicates were removed by a researcher. Two independent investigators screened the retrieved studies based on their titles and abstracts against the eligibility criteria. Subsequently, the same 2 researchers conducted full-text screening.

Data Charting Process

We extracted data using the framework proposed by Peters et al [14] and populated data extraction forms. The 2 reviewers independently charted the data, resolving discrepancies through discussion, and continuously updated the data charting form in an iterative process.

Data Items

The following data were extracted from each included study: article identifiers (author, year, and country), dataset size and source, modality type, model type, task, validation type, and primary metrics.

Critical Appraisal of Individual Sources of Evidence

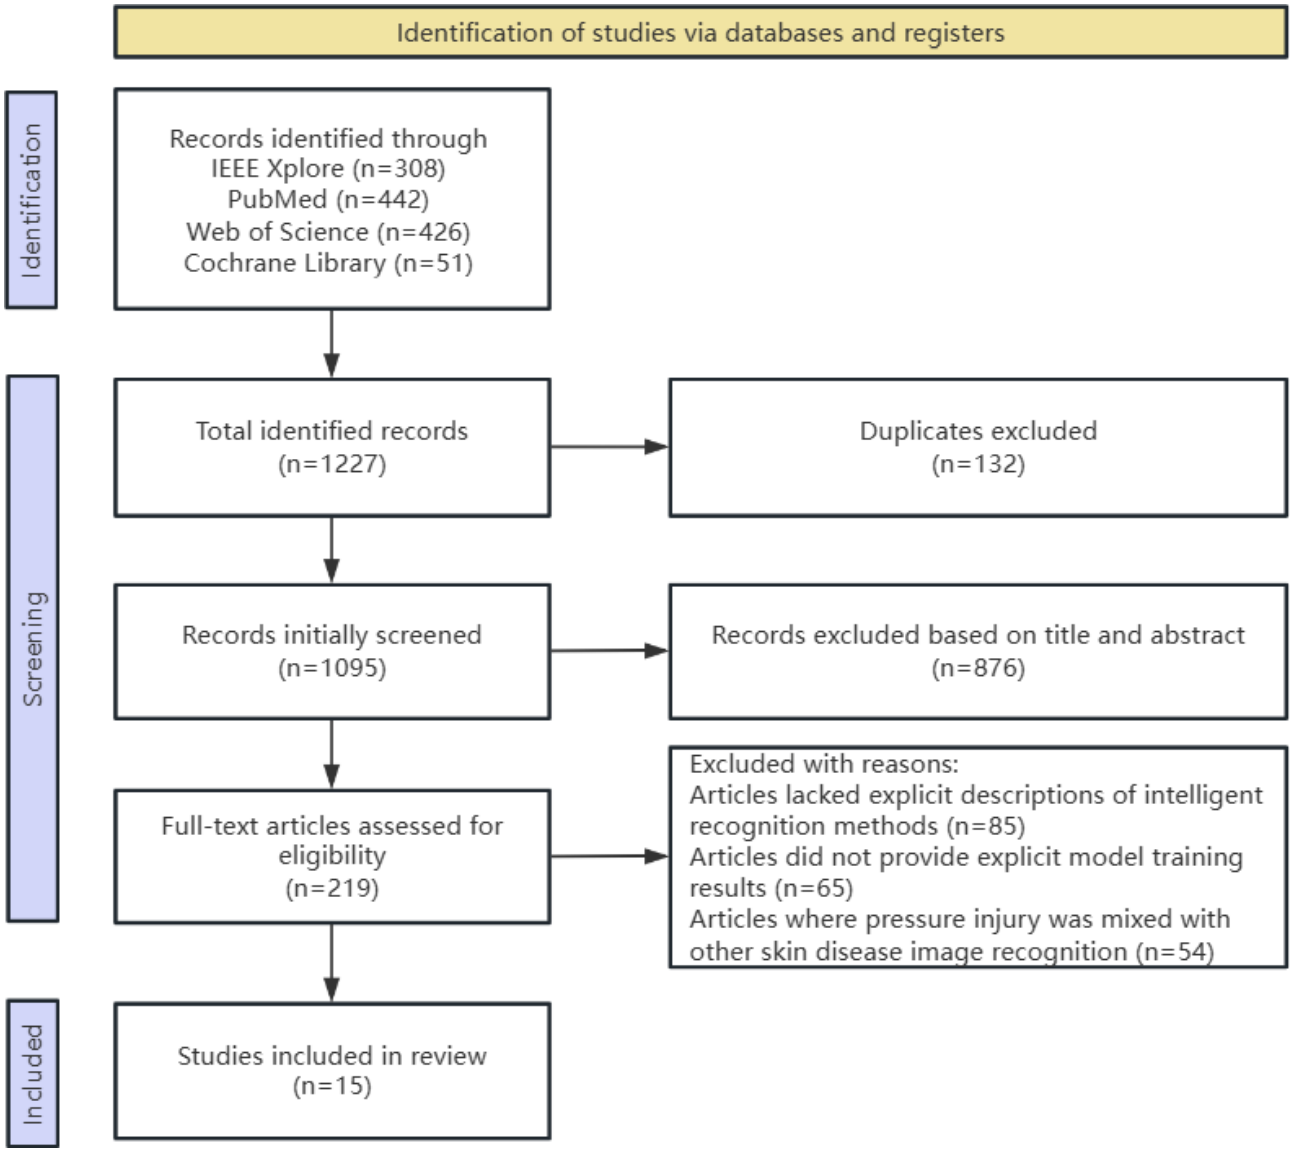
According to the methodological framework outlined in the PRISMA-ScR guidelines, this study did not undertake a formal critical appraisal or risk-of-bias assessment of individual studies. The primary aim of a scoping review is to map the breadth and nature of the existing evidence rather than synthesize effect sizes or assess the effectiveness of interventions. Therefore, the inclusion of studies of varying methodological quality, including those of lower quality, was intended to contribute to a comprehensive overview of the current state of research in this field.

XSL•FO
RenderX

Synthesis of Results

We synthesized the studies according to their dataset size and source, modality type, model type, task, validation type, and primary metrics.

Ethical Considerations



This scoping review used only previously published secondary data and did not involve direct human participant interaction.

Results

Selection of Sources of Evidence

The scoping review process is detailed in the flow diagram shown in Figure 1, presenting the stepwise filtering and the number of studies included at each step.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram.

Characteristics of the Sources of Evidence

Table 1 presents an overview of the 15 included studies. Regarding study design, all studies were retrospective. Geographically, 33.3% (n=5) of the studies were conducted in China; 20% (n=3) were from South Korea; 13.3% (n=2) were from Turkey; and 6.7% (n=1) each were from the United Kingdom, the United States, Germany, Japan, and Saudi Arabia.

Table . Characteristics of the included studies (N=15).

Study	Country	Dataset size and source	Modality type	Model	Task	Validation type	Primary metrics[a]
Lei et al [15], 2025	China	7677 images; single center	Unimodal images	AlexNet, VGGNet16, ResNet18, and DenseNet121	Classification	Internal	The classification performance of AlexNet, VGGNet16, ResNet18, and DenseNet121 yielded overall F_1-scores of 94.7%, 88.2%, 98.2%, and 97% (NR[b]) and overall accuracies of 87.7%, 82.4%, 92.4%, and 93.7% (NR), respectively.
Huang et al [16], 2025	China	883 images; CongresoEnfermeria dataset; single center; public	Unimodal images	SE-Swin Transformer and Cascade R-CNN[c]	Classification+detection	External	The Cascade R-CNN architecture achieved an mAP[d] of 80.9% (NR). The model achieved an accuracy of 87.1% (NR), surpassing other feature extraction models by at least 0.5 percentage points. Results indicate that Cascade R-CNN, with an accuracy of 86.6% (NR), outperformed Faster R-CNN, which achieved 82.5% (NR) accuracy.
Cho and Yoo [17], 2025	South Korea	16,850 images (HAM10000 dataset); multicenter; public data	Unimodal images	ViT[e]	Classification	External	The results showed accuracy and F_1-score values of 87.9% and 77.2% for ViT, 82.8% and 76.3% for ViT-Mixup, 93.9% and 76.4% for sViT, and 95.6% and 77% for PUC-ViT, respectively (NR).
Brehmer et al [18], 2025	Germany	763 images; multicenter	Multimodal images+patient data	ConvNextV2, EfficientNetV2, and TinyViT	Classification	Internal	The transformer-based TinyViT model demonstrated optimal performance in binary classification for PU[f], achieving an F_1-score of 93.2% (NR).

XSL•FO

Study	Country	Dataset size and source	Modality type	Model	Task	Validation type	Primary metrics[a]
Kimura et al [19], 2025	Japan	1007 images; single center	Unimodal images	CCM[g] and BCM[h]	Classification	Internal	The overall metrics for CCM were accuracy of 81.4% and F_1-score of 80.8% (NR). BCM achieved an accuracy of 87.1% and F_1-score of 85% (NR).
Wang et al [20], 2024	China	1519 images; multicenter	Multimodal images+text	ResNext+wFPN	Classification	Internal	The accuracy of the phase 3 PI[i] increased from 60.3% to 76.2%. The accuracy of stage 1, 2, and 4 PI were 87%, 78.8%, and 84.5% (NR), respectively. The network's overall accuracy, precision, recall, and F_1-score were 81.5%, 80.8%, 81.6%, and 81.1% (NR), respectively.
Gui et al [21], 2024	China	1385 images; single center	Multimodal images+heat map	SE-Inception	Classification	Internal	The SE-Inception model demonstrated exceptional accuracy (93%) and AUC[j] (94%; NR).
Zalluhoğlu et al [22], 2024	Turkey	1202 images; single center	Multimodal images+3D architecture data	Fused CNN	Classification	Internal	Experimental results with a test accuracy of 93%, precision of 93%, recall of 92%, and F_1-score of 93% (NR).

Study	Country	Dataset size and source	Modality type	Model	Task	Validation type	Primary metrics[a]
Swerdlow et al [23], 2023	United States	969 images; multicenter	Unimodal images	Mask-R-CNN	Classification+segmentation	Internal	The overall classification accuracy of the Mask-R-CNN model was 92.6% (NR), with a segmentation accuracy of 93% (NR). The F_1-scores for stages 1-4 were 84.2%, 94.7%, 90.7%, and 94.4% (NR), respectively. The Dice coefficients for stages 1-4 were 92%, 85%, 93%, and 91% (NR), respectively.
Kim et al [24], 2023	South Korea	3098 images; multicenter	Unimodal images	SE-ResNext101	Classification	External	The model achieved top-1 accuracy scores of 79.3% and 71.7% (NR) and F_1-scores of 79.1% and 71.5% (NR) on the internal and external test sets, respectively.
Fergus et al [25], 2023	United Kingdom	4290 images; single center	Unimodal images	Faster R-CNN	Classification	Internal	The research findings used a confidence score threshold of 75% (NR), yielding an average precision of 67.9% (NR), a recall of 69.9% (NR), and an F_1-score of 67.8% (NR).

Study	Country	Dataset size and source	Modality type	Model	Task	Validation type	Primary metrics[a]
Seo et al [26], 2023	South Korea	2464 images; single center	Unimodal images	VGGNet16, ResNet50, ResNet152, DenseNet201, and EfficientNet-B4	Classification	Internal	For EfficientNet-B4, the macro–F_1-score was calculated to be 89.4% (NR), and the average performance of 2 experienced nurses was reported as 87.8% (NR). EfficientNet-B4 achieved an accuracy of 91.4% (NR). The classification performance of ResNet152, VGGNet16, ResNet50, and DenseNet201 yielded overall accuracies of 84.1%, 83.7%, 82.9%, and 82.1% (NR), respectively. EfficientNet demonstrated superior accuracy to that of nurse B (86.3%; NR) in classifying PIs, although it remained inferior to that of nurse A (94.2%; NR), who had 19 y of experience.
Aldughayfiq et al [27], 2023	Saudi Arabia	Medetec image database (≥1000 images)	Unimodal images	YOLOv5	Detection	External	The YOLOv5 model achieved an overall mAP of 76.9% (NR) on the validation set.
Liu et al [28], 2022	China	528 images; single center	Multimodal images+clinical information	Inception-ResNet-v2	Classification	Internal	In the classification task of erythematous vs nonerythematous wounds, the Inception-ResNet-v2 model achieved an accuracy of 98.5% (NR) and an F_1-score of 94.1% (NR). In the classification task of necrotic tissue, the model attained an accuracy of 97% (NR) and an F_1-score of 93.5% (NR).

Ay et al [29], 2022	Turkey	1091 images from the Pressure Injury Image Dataset; public	Multimodal images+clinical information	DenseNet121, InceptionV3, MobilNetV2, ResNet50, ResNet152, and VGGNet16	Classification	Internal	DenseNet121 achieved a mean AUC of 91% (NR), InceptionV3 achieved a mean AUC of 85% (NR), MobilNetV2 achieved a mean AUC of 85% (NR), ResNet50 achieved a mean AUC of 92% (NR), ResNet152 achieved a mean AUC of 93% (NR), and VGGNet16 achieved a mean AUC of 91% (NR). ResNet152, ResNet50, VGGNet16, DenseNet121, InceptionV3, and MobileNetV2 yielded overall accuracies of 77.2%, 74.6%, 71.8%, 67.2%, 63.1%, and 54.8% (NR), respectively.

[a]Primary metric values are presented as percentages.

[b]NR: not reported (absolute value) in the original publication.

[c]CNN: convolutional neural network.

[d]mAP: mean average precision.

[e]ViT: vision transformer.

[f]PU: pressure ulcer.

[g]CCM: cluster-based classification model.

[h]BCM: binary classification model.

[i]PI: pressure injury.

[j]AUC: area under the curve.

Synthesis of Results

In total, 40% (6/15) of the studies applied multimodal integration, whereas 60% (9/15) applied unimodal imaging. This review involved 26 models, including AlexNet, VGGNet16, ResNet18, DenseNet121, SE-Swin Transformer, Cascade R-CNN, vision transformer, ConvNeXtV2, EfficientNetV2, Meta Former, TinyViT, CCM, binary classification model, ResNext+wFPN, SE-Inception, Mask-R-CNN, SE-ResNext101, Faster R-CNN, ResNet50, ResNet152, DenseNet201, EfficientNet-B4, YOLOv5, Inception-ResNet-v2, InceptionV3, and MobilNetV2. In total, 46.7% (7/15) of the studies [17,21,23-25,27,28] applied a single model for training, comparing the accuracy of intelligent PI recognition achieved through model application against that of subjective assessments conducted by health care professionals to evaluate model training effectiveness. A total of 40% (6/15) of the studies [15,16,18,19,26,29] applied 2 to 6 models for training, comparing the training outcomes of different models to determine the optimal model capable of achieving the highest accuracy in intelligent PI recognition. In total, 13.3% (2/15) of the studies [20,22] applied multiple models in combination to assess their accuracy in intelligent PI identification. Among all models mentioned, VGGNet16 was applied most frequently, featuring in 20% (3/15) of the studies [15,26,29]. DenseNet121 was applied in 13.3% (2/15) of the studies [15,29], ResNet50 was applied in 13.3% (2/15) of the studies [26,29], and ResNet152 was applied in 13.3% (2/15) of the studies [26,29]. The remaining models were each applied once. CNNs included algorithms such as AlexNet, VGG, ResNet, DenseNet, and

XSL•FO
RenderX

EfficientNet. AlexNet, proposed by Krizhevsky et al [30], used a substantial number of parameters, resulting in extended training times and significant computational demands. VGG [31] used small convolution kernels and greater depth but had a large number of parameters and high computational cost. ResNet [32] introduced residual connections, allowing the network to learn identity mappings. DenseNet introduced dense connections, where each layer connects directly to all preceding layers [33]. EfficientNet [34] involved the coordinated scaling of the network's depth, width, and resolution rather than scaling a single dimension.

Intelligent PI Identification Training Methods Based on Deep Learning

Establishment of a PI Image Database

All studies included in this review that trained intelligent PI identification models first established an image dataset. The number of images in the datasets varied considerably across the included studies, ranging from 395 to 7677. The methods of image acquisition differed. One study obtained them from the Pressure Injury Image Dataset via a public platform [29]. In the study by Swerdlow et al [23], the images were acquired through a specialized company: the PI wound data repository was provided by eKare, which offers professional wound imaging and analysis services. Most studies established a PI image collection by reviewing images of inpatients with PIs and compiling those that met specified criteria.

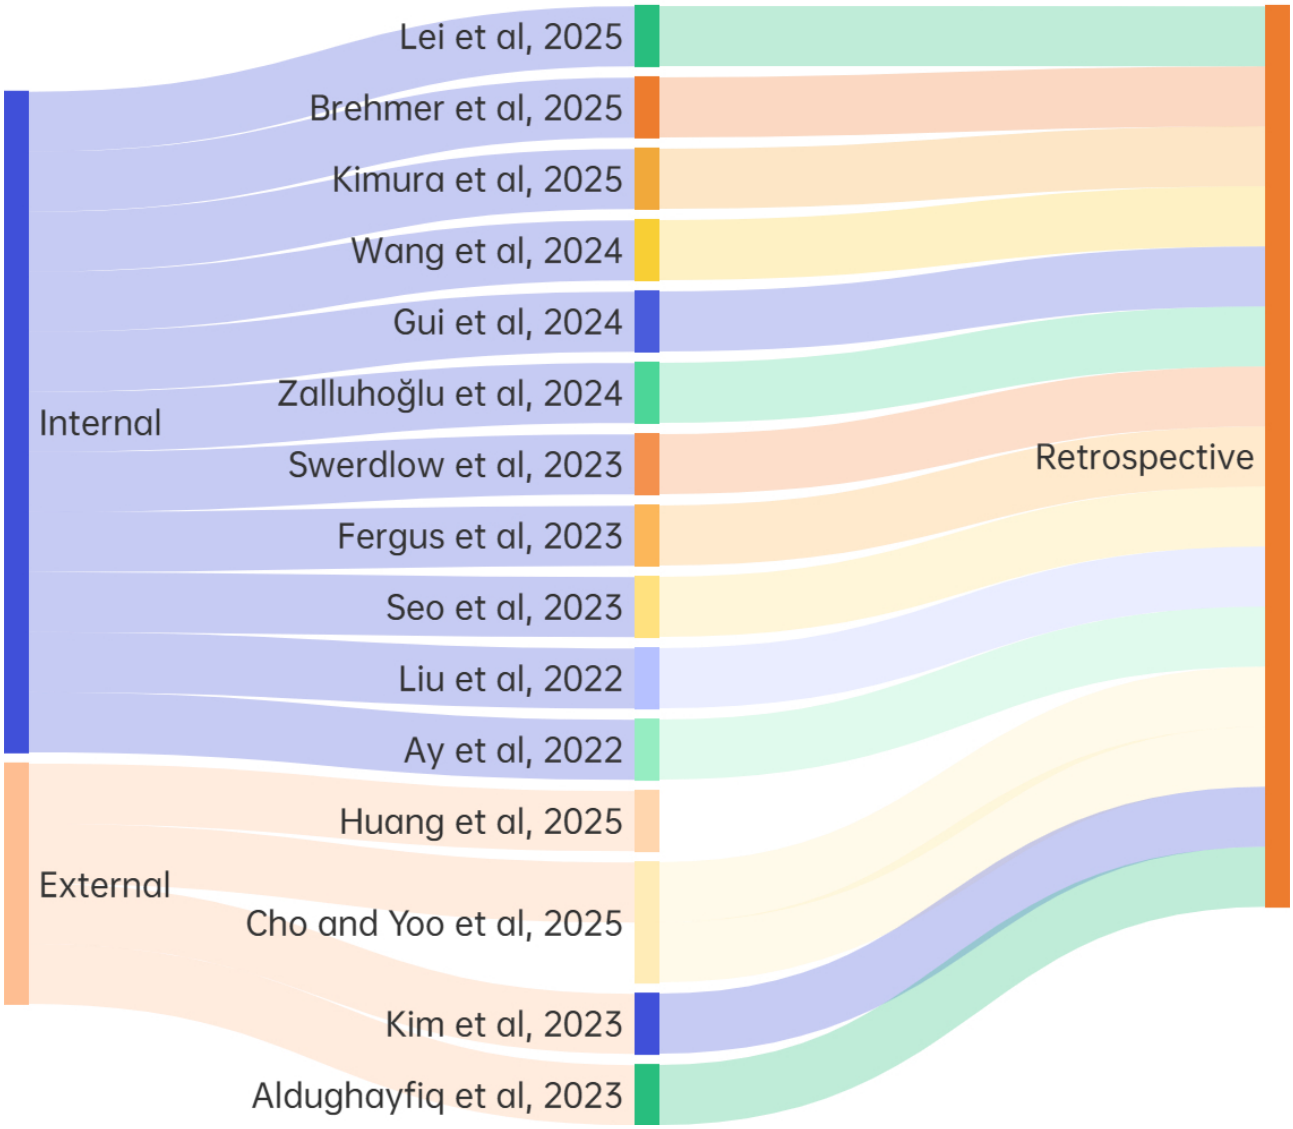
Image Processing

For data augmentation, original PI images underwent flipping, rotation, and cropping to augment the number of baseline samples. For preprocessing, both baseline samples and augmented data underwent image normalization to reduce computational load. Processed images were proportionally divided into training, validation, and test sets.

Developing Intelligent PI Identification Models

The final step for the literature included in this review was used to inform model training configuration and human-machine comparisons. Transfer learning was conducted using 26 training models based on the CNN framework. An intelligent PI staging recognition model was developed through deep learning.

Effectiveness of Intelligent PI Detection Based on Deep Learning



Among the studies included in this review, the accuracy rates for intelligent PI staging identification varied across different models, fluctuating between 54.8% and 93.7%. We present performance figures for illustrative purposes only and do not compare the models' accuracy. One study indicated that the DenseNet121 model achieved an identification accuracy of 93.7% (not reported [NR]) [15], whereas another study reported an accuracy rate of 67.2% (NR) for the same model [29]. VGGNet16 demonstrated relatively stable accuracy across 20% (3/15) of the studies [15,26,29], achieving values of 83.7%, 82.4%, and 71.8% (NR), respectively. ResNet152 recorded accuracy rates of 84.1% and 77.4% (NR) in 13.3% (2/15) of the studies [26,29]. ResNet50 achieved accuracy rates of 82.9% and 74.6% (NR) in 13.3% (2/15) of the studies [26,29]. The classification performance of AlexNet, VGGNet16, ResNet18, and DenseNet121 yielded overall accuracies of 87.7%, 82.4%, 92.4%, and 93.7% (NR), respectively, with corresponding F_1-scores of 94.7%, 88.2%, 98.2%, and 97.0% (NR) [15]. The SE-Swin Transformer model proposed in the study by Huang et al [16] achieved an accuracy of 87.1% (NR), surpassing other feature extraction models by at least 0.5 percentage points, as well as a mean absolute precision of 80.9% (NR). The results of the study by Cho and Yoo [17] indicated that the PUC-ViT model achieved an accuracy rate of 95.6% (NR) and F_1-score of 95.4% (NR). Among the 4 models applied in the study by Brehmer et al [18]—ConvNeXtV2, EfficientNetV2, MetaFormer, and TinyViT—the transformer-based TinyViT model demonstrated the most effective performance in the binary classification of pressure ulcers, achieving an F_1-score of 93.2% (NR). Among the 2 models applied in the study by Kimura et al [19], the CCM achieved an accuracy of 81.4% (NR), a precision of 81.6% (NR), and an F_1-score of 80.8% (NR). The binary classification model attained an accuracy of 87.1% (NR), a precision of 84.1% (NR), and an F_1-score of 85% (NR). The study by Wang et al [20] increased the accuracy rate for stage 3 PI diagnosis from 60.3% to 76.2% (NR) using ResNext+wFPN. The F_1-scores for stage 1 to 4 PI diagnosis were 81.5%, 80.8%, 81.6%, and 81.1% (NR), respectively. In the study by Gui et al [21], the SE-Inception model achieved an accuracy of 93% (NR) and an area under the curve of 94% (NR). In the study by Zalluhoğlu et al [22], a semiduplex CNN achieved an accuracy of 93% (NR) and F_1-score of 93% (NR). In the study by Swerdlow et al [23], the Mask-R-CNN model achieved an overall classification accuracy of 92.6% (NR) and a segmentation accuracy of 93.0% (NR). For stages 1 to 4, the model obtained F_1-scores of 84.2%, 94.7%, 90.7%, and 94.4% (NR) and Dice coefficients of 92%, 85%, 93%, and 91% (NR), respectively. In the study by Kim et al [24], the model achieved top-1 accuracy scores of 79.3% and 71.7% (NR) and F_1-scores of 79.1% and 71.5% (NR) on the internal and external test sets, respectively. The study by Fergus et al [25] used a confidence score threshold of 75% (NR), yielding an average precision of 67.9% and F_1-score of 67.8% (NR). In the study by Seo et al [26], for EfficientNet-B4, the macro–F_1-score was calculated to be 89.4% (NR), and the average performance of 2 experienced nurses was reported as 87.8% (NR). EfficientNet-B4 achieved an accuracy of 91.4% (NR). In the study by Aldughayfiq et al [27], the YOLOv5 model achieved an overall mean average precision 50 of 76.9% (NR) on the validation set, enabling it to accurately detect and classify PIs with a high degree of confidence. In the study by Liu et al [28], the Inception-ResNet-v2 model achieved an accuracy of 98.5% and an F_1-score of 94.1% (NR). In the classification task of necrotic tissue, the model attained an accuracy of 97% and an F_1-score of 93.5% (NR). Finally, in the study by Ay et al [29], ResNet152, ResNet50, VGGNet16, DenseNet121, InceptionV3, and MobileNetV2 achieved overall accuracies of 77.2%, 74.6%, 71.8%, 67.2%, 63.1%, and 54.8% (NR), respectively, with corresponding mean area under the curve values of 93%, 92%, 91%, 91%, 85%, and 85% (NR), respectively.

RenderX

Mapping the Translational Landscape: From Retrospective Development to Clinical Validation

The validation Sankey diagram (Figure 2 [15-29]) delineated a critical attrition curve, revealing that while all 15 studies had retrospective designs, the flow of evidence was sharply constricted at the validation checkpoint, with only 26.7% (4/15) incorporating external test sets. For the purpose of this review, "external validation" was broadly defined to include any testing on data not used during model training, "multicenter" was defined as testing on data from a physically different institution from those of the training data, and "public dataset" was defined as testing on a publicly available benchmark dataset distinct from the authors' private training data.

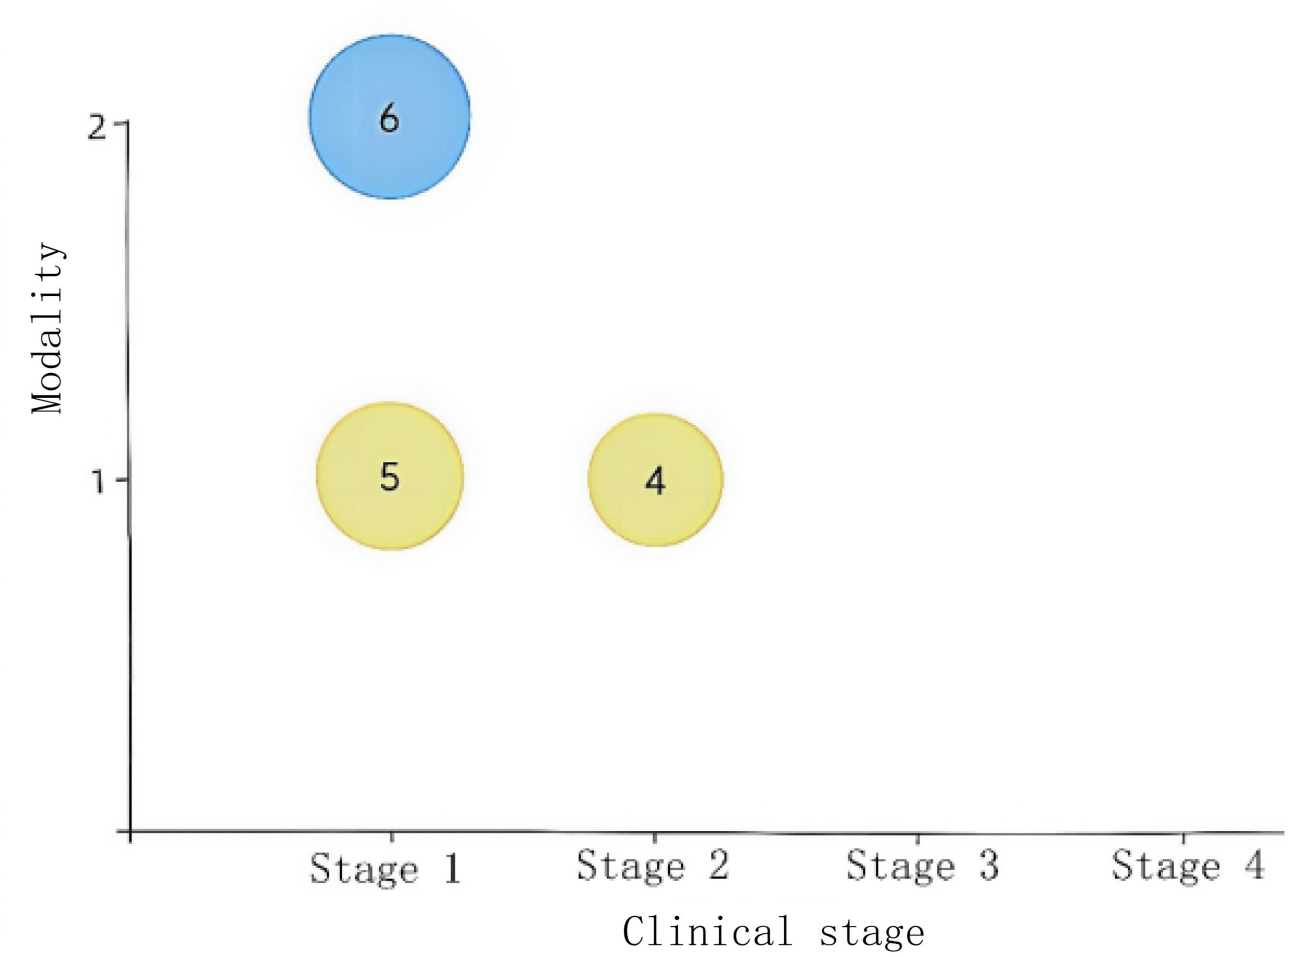

Figure 2. Validation Sankey diagram [15-29].

This bottleneck was further elucidated by the grouped bubble chart (Figure 3), which mapped the intersection of modality and clinical stage. While most of the research (11/15, 73.3%) remained concentrated at stage 1 (development), a notable finding was that 54.5% (6/11) of the studies in stage 1 were multimodal. This suggested that while the field was dominated by retrospective single-modality development, multimodal integration appeared to be a distinguishing characteristic of the studies that will progress toward clinical validation.

XSL•FO
RenderX

Figure 3. Grouped bubble chart of data modality vs clinical stage illustrating the distribution of the included studies (N=15). The x-axis represents the clinical stage of algorithm deployment: stage 1 corresponds to algorithm development, stage 2 corresponds to technical validation, stage 3 corresponds to workflow integration, and stage 4 corresponds to clinical trial. The y-axis categorizes studies by data modality: unimodal (1) vs multimodal (2). The bubble size is proportional to the number of studies, whereas bubble color denotes the modality type (blue for multimodal; yellow for unimodal).

Discussion

Summary of Evidence

This scoping review mapped the contemporary landscape of deep learning in PI identification, revealing a field characterized by a profound modality chasm between computational sophistication and clinical utility. While the evolution of unimodal imaging exhibits diminishing returns, with marginal performance gains despite increasing model complexity, the integration of multimodal data remains nascent and fragmented.

Accuracy of Intelligent PI Identification Models: Generally High, With Variations Observed

On the basis of the results of the studies included in this review, the DenseNet121 intelligent model achieved an identification accuracy of 93.7%. However, in another study, an accuracy of 67.2% was reported for the same model. The former was a unimodal study, whereas the latter was a multimodal one. Although the former demonstrated high accuracy in internal validation, it was inherently limited by the physical constraints of visible light and lacked the physiological context necessary to distinguish ischemic tissue or assess the condition of subcutaneous tissue. The cross-study comparisons of accuracy are not valid for selecting a single best model. Owing to the lack of standardized benchmark tests, it is not possible to compare accuracy rates across different datasets, class definitions, and levels of data annotation accuracy. One must also consider multiple factors. First, there was a difference in dataset size. The study in which high accuracy was achieved used a larger dataset comprising 7677 images, whereas the study with lower accuracy used 1091 images. This disparity prevented the model from adequately learning features. In a study by Wang et al [35], an intelligent burn depth recognition model was established using 5637 complete burn wound images to achieve satisfactory recognition results. Therefore, future research can increase the size of the dataset to enhance the sample balance and obtain more precise outcomes. Second, the class definitions differed significantly. Studies that achieved high accuracy used stratified sampling to maintain category proportions, whereas those with low accuracy used random splitting, which resulted in inconsistent distributions between the test and training sets. For instance, the training set may predominantly feature mild injuries, whereas the test set may contain mostly severe ones [36]. Consequently, future researchers should clearly delineate the image datasets to ensure a balanced category distribution in the test set. Third, regarding data annotation accuracy, studies with better performance tend to employ larger and more

XSL•FO
RenderX

specialized annotation teams—in the most rigorous datasets, including five professionals—while the studies with poorer performance more often rely on smaller teams, such as two professionals. This may lead to inconsistent annotations for visually ambiguous cases. This underscores the necessity for at least 3 professionals to perform normative annotation in future studies, thereby reducing ambiguity [37]. The research methodology of the primary studies included in this scoping review and process were meticulously executed, with a well-structured experimental design [29]. Although DenseNet121 exhibited lower recognition accuracy, ResNet50 demonstrated superior performance, suggesting that the experimental design may be more suited to training ResNet50. It is recommended that future research designs focus on the design and training of a single model. Clinical AI systems should not be judged on technical performance alone but also on clinically meaningful utility [38]. Images cannot quantify blood flow. For instance, distinguishing a stage 1 PI (nonblanchable erythema due to occlusion) from healthy, well-perfused skin is notoriously difficult through color alone. Thermal imaging is required to visualize temperature gradients and perfusion changes. The viability of granulation tissue depends on oxygen saturation. Hyperspectral or spatial frequency-domain imaging is necessary to measure hemoglobin oxygenation and water content. The path to clinical-grade reliability lies in fusing these heterogeneous data sources. Future PI research should focus on tangible clinical benefits. A notable finding of this review is that, despite the availability of more advanced architectures, VGGNet16 remained widely adopted. This suggests that researchers tend to favor established baseline models over architectural innovation. Although VGGNet16 provides a stable benchmark, its inherent limitations—particularly its large parameter size and lack of multi-scale feature integration capabilities—likely constrain the potential of multimodal systems [39].

Application of Intelligent PI Identification Models Demonstrates Substantial Clinical Value

Of the 15 included studies, 2 (13.3%) compared the models with human professionals [18,26]. Regarding the task of staging PIs, only one of these studies indicated that deep learning models achieved a lower identification accuracy than nurses with 19 years of experience [26]. On the basis of the evidence, valid benchmarking should only occur under the following specific circumstances: stratified by experience level (eg, novice nurses, general ward nurses, and certified wound care specialists), simulated time constraints, rigorous blinding, and input parity. In both accuracy and speed, the other models (ResNet152, VGGNet16, and ResNet50和DenseNet201) outperformed nurses with varying years of experience. For less experienced health care personnel, accurately staging PIs remains challenging, potentially influenced by inadequate training, information gaps, observer bias, and the diverse appearance of wounds [40]. The skin tone, age, and health status of the patient may also interfere with visual assessment [41]. Intelligent recognition models can rapidly learn from medical data, accumulating within a short time frame the expertise that a wound specialist might gain over months or even years. Moreover, computers process data using mathematical algorithms that make probabilistic judgments based on objective rules, ultimately delivering results. This approach solves issues such as the inability to quantify PI staging and the lack of objectivity in diagnosis [29]. In addition, wound healing monitoring can be enhanced through a thermal imaging–based smartphone app, which provides a related example of technology-enabled wound assessment and may help position PI AI within a wider digital wound care landscape [42].

The Imperative for Multimodal Integration: Beyond Visual Confirmation

The notable scarcity of true multimodal studies identified in this review underscores the next frontier for research. Our findings suggest that meaningful transition requires the integration of heterogeneous data sources. Currently, existing multimodal attempts are limited to incorporating thermal or basic clinical data. However, to bridge the translational gap, future systems must evolve from superficial sensor fusion to deep multimodal integration. This requires synergizing imaging data with longitudinal electronic health record, nutritional biomarker, and mobility data to capture a holistic view of patient health [43].

Limitations

A limitation of this scoping review is the absence of a formal methodological quality appraisal of the included studies. According to standard scoping review methodology, the focus was on mapping the landscape of available evidence rather than assessing the risk of bias or the certainty of evidence.

Conclusions

The current landscape of deep learning in PI identification is heavily skewed toward unimodal imaging, creating a modality gap that hinders clinical translation. While unimodal models demonstrate high accuracy in controlled settings, they lack the physiological context required for robust wound assessment. Future research must prioritize bridging the gap from unimodal imaging to true multimodal integration, shifting the focus from algorithmic architecture to the fusion of heterogeneous data sources to achieve clinical-grade reliability.

Abstract

Background: Public reporting systems (PRSs) in health care are defined as digital platforms that make comparative health care performance data available to the public (eg, Hospital Compare in the United States, NHS Choices in the United Kingdom, national quality registries in Europe, and MyHospital in Australia). These systems aim to improve transparency, accountability, and patient choice. While these systems have been widely studied from policy and clinical perspectives, the information system (IS) foundations that enable their operation, including architecture, interoperability, data governance, APIs, usability, and technical performance, remain underexplored.

Objective: This study aims to map the extent and nature of the published literature addressing the technological foundations of PRSs in health care and to identify persistent gaps in IS scholarship.

Methods: This scoping review followed the Joanna Briggs Institute guidelines and was reported in accordance with the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews). Seven databases were searched: PubMed, Web of Science, Scopus, IEEE (Institute of Electrical and Electronics Engineers), ACM (Association for Computing Machinery), AIS (Association for Information Systems) eLibrary, and Cochrane. The search covered articles published between 2000 and 2026. Eligible articles included peer-reviewed journal articles and conference papers on PRSs in health care. Data were charted according to study characteristics, including 6 IS-specific coding dimensions: architecture, interoperability, data governance, APIs, usability, and technical performance. Descriptive statistics were used to summarize the findings, and a narrative synthesis was conducted to identify thematic trends and research gaps.

Results: A total of 1882 records were identified across 7 databases. After deduplication, 1127 records were screened, and 233 studies were included in the review. Most of the included studies originated from the United States (n=157, 67.4%), followed by Europe (n=43, 18.4%). Of the 233 included studies analyzed, 60.5% (n=141) used quantitative methods, whereas 24.0% (n=56) used qualitative methods and 15.5% (n=36) used mixed methods. Applying a structured IS coding framework to all 233 studies revealed that the technical substrate of PRSs remains underexplored.

Conclusions: Despite the centrality of IS infrastructure to public reporting, existing scholarship predominantly frames these systems as policy or social tools while neglecting their technical underpinnings. This oversight has practical implications, including poor system usability, weak interoperability, and noncompliance with data regulations, which can undermine patient trust and system effectiveness. Addressing this gap requires interdisciplinary approaches that integrate IS frameworks, sociotechnical analysis, and usability evaluation to ensure that PRSs are effective, equitable, and technically robust.

Introduction

In recent years, discussions on public reporting systems (PRSs) have increased due to changes in the health care sector [1,2] and the need for a consumer-centric approach to the delivery of health care [3,4]. PRSs refer to digital platforms or portals that publicly share comparative health care performance metrics [5]. Examples include Hospital Compare in the United States (publishing hospital quality indicators such as readmission and mortality rates), NHS Choices in the United Kingdom (a national portal providing performance ratings and patient experience scores), ProPublica's Surgeon Scorecard (a journalist-led initiative reporting surgeon-specific complication rates), various national quality registries in Europe (tracking outcomes in areas

XSL•FO
RenderX

such as cardiac surgery or joint replacement), and MyHospitals in Australia (reporting hospital activity and performance data) [6-11]. These platforms serve a common purpose: to enhance accountability, transparency, and patient choice [5,11,12].

Public reporting in health care started in the mid-1980s in the United States, but its roots go back to Florence Nightingale's 1858 - 1859 publication of Crimean War hospital mortality data using "coxcomb" diagrams [13]. Since then, it has been adopted and implemented in numerous countries worldwide [14,15]. These systems are designed to make comparative health care performance data accessible to a broad audience, thereby supporting consumer choice as well as provider accountability and transparency [15-17]. Public reporting is defined by Totten, Wagner [18] as "data, publicly available or available to a broad audience free of charge or at a nominal cost, about a health care structure, process, or outcome at any provider level (individual clinician, group, or organizations [e.g., hospitals, nursing facilities]) or at the health plan level" (p 3). According to Cacace et al [19], quality measurement and public reporting improve health care through 2 pathways of change: improvement through selection and improvement through change.

Improvement through selection occurs when users make their choices based on the comparative information available to them [20]. Reported comparative information enables users to make better health care decisions. This suggests that when users choose, they identify outcomes relevant to them and learn about performance levels [20].

Improvement through change is a pathway in which health care providers improve their services based on published comparative data [20]. For example, a hospital can improve postoperative care to reduce infection rates. This type of improvement originates with the provider, thereby improving the quality of care received by users. The user is the main beneficiary of both pathways of change, as each leads to improved quality of health care services.

According to Werner and Asch [21], public reporting has been associated with a small decline in mortality rates. There have been reported cases of the positive effects of public reporting on health care centers and providers [22]. Werner and Asch [21] report on the impact of public reporting on quality improvement interventions in nursing homes. The findings of this study [4] indicate that the public reporting of performance data has led health care organizations to improve and maintain high levels of performance.

According to research, one of the benefits of public reporting is the freedom of choice for consumers [23]. Freedom of choice in health care refers to consumers deciding on and selecting their own health care providers [24,25]. According to Zolkefli [25], this enhances consumer autonomy. This is a consumer-centric approach to health care delivery. The need for freedom of choice stems from the fact that the more choices consumers have, the greater their freedom and autonomy, which in turn leads to greater well-being and a sense of personal worth [25,26].

The growing role of PRSs in health care through information systems (ISs) and data use has fostered consumer or patient centrism in health care [27]. ISs, including digital platforms, big data analytics, and cloud technologies, play a significant role in providing health care information to patients and facilitating information sharing between providers and patients [28-30]. As a result, patients now have greater access to both quantitative and qualitative health care information, enabling more informed decision-making [31,32]. This has led to the development of digital platforms such as PRSs, which provide information to patients and the public.

Previous reviews have examined PRSs in health care settings [5,18,33], but to the best of our knowledge, no review to date has mapped public reporting from the viewpoint of studying the role, design, development, and use of ISs as an infrastructural cornerstone of public reporting. This review offers valuable insights for practitioners and researchers in ISs. It also provides a cross-disciplinary synthesis for health care policymakers and digital health stakeholders by integrating insights from the public health, informatics, and IS domains. It provides a roadmap that pinpoints what is already known, what remains unexamined, and where IS experts can intervene to build, evaluate, or refine the digital infrastructures underpinning PRSs [34-36].

While related domains such as patient portals, clinical quality registries, and digital dashboards have received attention in health informatics and ISs [37-43], these typically emphasize clinical outcomes or patient engagement in narrower contexts. What remains underexplored is the technological substrate specific to PRSs: how architectures are designed [44], interoperability standards (eg, Health Level Seven International [HL7] or Fast Healthcare Interoperability Resources [FHIR]) are implemented [45,46], data governance is operationalized [47], and usability is evaluated at scale [48-50]. This distinction motivates our scoping review and justifies treating public reporting as a distinct IS artifact rather than a generic health IT application.

This scoping review aims to map the extent to which the published literature addresses the technological foundations of PRSs and to identify the persisting gaps in IS scholarship. This scoping review is guided by the research question: *What research exists regarding the role of information systems in facilitating public reporting systems within health care?* The objective is not to evaluate the technical quality of existing systems but rather to map the attention given to technological dimensions in the literature, thereby pinpointing areas that have yet to receive attention from IS researchers. The review proposes recommendations for advancing research in public reporting from the IS perspective.

Methods

Design and Rationale

Scoping reviews are conducted to identify and map evidence that is available on a specific topic [34]. Munn et al [51] provide a detailed definition of a scoping review: "Scoping reviews are a type of evidence synthesis that aims to systematically identify and map the breadth of evidence available on a particular topic, field, concept, or issue, often irrespective of source (i.e., primary research, reviews, non-empirical evidence) within or across

XSL•FO
RenderX

particular contexts. Scoping reviews can clarify key concepts/definitions in the literature and identify key characteristics or factors related to a concept, including those related to methodological research" (p 950). Based on this definition, scoping reviews are important for understanding the existing body of evidence on a topic and shaping the direction of future research. The underlying difference between a scoping review and a systematic review is that scoping reviews have a broader scope and differ in their primary purpose [52]. A scoping review is necessary to explore the nature and status of PRSs in health care, as this research field remains scarcely mapped.

This scoping review was conducted according to the Joanna Briggs Institute (JBI) guidance [53] for scoping reviews and is reported in line with the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews; Checklist 1) [36]. The steps in this scoping review are documented below.

Protocol and Registration

The protocol was registered on the Open Science Framework on July 8, 2025 (Open Science Framework registration: osf.io/mnc8x), and updated on April 3, 2026, to enhance transparency and provide a permanent record of methods. Although prospective registration is preferable, no deviations from the prespecified eligibility, screening, data charting, or synthesis methods occurred, consistent with JBI and PRISMA-ScR guidance.

Eligibility Criteria (Population, Concept, and Context Framework)

The Population, Concept, and Context framework guiding eligibility in this review is summarized in Table 1.

Table . Population, Concept, and Context (PCC) framework.

PCC element	Operational definition used in this review
Population	Any health service provider or health systems that make comparative performance information publicly available.
Concept	Public reporting of health care quality or performance, including systems that provide comparative information for public access.
Context	All countries, all levels of care (primary, secondary, tertiary, long term), and all payer or ownership models. No setting restrictions.

Inclusion and Exclusion Criteria

The inclusion and exclusion criteria applied in this study are detailed in Textbox 1.

We limited inclusion to English-language publications because most of the indexed work in this domain is in English. We also limited the timeframe to January 1, 2000, to February 4, 2026, to capture the modern era of web-based public reporting and contemporary health information standards [54-56].

Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria

- English language
- Published between January 1, 2000, and February 4, 2026
- Papers that describe, design, or evaluate
- Any source describing real-world or pilot public reporting tools

Exclusion criteria

- Reporting designed solely for internal quality improvement, audit surveillance, or regulatory compliance
- Health care is mentioned, but the article does not study reporting
- Gray literature
- Editorials, protocols, dissertations, not accessible in full texts

Calibration and Reliability

Two reviewers (ED, MM) piloted the screening of 50 records to calibrate the application of the eligibility criteria. Disagreements were discussed, and the decision rules were refined. Agreement during the pilot was substantial (Cohen k=0.74 for title or abstract, k=0.81 for full text). Following calibration, we proceeded with dual-independent screening of all remaining records. Disagreements were resolved by consensus with a third reviewer (RS) when required.

Rationale for Timeframe

The rationale for the January 1, 2000, to February 4, 2026 timeframe is that since the early 2000s, public reporting has progressed from static consumer-oriented portals to interactive dashboards, integrated reporting platforms, and interoperability-focused systems. This reflects the evolution of the IS infrastructure underpinning public reporting.

XSL•FO
RenderX

Information Sources and Search Strategy

A comprehensive literature search was conducted across 7 databases with the assistance of an academic librarian. The databases were ACM (Association for Computing Machinery), IEEE (Institute of Electrical and Electronics Engineers), Web of Science, PubMed, Scopus, Cochrane (Cochrane Collaboration), and AIS (Association for Information Systems) eLibrary. These 7 databases were chosen because of the interdisciplinary nature of the research question. Public reporting spans both health care and ISs, which shaped the decision to search databases from both domains. The search strategy was developed with an academic librarian, using keywords and synonyms related to public reporting (eg, "public performance," "report card," "quality report") combined with "healthcare" using Boolean operators. The second strand was an IS-targeted search, adding technical synonyms including "architecture," "interoperability," "FHIR," "HL7," "data governance," "application programming interface (API)," "usability," "user experience," "dashboard," and "platform," combined with the public reporting terms. Full search strings for all 7 databases are provided in Multimedia Appendix 1. The search was carried out across titles, abstracts, and keywords. A total of 1882 articles were retrieved and imported into the EndNote reference management software for further analysis. Reviewers (ED, MM) removed duplicates before conducting further screening.

Data Charting

An extraction spreadsheet for charting was developed in Microsoft Excel to extract the relevant information needed to address the objectives of this review. The data extraction was piloted on 50 articles included in this review, and all modifications were made based on discussions and feedback from the reviewers, in an iterative process. The modifications included the addition of new columns for extracting the aim of the study and the results of all 233 articles.

All 1127 records were manually screened by 2 independent reviewers (ED and MM) in 2 stages (title or abstract screening and full-text screening). The final set of 233 included articles was read in full and manually charted by the reviewers (ED and MM), ensuring comprehensive coverage of the evidence base. Discrepancies at each stage were resolved through consensus, with RS acting as a third reviewer when required.

The complete extraction table, containing study-level details for all 233 included articles, is provided in Multimedia Appendix 2.

Data Items

The data items included the following:

- Authors
- Affiliation
- Country
- Title
- Year
- Journal
- Type of study
- PRS type
- Method
- Sample size
- Main outcome
- Field
- Architecture
- Interoperability
- Data governance
- APIs
- Usability
- Technical performance
- Quantitative, qualitative, or mixed method

IS Coding Framework and Reliability

Each of the 6 IS dimensions was coded using the following categories: absent (the study explicitly indicated that the dimension was absent), limited (the dimension was mentioned briefly without technical detail), moderate (the dimension was described with some technical or operational detail), strong (the dimension was examined systematically with substantial technical detail), and not reported (the study did not provide sufficient information to assess the dimension). For borderline cases, hybrid categories (limited/moderate and moderate/strong) were used. Reviewers also retained qualitative justification notes for each classification. Interrater reliability for the IS coding dimensions ranged from 0.71 to 1.00 (Cohen *k*), indicating substantial to almost perfect agreement.

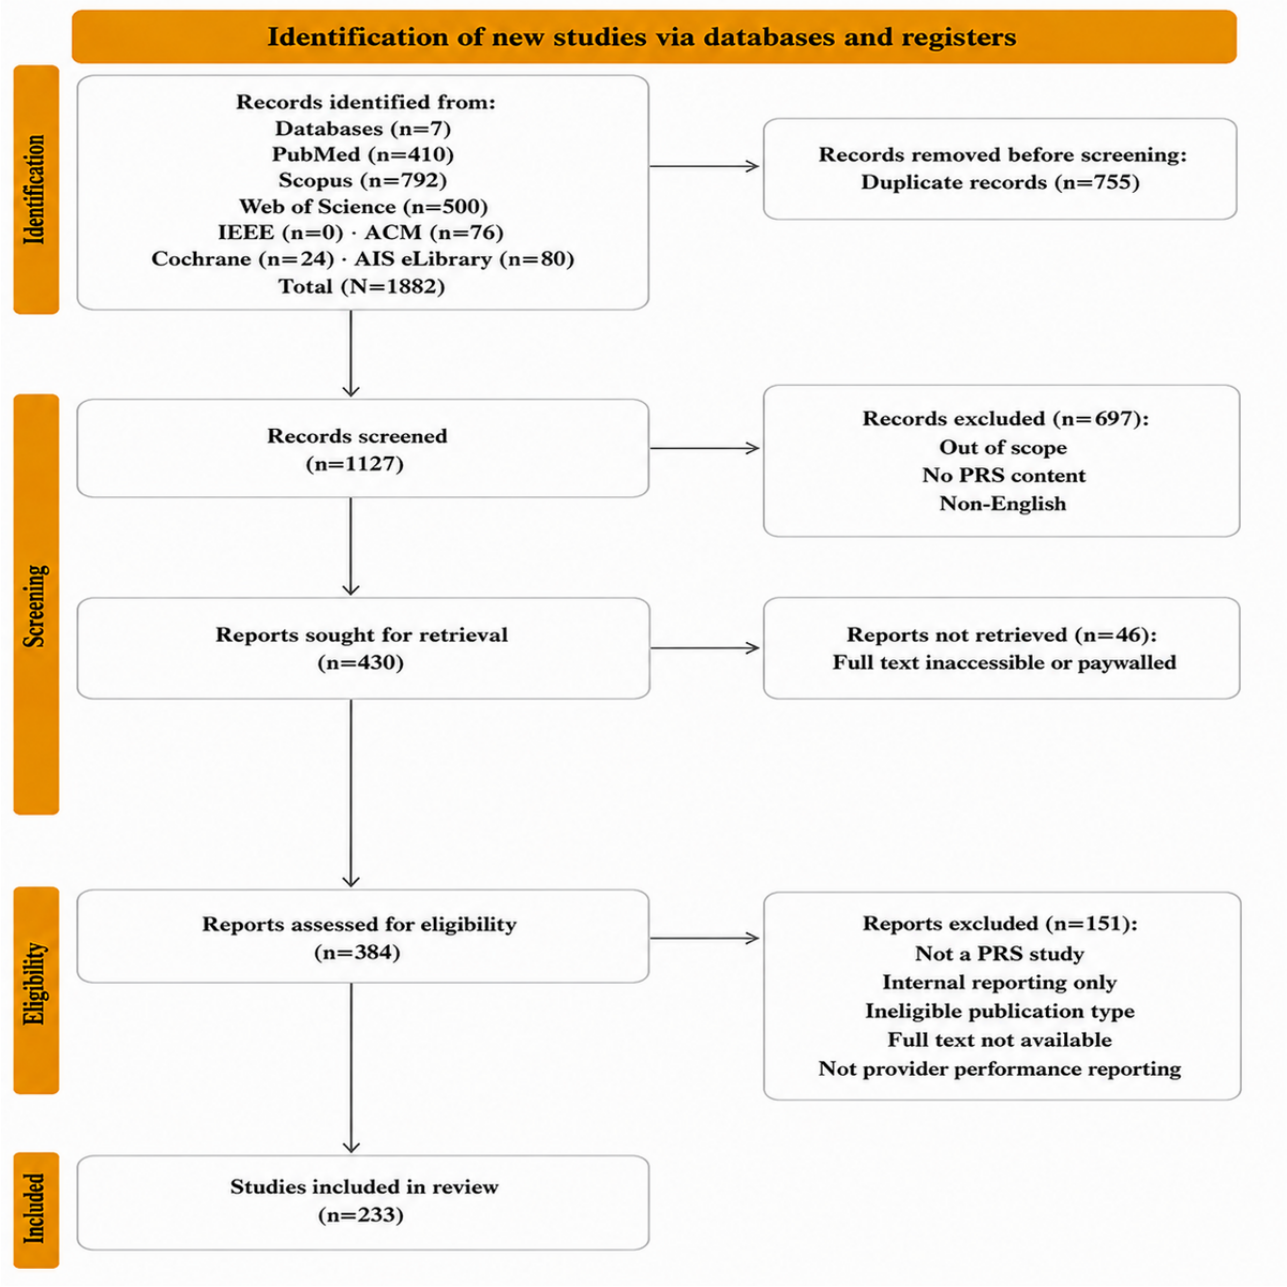
Data Analysis and Presentation

Descriptive statistics (frequencies, percentages, and graphs) were used to summarize study characteristics including geographic distribution, study design, and publication trends. Nominal data were presented in tables and figures. Narrative synthesis was used to identify overarching themes, interpret the quantitative coding findings, and identify research gaps.

Critical Appraisal

Consistent with the JBI guidance for scoping reviews, we did not undertake a formal risk-of-bias appraisal because the objective of a scoping review is to map the breadth and nature of the evidence rather than to synthesize effectiveness or causality.

Results



Study Selection

The database search yielded 1882 articles across 7 databases: PubMed (n=410), Scopus (n=792), Web of Science (n=500), IEEE (n=0), ACM (n=76), Cochrane (n=24), and the AIS eLibrary (n=80). All articles were imported into Endnote, where 755 duplicate articles were identified and removed, leaving 1127 unique records for title, abstract, and keyword screening. Two reviewers (ED and MM) independently screened 1127 articles against the inclusion criteria listed in Textbox 1. Conflicts were resolved by consensus. Of these, 697 articles were excluded, leaving 430 articles for phase 2 of full-text screening against the exclusion criteria. The same reviewers (ED and MM) independently screened 430 articles for full-text retrieval, of which 46 could not be obtained due to inaccessible or paywalled full texts. The 384 retrieved articles were independently assessed for eligibility by the same 2 reviewers.

XSL•FO
RenderX

A further 151 articles were excluded at full-text review for the following reasons: not a PRS study, reporting designed solely for internal quality improvement purposes, ineligible publication type, full text not available upon further attempts, or not concerned with provider performance reporting. Disagreements at both screening stages were resolved through discussion, with a third reviewer (RS) acting as arbitrator where consensus could not be reached. A final corpus of 233 articles was included in the review. The full study selection process is presented in the PRISMA-ScR flow chart in Figure 1.

Figure 1. PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses for Scoping Reviews) flow diagram of the search and study selection process. ACM: Association for Computing Machinery; AIS: Association of Information Systems; IEEE: Institute of Electrical and Electronics Engineering; PRS: public reporting system.

Characteristics of Included Articles

The characteristics of the included articles in this scoping review are reported in Tables 2 and 3. The 233 included articles span 18 countries and settings (Table 2). The United States dominates the literature, accounting for 157 articles (67.4% of all included studies), reflecting the prominence of US-based PRSs such as Hospital Compare, Nursing Home Compare, and the Centers for Medicare & Medicaid Services (CMS) quality programs. Germany is the second most represented country, with 14 (6.0%) articles, followed by multicountry or international studies, also with 14 (6.0%) articles, which include systematic reviews, cross-national comparisons, and studies covering multiple high-income countries. The United Kingdom contributes 12 (5.2%) articles, with studies drawing primarily on NHS and Hospital Episode Statistics data. Australia and the Netherlands each account for 7 (3.0%) articles, and Canada accounts for 6 (2.6%) articles. Norway contributes 3 (1.3%) articles, while Japan, France, and China each have 2 (0.9%) articles. The remaining countries—Tajikistan, Belgium, Republic of Korea,

XSL•FO
RenderX

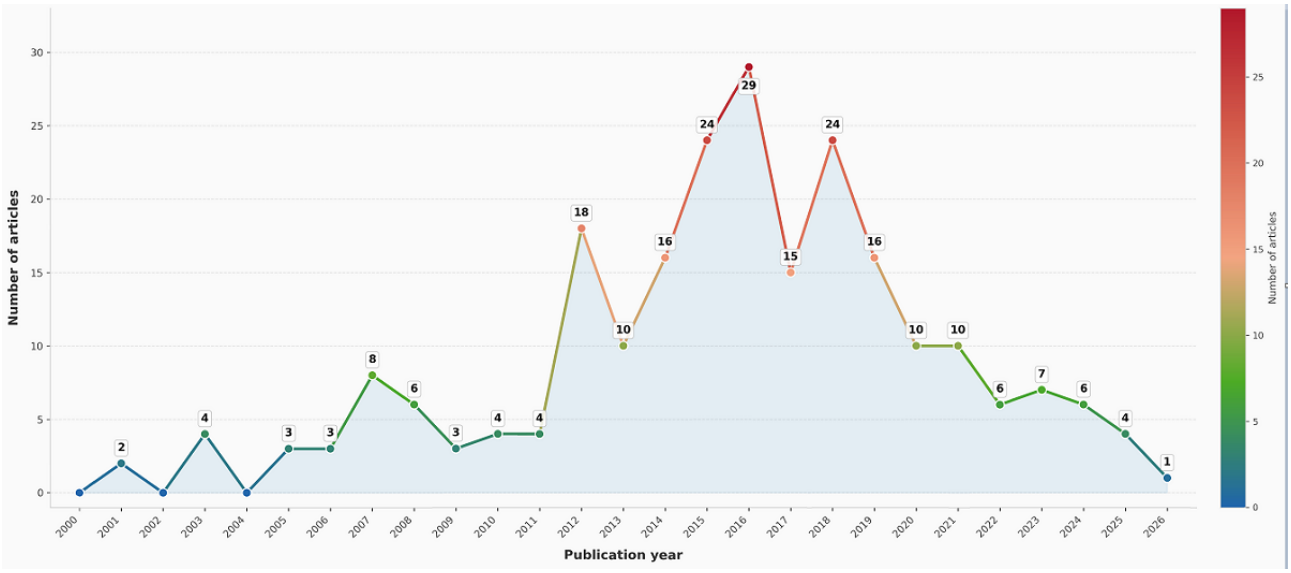
Switzerland, Sweden, Italy, and Finland—each contribute a single (0.4%) article, reflecting emerging but limited international scholarship on PRSs outside North America and Western Europe.

Table . Geographic distribution of the 233 included studies by country (n=233).

Countries	Studies, n (%)
United States	157 (67.4)
Germany	14 (6.0)
Multicountry	14 (6.0)
United Kingdom	12 (5.2)
Netherlands	7 (3.0)
Australia	7 (3.0)
Canada	6 (2.6)
Norway	3 (1.3)
Japan	2 (0.9)
France	2 (0.9)
China	2 (0.9)
Tajikistan	1 (0.4)
Belgium	1 (0.4)
Republic of Korea	1 (0.4)
Switzerland	1 (0.4)
Sweden	1 (0.4)
Finland	1 (0.4)
Italy	1 (0.4)

Table . Methodological characteristics of the 233 included studies.

Study design	Studies, n (%)
Quantitative	141 (60.5)
Qualitative	56 (24.0)
Mixed methods	36 (15.5)



Study Design

The included articles reflect a predominantly quantitative literature (Table 3). The largest group comprises quantitative observational studies (n=100, 42.9%), encompassing cohort studies, cross-sectional analyses, retrospective database studies, and longitudinal evaluations of publicly reported quality metrics. The second-largest group comprises qualitative, conceptual, and review studies (n=56, 24.0%), including systematic reviews, narrative reviews, policy analyses, conceptual papers, and qualitative interview studies examining stakeholder perceptions and implementation experiences. Mixed methods studies account for 36 (15.5%) articles, combining qualitative and quantitative approaches. Methodological and validation studies represent 27 (11.6%) articles, focusing on statistical methods such as risk adjustment, profiling methods, measure development, and simulation studies. Finally, quantitative survey, experimental, and cohort studies make up 14 (6.0%) articles, including randomized web experiments, online surveys, and choice experiments examining consumer responses to publicly reported information.

Figure 2 shows a clear trend in publications on PRSs, rising steadily from 2001 to 2016, followed by a gradual decline (Multimedia Appendix 3). Output was sparse in the early 2000s, averaging fewer than 5 studies per year prior to 2012, with a brief exception in 2007-2008. A sharp increase began around 2012 (n=18), reaching a peak in 2016 (n=29, 12.4%). After 2016, publication volume declined but remained relatively active through 2019 to 2021, with 16 studies in 2019 and 10 studies in each of 2020 and 2021. Output tapered further from 2022 onward, with only 1 study recorded in 2026, reflecting the early search date. Overall, the bulk of the literature was published between 2012 and 2019, accounting for more than half of all included articles.

RenderX

Figure 2. Annual distribution of included studies by publication year (2000 - 2026).

IS Dimension Coverage

The central quantitative finding of this review is summarized in Table 4, which presents the distribution of IS coding levels across all 6 dimensions for the 233 included studies.

Table . Information systems dimension coverage across the 233 included studies, assessed using a structured coding framework comprising 6 core technical substrate dimensions[a].

Dimension	Absent, n (%)	Limited, n (%)	Limited/moderate, n (%)	Moderate, n (%)	Moderate/strong, n (%)	Strong, n (%)	Not reported, n (%)
Architecture	—[b]	69 (29.6)	1 (0.4)	35 (15.0)	—	16 (6.9)	112 (48.1)
Interoperability	—	60 (25.8)	1 (0.4)	34 (14.6)	1 (0.4)	14 (6.0)	123 (52.8)
Data governance	—	30 (12.9)	—	76 (32.6)	2 (0.9)	115 (49.4)	10 (4.3)
APIs[c]	9 (3.9)	—	—	—	—	1 (0.4)	223 (95.7)
Usability	—	78 (33.5)	3 (1.3)	52 (22.3)	4 (1.7)	38 (16.3)	58 (24.9)
Technical performance	—	59 (25.3)	5 (2.1)	69 (29.6)	1 (0.4)	93 (39.9)	6 (2.6)

[a]Absent: the study explicitly indicated that dimension was absent; limited: the dimension was mentioned briefly without technical detail; moderate: the dimension was described with some technical or operational detail; strong: the dimension was examined systematically with substantial technical detail; not reported: insufficient information was provided to assess the dimension. Hybrid categories (limited/moderate and moderate/strong) were used for borderline cases, and qualitative justification notes were retained in the extraction table.

[b]Not available.

[c]API: application programming interface.

Architecture

Architecture received no ISs relevant coding in 48.1% (n=112, not reported) of the studies and was rated limited or limited or moderate in a further 30.0% (n=70) of the studies, meaning 78.1% (n=182) of the included studies provide no substantive IS analysis of system architecture. Moderate architecture coverage was identified in 15.0% (n=35) of the studies. Strong architecture coverage was identified in only 16 (6.9%) studies. Exemplars include Cebul [57], describing an electronic medical record–integrated diabetes registry with explicit infrastructure detail (strong architecture, strong data governance, strong technical performance), Fu et al [58] demonstrate health information exchange–based automated quality reporting through the Long Beach Network for Health, and Friedrichson et al [59] describe an interactive national Extracorporeal Membrane Oxygenation dashboard built from merged public reimbursement data and hospital quality reports. These studies share a common feature: they were authored by teams that include IS or informatics researchers alongside clinical domain experts, a collaboration pattern absent from the vast majority of the corpus.

Interoperability

Interoperability received no IS relevant coding in 52.8% (n=123, not reported) of the studies and was rated limited or limited or moderate in a further 26.2% (n=61) of the studies. Collectively, 79.0% (n=184) of the included studies provided no substantive

XSL•FO
RenderX

engagement with interoperability standards. Strong interoperability coverage was found in only 14 (6.0%) studies. No study systematically evaluated FHIR-based exchange for PRS, and only 2 studies mentioned HL7 standards in any substantive technical sense. Mentions of "data sharing" or "online reporting portals" without reference to interoperability standards were common and were coded as absent. Studies with moderate interoperability typically described registry-to-claims data linkage processes; those with strong ratings (n=14) included national-scale registries with documented data integration pipelines.

Data Governance

Data governance was the strongest-performing dimension: 49.4% (n=115) of studies were rated strong, and 32.6% (n=76) were rated moderate, with a further 0.9% (n=2) rated moderate or strong. However, a critical finding concerns the nature of this governance coverage. Detailed examination reveals that strong and moderate governance ratings in this corpus almost exclusively reflect measurement governance, including risk adjustment methodology, measure validity, reliability testing, indicator construction rules, and statistical quality controls. Data stewardship governance, including data provenance tracking, access control frameworks, consent management, and alignment with regulatory frameworks such as General Data Protection Regulation or Health Insurance Portability and Accountability Act, was effectively absent. For example, measurement governance determined whether a hospital mortality indicator uses a 30-day or 90-day follow-up period and how risk adjustment is specified [60,61]; infrastructure data governance determines how source data are transferred, secured, versioned, and traced through the reporting pipeline [62-64]. This conflation between measurement validity and system-level data governance is a recurring conceptual error with implications for how PRSs evidence translates into system design.

APIs

APIs represent the most acute gap in the PRS literature. Nearly all studies (232, 99.6%) contained no discussion of APIs, open data end points, or programmatic data access. The single exception, Fife et al [65], described a wound registry-based Qualified Clinical Data Registry under Merit-based Incentive Payment System, mentioned open API support only as a future aspiration rather than an implemented technical feature. This finding is particularly significant given that the 21st Century Cures Act (2016, enacted 2021) and the CMS Interoperability and Patient Access Final Rule (2020) have made FHIR-based, open API access a regulatory requirement for health IT systems in the United States, the source of 67.4% (n=157) of this corpus. The literature has simply not registered this regulatory infrastructure shift.

Usability

Usability evidence was present but systematically skewed. Strong usability was identified in 16.3% (n=38) of the studies, with most of it concentrated in consumer-facing format experiments: icon versus numerical display, star ratings versus word labels, narrative versus structured performance data, and health literacy-focused accessibility work. These studies collectively constitute a well-developed subliterature on how patients read and respond to publicly reported data. By contrast, the usability of provider-facing data submission interfaces, administrator-facing reporting dashboards, and the data collection workflows that generate PRS data was almost entirely absent. The asymmetry is a structural gap in the field: rich knowledge of what patients see, near-zero knowledge of the systems that produce what they see.

Technical Performance

Technical performance was rated strong in 39.9% (n=93) of the studies and moderate in a further 29.6% (n=69) of the studies, but detailed coding revealed that this predominantly reflected statistical performance rather than IS system performance. C-statistics, calibration curves, model discrimination, receiver operating characteristic analyses, and measurement reliability coefficients, all statistical properties of measurement instruments, were routinely reported under what we initially coded as technical performance. Once IS performance (latency, throughput, scalability, uptime, data refresh frequency) was recorded separately from statistical performance, fewer than 8% (n=18) of the studies contained genuine IS system performance data. This conflation of measurement validity with IS performance pervaded the literature, representing a systematic miscategorization of what is technically known about PRS infrastructure.

Discussion

This scoping review mapped 233 studies on PRSs in health care published between 2000 and 2026. Applying a technical substrate framework, which is a core dimension of IS comprising architecture, interoperability, data governance, APIs, usability, and technical performance to all included studies, reveals a pattern of coverage that is both uneven and shallow in analytical depth.

Technical Substrate: A Core IS Dimension That Is Systematically Absent

The technical substrate, one of the core IS dimensions through which PRSs can be analyzed, is unevenly and sparsely represented across the 233 included studies. This is important because IS research has long argued that system quality, information quality, infrastructure, and the IT artifact itself should not be treated as neutral or invisible background conditions but as central objects of analysis [66-68]. Architecture received substantive IS engagement (moderate or strong) in only 21.9% (n=51) of the studies, interoperability was engaged at a strong level in only 6.0% (n=14) of the studies, and usability was addressed at a strong level in 16.3% (n=38) of the studies, though almost exclusively in consumer-facing format experiments rather than system-level evaluations.

Where technical substrate elements appeared, they were incidental rather than operationalized and were referenced without architectural specification, formal testing, or analytical depth. These are not marginal omissions. PRSs are, at their core, large-scale ISs that collect, aggregate, standardize, validate, and disseminate sensitive health care data across heterogeneous providers, administrative systems, and public interfaces. The

XSL•FO
RenderX

design choices embedded in their architecture determine what data are collected, how data are transformed, who can access them, and whether the resulting output is trustworthy and actionable. Health informatics research makes clear that secondary use of health care data requires explicit attention to data quality dimensions such as completeness, correctness, concordance, plausibility, and currency, as well as harmonized terminology, stewardship, and governance practices [69-71].

The absence of IS scholarship in this domain means that those design choices are being made without the theoretical or empirical guidance that IS research could provide. Without examining the technical substrate, stakeholders cannot generate actionable guidance for designing interoperable, trustworthy, user-centered reporting systems, which limits the capacity of public reporting to improve care quality and patient empowerment despite significant public investment.

Data Governance: Conflation of Indicator Quality With Infrastructure Governance

A critical interpretive finding concerns the nature of data governance coverage. On the surface, data governance appears to be a relative strength, with 82.8% (n=193) of the studies rated moderate or strong. However, detailed examination reveals that these ratings almost exclusively reflect measurement governance, including the validity, reliability, and statistical properties of performance indicators [72,73], rather than system-level data governance such as data provenance frameworks, access control architectures, consent management, or alignment with regulatory requirements such as the General Data Protection Regulation or the Health Insurance Portability and Accountability Act [70,74-77]. This conflation between indicator quality and infrastructure governance is not merely a semantic distinction; it represents a fundamental gap in the field's understanding of what makes PRSs trustworthy, secure, and sustainable. No included study examined how rules and responsibilities for data stewardship, security, and accountability are formally designed in PRSs. This is a gap with urgent practical implications for compliance risk and public trust.

Usability: Consumer-Facing Coverage and Provider-Facing Invisibility

A further structural asymmetry was identified in usability coverage. Consumer-facing usability constitutes a relatively well-developed subliterature, covering how patients read star ratings, navigate comparative dashboards, or interpret numerical versus icon-based displays, with strong usability identified in 16.3% (n=38) of the studies, concentrated in format experiments.

By contrast, the usability of provider-facing data submission interfaces, administrator-facing dashboards, and the data collection workflows that generate public reporting data is virtually absent. The systems that produce what patients see are, from a usability perspective, invisible in the literature. This absence is important because health care IS research has repeatedly shown that usability must be studied with the full sociotechnical work system, including users, tasks, tools, workflows, organizations, and the wider environment, rather than only at the final user-facing display layer [78-80].

This asymmetry has direct practical consequences: poorly designed provider-facing interfaces increase reporting burden, introduce data entry errors, and undermine the quality of the very outputs that consumer-facing usability studies seek to improve. An IS-informed approach to PRSs must address both ends of the data pipeline. This means evaluating not only the public interface through which patients compare providers, but also the upstream processes through which data are entered, validated, aggregated, transformed, and released. Such an approach aligns with IS success theory, which treats system quality, information quality, use, user satisfaction, and net benefits as interdependent, and with sociotechnical health IT research, which emphasizes that system outcomes depend on the interaction between technical design and organizational work practices [66,80].

Geographic Concentration and the Regulatory Evidence Gap

Geographically, 67.4% (n=157) of the included studies originate from the United States, yet the regulatory infrastructure shaping US health data interoperability, including the 21st Century Cures Act (2016/2021) [81] and the CMS Interoperability and Patient Access Final Rule (2020) [82], which mandate FHIR-based open API access for health IT systems, is simply not reflected in the literature.

The corpus has not registered this regulatory shift, leaving a significant and growing gap between regulatory requirements and research evidence. This is consistent with the broader Global North dominance in the corpus. Europe ranked second at 18.4% (n=43), led by Germany and the United Kingdom. This distribution underscores an important limitation: contexts with constrained digital infrastructures or limited regulatory capacity face unique challenges in implementing PRSs, yet these challenges remain underexplored. Representation from Asia was limited, while Africa and South America were not represented in the included studies. This is a notable underrepresentation of low- and middle-income countries.

Structural Drivers of the IS Gap

The disciplinary absence of IS scholarship in PRS research appears to reflect structural features of the field rather than a merely accidental omission. Three drivers may help explain this pattern. First, PRS research is predominantly published in health services research, public health, and health policy journals whose editorial cultures do not include IS expertise, creating a self-reinforcing publication environment [83-85]. Second, health care research funders historically prioritize clinical outcomes and health services effectiveness over system design: infrastructure expenditure for PRSs is absorbed into procurement budgets without generating peer-reviewed IS scholarship.

Third, the dominant paradigm in PRS research concerns whether public reporting changes behavior, including patient choice, provider performance, reputation, or market share, rather than how the IS enabling it is designed, maintained, or improved. This reflects a broader tendency in health policy research to treat digital infrastructure as a background condition rather than an object of inquiry in its own right [3,80,86].

XSL•FO
RenderX

These findings should not be read as an argument for technological solutionism. Sociopolitical factors, including provider resistance, regulatory constraints, patient health literacy, and health care market structures, shape the effectiveness of PRSs in ways that improved system architecture alone cannot resolve. The IS contribution is to make these technical dimensions legible, improvable, and empirically tractable, not to claim that they are determinative of outcomes.

Comparison to Prior Work

Prior scoping reviews and systematic reviews of public reporting have concentrated on its policy effects: whether public reporting changes provider behavior, reduces mortality, improves patient experience, or influences hospital choice. Fung et al [33], Campanella et al [22], and Cacace and Geraedt [5] established the evidentiary landscape for these questions. This review does not duplicate that work but adds a complementary dimension: it asks not whether public reporting works but whether the ISs that deliver it are being studied adequately.

This review is the first, to our knowledge, to apply a systematic IS coding framework to the public reporting literature and to demonstrate, with quantitative evidence rather than narrative assertion, that the architectural, interoperability, governance, and API dimensions are largely invisible in the research corpus.

Adjacent literatures are more advanced: patient portal usability has been well studied, and electronic health record interoperability has received sustained informatics attention. PRSs share infrastructure with all 3 but have not benefited from the IS analysis that those adjacent domains have received.

The exemplar studies identified in this review, including Cebul [57], Fu et al [58], Friedrichson et al [59], and Dehmer et al [87], demonstrate that IS-informed public reporting research is feasible and productive. These studies were consistently authored by teams that include IS or informatics researchers and clinical domain experts. Their scarcity underlines the structural driver of the IS gap: it is not that PRSs are technically unanalyzable, but that the research communities studying public reporting and those studying health ISs have remained largely separate.

Limitations

First, although we added a supplementary IS targeted search strand and expanded to 7 databases including the AIS eLibrary, it remains possible that IS native literature using heterogeneous terminology was not fully captured. Future reviews should refine the dual-strand approach and consider forward citation searching from the 5 exemplary studies identified here.

Second, our IS coding involved judgments about coverage level that are inherently interpretive. Interrater reliability was substantial to nearly perfect across dimensions (Cohen *k* range 0.71 - 1.00, as reported in the *Methods* section), but residual subjectivity cannot be eliminated, particularly for the distinction between limited and moderate.

Third, the corpus is dominated by literature from the United States (n=157, 67.4%), which limits generalizability to health care systems with different IS infrastructure and regulatory contexts. Low- and middle-income country settings, where PRSs may be developing on entirely different technical foundations (mobile-first, low-bandwidth architectures), are almost entirely absent.

Fourth, as this was a scoping review conducted per JBI guidance, formal critical appraisal was not performed.

Fifth, although the inclusion period extended to February 4, 2026, the searches were conducted early in the year. Publications from later in 2026 are therefore not represented, which may limit the review's ability to capture the most recent regulatory and interoperability-related developments, including the ongoing implementation of the 21st Century Cures Act and FHIR-based interoperability mandates.

Recommendations for Future Research

We identified several critical gaps in the literature on PRSs, with direct implications for practice. First, the included studies show a significant lack of research on the technical substrates, a core IS dimension of PRSs. Yet, these technical foundations, namely architecture, interoperability, APIs, technical performance, and data governance, are precisely what make PRSs feasible in practice. More research is therefore needed on the technical substrates of PRSs, especially because these systems function as information platforms for patients, providers, policymakers, and the public.

Second, future research should investigate data enhancement for PRSs in health care. Improvements in data quality, completeness, timeliness, and usability are directly linked to the quality of information presented through PRSs. Third, the role of API integration is notably absent from current studies, despite its practical importance. Without robust APIs and interoperable standards, health systems risk perpetuating data silos and increasing the reporting burden on providers. Research should therefore investigate how integration can streamline data flows and enable scalable, efficient, and user-friendly reporting infrastructure.

Fourth, data governance is essential in any data-intensive system. PRSs are data-driven, yet no included study examined how rules and responsibilities for data stewardship, security, accountability, and privacy are designed in these systems. This gap has urgent practical implications. Without strong governance, organizations face compliance risks, privacy breaches, reduced data integrity, and erosion of public trust. Future research should therefore examine how data governance frameworks can safeguard both data quality and public confidence.

Finally, qualitative multiple case research should be used to examine PRSs across different national and organizational contexts. This approach would allow an in-depth exploration of how institutions, policy environments, technical infrastructures, and stakeholder expectations affect the adoption and implementation of PRSs. It would also support the identification of implementation challenges and best practices, offering practical guidance for governments and health organizations seeking to design PRSs that work in real-world conditions.

XSL•FO
RenderX

A comprehensive understanding and effective use of PRSs require an integrated evidence base that spans technical, organizational, and policy dimensions. By highlighting the practical risks of overlooking the technical substrate, this review underscores the need to realign future research priorities. In particular, future scholarship should incorporate IS research more directly into the study of PRSs and generate actionable insights to design reliable, interoperable, scalable, and equitable public reporting infrastructures.

Based on our findings, we propose 6 specific IS focused research questions (RQs):

- RQ1: Architecture: What technical IS architectures (centralized vs federated registry; FHIR-native vs claims-based) are most effective for enabling accurate, timely, and scalable PRS data pipelines, and what implementation trade-offs arise across different health care system types?
- RQ2: APIs and interoperability: What API architectures (Representational State Transfer, Fast Healthcare Interoperability Resources, Release 4, Substitutable Medical Applications and Reusable Technologies on FHIR, clinical decision support Hooks) are most effective for enabling real-time, automated data submission to national PRS platforms, and what is their relative implementation burden for small versus large provider organizations?
- RQ3: FHIR adoption effects: How does the adoption of HL7 FHIR-based interoperability standards affect data acquisition cost, timeliness, completeness, and accuracy in national quality registries, compared with traditional administrative claims-based approaches?
- RQ4: IS success model applied to PRS: Using the DeLone and McLean IS success model as a theoretical lens, which IS quality dimensions (information quality, system quality, service quality) are most predictive of the impact of PRSs on provider behavior change and measurable quality improvement?
- RQ5: Data governance: How are data governance responsibilities, including stewardship, accountability, privacy, security, and compliance, designed and implemented in PRSs, and how do these governance arrangements affect data integrity, public trust, and system sustainability?
- RQ6: Comparative sociotechnical implementation: How do institutional, policy, organizational, and technological factors shape the adoption and implementation of PRSs across different countries and health care settings, and what best practices can be identified through qualitative multiple case research?

Conclusions

This scoping review maps research on PRSs in health care published between January 2000 and February 2026 and provides, to our knowledge, the first systematic quantitative characterization of the extent to which the technical substrate of PRSs, comprising architecture, interoperability, data governance, APIs, usability, and technical performance, has been addressed in the published literature. Across 233 studies, APIs were absent or not reported in 99.6% (n=232) of the studies. Architecture was not reported, limited, or limited or moderate in 78.1% (n=182) of the studies, while interoperability was not reported, limited, or limited or moderate in 79.0% (n=184) of the studies. These gaps are not merely academic. PRSs that lack interoperable, API-enabled infrastructure are unlikely to be effectively integrated into clinical workflows, updated in real time, or queried by third-party developers. Similarly, platforms without explicit data stewardship governance are vulnerable to provenance failures, reidentification risks, and regulatory noncompliance. Platforms whose provider-facing usability has never been studied may impose unmeasured reporting burdens that compromise data quality and erode clinical trust.

Advancing the field requires interdisciplinary collaboration between health care outcomes researchers, health informatics scholars, IS scientists, and the practitioners who build and maintain reporting systems. The 6 research questions proposed here offer a traceable starting point. The 4 exemplary studies identified, spanning electronic medical record–integrated diabetes registry, health information exchange–based automated reporting, national Extracorporeal Membrane Oxygenation dashboard, and national clinical dashboards, offer architectural templates. The DeLone and McLean IS success model within sociotechnical systems perspectives provides a conceptual scaffold. Without systemic examination of the technical substrate, which is a core dimension of ISs, PRSs risk becoming well-intentioned tools that deliver incomplete or inaccessible data, frustrate patients with poor usability, and burden providers with fragmented noninteroperable platforms. As a result, they may fall short of becoming the reliable, equitable, and technically robust digital infrastructures that genuine health care transparency demands.

Acknowledgments

The authors thank the university library information specialists at the University of Turku for their assistance with database search design and strategy development. Generative AI (Microsoft Copilot) was solely used to support grammar checking, improve clarity, and assist the authors in interpreting and understanding the editor's and reviewer's comments. It was not used for ideation, study design, data analysis, interpretation of results, or drafting the original manuscript.

Abstract

Background: Widespread and sustained uptake of AI-based clinical decision support systems (CDSSs) in real-world health care settings is uncommon, despite their potential to improve patient care and reduce clinician burnout. Although previous studies have examined determinants of implementing AI-based CDSSs, limited evidence has synthesized barriers and facilitators identified during actual clinical implementation and use.

Objective: The objectives of this scoping review were to (1) map and synthesize barriers to and facilitators of implementing AI-based CDSSs in real-world health care settings and (2) draw on this knowledge to inform future implementation strategies.

Methods: Five electronic databases (MEDLINE, Embase, CINAHL, APA PsycInfo, and the Cochrane Library) were searched from inception to May 2022. Eligible studies included primary research describing real-world implementation processes or reporting determinants (barriers and facilitators) of implemented AI-based CDSSs in any health care setting. Studies focused on non-decision support tasks, non-AI CDSSs, patient-facing tools, or development or effectiveness without implementation were excluded. No study design restrictions were applied. Full texts were reviewed to extract explicit statements describing determinants influencing implementation. These determinants were classified as barriers or facilitators and mapped to the Consolidated Framework for Implementation Research (CFIR) by 2 independent reviewers. A qualitative synthesis was conducted.

Results: After removing 4234 duplicate records, 10,875 articles were screened by title and abstract, which excluded 10,355 articles. After further exclusions based on full-text availability, 494 full-text articles were assessed for eligibility, of which 13 met the inclusion criteria. Nine of these studies reported explicit implementation determinants and were included in the CFIR-based synthesis. Studies were primarily conducted in the United States and involved multicenter implementation of machine learning-based CDSSs in critical care and emergency medicine settings. A total of 28 determinants (16 barriers and 12 facilitators) were identified. Barriers were most frequently mapped to the inner setting, innovation, and individuals domains, whereas facilitators were most frequently mapped to the implementation process and innovation domains. Common barriers included limited algorithm interpretability, data quality and management challenges, misalignment with clinical workflows, and insufficient user capability and motivation. Facilitators included early and ongoing assessment of end-user needs, stakeholder engagement, peer endorsement, and robust supporting evidence.

Conclusions: This review identified key determinants influencing the real-world implementation of AI-based CDSSs, highlighting the importance of system design, organizational context, and implementation strategies. However, the small number of studies reporting explicit implementation determinants underscores a critical gap in the literature, suggesting that many real-world implementations do not adequately evaluate or report factors influencing adoption and sustained use. Addressing this gap will be essential for advancing the translation of AI-based CDSSs into routine clinical practice. These findings provide a foundation for developing targeted implementation strategies and emphasize the need for more rigorous, implementation-focused research in real-world health care settings.

KEYWORDS

machine learning; artificial intelligence; AI; clinical decision support; personalized medicine; implementation science

Introduction

AI refers to the capability of computerized systems to perceive, synthesize, and infer information in a manner mimicking the human brain. This can be achieved through symbolic representations of existing knowledge bases (ie, rule-based AI) or purely data-driven approaches, such as machine learning (ML) [1]. In health care, AI can help clinicians personalize patient care by aiding diagnosis, treatment planning, and risk stratification as well as decreasing their cognitive burden (eg, via task automation) [2]. Recent advances in health IT and digital medicine have also allowed AI to emerge as a driver of efficient, accurate, and confident decision-making [3]. Clinical decision support systems (CDSSs) using AI can leverage the large amounts of health data generated during routine practice to provide patient-level insights and optimize care [4].

The emerging potential of AI to improve patient care is demonstrated by an increasing number of studies describing the development of AI-based CDSSs. However, these tools often do not see successful adoption and integration into clinical practice. Implementing innovations in health care is complex, primarily due to the broad range of interested parties involved (health care providers, patients, caregivers, etc), criticality of the decisions being made, and strict regulations and standards within the space [5,6]. Several challenges unique to AI-based CDSSs add to this complexity, including concerns about legal accountability; limits to autonomy; and data quality, security, and privacy [7-9]. Understanding these determinants represents a foundational step in developing robust strategies that promote successful implementation and sustained use to realize the full clinical benefit of AI-enabled decision support [6].

Although these issues have been explored extensively in the literature, many studies have focused on implementation planning, feasibility, or anticipated adoption challenges rather than determinants identified during real-world implementation. Hence, this scoping review aimed to (1) map and synthesize barriers to and facilitators of implementing AI-based CDSSs in real-world health care scenarios and (2) draw on this knowledge to inform future implementation strategies.

Methods

Design

This scoping review was conducted according to the Joanna Briggs Institute methodology and reported following the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) checklist. Ethics approval was not required as all data used were published prior to study initiation.

Data Sources, Search Strategy, and Article Selection

A detailed protocol for this review has been published previously [3]. In brief, potential evidence sources were identified by searching 5 electronic databases (MEDLINE, Embase, CINAHL, APA PsycInfo, and the Cochrane Library) for articles describing clinical decision support, implementation and/or determinants, and AI or ML published from database inception until May 10, 2022. These databases were selected to capture clinical and health service literature relevant to the real-world implementation of AI-based CDSSs. Given the focus on implementation within clinical practice environments, databases indexing biomedical and health service research were prioritized. Technical and engineering databases were not included as they predominantly index studies focused on algorithm development, model performance, or technical validation rather than real-world clinical implementation.

Key search concepts and corresponding keywords are listed in Table 1. The full electronic search strategy for MEDLINE (Ovid) is provided in Table S1 in Multimedia Appendix 1 [10-18]. Search strategies for the other databases were adapted from this core strategy using database-specific operations and syntax. The titles and abstracts of the articles returned from the search were screened for potential relevance by 3 independent reviewers, requiring agreement from at least 2 reviewers to be included for full-text screening. The full-text screening and selection of final articles was carried out by 2 independent reviewers according to the eligibility criteria described in the following section. Disagreements were handled by a third reviewer who participated in the initial abstract screening. Reasons for exclusion at the full-text stage were recorded and are summarized in the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram.

[a]Concepts were combined using the Boolean and proximity operator "AND," and the search terms within each concept were combined using "OR."

Eligibility Criteria

Primary research describing the implementation process or reporting determinants (barriers and facilitators) of implemented AI-based CDSSs was considered eligible for inclusion. AI was defined as any computerized system with capabilities for perceiving, synthesizing, and inferring information in a humanlike manner, encompassing both traditional rule-based and modern data-driven techniques [1]. Clinical decision support was defined as the generation of actionable diagnostic or prognostic insights intended to aid clinicians in making personalized decisions about patient care, which resulted in the exclusion of studies focusing on nondecision task automation, for example, image segmentation and recognition tasks in radiology. Studies were also excluded if they described non-AI-based CDSSs or solely patient-facing aids or if they reported on the development and/or effectiveness of AI-based CDSSs but did not describe their implementation. Eligibility was not limited by study design or language. A summary of the inclusion and exclusion criteria is provided in Table 2.

Table . Eligibility criteria for identifying studies on the implementation of AI-based clinical decision support systems (CDSSs).

Domains	Inclusion criteria	Exclusion criteria
Population and setting	Clinical health care settings involving patient care	Nonclinical or purely simulated settings
Intervention	AI-based CDSSs	Non-AI CDSSs or tools not intended for clinical decision support
CDSS function	Provides treatment planning or prognostic decision support	Limited to nondecision tasks (eg, segmentation and data processing)
Implementation focus	Reports implementation process or determinants (barriers and facilitators)	Model development, validation, or performance evaluation only
End user	Intended for clinician use	Patient-facing decision aids
Study design	All study designs	None (no design restrictions)

Quality Assessment

Consistent with scoping review methodology and the objective of mapping the breadth of available evidence, a formal assessment of risk of bias or methodological quality of the included studies was not conducted.

Data Extraction and Analysis

Bibliometric information, study characteristics, reported determinants, and implementation details were abstracted from the articles selected for inclusion using a standardized data extraction form developed and piloted by 2 independent reviewers. Prior to full data extraction, reviewers completed a calibration exercise using a subset of included studies to ensure consistency in data abstraction. A split-half approach was used whereby each reviewer extracted data from a subset of studies and cross-checked the extracted data to identify and resolve discrepancies.

All abstracted determinants were mapped to the updated Consolidated Framework for Implementation Research (CFIR) to inform our analysis of implementation experiences [19]. The CFIR was selected as it provides a comprehensive and widely used framework for systematically categorizing multilevel determinants influencing implementation in health care settings [19,20]. The CFIR contains 5 main domains: innovation, inner setting, outer setting, individuals, and implementation process. The innovation domain refers to characteristics of the system being implemented. The inner setting and outer setting domains refer to the setting in which the innovation is being implemented

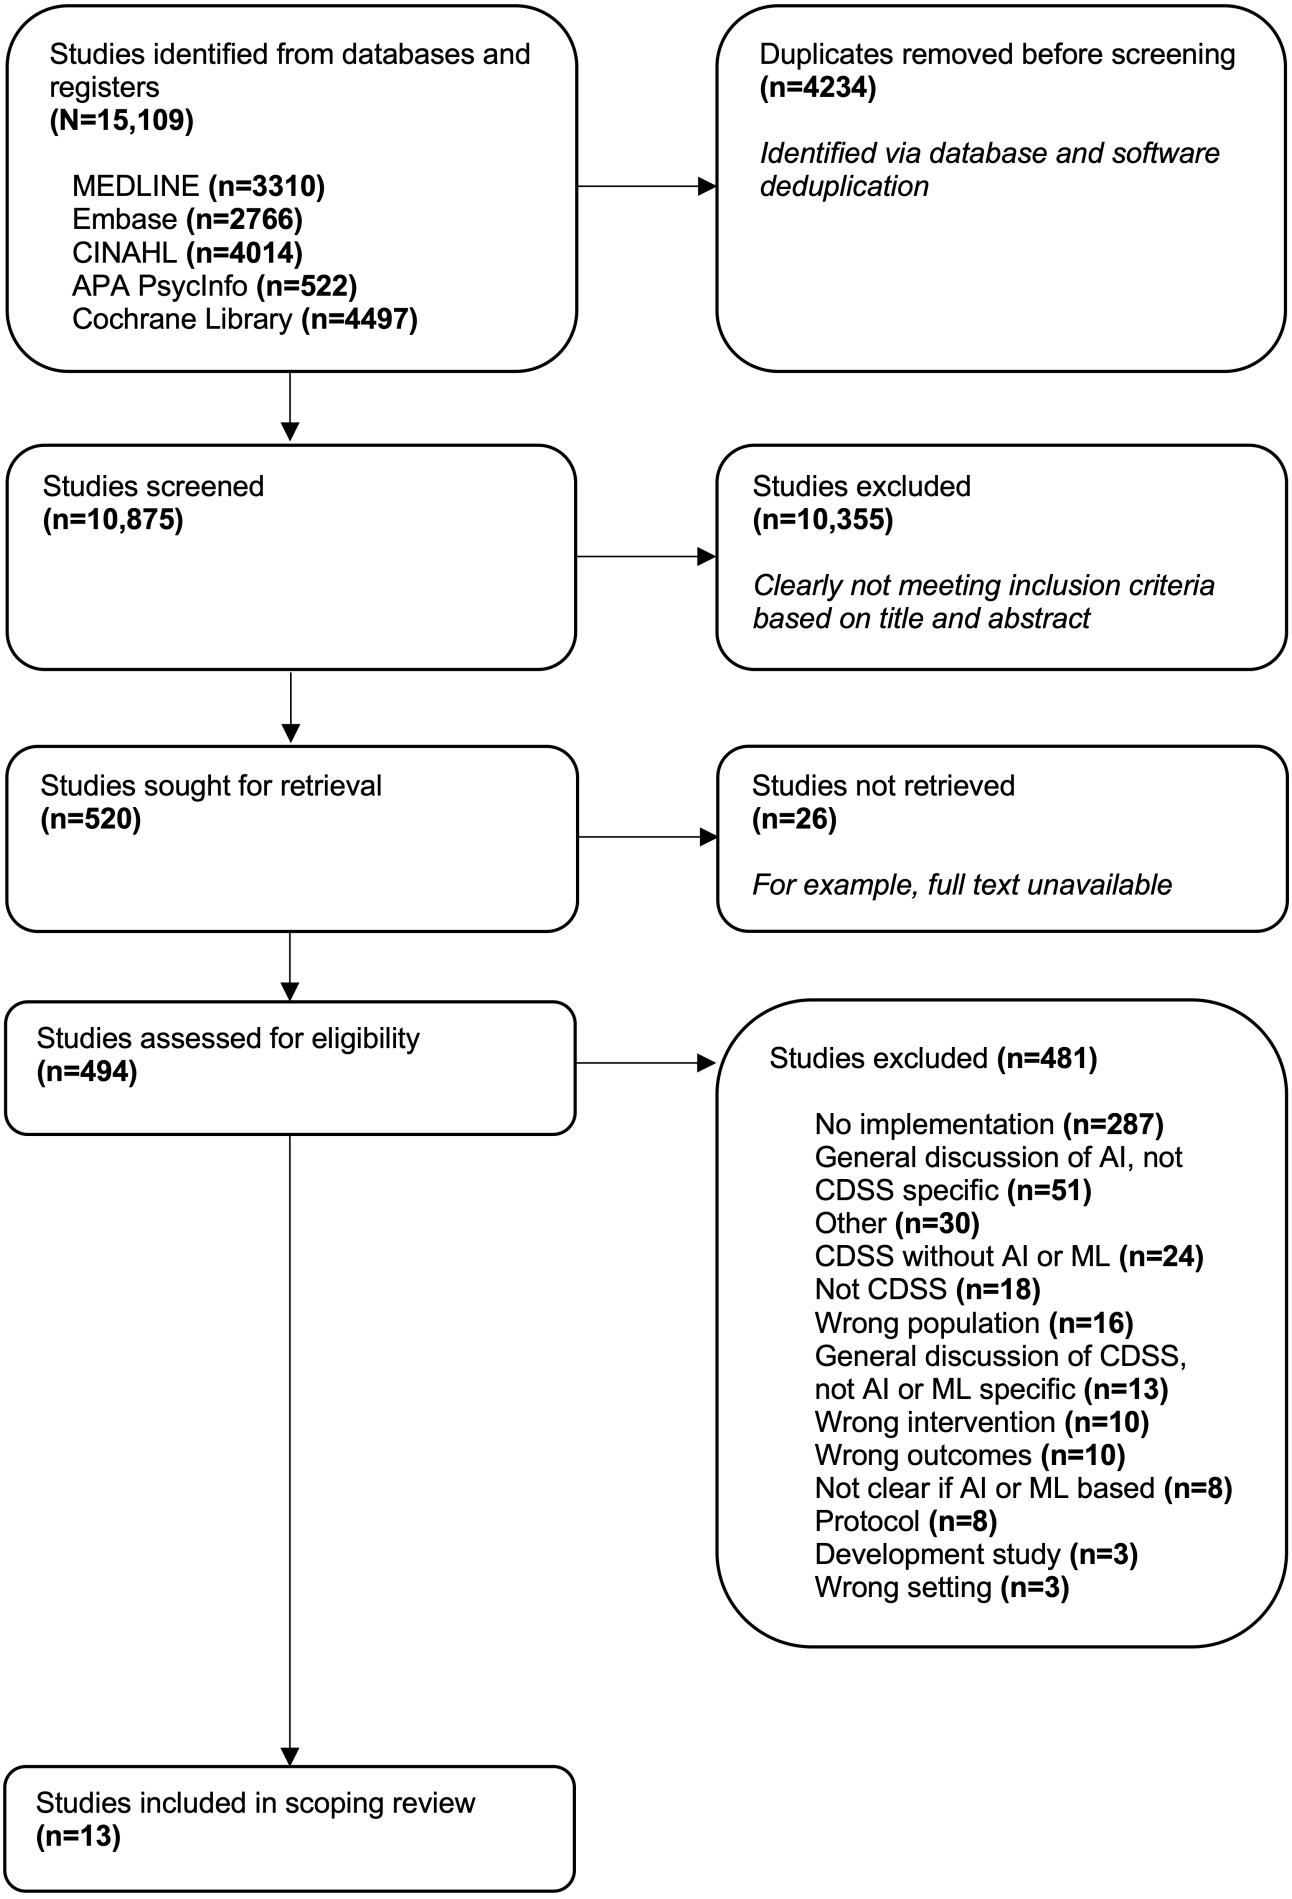
XSL•FO
RenderX

(eg, clinical unit or department) and the setting in which this inner setting exists (eg, hospital or health system), respectively. The individuals domain refers to characteristics of the individuals involved in implementation (eg, leaders, innovation deliverers, and innovation recipients), and the implementation process domain describes the activities and strategies being used to implement the innovation.

Determinants were identified by reviewing the full texts of the included studies to extract explicit statements describing factors that influenced the implementation of AI-based CDSSs. Extracted data consisted of verbatim quotations or clearly stated author interpretations reflecting barriers to or facilitators of implementation.

Two reviewers independently identified and extracted eligible determinant statements and classified them as barriers or facilitators based on whether they were described as hindering (barriers) or supporting (facilitators) implementation processes or outcomes. These determinants were then mapped to CFIR domains and constructs. Mapping decisions were based on the underlying meaning and implementation context of each extracted statement, with determinants assigned to the CFIR construct that most closely reflected the primary implementation-related factor described. General descriptions of system features, usability outcomes, or design characteristics were not considered determinants unless they were explicitly linked to implementation processes or outcomes. Discrepancies were resolved through discussion and consensus. Only studies reporting explicit implementation determinants were included in the CFIR-based synthesis.

Results



Study Characteristics

A total of 15,109 evidence sources were identified in our initial search, of which, after removal of 4234 (28.0%) duplicate records, 10,875 (72.0%) studies were screened based on title and abstract. Following title and abstract screening, of the 10,875 screened studies, 10,355 (95.2%) were excluded. After removing based on full text availability, 494 (4.5%) articles were assessed for eligibility. Of these 494 articles, 13 (2.6%) met the inclusion criteria and were included in the final review (Figure 1). Study-level characteristics for each included source of evidence are summarized in Table 3.

Most excluded studies did not report on system implementation at all or did not describe it in sufficient detail (Figure 1). Nearly all included articles (11/13, 85%) were published between 2019 and 2022 by scholars from the United States. Over half (7/13, 54%) of the selected studies discussed AI-based CDSSs developed for use in critical care (ie, sepsis or delirium) and emergency medicine settings, and most systems (8/13, 62%) were ML based and implemented at a multicenter scale (Table 3).

Of the 13 included studies, 9 (69.2%) explicitly reported implementation determinants (barriers and/or facilitators) and were therefore included in the CFIR mapping. The remaining 4 (30.8%) studies did not meet the criteria for explicit determinant extraction as they focused primarily on system design, usability, or general implementation considerations without clearly identifying barriers or facilitators tied to the implementation process. Extracted quotations, CFIR mappings, and barrier and facilitator classifications are provided in Table S2 in Multimedia Appendix 1 [10-18].

Principal Determinants of Implementation

Overview

This synthesis is based on the 9 included studies that explicitly reported determinants (barriers and facilitators) of implementing AI-based CDSSs. A total of 26 quotes were extracted, from which 28 distinct determinants were identified and mapped to the CFIR. Of these 28 determinants, 16 (57.1%) were classified as barriers, and 12 (42.9%) were classified as facilitators. A detailed breakdown of the CFIR domain and construct mappings is provided in Table 4. Full study excerpts with corresponding classifications and mappings are presented in Table S2 in Multimedia Appendix 1 [10-18].

Outer setting	
External pressure	[10,11]

Barriers were most frequently mapped to the inner setting domain (6/16, 38%), followed by the innovation (5/16, 31%), individuals (4/16, 25%), and outer setting (1/16, 6%) domains, with no barriers mapped to the implementation process domain. In contrast, facilitators were most frequently mapped to the implementation process domain (6/12, 50%), followed by the innovation (3/12, 25%), inner setting (2/12, 17%), and outer setting (1/12, 8%) domains, with no facilitators mapped to the individuals domain.

Overall, determinants were most commonly mapped to the innovation (8/28, 29%) and inner setting (8/28, 29%) domains, followed by the implementation process (6/28, 21%), individuals (4/28, 14%), and outer setting (2/28, 7%) domains. Within the innovation domain, the evidence base and complexity constructs were most frequently represented, whereas compatibility and structural characteristics accounted for most of the inner setting mappings. Determinants mapped to the implementation process domain were exclusively identified as facilitators, whereas those mapped to the individuals domain were exclusively identified as barriers.

Innovation

A large proportion of determinants identified in this study were mapped to the innovation domain, which focuses on the characteristics of the system being implemented [19]. Key determinants within this domain were related to system complexity, the strength of the evidence base, transparency of AI models, concerns related to data quality and consistency, and perceived relative advantage over existing clinical practices. These determinants were reported across multiple studies and reflect common considerations related to the design and functionality of AI-based CDSSs.

Inner Setting

Determinants mapped to the inner setting domain, which refers to the setting in which the innovation is implemented (eg, hospital, clinic, or health care organization), were also identified as important when implementing AI-based CDSSs [19]. Key determinants within this domain included availability of IT infrastructure and hardware and data management requirements. Several studies highlighted the importance of integrating new systems into existing clinical practice without disrupting workflows [10,13,14,17].

Individuals

A small number of determinants identified in this study were mapped to the individuals domain, which explores the roles and characteristics of those directly involved with the innovation and its implementation [19]. Determinants within this domain included user skills, motivation, and the roles of team leads and opinion leaders, as well as considerations related to assessing user needs and preferences.

Implementation Process

Determinants mapped to the implementation process domain, which encompasses the strategies and activities used to plan, execute, and sustain implementation [19], included activities such as planning, engaging stakeholders, and establishing multidisciplinary teams to support implementation.

Outer Setting

Determinants mapped to the outer setting domain, which refers to external influences on implementation, such as policies, regulations, and broader health care system factors [19], included the use of periodic feedback on guideline concordance to support sustained clinician engagement. Additional determinants reflected concerns about potential regulatory use of AI-based CDSSs to standardize care in ways that may conflict with clinician judgment, as well as the need for external validation (eg, clinical trial evidence) to support trust in system recommendations. No determinants were mapped to the policies and laws construct of the outer setting domain.

Discussion

Principal Results

Despite a recent increase in publications describing the development of AI-based CDSSs, successful real-world implementations in health care remain limited. Given their potential to improve the quality of patient care and reduce clinician burden, a better understanding of how to effectively implement these tools is needed [8].

This scoping review identified several key determinants from studies describing real-world implementations, including the robustness of the evidence base supporting efficacy claims, the availability of sufficient IT infrastructure, how well the system can be integrated with current clinical workflows and processes, and the overall complexity of the system. Assessing clinician needs, outlining and reviewing implementation plans, forming multidisciplinary implementation teams, encouraging clinician adoption and participation in implementation, and providing performance-based feedback were also found to be primary facilitators of implementation. Conversely, barriers may be faced when clinician end users and/or implementation leads lack the capabilities or motivation to fully commit to the project. Other determinants included the generalizability of the AI models to different patient populations, the relative advantage offered by the system compared to current practice, access to training sessions and educational materials for users, data availability, and shared values about clinician and patient needs.

Notably, only a small number of studies reported explicit implementation determinants, highlighting a critical gap in the literature. This suggests that many real-world implementations of AI-based CDSSs may not adequately evaluate or report factors influencing adoption and sustained use. Addressing this gap will be essential for advancing the translation of these systems into routine clinical practice.

Principal Determinants of Implementation

Innovation

Our findings indicate that a large proportion of implementation determinants were related to the innovation domain, highlighting the importance of system-level characteristics in shaping the adoption of AI-based CDSSs. In particular, the complexity and evidence base underpinning these systems appear to play a central role in influencing initial acceptance by clinician end users.

For many clinicians, the importance of practicing evidence-based medicine contributes to a (potentially well-founded) mistrust of black-box AI models making predictions for which credibility cannot be easily confirmed. They may also face additional difficulties in shared decision-making environments where sufficient levels of patient understanding are required [13,25]. This “black-box problem” is increasingly evident for modern ML algorithms, for which a significant trade-off is often made between performance and explainability [25,26].

Clinicians may also have doubts about the accuracy, generalizability, and clinical credibility of AI-based CDSSs [8,11,27]. These reservations are often fueled by concerns surrounding data quality, consistency, and breadth resulting from firsthand experiences with electronic medical record systems and scattered data management strategies [13,28,29].

Even when trust is not a limiting factor, many clinicians will still resist adopting AI-based CDSSs if they do not see them as providing any considerable advantage over their current ways of practicing [10,17].

Inner Setting

Determinants related to the inner setting domain were also identified as important in this review, highlighting the role of the organizational context in the implementation of AI-based CDSSs. In particular, factors related to workflow integration, infrastructure, and data management appear to influence the successful adoption of these systems.

Several studies included in this review underlined the importance of properly integrating new systems into existing clinical practice without disrupting workflows [10,13,14,17]. This requirement is echoed again in the literature, which emphasizes that systems requiring additional time and attention for use are more likely to face challenges with initial uptake by end users [27,30].

Implementations of AI-based CDSSs may also suffer in settings without the required IT infrastructure and/or hardware to support system functions [12,13,18]. ML-based systems in particular require large amounts of data for model training, and generating a single inference often requires inputting hundreds of patient variables. This necessitates strict requirements for the collection,

XSL•FO
RenderX

standardization, and storage of data, as well as automatic data entry capabilities to avoid workflow disruption and clinician fatigue [31-33].

Individuals, Implementation Process, and Outer Setting

Determinants related to the individuals, implementation process, and outer setting domains were less frequently identified in this review but still highlight important considerations for the successful implementation of AI-based CDSSs. In particular, factors related to user capability, motivation, engagement, and broader organizational and system-level influences appear to affect both initial uptake and sustained use of these systems.

AI-based CDSSs are overall more complex to install, maintain, and use than their non-AI counterparts. As such, implementation projects may benefit from selecting team leads who have experience in informatics or IT [10].

Considerable challenges may also be faced if clinician end users feel that they lack the skills to properly understand and incorporate AI recommendations into their guidelines for practice [9,18]. Beyond initial uptake, sustained adoption may also fail if the clinician end users and/or opinion leaders in their circle lack motivation to use the newly implemented system [10,11]. Assessing the priorities, preferences, and needs of the clinician end users prior to implementation can help pre-emptively address trust and workflow integration–related hurdles [10,11,15]. Actively engaging clinician end users to encourage and support adoption can also facilitate successful implementation, and regularly sharing performance-related feedback with individual users, for example, concordance with existing clinical guidelines, can help sustain long-term interest [10,18].

In addition, discussing plans with local hospital administrators and IT staff and establishing multidisciplinary teams to coordinate the process can help identify and remove organizational barriers to successful implementation [10].

Economic and infrastructure-related considerations may also influence the implementation of AI-based CDSSs, particularly across different health care systems and resource settings. Previous literature has identified barriers such as insufficient computing resources, limited IT infrastructure, and inconsistent internet connectivity, challenges that may be especially pronounced in low- and middle-income countries [33,34]. Although these determinants were not explicitly identified in the included studies, their absence may reflect underreporting within the current implementation literature rather than a lack of relevance.

Interestingly, no determinants were mapped to the policies and laws construct of the outer setting domain despite the fact that concerns about legal accountability, autonomy, and data security and privacy are often cited when discussing AI-based health care applications [8,27,31,35,36].

Implications for Implementation Practice

The determinants identified in this review can be used to guide future implementation projects through the designation of appropriate strategies that mitigate barriers and leverage facilitators to successfully implement AI-based CDSSs. Our results support the use of several strategies derived from the Expert Recommendations for Implementing Change project, which aimed to synthesize knowledge from a wide range of implementation science and clinical practice experts [37].

First, developing and distributing educational materials explaining how the specific AI-based CDSS works, detailing the results of clinical trials or other external validation tests, and describing the patient population the system was developed with may help reduce barriers related to the innovation's complexity and evidence base. Adopting an integrated knowledge translation approach that directly involves end users in both the design and implementation of new innovations could help mitigate these barriers further upstream [38]. Conducting educational meetings targeted toward different stakeholder groups, including clinicians, patients, caregivers, hospital administrators, and IT staff, to teach them about the innovation and its clinical benefit may also help reduce initial resistance to uptake [37].

End user resistance can also be eased through the identification of clinical champions; these individuals encourage uptake by raising awareness and providing motivation and leadership to their peers [37,39]. Uptake can be further encouraged through the influence of local opinion leaders, who should be identified and informed about the benefits of the innovation prior to its implementation [37].

Finally, implementation teams should aim to capture and share knowledge throughout the implementation process. Regular engagement sessions with clinician end users allowing for reflection on implementation efforts can be used to collect information about what specific strategies worked in their local context, which can later be disseminated to help inform future implementations of AI-based CDSSs [37].

Comparison With Prior Work

The determinants identified in this scoping review, particularly those related to algorithm interpretability, data availability and quality, and workflow integration, are already well documented in the literature [40,41]. However, many of these studies identified barriers and facilitators based on anticipated implementation challenges prior to real-world deployment. Thus, our focus on accounts of real-world implementation represents a major strength of this scoping review, bridging the gap between theory and practice to provide actionable insights.

Furthermore, the determinants identified in this review are not limited to a single clinical domain, as is often the case with previously published work in this area [41,42]. Synthesizing determinants across a broader clinical context allows for more generalizable considerations that can be applied to a wider range of future CDSS implementations.

Recent interview-based work exploring stakeholder perspectives on improving AI-based CDSSs and their integration into care identified similar challenges related to workflow integration, evidence quality and transparency, clinician trust, training and education, and organizational readiness [43].

Although our findings are well supported, there are some determinants commonly cited in the literature that were not

XSL•FO
RenderX

reported in the articles included in this scoping review. Notably, there was no mention of the effects of cost and willingness to pay, which are known to be key drivers of success for health care innovations [44]. This could potentially be a result of our focus on real-world implementations as these projects would likely have undergone a cost-benefit analysis prior to initiation at a given hospital or health system. However, it is important to note that AI-based CDSSs in particular require additional investments to deploy and maintain extensive IT infrastructure, as well as providing training for end users; these costs must be balanced by an improvement in the quality of patient care for implementation to be supported by hospitals and health systems [27,45,46].

Finally, consistent with our finding that only a limited number of studies explicitly reported implementation determinants, a recent scoping review examining patient-related benefits of AI-based CDSSs in sepsis care also emphasized the need for further implementation-oriented and prospective research to support real-world clinical integration [47].

Limitations

This study has several limitations. First, this review adopted a broad definition of AI, encompassing both rule-based and data-driven systems. While this approach enabled the inclusion of a larger body of literature and a broader range of implementation determinants, the findings may not be specific to contemporary AI-based implementations. Therefore, some identified determinants may reflect broader CDSSs or health IT implementation considerations.

Second, our strict definition of clinical decision support and focus on real-world implementation studies resulted in a narrow scope and a limited number of included studies, which constrained the depth of analysis. As a result, unsuccessful, aborted, or prerollout implementation attempts may have been underrepresented despite their potential to provide important insights into barriers preventing real-world adoption. However, we feel that this approach was justified by our aim to address the knowledge gap pertaining to the real-world implementation of AI-based CDSSs. In addition, among the included studies, most did not report implementation outcomes in sufficient detail to identify determinants that were most influential to the successful adoption, integration, and sustained use of AI-based CDSSs over time.

Third, most included studies were conducted in the United States and within selected clinical contexts, which may limit the transferability of findings to other health care systems, organizational structures, and clinical settings.

Fourth, although our search strategy focused on major biomedical and health sciences databases, it is possible that relevant studies published in technical or engineering venues were not captured. Given our focus on real-world clinical implementation, we anticipate that most eligible studies would be indexed in clinically oriented databases.

Fifth, there was a limited representation of patient perspectives in the included studies. While this may partially reflect our focus on clinician-facing tools, understanding how patients perceive the use of AI-based CDSSs in their care remains an important area for future research.

Finally, this review is subject to temporal limitations. The literature search was conducted in 2022, and given the rapid evolution of AI in health care, additional relevant studies may have been published since that time. As such, the findings should be interpreted as reflecting the evidence base available at the time of the search.

Conclusions

This review identified key determinants influencing the real-world implementation of AI-based CDSSs, emphasizing the importance of system design, organizational context, and implementation strategies. However, the limited number of studies reporting explicit implementation determinants underscores a critical gap in the literature. Future work should prioritize the systematic identification and reporting of implementation determinants to better inform adoption and sustainability. These findings provide a foundation for developing targeted implementation strategies and highlight the need for more rigorous, implementation-focused research to support the successful integration of AI-based CDSSs into routine clinical practice.

Acknowledgments

The authors would like to acknowledge Diane Lorenzetti, PhD, from the University of Calgary for her assistance with the initial literature search.

Funding

This work was supported by a Project Grant from the Canadian Institutes of Health Research (PJT 178027) and an Accelerating Innovations into CarE Concepts Grant from Alberta Innovates (212200473).

Data Availability

The data underlying this study are derived from published articles identified through a systematic search. Extracted data supporting the findings of this review are available within the article and its supplementary materials. Additional details regarding the data extraction process are available from the corresponding author on reasonable request.

Abstract

Background: Health information technology (HIT) interventions are complex, context-dependent, and often insufficiently theorized, which can hinder their design, implementation, and evaluation. Program theory approaches such as logic models and theory of change (ToC) are well-established in public health and implementation science for articulating causal assumptions. Their use in medical informatics, however, appears inconsistent. A systematic overview of how logic models and ToC have been applied to HIT interventions is therefore needed to support theory-informed development and cumulative learning in the field.

Objective: We aimed to map how logic models, ToC, and related program theory approaches have been conceptualized, constructed, and applied in HIT-related interventions across disciplines. A secondary objective was to identify implications for medical informatics research and practice.

Methods: Following PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews), searches were conducted in PubMed, Web of Science, Academic Search Elite, APA PsycArticles, and CINAHL. Eligible publications used a logic model, ToC, or related construct within an HIT intervention in any health care or social-care setting. Next, 2 reviewers independently screened records and extracted data on study characteristics, type and purpose of HIT, model structure, theoretical foundations, and reported benefits and challenges.

Results: A total of 69 publications (2012 - 2025) met the criteria. Use of program theory increased markedly after 2020 and spanned medical informatics, public health, health services research, and implementation science. Logic models were most frequently applied to patient-facing and self-management technologies, particularly mobile health, telehealth, and home-based remote monitoring. Most models were used to support HIT development or evaluation. Of the total, 60 (87%) studies provided a logic model visualization, although structures varied considerably. Out of 69, 50 (72%) studies cited guidelines for model development, most commonly UK Medical Research Council guidance, realist evaluation, or the Kellogg Logic Model. Out of 69 studies, 28 (41%) used behavioral or implementation frameworks, such as Capability, Opportunity, Motivation–Behavior model (COM-B), Consolidated Framework for Implementation Research (CFIR), Expert Recommendations for Implementing Change (ERIC), Fit between Individuals, Task, and Technology (FITT), or Non-adoption, Abandonment, and challenges to the Scale-up, Spread, and Sustainability (NASSS) to populate model content. Only 3 (4%) studies reused an existing model. Reported benefits concerned improved theorization, structured evaluation, and stakeholder engagement; challenges included limited empirical evidence, high resource demands, and tensions between specificity and generalizability.

Conclusions: Program theory approaches are increasingly used to conceptualize and evaluate HIT interventions; yet, their application in medical informatics remains fragmented. More systematic and theory-informed use of logic models could enhance conceptual clarity, methodological rigor, and cumulative learning. Future work should promote model reuse, establish repositories, strengthen reporting standards, and integrate program theory in HIT education and research to support coherent development, evaluation, and scaling of digital health interventions.

Introduction

Background

Health information technology (HIT) is expected to improve the quality, efficiency, and equity in care delivery. Yet, many HIT implementations fall short of intended outcomes because these interventions are complex, context-dependent, and insufficiently theorized during their design and implementation [1]. Guidance on complex interventions emphasizes explicit theorization and iterative refinement with stakeholders across the lifecycle of development, piloting, evaluation, and scaling up [2,3].

At the core of theory-informed evaluation lies program theory—an explicit account of how and why a program is expected to produce outcomes by linking resources, activities, mechanisms, and outcomes. Program theory renders assumptions testable and provides a scaffold for both program design and evaluation [4]. A program in this perspective is "a set of organized activities or interventions supported by resources designed to achieve a specific result" [5].

The concept of program theory originates from evaluation research in the social sciences to explain how social interventions produce outcomes through explicit causal pathways [4]. This tradition later informed theory-driven evaluation approaches in health services research [6].

In this review, we understand a program broadly as any organized digital health initiative—ranging from single HIT implementations to complex, multicomponent interventions, such as disease management programs that include HIT as one component—that seeks to produce change at the individual, organizational, and/or system level.

Two prominent operationalizations of program theory are logic models and theory of change (ToC). Traditional logic models provide simplified, often linear depictions of inputs, activities, outputs, and outcomes to support planning, communication, and evaluation of complex interventions. However, they often underspecify mechanisms on how, why, and under which conditions elements are linked [5,7].

In contrast, ToC makes causal pathways explicit, visually mapping how and why an intervention leads to impact [7]. ToC thus places greater emphasis on causal links, context, and preconditions, articulating the evidence that underpins each link. Theories from sociology, behavioral science, or other disciplines can be inserted in the ToC to explain why specific links hold. Both logic models and ToC support planning, implementation, and evaluation, but they differ in flexibility, granularity, format, and how explicitly they depict causal pathways [7].

The UK Medical Research Council (MRC) has been central in mainstreaming logic models and program theory for complex health-related interventions. The 2015 MRC guidance on process evaluation formalized how to examine implementation, mechanisms, and context [2]. The 2021 MRC update reframed development and evaluation as iterative processes, positioning program theory and interaction between the intervention and its context as core elements to consider [3]. Integrating ToC into the MRC approach has been proposed to strengthen stakeholder engagement, articulate assumptions, and guide indicator selection along causal pathways [7].

Across disciplinary fields, the use of program theory is diverse. In public health, ToC and logic models have been used to structure multilevel, multifaceted, and multisectoral interventions [5]. In health technology assessment (HTA), logic models help identify how the complexity and context explain the outcomes of the interventions, both in single studies and in systematic reviews [8]. In implementation science, logic models have been used to support the choice of implementation strategy [9] and to build an implementation research logic model (IRLM) that links determinants, strategies, mechanisms, implementation outcomes, and clinical outcomes [10]. Methodological advances have led to typologies of logic models that explicitly account for the complexity that arises when interventions adapt to their context [11].

Research Problem

Although HIT interventions are complex, the explicit use of program theory in medical informatics remains limited. Some examples illustrate their potential, including a ToC for electronic health record (EHR) implementation in Nigeria [12], a theory-informed internet intervention for emotional distress in primary care [13], a logic model for patient portals [14], or a ToC for extracting evidence from HIT studies [15]. Yet, these seem exceptions rather than standard practice in medical informatics.

At the same time, HIT is frequently embedded as one component within complex programs studied in public health, HTA, and implementation science where logic models and related approaches are routinely used. Examples include a maternal health program based on a digital exchange platform [16], an early intervention rehabilitation service for children integrating telerehabilitation [17], or an app-based intervention for cardiac care at home [18].

To our knowledge, no review has systematically examined how logic models and ToC are used in HIT-related interventions. Given their widespread use in other fields, clarifying their application in HIT is essential for theorization, evaluation, and cumulative learning in medical informatics. Mapping how logic models and ToC are conceptualized, constructed, and applied can reveal how HIT is framed, implemented, and evaluated, and generate methodological insights to strengthen medical informatics as a theory-informed discipline [19].

Research Question

This scoping review aims to answer the following questions:

1. How are logic models for HIT-related interventions conceptualized, constructed, and applied in disciplines such as medical informatics, health services research, and health policy?
2. What practical consequences result from this for medical informatics research across clinical, public health, and policy settings?

RenderX

Methods

Overview

The reporting of this review adheres to the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) [20]. The protocol was developed and published a priori [21].

Eligibility Criteria

We included studies that met the following criteria (Population Concept Context [PCC] framework):

- Population: Studies and reports focusing on HIT interventions, including, but not restricted to, EHRs, clinical decision support systems, telemedicine platforms, mobile health (mHealth) apps, and patient portals.
- Concept: Explicit use or description of program theory approaches, including logic models, ToC, program logic, program theory, results chains, or related conceptual frameworks. Logic models may have been used for purposes such as design, implementation, evaluation, or communication.
- Context: Health care and social care settings, including hospitals, community care, long-term care, and underserved populations.
- Types of sources: Empirical studies (quantitative, qualitative, and mixed methods), conceptual or methodological papers, case studies, and evaluations.
- Language: English.
- Time frame: No restrictions on publication date.

We excluded studies presenting theoretical models that do not describe program theory or logic models in relation to a specific HIT. Papers, commentaries, editorials, or conference abstracts without sufficient detail were likewise excluded.

Information Sources

A systematic search was done in PubMed, in Web of Science and (via EBSCOHost) in Academic Search Elite, APA PsycArticles, and CINAHL. Searches were complemented by AI-assisted search tools (Semantic Scholar, Connected Papers, ResearchRabbit, and Elicit).

Search Strategy

The search strategy was developed iteratively, combining controlled vocabulary (MeSH) and free-text terms for four conceptual blocks:

1. Logic models and related terms (such as “logic model*,” “theory of change,” “results chain,” “programme logic,” and “program theory”).
2. HIT (such as “medical informatics,” “health information systems,” “digital health,” “electronic health record,” “electronic health record,” “telemedicine,” “clinical decision support systems,” and “mHealth”).
3. Application and purpose (such as “program evaluation,” “implementation science,” “evaluation,” “design,” “planning,” and “development”).
4. Care setting (such as “healthcare,” “social care,” “community care,” and “long-term care”).

The search query is documented in Multimedia Appendix 1.

Screening and Data Extraction

Screening was conducted in 2 stages. First, the title and abstract of all records were screened by 2 independent reviewers (EA and IH) using the predefined inclusion and exclusion criteria. Discrepancies were resolved through discussion. Second, the full text of potentially eligible studies was screened, again by 2 independent reviewers (EA and IH). Reasons for exclusion at the full-text stage were recorded.

A structured data extraction form was developed, piloted, and iteratively refined. The form included the following domains:

- Bibliographic details (journal, year, and country).
- Study context (objective, health care setting, type of HIT system, and phase of HIT lifecycle).
- Characteristics of the logic model (purpose, novelty, level of system modeling, visual representation, components of the logic model, guidelines or frameworks guiding the development of the logic model, and frameworks or theories for populating the logic model).
- Usefulness (reported benefits and challenges).

Extraction was supported by AI-based tools (eg, ChatGPT [OpenAI]-based extraction). Each extraction was verified and revised manually by 2 reviewers (EA and IH) to ensure accuracy.

Synthesis of Results

Our synthesis of results focuses on the health system levels addressed, the benefits and challenges explicated, and the theoretical foundations that the logic models are built on, in terms of the guidelines, frameworks, and theories used to structure the model and populate its content.

We used a combination of quantitative and qualitative synthesis approaches. Health care settings and HIT type were classified into categories. The phases of HIT interventions were classified based on the MRC 2021 framework into development, piloting (feasibility), evaluation, and scaling-up [3].

We categorized each logic model according to the health system level it addressed. The micro level referred to individuals and direct care processes (eg, patient-provider interactions). The meso level captured organizational or institutional dimensions (eg, workflows and management structures), while the macro level encompassed regional or national health system and policy contexts. Studies could address one or several levels simultaneously.

To allow for a more precise analysis of the theoretical foundations of logic models and theories of change, we distinguished a priori between two complementary types of theoretical guidance: (1) structuring guidance (used to build and organize the model) and (2) content-populating frameworks and theories (used to specify determinants, mechanisms, and context).

For structuring guidance, we extracted guidelines and frameworks on how to develop a logic model or a ToC, such as the MRC framework, Kellogg Logic Model [22], or IRLM [10]. These guidelines and frameworks provide overarching

XSL•FO
RenderX

meta-methodological guidance on how to conceptualize and develop a logic model.

For content-populating frameworks and theories, we extracted frameworks or theories guiding the population of the model's content, such as the theory of planned behavior [23] or the Consolidated Framework for Implementation Research (CFIR) [24]. These frameworks and theories inform the specific causal mechanisms, determinants, and contextual factors that are represented within the model. These frameworks and theories help to explain why and under what conditions a specific intervention is expected to produce its intended outcomes.

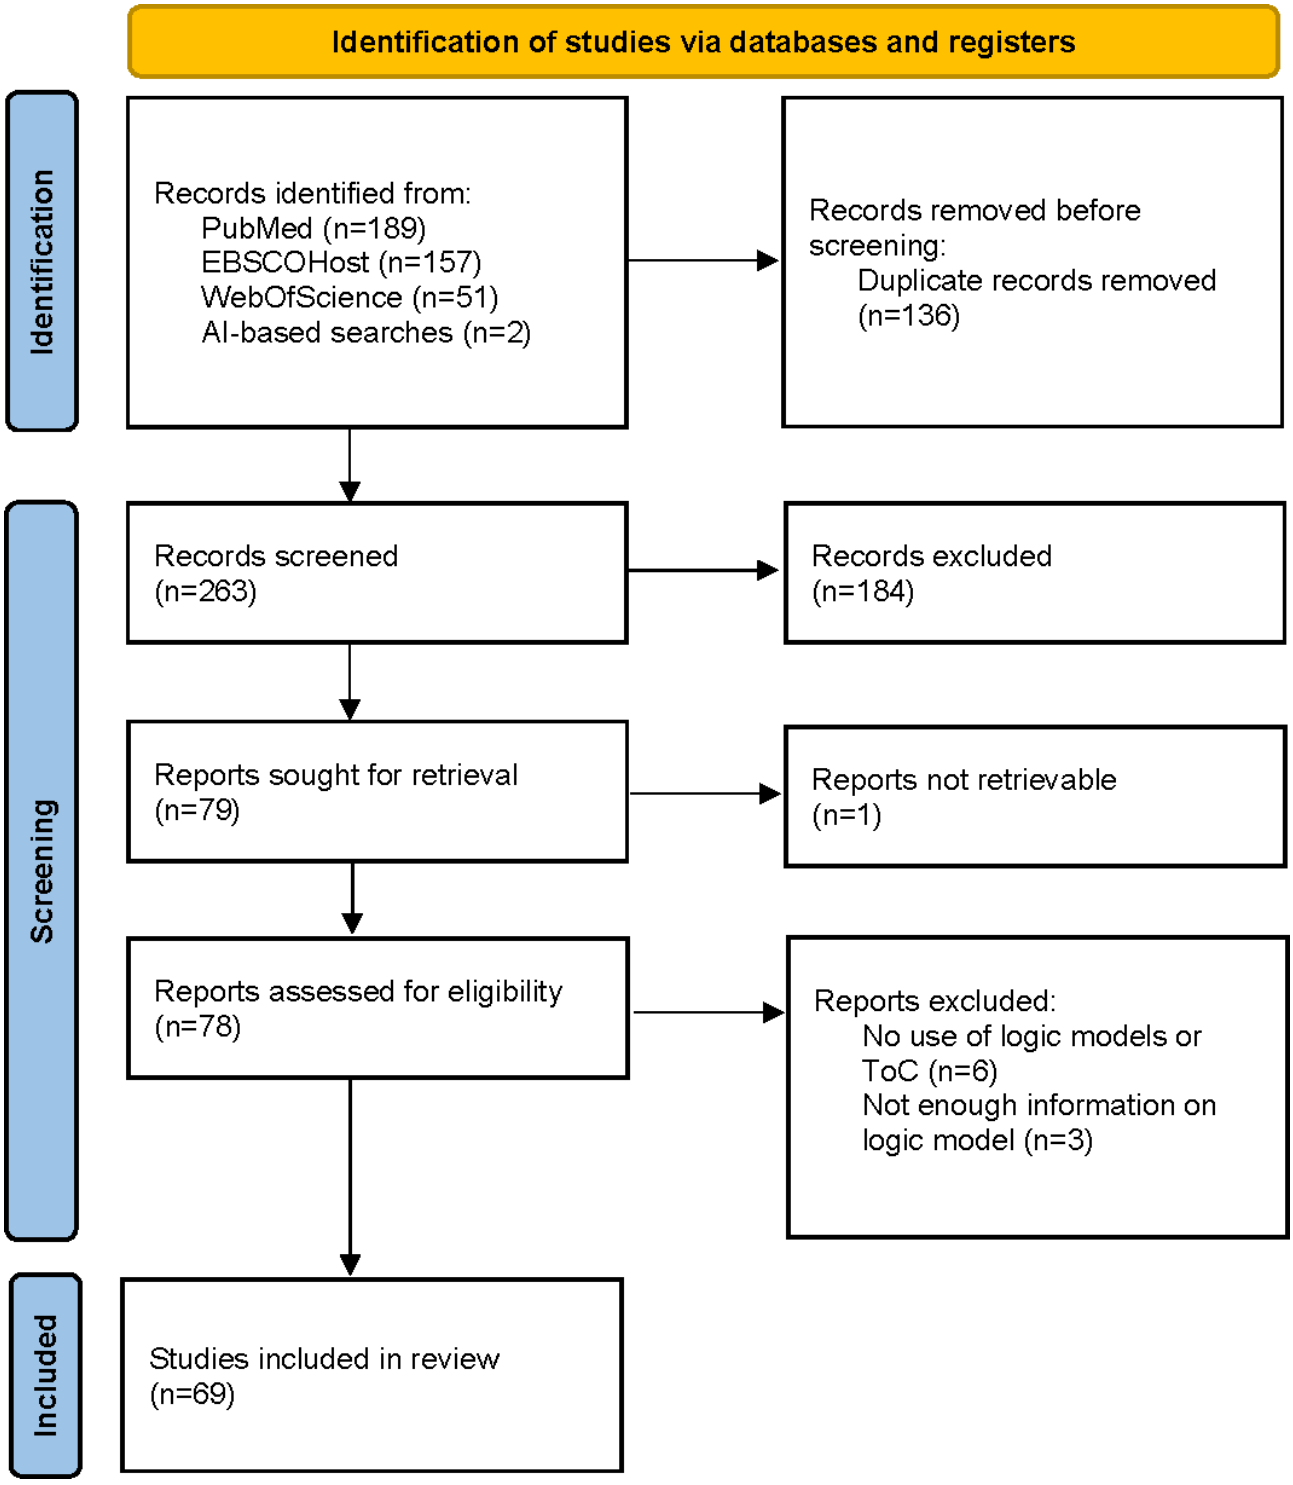
Reported benefits and challenges were analyzed using inductive quantitative text analysis.

No formal risk-of-bias or quality assessment was performed, consistent with scoping review methodology.

Ethical Considerations

Ethics approval was not required as this review is based on secondary analysis of published literature.

Results



PRISMA Diagram

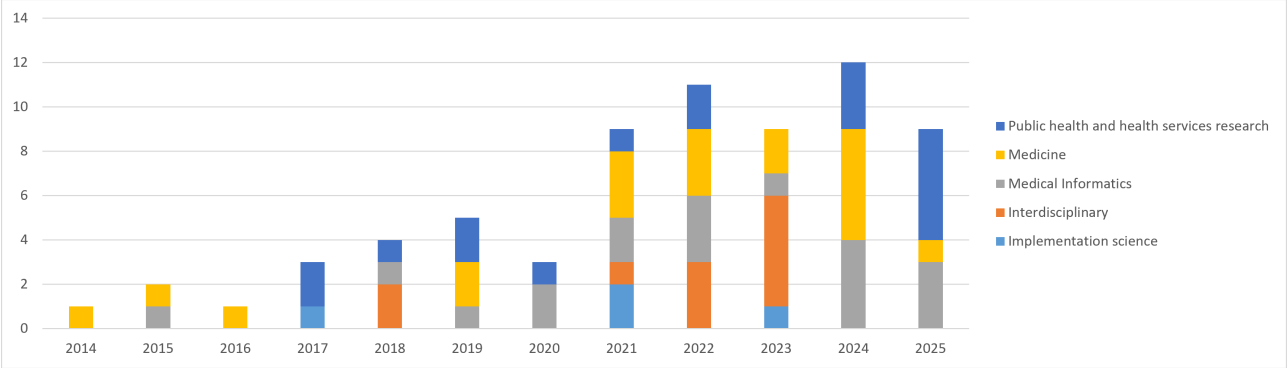
The PubMed query retrieved 189 records. Combined with additional queries in other reference databases, the search yielded 263 unique records. AI tools contributed only 2 references. After checking inclusion and exclusion criteria, 69 papers [12,13,16-18,25-77] remained to be included in the review (Figure 1). Of the 69 studies, 58 (84%) papers [12,13,15-18,25-87] were primary studies, 6 (9%) papers were reviews [15,78-82], and 5 (7%) papers were study or review protocols [83-87].

The extracted data for all 69 studies can be found in Multimedia Appendix 2.

XSL•FO
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) statement flow diagram. ToC: theory of change.

Year of Publication



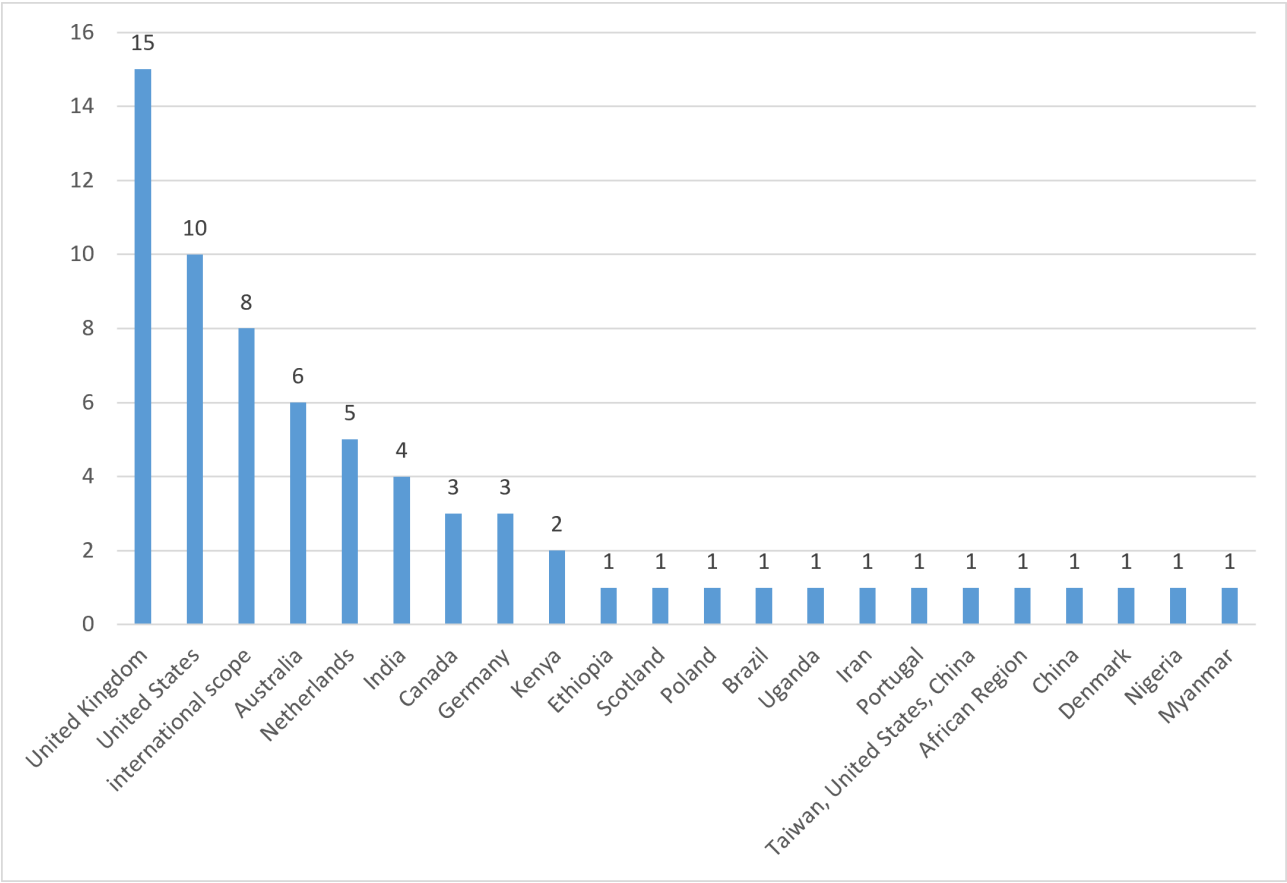
Included papers were published from 2012 to 2025, with a marked increase after 2020 (Figure 2).

Out of 69, 19 (27%) papers were published in medical journals (including 1 nursing journal), 18 (26%) papers were published in journals that can be related to medical informatics as a discipline, and 17 (25%) papers were published in public health or health services research journals. Another 11 (16%) studies were published in interdisciplinary journals, and 4 (6%) papers in implementation science journals.

The clear post-2020 increase indicates a rapidly growing uptake of program theory in HIT, especially in early lifecycle phases. This variety indicates a broad interest from various fields in developing and evaluating HIT as part of health-related interventions.

XSL•FO
RenderX

Figure 2. Publication year of the included studies (n=69 studies).



Country

Just over half of the included papers (n=36; 52%) came from just 4 countries: the United Kingdom, the United States, the Netherlands, and Australia. Moreover, 13 (19%) papers came from low-income countries such as India and Kenya (Figure 3).

Studies are therefore concentrated in a few high-income countries alongside notable contributions from resource-constrained settings.

Figure 3. Country where a study took place or region covered by a review (n=69 studies).

HIT and Health Care Setting

About half of the studies (n=33, 48%) took place in home-based or remote health care settings where HIT is to be used by patients or their families. Examples are HIT for self-management of diabetes [46] or telemedical care of infants at home [40]. Moreover, 11 (16%) studies took place in integrated health and social care settings, which comprise interventions not limited to a specific health care setting but covering several settings, such as hospital and social care. Examples include a cross-sectoral intervention to improve youth mental health services [34]. The other studies were located in a variety of clinical settings such as hospitals or primary care (Figure 4).

About half of the studies (n=31, 45%) cover patient-facing and self-management applications, such as mHealth apps. The remaining studies (n=38) cover a mix of HIT types (Figure 5).

XSL•FO
RenderX

Figure 4. Health care setting where a study took place (n=69 studies).

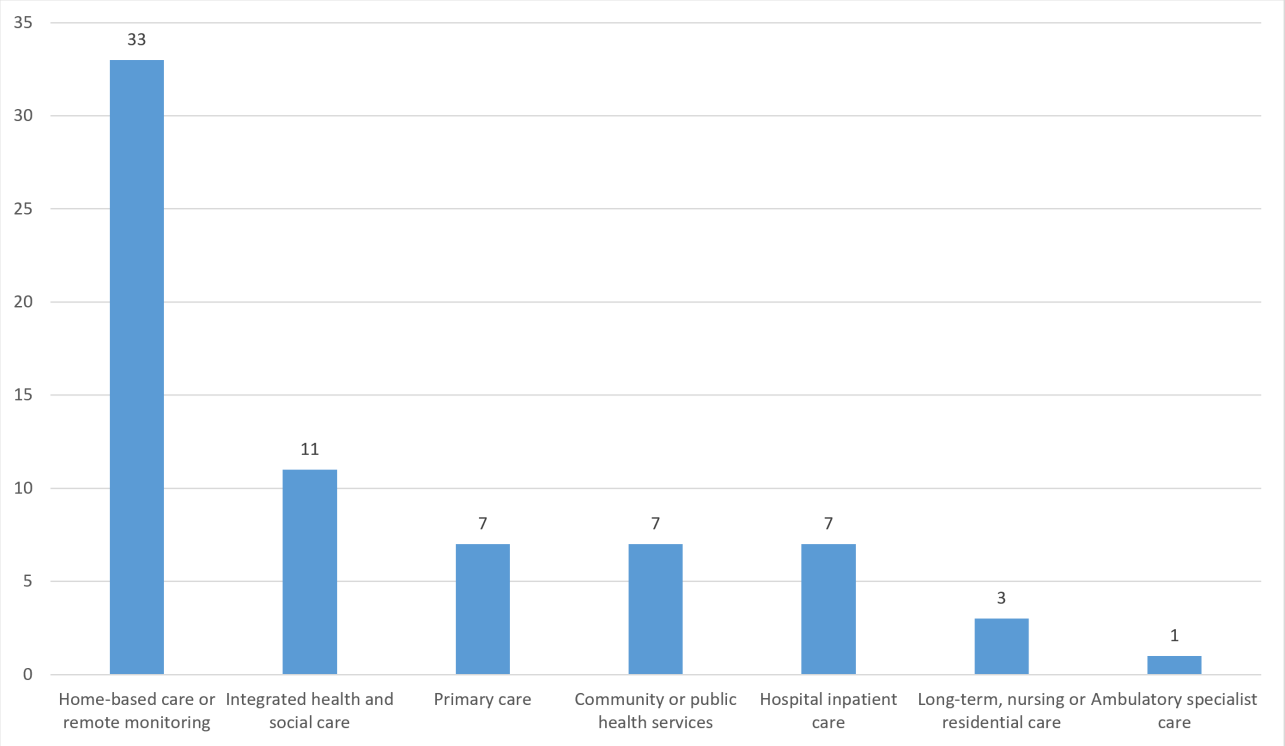


Figure 5. HIT type of included studies (n=69 studies).

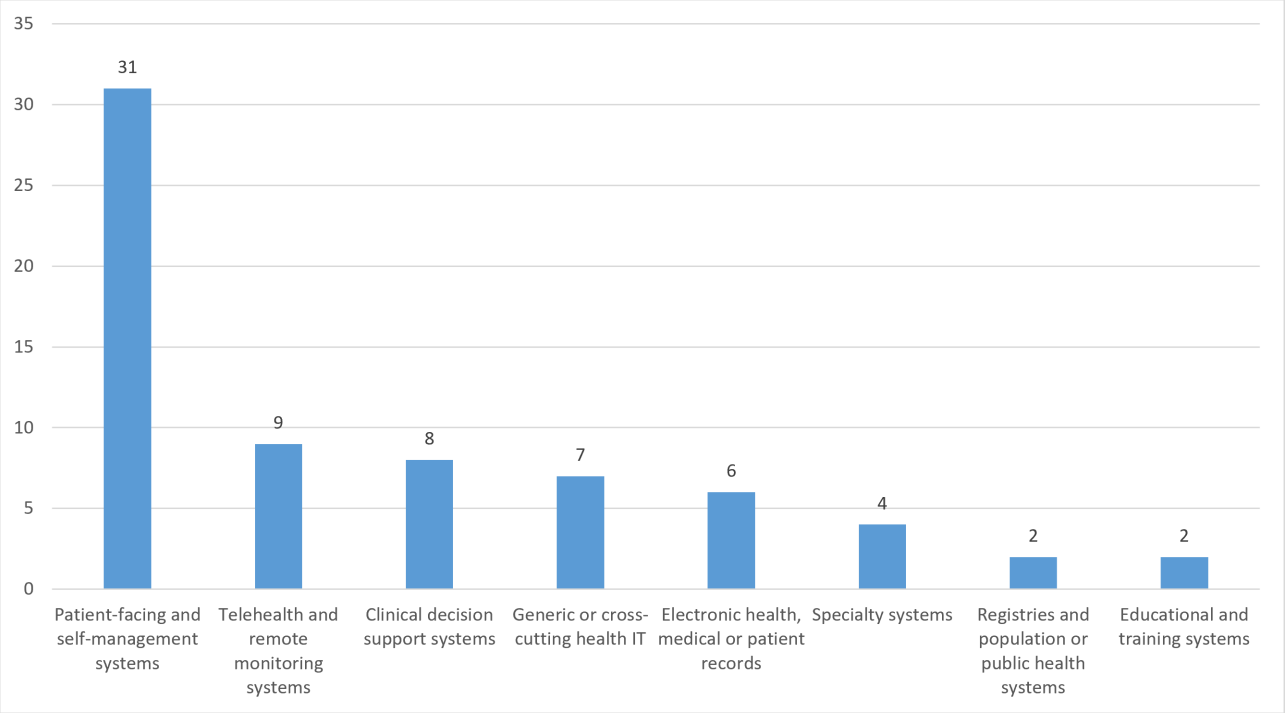

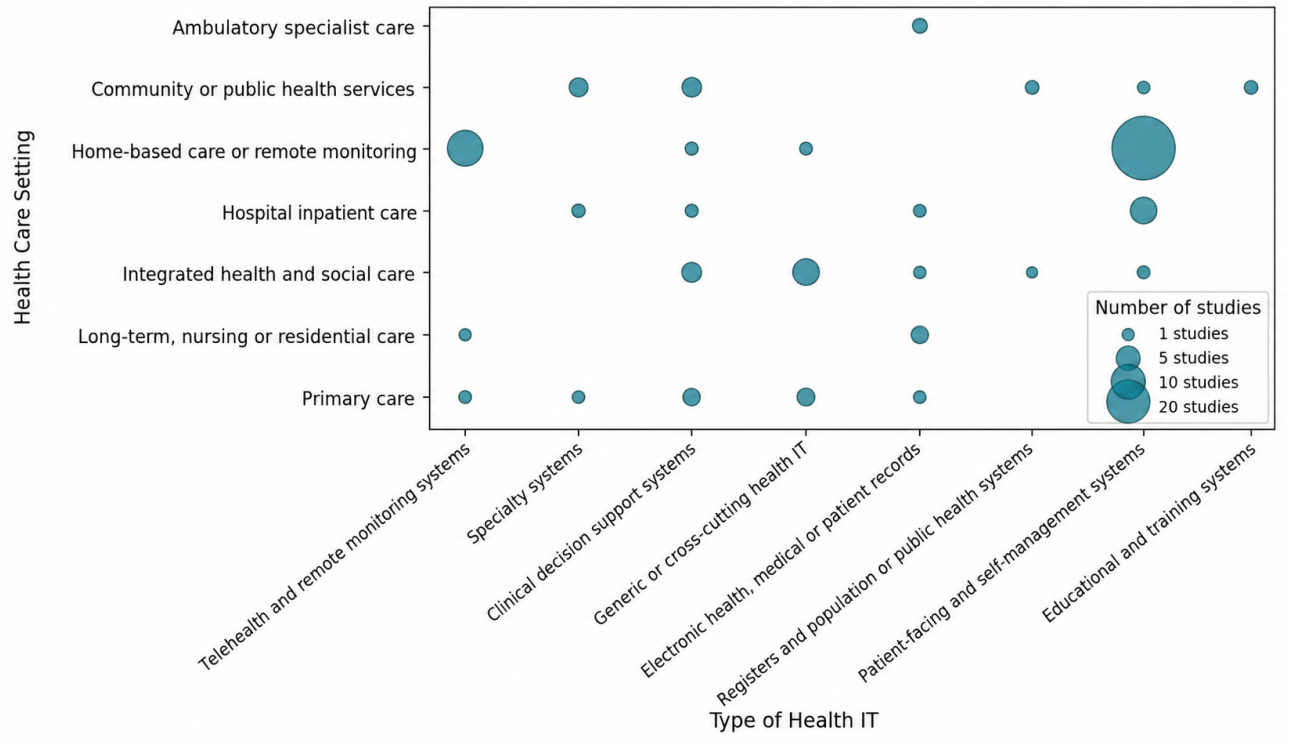

Figure 6 illustrates the correlation of logic model applications across different types of HIT and different care settings. Most studies focused on patient-facing and self-management systems, particularly in home-based or remote-care contexts. In contrast, EHR and clinical decision support systems were mainly represented in institutional settings, such as hospitals or primary care.

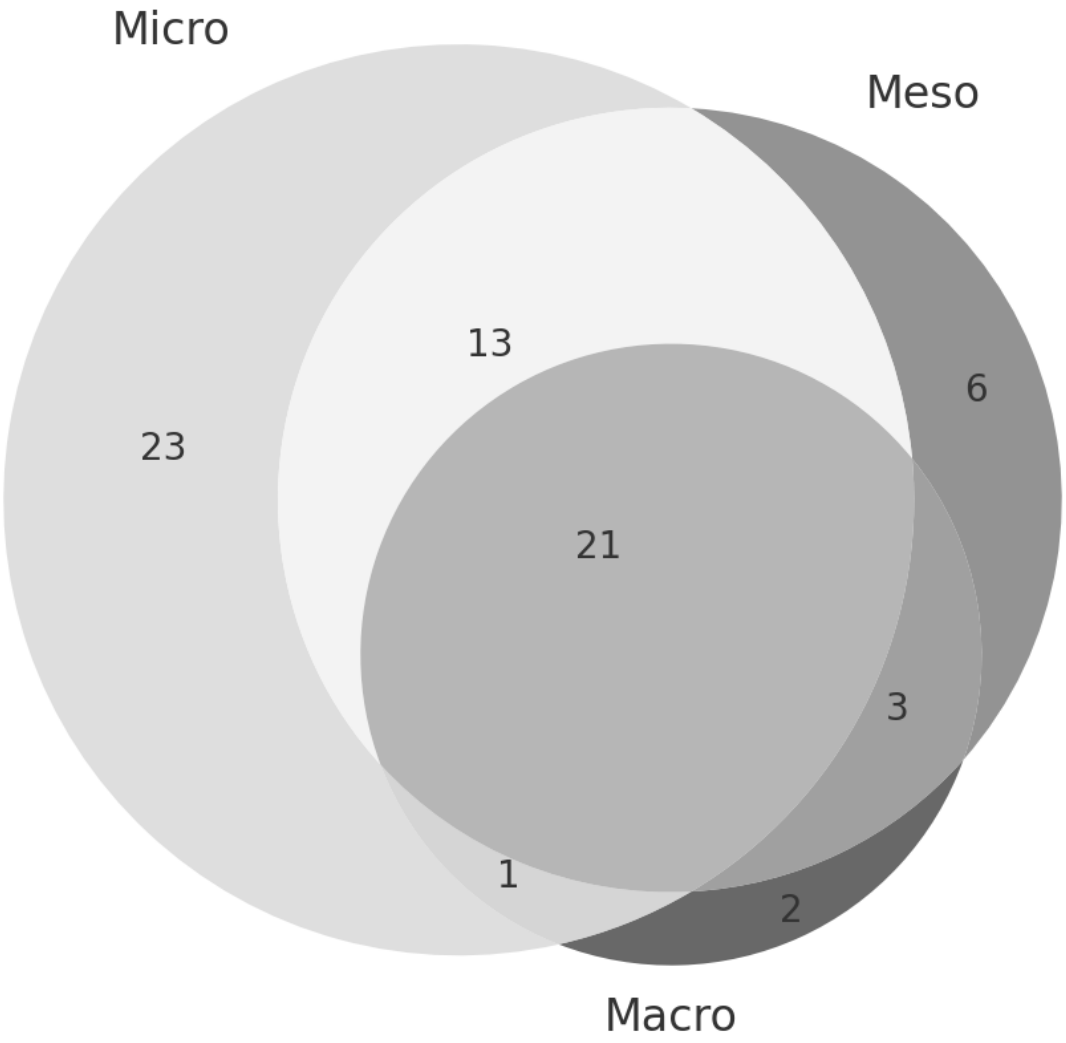
XSL•FO
RenderX

Figure 6. Relationship between type of Health Information Technology and health care setting (n=69 studies). The bubble size represents the number of studies using a logic model for each combination.

Summarizing, logic model use is most prevalent for patient-facing, home-based, and remote interventions, aligning with the need to capture behavioral and contextual mechanisms in these settings. Institutional HIT (eg, EHR or clinical decision support systems) is comparatively less represented and more often situated in the clinical environment.



Level of System Modeling

Logic models and ToC were categorized to address the micro level of the health system, focusing on individuals and direct care processes; the meso level, focusing on the health care institution; and/or the macro level, thus focusing on the regional or national health system. Papers could address more than one level.

Overall, 58 (84%) papers addressed the micro level, 43 (62%) papers addressed the meso level, and 27 (39%) papers addressed the macro level, with most papers addressing more than one level (Figure 7). For example, on the micro level, 1 study used a logic model to analyze how software features influence outcomes when developing a self-help digital intervention for young people with Tourette syndrome [28]. On the meso level, 1 study developed a logic model to understand context factors relevant for adopting electronic medication administration systems in long-term care facilities [47]. On the macro level, 1 study developed a logic model to understand scaling-up of an electronic consult service across Canadian provinces [86].

XSL•FO
RenderX

Figure 7. Overlap between micro, meso, and macro focus in the included studies (n=69).

In total, 21 studies covered all 3 levels (micro, meso, and macro). For example, 1 study investigated how context and mechanisms influence the outcomes of integrated care for type 2 diabetes in 2 Dutch care groups [32]. This study found barriers and facilitators on the individual patient and professional (micro) level (such as user resistance), on the organizational (meso) level (such as lack of qualified nurses), and on the political (macro) level (such as financial pressure and health insurer cooperation).

Summarizing, most models prioritize microlevel processes, with fewer addressing organizational and policy levels, indicating an emphasis on proximal change over systemic effects.

Visualizations of Logic Models

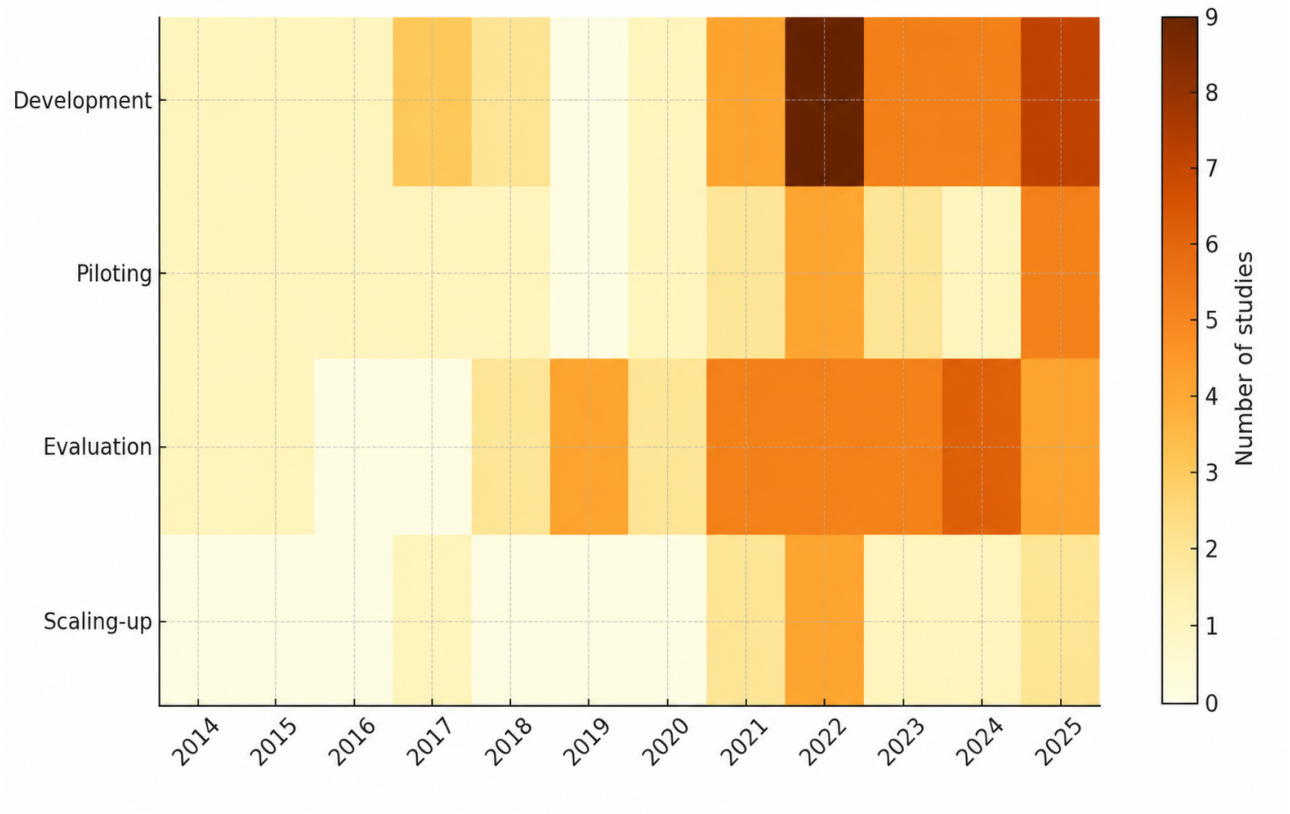
A clear majority of the studies (60/69, 87%) presented a visualization of the logic model or referred to a visualization reported elsewhere. From these 60 studies, 6 studies applied the most condensed structure, the context-mechanism-outcome (CMO) configuration. These studies referred to realist evaluation as the theoretical foundation guiding the construction of the logic model. Most of the papers used more detailed structures; however, we could not identify a specific pattern suggesting that the theoretical guideline or framework chosen to guide the development of a logic model would define the components of the graphical representation.

All logic models with visualizations (n=60) included outcomes in their models. About half of these studies (31/60, 52%) categorized these outcomes based on their temporal distality (short-term or long-term outcomes) or their attributability to the intervention. About half of these studies (31/60, 52%) included context and/or determinants (also named “assumptions” and “enablers and barriers”) in the visualizations. A third of these papers (20/60, 33%) included the problem to be solved with the intervention (or “purpose” or “goal”) in the visualization.

Overall, the visualizations varied notably in how the intervention and its mechanisms were labeled, including labels such as inputs, technology, activities, intervention, mechanisms, processes, and implementation strategy.

XSL•FO
RenderX

Purpose of Using Logic Models



Using the MRC 2021 framework [3], we analyzed which of the 4 phases of an intervention was supported by the logic model:

1. HIT development (n=39 studies, 57%): Logic models were used to support needs analysis, develop a program theory, identify components and mechanisms of the HIT intervention to be developed, and engage with stakeholders.
2. HIT piloting (n=20, 29%): Logic models were used for testing of acceptability, usability, and feasibility, for training, for small pilots, and for refining the program theory of the newly developed HIT intervention.
3. HIT evaluation (n=35, 51%): Logic models were used to support assessment of implementation fidelity, economic aspects, and effectiveness of the HIT intervention.
4. HIT scaling-up (n=11, 16%): Logic models were used to support sustainability of the HIT intervention in real-world contexts, to scale it up to other settings, and to evaluate long-term effects.

Most papers covered more than one phase of the intervention phases. For example, 12 studies covered development and piloting; 5 studies covered evaluation and implementation; and another 5 studies covered development, piloting, and evaluation.

To illustrate the temporal distribution of logic model applications, all 69 included studies were analyzed by publication year and lifecycle phase (development, piloting, evaluation, and scaling-up). Figure 8 displays aggregated frequencies per year and phase. Higher color intensity represents a larger number of studies. The use of logic models across all lifecycles phases increased strongly after 2020, with the development phase most dominant in all years.

Figure 8. Use of logic models across different phases of the health information technology lifecycle over time (2014 - 2025).

Summarizing, logic models predominantly support development and evaluation, with fewer applications in piloting and scaling-up.

Use of Existing Logic Models

Only 3 (4%) studies explicitly stated that they reused an existing logic model or ToC:

The first study developed a ToC for a new moderated online social therapy for youths. For building their ToC, the authors reviewed examples of ToC frameworks in comparable youth web-based mental health programs [34].

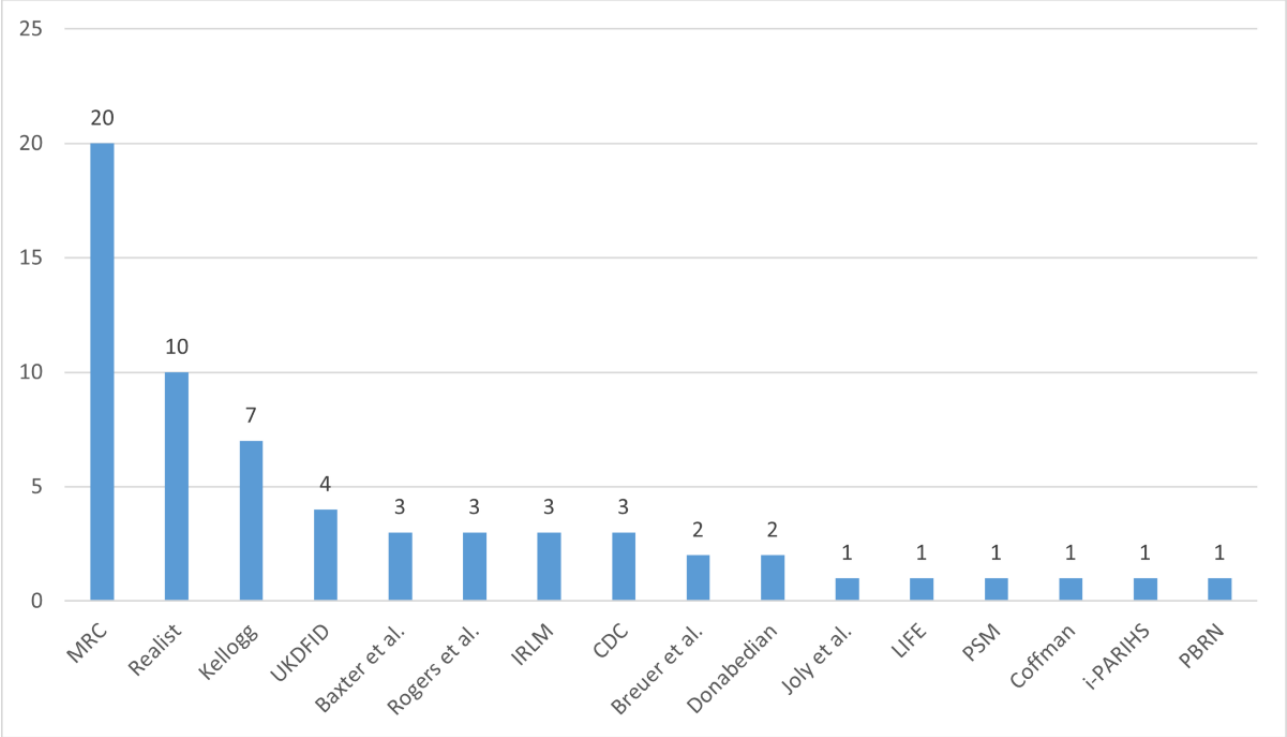
The second study developed a logic model to determine how eHealth was adopted in pharmaceutical care during COVID-19. For building this logic model, the authors reused a logic model for pharmaceutical care published by another group [79].

The third study presented a ToC describing how geospatial data and technologies can improve immunization coverage and equity. For building this ToC, the authors reused a ToC for the use of geospatial technologies for immunization programming published earlier [33].

The remaining studies either developed a new logic model or ToC (n=63, 91%) or did not give clear information on reusing an existing logic model (n=3, 4%). However, many studies referred to guidelines and frameworks that helped them to develop their logic model by providing templates or structural patterns – this is further analyzed in the next section.

XSL•FO
RenderX

Guidelines, Frameworks, and Theories



As described in the Methods section, we differentiate between two types of theoretical guidance observed in the included studies: (1) guidelines or frameworks on how to develop a logic model or a ToC, and (2) frameworks or theories guiding the population of the model's content.

Guidelines or Frameworks on How to Develop a Logic Model

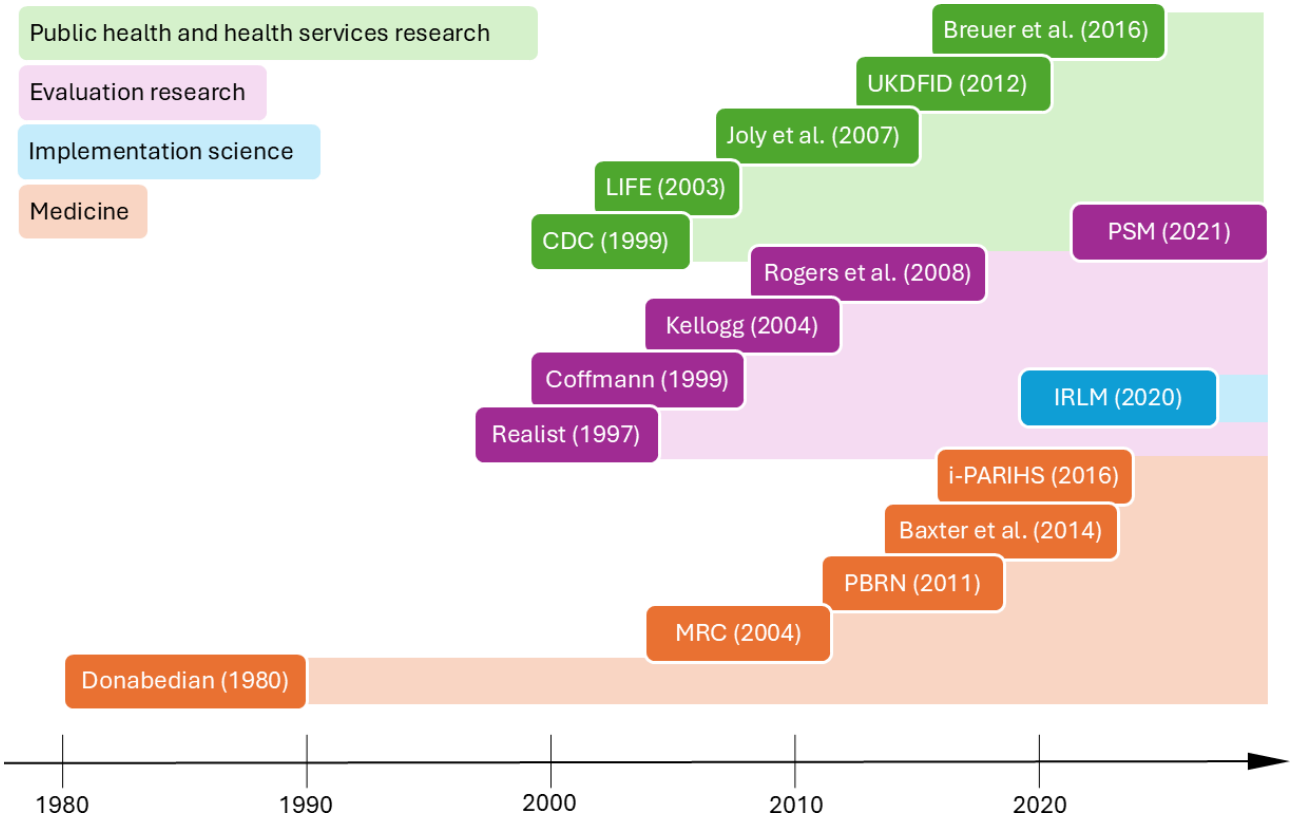
Overall, 50 (72%) studies presented information on which guidelines or frameworks on how to develop a logic model the studies used. Of these studies, 37 used 1 guideline or framework and 13 studies used 2 guidelines or frameworks. Out of 69, 19 (28%) studies did not mention any guideline or framework.

Figure 9 illustrates the guidelines and frameworks used to develop the logic model by the 50 studies. None of the identified guidelines and frameworks is specific for HIT or health informatics.

Figure 9. Guidelines and frameworks on how to develop a logic model as mentioned in 50 studies. For an explanation of all theories and frameworks, refer to Multimedia Appendix 3. CDC: Centers for Disease Control and Prevention; i-PARIHS: Integrated Promoting Action on Research Implementation in Health Services; IRLM: Implementation Research Logic Model; LIFE: Local Initiatives for Faith and Evaluation; MRC: Medical Research Council guidance; PBRN: Practice-Based Research Network; PSM: Participatory Systems Mapping; UKDFID: UK Department for International Development.

The most frequently mentioned framework is the MRC guidance (20 studies, 29% of all studies), which provides a comprehensive framework for developing and evaluating complex interventions in health and social care [3]. The MRC guidelines have been updated frequently and are often cited as meta-guidance for developing and structuring logic models.

The next most frequent category is "Realist Evaluation" (10 studies, 15%), indicating that the authors seek to explain how, why, for whom, and under what conditions interventions work by analyzing the interaction of context, mechanisms, and outcomes (CMO configurations).



The third most often mentioned framework is the Logic Model Development Guide of the Kellogg Foundation (7 studies, 10%), which is a practical manual that explains how to design, apply, and interpret logic models for program planning and evaluation [22]. It is one of the oldest, most widely used nondisciplinary guides for constructing program theory.

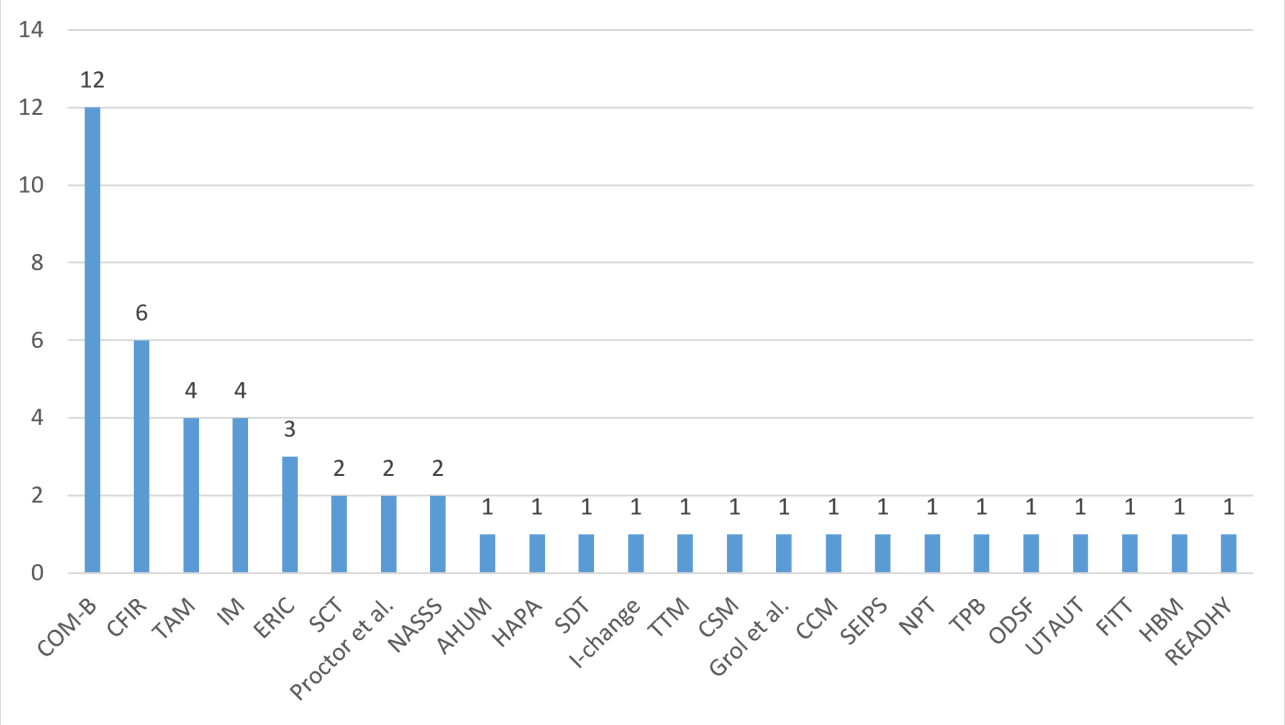
For explanation and references for each guideline and framework, refer to Multimedia Appendix 3.

Figure 10 illustrates the timeline of these guidelines and frameworks used to develop a logic model. We mapped their chronological appearance across disciplinary domains based on the versions referenced in the included papers. The assigned domains are indicative; several guidelines and frameworks could be appropriately classified into more than 1 domain.

XSL•FO
RenderX

Figure 10. Timeline of guidelines and frameworks used to develop logic models in 50 studies. The x-axis shows the publication year of the study that cited each guideline or framework. For an explanation of all theories and frameworks, refer to Multimedia Appendix 3. CDC: Centers for Disease Control and Prevention; i-PARIHS: Integrated Promoting Action on Research Implementation in Health Services; IRLM: Implementation Research Logic Model; LIFE: Local Initiatives for Faith and Evaluation; MRC: Medical Research Council guidance; PBRN: Practice-Based Research Network; PSM: Participatory Systems Mapping; UKDFID: UK Department for International Development.

Summarizing, most studies cite structuring guidance, led by MRC, realist evaluation, and Kellogg, none of which are HIT-specific.



Frameworks and Theories for Populating the Logic Model

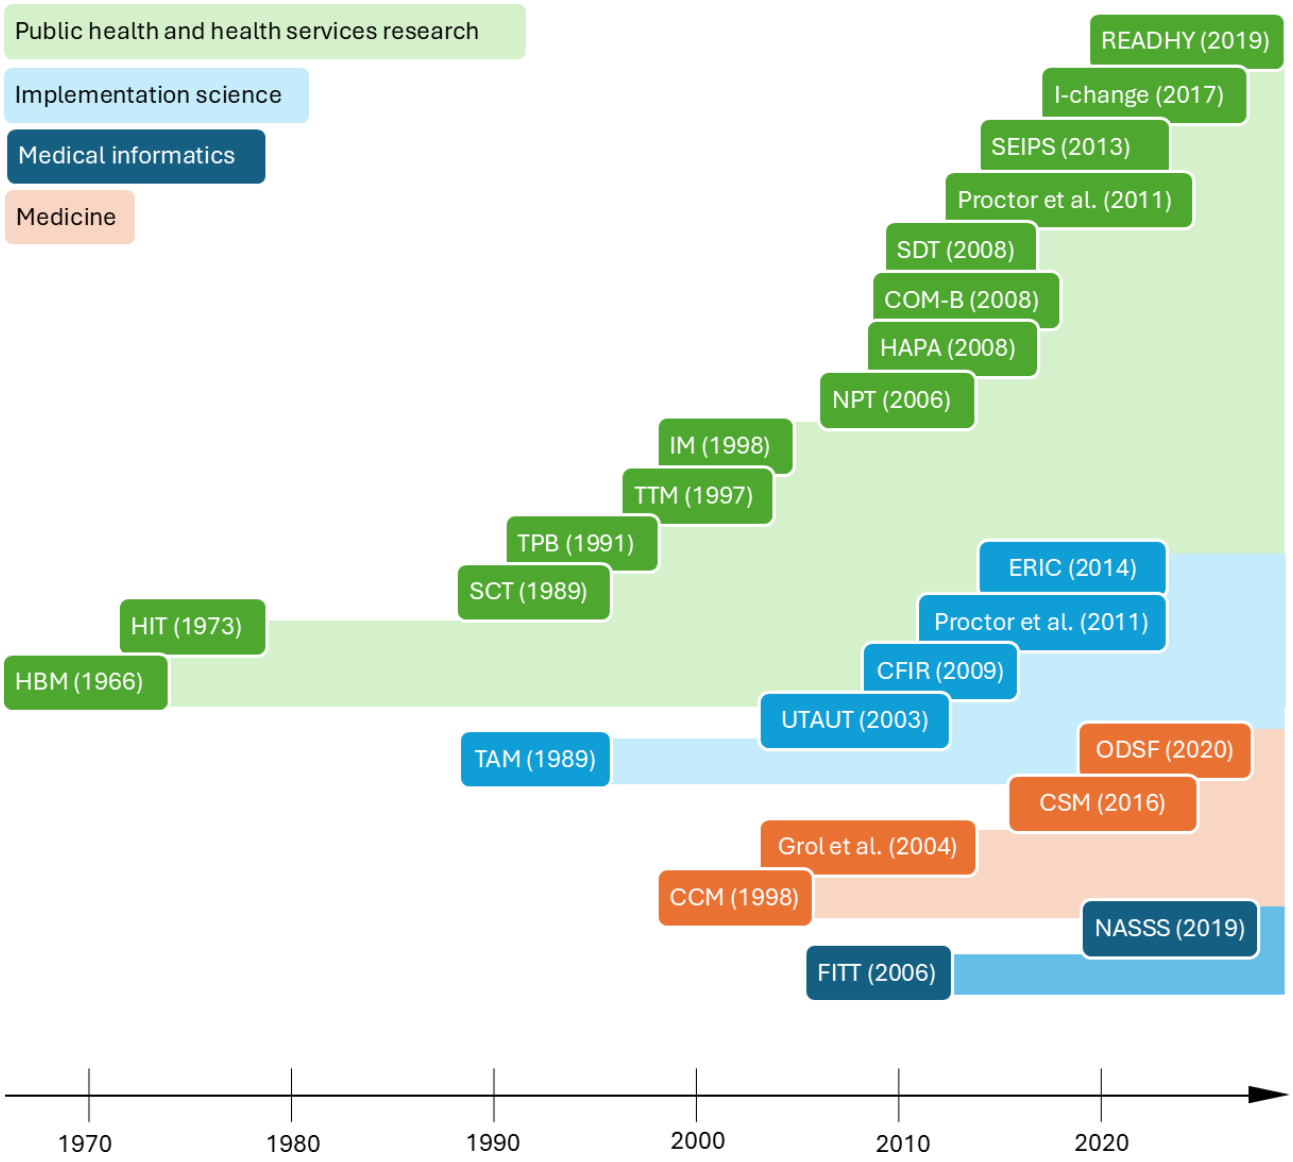
Overall, 28 (41%) studies presented information on which frameworks and theories they used to populate their logic model. Out of 69, 15 (22%) studies used 1 framework or theory, 4 (6%) studies used 2, 8 (12%) studies used 3, and 1 (1%) study even used 4 frameworks or theories. Moreover, 41 (59%) studies did not mention any framework or theory.

Figure 11 illustrates the frameworks and theories used by the 28 studies. Only the Fit between Individuals, Task, and Technology (FITT) framework [88] and the Non-adoption, Abandonment, and challenges to the Scale-up, Spread, and Sustainability (NASSS) framework [89] originated in health informatics; the other frameworks and theories are rooted in other domains.

XSL•FO
RenderX

Figure 11. Frameworks and theories for populating a logic model as mentioned in 28 studies. For an explanation of all frameworks and theories, refer to Multimedia Appendix 3. AHUM: Andersen Healthcare Utilization Model; CCM: Chronic Care Model; CFIR: Consolidated Framework for Implementation Research; COM-B: Capability, Opportunity, Motivation–Behavior; ERIC: Expert Recommendations for Implementing Change; FITT: Individual, Technology and Task Framework; HAPA: Health Action Process Approach; HBM: Health Belief Model; HIT: Health Information Technology; IM: Implementation Mapping; NASSS: Nonadoption, Abandonment, Scale-up, Spread, and Sustainability; NPT: Normalization Process Theory; ODSF: Ottawa Decision Support Framework; READHY: Readiness and Enablement Index for Health Technology; SCT: social cognitive theory; SDT: self-determination theory; SEIPS: Systems Engineering Initiative for Patient Safety; TAM: technology acceptance model; TTM: Transtheoretical Model of Health Behavior Change; UTAUT: unified theory of acceptance and use of technology.

The most frequently mentioned framework (11 studies, 16% of all studies) is the Capability, Opportunity, Motivation–Behavior model (COM-B), which identifies that behavior results come from addressing capability, opportunity, and motivation. COM-B is the core of the behavior change wheel framework [90].



The second most frequently used framework is the CFIR (6 studies, 10%), which is a theory-based framework used to guide the implementation of complex interventions in health care and related fields [24]. CFIR describes determinants of implementation success.

For explanation and references for each found framework or theory, refer to Multimedia Appendix 3.

Figure 12 illustrates the timeline of these frameworks and guidelines. We mapped their chronological appearance across disciplinary domains based on the versions referenced in the included papers. The assigned domains are indicative; several frameworks and theories could be appropriately classified into more than 1 domain.

XSL•FO
RenderX

Figure 12. Timeline of frameworks and theories for populating a logic model as used in 28 studies. The x-axis shows the publication year of the study that cited each framework or theory. For an explanation of all theories and frameworks, refer to Multimedia Appendix 3. CCM: Chronic Care Model; CFIR: Consolidated Framework for Implementation Research; COM-B: Capability, Opportunity, Motivation–Behavior; ERIC: Expert Recommendations for Implementing Change; FITT: Individual, Technology and Task Framework; HAPA: Health Action Process Approach; HBM: Health Belief Model; HIT: Health Information Technology; IM: Implementation Mapping; NASSS: Nonadoption, Abandonment, Scale-up, Spread, and Sustainability; NPT: Normalization Process Theory; ODSF: Ottawa Decision Support Framework; READHY: Readiness and Enablement Index for Health Technology; SCT: social cognitive theory; SDT: self-determination theory; SEIPS: Systems Engineering Initiative for Patient Safety; TAM: technology acceptance model; TTM: Transtheoretical Model of Health Behavior Change; UTAUT: unified theory of acceptance and use of technology.

Summarizing, logic model content is commonly populated with behavioral and implementation frameworks (notably COM-B and CFIR), with only NASSS and FITT originating in health informatics.

Model Components

Some logic models provided clear causal linkages between inputs, activities, outputs, and outcomes, while others were schematic or purely illustrative, lacking operational definitions or indicators.

For example, 1 study presented a logic model of around 10 items organized into CMO to describe the uptake of a vision screening program [85,91]. Another study presented a logic model of around 40 items, organized into problems, inputs, intervention, outputs, measurable effects, wider benefits, and long-term change to describe the introduction of EHRs for maternal and child health [12]. This shows the varying level of details among the included studies.

Reported Benefits and Challenges of Using Logic Models

Overall, we could extract 92 statements on perceived benefits of using logic models from 51 papers. The remaining 18 papers did not report any specific benefits of using a logic model. Reported benefits focus around clarifying causal assumptions, supporting targeted implementation and evaluation, and enabling stakeholder dialogue (Table 1).

XSL•FO
RenderX

Table . Reported benefits of using a logic model (from n=51 studies).

Reported benefits of using logic models	Studies, n
Support targeted, theory-based implementation	21
Explicate how the intervention leads to outcomes and long-term change	13
Identify success factors and potential causes of problems	13
Support testing and evaluation	12
Synthesize evidence	9
Support dialogue with stakeholders	9
Show areas for improvement	6
Articulate and clarify assumptions	4
Allow generalization to other contexts	3
Captures learning for future implementations	2
Sum	92

Also, we could extract 58 statements on perceived challenges of using logic models from 40 papers. The remaining 29 papers did not report any specific challenges of using a logic model. Challenges include limited evidence to populate models, resource intensity, and tensions between specificity and generalizability (Table 2).

Table . Reported challenges of using logic models (from n=40 studies).

Reported challenges of using logic models	Studies, n
Not enough evidence available to build LM[a]	8
ToC[b] is too general, not context-specific	7
ToC is too context-specific, cannot be generalized	7
Building ToC is time-consuming	7
Not all stakeholders were involved in LM development	6
Not all assumptions, factors, or outcomes can be measured	6
ToC does not cover full details	5
Difficult to choose the right LM template and tool	3
LM predictions were not met by reality	2
LM should include also practical evidence	2
Stakeholders may disagree	1
Stakeholder not trained in ToC	1
Social desirability reflected in ToC	1
Implementation was not fully done according to LM	1
Difficult to select the right theory	1
Total replies	58

[a]LM: logic model.

[b]ToC: theory of change.

Discussion

Principal Results

This scoping review identified 69 studies that developed or applied a logic model or ToC in the context of HIT. The number of publications has increased markedly since 2020, suggesting a growing recognition of the importance of program theory approaches in general for conceptualizing and evaluating complex HIT interventions.

Across the included studies, the most frequent purposes of using logic models were descriptive (to explain program components and mechanisms) and evaluative (to structure data collection and outcome assessment). Most logic models were newly developed for a specific project. Yet, they were often built on existing frameworks or theories that provide templates or guidance to build logic models for a specific domain or context (such as IRLM).

XSL•FO
RenderX

Geographically, while most studies originated from high-income countries, a considerable share came from resource-constrained settings. Many of these studies focused on HIT designed to improve health care access or to support service coordination, particularly mobile and telehealth interventions. Frequent use in resource-constrained contexts partly reflects funder requirements that encourage ToC or logic models for planning, monitoring, and evaluation [92,93]. Thus, their relatively high representation may reflect reporting practices within international development programs.

Regarding the types of technologies, logic models were most often applied to patient-facing and self-management systems (eg, mHealth apps) and to interventions involving telehealth and remote monitoring. In contrast, institutional HITs, such as EHR, were less frequently represented. This may reflect greater user interaction, context dependence, and behavior change in patient-facing technologies; areas where program theory helps capture mechanisms.

In our review, a broad spectrum of theories and frameworks was identified; yet, their application clustered around a few recurrent approaches. Frameworks such as the MRC guidance, Kellogg, or IRLM were often used as a guide on how to develop a logic model, while behavioral models and implementation-oriented frameworks, such as COM-B, CFIR, NASSS, FITT, or Unified Theory of Acceptance and Use of Technology (UTAUT), often informed the population of logic model content. This dual pattern reflects a distinction—methodological frameworks provide structure, while theoretical frameworks explain behavioral and contextual mechanisms.

Many studies combined elements from multiple frameworks or theories when populating their logic model, resulting in considerable conceptual heterogeneity of the developed logic models. An earlier review of HIT evaluation frameworks identified 6 dominant frameworks (CFIR; Reach, Effectiveness, Adoption, Implementation, and Maintenance Framework; technology acceptance model; UTAUT; diffusion of innovation theory; and normalization process theory) which guided HIT evaluation [91]. As we covered more phases besides HIT evaluation, we found a much greater heterogeneity of frameworks and theories.

The visualization of logic models was common, as almost all included studies presented at least 1 graphical representation. However, the level of structure and detail of these visualizations varied. Most visualizations lacked visible alignment with a guidance or framework such as the MRC or Kellogg. This suggests that model structure and graphics are driven more by practical needs and study phase than by a specific theoretical framework. This contextuality may limit comparability and reuse of logic models across studies.

This diversity in the included logic models may thus be related to both the type of HIT and the methodological purpose or phase of use. Logic models describing patient-facing or behavioral interventions, such as mHealth apps or telemonitoring systems, often adopted detailed, multilayered visualizations to represent behavioral mechanisms and contextual enablers. In contrast, logic models for institutional HIT, such as EHRs or decision support tools, tended to remain schematic, focusing on input-process-output sequences that mirror technical implementation steps rather than theoretical constructs.

The analysis by system level revealed that logic models were predominantly situated at the micro level, focusing on individual users, care teams, or patient-provider interactions. Fewer studies addressed the meso level (organizational or workflow integration), and even fewer considered the macro level (policy or system-wide implementations). This pattern shows that logic models in HIT focus more on project-level use than on system or policy assessment. Considering the systemic nature of many HIT solutions, including macro level considerations is recommended in future studies.

Several benefits of logic model use were reported across studies. Logic models helped clarify intervention components and causal assumptions, facilitated stakeholder engagement, and supported alignment between program design and evaluation. They also served as communication tools among interdisciplinary teams and as frameworks for monitoring the intervention over time. Some studies emphasized that the process of developing a logic model – rather than the final visualization – was most valuable for building shared understanding and identifying priorities.

Conversely, the main found challenges included lack of evidence to populate the logic model, the resources required for model development, and the trade-off between specificity and generalizability of the logic model. Earlier studies had also noticed that resource management may be a critical issue, especially in staged processes of logic model development where the model is iteratively developed together with multiple stakeholder groups [94].

Trade-Offs of Logic Models for HIT

Our findings highlight a core tension—logic models help structure complexity; yet, their use requires balancing complexity versus feasibility and specificity versus generalizability.

The first key trade-off concerns the complexity versus feasibility. Highly detailed logic models can capture the multifaceted interactions between technology, users, and context, but they risk becoming complex [94] and difficult to operationalize in real-world settings. Conversely, simpler models are easier to communicate but may obscure critical mechanisms and contextual dependencies. This prompts the question of what constitutes a “good” logic model that can balance simplicity, comprehensiveness, and interpretability. Previous work has shown that visual models play a key role in communicating complex information system structures and their effects [95]. Yet, there seems to be no shared benchmarks for an optimal level of abstraction for HIT logic models in different settings.

A second trade-off concerns the balance between specificity and generalizability. Logic models developed for narrowly defined interventions (such as mHealth or telemonitoring programs in maternal care) offer detailed causal mapping but have limited transferability beyond their original context. Interventions depicted in a narrow manner remain difficult to compare with other interventions, and to reproduce and apply in other settings. In contrast, models grounded in general

XSL•FO
RenderX

frameworks (eg, MRC and Kellogg) enable cross-study comparison but often require substantial adaptation to each setting. Better awareness of general frameworks among local researchers and developers could encourage reporting of balanced logic models with sufficient generalizability and specificity.

In our review, only 3 studies explicitly reported building their model on an earlier one, highlighting that reuse of existing logic models remains rare. Accessible repositories, combined with domain-specific frameworks, could help researchers build on previous models and improve methodological continuity. This could address the current fragmentation that may contribute to a replication crisis in health informatics [96].

Practical Steps to Enable Reuse

To translate the goal of reuse into practice, we suggest a minimal set of reporting elements and infrastructure supports for HIT-related logic models; authors should provide structured, consistent metadata for each model: (1) intended purpose and lifecycle phases addressed (development, piloting, evaluation, and scaling-up); (2) health system level modeled (micro, meso, and macro); (3) guidelines used to develop the model (eg, MRC and Kellogg); and (4) frameworks or theories used to populate causal content (eg, COM-B, CFIR, and NASSS or FITT), together with a clear statement on whether the model is new, adapted, or reused from previous work. Standardized visualizations should explicitly depict components, outcomes over time, and contextual determinants and assumptions to aid comparability across studies. Providing these details consistently would reduce heterogeneity, enhance interpretability, and make logic models more readily adaptable across HIT settings.

Journals and funders could also require explicit program theory reporting for HIT (analogous to existing evaluation reporting standards such as Standards for Reporting Health Informatics [STARE-HI] [97]), and support the creation and use of accessible repositories for logic models to prevent starting from scratch in each project.

Strengths and Limitations

This scoping review provides, to our knowledge, the first systematic mapping of how logic models and ToCs are used within HIT research. By analyzing 69 peer-reviewed studies across diverse disciplines, the review offers a comprehensive overview of the purposes and scope of HIT logic models. A strength lies in the systematic and transparent data extraction process, which covered not only descriptive features but also visual and theoretical aspects of each logic model.

Some limitations must, however, be acknowledged. First, although major bibliographic databases were searched, inclusion was restricted to peer-reviewed, English-language publications, and gray literature was not systematically explored. Because logic models are often used in program management and development cooperation, additional project reports may exist outside the scientific literature. Nevertheless, it is unlikely that inclusion of such sources would have altered the main findings of this review, as our analysis focused on scoping the nature rather than the frequency of logic model use.

Second, the heterogeneity of reporting limited the depth of analysis. Many studies did not provide sufficient detail on model development or theoretical basis. No validated appraisal tool currently exists for assessing the quality of logic models, making it difficult to distinguish between well-grounded models and more schematic representations.

Finally, the review reflects a snapshot of the literature up to 2025. Given the rapid evolution of HIT and the increasing integration of implementation science frameworks, future studies may show substantial changes in how logic models are constructed and applied. Continuous updating and cross-field comparison will therefore be essential to monitor progress toward methodological standardization and deeper theoretical integration.

Comparison With Other Fields

The use of program theory and logic models is well-established across several health and social science domains, as reflected in the range of guidelines and frameworks identified in this review. For health informatics, however, only 2 specific frameworks – FITT and NASSS – were identified.

In public health, logic models and theories of change have been a standard requirement for designing, implementing, and evaluating complex interventions [3]. They are embedded in national and international frameworks, such as those of the Centers for Disease Control and Prevention [98], the World Health Organization [93], and the UK NICE [99], all of which emphasize explicit articulation of causal assumptions and outcome chains. In contrast, comparable guidance for HIT remains scarce. Besides, HIT interventions often focus on evaluating short-term metrics or user acceptance measures, with limited attention to underlying mechanisms of change, long-term outcomes, or system-level effects [100].

In implementation science, logic models have evolved into comprehensive meta-frameworks that link determinants, strategies, mechanisms, and outcomes. Frameworks such as the IRLM and the CFIR are now widely adopted to integrate evidence and guide evaluation across multiple levels of health systems. Comparable developments in health informatics or HIT-specific adaptations are not yet visible.

In HTA, logic models have been promoted as a backbone for evidence synthesis and for structuring complex evaluation questions [101,102]. In contrast, few HIT-focused systematic reviews currently apply logic models; in our scoping review, only 6 such reviews were identified. For example, 1 paper on patient decision aids developed several CMO models to explain why and how these tools were successfully implemented in routine care [81].

Overall, program theory from other fields is increasingly used for HIT, but HIT-specific methodological development remains nascent. Only since around 2020 has the systematic use of program theory become visible, but HIT-specific methodological guidance or reporting standards have yet to be developed.

Future Research Directions

Going forward, advancing the use of logic models in HIT research requires a shift from representation toward explanation

XSL•FO
RenderX

and learning. This can be achieved by embedding logic models within evidence-informed development and evaluation cycles, where theoretical and empirical findings feed back into model refinement. Integration with mixed methods designs and implementation frameworks, such as CFIR, IRLM, or NASSS, can help link HIT interventions to contextual factors, thereby helping to achieve the desired outcome of the intervention [91]. Stakeholder-inclusive and iterative model development – involving users, clinicians, managers, and policymakers from the outset – should be promoted as a best practice to ensure that models remain both valid and actionable.

Future work should also address the need for standardization and transparency. Reporting guidelines analogous to STARE-HI [97] could be expanded to require explicit reporting of program theory for HIT evaluations, ensuring consistent description of logic model structure, purpose, and development process. For policy, funding agencies and evaluators should consider making explicit program theory or logic model articulation a requirement for HIT projects, aligning expectations for design, monitoring, and impact assessment.

Another promising direction involves the use of computational and AI-assisted tools to support logic model construction and analysis. Natural language processing and machine learning techniques could assist researchers in extracting components and causal relationships from qualitative data or literature, automatically populating logic model structures, and visualizing linkages between intervention components and outcomes. Such tools would not replace human interpretation but could enhance efficiency, reproducibility, and scalability of program theory development.

Finally, capacity building and education are essential. Educational guidelines in medical informatics, such as the International Medical Informatics Association Recommendations on Health and Medical Education [103], could integrate program theory throughout the HIT innovation lifecycle in their curriculum recommendations.

Funding

This project was partly supported by funding from the State of Tyrol.

Abstract

Background: Health care public reporting (PR) refers to making information about the quality and performance of health care providers available to the public. The primary targeted use of PR is the selection of a health care provider. Previous studies suggest that PR has improved health care quality; however, the overall adoption rate of PR systems remains low. Misalignment between PR information and users' actual needs can explain this gap.

Objective: This study conducts a systematic literature review of PR systems in health care, aiming to explore how data encoding and presentation influence user utilization, with particular attention to the impact of data inconsistencies and inaccuracies on actual use.

Methods: A literature search was conducted on 5 electronic databases (Web of Science, CINAHL, Embase, PsycINFO, and PubMed), focusing on studies providing information in health care from an individual perspective. Subsequently, the quality of the included studies was assessed using the Mixed Methods Appraisal Tool (McGill University). Finally, a total of 25 empirical studies were included in this study.

Results: Among the 25 studies, 40% (10/25) investigated website presentation formats, 20% (5/25) explored dashboard-based data presentation formats in PR systems, 48% (12/25) examined data quality, and 20% (5/25) addressed user heterogeneity. Quantitative methods were used in 80% (20/25) of studies, while qualitative and mixed method designs accounted for 16% (4/25) and 4% (1/25), respectively. Findings suggest that standardized website and dashboard guidelines improve data reliability and user comprehension and that user heterogeneity mediates the effects of structural and process indicators on outcomes. Data collection was completed in February 2025, and the study was projected to be fully completed by September 2025.

Conclusions: This study provides an integrated structure-process-outcome–based framework for PR in health care. By presenting data through dashboards, inconsistencies and inaccuracies in data across different web pages can be mitigated, thereby decreasing conflicting information and improving comprehension in PR systems. Based on the literature findings and identified knowledge gaps, this study also proposes future research directions for online PR.

KEYWORDS

digital health; public reporting systems; data and information process; health literacy; quality indicators

Introduction

Background

Digital health refers to the development and use of digital technologies to enhance health-related knowledge and practices [1]. It is not only a technological concept but also profoundly shapes how people access health information. For instance, a 2023 report by Digitalis Medical indicates that 7% of all daily Google searches are health-related, equating to approximately 70,000 health care searches every minute [2].

The core function of public reporting (PR) systems is to assist individuals in selecting health care providers and services [3]. Improving the use of the PR system requires understanding how data are encoded and decoded in digital health. This understanding is crucial for individuals who use the PR system to proactively manage their health and engage in recommended behaviors [4].

Previous studies have shown that inconsistencies or errors in PR data can affect trust and reduce users' confidence in the reporting system [5]. Such inconsistencies not only challenge data reliability but also influence how users understand PR information. However, empirical research on these data inconsistencies remains fragmented. For example, some studies suggest that information presentation affects users' actual use of PR systems [6,7]. Moreover, these studies largely remain focused on information presentation formats, while research on

XSL•FO
RenderX

data heterogeneity within systems remains limited, underscoring the complexity of PR data usage.

Patient activation measure (PAM) refers to an individual's knowledge, skills, and confidence essential for managing their own health and health care [8,9]. Although patients show strong interest in accessing PR information to make informed health care decisions, the overall adoption of the PR system remains low, largely due to information presentations that do not match patients' comprehension levels [10-12]. Therefore, exploring data generated in real-world physician-patient co-management contexts may help alleviate data communication challenges and support informed decision-making [13,14].

To address this gap, this study conducts a systematic literature review to provide an overview of current research on PR in digital health information systems. To achieve this objective, we address the following research questions: (1) How do system-level structural indicators influence process indicators, and subsequently influence outcome indicators? and (2) How do decoding errors in PR systems and user-system interactions influence users' information use?

Accordingly, we systematically identified and reviewed 25 empirical studies on information presentation in PR in health care contexts. Drawing upon the structure-process-outcome (SPO) theoretical framework, we categorized and synthesized the structural indicators (website guidelines and dashboard guidelines), process indicators (data quality guidelines and data process criteria), and outcome indicators (user satisfaction and surgical mortality). Meanwhile, we position user heterogeneity as a mediating variable that links process indicators to outcome indicators. Specifically, variations in contextual and individual-level factors (age, gender, political affiliation, employment status, income, and area of residence) can influence the interactions of users' engagement with information.

The remainder of this paper is structured as follows: the "Methods" section describes the methodology for planning and conducting the literature review, focusing on recent research; the "Results" section presents the findings in response to the 2 research questions; and the "Discussion" section discusses the progress and identifies challenges in current literature, concluding with recommendations for future research. Checklist 1 presents the PRISMA-P (Preferred Reporting Items for Systematic Review and Meta-Analysis Protocols) 2020 checklist which outlines recommended items to address in a systematic review protocol. Multimedia Appendix 1 contains the search strategies used in each database. Multimedia Appendix 2 shows the Mixed Methods Appraisal Tool (MMAT; McGill University) quality assessment report. Multimedia Appendix 3 contains the key characteristics of the included studies. Multimedia Appendix 4 includes additional details of the included studies.

Theoretical Background

Overview

The presentation of information in public reports significantly influences user engagement with these systems [15]. To gain an understanding of individual users' attitudes toward the PR system and how this forms health information adoption behavior, it is necessary to explore the information presented in the PR systems. While information is composed of data, the way data is structured determines how information is understood [16]. Based on this premise, this study assesses whether existing PR data align with users' informational needs and examines how such alignment influences users' adoption of PR systems.

PR and Quality Indicators

PR in health care refers to the disclosure of performance-related information about providers, organizations, or systems to the general public. Such information is typically nonanonymous, identifying specific professionals or institutions, thereby enabling direct comparison and accountability [17,18]. By disclosing the performance data, individuals (patients and nonpatients) can choose higher-performing providers and make health plan decisions [17,19].

The assessment of PR systems, rather than direct health care delivery, has increasingly drawn academic attention. Donabedian [20] addresses this issue by conceptualizing health care quality through the SPO framework. In health care, structure indicators refer to the system's resources and organizational arrangements, and process indicators include all service delivery activities such as diagnosis, treatment, nursing, and patient education. Finally, outcome indicators reflect the resulting health effects, including patient health improvements, satisfaction, and mortality rates. By applying the SPO framework in this manner, we shift the focus from assessing health care delivery quality to evaluating how PR system structures and processes influence user outcomes.

In recent times, we have also seen that PR in health care is demanded from the perspective of environmental, social, and governance (ESG) reporting, which involves public disclosure of an organization's performance and its impacts on environmental, social, and governance factors [21]. Currently, PR seems to be moving toward health care processes beyond basic clinical activity, such as PR on clinical trials [22]. In the era of the current artificial intelligence revolution, the impact of artificial intelligence on PR is, of course, an important topic [23,24].

Although defining and measuring quality in health care remains challenging, extensive evidence supports the essential role of the SPO framework in measuring health care quality [20,25]. Within the structural dimension, PR systems are an important component [25]. The health care system is depicted through structural indicators, which in turn influence process indicators, ultimately affecting outcome indicators [20]. PR has to inform its users of all these health care components. Previous research on process indicators in PR primarily focused on operational standardization, consistency, and service standard implementation [15,26]. However, few studies have examined the structural dimension from an individual-system interaction perspective.

At the process level, patient-physician collaboration (PPC) generates substantial user data [27]. During interactions between health care organizations and users, systems serve as supporting tools that can enhance treatment efficiency. The data generated in this process holds significant value for collection and use

XSL•FO
RenderX

[28]. The fine details of PPC, however, remain a difficult item to document in PR.

Existing research has paid insufficient attention to patient-generated data from the PPC process, particularly in the digital era, where the processes of data collection, organization, and use remain inadequate compared to the opportunities that digital data processing could offer. Such gaps may lead to unintended consequences, including users' mistrust of PR systems.

Finally, outcome indicators include subjective or functional metrics, such as in our sample, patient satisfaction and mortality rate [29,30]. Online PR websites enable individuals to interact directly with information, whereas individuals often rely on their own knowledge to evaluate content [17]. In contrast, in offline settings, user interaction is typically mediated by health care institutions, resulting in a more indirect experience [31].

Previous research indicates that attitudes formed through direct experience are more effective in predicting behavior than those formed through indirect experience [32]. However, studies examining interactions between individuals and system information in online environments in a PR context remain relatively limited. Taken together, these gaps highlight the need for a framework that integrates system information processing into the SPO dimensions of PR.

Sociotechnical Theory

According to Bostrom and Heinen [33], sociotechnical theory suggests that information systems should be designed so that the individual and technology operate as an integrated whole. In other words, the design of information systems should not only focus on data collection, processing, and transmission; the interaction between humans and information should also be emphasized. Within the context of PR, this principle is embodied through the interaction between PPC, user heterogeneity, and system-level demand for data reliability and standardization.

The operational goal of any PR system is to serve as a channel through which health care organizations and governments convey PR information to the public. This process enables individuals to filter health care information via the selection pathway and make health care choices suited to their needs [12]. PR information selection is both receptive and selective, and at the system stage, it primarily involves information processing.

In the context of PR, effective information processing is critical because it shapes how users understand and use performance data to make informed decisions. The information processing in PR systems involves a series of systematic steps that transform raw health data into actionable information for diverse stakeholders such as policymakers, providers, and the public [34]. On the PR website, data are symbols that represent the properties of objects and events [35].

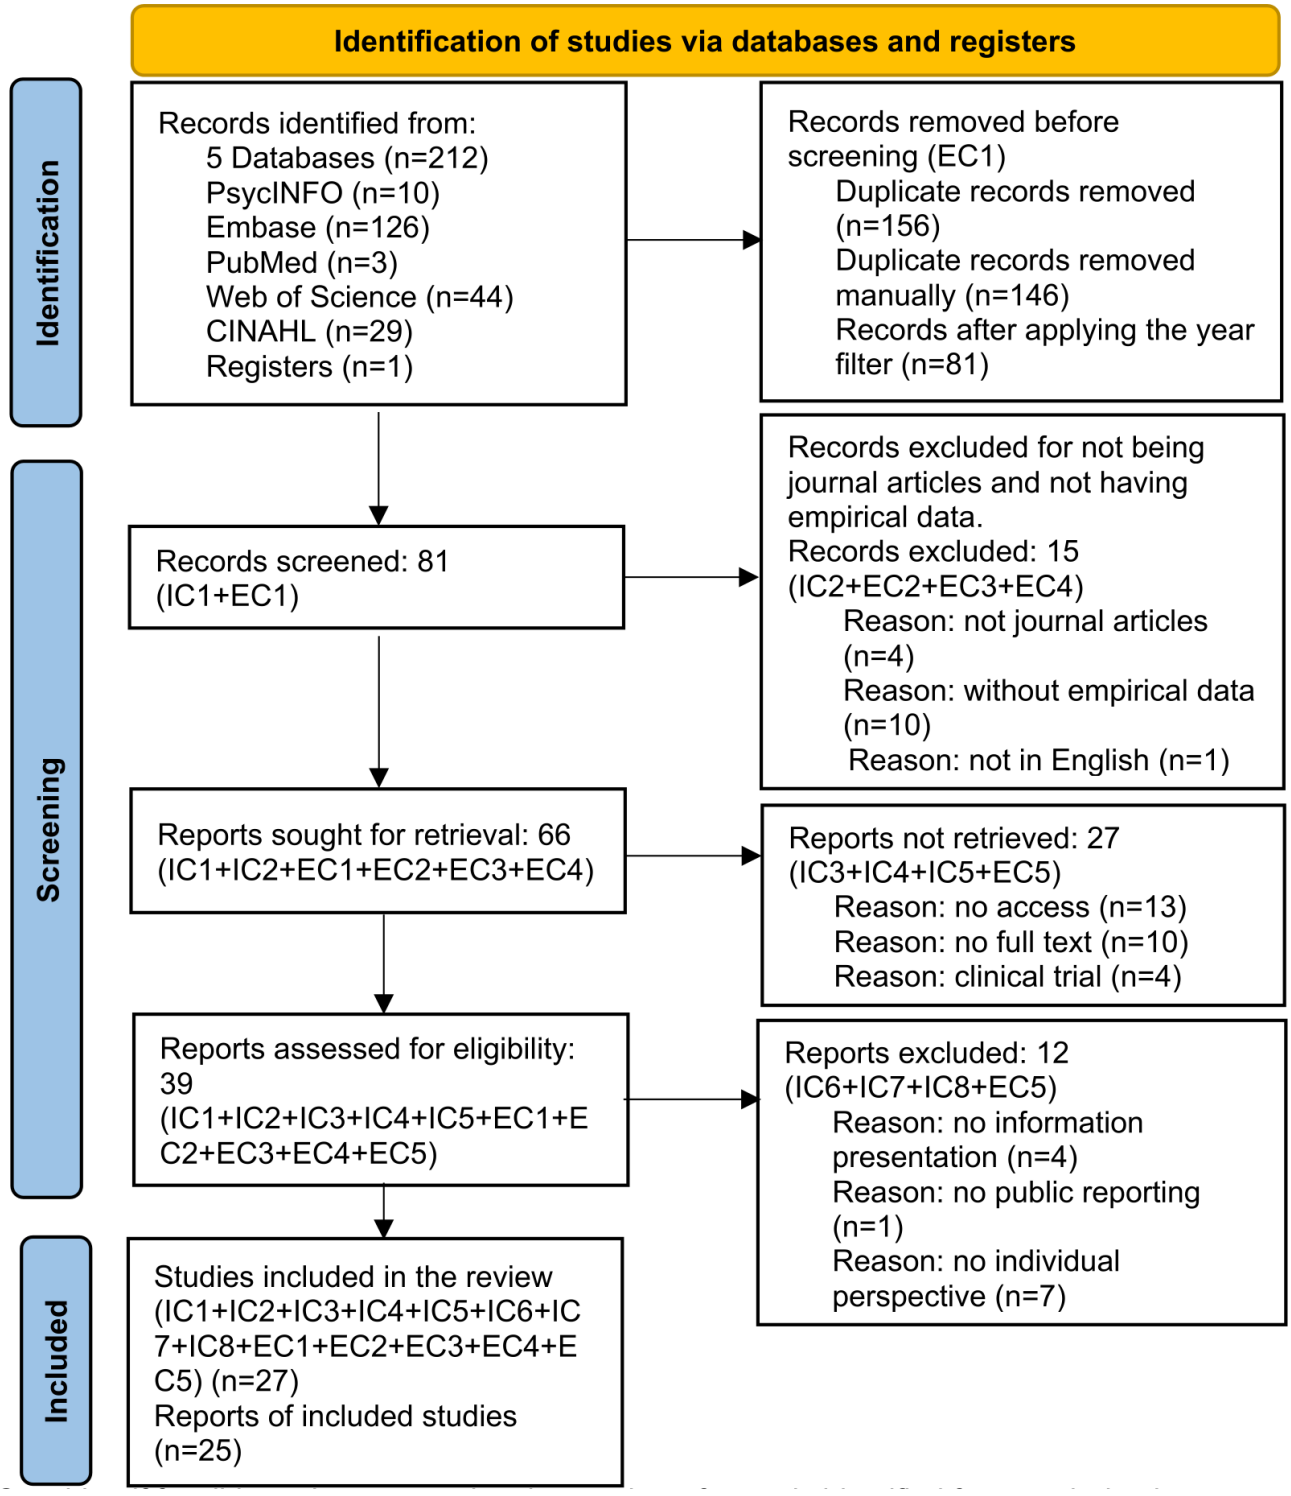
Information consists of processed data, with the processing directed at increasing its usefulness [16]. System information processing involves integrating data from multiple sources into a central database, which is then retrieved and displayed on websites [36]. Regarding quality indicators, many individuals still experience significant analytical challenges, particularly when information is not clearly presented [37]. Thus, it is necessary for the PR system to reduce information asymmetries and empower patients, families, and payers to select high-quality providers [38].

These studies provide insights into the interaction between PR information and individuals, particularly regarding how end users use PR information. Previous research has primarily focused on issues of data inconsistency and low accuracy in PR [39]. However, previous studies have provided insufficient investigation into how data inconsistency issues can be effectively addressed within the field of information systems. Specifically, it is equally important to consider the objective quality of the data, incorporating data guidelines to address data inconsistency.

These findings underscore the critical role of data quality in shaping the adoption of PR systems. However, extant research demonstrates several notable limitations. First, the analytical depth remains constrained. Most studies focus primarily on information presentation as the primary mode of data delivery; however, they often overlook how data processing within systems fundamentally influences website presentation and user interpretation.

Second, investigations in the PR domain have predominantly adopted an awareness-to-behavior framework, emphasizing the role of awareness in guiding user actions [17]. Nevertheless, the complex interrelations between data quality and adoption remain underexplored, resulting in substantive gaps between PR systems and users' actual attitudes. Consequently, there is a pressing need to examine online PR systems through a lens that integrates the system and individuals.

Methods



Overview

A systematic literature review requires clearly defined research questions, a transparent search process, data extraction, and data presentation [17,40]. Typical reviews cover a span of approximately 10 years. In this study, the time frame was set from 2016 to 2025. The rationale for selecting studies after 2015 is that, from this year onward, PR increasingly transitioned to internet-based platforms. The system reached its peak in July 2015, but then declined rapidly and has remained at a relatively low level since [41]. Additionally, the Hospital Consumer Assessment of Healthcare Providers and Systems star ratings system was launched, enhancing patients' visual understanding of hospital quality information [42].

We used the guidelines of Okoli and Schabram [43] and the framework proposed by Webster and Watson [44] to conduct our literature review. This review adopts a structured approach to the literature. As shown in Figure 1, the complete selection and synthesis process is summarized in the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram.

XSL•FO
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram of the selection process for public reporting systems retrieved from 5 databases between 2016 and 2025. EC: exclusion criteria; IC: inclusion criteria.

First, when designing the search strategy, efforts were made to capture all studies that met the inclusion criteria [45]. This research aims to explore the presentation of information in PR systems. Therefore, the search term was set to information; meanwhile, the research mainly focuses on PR, and the keyword includes "PR." The search term is provided in Multimedia Appendix 1, and the search date was September 14, 2025.

Second, PR has evolved as an interdisciplinary field, drawing from health policy and behavioral science. Conducting a review can be helpful to fill in the gap of data inconsistency and identify future directions from the information system perspective [46]. Access to these databases was obtained via Volter (Library of the University of Turku), ensuring that the user was logged in to minimize the number of ignored studies due to access issues. The data sources were chosen from Web of Science (multidisciplinary and broad literature search), CINAHL (health and public health information systems), Embase (health and public health information systems), PsycINFO (cognitive science, decision-making, and behavioral economics), and PubMed (biomedicine literature database).

XSL•FO
RenderX

Third, using tools to assess the risk of bias in studies is an important step described in systematic review protocols, as judgments made during this process may influence the analysis and interpretation of the review results [45]. Meanwhile, applying objective and reproducible methods helps ensure the appropriateness and fairness of the study findings [43]. The quality assessment protocol covers study methodology, level of structuring, study outcomes, and research topics. After the deduplication of studies (n=146) in EndNote (Clarivate) combined with manual checking, 81 studies were included in the final scoring pool.

Among the included studies, the methodologies involved both qualitative and quantitative approaches. The scoring table referenced from Hong et al [47] is provided in Multimedia Appendix 2.

Screening Process of the Systematic Review

In the screening process, 81 studies were initially included in the research pool. Review or descriptive studies that were not journal publications and did not contain empirical data were excluded. A total of 66 articles were retrieved, and full-text searches were conducted for these studies. During the full-text review, studies without accessible full text and clinical trial papers were excluded. Ultimately, 39 studies were included in the quality assessment.

Some of these studies examined PR systems from an organizational perspective. This study, however, focuses primarily on the individual perspective, specifically the alignment between individual users and the information presented in the PR system. Studies that explored system processes at the organizational level, which do not directly reflect the information presentation encountered by individual users, were excluded. Additionally, since this study focuses on PR systems in the health care domain, studies from non–health care fields were also excluded.

In Figure 1, abbreviated labels are used to represent inclusion criteria (IC) and exclusion criteria (EC).

The selection was conducted independently and double-checked manually. For clarity, the IC correspond to the following criteria: IC1 indicates studies published between 2016 and 2025, IC2 indicates empirical studies, IC3 indicates studies with open access, IC4 indicates studies with full text availability, IC5 indicates studies published after peer review, IC6 indicates studies focused on information presentation, IC7 indicates studies focused on the individual level, and IC8 indicates studies conducted in health care contexts. The EC corresponds to the following criteria: EC1 indicates studies published outside the 2016 to 2025 timeframe, EC2 indicates nonjournal studies, EC3 indicates nonempirical studies, EC4 indicates studies not published in English, and EC5 indicates clinical trials and other studies not focused on PR systems or individual-level information use.

After the initial full‐text screening, 27 studies were eligible for quality appraisal. The methodological quality of the included studies was assessed using the MMAT (2018 version) [47], a validated instrument specifically developed for appraising empirical studies in mixed-study systematic reviews. The MMAT evaluates 5 categories of study designs—qualitative research, randomized controlled trials, nonrandomized quantitative studies, quantitative descriptive studies, and mixed methods studies—each using 5 methodological criteria.

Following MMAT guidance, studies can be classified as low (1‐2 criteria met), moderate (3 criteria met), or high quality (4‐5 criteria met). All assessments were performed independently by the first and third authors, and discrepancies were resolved through discussion. Two studies with MMAT scores of 1/5 and 2/5 were excluded from the analysis, resulting in a final set of 25 studies for article synthesis.

Literature Synthesis

Thematic and Narrative Synthesis

We conducted a thematic synthesis of the included studies to extract key findings, which were then grouped into distinct themes [45]. Within each theme, dimensional indicators were identified and presented using an integration framework to address the first research question. This approach enables the qualitative integration of evidence across studies, highlighting patterns in structure indicators, process indicators, and outcome indicators.

Given the fragmented and broad scope of research in the field of PR, a narrative synthesis approach was adopted [48]. To enhance the transparency and rigor of the synthesis, descriptive statistics were also used to summarize the number of studies within each category and their methodological characteristics.

Regarding the research questions, the theme under the SPO framework is reported quantitatively, whereas subthemes (eg, website, dashboard, and data) are explored using a narrative approach. During synthesis, studies were grouped based on the specific dimensions of the SPO framework and their relevance to the research questions. Furthermore, a subset of studies investigated how structural indicators and process indicators influence the outcome indicators. Examining findings on the same aspects allows them to extend one another, which can be viewed as a form of confirmation [48].

SPO Framework–Based Results Mapping

Each subtheme in the “Results” section corresponds to a specific type of data extracted from the literature: (1) structure (website and dashboard): indicators describing the system design, presentation, and functionality were collected and summarized; (2) process (data quality and data process): studies reporting on data accuracy, completeness, accessibility, and workflow processes were analyzed; (3) outcome (patient satisfaction and surgical mortality): measures were extracted from studies evaluating the effect of PR systems on users’ decision-making, satisfaction, and clinical outcomes; and (4) user heterogeneity: information on demographic characteristics, health literacy, and contextual factors influencing user interaction with PR systems was also extracted and synthesized.

Quality Assurance and Integration

First, we conducted an initial synthesis using thematic analysis, presenting the study results in Multimedia Appendices 3 and 4. Subsequently, 1 author summarized and categorized the included

XSL•FO
RenderX

studies within an integrative framework. Based on this synthesis, an integrative framework was developed to organize the identified themes, which are further elaborated in the "Results" section.

Results

Overview

Among the 25 studies included in this review, 40% (10/25) explored PR from the perspective of information presentation formats, while 20% (5/25) of the studies focused on the dashboard in online PR. Additionally, 48% (12/25) of the studies examined PR systems from the perspective of data presentation, and 20% (5/25) addressed user heterogeneity. Finally, 12% (3/25) of the studies investigated PR from the perspective of patient satisfaction and surgical mortality.

Meanwhile, 80% (20/25) adopted quantitative methods, 16% (4/25) used qualitative designs, and 4% (1/25) used a mixed methods approach. Regarding data sources, 60% (15/25) collected secondary data (eg, web content analyses), while 40% focused on primary data through surveys, interviews, or focus groups. Data collection was conducted between February 2025 and September 2025.

Structure

Website

Among the included studies, 40% (10/25) of the studies examined PR from the perspective of information presentation formats on websites. For instance, studies found that the format of information presentation on PR websites can significantly influence public understanding and trust, policymaking, and pandemic response [49].

Specifically, the findings show that standardized data guidelines help improve the quality of PR websites, including accuracy, completeness, technical elements, design and aesthetics, readability, usability, and accessibility [50]. For example, challenges in information presentation may also result from mismatches between recommended reading levels for patient education materials (typically up to sixth grade) and the actual readability of websites, which seldom meet the needs of most patients [50]. Such mismatches create a gap between the health information users need and what is actually provided. Appropriate readability facilitates comprehension, enabling better disease management and adoption of healthy lifestyles [51].

Moreover, in terms of presentation formats, we found that online ratings may serve as a valuable source of information for both consumers and policymakers [52]. It is worth noting that storytelling techniques that convey narrative trends on dashboards can help users better understand the information presented in PR [53]. Additionally, supplementing this with characteristics of professional care institutions, which are often under-represented, can enhance the comprehensiveness of PR information [54].

Furthermore, the widespread use of aggregated ratings, such as star systems, may further strengthen consumer responses [55]. Interestingly, research has shown that "breadcrumb navigation" (forward-backward topic navigation) helps maintain the continuity of information, enabling users to quickly review previously read content and efficiently locate needed information [50]. Meanwhile, studies indicate that participants accessing "drill-down scores" tend to engage more deeply with the provided data (manifested as increased interactions on the website), but their impact on physician selection is lower than that of participants accessing "roll-up scores" [56].

Additionally, studies have found that over 90% of websites do not include accessibility features for individuals with disabilities, such as hearing, cognitive, neurological, motor, language, or visual impairments [51,57,58]. Therefore, considering accessibility benefits not only for disabled users but also the general population (eg, those using mobile devices, with slow internet, or limited bandwidth), it provides equal access to information for elderly individuals or residents in remote areas [51,57,58].

Dashboard

In our sample, a lot of discussion revolved around dashboards. We see them as a subcategory of web-based information, offering more dynamic and versatile analysis possibilities than static websites.

Overall, 20% (5/25) of studies examined the presentation of information on dashboards. Relevant and high-quality data are crucial for constructing dashboards, and research indicates that data sources are key factors in dashboard development [59,60]. Dashboards are especially useful in presenting epidemic and pandemic trends, such as those of COVID-19 [61], but can also be used in classical resource selection performed by PR users.

In terms of content presentation, dashboards should serve as tools that clearly link current trends with past policy decisions and individual behaviors, thereby enhancing the use of indicators [61]. However, evidence suggests that known and validated presentation techniques were overall underused, especially explanatory narratives [61]. To enhance usability, effective dashboards include: (1) understanding the audience and their information needs; (2) managing the type, quantity, and flow of displayed information; (3) clearly reporting data sources and methods; (4) linking time trends with policy decisions; (5) providing "close-to-home" data; (6) segmenting populations into relevant subgroups; and (7) using storytelling and visual cues [61].

Among these studies, the predominant approach involved data provision (specificity of geographic breakdowns, range of indicators reported, and explanations of data sources or calculations) and advancements enabled by the technologies employed (customization of time trends and interactive or visual chart elements) [53]. Meanwhile, studies also note that the clarity of data sources and methods has improved in dashboard development [53]. Teams differ in how they explore and define the purposes of dashboards. Some view dashboards as tools for presenting raw data to the public, while others attempt to provide explanations through narrative or visualization [59].

Moreover, 8% (2/25) of studies viewed the purpose of dashboards as solely presenting data (raw numbers) for the

XSL•FO
RenderX

public to interpret independently, whereas others sought to provide explanations through narrative or visual methods [53]. Additionally, incorporating storytelling elements and visual cues within dashboards has been shown to enhance users' ability to process information effectively [53]. For example, the development of dashboards that allow users to create profiles and receive personalized scores enables consumers to "see themselves in the data" [62].

Process

Data Quality

Overall, 48% (12/25) of studies examined PR from the perspective of website data. Notably, 32% (8/25) of studies indicated that standardized data guidelines help improve the quality of PR websites [15,45-47,58,59]. Additionally, some research described implementing check types within a data quality framework covering conformance, completeness, and plausibility, including both verification and validation [63].

Data Process

In the context of PPC, the generation of data encompasses multiple sources and activities. By using the data quality framework, data were collected across 4 domains, multiple measures, and time periods to examine access and equity; efficiency and sustainability; quality, safety, and patient orientation; and employee engagement [60].

Among these studies, 28% (7/25) investigated chart information on PR websites. The use of publicly reported data by consumers, policymakers, and researchers has grown substantially [64]. Most websites use charts, graphical elements, and quantitative descriptions as tools to convey differences between hospitals [65]. In addition, some research suggests adding charts to improve navigation [15]. For example, appropriate disease-related images and illustrations help patients better understand the information [50].

Meanwhile, the trend toward simplified composite rating systems may be reasonable to improve consumer responses to PR [55]. Previous research identified seven key elements that enhance user understanding [7]. The elements include unmarked bar charts, bar charts with simple symbols, bar charts with traffic light indicators, bar charts with thumbs-up symbols, provider rankings based on performance, clearly indicating whether higher values represent better performance, and implying quality levels through performance ranges without explicitly marking scale directions [7].

Furthermore, the transparent communication of standardized databases provides a crucial supplement to the missing components commonly observed in observational research [63]. This transparency can enhance the effectiveness of PR tools, as consumers may question the reliability of the quality information provided and consequently avoid using report cards [66].

Within the PPC process, presenting data in a structured format on dashboards can facilitate clear communication between health care providers and patients [67]. Meanwhile, PR websites can also serve as supplementary materials recommended by physicians, thereby reducing the need for face-to-face education and consultation [50].

Moderating Variable

User Heterogeneity

Overall, 20% (5/25) of the studies examined user heterogeneity, suggesting that themes such as simplicity, trust, collaboration, software and data integration, and adaptability have facilitated the development of PR systems [67]. However, the use of identical data across different websites may result in confusion or even contradictions regarding the same provider [15].

Moreover, research has highlighted that improvements in data timeliness, the level of detail available, and the categorization of comparable population groups can enhance the quality and effectiveness of PR [60]. For instance, individuals with higher health literacy tend to spend more time reviewing PR information than those with lower health literacy [68].

Individual Characteristics and Contextual Factors

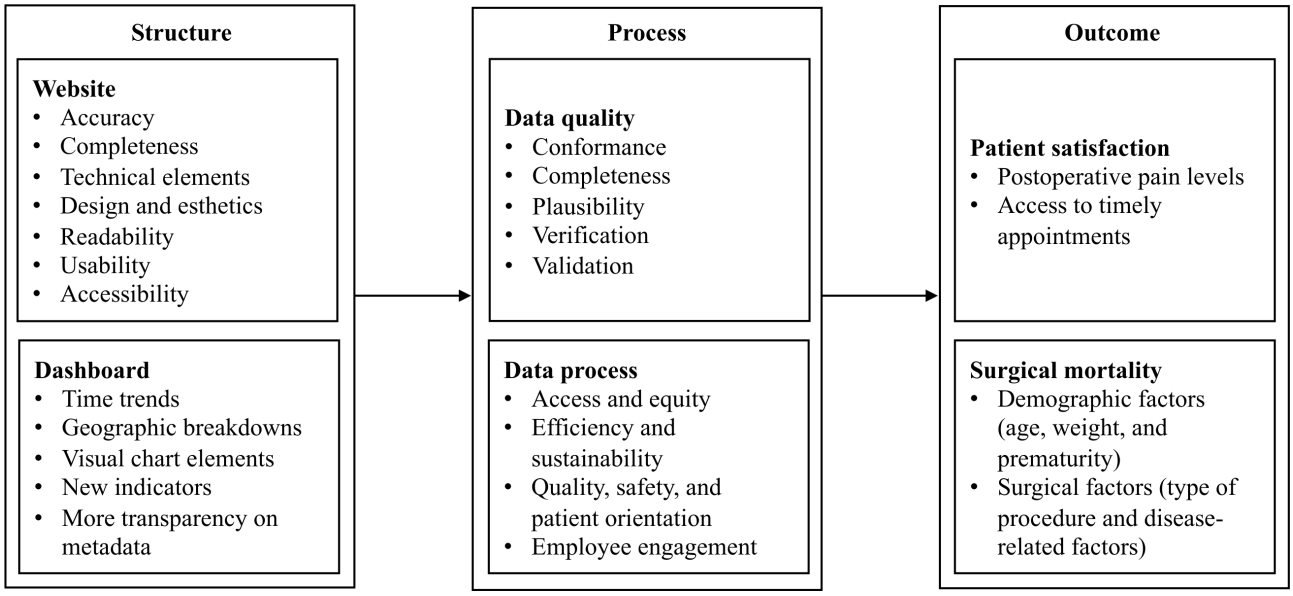
Similarly, individual characteristics and contextual factors, such as age, political orientation, employment status, income level, and residential area, significantly influence users' adoption of PR information [38]. Younger adults are generally more likely than older adults to trust information from all sources [38]. In addition, political orientation, employment status, income level, and residential location are correlated with trust in medical quality information from companies, government agencies, or family and social network sources [38]. Collectively, these findings indicate that both individual characteristics and contextual factors are critical determinants of the perception of PR information.

Outcome

Patient Satisfaction

Overall, although patients generally prefer to obtain health information from medical professionals, the media remains an important source of information [69]. Within the PPC process, patient satisfaction primarily depends on the quality of care and service delivery. Specifically, patient satisfaction appears to depend largely on postoperative pain levels and access to timely appointments [70].

Surgical Mortality



In addition, studies have pointed out that the variables influencing patient risk levels in surgical mortality include demographic factors such as age, weight, and prematurity, surgical factors such as the type of procedure, as well as disease-related factors [71].

A Framework to Understand the PR Quality Indicators in Health Care

The framework used in this study is based on the Donabedian quality model [20]. As shown in Figure 2, the system constitutes a key component of structural indicators [20]. User heterogeneity functions as a mediating mechanism linking the structural indicators and process indicators to outcome indicators. Specifically, the structural indicators and process indicators features of PR systems jointly shape users' perception of the information [38].

XSL•FO
RenderX

Figure 2. Integrative structure-process-outcome (SPO) framework for public reporting systems in health care.

The presentation format of PR websites refers to the channel through which users directly interact with the displayed content of the PR systems. Adherence to the website quality dimension and the dashboard quality dimension in the presentation format facilitates users' understanding of the system in a structured context.

Previous studies have indicated that data inconsistencies negatively affect the actual use of the system, thereby influencing users' adoption of the system [72]. The reviewed study indicates that the dashboards present data that have been processed and integrated within the underlying data architecture, resulting in higher accuracy and consistency. This, in turn, helps users use information that is more reliable and precise.

While structural indicators define the foundational quality of PR websites, process indicators determine how these systems function and generate reliable data. In terms of process indicators, data quality encompasses conformance, completeness, plausibility, verification, and validity. Data processes include accessibility and equity, efficiency and sustainability, quality, safety, patient-centered orientation, as well as employee engagement.

Building on the research gap regarding data inconsistency in existing PR, this study examines the dimensional indicators of data generated within process metrics. Standardizing data generated through PPC processes facilitates process-level data handling, thereby supporting the further use of the data. This aligns with prior findings from reviewed studies indicating that standardized data guidelines help users make better-informed health decisions [51].

User heterogeneity consists of individual characteristics and contextual design features [37]. Prior research suggests that dashboard design often fails to account for distinct user groups, leading to limited engagement [59]. Integrating contextual factors, health literacy levels, and individual characteristics into the design of PR systems allows for a more targeted presentation of information, thereby enhancing user comprehension and decision-making [37,59,68].

Previous research has shown that demographic variations influence information perception [73]. In line with this evidence, the reviewed studies identify multiple factors associated with users' interactions with PR systems, including age, gender, political orientation, employment status, and region of residence. Beyond demographic variations, health literacy and contextual design features jointly shape how users interpret and use PR data [37].

The reviewed studies have demonstrated that audiovisual and narrative information can positively influence satisfaction measures; contextual features such as storytelling techniques, interactivity, and visual chart elements enhance user understanding [37]. Health literacy plays a critical role in users' ability to interpret PR data. The reviewed studies found that individuals with higher health literacy are better able to comprehend PR information, which may explain their longer visual attention to such content [68]. This suggests that health literacy influences both the depth and quality of patient engagement in PPC processes. To address this, design features such as explanatory narratives [59], temporal trends and interactive functions [57], and appropriate visual chart elements can assist users with varying levels of health literacy in better understanding PR information [68].

This study further notes that within PR, patient satisfaction is primarily affected by postoperative pain levels (higher pain correlates with lower satisfaction) and access to timely appointments [70], consistent with previous findings linking health status to user satisfaction. Meanwhile, demographic factors (age, weight, and prematurity) and surgical factors (type of procedure and disease-related factors) influence surgical mortality [71].

By mapping the reviewed studies to the SPO framework, we illustrate that system data are no longer confined solely to structural indicators; they also play a role in process and outcome indicators. Accordingly, this study identifies website guidelines and dashboard guidelines under structural indicators, data quality and data processes under process indicators, and patient satisfaction and surgical mortality under outcome

XSL•FO
RenderX

indicators. Furthermore, the underlying database sources are displayed within dashboards, helping to address inconsistencies between databases across different systems.

Discussion

Principal Findings

Health technology assessment ensures that medical innovations genuinely improve patient outcomes rather than merely increasing the burden [74]. In this literature review, we synthesized the findings of 25 empirical studies by categorizing them under structural indicators, process indicators, and outcome indicators [20]. Our main findings indicate that structural indicators (website and dashboard guidelines) and process indicators (data quality and data processes) jointly influence user outcomes, such as satisfaction and surgical mortality, with user heterogeneity mediating these effects.

This study adopts a dual perspective of the individual and the system in selection pathways to systematically examine the mechanisms through which information presentation and user interaction operate within PR systems [19]. Existing literature indicates that the presentation of information within information systems not only supports patients in selecting health care providers and using report cards [68] but also influences the quality of user decision-making [55]. Consistent with prior research, the mode of information presentation, the level of aggregation, and report personalization significantly affect the extent of user engagement in decision-making [7,62]. However, this study finds that the operability and data-display characteristics of dashboards play a unique role in supporting individualized decisions [53,61] and that the supplementation of online information can enhance users' understanding of the data [51]. Additionally, the personal and contextual characteristics of health care information sources affect users' adoption in PR systems [37].

Regarding consistency, most studies emphasize the importance of PR dashboards for user decision-making [67], while user health literacy and individual characteristics modulate actual information use [68]. This study further highlights that the standardized design of data and websites can enhance decision-making effectiveness [60]. Unified dashboard guidelines, along with aggregation and search functionalities, can reduce information conflicts and increase user comprehension and trust [59,68].

In terms of heterogeneity, studies have examined the impact of different information types (eg, online reviews, report cards, and dashboards during the pandemic) and diverse user groups (classified by age and health status) on decision-making [54]. Specifically, users differ in their focus on data operability versus information sources [37,61]. Common challenges in PR include missing information, delayed updates, complex formats, lack of standardization, and limited accessibility for users with low health literacy [51,68].

Regarding the user selection pathway, the system is considered a critical avenue for decision-making. Dashboards can mitigate existing issues in PR, such as missing data, delayed updates, and information confusion. As Donabedian [20] noted, while quality indicators are difficult to measure, their establishment contributes to improving actual health care quality. Standardized data guidelines and structured information presentation can support more effective decisions within structural and process indicators, while reducing information asymmetry and enhancing the quality of health services [55].

In summary, by referencing different PR scenarios and information types, this study proposes practical system optimization recommendations and categorizes differences among user groups as user-consciousness heterogeneity, which serves as a moderating variable. It emphasizes the role of standardized guidelines in facilitating the flow of information.

Future Research Agenda

Overview

In the era of digital health, the adoption of PR has evolved. From the perspective of availability, it is possible to examine the innovativeness of technologies in shaping users' perceptions of what they can accomplish [75]. Information systems, as a critical component of structural indicators [20], also play a significant role in enhancing patient awareness [15]. Based on the classification of diverse user groups and the multiple roles involved in the PPC process, incorporating dashboards and other visualization tools into system design can facilitate the adoption of PR information.

Based on the analysis of the studies included in this review, the public's understanding and use of PR remain at a preliminary stage across different population groups [76,77]. To advance the practical use of PR information, future studies should adopt diverse methodological and theoretical approaches to explore how enhancing awareness can foster trust between health care organizations and various demographic groups. Research on this topic should be further expanded along four key dimensions: conceptual understanding, thematic exploration, methodological innovation, and technological development.

Conceptual Agenda

User attitudes are fundamental determinants of behavioral intentions and actual behaviors [17]. Underlying these attitudes are user cognitions, particularly awareness and understanding, which align with levels 1 and 2 of the PAM. While existing research highlights the role of health literacy in PR and its connection to PAM, little attention has been paid to its functional and interactive dimensions [78].

Although system design and information presentation can foster awareness and literacy, the conceptual link between the two remains underexplored. From a systems perspective, perception marks the initial awareness stage; subsequent information processing drives decision-making and system adoption. Information framing, as shown in media studies, shapes comprehension and interpretation [79]. Empirical evidence shows that most patients remain at level 1 of PAM [10]. Enhancing health literacy may help users progress from basic awareness to initial engagement.

Thematic Agenda

This study notes that participants with more severe health conditions tend to seek care more frequently than healthier individuals, making the process of choosing a physician particularly important for them. Notably, significant differences in decision quality are observed among these participants [56]. Previous research on the design of PR websites has largely focused on conditions such as hypertension, diabetes, and infectious diseases [15]. The future PR system should pay greater attention to the needs of patients with complex conditions, such as those with multiple comorbidities.

Moreover, this study points out that contextual factors, health literacy, and individual characteristics affect an individual's adoption. Future research should explore how individuals' emotional states and literacy capacities interact with and interpret PR information. For instance, Shaller [80] proposed a context-based consumer choice framework that emphasizes the integration of users' decision contexts, emotional states, and literacy capacities.

Methodological Agenda

Primary data collection was primarily used in surveys, experiments, and semistructured interviews, whereas qualitative approaches, such as interviews, focus groups, and thematic content analysis, remained less common. Mixed method studies were rare, typically combining expert evaluation with descriptive and thematic analyses.

Methodologically combining natural language processing, causal inference, and experimental designs could advance the understanding of how system-level indicators interact with user heterogeneity, health literacy, and decision-making behaviors in the PR system.

Technological Agenda

In health care organizations, the PPC extends beyond physicians and patients to include family members, friends, caregivers, and other stakeholders. Future system designs that integrate and accommodate these multiple roles could enhance communication between actual users and the system.

Previous studies have indicated that patients with poorer health conditions exhibit more pronounced differences in decision-making [56]. Population segmentation can be categorized into low-health-demand, multiple comorbidities, medically complex, and frail groups [77]. Future research could explore the heterogeneity of responses across these groups in relation to information presentation. For example, web design could incorporate switchable versions to accommodate the health information needs of patients with different health conditions.

Limitations

First, this study retrieved literature through keyword searches within selected databases. This approach may have limited the scope of study selection and potentially excluded relevant studies from other databases.

Second, this study explored PR systems from the perspective of individuals in health care. Even though employees act as individual users of the PR system, broadening the search term to include employees of health care organizations in their dual roles can bring new insights. It can be helpful to explore the interaction between employees in the organization and individuals within the sociotechnical theory. Additionally, given that qualitative research methods are interpretive, potential subjective biases may exist when evaluating study findings.

Conclusions

This study provides the following contributions to the existing literature. First, we synthesized within the SPO framework. By systematically analyzing current research on the use of PR information presentation, this study provides an overview of the website and dashboard dimensions in the structure indicators, data quality and data process in the process indicators, and patient satisfaction and surgical mortality in the outcome indicators. Moreover, this study contributes to the literature by identifying contextual factors, such as health literacy, individual characteristics, political affiliation, employment status, income, and area of residence that influence users' perceptions.

Second, this study builds a connection between data appearing during PPC and the PR systems in the structure quality dimension. Finally, this research outlines future research directions from conceptual, methodological, thematic, and information system perspectives. These insights provide valuable guidance for advancing research in this field, bridging existing gaps, and improving the overall quality of academic inquiry.

Acknowledgments

The authors thank Professor Hongxiu Li for her guidance in conceptualizing the study and providing comments on the manuscript. We also acknowledge the librarians at the University of Turku for their assistance with refining the search strategies. Finally, the authors are grateful to the anonymous reviewers for their comments on the conceptual framing and comments regarding the search strategy.

Funding

LD was financially supported by the Chinese Scholarship Council (grant 202306770017). The funder had no role in the study design, data collection, analysis, interpretation, or manuscript writing.

Data Availability

All extracted data, coding notes, and synthesis outputs generated in this study are publicly available in the Open Science Framework repository at [81]. This includes structured data files (ciw/ris/nbib). Access is unrestricted. Researchers can download and use these materials for noncommercial purposes. During the preparation of this manuscript, generative artificial intelligence (AI; ChatGPT) was used solely for translation and language polishing purposes. All outputs generated by the AI were carefully reviewed and verified by the authors to ensure accuracy and appropriateness. The AI was not involved in study design, data collection, analysis, interpretation, or in writing the scientific content of the manuscript.

Abstract

Background: Kidney transplant recipients require lifelong self-management and follow-up care to maintain allograft function. Mobile health (mHealth) effectively improves self-management behaviors and clinical indicators, consequently enhancing nursing care quality. However, these apps commonly face challenges, including low adoption rates and high discontinuation. Although researchers have explored associated facilitators and barriers from various perspectives, a systematic review of these influencing factors is lacking.

Objective: The objective of this study was to systematically review the influencing factors of mHealth apps in kidney transplant care and to provide evidence for developing targeted interventions.

Methods: The systematic review followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines, and the protocol was registered in PROSPERO (International Prospective Register of Systematic Reviews, CRD420251091361). PubMed, Web of Science, Embase, MEDLINE, and Chinese databases, including China National Knowledge Infrastructure, Wanfang Data, China Science and Technology Journal Database, and SinoMed, were searched from inception to March 2025. The Mixed Methods Appraisal Tool was used for quality assessment given its suitability for appraising diverse study designs. Influencing factors were identified and coded according to the Consolidated Framework for Implementation Research due to its utility in systematically identifying multilevel implementation factors.

Results: A total of 19 studies (all English-language publications) were included, comprising 9 qualitative studies, 5 mixed methods studies, and 5 quantitative studies, involving 1265 kidney transplant recipients and 34 health care providers. A total of 16 facilitators and 14 barriers were identified and categorized into 5 domains: intervention characteristics, outer setting, inner setting, characteristics of individuals, and process.

Conclusions: The use of mHealth apps in kidney transplant care is influenced by multidimensional factors, with intervention characteristics constituting the most prominent domain, while the outer setting and process domains are relatively underrepresented. Future research should investigate these influencing factors and implement multidimensional strategies to optimize mHealth apps in kidney transplant care.

mobile health; mHealth; kidney transplant; nursing care; influencing factors; systematic review; Consolidated Framework for Implementation Research; CFIR

Introduction

Kidney transplantation is currently the most effective treatment for end-stage renal disease, effectively alleviating clinical symptoms and prolonging patient survival [1,2]. Research indicates that the 1-year survival rate for kidney transplant recipients has reached 97.8%, with the 5-year survival rate at 88.1% and the 10-year survival rate at approximately 60% [2]. However, due to the risks of graft rejection and long-term immunosuppressant use, kidney transplant recipients require lifelong self-management and follow-up care to maintain allograft function [3].

XSL•FO
RenderX

The World Health Organization defines mobile health (mHealth) as "medical and public health practice supported by mobile devices, including mobile phones, patient monitoring devices, personal digital assistants, and other wireless technologies" [4]. Currently, mHealth has been applied across multiple domains of kidney transplant care, including medication adherence reminders [5], weight management [6], and postoperative self-monitoring [7]. Studies demonstrate that mHealth interventions can effectively enhance self-management behaviors, improve treatment compliance, optimize clinical outcomes, and elevate nursing care quality [8-10]. Additionally, mHealth apps can reduce transportation costs and time burdens for recipients, mitigate disease exposure risks, and decrease nosocomial infection rates [11,12]. Nevertheless, challenges persist, including low software adoption rates, high discontinuation rates, and short user retention periods [13]. Existing research has explored facilitators and barriers from the perspectives of device functionality, user experience, and management protocols [11,14,15], yet it lacks a comprehensive synthesis of these influencing factors.

The Consolidated Framework for Implementation Research (CFIR) was developed by Damschroder et al [16]. As a widely recognized and extensively cited framework in implementation science, it is applicable to all implementation stages, including preimplementation, active implementation, and sustainability [17]. This theoretical framework encompasses 5 domains (intervention characteristics, outer setting, inner setting, characteristics of individuals, and process) and 39 underlying constructs. It enables systematic identification of multidimensional and multilevel influences during intervention implementation processes. Guided by the CFIR framework, this study aims to systematically evaluate the influencing factors of mHealth apps in kidney transplant care, identify key facilitators and barriers, and provide evidence-based recommendations for developing targeted intervention strategies.

Methods

Search Strategy

A comprehensive computerized search was conducted across 8 English and Chinese databases: PubMed, Web of Science, Embase, MEDLINE, China National Knowledge Infrastructure, Wanfang Data, China Science and Technology Journal Database, and SinoMed, covering literature from inception to March 2025. The search focused on identifying influencing factors of mHealth apps in kidney transplant care. Search terms were structured using a combination of Medical Subject Headings and keywords. English search terms: “kidney transplant* OR renal transplant* OR kidney graft* OR renal graft* OR kidney allograft* OR renal allograft* OR transplanted kidney OR kidney homotransplantation* OR renal homotransplantation*,” “tele?medicine OR telemedicine OR mobile health OR m?Health OR mHealth OR tele?health OR telehealth OR e?Health OR eHealth OR tele?rehabilitation OR telerehabilitation OR tele?monitoring OR telemonitoring OR video?conferencing OR videoconferencing OR online OR technolog* OR mobile information technolog* OR electronic OR digital OR Internet-based OR app* OR mobile app* OR software OR wearable electronic device* OR WeChat OR platform* OR smartphone*,” “motivator* OR motivation* OR enabler* OR promote OR drive OR encourage OR facilitator* OR barrier* OR obstacle* OR challenge* OR difficult* OR issue* OR influencing factor* OR impact factor* OR relative factor* OR experience* OR perception* OR opinion* OR feeling* OR need* OR attitude*.” The search strategy was adjusted according to different databases. Key adaptations included the use of database-specific subject headings (eg, Medical Subject Headings in PubMed, Emtree in Embase) and adjustments in field tags (eg, [Title/Abstract] in PubMed; ab, kw, ti in Embase). Taking the PubMed database as an example, the search query is provided in Multimedia Appendix 1. To ensure comprehensive reporting, the PRISMA checklist is provided in Checklist 1.

Inclusion and Exclusion Criteria

Inclusion criteria:

1. Study subjects: kidney transplant recipients and stakeholders involved in mHealth apps (eg, health care providers, caregivers);
2. Study content: facilitators, barriers, or influencing factors related to the application of mHealth, with mHealth functions relevant to transplant care;
3. Study design: qualitative, quantitative, or mixed methods studies.

Exclusion criteria:

1. Conference abstracts, unpublished data, or inaccessible full texts;
2. Secondary literature (reviews, systematic reviews) or duplicate publications;
3. Non-Chinese or non-English publications.

Literature Screening and Data Extraction

Two researchers trained in evidence-based nursing systematically and independently conducted the screening process using predefined protocols. Duplicates were removed using NoteExpress 3.8 software. Initial exclusion was performed through title and abstract screening, followed by full-text assessment. Discrepancies were resolved through consultation with a third researcher.

Data extraction was independently performed by 2 researchers. To ensure accuracy and completeness, all extracted data were cross-checked against the original full-text articles by a third researcher. Any disagreements or uncertainties were resolved through team discussion. The data extraction form was independently developed by the researchers, subsequently refined through research team discussions, and ultimately finalized for implementation. Extracted data included authors, publication year, country, study design, sample size, study population, sampling method, data collection methods or tools, names and functions of mHealth apps, and Mixed Methods Appraisal Tool (MMAT) rating.

Quality Assessment

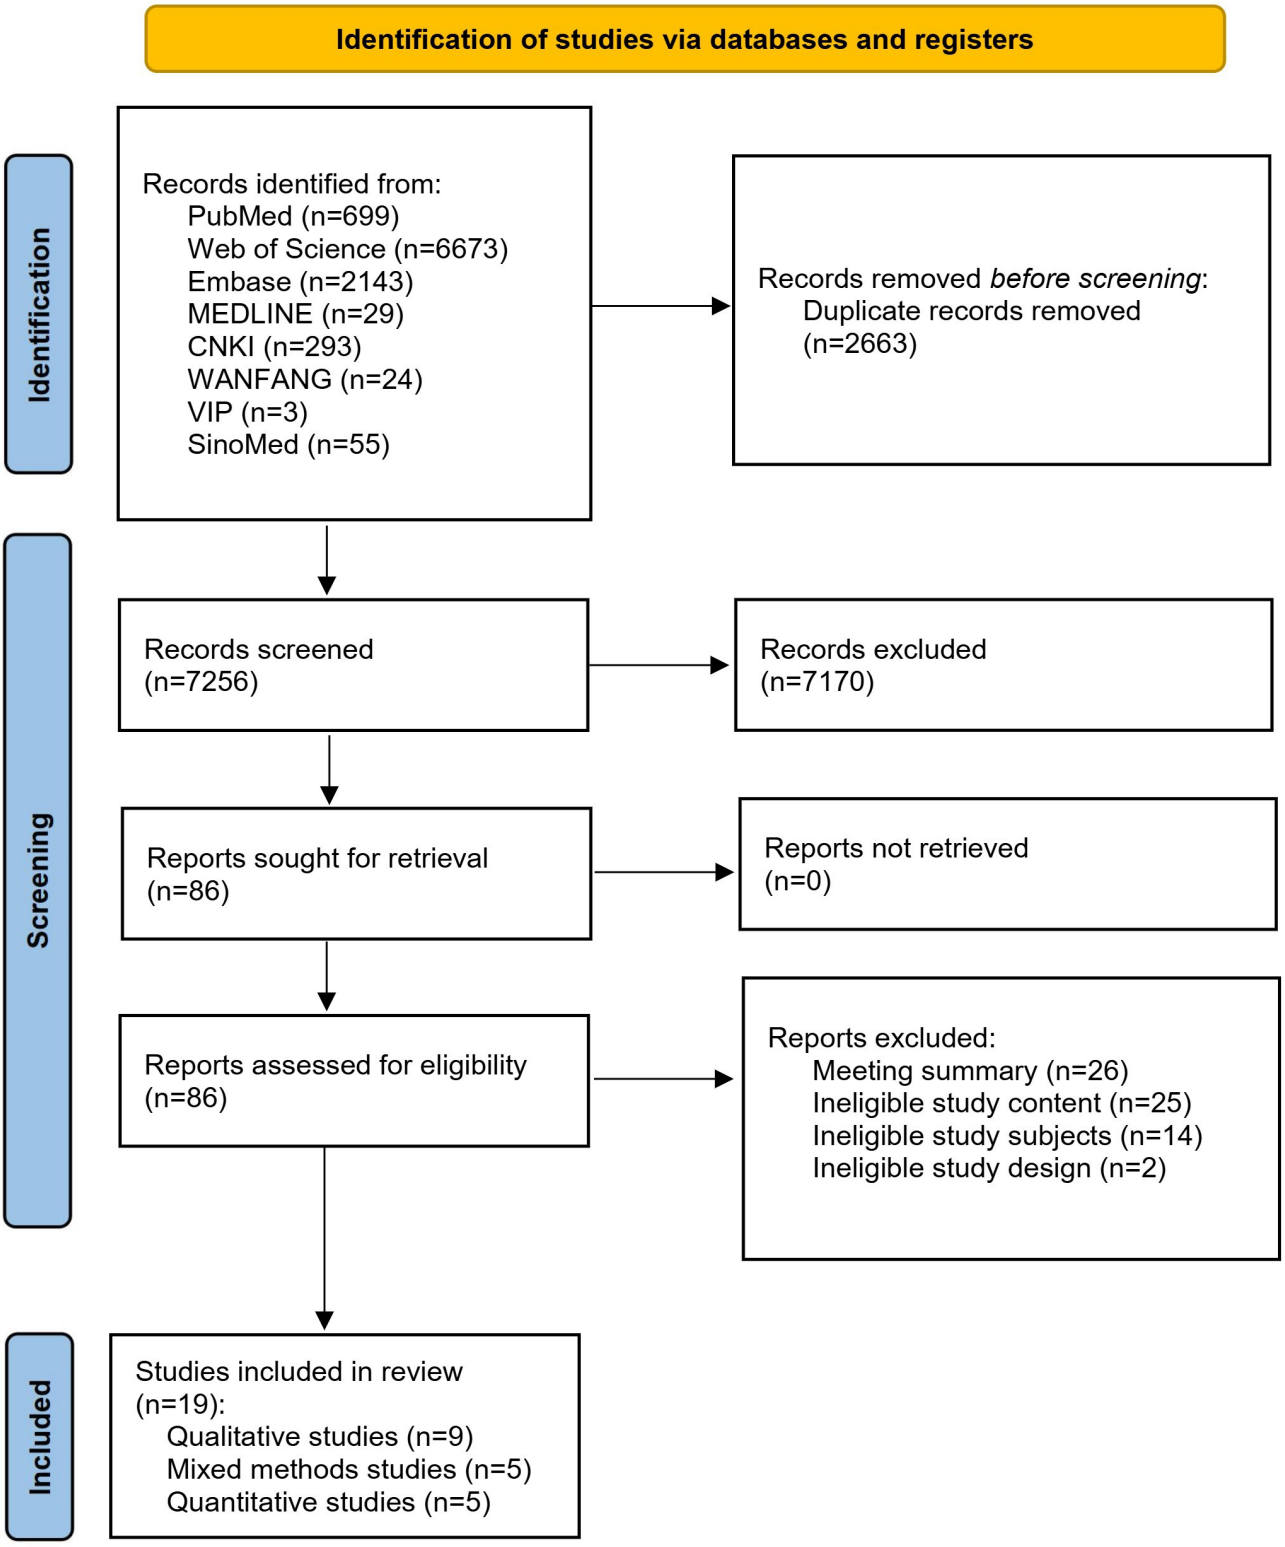
Given the heterogeneity of study designs, 2 researchers independently evaluated the methodological quality of included studies using the MMAT, 2018 edition [18]. Discrepancies were

XSL•FO
RenderX

resolved through consensus discussions with a third researcher. The MMAT was developed by a research team at McGill University, Canada, in 2006 and updated in 2018 [18]. It is designed to appraise the quality of qualitative, quantitative, and mixed methods research studies. The tool comprises 2 screening questions and 15 appraisal criteria. After addressing the 2 screening questions, the appropriate study category is selected for appraisal. Qualitative and quantitative studies require the evaluation of 5 criteria each. Each item was rated as "Yes," "No," or "Unclear." A rating of 5***** or 100% indicates fulfillment of all quality criteria, 4**** or 80% indicates fulfillment of 80% of the criteria, and so forth. For mixed methods studies, all 15 criteria (instead of 5) must be appraised. The overall quality rating adheres to the principle that the quality of the whole is determined by its weakest component.

Data Synthesis

This study conducted data analysis anchored in the 5 domains of the CFIR [16] and adhered to the Joanna Briggs Institute guidelines [19] for mixed methods systematic reviews. The analytical process involved: (1) integrating findings from distinct research methodologies separately; (2) translating quantitatively synthesized results into qualitative narratives and merging them with qualitatively synthesized evidence; and (3) finally establishing integration categories, inducing thematic patterns, and deriving consolidated outcomes.



Results

Literature Search Results

A total of 9919 relevant studies were retrieved from the databases. After removing duplicates, 7256 studies remained. Following preliminary screening, 86 studies were retained. Ultimately, 19 studies were included after full-text review. The literature selection process and the list of included studies are presented in Figure 1 and Table 1, respectively.

[a]The Mixed Methods Appraisal Tool (MMAT) uses the following rating system: 5***** indicates full compliance with 100% of the quality assessment criteria, 4**** corresponds to meeting 80% of the criteria, 3*** signifies adherence to 60%, 2** represents 40%, and 1* denotes meeting 20% of the standards.

Characteristics of the Included Studies

All included studies were published in English, with publication years spanning from 2009 to 2025. These studies originated from 8 countries, with the United States contributing the highest number of publications [11,14,26,28,30,33,35]. The research designs comprised 9 qualitative studies, 5 mixed methods studies, and 5 quantitative studies. The study populations included 1265 kidney transplant recipients and 34 health care professionals. The basic characteristics of the included studies are summarized in Table 1.

Quality Assessment of the Included Studies

A total of 9 qualitative studies exhibited high overall quality, each scoring 5*****. Among the 5 quantitative studies, 1 [14] did not clearly describe whether the sampling method was appropriate for addressing the research questions, another [14] failed to specify the representativeness of the sample relative to the target population, 1 [30] lacked clarity on the risk of nonresponse bias, 1 [26] did not explicitly address confounding factors in the study design or analysis, and 1 [31] did not confirm whether interventions were implemented as intended during the research period. The 5 mixed methods studies demonstrated lower overall quality: 4 studies [21,23,25,35] did not justify the rationale for adopting a mixed methods design to address the research questions, 4 [21,23,25,35] inadequately explained the integration of qualitative and quantitative results, 4 [21,23,25,35] insufficiently addressed discrepancies or heterogeneity between quantitative and qualitative findings, and 3 [21,25,35] failed to cohesively integrate distinct components of their research. The MMAT scores for all included studies are presented in Table 1.

Factors Influencing the Application of mHealth in Kidney Transplant Care

This study identified 16 facilitators and 14 barriers influencing the application of mHealth in kidney transplant care. Based on the CFIR, both facilitators and barriers were categorized into 5 domains, as detailed in Table 2.

XSL•FO
RenderX

Table . Factors influencing the application of mHealth in kidney transplant care.

Category	Facilitators	Barriers
Intervention characteristics	Evidence strength and quality: • Authoritative content [21,22] Relative advantage: • Convenience and flexibility (time-, effort-, and cost-saving) [11,21,22,24,27,29,35] • Reduced infection risk [11,22,24,31] • Improved comfort [11] Design quality and packaging: • User-friendly design (easy to understand, operate, and humane) [22,28,29,35] • Personalized design [15,22,28]	Evidence strength and quality: • Lack of authoritative content [34] Complexity: • Communication/interaction limitations [11,20,22,24,27] • Privacy/security risks [22,23] • Negative online content [22] Design quality and packaging: • Poor design (complex operation, unclear content, inappropriate sizing) [15,21,25,26,28,30,34,35]
Outer setting	Patient needs and resources: • No additional costs [33]	Patient needs and resources: • External environmental interference [23,24] • Extra costs [30]
Inner setting	Networks and communications: • Professional support [23,32] • Peer support [15,20,21]	Structural characteristics: • Unstable network/equipment [24] Networks and communications: • Lack of multidisciplinary team support [24] Compatibility: • Time conflicts [20] • Conflicts with user habits [25,35]
Characteristics of individuals	Knowledge and beliefs about the intervention: • mHealth literacy [14,21] Self-efficacy: • Self-efficacy [23,32] Individual identification with organization: • Perceived benefits [20,21,29,31,34] Other personal attributes: • Intrinsic motivation (curiosity, altruism, responsibility) [20,23,26,29] • Demographics (race) [33]	Knowledge and beliefs about the intervention: • Lack of mHealth literacy [21,22,24,30] Other personal attributes: • Poor physical condition [24,30]
Process	Engaging: • Training on device functions [15,30] • Executing: SMS/email reminders [15]	Engaging: • Lack of training on device functions [27]

Facilitators

Intervention Characteristics

Intervention characteristics are critical predictors of the successful application of interventions. The authoritative content of mHealth platforms can effectively alleviate user concerns and enhance their confidence in using these tools (“These sorts of webpages would need to carry some sort of certification so that we, the individuals, know we are getting professional advice as opposed to some blogger.” [21]). Compared to traditional face-to-face care models, mHealth offers advantages such as convenience and flexibility ("Now [with telehealth] it’s very convenient for me because I can even take calls while I’m working in the office or whether I’m home.” [24]; “I think video visits might actually help with compliance, especially for socioeconomically disadvantaged or older patients that don’t drive.” [11]), reduced infection risks (“I prefer [eHealth], I’m so scared of COVID. I don’t want to get sick, so I’m happy to do the online, video calls and things like that.” [22]), and enhanced comfort ("I was comfortable sharing personal information since, like I said, I’m in my own house. So, it’s easier to actually sometimes talk to the doctor when you’re at home.” [11]). These advantages serve as key motivators for users to persist with mHealth. Additionally, some users emphasized that designs featuring clear language (“Level of language, get the language to a layperson’s point of view. Doctors would understand what it was and so would the person who is reading it… [or else] they would go away from it.” [22]), ease of use (“You know, it’s user-friendly, going to it isn’t complicated. […] It’s pretty easy to figure out. […] You quickly get the hang of it.” [29]), human-centered care ("The nurse came across as very professional […] as someone who cares about your health […] Me, I found her to be warm. Even though it was a video, it’s. it’s not. it can seem a little cold, but it’s someone who’s talking to us, deep down.” [29]), and personalization (“If something was going wrong, yes, rather

XSL•FO
RenderX

than just getting an automatic message that was just saying 'keep going for your goals!' and you're like 'well I haven't been on 3 weeks'. I would prefer something more personable." [15]) would make mobile devices more appealing.

Outer Setting

Users' needs and resource accessibility are critical external factors determining the adoption of mHealth. If mHealth solutions require no additional financial burden on users, their willingness to adopt is significantly enhanced (79% of users endorsed this view [15]).

Inner Setting

Multidisciplinary collaboration and communication are central to the successful application of mHealth. Regular communication and professional guidance from health care providers motivate patients to adhere to care plans ("I think, um, it will be helpful [for my adherence] because I spoke to my physio quite a bit. She used to call me and, um, she would—I'd tell her sometimes—and she'd be like, you know what, you know keep busy, do this and do that and stuff like that. She would give me advice." [23]). Some patients highlighted that sharing experiences and emotional support with peers fosters a sense of connection, alleviates loneliness, and strengthens their resolve to persist ("When I had a question, I could send a text and they [peers] responded right away, right away. So it was really good, you know." [20]; "Being together, that always motivates more than when we're alone." [20]).

Characteristics of Individuals

Individual characteristics are pivotal factors influencing the adoption of mHealth. An individual's mHealth literacy directly impacts the effectiveness of mHealth use. Those with higher mHealth literacy exhibit stronger technical proficiency, information evaluation skills, and greater acceptance of mHealth ("Factors associated with mHealth use include higher eHEALS scores and higher education, with odds ratios [ORs] of 1.21, 95% CI 1.06 - 1.38 and 7.78, 95% CI 2.19 - 27.7, respectively." [21]). Self-efficacy reinforces individuals' confidence in using mHealth ("I was just [pause] following the program through. Um, but that was just my personal thing, just because I have—you know—I have the knowledge and the confidence to do my own thing." [23]). Some patients noted that using mHealth offers benefits such as enhanced self-management ("Patient portal containing access to all of the above suggestions in one unified system, where my blood results, education, and app monitoring can all be tracked by myself at a click of a button. This will ultimately increase self-management among patients and allow for more detailed 'healthier life' conversations with health professionals." [21]) and disease-related knowledge ("All important things are included [in this platform]: where I have to take precautions, what I need to do. Everything is well explained." [34]). Intrinsic motivations such as curiosity ("It was out of curiosity. I'm naturally curious. So I really wanted to see how far it went..." [29]), altruism ("Well, I did it for you… it was to help you out, because you help me in a way. Your aim… the reason that you're doing this, I imagine, is to help me." [29]), and a sense of responsibility ("So, my point there is in terms of being accountable to something. Even though it's not a human being, you are being accountable to a system…" [23]) drive patients to persist. Additionally, race influences attitudes toward mHealth ("Black individuals exhibited more positive attitudes than White individuals [mean 4.25, SD 0.88 vs mean 3.76, SD 1.07; *P*=.02]." [33]).

Process

Supportive strategies during the implementation process are critical factors for ensuring the sustainability of mHealth interventions. Participants emphasized that receiving training prior to using mHealth builds operational confidence and foundational knowledge, reducing adherence decline or misuse caused by technical unfamiliarity ("I think the first steps you need it face-to-face to start with… then you can do it on your own at home." [15]). Additionally, reminder features in devices play a role in encouraging adherence ("If there's a 12-week program, what would be useful would be a text reminder or an email reminder." [15]).

Barriers

Intervention Characteristics

Inherent limitations of mHealth may hinder its application. When mHealth platforms provide content lacking official certification or conflicting with clinical recommendations, patients may question its reliability ("My doctor advised taking tacrolimus between meals, but the platform instructed me to take it 1 h before or 1.5 - 2 h after meals." [34]). User-unfriendly designs, such as overly lengthy interfaces ("Instead of scrolling through all the different things because that's [the excessively long pages] what drives me crazy with apps." [28]) or bulky devices ("The mobile health device [MEMS] is too large to carry around or travel with." [35]), foster resistance and reduce willingness to continue use. The virtual nature of mHealth limits nonverbal interaction ("I like face - to - face because my doctor tells me if he thinks that I'm putting on weight or I'm not doing the right thing." [24]; "Telehealth can't take your blood pressure… and they can't take a look at your wound or check you or examine you or weigh you. Sitting down, I could have gained 25 kg, but no one would know." [22]). Participants also expressed concerns about privacy breaches ("Hearing about hackers, and you don't want your records and things like that when you subscribe to these sites and things. You're putting yourself at risk and your whole medical history at risk. There are things in my medical history that I don't want people to know." [22]). Additionally, exposure to negative online content during use imposed psychological burdens ("Sometimes it got a bit depressing… it was like really a bit of a mental burden as well, just like constantly getting notifications about this message and that message and someone dying. Sometimes when you're in a difficult headspace, it can be really hard to be confronted with that." [22]).

Outer Setting

The inability of external resources to meet user needs can hinder the application of mHealth. The use of mHealth may be interfered with by external environments, thereby negatively impacting its effectiveness ("Because I think face - to - face, you're in the room, you're kind of in the moment, with

XSL•FO
RenderX

telehealth, you can get distracted. You can get a bit confused" [24]; "If you're doing telehealth, then you might miss something like the dog barking in the background or the kids screaming." [24]). Additionally, participants noted that additional costs associated with mHealth reduce willingness to use such services, as these expenses impose financial burdens [30].

Inner Setting

Structural barriers within mHealth systems represent core constraints affecting their application. Participants reported that unstable network equipment compromises their user experience ("Like when the internet's down, when it's slow, which it is often at my place. Even my phones aren't that good. The landline, even… [Whether I can use mHealth normally] just depends on if everything's working." [24]). Compared to traditional face-to-face clinical models, mHealth struggles to ensure patients receive simultaneous support from multidisciplinary teams ("When I do telehealth, you become sort of like missing out on all the other aspects of allied health." [24]; "Nurses are a part of my training team as a nephrologist, and I feel that connect with the nurses is completely cut off [with telehealth]." [24]). Some mHealth services require advance appointments, yet users often fail to attend due to personal scheduling conflicts ("The schedule was a problem, it [mHealth] just didn't work for me at all." [20]). Additionally, some participants expressed difficulty adapting to new self-management models via mHealth due to entrenched habits (eg, medication or exercise routines) ("When the situation differs from my routine, it [mHealth] gets in the way and is hard to accommodate." [35]).

Characteristics of Individuals

User characteristics directly influence the effectiveness of mHealth adoption. For users with limited mHealth literacy, such as older adults or those with lower education levels, technical challenges encountered during mHealth use often lead to abandonment of the technology ("Not being a tech-savvy person, I find trying to navigate and download apps very stressful." [21]; "The problem is that when you get older, it's harder for you to understand and pick up if you are not constantly on the computer. I don't use it much." [22]). Additionally, users' physical conditions impact mHealth utilization, with patients reporting that visual impairments and limited hand dexterity hinder their engagement with mHealth platforms [30].

Process

Insufficient training on mHealth use results in ongoing challenges for users during later implementation ("I would say it is incredibly complex in the sense that when the doctor says it, it sounds logical and totally correct, but when you come home, then what? Because then if I make a slight deviation, is it the same, or is it a new situation?" [27]).

Discussion

Principal Findings

An important finding of this review is that, despite the comprehensive 5-domain analytical structure offered by CFIR, a notable imbalance exists in the focus of existing research. Influencing factors are predominantly concentrated within the domains of intervention characteristics, characteristics of individuals, and the inner setting. In contrast, factors related to the outer setting and process domains, such as policy support and stakeholder collaboration, remain significantly underrepresented.

This pattern may be explained by 2 primary reasons. First, the majority of included primary studies focused on technology acceptance and user experience. Their participants were predominantly kidney transplant recipients, who are generally not in a position to provide in-depth perspectives on macrolevel issues such as health care policies, regional resource distribution, or multistakeholder coordination. Second, evidence concerning the complex factors of the outer setting and process is more likely to reside in what is known as "grey literature," including project evaluation reports, dissertations, or specific policy studies, which was not captured by our predefined academic database search.

Optimizing mHealth Design and Performance to Enhance User Experience

The findings of this study indicate that the application of mHealth is closely tied to its inherent characteristics. The domain of intervention characteristics contains the highest number of influencing factors, which aligns with prior studies [36]. For successful integration into the workflow, the intervention needs to align with the prevailing value system of key stakeholders.

After enduring the hardships of dialysis, most kidney transplant recipients highly value their transplanted kidney and exhibit heightened caution in health management [37]. The authoritative nature of mHealth content helps build trust in the platform and strengthens users' confidence. Studies [38,39] reveal that approximately 30% of kidney disease–related apps on the market lack clinically validated content, posing risks such as incorrect medication advice or deviations from the latest guidelines, which significantly undermine patient trust and hinder sustained use. Therefore, mHealth development should be grounded in evidence-based medicine and clinical guidelines, with regular updates. Prior to releasing content, experts in kidney transplantation should review materials to ensure scientific rigor. The design and performance of mHealth directly impact user experience. Kidney transplant recipients vary widely in age, educational background, and health literacy. With global population aging, the proportion of older recipients is rising [40,41]. Older users may struggle with complex medical terminology or operational workflows due to cognitive decline or limited technical adaptability. Thus, mHealth design should prioritize accessibility, using plain language and intuitive interfaces to lower barriers and improve acceptance. Kidney transplant recipients commonly face psychological challenges such as anxiety and depression [42]. Research [43] shows that integrating emotional support features into mHealth can alleviate patient anxiety and enhance long-term engagement. Additionally, lifelong self-management is essential for recipients. If apps lack personalized feedback, users may abandon them due to perceived low value. To address this, personalized features such as achievement badges to motivate

XSL•FO
RenderX

users or tailored notifications to boost engagement could be incorporated.

mHealth is a double-edged sword. While offering advantages such as convenience, flexibility, and reduced infection risks, it also has limitations, including security risks, hindered clinician-patient interaction, and exposure to negative content, which diminish user willingness to adopt it. Studies [44,45] highlight widespread patient concerns about data security in mHealth, particularly for long-term conditions such as kidney transplantation, where sensitivity to privacy breaches is heightened [46]. Thus, health care providers should strengthen awareness of data protection and regularly debug and update software to prevent cyberattacks. Beyond safeguarding privacy, stakeholders could enhance user experience by improving content moderation and integrating wearable devices to mitigate mHealth's shortcomings.

Strengthening Multidimensional Support Systems to Improve Resource Accessibility

The findings of this study reveal that the adoption of mHealth is influenced by multiple internal and external factors. Additionally, outer setting factors are relatively few among all influencing factors. This aligns with a prior scoping review by Rangachari et al [47].

Peer, professional, and multidisciplinary team support significantly impact kidney transplant recipients' engagement with mHealth, suggesting that health care providers should establish multidimensional support strategies. Peer support fosters emotional resonance and experience sharing among patients with similar backgrounds, reducing loneliness and enhancing willingness to use mHealth. Therefore, integrating peer communication modules into mHealth platforms is recommended; however, medical advice or medication sharing should be explicitly prohibited to ensure compliance. Guidance and feedback from health care professionals can alleviate patients' technological apprehensions. Studies [48] indicate that lack of clinician support is a barrier to mHealth adoption, aligning with this study's conclusions. Thus, remote follow-ups by professionals to guide patients, alongside accessible channels for reporting issues, are proposed to build trust and sustain engagement. The development and implementation of mHealth require collaboration and guidance from multidisciplinary teams. Without such support, unresolved technical or medical challenges during use may lead to unmet needs and reduced compliance [49]. Future initiatives should establish mHealth teams comprising physicians, specialist nurses, rehabilitation therapists, and IT engineers to optimize application effectiveness. Additionally, internal and external factors such as additional costs and unstable network infrastructure hinder mHealth accessibility. Expenses related to data consumption or smart device procurement may impose financial burdens on patients. Research [50] reports that 23% of patients in resource-limited settings abandon mHealth due to unaffordable device costs. To address this, governments and hospitals should establish subsidy mechanisms to reduce user expenses. Developing low-data or offline versions of mHealth platforms could simultaneously mitigate data consumption and connectivity issues, thereby improving resource accessibility.

Stimulating Individuals' Intrinsic Motivation, Enhancing Perceived Benefits, and eHealth Literacy

The findings of this study indicate that the application of mHealth is influenced by individual characteristics, such as intrinsic motivation and perceived benefits. Notably, factors at the individual level are relatively numerous among all identified influences, which is similar to the findings of the previous review by Neil-Sztramko et al [51].

Intrinsic motivation refers to an individual's inherent tendency to seek novel challenges, develop competencies, and engage in exploratory learning driven by personal interest or enjoyment of the activity itself, which is more likely to sustain long-term behavioral adherence [52]. For users lacking intrinsic motivation, motivational interviewing techniques such as goal setting, reflective practices, verbal persuasion, and action planning can be used to initiate and reinforce their motivation, thereby promoting behavioral persistence [53]. This study also reveals that perceived benefits can enhance users' sustained engagement with mHealth. Research demonstrates [54] that perceived benefits indirectly influence behavioral adoption through the mediating role of self-efficacy. Health care professionals should acknowledge and encourage users' perceived benefits, reinforce positive experiences through multiple channels, and further enhance self-efficacy to facilitate long-term mHealth adherence. When users fail to perceive benefits, their behavioral persistence may be compromised [55]. In such cases, practitioners should promptly adjust intervention strategies through telephone follow-ups, video demonstrations, and other methods to strengthen perceived benefits and improve self-efficacy. Furthermore, this study identifies that insufficient eHealth literacy constitutes a barrier to mHealth utilization. Some users experience difficulties in independently operating smartphones or applications due to age, educational background, or limited digital skills, leading to resistance or abandonment of mHealth tools. Therefore, beyond simplifying the usability of mHealth systems during development, health care providers should strengthen preimplementation training on device functionalities. Personalized training programs tailored to users' varying health literacy levels should be developed to compensate for eHealth literacy deficiencies.

Limitations

Limitations of the Included Studies

The inclusion of studies with varied methodological quality, while ensuring comprehensive analysis, may have introduced potential bias. The lower overall ratings for some mixed methods studies primarily reflected limitations in their integrative components rather than in the qualitative or quantitative parts from which data were extracted. Future studies should be more methodologically rigorous and better designed to enhance the overall quality and reliability of the evidence base in this field. All included studies were published in English and conducted in developed countries, introducing both linguistic and geographic bias. Consequently, the findings primarily reflect contexts with abundant resources and well-developed digital infrastructure, which may limit the generalizability of the conclusions. It is imperative to conduct research focusing on developing countries and non–English-speaking regions. No

XSL•FO
RenderX

subgroup analysis was conducted for key variables (eg, age, mHealth type). This was primarily because most studies did not stratify outcomes by age or treated mHealth as a broad concept without specifying functional types, hindering the extraction of subgroup-specific factors. Publication bias was not formally assessed. Due to the nature of this review, which included diverse study designs and focused on synthesizing influencing factors rather than quantifying a single effect size, standard graphical tests for publication bias (eg, funnel plots) were not applicable or were not conducted.

Limitations of the Review Methodology

The transformation from quantitative evidence to qualitative descriptions may have resulted in inevitable information loss. The lack of evaluation of literature in languages other than Chinese and English may have led to the omission of some influencing factors. Although 2 researchers independently performed literature screening and data extraction to minimize subjective bias, the results of consistency testing were not reported. This shortcoming represents a methodological limitation regarding the transparency of the selection process.

Conclusion

Guided by the CFIR, this study systematically analyzed the influencing factors of mHealth apps in kidney transplant care, which were categorized into 5 domains: intervention characteristics, outer setting, inner setting, characteristics of individuals, and process. The findings revealed that intervention characteristics constituted the most prominent influencing domain, while the outer setting and process demonstrated relatively fewer associated elements. Future research should further investigate the impact of these identified factors on mHealth apps in kidney transplant care. Additionally, health care providers should adopt multidimensional strategies targeting these determinants to optimize mHealth integration into clinical practice.

Acknowledgments

The authors express their sincere gratitude to all authors whose papers were included in this meta-synthesis.

Data Availability

The data are from published academic research literature and can be found in the original article.

Abstract

Background: MedlinePlus, developed by the National Library of Medicine (NLM) in the United States, is one of the most widely used, authoritative, consumer-grade health information resources on the web. Although extensively used and discussed in scholarly work for health literacy and patient education, it is unclear how MedlinePlus has been integrated into clinical care or embedded within health informatics applications.

Objective: This study aimed to understand how MedlinePlus has supported patients and caregivers by increasing access to health information for clinical care and illness management. The insights on this topic will inform the design and development of patient-facing digital health intervention tools for improved health communication, decision engagement, informed decision-making, and health outcomes.

Methods: We conducted a systematic literature review following the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines. First, we developed a comprehensive literature search strategy, searched 9 citation databases, and aggregated and deduplicated search results before importing them into Covidence for manual screening using predefined inclusion and exclusion criteria. Second, reviewers independently assessed all studies at the title-abstract and full-text levels, resolving discrepancies through ongoing discussions. Third, we applied the PICO (problem/population, intervention, comparison, and outcome) and the Collaborative Chronic Care Model as guiding frameworks for data extraction and analysis. All included studies underwent quality assessment using the Mixed Methods Appraisal Tool.

Results: In total, 28 studies reported in 27 sources met our inclusion criteria. We categorized the extracted data into 4 areas. First, regarding bibliometrics, the studies were reported between 2004 and 2024, with 2010 having the highest number of studies. Of these studies, 25 were conducted in the United States, 2 were conducted in Iran, and 1 was conducted in Argentina. Health informatics journals and conference proceedings, as well as library science journals, were prominent publishing venues. The NLM funded half of the studies. Second, regarding participants, most studies focused on outpatients. Other participant roles included physicians, nurses, hospital staff, pharmacists, and librarians. Fewer than half of the studies addressed the social determinants of health. Third, regarding intervention, most studies implemented MedlinePlus information interventions within clinical settings. Other interventions occurred in community pharmacies, community organizations, libraries, online health platforms, or patient portals. Fourth, regarding outcome, only 4 studies assessed clinical outcomes, and the findings were mixed and inconsistent. However, 24 of 28 studies reported positive nonclinical outcomes, including improved attitudes toward and satisfaction with MedlinePlus and enhancements in patients' information-seeking behaviors, confidence, and willingness to engage in decision-making, physician-patient communication, self-management, and self-efficacy.

Conclusions: This systematic literature review is the first comprehensive examination of how MedlinePlus has been integrated into clinical care, supporting patients and caregivers with enhanced access to health information. Our findings offer evidence and insights through the Collaborative Chronic Care Model lens and can guide the development of digital health interventions to improve patient health.

KEYWORDS

MedlinePlus; health information access; information intervention; information prescription; patients and caregivers; systematic literature review

Introduction

The National Library of Medicine (NLM) in the United States launched the MedlinePlus website in 1998 to provide the public with free access to "high-quality, relevant health and wellness information that is trusted, easy to understand, and free of advertising" [1]. Being available in both English and Spanish, MedlinePlus provides content covering more than 1000 diseases and health conditions, almost 300 medical test descriptions, more than 1500 brand-name and generic drugs, 1300 genetic conditions and 1400 genes, and dietary supplements and herbs, as well as more than 4000 medical encyclopedia articles and healthy recipes. In addition to textual content, MedlinePlus offers animated health videos produced by the NLM or selected from accredited external organizations and plentiful interactive health assessment tools, enabling people to assess their risk for diseases or health conditions and maintain healthy lifestyles [2].

Over the past two decades, the NLM has continuously expanded and enhanced MedlinePlus by adding new features and content to meet the evolving needs of its users. In particular, in the era of electronic health records (EHRs), when patients' and caregivers' engagement in shared decision-making is empowered by their access to medical records, the NLM activated MedlinePlus Connect [3]. This application programming interface service links MedlinePlus content to patient portals and EHRs, greatly extending the scope of MedlinePlus information availability, compatibility, and usage. For example, studies show that patient portals embed MedlinePlus to improve medical record comprehension [4,5].

MedlinePlus has become a widely used free health information resource, serving millions of users worldwide and supporting health care professionals, educators, and researchers in providing evidence-based health education and improving health literacy. In particular, it has been frequently cited in the scholarly literature on the concept and practice of information prescription (IP) because of its demonstrated utility in patient care. IP refers to the physician's prescription of current, personalized, evidence-based, and reliable health information to patients as part of their treatment plan to understand, manage, and control their health problems and to better engage in their health care [6-8]. Although IP can take paper or electronic format, the Information Rx (IRx) program, initiated in 2002 by the American College of Physicians Foundations and the NLM, provided physicians with prescription pads designed to guide patients to relevant content on the MedlinePlus website, tailored to their specific health conditions [9]. The IP and IRx initiatives positioned MedlinePlus as one of the key resources in disseminating consumer-grade health information. A recent scoping review confirmed that "the most commonly prescribed website to produce IP content is MedlinePlus," compared with 15 other identified IP contents [8].

Although researchers unanimously agree on the value of IP and IRx in patient education, self-management, and decision engagement, the integration of MedlinePlus into clinical practice, particularly embedding it within health care applications such as EHRs or digital health interventions, is unknown. No studies have systematically examined the extant research evidence about how MedlinePlus has been adopted, implemented, or integrated to improve patient care and health outcomes, especially in the context of designing and developing health information technology (Health IT). To address this gap, this study aimed to investigate the role of MedlinePlus in supporting patients and their caregivers by increasing access to health information pertinent to their care and illness management, with a focus on Health IT. A systematic mapping of the literature will inform the design and development of patient-centered digital health interventions that enhance health communication, decision engagement, informed decision-making, and health outcomes.

Methods

This study used a systematic literature review methodology, adhering to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines (Checklist 1) [10] for literature search, study selection, and data extraction.

Literature Search

A literature search strategy was first developed by connecting the 2 main keywords "MedlinePlus" and "Medline Plus" with the Boolean operator "OR" and then customizing the query based on the field codes of the chosen citation database. This strategy was executed across 9 citation databases, including PubMed, Embase, CINAHL, Global Health, PsycINFO, Cochrane Database of Systematic Reviews, Scopus, Web of Science, and Dimensions. The first 5 databases are well-known research article indexing resources in the health sciences and are primary sources for clinical studies, including Health IT and digital health interventions. We also searched the Cochrane reviews, the gold standard for systematic reviews in biomedical and health sciences, to identify relevant reviews and examine their cited empirical studies, ensuring comprehensive coverage of the literature. Furthermore, Scopus, Web of Science, and Dimensions were included because they index a broad range of peer-reviewed research articles across medicine and health sciences and are commonly used in systematic reviews and evidence-mapping studies. Our initial search was conducted in October 2021 and was updated in October 2022 and in September 2024 (Multimedia Appendix 1). In addition, we checked all references of the included articles (backward searching) and newer articles that cited the included studies (forward searching) in Scopus for an exhaustive literature search.

Study Selection

The search results from each database were exported, aggregated, deduplicated, and imported into Covidence [11] for

XSL•FO
RenderX

screening. Independent reviewers from our research team conducted the screening process, initially at the title-abstract level (FY, Erin Harvey, and Pengxuan Wang), followed by a full-text assessment (FY and XW). Discrepancies between reviewers were resolved through discussion to achieve agreement.

The studies were included if they (1) used MedlinePlus as the primary or one of the primary information or education resources for patients and/or their caregivers; (2) targeted patients or caregivers, as indicated by the recruited participants or by the research aims; (3) were English literature; and (4) were original research articles. The studies were excluded if they were (1) non-English literature, (2) did not use MedlinePlus as one of the information sources, (3) did not include patients or caregivers as direct information recipients (eg, only physicians or other health care professionals are information or training recipients), (4) were not original research articles (eg, perspectives, comments, editorials, news, bulletins, erratum, or abstract only), (5) were information readability or coverage assessment studies, or (6) were information retrieval, search behavior, or query analysis studies.

Data Extraction and Synthesis

To achieve the research aim, we adopted 2 frameworks to guide our data extraction and synthesis process. The first is the PICO (problem/population, intervention, comparison, and outcome) framework [12], widely recognized and used in evidence-based practice and research in health sciences. The PICO framework systematically addresses the targeted population, specific intervention or exposure, intervention comparison to an alternative (if applicable), and desired outcomes or end points. The second framework is the Collaborative Chronic Care Model (CCCM) [13], a refined version of the widely adopted original chronic care model. The CCCM emphasizes collaborative, continuous, evidence-based, and proactive care delivery for individuals with chronic, medical, or mental health conditions. The CCCM encompasses 6 major elements: health system organization, work role redesign, self-management support, decision support, information management, and community linkages. We created a customized data extraction framework (Table 1) and organized the data accordingly. Guided by the PICO and CCCM frameworks, our data extraction focused on the following 4 aspects: bibliometrics, participants, interventions, and outcomes.

Table . Data collection, extraction, and analysis framework.

Measure	Data extraction metrics	Data source	Analysis
Bibliometrics	Study distribution by year, source, country, and funding; authors and institutions; and citation and digital impact	Full-text article, Scopus, Altmetric Explorer	Quantitative
Participants	Participants' role, diagnosis, demographics (including SDOH[a]), sample size, and age range	Full-text article	Qualitative and quantitative
Interventions	Intervention features, information content, additional interventions, and setting	Full-text article	Qualitative
Outcomes	Clinical outcome, nonclinical outcome, outcome comparison, study duration, and follow-up method	Full-text article	Qualitative and quantitative

[a]SDOH: social determinants of health.

Bibliometrics

Bibliometrics capture the document details of the included studies, including reporting year, source title, funding sources, author names and affiliations, and citation impact. We assessed the citation impact of included studies using both raw citation counts (ie, how many times an article has been cited) and the field-weighted citation impact (FWCI), a field- and time-normalized citation impact metric [14] provided by the Elsevier Scopus database. An FWCI of 1 indicates that, compared with papers published in the same field and time, this article is cited at the global average level; a value greater than 1 suggests that it is cited more than the worldwide average and vice versa. Being an improved citation impact measure, FWCIs have been commonly adopted by research impact evaluators [15,16]. In addition, we used Altmetrics to capture the publication's digital attention [17], with scores obtained from Altmetric Explorer [18] through an institutional subscription. The composite Altmetric Attention Score (AAS) is a weighted and quantified measure of the online attention and engagement that a research output (eg, journal article) has received by tracking various sources such as public policy documents, mainstream news, social networks, blogs, and other platforms. Generally, an AAS of 20 or higher is considered good [19] and is often used as a benchmark in research evaluations [20].

Participants

The participant category captures participants' roles, patient diagnoses, CCCM-aligned demographics (including social determinants of health [SDOH]), sample size, and age range of patients and caregivers who used MedlinePlus. Participant roles include physicians, nurses, research associates, patients, and caregivers involved in using MedlinePlus as an information intervention. Demographics include SDOH, such as self-management skills, education and literacy levels, and economic and financial factors (eg, income, employment, and

XSL•FO
RenderX

health insurance). Reporting SDOH and demographic characteristics (eg, race, gender, and primary language) provides contextual information and aligns with CCCM's emphasis on whole-person care and linkage to community resources.

Interventions

Interventions describe how MedlinePlus was used as a health information intervention, including the type of content assessed, platform features used, and modes of delivery. Using the CCCM-aligned construct of intervention delivery, we systematically documented the key intervention attributes, including intervention features, health information content, any additional interventions beyond the MedlinePlus resource, and the settings where the interventions were implemented.

Outcomes

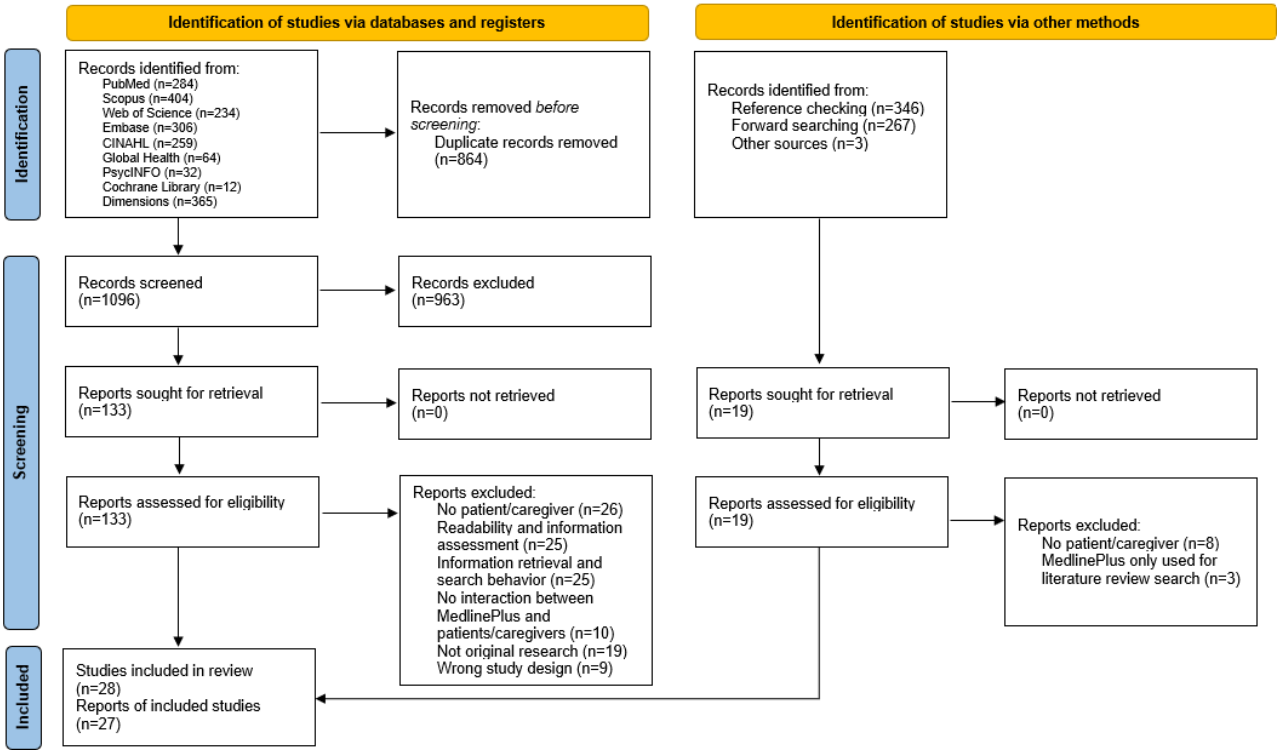
Outcomes cover clinical and nonclinical outcomes as well as outcome comparison and assessment, if applicable. Clinical outcomes are associated with "a measurable change in symptoms, overall health, ability to function, quality of life, or survival outcomes that result from giving care to patients" [21]. Nonclinical outcomes encompass a wide range of measures, including participants' attitudes toward health information resources, health information–seeking behavior, experience with health information interventions, information usage, and perceptions. We also examined the study durations and follow-up methods used to assess outcomes of MedlinePlus as an information intervention.

In total, 3 reviewers (FY, Pengxuan Wang, and XW) independently extracted data from the Scopus database, Altmetric Explorer, and the full-text articles of the included studies. We recorded data in a Microsoft Excel template for each included study based on our data extraction framework and discussed and reconciled data inconsistencies to reach consensus.

Quality Assessment

Two reviewers (FY and XW) independently assessed the quality of the included studies using the Mixed Methods Appraisal Tool (MMAT) [22] by following the MMAT user guide. MMAT has been widely used in systematic reviews to appraise qualitative studies, quantitative studies, randomized controlled trials (RCTs), nonrandomized studies, and mixed methods studies [23,24]. The MMAT tool offers a checklist. First, each study undergoes 2 screening questions to ensure that it is an empirical study (ie, "S1. Are there clear research questions?" and "S2. Do the collected data allow addressing the research questions?"). Second, reviewers select an appropriate study category for each included study. Third, based on the 5 criteria in the selected category, reviewers rate each criterion as "Yes," "No," or "Can't tell," documenting any observations in a "Comments" column. We rated "Yes" when a study provided sufficient information to fully comply with the criteria, "No" when the study failed to meet the criteria, and "Can't tell" when the information in the full-text article was insufficient, unclear, or partially met the criteria.

After discussing and resolving discrepancies between the 2 reviewers' independent ratings, the research team achieved consensus and presented the final rating results at the criteria level for all included studies, following the MMAT user guide (Multimedia Appendix 2).



Results

Literature Search and Study Selection

In total, 28 studies reported in 27 sources met our inclusion criteria (Figure 1). Cohen κ measured the interreviewer agreement, which was 0.63 at the title-abstract level and 0.9 at the full-text level, indicating substantial agreement between reviewers. The results of all included studies are delineated by 4 categories of measures in Tables 2-5.

Bibliometrics

The included studies were reported between 2004 and 2024 (Table 2). The year 2010 had the highest number of studies (n=4), followed by 2013 (n=3). The years 2006, 2007, 2012, and 2016 each had 2 studies, while all other years had either 1 or no studies (Figure 2).

Figure 2. Number of included studies by year (2004-2024).

XSL•FO
RenderX

Of the 28 studies, 25 were conducted in the United States, with 2 conducted in Iran [34,44] and 1 conducted in Argentina [4]. The document types varied and included 1 book chapter [34], 4 health informatics conference proceedings (ie, AMIA Annual Symposium [5], Studies in Health Technology & Informatics [4,37], and IEEE International Conference on Healthcare Informatics [46]), and 1 doctoral dissertation [43]. The remaining studies were published in 12 academic journals. The *Journal of Consumer Health on the Internet* was the most frequent publication venue, with 5 publications, followed by the *Journal of the Medical Library Association* (4 publications), the *Journal of the American Medical Informatics Association* (2 publications), and *Information Services & Use* (2 publications).

In total, 20 publications reported funding support from 9 agencies. The NLM was the primary funder, supporting 15 studies. Other funders included several US federal agencies (eg, Agency for Healthcare Research and Quality, National Center for Advancing Translational Sciences, National Institute of Nursing Research, and Department of Defense), 1 foundation program (ie, Robert Wood Johnson Generalist Faculty Scholars Program), and Tabriz University of Medical Sciences in Iran.

A total of 125 individuals from 65 organizations contributed to the included studies. Notable contributors included authors from the NLM (3 publications), George Washington University (2 publications), University of Missouri (2 publications), and Columbia University Medical Center (2 publications).

Of the 27 sources, 22 were cited in scholarly works. Eight publications had FWCI scores above 1.0, with the study by Ramesh et al [37] having the highest FWCI of 5.79 (Table 2), indicating that the publication has received more citations than expected for its field. Altmetric scores were available for 11 publications, with the highest score of 63 by McCarthy et al [35], indicating that it is widely shared, discussed, and referenced across multiple platforms. This paper is also the only one with an AAS above 20, indicating high engagement (frequent mentions across multiple sources, including news, policy reports, and mainstream discussions).

Participants

Of 28 studies, 18 involved outpatients, while 5 focused on inpatients and their family members. Notably, 2 studies designed digital information interventions incorporating MedlinePlus but recruited their participants for testing either through crowdsourcing [37] or from a local community [45]. Patients represented a range of clinical conditions, such as diabetes, cardiovascular or heart valve diseases, pediatric cancer, heart failure, and depression. More than half of the studies recruited patients with multiple or varied diagnoses (Table 3).

XSL•FO

[a]SDOH: social determinants of health.

[b]T1: first evaluation study; and T2: second evaluation study.

[c]N/A: not reported in the full-text article.

[d] The majority of the participants in a study were within the specified age range or means.

[e]ED: emergency department.

In addition to patient participants, several studies also involved health care professionals: 12 involved clinicians with various backgrounds, 3 targeted nurses, 2 included research assistants, and 2 involved other hospital staff. Community-based participants comprised librarians from medical, health sciences, or public libraries (9 studies) and pharmacists or pharmacy students (3 studies).

SDOH factors were captured in the patients' demographic data. The studies explicitly addressed underserved and low socioeconomic status groups [29,38,41,45] and participants with low [31] or varied health literacy levels [37,38]. Several studies either focused on or included racial and ethnic populations, such as African American populations [26,38], Spanish-speaking underserved populations [29,32,45], indigent patients [31], Asian populations [37], Persian populations [34], or diverse race populations [5].

Health insurance status was detailed in 6 studies [5,6,25,31,35,43], with 3 indicating that partial participants were uninsured, while 2 reported that the vast majority were insured. While 1 study reported that 148 (75%) of 197 study participants had an annual income exceeding $50,000 [25], other studies reported low income or unemployment among their participants [29,31,38,41,45]. In addition, internet access was addressed in multiple studies. While 3 studies reported secure internet access [6,25,45], 2 studies indicated that participants had limited internet or computer access [28,31], highlighting persistent access barriers relevant to digital health implementation.

The sample sizes in these studies ranged from 10 to 12,877 participants. Most studies had sample sizes under 300 participants, while several studies reported larger samples exceeding 500 participants [5,7,28,31,35,36]. Among studies

XSL•FO
RenderX

reporting age, participants ranged from 17 to 88 years, with mean ages typically ranging between 35 and 65 years.

Intervention

Table 4 presents that 13 studies explicitly identified their main intervention feature as either “information prescription” or “information Rx.” Two of them [6,7] investigated the effectiveness of IPs delivered via paper or email. Additionally, 3 studies [31,33,41] investigated the use of kiosks to deliver multimodal MedlinePlus information. While most studies used MedlinePlus resources on desktops or laptops, 2 studies explored iPad or tablet use [41,42], and 6 studies embedded MedlinePlus information as hyperlinks in patient portals of EHRs [4,5,32,36,37,39].

[i]API: application programming interface.

[j]iPICS: Interactive prostate cancer information, communication, and support program

Primarily using MedlinePlus web resources, the interventions encompassed a broad range of health information topics, tutorials, and medical term explanations. Additional intervention practices included (1) hands-on computer and health information search training for patients [25,39,41,45]; (2) training for physicians, nurses, staff, and students [6,26,41,42]; (3) the use of other web-based health resources provided by health professionals or organizations [30,34,42,45]; (4) the distribution of supplementary MedlinePlus materials such as bookmarks, pamphlets, brochures, magnets, or waiting room TV loops featuring MedlinePlus videos [9,27,31,33,35,36,40-42]; (5) patient health education or counseling offered by health care professionals as part of the intervention [32,33,35]; and (6) access to librarian assistance, instruction, or training [7,31,35,40,44]. Two recent studies either customized MedlinePlus content with additional local community components (eg, recipes, infographics, and local resource listings) [45] or integrated MedlinePlus into a digital platform with the research team's self-curated health information [46].

Most studies implemented MedlinePlus interventions in a clinical setting, such as clinics or hospitals, while others used MedlinePlus in community pharmacies [26,33], a community health resource center [45], libraries [30,36], an online platform [46], or patient portals [4,5,37].

Outcome

Overall, studies reported more nonclinical outcomes than clinical outcomes (Table 5). Of 28 studies, 4 measured clinical outcomes [29,35,43,44]. Two of these studies reported significant differences between the intervention and control groups. For instance, Fawcett [43] reported significant changes in diabetic foot ulcer measurements ($F_{2,26}$=3.91; P=.03; and χ^2_2=18.5; P<.001). Kazemi Majd et al [44] found fewer patients in the intervention group died or were readmitted compared to the control group during 1 year (relative risk 0.47, 95% CI 0.20 - 1.06; P=.005), but not in the first 6-month follow-up (relative risk 0.6, 95% CI 0.15 - 2.40; P=.05). However, the other 2 studies [29,35] reported no significant differences in clinical outcomes between the intervention and control groups, although a difference in patient behavior was noted, with the intervention group being more likely to use the internet or fill their prescriptions.

[s]PAM: Patient Activation Measure.

Most studies (24/28) reported positive nonclinical outcomes, focusing on (1) participants' attitudes, satisfaction, and behaviors related to online health information resource usage and information-seeking behaviors; (2) frequency and user experience of MedlinePlus usage; and (3) perceived usefulness, trust, ease of use, and competency in using MedlinePlus information for health decision-making, physician communication, self-management, and self-efficacy on finding professional help and disease knowledge.

The study durations varied, typically around 12 months, ranging from 1 to 34 months. Most studies used surveys or interviews for participant follow-ups.

Quality Assessment

All studies were empirical with clear research goals, objectives, or research questions, and they collected data to address their research questions, achieving MMAT S1 and S2. Among them, 2 qualitative studies were analyzed by MMAT criteria from 1.1 to 1.5, and only one criterion (ie, MMAT 1.1) was met in each study [34,36]. For 7 RCTs evaluated by MMAT 2.1 to 2.5, the number of criteria met ranged from 1 to 5, with many studies lacking sufficient details on either the outcome assessors blinded to the intervention (MMAT 2.4) or follow-up response rates of adherence to the intervention (MMAT 2.5). Each of the 4 nonrandomized studies met at least two criteria (eg, MMAT 3.2 and 3.5), and only one study [5] met MMAT 3.4 by addressing potential confounding variables adequately. Seven quantitative descriptive studies met 2 or 3 criteria (MMAT 4.3 and 4.5), and the majority rarely provided sufficient information about their sampling strategies or reduced nonresponse bias risk (MMAT 4.1, 4.2, and 4.4). Finally, among 8 mixed methods studies, 1 did not meet any criteria, while 6 met only 1 criterion. The study by Wilcox et al [39] met all 5 criteria. Most mixed methods studies lacked sufficient details on whether and how the qualitative and quantitative findings were integrated and interpreted (MMAT 5.3). Overall, when considering the average number of MMAT criteria met per study type, qualitative studies had the fewest met criteria (one per study), while nonrandomized studies had the most (ie, an average of 3.25 criteria per study). Detailed quality assessment results were documented in Multimedia Appendix 2.

Discussion

Bibliometrics

As the primary funding agency for half of the included studies, the US NLM has sustained MedlinePlus as a reliable and trusted health information resource. While most included studies took place in the United States, 3 studies were conducted in developing countries, demonstrating MedlinePlus's applicability and value across cultural, medical, and organizational contexts [4,34,44].

Despite nearly 25 years of availability, MedlinePlus has generated a relatively small body of empirical research examining its role in clinical care and chronic disease management. The limited number of identified studies (n=28), coupled with generally below-average citation impact (ie, FWCI scores <1.0) and below-benchmark Altmetric scores (<20), suggests that MedlinePlus has been underused and underexamined in health care practice and research. These gaps highlighted missed opportunities to rigorously document its

XSL•FO
RenderX

implementation effectiveness and potential contribution to patient- and caregiver-centered care.

Participants

Guided by the CCCM framework, this review highlights the engagement of diverse participant groups with MedlinePlus across coordinated and team-based care settings, including health care professionals, inpatient and outpatient contexts, patients with varied health conditions, family caregivers, pharmacists, and librarians. In particular, medical or public libraries often played a critical role in "physician-directed" information delivery [6], improving community health literacy [47], and serving as community partners to make MedlinePlus accessible to broader audiences. These findings underscore its potential role in integrated care delivery.

Although most studies reported patients' ages, races, and socioeconomic backgrounds, many lacked SDOH-related specifics such as health insurance, annual income, employment, or health literacy. This gap limits our understanding of how sociodemographics impacted MedlinePlus use, especially given the strong association between health literacy, internet access, and digital engagement [48].

Intervention

As an information intervention in clinical care, early studies on MedlinePlus [25,26,28] were directly influenced by the paper-based IP or Information Rx program launched by the NLM in 2002. However, later work reflected a growing interest in integrating MedlinePlus into EHR-enabled environments. For example, Ramesh et al [37] highlighted earlier efforts to embed MedlinePlus within Health IT systems. This trend continues, with more recent studies incorporating MedlinePlus into patient portals [4,5,39,41] and stand-alone digital health platforms for patients and caregivers [45,46], supporting their self-management and health information access beyond traditional clinical settings.

Several studies explored the use of kiosks in community pharmacies to deliver multimodal MedlinePlus information [31,33,41], aligning with the community linkage in the CCCM framework. Other studies also reported disseminating MedlinePlus information via iPad or tablet, or combining MedlinePlus content with additional resources, such as the American Heart Association patient materials, RxList, Mayo Clinic, and even religious texts (ie, the Holy Quran). These interventions were implemented across settings, from clinics to virtual environments, highlighting MedlinePlus' adaptability and versatility in supporting varied models of health information delivery.

Outcome

Clinical outcomes were reported in only 4 studies. Their results varied from no to significant differences in assessed measures, sometimes with mixed results even within the same study. These inconclusive results indicate the complex nature of directly linking MedlinePlus information interventions to patient health improvements. Researchers identified barriers, including inconsistent physician participation [27], small sample sizes [6], low computer literacy [29] or digital divide [5], limited evaluation periods [29], and information intervention design challenges [35]. Nevertheless, most studies reported nonclinical outcomes, including notable improvements in participants' attitudes, satisfaction, and behaviors related to online health information seeking. These nonclinical outcomes highlight the benefits of using MedlinePlus in enhancing patients' health engagement, communication, education, and self-efficacy, providing strong evidence to inform physician-directed health information interventions that complement routine clinical care.

Overall, in light of the identified research gaps, we recommend the following priorities for future research. First, additional studies are needed to rigorously examine the impact of MedlinePlus on patient- and caregiver-centered health outcomes and ensure transparent reporting and effective dissemination of findings within and beyond scholarly communities. Second, more rigorously designed RCTs are needed to evaluate its clinical efficacy. The existing RCTs missed or underreported several key methodological components. Thus, future studies should provide detailed information on allocation concealment, randomization implementation, and follow-up response rates regarding participants' adherence to the intervention. Third, digital solutions should seamlessly integrate MedlinePlus content into patients' health care journeys, such as through personalized apps or culturally adapted digital health platforms. Although the most recent 2 studies [45,46] suggest these burgeoning trends, future studies shall ensure that patients receive relevant information tailored to their specific needs, preferences, and literacy levels. Finally, future research shall consistently collect and report SDOH-related demographics, such as income, insurance, education, and health literacy, and support MedlinePlus as an equitable intervention responsive to the care needs of patients and caregivers of different backgrounds.

Despite its global importance, MedlinePlus faces challenges from rapid technological advances (eg, keeping pace with evolving web design and digital infrastructure), competition from commercial products (eg, Healthwise within EPIC EHRs), and uncertainties about the long-term sustainability of federal funding amid federal priority shifts. However, the synthesized evidence from this review demonstrated consistent nonclinical benefits and clinical potentials, validating MedlinePlus' enduring value and utility. The findings provide evidence to inform future Health IT innovations, investments, and policy decision-making.

Limitations

This study has several limitations. First, although we aimed to identify all relevant studies, we may have missed those published in languages other than English or not indexed in the 9 bibliographic databases we searched. Second, we excluded articles that reported the use of MedlinePlus for nonpatient or noncaregiver populations. While this exclusion helped us focus on MedlinePlus's role in clinical care, it might have limited the interpretations of MedlinePlus's real impact beyond clinical contexts. Third, the included studies are heterogeneous in their research designs, and many lack demographic information on socioeconomic status, constraining a comprehensive understanding of how SDOH-related demographics influence MedlinePlus utilization. Future studies shall address this gap

XSL•FO
RenderX

by ensuring more complete and consistent demographic data collection and reporting.

Conclusions

This systematic literature review is the first to examine how MedlinePlus has been integrated into clinical care, supporting patients and caregivers through increased health information access. Researchers agree that promoting MedlinePlus resources will help address the digital divide, particularly for individuals who are homebound, reside in rural areas, or are underserved. Although health care providers are the key stakeholders in advocating MedlinePlus, the effective delivery and optimization of MedlinePlus health information for patient care requires collective and coordinated community efforts. Our synthesis through the CCCM-guided lens will serve as a foundation for future research and practice in designing and developing accessible, equitable, and scalable digital health information solutions to improve patient engagement, health literacy, self-management, and health outcomes.

Acknowledgments

We would like to thank all team members, particularly our graduate students, Erin Harvey and Pengxuan Wang, for their assistance with study selection. This manuscript was prepared in Microsoft Word with a Grammarly plug-in. Text edits suggested by Grammarly were reviewed and cross-checked using ChatGPT 4o for grammar, word choices, and sentence structures. All editing recommendations by generative artificial intelligence tools were carefully evaluated before being accepted or dismissed.

Funding

The US Department of Defense supported this project through funding (W81XWH-21-1-0263, principal investigator: LS). However, the authors take full responsibility for the information in this study, which does not necessarily reflect the views of the US Department of Defense.

Abstract

Background: Chronic obstructive pulmonary disease (COPD) is a leading cause of morbidity and mortality worldwide, with frequent exacerbations of COPD (ECOPD) significantly impacting patient health and health care systems. Predicting ECOPD early would increase patients' quality of life and decrease the economic burden. The advancement of wearable technologies and Internet of Things (IoT) sensors has enabled continuous remote monitoring (RM), offering new opportunities for early ECOPD prediction. However, effectively leveraging wearable data requires robust artificial intelligence (AI) frameworks capable of processing heterogeneous physiological and environmental information.

Objective: This systematic review aims to provide a comprehensive overview of both hardware and software solutions for predicting ECOPD using RM. From the reviewed literature, we first focus on key physiological and environmental variables essential for COPD monitoring that can be extracted from wearables and IoT sensors. Second, we describe the wearable and IoT devices currently deployed in COPD management. Finally, we review machine learning, including deep learning models, used for ECOPD prediction, discussing limitations for real-world implementation. By bridging AI-driven data processing with real-world sensor applications, this review aims to outline the current landscape, existing challenges, and future directions for developing effective RM solutions for ECOPD predictions.

Methods: A comprehensive search was conducted following the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines to identify studies using AI or machine learning techniques for predicting ECOPD in in-home contexts.

Results: This review identified 26 studies that met the inclusion criteria. Twenty studies aimed at predicting or detecting exacerbations at the onset. The variables tracked most frequently were heart rate (n=9), peripheral oxygen saturation (n=9), and symptoms (n=8). Daily or weekly sampling was most common (n=14). Most studies (n=13) applied machine learning models—primarily random forest (n=5), CatBoost (n=2), decision trees (n=2), and support vector machines (n=2). Deep learning was used in 3 papers, while the remaining applied rule-based logics and probabilistic models. Wearables and IoT were used in only 6 out of 20 studies. Six papers analyzed changes in vital parameters during prodromal phases, defined as the period shortly before the onset of an exacerbation. Three studies collected data continuously, 2 daily, and 1 compared once-daily versus overnight monitoring; 4 of these 6 used wearable devices.

Conclusions: Overall, current evidence highlights the potential of continuous monitoring of physiological and environmental variables for early ECOPD prediction, offering advantages over questionnaires or once-daily measurements. While wearables and IoT devices show promise, their use remains limited. Many studies rely on balanced datasets that do not mirror real-world exacerbation patterns and lack external validation across diverse populations. Future research should emphasize large-scale validation, integration of multimodal data, and translation of AI models into clinically feasible tools to enable timely intervention and improve COPD management.

Introduction

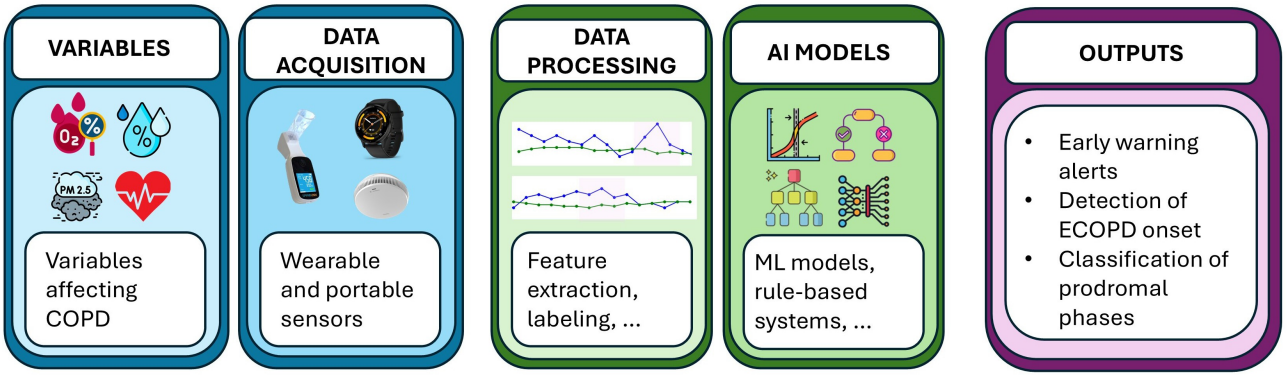
Chronic obstructive pulmonary disease (COPD) is a heterogeneous lung condition characterized by chronic respiratory problems, including dyspnea, cough, sputum production, and exacerbations. These issues can be attributed to abnormalities of the airways (bronchitis and bronchiolitis) and/or alveoli (emphysema) leading to persistent, often progressive, airflow obstruction [1]. COPD is a major global health issue, causing significant morbidity and mortality worldwide, and placing an increasing burden on health care systems and the economy. The current global estimated prevalence of 10.3% is projected to rise, particularly in high-income countries, mainly due to an aging population [1]. According to the World Health Organization, COPD was responsible for 3.5 million deaths in 2021 alone, making it the fourth leading cause of death worldwide [2].

The primary factors contributing to disease progression, hospitalization, and readmission are exacerbations of COPD (ECOPD), which refers to acute episodes of disease worsening. According to the Global Initiative for Chronic Obstructive Lung Disease (GOLD) definition, these are defined as “an event characterized by increased dyspnea and/or cough and sputum that worsens in less than 14 days, which may be accompanied by tachypnea and/or tachycardia and is often associated with increased local and systemic inflammation caused by infection, pollution, or other insults to the airways” [1,3]. ECOPD episodes are classified as mild or moderate, according to the medication treatment, or severe, if hospitalization or emergency room (ER) visits are required [1]. Thus, the severity of ECOPD is graded post hoc, based on the medication used and the setting, and is determined by the patient’s subjective perception of symptoms.

Currently, there is no single universally recognized gold standard to assess ECOPD. Instead, exacerbations are commonly identified through a combination of symptom-based or event-based assessments, patient self-reports, and clinical evaluation [4]. ECOPD is defined as event-based, using objective criteria such as health care use or specific treatments, including self-administration of medication or unscheduled visits to the ER and/or hospital admission. Alternatively, it can be defined as symptom-based, relying on patient-reported changes in symptoms. An increase in symptoms such as dyspnea, cough, or sputum production for a minimum number of consecutive days, or changes in symptoms recorded in daily diaries or questionnaires. However, it is logical that the symptoms precede the event, as they are the underlying cause.

It is estimated that approximately 30% to 50% of people diagnosed with COPD experience at least one exacerbation yearly, often requiring hospitalization to stabilize the patient [5]. A significant concern following these hospitalizations is the high rate of readmissions. Data from the European COPD audit revealed that 35.1% (5337/15,191) of patients were readmitted within 90 days of discharge [6]. ER visits and hospitalizations due to signs and symptoms of ECOPD are the main reason for COPD-related costs, which can account for up to 56% of the annual respiratory disease budget, equating to €38.6 billion (US $45.7 billion) [7,8]. A qualitative study by Locke et al [9] found that most patients can distinguish worsening disease symptoms from baseline symptoms, but a reluctance to seek care was a typical response of many persons with COPD when developing ECOPD. Most delayed action until a critical threshold was reached, when the urgency of their symptoms surpassed the personal and initial barriers they faced. In contrast, early recognition and prompt treatment by a physician can improve the outcomes of ECOPD [10]. These findings underscore the importance of implementing strategies aimed at early recognition of disease worsening, enabling prompt therapeutic action.

To achieve effective early prediction, it is essential to identify key parameters for monitoring and establish consensus on alerting thresholds. This process involves identifying patients at high risk before the onset of severe symptoms. Machine learning (ML) models, particularly those integrated with emerging Internet of Things (IoT) technologies, offer promising solutions for accurately and remotely sensing vital parameters. Equally important is determining the optimal time window for early prediction. This window should allow for sufficient lead time to initiate interventions that could prevent or attenuate an exacerbation. If the time frame is too short, there may not be sufficient time to act effectively. Conversely, a time frame that is too long, such as forecasting ECOPD risk over the next 12 months, may have limited clinical utility, as it does not inform the timing of specific interventions. Therefore, determining the optimal lead time for prediction is critical for maximizing both predictive accuracy and clinical actionability. This choice must balance the need for early warning with the relevance and reliability of available data in the lead-up to an exacerbation.



Beyond achieving accurate early prediction, ensuring clinical translation and adoption is equally important. Recent reviews, such as Qi et al [11], underscore the importance of structured validation frameworks and clinical interpretability as essential prerequisites for integration into clinical practice. Consequently, these considerations are as important as the previously discussed factors in the development of early prediction models. In particular, it is essential to ensure that the model is both generalizable and explainable for successful clinical adoption.

From a practical perspective, ECOPD prediction involves several fundamental steps, including the identification of physiological variables and external factors that change and/or

XSL•FO
RenderX

contribute to the lead-up to an exacerbation. It also involves the selection of wearable and/or portable devices to collect these variables. It is then important to identify key parameters that change during prodromal phases, that is, before exacerbation of symptoms, as such information may positively influence model performance. The collected data are then preprocessed using various techniques and subsequently fed into artificial intelligence (AI)/ML algorithms. The objective of the algorithm could be early warning generation (with varying prediction windows), the detection of exacerbation onset, or the classification of prodromal phases. The entire ECOPD prediction pipeline is illustrated in Figure 1.

Figure 1. Schematic overview of exacerbations of chronic obstructive pulmonary disease prediction pipeline. AI: artificial intelligence; COPD: chronic obstructive pulmonary disease; ECOPD: exacerbations of chronic obstructive pulmonary disease.

The goal of this systematic review is to analyze existing research on AI- and IoT-based wearable systems for remote COPD monitoring, focusing on which variables are evaluated to assess and/or predict exacerbations, the granularity of the collected data, and the device type used to enable remote patient monitoring (RPM). It highlights state-of-the-art results on prediction accuracy and area under the curve (AUC), outlining which AI and ML techniques are most commonly used. It focuses on examining existing data frameworks, the AI models used for predicting ECOPD, and identifying challenges in their real-world application, as well as gaps in the current research.

The research questions can be summarized as follows:

1. Which key physiological variables are most relevant for predicting COPD exacerbations? Does the data resolution (eg, sampling frequency) influence model performance? Is there any standardization in the IoT devices used for RPM in COPD management?
2. Which AI models are used to predict ECOPD, and how accurate are they?
3. What are the gaps in current research regarding wearable IoT and AI for COPD monitoring, and what should be prioritized in future studies?

The first research question aims to identify which physiological and environmental variables are most commonly used, exploring the frequency of data collection and its impact on the outcome. It further reviews the types of wearables and IoT devices used, and whether there is any standardization across studies. The second research question discusses the ML techniques applied, including performance metrics and limitations. It also clarifies how exacerbations are defined, which influences model training and evaluation. Finally, the third one synthesizes insights from all thematic areas to identify limitations in current approaches and propose future directions. Each of these points is examined thoroughly in the “Discussion” section.

To support this analysis, we also categorize the reviewed articles based on their primary objectives. Studies that focused on developing models for predicting exacerbations are discussed in the section titled “Exacerbation Prediction,” while those that examined changes in vital parameters preceding exacerbations are presented in the section titled “Variable Changes in Prodromal Phases.” This second group of papers was deliberately included to highlight the importance of identifying discriminative input variables, which is critical for improving model performance and capturing the complex patterns of disease progression. Despite this thematic separation, the discussion of results remains structured around the 3 central research questions, ensuring a coherent and focused analysis.

Among the literature on reviewing ECOPD, this review adds key insights for developing an effective remote system for early ECOPD prediction. We identify monitored variables that have discriminative power to predict ECOPD, underscore the need for a universal definition of ECOPD, and review state-of-the-art telemonitoring solutions and early prediction methods. By doing so, this review aims to lay a solid foundation for improving outcomes and their validation within the context of RPM for ECOPD. This review aims to emphasize the necessity of future research in 3 key areas: reducing the burden on medical specialists through automated data detection and prediction, alleviating patient burden by minimizing active participation in data collection, and enhancing predictive models through multimodal strategies.

Methods

Eligibility Criteria, Information Sources, and Search Strategy

The review was conducted in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [12]. A comprehensive search was carried out in PubMed, Scopus, IEEE Xplore, and Embase during March 2025. The search strings can be found in Multimedia Appendix 1.

XSL•FO
RenderX

Only peer-reviewed, full-text articles published in English were considered. The following publication types were excluded: systematic reviews, meta-analyses, book chapters, editorials, letters, and conference abstracts. However, full papers in conference proceedings were included.

Studies were eligible for inclusion if they met the following criteria:

1. Population: patients with COPD, undergoing exacerbations of the condition.
2. Settings: RPM
3. Measurements: objective (ie, measurable) physiological variables

The search strategy was based on three core concepts:

1. Wearable and remote monitoring (RM) technologies (eg, wearable sensors, smartwatches, home monitoring, and IoT sensors)
2. COPD
3. ML and AI approaches for the prediction or detection of ECOPD

Both controlled vocabulary terms (eg, MeSH [Medical Subject Headings] in PubMed) and free-text keywords were used. The search strategies were adapted for each database's specific syntax and indexing system.

No additional filters or limitations were applied during the search process.

Selection Process and Data Collection

The screening process was conducted using Rayyan (Qatar Computing Research Institute) [13], a web-based tool for systematic review management. Duplicate records were first identified automatically by the platform, but their final removal was performed manually by the first reviewer to ensure accuracy.

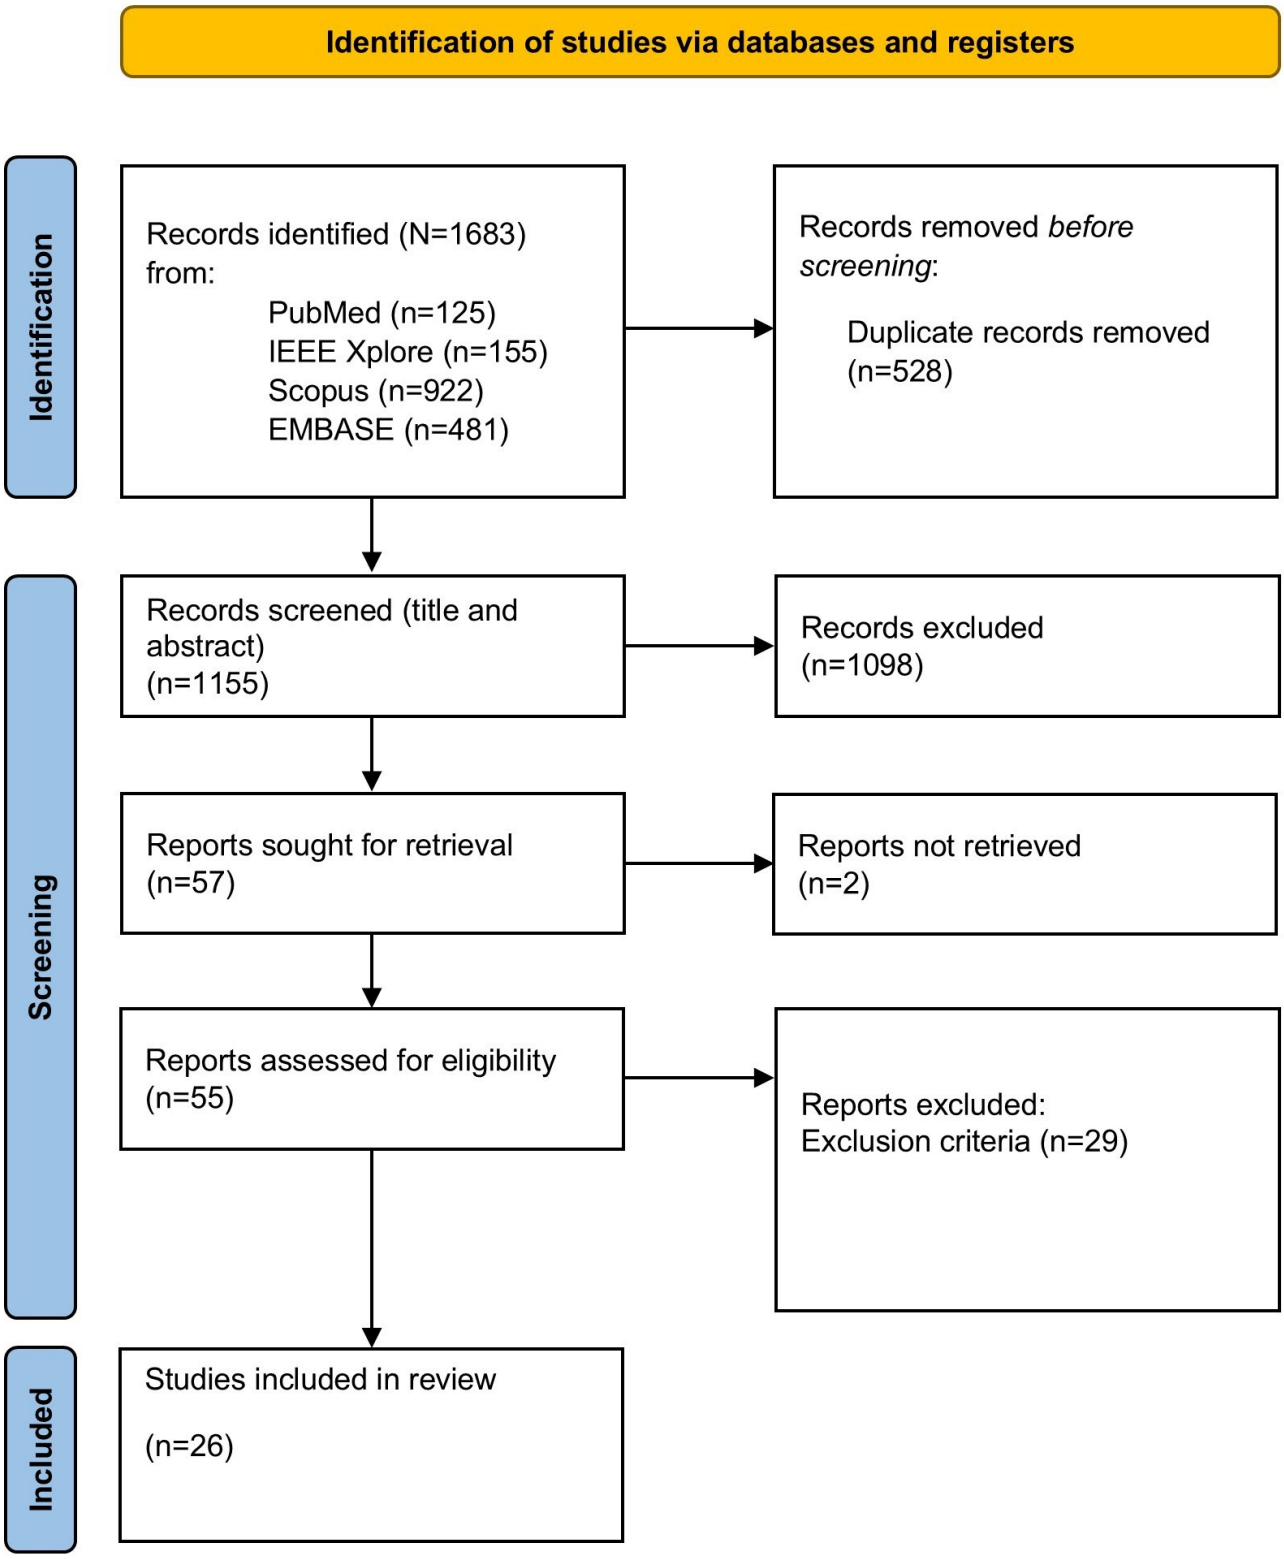
Two reviewers (MM and JG) independently screened the articles, initially based on titles and abstracts, followed by full-text screening for eligibility. In cases of disagreement, conflicts were resolved through discussion until consensus was reached. Articles were selected for inclusion if they met all predefined eligibility criteria.

Following the screening, the first reviewer (MM) manually extracted the relevant data using Microsoft Excel. The second reviewer (JG) subsequently verified the data for completeness and accuracy.

The following data items were extracted: title, authors, year of publication, journal, aim of the study, population characteristics, study duration, definition of exacerbation, monitored parameters, devices used, sampling frequency, machine learning or deep learning models used, and main outcomes.

Risk of Bias Assessment

The risk of bias was assessed by one reviewer (MM) and verified by a second (JG). Any disagreements between reviewers were resolved through discussion to reach consensus. To ensure a comprehensive evaluation, several risk of bias assessment tools were applied. Twenty prediction model studies were evaluated using the PROBAST (Prediction Model Risk of Bias Assessment Tool) [14], which is specifically designed for evaluating prediction model studies. PROBAST assesses bias across 4 domains: participants, predictors, outcomes, and analysis. Five observational studies were evaluated using the Newcastle-Ottawa Scale [15], while the only randomized controlled trial (RCT) intervention study was assessed with RoB 2 (Cochrane Collaboration) [16].



Results

Study Selection

The study selection process is illustrated in the PRISMA flow diagram (Figure 2).

XSL•FO
RenderX

Figure 2. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram.

The systematic search yielded a total of 1683 records: 125 from PubMed, 155 from IEEE Xplore, 922 from Scopus, and 481 from Embase. Prior to screening, 528 duplicate records were removed, resulting in 1155 unique records for title and abstract screening. Based on the predefined inclusion and exclusion criteria, 1098 records were excluded at this stage.

The remaining 57 articles were retrieved for full-text assessment. Of these, 2 records could not be accessed despite efforts to contact the authors via ResearchGate. As a result, 55 full-text articles were assessed for eligibility.

Full-text assessment followed the same inclusion and exclusion criteria as title and abstract screening. After full-text screening, 26 studies [17-42] met the inclusion criteria and were included in this systematic review.

Study Characteristics

Exacerbation Prediction

The key characteristics of the studies related to exacerbation prediction are summarized in Table 1. Across the 20 included studies [17-36], sample sizes range from 9 to 177 participants, and study durations vary from 1 month to 4 years. Some studies are outliers. For example, Wu et al [17] do not explicitly state the length of the monitoring period, and in the study by Lin et al [18], the follow-up of the participants ranged from 16 to 448 days, with an average testing period of 206 days per patient.

Definitions of exacerbation also varied substantially. In 3 studies [20,28,35], exacerbations were identified by clinical judgment; 4 studies [24,25,27,29] used event-based definitions such as hospitalization or changes in medication. Two studies relied on symptom-based criteria [23,31], 2 adopted the GOLD definition [19,22], and one relied on self-reported exacerbations, validated by clinicians [21]. In the study by Wu et al [17], the definition was not clearly reported ("NA"), but it is highly probable that they adopted the same of their previous study [19]. In other studies, authors used custom rule-based criteria, often operationalized in the study's algorithm.

[y]HRV: heart rate variability.

Most of the included studies used ML techniques, with a few also incorporating deep learning models. Notably, time-series analysis was explicitly used in only a subset of the studies, whereas many applied ML techniques to static or aggregated data. Of the reviewed studies, 13 reported their best performance using traditional ML techniques [17,21-25,28,29,32-36], while 2 relied on rule-based systems [18,27], 1 on a Bayesian model [31], 1 on a finite state machine [20], and 3 on deep learning architectures [19,26,30]. Overall, the prevalence of simpler modeling approaches is consistent with the generally small size of the datasets used in these studies.

The monitored variables and sampling frequencies exhibit significant heterogeneity in terms of both sensor modalities and data collection protocols. The variables tracked most frequently are heart rate (HR; 9 studies [17,19,21,24,26,29,30,32,34]), peripheral capillary oxygen saturation (SpO2; 9 studies [17,20,24,26,29,30,32-34]), and symptoms (8 studies [17,19,21,26,30,31,34,35]).

To clarify which parameters are being monitored in each study, we have categorized the papers according to the physiological and environmental variables they focus on (1) monitoring of physiological variables (eg, oxygen saturation and HR) [18,20,24,26,29,31,32,34,36], (2) monitoring of respiratory variables (eg, forced vital capacity [FVC] and peak expiratory flow [PEF]), breathing sounds, or coughing [22,23,25,27,33], (3) monitoring of environmental variables [21,28], (4) monitoring of both physiological and environmental variables [17,19,30], and (5) monitoring also forced expiratory volume in 1 second (FEV1) [21,28,31,32].

The only exceptions stand in Patel et al [35], which is monitoring FEV1 and finger-prick C-reactive protein, where the latter is a physiological variable but invasively measured from blood samples.

The sampling frequency varied across studies. Daily sampling was used in 7 studies [17,20,23,24,26,30,32], while a few studies collected measurements multiple times per day (2 - 3 times). Some studies collected data weekly, and 6 studies [17,21,27,28,30,34] used continuous monitoring. Only in the study by Lin et al [18], the sampling frequency explicitly stated, set at 20 Hz. For the remaining studies, no raw sampling is specified. Specifically, in Wu et al [17,19], data synchronization occurs every 15 minutes, while in the study by Atzeni et al [21], it happens every 30 hours. Once again, in the study of Crooks et al [27], the system continuously analyzes audio input, but the actual sampling frequency of the raw audio is not specified. In the study by Kolozali et al [28], the sampling frequency is not explicitly reported. However, based on the data volume (54 million points over 106 participants), acquisition intervals likely range from subminute to several minutes depending on the sensor.

As the review focuses on wearables and IoT sensors, it is important to note that only a minority of the studies explicitly mention the specific devices used, and that there is substantial heterogeneity in device types, specifically wearable and portable sensors.

Wearable devices, which are continuously worn on the body, included the Fitbit Versa smartwatch and EDIMAX AirBox environmental sensor [17,19], custom-made Personal Ambient Monitor worn around the waist [21], a stationary microphone (Jabra 510+, Jabra GN) at the bed table [27], air pollution sensors and activity-related sensors, not further specified [28], accelerometer-based wrist-worn wearable devices: GeneActiv [18], O2 of Zoetek Inc smartwatch [36].

Portable devices, which are intermittently used or carried by the patient, included pulse oximeter ([20,29,34] which included also a pedometer), portable spirometers and electronic

XSL•FO
RenderX

stethoscopes [22], electronic sensor ad hoc designated [23], electronic stethoscopes and a microphone [25], home monitoring unit (TeleMed-Care Health Monitor: TMC-Home, TeleMedCare Pty Ltd) [32], noninvasive ventilator (RESmart GII BPAP Y-25T, BMC Medical Co, Ltd) [33], and Vitalograph, Ireland, to measure FEV1 [35].

This taxonomy highlights the lack of standardization in both device selection and reporting across studies, complicating direct comparison and synthesis of findings.

Variables Changes in Prodromal Phases

The key characteristics of the studies related to the analysis of physiological variables in prodromal phases are presented in Table 2.

The 6 included studies [37-42] report sample sizes ranging from 16 to 104 participants, with durations spanning 21 days to 6 months. Two studies stand out as outliers: in Kim et al [42], it is not explicitly stated, and in Cooper et al [41], all participants collectively provided 2618 days.

The definitions of exacerbation also varied. Two studies used event-based definitions [39,40], 2 studies relied on symptom-based criteria [37,38], and one adopted multiple definitions [41], in order to see how many different exacerbations were captured, according to the applied definition. In one instance, the definition was not clearly reported ("NA"), not even in the study protocol [43].

Table . Characteristics of included studies (variable changes in prodromal phases).

Study	Population (study duration)	Exacerbation definition	Model	Parameters monitored and sampling
Hawthorne et al [37] (2022)	35 (6 weeks)	Symptom-based (mild), symptom-based and medication (moderate), hospitalization (severe)	NA[a]	RR[b], HR[c], T[d], activity/continuous
Coutu et al [38] (2024)	21 (21 days)	Symptom-based	Linear mixed-effects models	RR, RRV[e], HR, HRV[f], T, ED[g] activity, activity, sleep/continuous
Zimmerman et al [39] (2020)	16 (8 - 9 months	Increase in respiratory symptoms requiring oral corticosteroids and/or antibiotics, with or without medical review and/or hospitalization.	Linear mixed-effects models	Respiratory variables/daily
Al Rajeh et al [40] (2020)	83 (6 months)	Event-based	NA	Symptoms - PEF[h], HR, SpO_2[i]/daily- daily vs overnight
Cooper et al [41] (2020)	17 (2618 patient-days)	Multiple	SPC[j], concordance analysis	Symptoms, respiratory variables, SpO_2/daily
Kim et al [42] (2021)	104 (NA)	NA	LR[k]	PM2.5[l]/continuous

[a]Not available.

[b]RR: respiratory rate.

[c]HR: heart rate.

[d]T: temperature.

[e]RRV: respiratory rate variability.

[f]HRV: heart rate variability.

[g]ED: electrodermal activity.

[h]PEF: peak expiratory flow.

[i]SPO2: peripheral capillary oxygen saturation.

[j]SPC: statistical process control.

[k]LR: logistic regression.

[l]PM2.5: particulate matter ≤2.5 µm.

The included studies used statistical analysis to inspect the correlations between exacerbations and variation in physiological variables, including HR, respiratory variables, and in one study [42], PM2.5 (particulate matter ≤2.5 µm) is considered. Three studies collect data continuously [37,38,42], 2 daily [39,41], and one assesses the difference between once daily and overnight monitoring [40].

Regarding the devices used, it can be highlighted that 4 studies [37,38,40,42] out of 6 [37-42] use wearable devices, specifically:

XSL•FO
RenderX

1. Hawthorne et al [37]: chest-worn multiparameter monitoring system (Equivital LifeMonitor EQ02)
2. Coutu et al [38]: a biometric wristband (EmbracePlus, Empatica Inc) and a biometric ring (Oura Gen III, Oura Health Oy)
3. Al Rajeh et al [40]: wristband pulse oximeter (Nonin 3150) for overnight monitoring (measurement recorded every 4 s), or finger pulse oximeter (Nonin G92) for once-daily (morning) monitoring.
4. Kim et al [42]: IoT to measure PM2.5 indoor: a sensor-based light scattering measurement device (CP-16-A5, Aircok Inc).

Meanwhile, Zimmermann et al [39] and Cooper et al [41] both use portable devices to monitor respiratory trends daily. Specifically, the former uses a FOT (Forced Oscillation Technique) telemonitoring device (Resmon Pro Diary, Restech Srl) to monitor respiratory variables every morning, and the latter RPM (handheld spirometer [SpiroPro, eResearch Technology] and pulse oximeter [Onyx II, Nonin Medical]).

Risk of Bias

The only RCT [40] has been assessed as low risk in the randomization process, measurement of the outcome, and selection of the reported results. However, certain issues have been identified regarding deviations from the established interventions. These include the unfeasibility of binding the participants and a high rate of participant dropout. Due to these concerns, a high risk has been assigned to missing data.

The Newcastle-Ottawa Scale results are reported in Table 3. Overall, no study raises concerns.

Table . Risk of bias assessment (Newcastle-Ottawa Scale).

Study (year)	Selection (0 - 4)	Comparability (0 - 2)	Outcome (0 - 3)	Total score (0 - 9)
Hawthorne et al [37] (2022)	3	2	3	8/9
Coutu et al [38] (2024)	3	2	3	8/9
Zimmerman et al [39] (2020)	3	2	3	8/9
Cooper et al [41] (2020)	3	2	3	8/9
Kim et al [42] (2021)	3	2	2	7/9

Finally, most of the studies are related to prediction models; therefore, the risk of bias has been assessed with the PROBAST, which evaluates Participants and Data Sources (P), Predictors (Pr), Outcome (O), and Analysis (A). The results are summarized in Table 4. A high risk of bias was identified in the study by Wu et al [17] due to an unclear definition of outcomes and ambiguity in the sample breakdown, which adds uncertainty to the findings. In the study by Kronborg et al [24], the use of a very small cohort (9 patients selected from 108), a low number of positive samples (17 exacerbation periods), and reliance on self-reported data introduce a high risk of bias. Nunavath et al [26] present potential bias arising from synthetic oversampling, exclusion of one class, and the use of triage labels as proxies for exacerbation severity. Kolozali et al [28] apply complex modeling techniques without external validation and with unclear measures to control for overfitting, raising concerns about model reliability. In the study by van der Heijden et al [31], the small sample size, the use of self-reported predictors that are not clearly linked to outcomes, and the use of symptoms to both define exacerbations and as input features for prediction models contribute to a heightened risk of bias.

In the “Discussion” section, we discuss how biases in study design and analysis can lead to inflated predictive performance metrics.

[a]PROBCAST: Prediction model Risk of Bias Assessment Tool.

Study Analyses

Exacerbation Prediction

The results of the studies related to exacerbation prediction are summarized in Table 5. As anticipated, a broad range of ML and rule-based models have been deployed, with most aiming to forecast exacerbation of COPD between 1 and 7 days ahead. Furthermore, several studies reported overall accuracy without sufficient sensitivity-specificity trade-offs, thereby limiting assessment of clinical utility, and a lack of standardized reporting metrics hinders cross-study comparability. For this reason, we focus our comparisons on studies reporting the same performance metrics.

XSL•FO
RenderX

Table . Results of included studies (exacerbation prediction).

Study (year)	Outcomes	Performance metrics	Notes
Wu et al [19] (2021)	Early detection of exacerbations (7 days)	Accuracy=0.9357, AUROC[a]=0.9699, sensitivity=0.9452, specificity=0.9253, precision=0.9393, F_1-score=0.9323	DNN[b] on balanced dataset+feature importance
Merone et al [20] (2017)	Detection of the onset of ECOPD[c]	Accuracy=98.4, recall=92.9, specificity=99.3, precision=95.1, F_1-score=94.0	Participant specific
Atzeni et al [21] (2022)	Early detection of ECOPD (1 day)	Cluster 1: AUC[d]=0.90, AUPRC[e]=0.7, sensitivity=0.83, specificity=0.86; Cluster 2: AUC=0.82, AUPRC=0.56, sensitivity=0.75, specificity=0.78	KNN[f]+RF[g] + SHAP[h]
Yin et al [22] (2024)	Predict ECOPD (k=1, 2, 3 days)	AUC (k=1)=0.9721 (95% CI 0.9623 - 0.9810), F_1-score=0.846	CatBoost, balanced test set+feature importance
Fernandez-Granero et al [23] (2018)	Early detection of ECOPD (4.4 days margin)	Accuracy=87.8%, sensitivity=78.1%, specificity=95.9%, PPV[i]=94.1%, NPV[j]=83.9%, F_1-score=0.8	NA[k]
Wu et al [17] (2022)	Early detection of ECOPD (7 days)	Accuracy=72.4%, sensitivity=62.5%, specificity=78.3%, precision=63.3%, F_1-score=62.9%	DNN, external test set, feature importance, and SHAP
Kronborg et al [24] (2021)	Classification of prodromal periods (14 days)	AUC=0.95, sensitivity=0.94 (AUC gain=0.24 in a 2-layer model)	SVM[l] (RBF[m]), 2-layer model
Fernandez-Granero et al [25] (2015)	Early detection of ECOPD (mean 5, SD 1.9 days)	Accuracy=75.8%, sensitivity=73.76%, specificity=97.67%, PPV=84.66%, NPV=95.53%	NA
Nunavath et al [26] (2018)	ECOPD prediction (k=1, 3 days)	1-day: accuracy=82.5%, loss=0.50; 3-day: accuracy=88%, loss=0.345	Excludes moderate risk patients
Crooks et al [27] (2021)	Alarm system (3 days ahead)	Cough: alerts 3.4 (SD 2.8) days early (success rate=45%), 1 false/100 days; Questionnaire: alerts 3.4 (SD 2.9) days early (success rate: 88%), 1 false/10 days	Participant-specific baseline for cough frequency
Kolozali et al [28] (2023)	Prediction of daily symptoms (1 day in advance)	Accuracy=38.67% and F_1-score=0.19 (personalized), 19% and 0.10 (population)	Includes recovery phase
Shah et al [29] (2017)	Early detection of ECOPD (7 days)	Mean AUC=0.682 (95% CI 0.681 - 0.682), specificity=36% (at 80% sensitivity), 68% (at 60% sensitivity)	Analysis of prodromal variables
Orchard et al [30] (2018)	Next day hospital admission prediction	AUC=0.740 (95% CI 0.673 - 0.803)	No improvement with weather data
Van der Heijden et al [31] (2014)	Early detection of ECOPD (1 day)	Dval[n] AUC=0.90, TPR[o]=0.87, FPR[p]=0.12; Ddedup[q] AUC=0.82, TPR=0.78, FPR=0.19	External validation cohort, Bootstrapping dataset
Mohktar et al [32] (2015)	Classify high or low risk (1-day advance)	Accuracy=71.8%, specificity=80.4%, sensitivity=61.1%, PPV=71.4%, NPV=72%	Stable days excluded, feature importance
Jin et al [33] (2018)	Classification of prodromal periods (7 days)	Accuracy=74.5% (LDA[r]), 73.7% (SVM), 75% (RF); sensitivity=NA, 77.6%, 78.3%; specificity: lowest, 42.9%, 42%	Feature importance

[s]FDR: false discovery rate.

Deep neural networks and tree-based ensemble methods achieved strong performance with AUC values approaching 90%. Wu et al [19] reported one of the best-performing models using a deep neural network with a 7-day prediction window, achieving an area under the receiver operating characteristic curve (AUROC) of 0.97, accuracy of 93.6%, and sensitivity of 94.5%. Nonetheless, the test set is balanced 1:1, thus not representing the real-world distribution. Similarly, CatBoost-based models by Yin et al [22] and Moraza et al [34] achieved AUROC values above 0.89, indicating strong discriminatory power for short-term prediction. However, Yin et al [22] used a 5-fold cross-validation with a balanced test set, which does not reflect real-world class imbalance.

Other models, such as those by Atzeni et al [21] and Kronborg et al [24], also achieved high AUROC scores (≥0.90) in specific patient clusters or multilayer support vector machine setups.

Only Wu et al [17] and van der Heijden et al [31] performed external validation on a different cohort, while Moraza et al [34] used prospective validation data sampled from the sample cohort.

Studies using random forest models (eg, [17,33,36]) demonstrated varying levels of performance. Wu and Jin typically reported moderate overall accuracies between 72% and 80%, with trade-offs in sensitivity and specificity. Jin et al [33] reported relatively balanced sensitivity (~76% - 78%) but consistently low specificity (~41% - 43%), suggesting a higher false positive rate. In contrast, Hsiao et al [36] reported a notably high accuracy of 0.94 and specificity of 0.93, but with lower precision (0.57) and sensitivity (0.48), highlighting strong negative class identification at the cost of reduced detection of true positives.

Models with rule-based or alert systems (eg, [27]) demonstrated real-world feasibility with fewer false positives, though at the expense of lower sensitivity (45% ECOPD detection with cough-based alarms), also using baseline personalization. Personalization appeared to significantly improve predictive performance. Patel et al [35] used a personalized baseline approach, achieving high sensitivity (97.9%) and negative predictive value (99.8%), despite a modest positive predictive value (PPV; 38.4%), indicative of a low false-negative rate, which is important for safety but less efficient for resource use. Other studies have also underscored the value of patient-specific modeling (eg, [20] with 98.4% accuracy in a participant-specific setup).

XSL•FO
RenderX

Lower-performing models (eg, [28]) demonstrated limited predictive power in both personalized (38.7%) and population-level (19%) settings, potentially due to inclusion of recovery phases or inadequate feature representation. Similarly, Lin et al [18] achieved moderate sensitivity (62.9%) but low precision (~38%), leading to high false discovery rates.

Finally, 3 studies [23,25,26] highlighted temporal margins for predictions: they reported early detection windows of ~3‐5 days with variable sensitivity and precision, balancing warning time with model reliability. Notably, Nunavath et al [26] excluded deteriorating patients from their model, considering only stable and urgent cases—once again failing to reflect real-world distributions.

Studies can be further categorized according to the selection of the prediction window [17,19,29,35,36]. Predict exacerbations 7 days ahead. Choosing a shorter time window (1‐3 days), there are [21,22,26-28,30,31,34]. Meanwhile, the other papers focus on classification tasks. As shown in Table 5, high performance is reported across both short and long prediction windows.

Some studies analyzed which variables were most important for prediction. Wu et al [17] highlighted COPD Assessment Test score, fine particulate matter (PM10), and carbon monoxide; Atzeni et al [21] emphasized symptoms in previous days and a higher frequency of exacerbations in the past 30 days; and Mohktar et al [32] identified raw FEV1 and mean SpO2 as key features. Shah et al [29] observed lower SpO2, higher respiratory rate (RR), and elevated HR during the prodromal phase, concluding that SpO2 was the most predictive feature. Overall, all studies, apart from Orchard et al [30], concluded that including all features led to better results.

Finally, models often lack explainability, which can be a fundamental element to build clinicians' trust in the black box model. In this review, interpretability was addressed in only 7 [17,19,21,22,32-34] out of 20 studies [17-36].

Variables Changes in Prodromal Phases

The results of the studies related to the analysis of changes in physiological variables in prodromal phases are summarized in Table 6. Hawthorne et al [37] identified significant changes in HR and RR up to 3 days prior to exacerbations, with increases of 8.1 bpm and 2.0 breaths/minute, respectively. Coutu et al [38] found significant associations between higher EXACT-PRO (Exacerbations of Chronic Pulmonary Disease Tool–Patient-Reported Outcome) scores and reduced RR variability, step count, and sleep efficiency, suggesting that deterioration in these metrics may indicate worsening symptoms. Similarly, Zimmermann et al [39] demonstrated that variability in inspiratory reactance was significantly related to COPD Assessment Test scores.

XSL•FO
RenderX

Table . Results of included studies (variable changes in prodromal phases).

Study (year)	Outcomes	Performance metrics
Hawthorne et al [37] (2022)	Monitor changes in vital signs 3, 2, and 1 days before ECOPD[a]	HR[b] and PA[c] were associated with EXACT[d] score (P<.001). Three days prior to exacerbation: RR[e] increased by 2.0 (SD 0.2) breaths/min (7 of 11 cases), HR increased by 8.1 (SD 0.7) bpm (9 of 11)
Coutu et al [38] (2024)	Estimate the association between physiological variables and EXACT-PRO[f] score	Significant unadjusted associations included RR variability (−1.45 [−2.84, −0.073] points per breath/min), daily step count (−0.56 [−0.82, −0.31] points per 1000 steps), and sleep efficiency (−0.12 [−0.20, −0.037] points per % asleep), with bracketed values representing 95% CIs.
Zimmerman et al [39] (2020)	Timing of variability in FOT[g] measures and symptom change before AECOPD[h]	Xinsp and SDXinsp were related to mean CAT[i] score (0.59 [1.02, 0.15], P=.009; 1.57 [0.65 - 2.49], P=.001)
Al Rajeh et al [40] (2020)	Compare overnight versus daily HR and SpO2[j] monitoring	Daily HR: max increase +7 bpm on day 1 (P=.007, not clinically significant). Overnight HR: +10 bpm on day 1 (P=.04). Composite oximetry score increased from day 7 to 0 (overnight), and on days 1 and 0 (daily): sensitivity 84.6%, PPV[k] 91.7%
Cooper et al [41] (2020)	Identify monitored variables linked to exacerbations	Agreement between FVC[l] drop (7-day avg 1.645 SD) and self-reported health care use (Cohen κ=0.747, P<.001); bronchodilator use and Anthonisen criteria (Cohen κ=0.611, P<.001)
Kim et al [42] (2021)	Association between PM2.5[m] and questionnaire responses	Mean PM2.5 over 4 months was higher in patients with exacerbations (22.89, SD 5.52 g/m^3) vs no-exacerbation patients (20.36, SD 4.63 g/m^3), P<.02

[a]ECOPD: exacerbation of chronic obstructive pulmonary disease.

[b]HR: heart rate.

[c]PA: physical activity.

[d]EXACT: Exacerbations of Chronic Pulmonary Disease Tool.

[e]RR: respiratory rate.

[f]EXACT-PRO: Exacerbations of Chronic Pulmonary Disease Tool–Patient-Reported Outcome.

[g]FOT: Forced Oscillation Technique.

[h]AECOPD: acute exacerbation of chronic obstructive pulmonary disease.

[i]CAT: COPD Assessment Test.

[j]SpO2: peripheral capillary oxygen saturation.

[k]PPV: positive predictive value.

[l]FVC: forced vital capacity.

[m]PM2.5: particulate matter ≤2.5 µm.

Al Rajeh et al [40] compared daily versus overnight monitoring and found that overnight HR increases (+10 bpm) and composite oximetry scores provided better predictive performance for exacerbations (sensitivity 84.6%, PPV 91.7%) than daily metrics. Cooper et al [41] highlighted that significant drops in FVC aligned closely with health care use (Cohen κ=0.747), and bronchodilator use correlated with the Anthonisen criteria (Cohen κ=0.611). Finally, Kim et al [42] reported a significant association between higher ambient PM2.5 levels and increased exacerbation risk, with exposed patients showing a mean concentration of 22.89 (SD 5.52) µg/m³ compared to 20.36 (4.63) µg/m³ in those without exacerbations (P<.02).

Overall, these studies underline the potential of continuous monitoring of physiological and environmental variables to provide early indicators of ECOPD and support timely intervention.

Discussion

Principal Findings

In this section, we will discuss the key findings from the literature. We begin by examining how exacerbations are defined across studies, followed by an analysis of the most commonly monitored parameters and those shown to be discriminative for

XSL•FO
RenderX

ECOPD prediction. Next, we will review the structure and limitations of predictive models, with particular emphasis on personalized approaches. Finally, we consider the devices used, identify current gaps in the literature, and outline directions for future research.

Dataset Availability

Data are available upon reasonable request for the studies by Atzeni et al [21] and Moraza et al [34].

Exacerbation Definition

A key issue is the lack of a universally accepted definition of COPD exacerbation, as existing classifications vary according to context, severity criteria, and data availability. This inconsistency poses challenges for ML and deep learning models, which depend on reliable and standardized outcome definitions for effective training and validation [44]. Without agreement on the condition targeted, achieving this goal becomes more difficult. As discussed in the "Results" section, this heterogeneity complicates comparisons across studies, as differing criteria can capture distinct sets of events.

To establish a unique definition, it should be based on objectively measurable variables. There is an ongoing effort in the literature to identify predictive variables for COPD exacerbations. However, there is still no consensus on which variables to use or on the time window before the exacerbation during which they show significant changes. This issue is further complicated by patient-specific thresholds and variations in physiological variables. In this context, a patient-specific model could help mitigate the situation. However, there is common agreement on the variation of HR, RR, and SpO2, with FEV1 also being very significant. Therefore, it is important to consider that the changes in these variables could help identify the onset of exacerbations.

Variables Changes in Prodromal Phases

Physiological Variables

HR, RR, and SpO2 have shown promising predictive power. Moraza et al [34] identified RR, HR, and SpO2 as the most informative features. Likewise, Shah et al [29] found SpO2 to be the most predictive feature, followed by RR; while HR was the least predictive.

Al Rajeh et al [40] evaluated whether measuring changes in heart rate and oxygen saturation overnight is superior to once-daily monitoring of both variables and to assess symptom changes in facilitating earlier detection of COPD exacerbations. Concluding that COPD exacerbations are linked to measurable changes in cardiorespiratory signals, particularly HR and PEF. During the preexacerbation phase, both the mean HR and its variability increased significantly compared to the stable phase, while oxygen saturation remained consistent. Notably, overnight HR monitoring provided a clearer signal (lower variability) than once-daily measurements, enhancing the ability to detect exacerbations early. Combining HR with oxygen saturation data yielded the best performance for early detection (PPV over 90% for the detection of exacerbations), with overnight pulse oximetry outperforming once-daily monitoring.

Coutu et al [38] found that variability in RR and SpO2, rather than their absolute values, was more strongly associated with symptom fluctuations in patients with COPD. For instance, nighttime RR variability was significantly correlated with symptom scores, whereas mean RR showed no significant association in univariable analysis. Interestingly, these associations differed between individuals with persistent worsening and those who recovered, suggesting that physiological variability may serve as a more sensitive marker than single-time measurements.

Together, these findings emphasize the importance of continuous or high-resolution monitoring, particularly overnight measurements, in identifying early indications of physiological instability. However, differences in signal relevance across patient subgroups highlight the need for individualized monitoring strategies.

Environmental Variables

ECOPDs are influenced by a range of seasonal, environmental, and meteorological factors. Studies have shown that variables such as temperature, humidity, air pollution, and seasonal fluctuations significantly affect both the frequency and severity of ECOPDs [45,46]. Given their impact, incorporating these variables into predictive models can substantially improve model robustness and generalizability. For instance, Kim et al [42] found that patients who experienced exacerbations had been exposed to higher levels of PM2.5 in the preceding 4 months, compared to those without exacerbations.

To date, the integration of indoor environmental variables, outdoor weather conditions, and physiological variables has been explored only by Wu et al [17,19]. They reported that, compared to using clinical questionnaire data alone, incorporating lifestyle and environmental variables led to a 10% increase in accuracy and a 20% improvement in AUROC, highlighting the added predictive value of these factors.

Kolozali et al [28] found that air pollution data collected via personal air monitors were nearly as effective as peak flow measurements, reinforcing their potential predictive value. However, in Atzeni et al [21], when personal air monitor data were combined with symptom reports, SHAP (Shapley Additive Explanations) analysis indicated that symptoms and prior exacerbation history contributed more significantly to the model's predictions. Indeed, the use of questionnaires remains a prevalent method in many studies. The main limitation of questionnaires is their reliance on active user participation, which introduces subjectivity and can intuitively lead to incomplete or missing data.

Overall, environmental variables have been shown to be discriminative and influential in exacerbation prediction, yet they remain underused in the studies reviewed. Incorporating these variables could further enhance model performance.

Respiratory Variables

Similarly, the extraction of respiratory features still requires portable devices rather than fully automated data collection, making the process invasive and burdensome for users. Despite their strong predictive value, features such as sound recordings,

XSL•FO
RenderX

breathing patterns, and respiratory variables—including FEV1, identified as highly informative by Atzeni et al [21] and Mohktar et al [32]—and FVC drop, shown to align with exacerbation events in Cooper et al [41], present practical limitations. These methods are not well-suited for passive RM using consumer-grade devices, especially in scenarios requiring minimal user involvement.

Noninvasive monitoring methods are gaining traction, including smartphone-based algorithms capable of passively detecting cough frequency without raising privacy concerns [47]. Complementing this, Hawthorne et al [37] demonstrated that high-frequency wearable monitoring can detect physiological changes in the days leading up to an exacerbation—specifically, an average increase of 2.0 (SD 0.2) breaths/minute in RR for 7 out of 11 exacerbations, and a rise of 8.1 (SD 0.7) bpm in HR for 9 out of 11 cases.

Studies Reporting Higher Predictive Metrics: Risk of Bias

Overall, it is important to note that several studies reporting high performance also exhibited elevated risk of bias, in particular in their analysis, participant selection domain and outcome definition. For instance, Wu et al [19] and Yin et al [22] reported AUROC values above 0.95, but relied on balanced datasets, highly selected cohorts, and did not include external validation, which are factors known to inflate performance estimates. Similarly, Nunavath et al [26] excluded moderate-risk patients and synthetically oversampled high-risk patients to balance the dataset. This does not reflect real-world prevalence and could alter results. In contrast, studies incorporating external or prospective validation, such as Van der Heijden et al [31] and Moraza et al [34], generally reported more conservative yet clinically credible performance. Furthermore, studies [18,20,23-25,31-33,36] rely on relatively small cohorts (9 - 22 participants), which increases the risk of overly optimistic performance estimates. This concern is amplified by the fact that only study [31] validates its finding on an independent cohort.

Balancing of the datasets, lack of external validation, and reliance on small datasets might bias the results. As discussed in the next section, these limitations affect not only the methodological soundness of the studies but also their feasibility in real-world settings and their potential for clinical acceptance.

Studies Reporting Higher Predictive Metrics: Limitations

One of the main limitations in comparing these studies is the lack of standardized evaluation metrics as shown in Table 7. Consistent reporting of AUROC would be beneficial, as it would highlight the model's ability to distinguish between a random positive instance and a random negative instance, and is particularly suitable for imbalanced datasets, which is often the case for ECOPD prediction. Additionally, reporting the F_1-score, which represents the harmonic mean of precision and recall, would be valuable, since accuracy alone can be misleading in imbalanced settings. Nonetheless, we compare studies reporting similar metrics, where possible.

XSL•FO
RenderX

Table . Summary of prediction results and limitations.

Study (year)	Small cohort (≤50)	Prediction window	Main results	External validation	Balanced dataset	Explainability
Wu et al [19] (2021)	No	7 days ahead	AUROC[a]=0.97, accuracy=93.6%	No	Yes	Yes (feature importance)
Merone et al [20] (2017)	Yes	Detect onset	Accuracy=98.4%, F_1-score=94.0	No	No	No
Atzeni et al [21] (2022)	No	1 day ahead	AUC[b]=0.82 - 0.90	No	No	Yes (SHAP[c])
Yin et al [22] (2024)	No	1 - 3 days ahead	AUROC=0.97 (k=1)	No	Yes	Yes (feature importance)
Fernandez-Granero et al [23] (2018)	Yes	~4.4-day margin	Accuracy=87.8%, F_1-score=0.8	No	No	No
Wu et al [17] (2022)	No	7 days ahead	Accuracy=72.4%, F_1-score=62.9%	Yes	No	Yes (feature importance and SHAP)
Kronborg et al [24] (2021)	Yes	Prodromal classification (14 days)	AUC=0.95	No	No	No
Fernandez-Granero et al [25] (2015)	Yes	~5 days ahead	Accuracy=75.8%	No	No	No
Nunavath et al [26] (2018)	No	1 - 3 days ahead	Accuracy=88% (3 days)	No	No	No
Crooks et al [27] (2021)	Yes	~3 days ahead (alerts)	Alerts 3.4 days early	No	No	No
Kolozali et al [28] (2023)	No	1 day ahead	Accuracy=38.7%, F_1-score=0.19	No	No	No
Shah et al [29] (2017)	No	7 days ahead	Mean AUC=0.68	No	No	No
Orchard et al [30] (2018)	No	1 day ahead	AUC=0.74	No	No	No
Van der Heijden et al [31] (2014)	Yes	1 day ahead	AUC=0.82 - 0.90	Yes	No	No
Mohktar et al [32] (2015)	Yes	Next-day prodromal	Accuracy=71.8%	No	No	Yes (feature importance)
Jin et al [33] (2018)	Yes	Prodromal classification	Accuracy=~75%	No	No	Yes (feature importance)
Lin et al [18] (2020)	Yes	30-day readmission	Sensitivity=63%, precision=38%	No	No	No
Moraza et al [34] (2025)	No	3 days ahead	AUROC=0.89 - 0.91	Prospective	No	Yes (SHAP)
Patel et al [35] (2021)	No	7 days ahead	Sensitivity=97.9%, NPV[d]=99.8%	No	No	No
Hsiao et al [36] (2023)	Yes	7 days ahead	Accuracy=0.94	No	No	No

[a]AUROC: area under the receiver operating characteristic curve.

[b]AUC: area under the curve.

[c]SHAP: Shapley Additive Explanations.

[d]NPV: negative predictive value.

Table 7 outlines the other limitations that were identified in our review. This includes small cohort sizes, the absence of external validation, the use of balanced datasets, limited explainability, and heterogeneity in prediction windows. Overall, these factors limit the real-world feasibility and clinical application of the proposed models.

The highest accuracy is reported in studies by Wu et al [19], Merone et al [20], and Hsiao et al [36]. However, as none of these studies included external validation on an independent cohort, the risk of overfitting remains high. This concern is particularly relevant in the study by Merone et al [20] and Hsiao et al [36], which involved very small sample sizes of 22 and 13

XSL•FO
RenderX

participants, respectively. In contrast, while the sample size in the study by Wu et al [19] is larger, a subsequent study using the same platform [17] performed external validation and reported a noticeable drop in performance. Moreover, a study by Wu et al [19] used a balanced dataset, which does not reflect real-world class distributions, thereby further limiting the reliability of the reported results. This highlights how larger cohorts and independent validation are needed for real-world feasibility. Overall, small cohorts, artificially balanced datasets, a lack of external validation, and limited model interpretability hinder the real-world applicability of current predictive models.

The highest AUC scores have been reported in studies by Yin et al [22], Kronborg et al [24], and van der Heijden et al [31]. Specifically, Yin et al [22] did not perform external validation and relied on a balanced dataset, while Kronborg et al [24] did not perform any prediction but only classified prodromal phases, and did not validate their results on an independent cohort despite the small sample size. Additionally, Yin et al [22] and van der Heijden et al [31] focus on one-day-ahead predictions, which may not provide enough time for intervention. Thus, the main limitation of these studies is their limited real-world applicability.

Due to the substantial heterogeneity across studies (Table 7), no consistent conclusion can be drawn regarding whether shorter or longer prediction windows lead to improved model performance. Nonetheless, these very short prediction windows offer limited opportunities for preventive intervention. For example, early administration of corticosteroids (oral or inhaled) has been shown to shorten the duration of exacerbations and reduce the risk of hospitalization [48]. Therefore, the primary goal should be to predict exacerbations sufficiently early to enable timely clinical intervention. Ideally, predictive models should identify the risk of exacerbation within a window of 1 to 10 days before the onset. Prediction windows that are too short (eg, 1 - 2 days) may not provide adequate time for intervention, depending on the patient themselves and the severity of the exacerbation, while windows that are too long (eg, over 10 days) may incorporate excessive noise and reduce model reliability. Nevertheless, this remains uncertain, as the optimal prediction window may vary significantly between individuals. A lead time of 2 days could be sufficient in some cases, depending on patient-specific factors and the severity of the exacerbation. Thus, personalization is key.

Personalization

Current COPD exacerbation prediction models often lack personalization. For biomedical applications, tailoring models to individual patients is crucial for improving prediction accuracy and enabling more effective interventions. In COPD-specific applications, accounting for intersubject variability and disease progression is essential, as models trained offline may struggle to adapt to changing patient states over time. In the study by Merone et al [20], parameters are optimized using data from similar patients, while Patel et al [35] incorporate a 2-week learning phase to establish a personalized baseline. While both models achieve good results, they do not provide a comparison to population-level models. In contrast, Kolozali et al [28] include this comparison, demonstrating improved accuracy and F_1-score for the personalized model over the general one. Finally, Atzeni et al [21] attempted to cluster patients, identifying 2 distinct groups. Cluster 1 includes patients with milder COPD, characterized by higher median PEF values and mild-to-moderate disease severity. In contrast, Cluster 2 consists of patients with more severe COPD who reported going out fewer days per week. Despite these differences, models trained on the entire dataset and evaluated separately on each cluster performed similarly to cluster-specific models.

Devices

One research question of this review examines the types of wearable IoT devices used for the RM of COPD. In the last decade, wearable devices, IoT sensors, and AI-enabled technologies have increasingly been recognized as invaluable instruments, allowing continuous, noninvasive, and real-time monitoring of diseased conditions and health [49]. Since COPD is chronic, it is essential to gather data continuously to detect trends and track disease progression. This is where wearable devices and home sensors come in handy to enable continuous RPM. This approach ensures that data collection happens passively, without requiring active involvement from patients, who are often older adults. Nevertheless, 2 key points emerged following the article screening.

First, wearable devices are primarily used in studies that analyze changes in vital parameters during prodromal periods [37-42]. Thanks to the high granularity of the collected data, subtle deviations from baseline can be highlighted before, during, and after exacerbation phases. However, these high-frequency data are often leveraged for modeling purposes rather than for early prediction.

Second, although recent RM approaches increasingly incorporate wearable devices that enable near-continuous remote collection and transmission of physiological data, research integrating these data streams into predictive models remains limited. So far, research combining RM and continuous data acquisition via IoT devices is still in its early stages. The few studies that integrate wearable devices with prediction models—such as [17-19,21,28,36]—typically rely on summary statistics, thereby losing the granular insights offered by high-frequency continuous data.

The current literature is limited by a lack of standardization in both device usage and the reporting of sampling frequency. Therefore, there is no evidence yet to draw conclusions on which is the most suitable device, or even to determine whether continuous data improves outcomes with respect to sampled data. Additionally, the frequent omission of raw sampling frequency represents a critical methodological gap. Reporting sampling frequencies should therefore be established as a reporting standard in future RPM research.

Finally, although wearable devices enable out-of-home monitoring, this review focused on in-home monitoring. This focus reflects the available published literature rather than the application of exclusion criteria related to out-of-home monitoring. Indeed, no search criteria excluded out-of-home monitoring. This outcome likely mirrors the typical daily

XSL•FO
RenderX

routines of many patients with COPD rather than a lack of interest in out-of-home monitoring. COPD predominantly affects older patients with reduced mobility and advanced disease stages, often affected by various comorbidities, such as diabetes, cardiovascular diseases, and/or cancer. As a result, in-home monitoring enables more continuous, reliable, and clinically meaningful data collection while minimizing patient burden and adherence issues. That said, we fully acknowledge that out-of-home monitoring remains an important and underexplored area, particularly for earlier disease stages or more active patients.

Models and Future Directions

As discussed above, most studies rely on ML techniques that require substantial human effort for feature engineering and often fail to capture temporal patterns, which may be significant on their own. van der Heijden et al [31] showed that dynamic Bayesian networks, learned from small, sparse clinical time series using structural expectation-maximization and bootstrapping, can accurately predict COPD exacerbations and are suitable for use in chronic disease management tools. Similarly, Nunavath et al [26] used a Long Short-Term Memory model to predict the health conditions of patients with COPD one day ahead with an accuracy of 84.12%. Thus, proving that neural networks, especially Long Short-Term Memory, show strong potential for remote COPD monitoring and decision support. However, both approaches rely on once-daily measurements, limiting their ability to capture high-resolution temporal dynamics. This limitation suggests that alternative pattern mining and time-series analysis techniques should be explored to assess whether finer-grained temporal data can further improve prediction accuracy.

It is also crucial to note that time-series analysis is particularly critical in small-data clinical settings. However, when compared with traditional ML techniques, time-series approaches may present important drawbacks, including limited explainability and an increased risk of overfitting when applied to small datasets. Additional challenges may include sensitivity to noise and missing data, which are frequent when data come from wearable sensors. Despite these limitations, when carefully designed and validated, time-series approaches hold significant promise for improving exacerbation prediction models.

In traditional ML pipelines, feature engineering and selection are crucial, and they often rely on domain knowledge. However, COPD symptoms and progression may have complex patterns that are difficult to handcraft into features. Therefore, it is hard to identify quantitative features to improve the prediction's outcome. To address these limitations, recent research has explored self-supervised learning (SSL) techniques, which not only can automatically extract latent features from biomedical signals, but also leverage a massive amount of unlabeled data, thus avoiding manual labeling. In SSL frameworks, models are trained using pretext tasks such as masked prediction, contrastive learning, or next-step prediction, and the learned representations can later be fine-tuned on smaller labeled datasets for downstream tasks. This paradigm has been shown to improve generalizability and robustness, making SSL a promising approach for COPD exacerbation forecasting.

Self-supervised learning has been successfully applied in many fields, such as natural language processing, computer vision, speech recognition, and robotics. In medical research, computer vision is the most investigated area [50]. Most existing COPD exacerbation studies focus on supervised learning with labeled datasets of vital signs, symptoms, and activity levels. For instance, studies typically involve random forests, survival analysis, or neural networks trained on labeled datasets to predict exacerbations by tracking vital parameters such as respiratory rate, oxygen saturation, and HR. However, as discussed, labeling exacerbations is not an easy task due to the conflicting and subjective definitions of the event. In this framework, SSL relies on unlabeled data or, more precisely, it does require labels but not human labeling, since pseudolabels are created during the pretext tasks. In pretext tasks, pseudolabels are used for representations that are generated automatically by considering the attributes of the dataset [51]. Still, even if not labeled, the large-scale dataset should contain lots of ECOPD events.

Some recent studies explore unsupervised or self-supervised approaches in medical anomaly detection, suggesting that these methods could provide useful features to improve early detection in COPD if adapted effectively for health care data structures. Several recent studies are indeed exploring self-supervised approaches for detecting and predicting COPD exacerbations or related anomalies, particularly focusing on imaging data and anomaly detection methods. Almeida et al [52] developed a self-supervised anomaly detection framework that identifies abnormal lung regions in patients with COPD, using computed tomography imaging and creating an "anomaly map" for lung regions. This framework allows for early detection of variations in lung health and highlights phenotypic manifestations such as airway disease and emphysema. This approach leverages self-supervised learning to capture data complexity without requiring detailed labels, making it practical for diverse, heterogeneous COPD presentations. The cOOpD study (derived from COPD and out-of-distribution [OOD] concepts) [53] poses COPD classification as an anomaly detection problem, applying contrastive learning to computed tomography scans of healthy lungs to establish a baseline of "normal" lung characteristics. The study leverages this baseline to identify deviations in patients with COPD, which is especially helpful in the absence of labeled exacerbation events. The study demonstrated promising applications in phenotyping COPD and predicting declines in lung function by detecting early abnormal patterns in lung images.

With some effort, SSL techniques can be applied to time series signals, such as those extracted from wearable devices, to achieve early prediction of ECOPD without the need for labels. For instance, recent work by Google [54] introduced a Large Sensor Model with adaptive and inherited masking, a novel SSL framework designed to learn robust representations directly from incomplete and heterogeneous wearable sensor data. Although not developed specifically for COPD, such a framework could be pretrained on large-scale unlabeled wearable data and subsequently fine-tuned, in downstream tasks, for ECOPD prediction. This approach may be particularly advantageous in real-world clinical settings, where sensor data

XSL•FO
RenderX

are often missing or irregular and annotated exacerbation events are limited.

Comparison With Prior Work

Similar systematic reviews have already been published, but substantial differences will now be discussed.

Sanchez-Morillo et al [55] published a systematic review of existing algorithms for the detection of exacerbations and clinical decision-making in the context of COPD and asthma. The article collects papers published between 2005 and 2015. First, the focus is not exclusively on COPD; second, it does not cover RM and IoT sensors, and furthermore, it is now outdated, not including the influence of environmental factors on ECOPD.

Al Rajeh and Hurst [56] conducted a systematic review on the effectiveness of monitoring physiological variables to predict ECOPDs, with a search updated until 2016. Out of 15 studies, 9 studies showed a reduction in SpO2 prior to exacerbation onset, 3 studies for peak flow, and 2 studies for respiratory rate reported a significant variation prior to or at exacerbation onset [56]. But exploring the significance of changes in variables in prodromal periods does not cover the predictive frameworks.

Finally, Glyde et al [57] published a dual narrative synthesis. One part focuses on RCTs evaluating RPM interventions aimed at treating or improving acute exacerbations of chronic obstructive pulmonary disease (AECOPD) and asthma, while the other examines ML models combined with RPM to predict AECOPD, with most studies assessing accuracy using retrospective data. In contrast, our review broadens the scope by including details on sensing technologies, real-world applicability, and future directions. We also present studies investigating changes in physiological variables during the prodromal phases of AECOPD, and focusing only on COPD.

Limitations

The main limitation of the present work is that data heterogeneity prevented a formal meta-analysis. Moreover, although the literature search was comprehensive, only a few studies met the inclusion criteria, making it difficult to draw statistically robust conclusions.

Conclusions

RQ1: Physiological and Environmental Variables, Data Collection, and Device Use

The review of studies modeling changes in physiological parameters during the prodromal phases of AECOPD highlights the importance of HR and oxygen saturation. Variations over time in these parameters appeared more discriminative than their absolute values. Environmental exposures were also found to have a significant impact on the incidence of exacerbations; however, these data remain underused. We therefore suggest that multimodal data integration represents a promising strategy for further improving ECOPD prediction.

Recently, there has been a shift toward using parameters measurable through wearable devices, reflecting the growing emphasis on continuous and noninvasive monitoring in COPD management. However, there is currently no standardization in device types, data acquisition protocols, and reporting of sampling frequency, limiting comparability across studies. Furthermore, despite the use of continuous monitoring, most studies rely on aggregated features and therefore do not fully exploit the granularity of the collected data.

RQ2: ML Approaches, Metrics, and Exacerbation Definitions

Numerous models have been developed for the prediction of ECOPD, with some demonstrating high performance. However, the absence of standardized output metrics hinders meaningful comparison across studies. In addition, key aspects such as external validation, real-time deployment, and the choice of prediction windows remain underexplored. The lack of a unique definition of ECOPD complicates model training and evaluation, as detection is often subjective and symptom-based. While personalization and the use of high-granularity data show potential for earlier detection, these approaches require more evidence to establish their effectiveness.

RQ3: Synthesis, Limitations, and Future Directions

Bringing these findings together, extracting meaningful patterns from high-frequency physiological and environmental data using IoT sensors could enable automated RM of COPD. Integrating time-series analysis with personalized baselines, along with ensuring external validation in independent cohorts and model interpretability, are critical next steps. Indeed, the lack of external validation and interpretability remains a major barrier to the application of AI models in clinical practice. Furthermore, many studies rely on small cohorts and, in some cases, artificially balanced datasets, which further limits their generalizability to real-world settings.

If implemented within a reasonable timeframe before symptom escalation, such models could allow timely interventions, potentially mitigating exacerbations and improving quality of life for patients with COPD, while also reducing the associated economic burden.

Acknowledgments

Generative artificial intelligence (AI) was not used in any portion of the manuscript generation. Nonetheless, grammar, syntax, and sentence-construction were checked with ChatGPT, DeepL Write, and Grammarly.

Funding

This research project was co-funded by the European Union (ERDF) via Interreg Meuse-Rhine (grant ID IMR6-00019).

Abstract

Background: Hearing loss affects approximately 432 million adults globally, with Deaf individuals representing a distinct linguistic and cultural minority that faces significant barriers to accessing health information. These challenges contribute to health disparities by limiting preventive education and timely health interventions.

Objective: This scoping review examines the effectiveness of digital communication technologies in promoting health literacy, awareness, and health-related skills among Deaf adults and children.

Methods: A comprehensive literature search was conducted across 5 major databases: MEDLINE, Embase, Scopus, Web of Science, and PubMed, focusing on peer-reviewed studies published in English within the past 10 years. Seventeen studies were included, encompassing a variety of research designs, including randomized controlled trials, cross-sectional surveys, and mixed methods approaches. Data extraction focused on intervention type, outcomes, and target populations.

Results: Findings indicate that video-based interventions are the most prevalent and effective, leveraging sign language, subtitles, and animations to enhance accessibility and comprehension. These digital tools improved health awareness, knowledge acquisition, and the practical application of health-related skills across both adult and child populations. Interventions ranged from stroke preparedness and cancer education to breast self-examination and cardiopulmonary resuscitation training. Social media platforms, SMS text messaging campaigns, and eHealth programs were also identified as effective in promoting preventive health behaviors. Despite these promising outcomes, several challenges remain, including limited digital literacy, inconsistent access to technology, and a lack of culturally and linguistically appropriate content. Additionally, most studies were geographically concentrated in the United States, with a limited number of high-quality randomized trials.

Conclusions: This review highlights the transformative potential of accessible digital technologies to reduce health disparities and promote health equity among Deaf individuals. Future research should prioritize inclusive, culturally sensitive, and user-centered designs and explore emerging platforms to maximize engagement and improve health outcomes.

KEYWORDS

deaf; digital; health; communication; literacy; Deaf individuals

Introduction

Hearing loss affects an estimated 432 million adults globally, representing over 5% of the world's population [1]. Among them, the Deaf population stands out as a distinct linguistic and cultural minority, enriched with its own traditions, values, and sign languages as the primary mode of communication [1]. The term "deaf" refers to individuals with profound hearing loss without the support of amplification devices in an audiological context. In contrast, the term "Deaf" carries a more specific cultural and linguistic identity within the Deaf community [2]. Despite this distinction, communication barriers persist and continue to pose significant challenges particularly in accessing timely, accurate, and critical health information. This gap in health communication not only limits access to preventive health education but also hinders timely action in managing or avoiding diseases [2]. For example, a scoping review from Rogers et al [3] found that Deaf individuals who use sign language reported suboptimal patient experiences, ineffective communication, unsatisfactory interactions with health care providers, and a lack of culturally competent health care professionals.

XSL•FO
RenderX

The issue of health literacy becomes even more pressing among Deaf children. Compared to adults, Deaf children are at heightened risk of health complications due to their developing immune systems. Currently, an estimated 34 million children live with hearing loss, and alarmingly, 60% of these cases are due to preventable causes [4]. Health literacy, defined as the capacity to obtain, process, and understand basic health information and services, plays a pivotal role in empowering Deaf children with the knowledge and skills to adopt preventive health behaviors and advocate for their well-being. Without equitable access to health education, Deaf individuals, both children and adults, remain vulnerable to adverse health outcomes. A recent study by Friedman et al [5] highlights that Deaf individuals are approximately 7 times more likely to experience lower health literacy compared to their hearing counterparts. This disparity is exacerbated by the lack of accessible health information in sign language and other appropriate formats, creating significant obstacles that contribute to poorer health outcomes, increased morbidity, and higher mortality rates within the Deaf population [6].

One of the most critical areas affected by limited health literacy is the prevention and management of chronic noncommunicable diseases. Noncommunicable disease, including cardiovascular diseases, diabetes, chronic respiratory diseases, kidney disease, and cancers, constitutes a major public health challenge, disproportionately affecting aging populations and contributing to over 41 million deaths annually worldwide [7-9]. These diseases are largely preventable through early intervention and lifestyle modifications, such as regular exercise, balanced nutrition, and reduced tobacco and alcohol use [10,11]. However, to adopt and sustain these preventive behaviors, Deaf individuals must first have access to comprehensible and culturally appropriate health information.

Amid the rapid advancement of technology in health care, digital solutions collectively termed eHealth have emerged as transformative tools for health promotion and disease prevention [12,13]. eHealth encompasses a broad range of digital platforms, including websites, mobile apps, social media, videos, and ebooks, offering unprecedented access to health education [14,15]. For Deaf individuals, digital communication technologies provide an opportunity to overcome traditional barriers by delivering health information through accessible mediums such as sign language videos, visual aids, and captioned content [16]. Furthermore, health care institutions and professionals can leverage these platforms to disseminate public health messages, promote preventive practices, and enhance disease awareness within the Deaf population [17].

Despite these advancements, there remains a notable gap in the literature concerning how digital communication tools are used to promote health literacy and health communication among both Deaf adults and Deaf children. Digital health literacy refers to the ability to seek, understand, appraise, and apply health information using digital technologies [18]. While this competency is essential for all individuals in an increasingly digital world, Deaf populations, defined here as individuals who identify culturally and linguistically and use sign language as a primary mode of communication, face unique challenges. Existing health interventions often fail to consider the language preferences, literacy levels, and visual learning styles of deaf users [18,19]. Therefore, a critical gap persists between technological availability and meaningful health engagement for Deaf adults and children. These 2 groups have distinct needs and preferences in accessing digital health information. Adults often engage with a variety of digital resources, including articles, social media, and research publications, while children benefit more from interactive and visually engaging educational content [20,21].

In this review, communication refers to the ways in which individuals access, interpret, and apply health information, particularly through digital platforms. This is closely aligned with key aspects of health literacy and digital health literacy, which involve understanding information, navigating digital tools, and expressing health-related needs or questions. The central aim of this review is to examine and synthesize existing evidence on the use of digital communication tools to enhance health literacy among Deaf adults and children. The review focuses on understanding how digital platforms, particularly those incorporating sign language, captions, and visual content, facilitate access to health information, knowledge acquisition, and the development of practical health skills. The central concepts are therefore: (1) the Deaf population as a distinct linguistic and cultural group with unique communication needs; (2) digital health literacy, which encompasses the ability to access, understand, and apply health information using digital tools; and (3) the role of digital technologies, particularly video-based and interactive formats, in promoting health education, awareness, and preventive behaviors. By highlighting differences and similarities across age groups, formats, and outcomes, the review aims to provide evidence-based recommendations to improve health communication and reduce disparities among Deaf individuals.

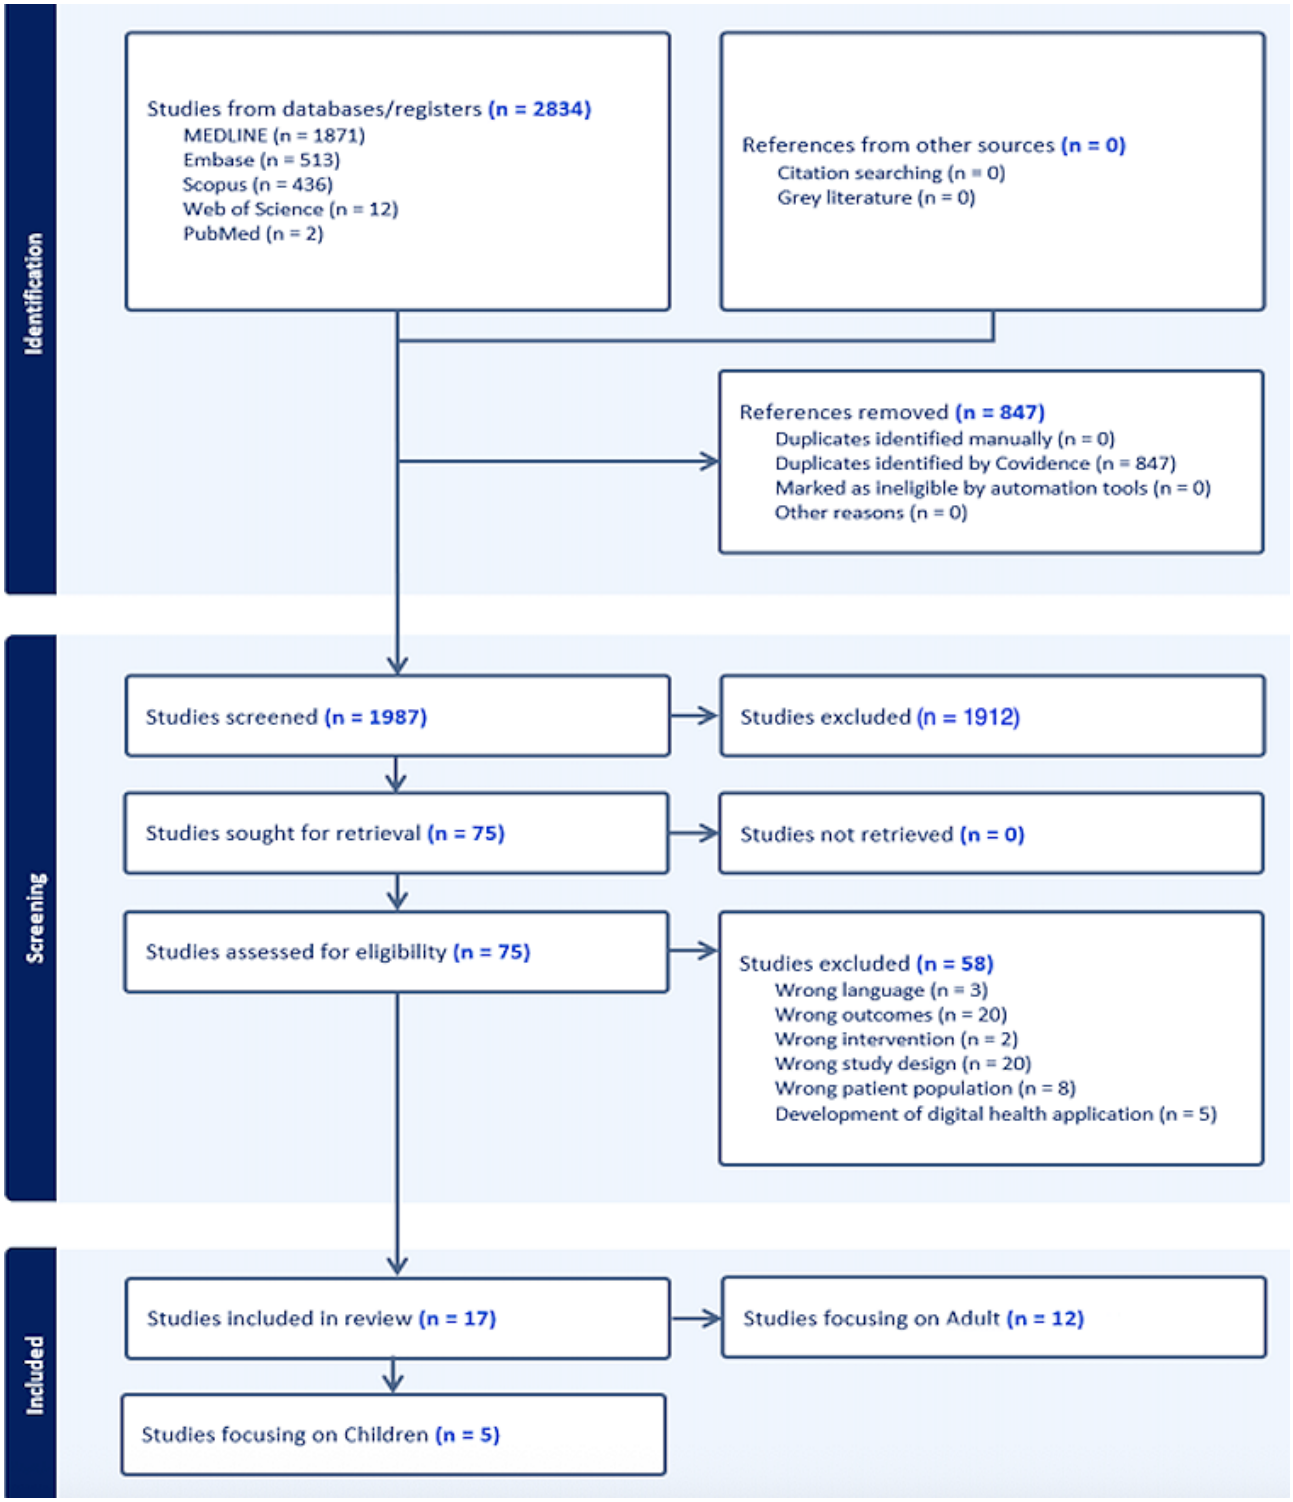
Methods

This review, registered at OSF [22], was guided by the central research question: “Is digital technology effective in promoting health prevention among adults and children who are deaf?” To address this question, a comprehensive and systematic search was conducted across 5 major electronic databases: MEDLINE, Embase, Scopus, Web of Science, and PubMed. The search was limited to peer-reviewed studies published in English within the past 10 years to ensure relevance to the evolving landscape of digital health technologies. Boolean operators were applied strategically to broaden or refine the search results, with “OR” used to connect synonymous terms and “AND” used to focus on specific intersections of interest. Additionally, Medical Subject Headings were incorporated to systematically capture 3 key concepts: Deafness and hard-of-hearing, digital communication technologies, and health promotion strategies. The complete list of Medical Subject Headings terms and search keywords is presented in Multimedia Appendix 1.

All identified studies were screened rigorously according to predefined inclusion and exclusion criteria. The selection process was managed using Covidence, an established software platform designed to facilitate systematic review workflows, including study screening and data extraction. Titles and

XSL•FO
RenderX

abstracts were screened independently by 2 reviewers (TH and ZC), with any disagreements resolved by a third and fourth reviewer (JR and UP). A PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram was developed to provide a visual summary of the study selection process. Following screening, data extraction was conducted systematically and recorded in an Excel spreadsheet. Extracted data included key information such as author(s), study objectives, study design, population characteristics, methodology, key findings, and study conclusions. This structured approach enabled a comprehensive synthesis of current evidence on the use of digital communication tools in promoting health literacy and preventive health behaviors among Deaf individuals.



Results

Results of Database Search

As a result of the comprehensive database search, a total of 2834 records were identified, and 847 records were removed. During the title and abstract screening phase, 1987 records were screened, and 1912 records were excluded, leaving 75 full-text articles deemed as eligible. During the full-text article review, 17 studies were included, and 73 studies were excluded, based on the reasons mentioned in Figure 1. This study identified 17 articles that were eligible to be included in this review. Of the 17 included studies, 5 (29%) focused on children (aged <18 y), while 12 (71%) focused on adults (aged >18 y). Tables 1 and 2 summarize the 17 articles [23-39] that met the inclusion criteria.

Table . Summary of adult studies reviewed.

Study	Country	Objectives	Sample size, n	Study population	Study design	Interventions/digital technology platforms	Data collection methods	Findings/outcomes
Crowe [37]	United States	To explore the potential benefits and challenges involved with TMH[a] with deaf individuals. In particular, the study seeks to explore whether Deaf individuals think that TMH services are a viable alternative to traditional face-to-face psychotherapy	422	• Deaf adults who used ASL[b] as their primary language (>18 y old)	Descriptive study	All participants will complete a questionnaire about their knowledge and use of TMH services. Platform: N/A[c]	Questionnaire and TMH services	• The use of TMH services has been demonstrated to be effective and efficacious with individuals who experience mental health challenges. • The findings suggest that Deaf individuals are open to receiving these types of services, especially when they have been unsuccessful in obtaining services elsewhere.

Study	Country	Objectives	Sample size, n	Study population	Study design	Interventions/digital technology platforms	Data collection methods	Findings/outcomes
Engelberg et al [36]	United States	To evaluate the impact of a healthy humor messaging strategy on cancer knowledge and health promotion among the Deaf community and assess immediate changes in cancer knowledge, retention of newly acquired knowledge, person-to-person promotion of a Deaf-friendly educational website, and repeat visits to the website	62	• Deaf adults who used ASL as their primary language (>18 y of age)	Pretest-posttest study	The participants watched video clips that included health messages about various cancer topics, followed by a joke signed in ASL with English subtitles. Platforms: Internet (to access video clips), video clips	Surveys	• The participants in this healthy humor messaging study had significant improvements in their health knowledge among participants in the Deaf community, both immediately postintervention and 1 wk later in nearly all topics tested. • Besides improvement in knowledge, participants reported that combining the health and humor messages increased their motivation to seek more information and to share it with others.
Ferguson et al [35]	United Kingdom		203		RCT[e] (randomized, single-blind)	Implementation of a series of short interactive RLOs for auditory rehabilitation Platforms: DVD, TV, PC, internet	Questionnaires	

XSL•FO
RenderX

Study	Country	Objectives	Sample size, n	Study population	Study design	Interventions/digital technology platforms	Data collection methods	Findings/outcomes
		To develop a series of short interactive online resources (RLOs[d]) for auditory rehabilitation, assess the accessibility, take-up, acceptability, and adherence of the RLOs, and evaluate the benefits and cost-effectiveness of the RLOs in first-time hearing aid users.		• Adults ages ≥18 y, • First-time hearing aid users, • Spoken English as first language or good understanding of English.				• This study demonstrates the effectiveness of online support in improving auditory rehabilitation outcomes for first-time hearing aid users. The study highlights the importance of providing tailored resources to meet individuals' needs and the potential of technology in enhancing accessibility and adherence to interventions. • The findings contribute to the field of hearing rehabilitation research and provide insights for future developments in patient education and support.
Haricharan et al [33]	South Africa		41				Baseline and exit questionnaires	

XSL•FO
RenderX

Study	Country	Objectives	Sample size, n	Study population	Study design	Interventions/digital technology platforms	Data collection methods	Findings/outcomes
		To assess the effectiveness of the SMS text messaging-based campaign in improving knowledge about hypertension and healthy living among Deaf individuals		• Adults (>18 y of age), communicate via SASL[f]	Pretest-posttest study, convenience sample	The campaign consisted of 20 SMS text messaging with medical information on hypertension and 57 SMS text messaging with information on how to avoid or manage high blood pressure through healthy living. Platforms: Mobile phone, SMS text messaging		• An analysis of participants' knowledge before and after the SMS text messaging campaign showed a significant increase in the overall test score between baseline and follow-up. • This study demonstrates that SMS text messaging is effective in improving Deaf people's knowledge of hypertension and healthy living. It also showed an SMS text messaging campaign to be acceptable to the target population.
Koçak Akgün and İldan Çalım [32]	Turkey		60	• Adult (>18 y of age) Deaf women	Quantitative, Quasi-experimental comparison group research (randomization, single blind)	Use of a BSE[g] training video with sign language for Deaf women Platforms: Video clip, DVD	Questionnaires (Individual Introduction Form, Champion's Health Belief Model Scale)	

XSL•FO
RenderX

Study	Country	Objectives	Sample size, n	Study population	Study design	Interventions/digital technology platforms	Data collection methods	Findings/outcomes
		The study determined that the researcher-developed training video incorporating sign language can significantly enhance breast self-examination (BSE) skills among Deaf women.						• The sign language training video significantly improved the BSE skills of Deaf women, as assessed through an evaluation checklist. • Women in group A who received video training with sign language performed BSE more correctly and completely than the group that received video training without sign language, highlighting the effectiveness of sign language in training video.
Kushalnagar et al [30]	United States	To investigate Deaf women's awareness of genetic testing, specifically BRCA 1/2[h] testing, and their use of eHealth platforms for health-related information.	325	• Deaf women	Cross-sectional study		Questionnaire	

XSL•FO
RenderX

Study	Country	Objectives	Sample size, n	Study population	Study design	Interventions/digital technology platforms	Data collection methods	Findings/outcomes
						The primary data for Deaf women were gathered using the HINTS[i]-ASL, while secondary data for hearing women were drawn from NCI's[j] HINTS 5 Cycle 1 survey. The study used survey items related to awareness of genetic testing and BRCA 1/2 testing, as well as eHealth platform use.		• The study found that Deaf women had lower awareness of genetic testing compared to hearing women. Only 37.6% of Deaf women had heard or read about genetic testing, while 82.6% of hearing women were aware of it. Additionally, only 15.5% of Deaf women had ever had BRCA 1/2 testing. The study also found that Deaf women were more likely to use the internet for health or medical information for themselves and others compared to hearing women.
Meyer et al [29]	Australia						Survey	

XSL•FO
RenderX

Study	Country	Objectives	Sample size, n	Study population	Study design	Interventions/digital technology platforms	Data collection methods	Findings/outcomes
		To seek the perspectives of key stakeholders regarding: (1) how eHealth could help meet the hearing and communication needs of adults with hearing impairment and their significant others and (2) how helpful each aspect of eHealth would be to key stakeholders personally.	Total 123: Adults with hearing impairment (n=39), significant others (n=28), and hearing care professionals (n=56)	• Adults with hearing impairment, significant others of adults with hearing impairment, and hearing care professionals	Group Concept Mapping Study	All participants completed a short online survey before completing one or more of the following activities: brainstorming, sorting, and rating. Platform: N/A		

XSL•FO
RenderX

Study	Country	Objectives	Sample size, n	Study population	Study design	Interventions/digital technology platforms	Data collection methods	Findings/outcomes
								• The research findings demonstrate the broad range of clinical applications of eHealth that have the capacity to support the implementation of patient- and family-centered hearing care, with self-directed educational tools and resources typically being rated as most helpful. • The study findings highlight the potential of eHealth interventions to support patient- and family-centered hearing care. • The use of ICTs[k] can enable a more biopsychosocial approach to hearing health care and facilitate

XSL•FO

Study	Country	Objectives	Sample size, n	Study population	Study design	Interventions/digital technology platforms	Data collection methods	Findings/outcomes
								the education and involvement of significant others in the hearing rehabilitation process.
Morris et al [28]	United States	The objective of the study was to examine the use of social media during public emergencies by people with disabilities	198	• Adults (>18 y of age) with any type of disability	Descriptive study	Participants will receive either web, voice phones interviews, or questionnaire with a series of questions. Platform: N/A	Web, voice phones interviews, questionnaire	

XSL•FO
RenderX

Study	Country	Objectives	Sample size, n	Study population	Study design	Interventions/digital technology platforms	Data collection methods	Findings/outcomes
								• The study shows that there are no significant differences in the use of social media during public emergencies by people with disability types. • The study also highlights the low engagement of social media during emergencies for both groups. • The role of social media in emergency communications is still not well established. These last 2 results suggest that effective emergency communications strategies need to rely on multiple media types and channels to reach the entire community.
	United States	82

Study	Country	Objectives	Sample size, n	Study population	Study design	Interventions/digital technology platforms	Data collection methods	Findings/outcomes
Meyer et al [29]		To investigate the acceptance and outcomes of a 6-wk supplemental eHealth education and support program for hearing aid management among parents of young children with hearing aids		• Parents of children with a behind-the-ear hearing aid	Pilot RCT (single-blinded)	The intervention of the study is an eHealth Program that lasted for 6 wk. It included weekly phone check-ins and watching a series of 8 videos, with two videos per week during weeks 2 through 5. Platforms: Internet, video clips, eHealth program	3 sets of questionnaires	• The study found that the eHealth program for hearing aid management provided benefit to parents. The intervention group showed significantly greater gains over time in terms of knowledge, confidence, perceptions, and monitoring related to hearing aid management. • However, significant differences between groups were not observed for hearing aid use time.
Pettersson et al [26]	Sweden	To compare use and perceived difficulty in the use of eHealth among people with and without impairment, and how different types of impairment were associated with perceived difficulty in the use of eHealth.	Background characteristics for participants with impairment (n=1631) and participants without impairment (n=1084)	• People with self-reported impairment	Cross-sectional comparative design	Platforms: Internet (booking health care appointments online), use of digital identification (Mobile BankID)	47-item questionnaire	

XSL•FO
RenderX

Study	Country	Objectives	Sample size, n	Study population	Study design	Interventions/digital technology platforms	Data collection methods	Findings/outcomes
								• The study shows participants with impairment reported less use and more difficulty in the use of eHealth compared to participants without impairment. People with communication, language, and calculation impairments, and intellectual impairments reported the least use and most difficulty in using eHealth. The hearing-impairment group does not show difficulty in the use of eHealth.
Rothpletz et al [25]	United States		27	• Adults (>55 y of age) who failed a hearing screening participated.	Quasi-experimental study	The participants completed the online modules on the IHHC websites Platform: Internet, computer, mobile	3 questionnaires	

XSL•FO
RenderX

Study	Country	Objectives	Sample size, n	Study population	Study design	Interventions/digital technology platforms	Data collection methods	Findings/outcomes
		This study measured help-seeking readiness and acceptance of existing IHHC[1] websites among a group of older adults who failed a hearing screening (phase 1). It also explored the effects of brief training on participants' acceptance of IHHC (phase 2).						• The study demonstrates the effectiveness of IHHC resources especially in older adults who failed a hearing screening. • In the training group, there was a significant increase in scores on the health care knowledge subscale from the baseline to the final evaluation, indicating that participants believed they were more knowledgeable about how to manage their hearing loss after taking the IHHC class.
Thorén et al [23]	Sweden	To show that the internet can be used in the rehabilitation of hearing-aid users.	76	• Experienced hearing-aid users, ranging in age from 26 to 81 y (mean 69.3 y)	RCT (open-blinded)		Questionnaires	

XSL•FO

Study Characteristics

The studies included in this review employed a diverse array of research designs, reflecting both methodological rigor and adaptability to the research context. Among the 17 studies reviewed, randomized controlled trials (RCTs) emerged as the most frequently used design, with 5 studies adopting this approach [23,25,27,32,34]. Notably, 4 of these were single-blinded RCTs [25,27,32,34], while 1 used an open-blinded format [23]. Beyond RCTs, the studies encompassed descriptive research [38], cross-sectional designs [26,30], group concept mapping [24], pretest-posttest evaluations [31,33], and quasi-experimental studies [39], offering a comprehensive methodological landscape to explore the effectiveness of digital health interventions among Deaf and hard-of-hearing populations. In terms of data collection approaches, the studies predominantly relied on quantitative methodologies, with 13 studies focusing on numerical outcomes and statistical analyses [23,25-27,30-37,39]. Four studies adopted qualitative methods to capture nuanced insights from participants [24,28,29,38]. Notably, Morris et al [28] stood out by employing a mixed methods approach that combined both interviews and questionnaires, providing a more holistic understanding of participant experiences.

Questionnaires were the most commonly used tool for data collection, featured in 13 studies [23,25-27,30-37,39], underscoring their practicality in assessing knowledge, attitudes, and behaviors in digital health interventions. Additionally, 4 studies implemented surveys to collect data [26,29,30,36], while 3 leveraged interviews to gather in-depth qualitative data from Deaf individuals [28,32,39]. This variety in data collection methods highlights the importance of tailoring research tools to ensure accessibility and inclusivity for Deaf individuals. All included studies were published within the past decade, emphasizing the growing interest and ongoing evolution of digital health technologies in this field. Publication years spanned from 2014 to 2023, with notable contributions in 2014 [28], 2015 [29], 2016 [30], 2017 [31], 2019 [32], 2021 [33], 2022 [34], and 2023 [39]. This distribution reflects a consistent and increasing academic focus on leveraging digital communication technologies to promote health prevention and education among Deaf individuals.

Overview of Health Promotion Outcomes: Comparing Adult and Child Deaf Populations

The differences and similarities between adult and pediatric groups are synthesized in Figure 2, providing an integrated overview of Tables 1 and 2. Building on this, Table 3 presents a comparative analysis of health promotion outcomes, highlighting distinct trends in how the health needs of Deaf adults and children are addressed. Video-based interventions dominated across both groups due to their flexibility, visual appeal, and accessibility features such as American Sign Language (ASL) interpretation and captions. Among adults, health promotion often focuses on chronic disease prevention and management. For example, SMS text messaging-based interventions aim to improve health knowledge in areas such as hypertension and cancer awareness [30,33]. These interventions underscore the priority of preventive health measures and chronic disease education within adult populations. In contrast, interventions for Deaf children focus on the prevention of common acute childhood illnesses and the development of healthy habits from an early age. Audiovisual media have proven effective in improving oral hygiene and increasing school engagement [31,38].

Figure 2. Summary of similarities and differences between Deaf adults and children.

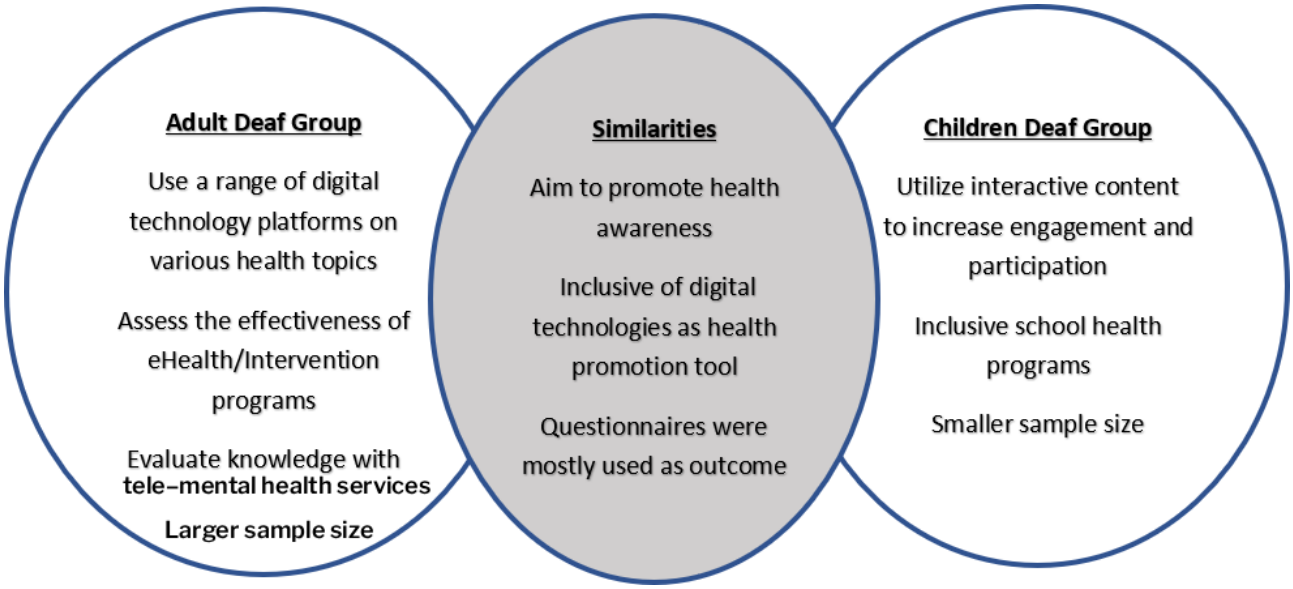

Table . Overview of health promotion outcomes in comparison with adult/children Deaf population.

Health promotion outcomes	In comparison with adult/children Deaf population
Health promotion methods	• Interactive and engaging digital technological tools, predominantly video clips to promote health in adult and children Deaf populations
Health needs and priorities	• Emphasis on prevention of common childhood illnesses in children Deaf population • Focus on early detection in chronic disease in adult Deaf population
Accessibility to eHealth	• Both adult and children Deaf populations reported less use and more difficulty in the use of all eHealth services when compared to people with other various impairments
Health knowledge	• Significantly increase in health knowledge mean score from baseline in adult Deaf population and children populations
Health-related skills	• Higher mean score in health-related practical skills in adult Deaf population and children populations
Engagement	• Improve overall mean school engagement to video-guided educational intervention in secondary school Deaf students

Despite their differing health priorities, both adult and child populations benefited significantly from digital health interventions, particularly in terms of knowledge acquisition and practical skills. Studies have shown that video-based learning can improve both health awareness and competency in life-saving skills like CPR across age groups. Nonetheless, accessibility remains a concern. A cross-sectional study in Sweden revealed that Deaf individuals, particularly those with deafblindness, were less likely to use eHealth services such as online health care appointment booking [26]. This finding

XSL•FO
RenderX

highlights the ongoing challenge of ensuring that digital platforms are inclusive and easy to navigate for Deaf and hard-of-hearing users.

Digital Technology in Communication: Characteristics

The reviewed studies demonstrated a diverse application of digital technologies as communication interventions aimed at improving health outcomes among Deaf individuals. These technologies included video clips, social media platforms, online courses, and SMS text messaging. Among them, video-based interventions were the most prevalently used, offering a versatile medium that integrates visual, auditory, and textual elements to enhance accessibility and comprehension. For example, Engelberg et al [36] used humorous video clips to deliver cancer awareness messages, effectively increasing cancer-related knowledge among Deaf individuals. Ferguson et al [35] implemented short, interactive videos with subtitles to support auditory rehabilitation for first-time hearing aid users. Koçak Akgün and İldan Çalım [32] developed a breast self-examination (BSE) training video incorporating sign language, providing Deaf women with practical, life-saving skills. Similarly, Muñoz et al [27] introduced an eHealth educational program that combined weekly phone check-ins with a series of instructional videos for parents managing young children's hearing aids.

Several studies further enhanced accessibility through the integration of sign language, subtitles, and animations. Ahmadi et al [39] created hygiene education videos for Deaf students, while Asogwa et al [38] used video-guided educational clips to foster school engagement. Kurniawati et al [31] promoted oral hygiene among Deaf children through audiovisual media, and Galindo Neto et al [34] developed a CPR training video that improved life-saving competencies. Springer et al [24] created an interactive stroke preparedness video incorporating ASL, which significantly improved stroke symptom recognition among Deaf students. These varied implementations highlight how video-based technologies have become instrumental in bridging communication gaps and addressing health education disparities among Deaf individuals.

The Effect of Digital Technology on Communication

Health Awareness

Digital technologies have emerged as powerful tools in raising health awareness and disseminating health information tailored to Deaf individuals. The inclusion of accessible features such as sign language, captions, and interactive elements has made health content more relatable and understandable. For instance, Springer et al [24] collaborated with Deaf interpreters and content creators to develop a culturally resonant stroke preparedness video. By transforming stroke education into a song interpreted in ASL, they made complex health messages both engaging and memorable. Similarly, Kurniawati et al [31] used a 2-minute video to promote oral hygiene among Deaf children, fostering awareness and positive behavioral change. Neto et al [34] reinforced health preparedness by offering CPR training through educational videos, equipping Deaf students with critical life-saving skills. Among adults, social media platforms such as Facebook and Instagram have served as channels for increasing health awareness.

A cross-sectional study by Kushalnagar et al [30] found that Deaf women informed about BRCA1/2 genetic testing were significantly more likely to seek health information online (χ^2=10.75, *P*=.001), highlighting the role of digital communication in empowering individuals to advocate for preventive health practices, including BSEs. Similarly, Asogwa et al [38] reported that 27% (56/208) Deaf respondents were more likely than 15% (123/811) participants from other disability groups to use social media for receiving emergency or health-related information.

Overall, the evidence indicates that Deaf individuals are receptive to digital health services, especially when they have been unable to access adequate health information or support through traditional means [37]. This is further illustrated in the findings of the Crowe study on the viability of tele–mental health (TMH) services for Deaf individuals. Participants expressed a clear willingness to engage with TMH, with a mean score of 2.47 (SD 1.83) for willingness to use TMH services themselves.

Education and Health-Related Knowledge

Digital communication technologies have consistently shown significant value in enhancing health knowledge across diverse Deaf populations. These tools provide flexible learning opportunities that overcome traditional barriers to accessing health education. Engelberg et al [36] reported a significant improvement in cancer knowledge among Deaf adults after exposure to an educational video that combined humor with health messaging (mean score increased from 6.63 to 8.84, *P*<.001). This approach not only boosted knowledge retention but also encouraged further health-seeking behavior, with 77% (48/62) of participants motivated to explore additional cancer information. In South Africa, Haricharan et al [33] demonstrated the value of SMS text messaging campaigns in raising awareness of hypertension and promoting healthy living among Deaf adults. Participants' knowledge scores significantly improved following the intervention (*P*=.003), underlining the feasibility of text-based interventions when video is impractical. For Deaf children, Kurniawati et al [31] highlighted the use of audiovisual media in promoting oral health. Knowledge scores rose markedly after intervention, from a mean of 10.39 to 12.73, confirming the role of visual storytelling and multimedia tools in delivering complex health messages to younger audiences.

Application of Health-Related Skills

Beyond raising awareness and disseminating knowledge, digital technologies facilitate the application of practical health skills, empowering Deaf individuals to take actionable steps toward improved health outcomes. Koçak Akgün and İldan Çalım [32] demonstrated the impact of sign language-integrated video instruction on BSE skills among Deaf women. Participants who viewed the sign-supported videos performed BSE more accurately than those without access to sign language support (*P*<.05). This reinforces the importance of accessible instructional content in cultivating life-saving self-care skills. Similarly, Neto et al [34] reported significant gains in both theoretical and practical CPR competencies among Deaf students following exposure to a specialized educational video. Compared with traditional lecture-based instruction, the video

XSL•FO
RenderX

intervention group exhibited higher accuracy in performing CPR, both immediately (P=.035) and after 15 days (P=.026). This finding illustrates how digital education strategies can enhance not only knowledge acquisition but also skill mastery in critical health procedures.

Discussion

Principal Findings

The adoption of digital technologies in health promotion has shown substantial benefits for both Deaf adults and children. These tools, especially interactive video interventions, have enhanced health knowledge, practical skills, and engagement levels within these groups. While the overarching goal remains the same, improving health education and inclusivity strategies, areas of focus, and outcomes differ notably between adult and child cohorts.

For Deaf adults, health promotion initiatives tend to address a broader spectrum of health concerns, including chronic conditions, mental health, and preventive care. Digital platforms such as mobile apps, video-based education, social media campaigns, and TMH services are increasingly leveraged to bridge gaps in health care accessibility. Notably, accessible formats such as sign language interpretation, captioning, and subtitles are essential in enhancing the usability of these interventions [19]. Studies indicate that these tailored approaches not only improve health knowledge but also foster greater engagement and more positive mental health outcomes among Deaf adults [40]. Larger sample sizes in many of these studies allow for broader generalizability of findings, strengthening the evidence base for these interventions. Conversely, health promotion efforts targeting Deaf children often emphasize prevention and early health education, with a focus on fostering positive health behaviors from an early age. Interactive content, such as gamified learning, storytelling videos, and visual-rich tutorials, has proven particularly beneficial in capturing and sustaining attention among younger audiences. School-based programs play a crucial role in this demographic, providing a structured and inclusive environment that encourages peer learning and community involvement [41]. Additionally, the involvement of Deaf role models has been identified as a beneficial practice, offering sociolinguistic and cultural perspectives that complement traditional audiological approaches [41]. However, these studies often involve smaller, localized sample groups, which can limit the generalizability of their findings beyond specific contexts.

Despite the promising outcomes, both Deaf adults and children continue to report lower utilization rates and greater difficulties in accessing eHealth services compared to their hearing counterparts. Barriers include limited digital literacy, inadequate internet access, and the scarcity of culturally and linguistically appropriate content. Questionnaires remain the primary tool for evaluating intervention effectiveness in both populations, ensuring consistency in outcome measurement but also underscoring the need for more diverse assessment methodologies in future research. While digital health tools have successfully enhanced health knowledge and practical health-related skills in both groups, their distinct developmental stages and priorities necessitate tailored approaches. Adults benefit from scalable, wide-reaching interventions that address complex health topics, whereas children require engaging, interactive formats that encourage active participation and early adoption of healthy behaviors. Ultimately, the shared success across both groups lies in the strategic use of accessible digital content. Video-guided educational interventions, in particular, have significantly increased engagement levels, especially among Deaf secondary school students, demonstrating that when designed with inclusivity in mind, digital tools can profoundly impact health outcomes.

The findings of this review highlight the transformative potential of digital communication technologies in advancing health education, awareness, and practical skills within these populations, particularly in contexts where conventional, speech-dependent health services remain inaccessible. Unlike hearing populations, who typically benefit from verbally mediated, face-to-face health communication, Deaf individuals often encounter persistent linguistic and communication barriers that limit access to health information. By prioritizing accessible design and tailoring interventions to the distinct needs of both deaf and Deaf adults and children, digital health initiatives can reduce these inequities and promote health equity. This review identifies a wide range of digital technologies, including mobile phones, personal computers, television, and SMS text messaging, delivered through platforms such as online courses, video-based content, email, and social media, that have been effectively used in health promotion and disease prevention. Effectiveness is conceptualized within an implementation science framework as the real-world impact of digital services on reach, acceptability, and user outcomes, with particular relevance to improving health literacy and advancing digital equity [42].

Nevertheless, while digital technologies show considerable promise in improving health outcomes, their successful implementation depends on overcoming several persistent challenges. Accessibility, digital literacy, and cultural relevance remain key concerns that need to be addressed to ensure the sustainability of these interventions. Leveraging digital communication effectively for Deaf children and Deaf adults presents unique challenges. One major challenge is the lack of accessible content in local sign languages. Many health platforms rely on text-based materials or spoken audio, which are not always suitable for Deaf individuals, especially those with limited reading literacy due to delayed language acquisition. Deaf children, in particular, may face language deprivation if they are not exposed to sign language early, affecting their ability to understand health content. Conversely, Deaf adults may carry long-standing gaps in health knowledge due to years of exclusion from accessible education and health care communication [18].

Conclusion

The reviewed studies illustrate the growing use of digital technologies, particularly video-based platforms, to enhance health awareness, education, and skill development among Deaf adults and children. These interventions, which often integrate sign language, captions, and visual storytelling, have shown

XSL•FO
RenderX

positive outcomes in improving health-related knowledge and enabling practical health actions such as BSE and CPR. Thus, the dominance of video-based interventions may reflect both user preference and gaps in research on emerging platforms. However, despite these promising results, significant digital health literacy gaps remain. Discrepancies persist due to the lack of inclusive design features, such as sign language options, and usability for Deaf individuals. Literacy development gaps are evident as many interventions are stand-alone with little to no follow-up, particularly for those with limited health knowledge. There is a lack of support where Deaf users are not equipped to assess the digital health content or apply information in decision-making contexts. Together, these gaps underscore the need for digital health interventions to move beyond surface-level accessibility. To be effective and equitable, such interventions must be linguistically aligned, developmentally appropriate, cognitively empowering, and embedded within inclusive health systems that recognize the unique needs of Deaf individuals.

Limitations

This review highlights important insights into the use of digital technologies for health promotion among Deaf populations; however, several limitations should be acknowledged. First, most of the studies included were conducted in the United States, limiting the generalizability of findings across different cultural, socioeconomic, and health care contexts. Future research should actively include more geographically and culturally diverse Deaf communities to enhance the global applicability and relevance of interventions. Second, only 3 of the 12 studies employed RCT designs. While observational and quasi-experimental studies offer valuable perspectives, the lack of high-quality RCTs reduces the strength of evidence and the effect of interventions. Future research should prioritize well-designed RCTs with double- or triple-blinded methods where feasible, to minimize bias and enhance the validity of outcomes.

Additionally, several studies relied on outdated technologies such as DVDs and CDs, which do not reflect current digital media usage trends. As digital access evolves rapidly, future interventions should focus on contemporary technologies, including mobile apps, video-based platforms, and interactive tools that are more relevant to today's Deaf populations. Another limitation of this review was the narrow scope of digital technologies considered. While the focus was intentionally placed on broader digital health tools rather than specific social media platforms, this approach may have overlooked the potential impact of emerging platforms like TikTok and Threads. These platforms play an increasingly significant role in health communication, particularly for younger audiences, and warrant further exploration in future research.

Future Research Directions

Despite these limitations, this review emphasizes the significant potential of digital technologies to reduce health disparities and improve health outcomes. To address these challenges, digital health communication must be co-designed with Deaf communities, prioritize sign language-first content, incorporate Deaf cultural perspectives, and be supported by inclusive policies and trained personnel. This approach can bridge the communication gap and promote equitable health outcomes for both Deaf children and adults. Future research could benefit from explicitly incorporating behavioral and communication theories to better explain why certain interventions succeed or fail, particularly as the evidence base grows. Tailoring interventions to the unique language and modality needs of Deaf individuals is likely to enhance engagement, comprehension, and ultimately health outcomes.

Acknowledgments

The authors gratefully acknowledge the institutional support provided by Monash University Malaysia during the preparation of this manuscript. Generative artificial intelligence tools were used in the preparation of this manuscript. Specifically, OpenAI's ChatGPT (GPT-4, April 2024 version) was used to assist with language editing and summarizing text for clarity and brevity. The tool was employed to refine the writing style, shorten sections for word count compliance, and enhance readability. All content was subsequently reviewed and edited by the authors to ensure accuracy and appropriateness.

Funding

This study was supported by the Ministry of Higher Education Malaysia under the Fundamental Research Grant Scheme—Conceptual model of designing contextualized and culturally appropriate digital videos on mental health literacy for the Deaf community in Malaysia (grant ID FRGS/1/2023/SKK06/MUSM/03/2), which funded the preparation of this manuscript. The funder had no role in the design, conduct, analysis, interpretation, or reporting of this study.

Data Availability

The data that support the findings of this study are available from the corresponding author upon reasonable request. The data are not publicly available due to the nature of the study design and data synthesis process.

Abstract

Background: Intraoperative bleeding is a critical event that impacts surgical safety and patient outcomes. Machine learning (ML) has demonstrated potential in prediction tasks, yet its methodological rigor and clinical translation face challenges.

Objective: This scoping review aims to systematically synthesize the current state of development, performance, and validation of ML models for predicting intraoperative bleeding, and to identify key barriers to their clinical implementation.

Methods: Following the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) guidelines, we systematically searched 7 databases (PubMed, Web of Science, Embase, CINAHL, CNKI [China National Knowledge Infrastructure], Wanfang, and VIP [China Science and Technology Journal Database]) from their inception to April 2025. Moreover, 2 reviewers (SY and PZ) independently screened studies, extracted data using the Checklist for Critical Appraisal and Data Extraction for Systematic Reviews of Prediction Modeling Studies (CHARMS), and assessed the risk of bias using the Prediction Model Risk Of Bias Assessment Tool (PROBAST). A narrative synthesis was used for data analysis.

Results: Out of 2651 screened records, 23 studies were included (sample sizes ranging from 48 to 48,543). Tree-based ensemble models (eg, random forests and extreme gradient boosting) were the most frequently used (16/23, 70%), followed by logistic regression (13/23, 57%), and deep learning (11/23, 48%). Model discrimination varied widely (mean area under the curve [AUC] 0.82, SD 0.08, range 0.63 - 0.93). Integration of multimodal data (electronic health records+imaging) was associated with higher performance. However, model validation was often inadequate; only 6 studies (6/23, 26%) performed external validation, and performance often declined (eg, AUC decreased from 0.85 to 0.63 in 1 study). Reporting exhibited selective bias; AUC was commonly reported (19/23, 83%), whereas key classification metrics, such as calibration (10/23, 43%) and precision (4/23, 17%), were often omitted. PROBAST assessment indicated a high risk of bias in all included studies (23/23, 100%).

Conclusions: While ML models demonstrate technical promise for predicting intraoperative bleeding, our PROBAST assessment revealed a universally high risk of bias across all included studies. This fundamental methodological limitation, coupled with a severe lack of external validation and poor transparency in reporting, severely constrains the current clinical reliability of these models. Future research must prioritize prospective multicenter validation, adherence to Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis (TRIPOD) reporting guidelines, and enhanced model interpretability to bridge the gap toward clinical utility.

intraoperative bleeding; machine learning; scoping review; clinical decision support; predictive models

Introduction

Background

Perioperative bleeding is a significant risk factor for surgical procedures and is strongly linked to increased patient mortality, higher rates of postoperative complications, and excessive use of health care resources [1]. Intraoperative bleeding control effectiveness directly impacts both surgical safety and patient outcomes [2]. Excessive blood loss compromises the surgical field. It prolongs the duration of surgery [3] while also

XSL•FO
RenderX

increasing the risk of severe adverse events, such as myocardial infarction and acute kidney injury [4]. While patient blood management strategies focus on optimizing preoperative risk assessment, facilitating real-time intraoperative interventions, and guiding postoperative transfusion decisions through accurate predictions of blood loss [5], current clinical practice still struggles with the reliability of predictive tools.

Intraoperative blood loss, quantified as estimated blood loss, is a fundamental quantitative metric in perioperative management, providing critical evidence to guide fluid resuscitation strategies, transfusion decisions, and the prevention and control of postoperative complications. Consequently, monitoring accuracy is regarded as a quality standard for perioperative care [6]. However, current clinical assessment methods exhibit dual limitations—subjective assessment techniques (eg, visual estimation of soaked gauze or suction canister volume) are susceptible to operator experience, resulting in high error rates, and calculation-based methods (relying on material weight differences) struggle to capture the dynamic blood loss process in real time [2]. Such inaccuracies can lead to erroneous transfusion decisions. Research has confirmed that inappropriate transfusion is an independent risk factor for postoperative infection and organ dysfunction [7]. Although existing risk assessment tools (the surgical blood loss score) are widely used [5,8,9], their inherent weaknesses, namely heterogeneous scoring criteria and a lag in advances in surgical techniques, are becoming increasingly apparent.

Although traditional prediction models (such as logistic regression) are widely used, they are constrained by linear assumptions and fail to effectively capture complex nonlinear interactions and multicollinearity among variables. Evidence suggests that predictive accuracy based on clinical experience is significantly lower than that achieved by machine learning (ML) methods [10]. With the advancement of hospital information platforms, vast amounts of high-dimensional, heterogeneous clinical data have been accumulated. Due to its unique advantages in processing such data and identifying nonlinear patterns [11], ML has rapidly emerged as a research hotspot in the field of intraoperative bleeding prediction. However, the existing body of research evidence exhibits significant fragmentation. Studies predominantly concentrate on single surgical procedures (eg, cesarean section [12] and spinal surgery [13]), resulting in a scarcity of cross-scenario algorithm comparisons; equally important, the methodological quality and validation rigor of these models are highly variable and often inadequate. Methodological limitations (such as inconsistent data preprocessing and the absence of standardized validation frameworks) have yet to be systematically evaluated and standardized. More critically, the clinical translation pathway is severely hindered by inadequate model generalizability, largely due to a pervasive lack of robust external validation. This fragmented landscape and lack of comprehensive evaluation, coupled with unaddressed methodological concerns, critically impede the understanding of ML's actual value and the identification of optimal implementation pathways for intraoperative bleeding prediction, necessitating the urgent integration and assessment of these methodologies through systematic approaches.

Research Objective

Therefore, based on the PRISMA-Scr (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) framework [14], this study establishes the following objectives:

1. To show how ML algorithms are used to predict bleeding during surgery in different settings;
2. To look at how ways of building and testing models (like picking features or choosing algorithms) affect their results (such as sensitivity and specificity);
3. To find the best-performing algorithms and define the criteria to judge them in specific fields; and
4. To highlight key problems that slow real-world use and suggest practical steps for future research and practice.

Methods

Overview

This scoping review was conducted following the methodological framework proposed by Arksey and O'Malley [15] and reported in accordance with the PRISMA-ScR guidelines [14] to ensure transparency and consistency. Given the focus on prediction models, the Checklist for Critical Appraisal and Data Extraction for Systematic Reviews of Prediction Modeling Studies (CHARMS) [16] was used to guide data extraction.

Search Strategy

A systematic literature search was conducted on April 10, 2025. The search followed the Population, Intervention, Comparator, Outcome, and Study design (PICOS) framework. Both controlled vocabularies (eg, Medical Subject Headings for PubMed and Emtree for Embase) and free-text terms were used. Searches focused on three concepts—population (patients undergoing surgery), predictive tool (ML models), and outcome (risk of bleeding during surgery). In total, seven databases were searched—PubMed, Web of Science, Embase, CINAHL Complete, CNKI (China National Knowledge Infrastructure), Wanfang Data, and VIP (China Science and Technology Journal Database). Table 1 details search strategies for each database. Reference lists of included studies and leading journals were also manually screened.

Study Selection

Initial search records were imported into EndNote X9 (Clarivate). Duplicates were removed using automated and manual deduplication. Moreover, 2 reviewers (SY and PZ) independently screened titles and abstracts for relevance, recording decisions separately. For records retained after screening, both assessed full-text articles for eligibility and recorded decisions independently. Assessment was blind to ensure objectivity. Disagreements were resolved through discussion or, if needed, a third senior researcher (HH). A systematic review decision matrix (Table 2) guided the application of eligibility criteria.

XSL•FO
RenderX

Table . Eligibility criteria.

Category	Inclusion criteria	Exclusion criteria
Population	Adult patients (≥18 y) undergoing surgery	—[a]
Predictive tool	ML-based models explicitly developed to predict intraoperative bleeding risk	Models predicting only postoperative bleeding or failing to distinguish intraoperative or postoperative outcomes
Outcome reporting	Reported at least one performance metric: area under the curve (AUC), sensitivity, or specificity	—
Study design	Primary research: retrospective or prospective cohort studies, case-control studies	Conference abstracts, reviews, case reports, editorials, letters
Publication status	Full text in Chinese or English (including peer-reviewed preprints)	Non–peer-reviewed manuscripts, publications not in Chinese or English
Data source	—	Nonclinical or invalid sources: animal experiments, simulated datasets, nonhospital data

[a]Not applicable.

Eligibility Criteria

Studies that did not meet the inclusion criteria were excluded during screening. Eligibility was determined using predefined criteria outlined in Table 2. The review decision matrix applied these criteria to the full texts to determine whether studies reported outcomes of intraoperative bleeding prediction.

Data Extraction and Synthesis

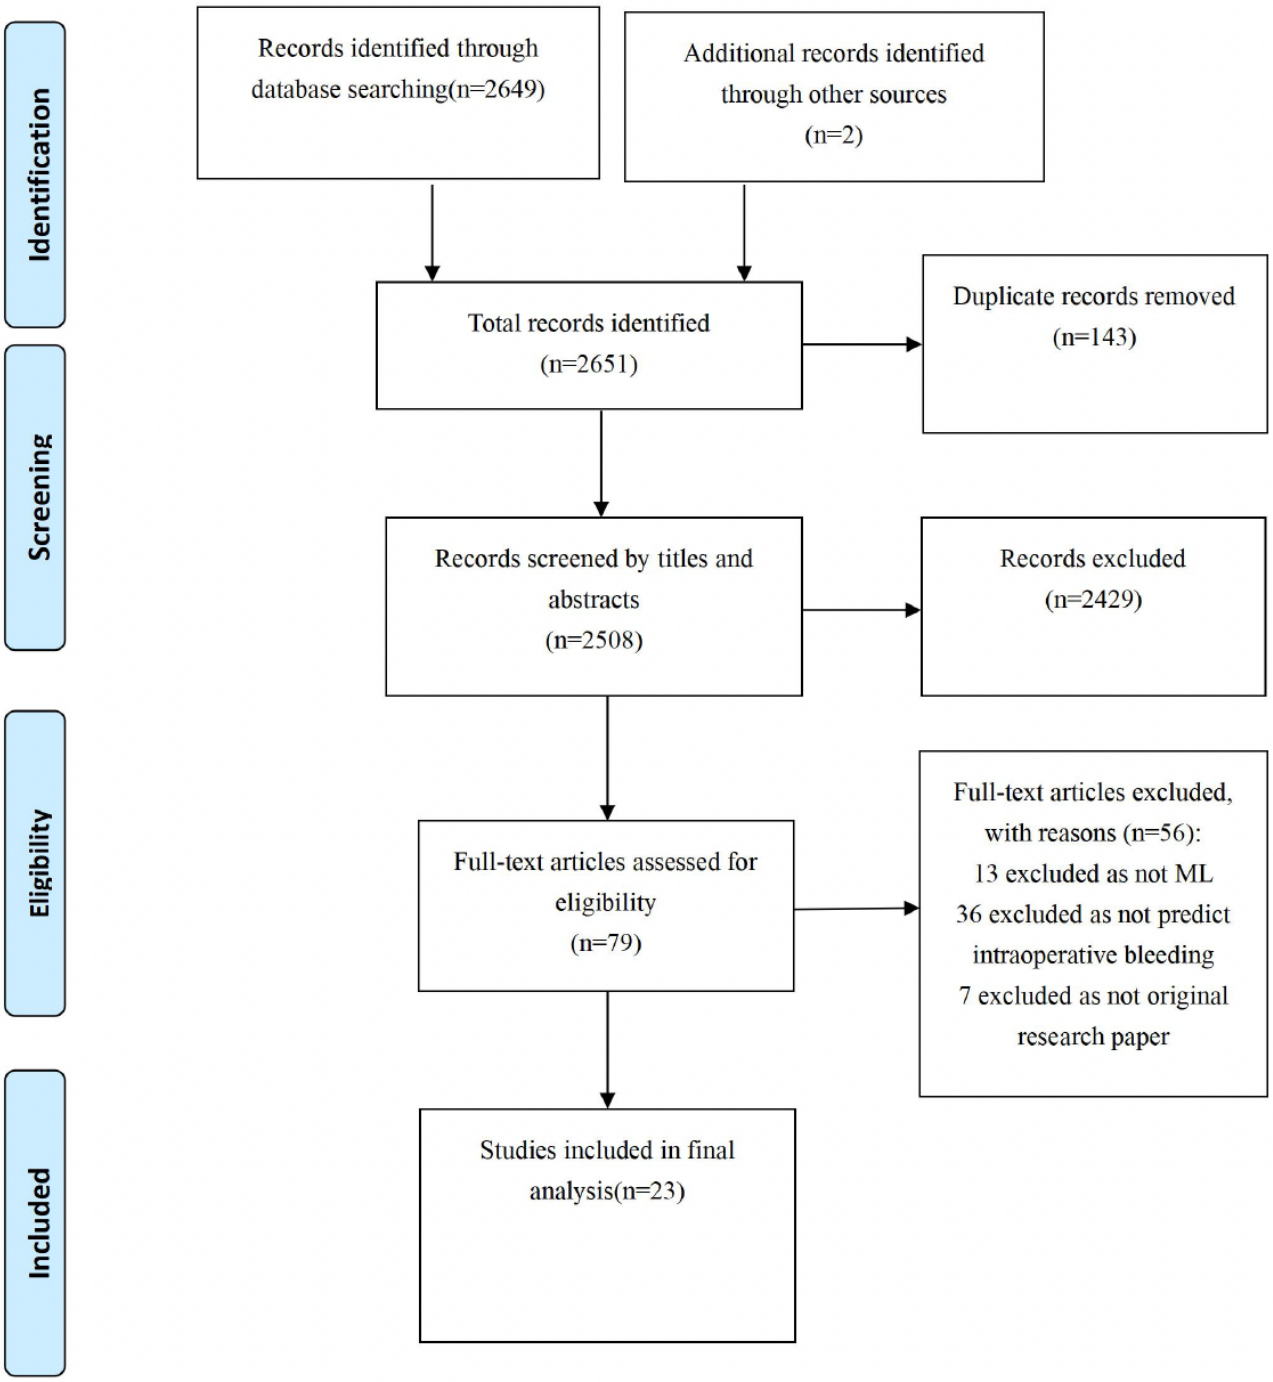
Data extraction was performed independently by 2 reviewers (SY and PZ) using a standardized electronic form based on the aforementioned CHARMS checklist. The reviewers extracted data on the following: (1) study characteristics (author, year, country, design, sample size, surgical type, and data source), (2) model development (candidate and final predictors, data preprocessing, and ML algorithms), and (3) model performance and validation (validation method, performance metrics such as area under the curve [AUC], sensitivity, specificity, precision, and calibration). Any discrepancies were resolved through discussion or by consultation with a third reviewer (HH). Given methodological heterogeneity across studies, including differences in algorithms, validation strategies, and outcome reporting, a narrative synthesis was used for data analysis. The primary studies in this review reported model performance metrics (eg, AUC and sensitivity) and their CIs, not traditional hypothesis-testing *P* values for intergroup comparisons. Therefore, *P* values were neither extracted nor assessed. This approach aligns with the methodological focus of prediction model research.

Risk of Bias and Quality Assessment

The risk of bias and applicability of the included studies were rigorously assessed using the Prediction model Risk of Bias Assessment Tool (PROBAST) [17]. PROBAST tool covers 4 domains—participants, predictors, outcome, and analysis. Furthermore, 2 reviewers (SY and PZ) independently assessed each study, with disagreements resolved by consensus or consultation with a third researcher (HH). The results of this assessment are summarized descriptively in the Results section.

Ethical Considerations

This study did not require ethical approval. We did not study any human or animal subjects, and we did not collect personal information or sensitive data.



Results

Search Results

The systematic search initially identified 2651 records. After removing 143 duplicates, 2508 records were screened based on titles and abstracts. Of these, 2429 records were excluded. The full texts of the remaining 79 articles were assessed for eligibility, of which 56 were excluded for reasons detailed in Figure 1. Consequently, 23 studies [10,12,13,18-37] met the inclusion criteria and were included in this scoping review (Figure 1).

RenderX

Figure 1. Flow diagram of the review process and the identification of studies via databases. ML: machine learning.

Characteristics of Included Studies

The detailed characteristics of the 23 included studies [10,12,13,18-37] are presented in Table 3. The sample sizes varied widely, ranging from 48 to 48,543 cases. All studies were retrospective in design, with 17 (74%) [10,20,21,23-31,33-37] being single-center investigations. The publication years were concentrated between 2019 and 2025, and the geographical distribution was highly skewed, with studies from China dominating (17/23, 74% [12,13,20-22,24,26,27,29-37]). The main surgical contexts were obstetric procedures (10/23, 43% [10,12,18,21,27,29,32,34,36,37]), orthopedic surgery (4/23, 17% [13,19,26,31]), and hepato-biliary surgery (4/23, 17% [20,23,30,35]). Considerable heterogeneity was observed in the definitions of intraoperative major bleeding across studies, ranging from ≥200 mL to >5000 mL.

[d]CT: computed tomography.

Technical Features and Performance of Prediction Models

All models were based on electronic health records (EHRs). A total of 8 studies (35%) [10,18,21,29,32-34,36] further integrated medical imaging data, including magnetic resonance imaging (MRI) or computed tomography, of which 7 (30%) [10,18,21,29,32,34,36] focused on predicting obstetric bleeding. In terms of algorithms, tree-based ensemble models were most frequently applied (12/23, 52% [10,12,13,23-25,27,30-32,35,37]), especially random forests (8/23, 34% [12,13,23,25,27,31,32,35]) and extreme gradient boosting (9/23, 39% [10,12,13,23,24,30,32,37]); logistic regression (13/23, 57% [12,13,18,20,23,24,26,27,30-33,37]) and deep learning (6/23, 26% [10,21,22,30,33,36]) models were also commonly used. Model discrimination performance is illustrated in Table 4. The AUC ranged from 0.63 to 0.93, with a mean of 0.82 (SD 0.08). Models incorporating multimodal data (eg, EHR+imaging) showed a performance advantage (mean AUC≈0.84, SD 0.075) over unimodal models relying solely on EHR (mean AUC≈0.82, SD 0.069). For instance, the support vector machine model by Xu [29], which fused MRI radiomic features with clinical data, achieved an AUC of 0.87.

Model Validation Strategies

Although internal validation was widely applied (22/23, 96% [10,12,13,18,20-37]), its methodological rigor was insufficient (Table 4). Only half of the studies (12/23, 52% [10,12,13,18,20,22-27,33]) established an independent test set to evaluate final performance; even fewer used cross-validation (9/23, 39% [10,12,21,26,27,30,31,33,37]). External validation was notably lacking, implemented in only 6 studies (26%) [12,13,18,19,32,34]. Critically, among the limited external validations, model performance generally declined. For example, the model by Shi et al [13] dropped from an internal AUC of 0.85 to an external AUC of 0.80; when de Reus et al [19] independently validated the same model in a multinational, multicenter setting, the AUC further decreased to 0.63.

Completeness of Performance Metric Reporting

There was substantial selective bias in the reporting of key performance metrics (Table 4). Discrimination metrics AUC were reported most frequently (19/23, 83% [10,12,13,18-20,23,24,26,27,29-37]), whereas reporting of essential classification metrics was incomplete: sensitivity (16/23, 70% [12,13,19,21,22,24,27-34,36,37]), specificity (14/23, 61% [12,19,21,22,24,27-29,31-34,36,37]). Reporting

XSL•FO
RenderX

rates for precision (4/23, 17% [13,22,30,37]) and F_1-score (4/23, 17% [12,13,19,30]) were very low. Furthermore, only 10/23 (43%) [13,18,19,25,26,28,32-34,36] of the studies reported model calibration (eg, calibration curves).

Data Preprocessing and Interpretability

Reporting of data-preprocessing pipelines was seriously deficient (Table 5). In total, 11 studies (47%) [10,20,21,23,30-34,36,37] did not describe any method for handling missing data. Only 3 studies (13%) [13,24,33] reported strategies to address class imbalance (eg, using the synthetic minority oversampling technique [SMOTE]). The vast majority of studies neither applied nor reported any model interpretability analyses (eg, Shapley Additive Explanations [SHAP] and local interpretable model-agnostic explanations), rendering the models essentially "black-box."

Table . Summary of data preprocessing methods in included studies (n=23).

Author	Missing data handling	Class imbalance handling	Data normalization or standardization
Akazawa and Hashimoto [10]	Not reported	Not reported	Not reported

Risk-of-Bias Assessment of Included Studies

Based on a systematic evaluation using the PROBAST (Table 6), all included studies (23/23, 100% [10,12,13,18-37]) were judged to have an overall "high" risk of bias. High risk primarily stemmed from 2 domains—the "participants" domain (23/23, 100% [10,12,13,18-37], due to selection bias inherent in retrospective designs) and the "analysis" domain (20/23, 87% [10,13,18,20-25,27-37], mainly attributable to inconsistent data preprocessing and shortcomings in validation strategies).

Table . Risk of bias assessment of included models (n=23 studies).

Discussion

Principal Findings

This systematic scoping review synthesizes the current state of ML in predicting intraoperative bleeding in patients undergoing surgery. The results indicate that ML models demonstrate good discriminative ability (mean AUC 0.82, SD 0.008) and, in some scenarios, outperform traditional methods [10]. Multimodal data (eg, EHR combined with medical imaging) can further enhance predictive efficacy, aligning with the paradigm shift from "unimodal perception" to "multimodal cognition" [38]. However, the PROBAST assessment reveals a fundamental contradiction; despite significant technical potential, current studies exhibit a universally high risk of bias, particularly in the analysis domain (22/23, 87% of the included studies [10,13,18,20-25,27-37]). This raises serious concerns that the reported performance metrics are likely overestimated. Specifically, this systematic risk of overestimation stems from three interconnected methodological shortcomings: (1) selective reporting and optimization bias, whereby studies tend to report only the best-performing models and favorable metrics (eg, AUC) while omitting critical measures such as calibration; (2) inadequate internal validation strategies, characterized by reliance on simple data splitting without temporal validation, which may lead to overfitting and overly optimistic performance estimates; and (3) insufficient handling of critical data issues, like class imbalance and missing data, which can artificially inflate discrimination metrics. Collectively, these flaws indicate that the reported mean AUC of 0.82 (SD 0.008) likely reflects optimal laboratory performance under ideal conditions, rather than the true generalizability of the models to independent, prospectively collected clinical data. This view is corroborated by the commonly observed performance degradation in the limited external validations available, where models often

XSL•FO
RenderX

exhibit significant drops in AUC when applied to independent cohorts [13,19]. Based on this, the subsequent discussion of this review will systematically focus on these three core aspects—the completeness of model performance reporting, the rigor of validation strategies, and the transparency of data preprocessing and interpretability.

First, there is severe selective bias in the reporting of model performance, which limits a comprehensive assessment of their clinical applicability. Current research is overly focused on reporting discrimination metrics (AUC reported in 19/23, 83% of studies [10,13,18,20-25,27-37]), while seriously neglecting calibration (reported in 10/23, 43% [13,18,19,25,26,28,32-34,36]) and key classification metrics (eg, precision and F_1-score, reported in 4/23, 17% [12,13,19,30]). This bias obscures two core issues. First, the widespread absence of model calibration assessment undermines the clinical credibility of predicted probabilities. Calibration reflects the consistency between predicted probabilities and actual risks, serving as the direct basis for risk stratification [39]. However, only a minority of studies reported calibration results [13,18,19,25,26,28,32-34,36]. More critically, calibration performance is unstable and cannot be inferred from a high AUC. For example, one study [33] reported good internal calibration, whereas independent external validation [19] revealed significant miscalibration. This suggests that calibration must be independently evaluated, as its issues are often exposed during external validation. Furthermore, its absence in most studies casts doubt on the reliability of their "risk probability" outputs. Second, incomplete reporting of key classification metrics hinders the judgment of model utility. Precision is crucial for assessing alert efficiency and preventing alarm fatigue, yet its reporting is severely inadequate [13,19,21,36]. This makes it impossible to quantify the model's false-positive risk. For instance, a model [12] reported high sensitivity (eg, identifying most true bleeding events) but lower specificity, implying a higher number of false-positive alerts. Without reporting precision, the accuracy of these alerts cannot be quantified, making it difficult to assess whether this high-sensitivity strategy would lead to "alert fatigue" in practice. Conversely, the model developed by Xue et al [30] achieved high accuracy (eg, most of its alerts are true), but its sensitivity might be low, potentially missing a considerable proportion of true bleeding events, which could increase the risk of clinical under-diagnosis. The systematic absence of these key metrics makes it challenging to evaluate model robustness across different clinical decision thresholds. Therefore, future research must strictly adhere to reporting guidelines, such as Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis (TRIPOD) [40] and comprehensively present calibration and classification metrics to bridge the gap between technical development and clinical practice.

Second, model validation strategies generally lack rigor. The widespread absence of external validation, in particular, weakens the reliability of their generalizability assessment. This review found that although over half of the studies (12/23, 52% [10,12,13,18,20,22-27,33]) established an independent test set, their internal validation mostly relied on simple data splitting, with only one study [33] using the more robust temporal validation method. This overreliance on simple hold-out methods, coupled with limited adoption of methods such as cross-validation, may lead to optimistic performance estimates. More critically, external validation is severely lacking (only 6/23, 26% [12,13,18,19,32,34]), and performance degradation is commonly observed in implemented validations. This directly reveals the limited generalizability of models developed on homogeneous data. For example, the model by Shi et al [13] experienced a decrease in AUC from 0.85 in internal validation to 0.63 during multinational, multicenter external validation [19]. Models by Yang et al [32] and Zheng et al [34] showed similar trends in external performance decline. A notable exception is the model by Chen et al [12], which was built on large-scale multicenter data and showed improved performance in external validation, suggesting that an appropriate study design can enhance generalizability. In summary, the generalizability of existing models has not been sufficiently or rigorously validated. To further confirm the effectiveness and broad applicability of models in real-world settings, future research must incorporate prospective design, temporal validation, and multicenter external validation as key components of model evaluation.

Furthermore, insufficient transparency in data preprocessing and the widespread lack of model interpretability constitute another systemic methodological defect hindering research reproducibility and clinical translation. This review found that over 40% (11/23) of studies [10,20,21,23,30-34,36,37] did not report methods for handling missing data, and only 13% (3/23) [13,24,33] addressed class imbalance. The reporting of data preprocessing steps is severely deficient and nonstandard (eg, failing to clearly describe key procedures such as handling missing values and normalization [10,19-22,26,27,29-31]), thereby directly compromising model robustness and reproducibility. Although a few studies adopted more rigorous methods (eg, multiple imputation [12,18], SMOTE [33], or adaptive synthetic sampling [24]), simpler strategies that may introduce bias (eg, direct case deletion [17,25,28]) remain common. This lack of transparency makes interstudy comparison and independent replication exceptionally difficult and may partly explain the performance decline observed for some models during external validation [19]. Concurrently, model interpretability analysis is far from standard practice. The vast majority of studies lack any explanatory analysis (eg, SHAP values and feature importance), rendering them "black boxes" that clinical decision-makers find difficult to trust. Although a few studies have attempted to apply interpretability techniques, such as SHAP values or feature importance rankings [19,22], to identify key risk features and enhance transparency, this has not become routine. Therefore, future research must be committed to promoting the standardized reporting of data preprocessing workflows and deeply integrating interpretability analysis throughout the entire model development and validation process, which is a key prerequisite for building trustworthy and clinically usable prediction tools.

Future Research Directions

Based on the findings of this review, to promote the transition of prediction models from "technically feasible" to "clinically applicable," future research should focus on four core directions.

XSL•FO
RenderX

First, promote rigorous validation and generalizability assessment. Model development must move beyond retrospective single-center designs, collect data through multicenter prospective studies, and use temporal validation and independent external validation as cornerstones of evaluation to rigorously test their robustness. Second, improve performance reporting and clinical utility evaluation. Research must strictly adhere to reporting guidelines, such as TRIPOD, and fully present performance metrics. Furthermore, methods such as decision curve analysis should be actively adopted to quantify the clinical net benefit of models across different decision thresholds, aligning evaluation with real-world decision-making scenarios. Third, standardize data processing and enhance model interpretability. Detailed reporting of data preprocessing workflows, along with the adoption of advanced methods for handling missing values and class imbalance, should become standard practice. Simultaneously, interpretability techniques, such as SHAP, should be integrated into the development pipeline as essential components to elucidate risk mechanisms and build clinical trust. Finally, explore clinical integration pathways and evaluate real-world impact. Current research in the field mostly remains at the stage of model development and technical validation, and its potential clinical value has not yet been substantiated. Specifically, building on preliminary evidence, future research should be dedicated to deepening and validating the following key translational aspects. First, promote the prospective application and effect evaluation of prediction models to guide preoperative blood preparation. Although existing models show potential to optimize blood preparation strategies [41,42], their impact on resource conservation and team response efficiency after integration into actual workflows remains to be confirmed by prospective studies. Second, expand the generalizability and clinical integration of real-time alert models. Although some studies have successfully developed real-time prediction models for intraoperative massive transfusion and demonstrated excellent performance [43], their generalizability across different surgical types and medical centers, as well as their actual alert efficacy and clinical acceptance after integration into anesthesia monitoring systems, requires further validation. Finally, and most challengingly, evaluate the improvement effect of model-based clinical decisions on patient hard endpoints through prospective interventional trials. Existing observational studies suggest that transfusion is associated with worse outcomes and higher costs [44]. Future well-designed studies are needed to confirm whether effective prediction-intervention strategies can ultimately achieve comprehensive benefits—such as reducing unnecessary transfusions and timely management of major bleeding—thereby lowering complications, improving patient prognosis, and saving medical costs.

Limitations

The limitations of this review primarily stem from the methodological quality of the included original studies. First, the search strategy may not have captured all relevant literature, posing a risk of omission. More critically, the widespread retrospective design and high risk of bias in the current field necessitate cautious interpretation regarding the true performance and generalizability of the evaluated models.

Conclusion

This scoping review indicates that research on ML for predicting intraoperative bleeding is growing rapidly in quantity, but the quality of studies has not improved correspondingly, constituting the main obstacle to clinical translation. Existing models are generally built on retrospective data and suffer from core methodological flaws, including a high risk of bias, a severe lack of external validation, and incomplete reporting of key performance metrics. Therefore, the clinical applicability and reliability of current models are far from established. To achieve the leap from methodological exploration to clinical utility, future research must meet higher standards—prioritize prospective design, enforce independent and multicenter external validation, strictly adhere to standardized reporting guidelines such as TRIPOD, and strive to explore effective pathways for integrating models into perioperative workflows.

Abstract

Background: The secondary use of health data holds substantial potential for advancing biomedical research, strengthening population health analytics, and enabling artificial intelligence–driven decision-making support. Yet, ensuring that such reuse respects patient autonomy, privacy, and regulatory obligations remains a major challenge. Conventional consent mechanisms are typically static, difficult to revoke, and offer limited transparency or accountability after data disclosure.

Objective: This review aimed to systematically examine blockchain-based frameworks that enable dynamic, auditable, and revocable consent for the secondary use of health data.

Methods: A structured literature search was conducted in PubMed, Scopus, and Web of Science covering the period 2020 to 2025. Following PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines, 55 peer-reviewed studies meeting predefined inclusion criteria were analyzed. Data extraction focused on four dimensions: (1) consent life cycle management, (2) auditability and traceability, (3) usability and patient empowerment, and (4) legal and ethical alignment.

Results: Findings indicate that blockchain technologies provide a robust foundation for automating consent life cycles, ensuring immutable auditability, and enabling decentralized patient control. Most frameworks used smart contracts, decentralized identifiers, and verifiable credentials to implement programmable and verifiable consent processes. Nevertheless, key challenges persist, including limited usability testing, complexities in real-time revocation propagation, interoperability gaps with clinical systems, and tensions with regulatory requirements such as the General Data Protection Regulation right to erasure. Only a small subset of studies reported real-world deployments or user-centered evaluations.

Conclusions: Blockchain offers substantial promise for improving the trustworthiness, transparency, and accountability of consent management for secondary health data use. However, wider adoption requires human-centered design approaches, stronger interoperability through standards such as Fast Healthcare Interoperability Resources, verifiable credentials, and consent receipts, and clearer legal guidance for compliance. Future research should prioritize integrating blockchain-enabled consent infrastructures into national and cross-border digital health ecosystems such as the European Health Data Space to support secure, patient-controlled, and ethically governed secondary data use.

Introduction

Background

The digitalization of health care has expanded how patient data are used and shared, raising important questions about consent, privacy, and individual control. While large-scale reuse of health data enables advances in biomedical research, population health analytics, and data-driven innovation, traditional consent models often fall short in this evolving landscape [1,2]. Conventional approaches are typically static, difficult to revoke, and provide limited transparency once data have been shared, making them poorly suited for continuous, cross-institutional, and cross-border secondary use of health data.

data enables advances in biomedical research, population health analytics, and data-driven innovation, traditional consent models often fall short in this evolving landscape [1,2]. Conventional approaches are typically static, difficult to revoke, and provide limited transparency once data have been shared, making them poorly suited for continuous, cross-institutional, and cross-border secondary use of health data.

Recent regulatory developments, notably the European Health Data Space (EHDS) Regulation, further reinforce the need for interoperable and trustworthy consent infrastructures for secondary use of health data. Acting as lex specialis over the General Data Protection Regulation (GDPR) in this context, the EHDS introduces dedicated governance mechanisms [3], access frameworks, and infrastructure requirements for health data reuse within the European Union. While the GDPR establishes baseline principles for lawful processing, including informed and revocable consent, the EHDS places additional emphasis on harmonized procedures, institutional accountability, and cross-border operability [4].

Recent implementation guidance further clarifies how patient rights under the EHDS should be operationalized in practice. In particular, the second joint action Towards the European Health Data Space (TEHDAS 2) guideline for Health Data Access Bodies specifies common principles and procedures for implementing opt-out mechanisms for the secondary use of electronic health data, emphasizing transparency, harmonized national processes, and citizen-facing tools to exercise opt-out rights [3]. This guidance highlights that EHDS compliance depends not only on legal provisions but also on concrete organizational and technical processes capable of managing consent and opt-out at scale.

At the same time, emerging technologies such as blockchain and decentralized identity offer new architectural possibilities for enforcing consent policies, maintaining immutable audit trails, and enabling patient-centric control without reliance on central intermediaries [5-7]. Blockchain-based systems can provide tamper-evident records, shared governance across institutions, and programmable enforcement of consent conditions through smart contracts, while decentralized identity mechanisms allow individuals to retain control over their identifiers and consent credentials.

Several recent surveys have explored blockchain in health care or digital consent in isolation; however, they typically address broad application domains or focus on usability, ethical, or governance perspectives without systematically analyzing how blockchain-based architectures support dynamic and revocable consent specifically for the secondary use of health data. As a result, there remains a fragmented understanding of how consent life cycles are technically implemented, how revocation is enforced across distributed systems, and how such frameworks align with evolving regulatory requirements under the GDPR and the EHDS [6-10]. This gap motivates this systematic review.

Unlike prior reviews that examine blockchain in health care broadly or address digital consent primarily from ethical or governance perspectives, this review analyzes dynamic and revocable consent as an enforceable life cycle across distributed systems, integrating architectural, operational, usability, and regulatory dimensions.

Accordingly, the aim of this systematic review was to examine and synthesize blockchain-based frameworks that support dynamic, auditable, and revocable consent for the secondary use of health data. Specifically, this review analyzes how existing approaches implement consent life cycle management, enable auditability and traceability, support patient empowerment and usability, and align with legal and ethical requirements under the GDPR and the emerging EHDS. By consolidating evidence from peer-reviewed studies published between 2020 and 2025, this review seeks to identify prevailing architectural patterns, implementation gaps, and priority directions for future research and real-world deployment.

This paper is organized as follows. The *Methods* section describes the systematic review protocol, including the search strategy, eligibility criteria, and data extraction and synthesis procedures. The *Results* section presents the findings of the review, organized around key analytical dimensions related to consent life cycle management, auditability, usability, and legal-ethical alignment. The *Discussion* interprets these findings in relation to existing literature, regulatory frameworks, and practical implications for the secondary use of health data.

Background and Rationale

The rapid advancements in digital technology over the past three decades have led to the emergence of digital health, which is revolutionizing health care [11]. The digital transformation of health care has redefined how clinical and research data are collected, managed, and reused. With electronic health records (EHRs) and other digital health systems being adopted so quickly, health care data have grown exponentially [12]. The EHRs, biobanks, and data-driven analytics platforms now form the backbone of modern health care systems by supporting clinical decision-making, personalized medicine, and population-level insights. Global policy initiatives, such as the World Health Organization's Global Strategy on Digital Health [2], emphasize the need for secure and interoperable infrastructures that enable the ethical data exchange and innovation.

Alongside this advancement, the secondary use of health data beyond direct patient treatment has become a key component of biomedical research, artificial intelligence (AI) model development, and public health surveillance [1]. However, these benefits raise the fundamental questions about patient autonomy, privacy, and consent governance. Legal frameworks such as the GDPR require that personal data be handled transparently. They also specify that consent must always be specific, informed, and easy to withdraw [13]. In the European Union, the recently adopted EHDS Regulation further establishes a dedicated legal framework for the secondary use of health data, acting as lex specialis over the GDPR in this domain and introducing cross-border governance and access mechanisms [4].

Despite these regulatory advances, current consent management models remain largely static [14]. Usually, the individuals sign a one-time authorization form that gives them data controllers

XSL•FO
RenderX

general authorization to reuse their data, but they are not given tools to control or withdraw their consent in a more precise way [15]. The centralized databases used for storing consent records often face a lack of transparency and auditability. In addition, they struggle to maintain real-time synchronization across the institutions, which creates single points of failure and reduces overall accountability. These weaknesses highlight the need for systems that support continuous, verifiable, and user-driven consent throughout the data life cycle.

From a technical perspective, these requirements challenge traditional centralized architectures and motivate the exploration of distributed trust infrastructures that can provide tamper-evident records, shared governance, and automated enforcement of consent policies across organizational boundaries.

In this context, blockchain and distributed ledger technologies (DLTs) have emerged as promising enablers due to their inherent properties of immutability, decentralization, and programmable logic. However, the choice of blockchain deployment model is critical in health care settings. Public, permissionless blockchains offer high transparency but raise concerns regarding scalability, governance, and the exposure of even pseudonymized metadata on global infrastructures, which may conflict with data minimization and purpose limitation principles.

Consequently, most health care–oriented frameworks favor permissioned or consortium DLTs, where participating nodes are operated by trusted health care authorities or institutions and where fine-grained access control and governance mechanisms can be enforced. Such models better align with regulatory expectations under GDPR and EHDS, while still enabling shared auditability and decentralized trust. These considerations underscore the need for consent management solutions that are not only legally compliant but also technically capable of operating in distributed, cross-institutional health care ecosystems. This background motivates the investigation of blockchain-based frameworks as potential trust layers for enabling dynamic, auditable, and revocable consent in the secondary use of health data.

Blockchain Deployment Models and Regulatory Constraints

Although blockchain technologies are frequently proposed as trust infrastructures for health care consent management, the choice of deployment model is critical. Public, permissionless blockchains, while offering high transparency and openness, are generally unsuitable for managing consent-related metadata in health care settings. Even when only pseudonymized identifiers, public keys, or decentralized identifiers (DIDs) are stored on-chain, the global replication of such metadata across open infrastructures lacks a clear need-to-know justification and may conflict with the GDPR principles of data minimization and purpose limitation.

Consequently, most health care–oriented consent management frameworks adopt permissioned or consortium-based DLTs, where participating nodes are operated by trusted health care institutions, public authorities, or regulated intermediaries. These models enable fine-grained access control, governance, and institutional accountability while still preserving shared auditability and tamper-evident records across organizational boundaries. Such architectural choices align more closely with GDPR requirements and with the governance expectations introduced by the EHDS framework for the secondary use of health data.

Evolution of Consent and the Need for Dynamic Models

Traditional consent models were designed for one-time clinical visits or specific research studies [15,16]. In an era of continuous data flows and distributed analytics, these static approaches have become increasingly inadequate. Individuals rarely could modify or revoke consent as data are repurposed for new studies, shared across borders, or integrated into AI training pipelines [17]. This gap between what patients expect and what technology currently delivers can weaken trust in the digital health ecosystems.

To address these concerns, dynamic consent was introduced as both an ethical and technical solution that allows individuals to modify, refine, or revoke their data sharing choices at any time through the user-friendly interactive platforms [18]. By enabling ongoing engagement and communication between data subjects and controllers, dynamic consent promotes transparency, autonomy, and contextual decision-making. It also aligns with key principles of the GDPR, particularly Article 7, which ensures revocability, and Article 17, which gives individuals the right to have their data deleted. Within the European context, these principles are further operationalized for secondary use through the EHDS Regulation, which emphasizes patient rights, governance, and cross-border data reuse under harmonized access mechanisms.

However, unlike primary use where consent is often the main legal basis, the EHDS introduces a governance model for secondary use in which data access may rely on specific legal bases but remains subject to a citizen's right to opt out. The TEHDAS guideline elaborates how Health Data Access Bodies should implement such opt-out mechanisms in practice, including registries and user interfaces for objections. This distinction is crucial for blockchain-based dynamic consent systems, which must interoperate with opt-out governance rather than assume that consent alone governs secondary use [3].

In contrast, most dynamic-consent implementations rely on centralized architectures that provide limited verifiability and poor interoperability across institutions. These systems may log user actions but cannot guarantee immutability, traceability, or real-time enforcement of revocation [19]. As secondary use increasingly involves multi-institutional and cross-border data flows, such limitations pose not only technical but also governance and compliance challenges. In particular, the lack of automated propagation of consent changes across distributed data custodians undermines the practical realization of revocability required by both GDPR and EHDS.

As secondary data use expands across jurisdictions and organizations, these limitations pose both technical and ethical challenges. This evolution highlights the need for consent

XSL•FO
RenderX

infrastructures that can (1) maintain a shared and tamper-evident history of consent decisions, (2) support fine-grained and time-bound authorizations, and (3) enable verifiable enforcement of revocation across organizational boundaries.

These requirements motivate the exploration of blockchain-based approaches as potential enablers of dynamic, auditable, and decentralized consent management in health care.

Blockchain Foundations for Dynamic Consent

Blockchain offers architectural features that can address many of the limitations of centralized consent management [5]. Consent events, such as granting, updating, and revoking permissions, can be recorded in a tamper-proof manner verifiable by all the participants' nodes, which is immutability, transparency, and decentralization. These properties enable shared trust across organizations without relying on a single central authority.

Smart contracts are self-executing programs that are stored on the blockchain that can automatically manage consent by granting or withdrawing access based on predefined conditions, such as specific time frames or user decisions [20]. This makes it possible to handle consent in real time, reducing the need for third-party involvement and manual reconciliation between data controllers.

Other technologies, such as DIDs and verifiable credentials (VCs), further enhance this process by enabling individuals to control their own digital identities [21]. With DIDs, users can create and manage their own digital identities without depending on the centralized systems. Meanwhile, VCs also make it possible to issue and share digitally signed proofs, such as consent records, which others can verify without revealing unnecessary personal information. Together, these tools enable a privacy-preserving, patient-centric consent framework where individuals maintain verifiable control over their data without exposing personal identifiers on-chain.

In most cases, blockchain is used as a coordination and auditing layer rather than a data storage layer. The sensitive health information remains off-chain, while only hashed references, metadata, and consent proofs are recorded on the ledger. This hybrid design supports GDPR's principles, such as data minimization and purpose limitation, and is also aligned with EHDS expectations for interoperable and trustworthy secondary-use infrastructures.

Accordingly, hybrid on-chain or off-chain architectures represent a baseline design pattern across health care blockchain systems, adopted from early proposals to recent implementations to address scalability and privacy constraints.

Although these technologies show potential for creating secure, adaptable, and revocable consent systems, it remains unclear how well they perform in real health care environments. Challenges persist in synchronizing on-chain consent states with off-chain policy enforcement points (PEPs), ensuring timely revocation propagation, and integrating with existing health information systems. This highlights the need for a comprehensive review of current research to examine how the blockchain is being applied to dynamic consent and to consider the technical, ethical, and legal issues that accompany it.

Identified Research Gaps

Blockchain and consent management have each been widely studied within digital health research. However, their intersection, particularly with respect to dynamic and revocable consent for the secondary use of health data, remains insufficiently explored. Most blockchain-focused studies adopt a broad perspective, emphasizing applications such as EHR management, supply chain traceability, or digital identity, while treating consent as a static or peripheral feature. These approaches rarely conceptualize consent as a programmable life cycle, enabling patients to grant, monitor, modify, and revoke permissions over time.

In contrast, research on dynamic consent has predominantly emerged from ethical, legal, and user experience perspectives, emphasizing patient autonomy, transparency, and trust. While this body of work provides important insights into participatory consent models, it often lacks a detailed examination of the technical infrastructures required to operationalize such models at scale. Key aspects, including verifiable audit trails, enforceable revocation, interoperability across heterogeneous data custodians, and tamper-resistant governance mechanisms, are seldom addressed in depth.

Across the primary literature, blockchain-based proposals for consent management are highly heterogeneous, spanning domains such as clinical trials, personal health records (PHRs), genomics, and health information exchange. Despite this diversity, there is a notable lack of systematic synthesis focused specifically on secondary-use governance, where consent must be enforceable across institutional and jurisdictional boundaries and over extended time horizons. As a result, the design patterns, architectural trade-offs, and operational limitations of blockchain-enabled dynamic consent systems for secondary health data reuse remain poorly consolidated.

More recent studies have proposed frameworks combining blockchain with decentralized identity technologies, including DIDs and VCs. However, these approaches vary considerably in architectural design, regulatory assumptions, and levels of empirical validation. Few studies move beyond proof-of-concept implementations to evaluate performance in realistic cross-institutional or cross-border settings. In particular, automated revocation propagation, latency guarantees, coupling with off-chain PEPs, and scalability under operational workloads remain weakly demonstrated.

Finally, although alignment with the GDPR is frequently asserted, the implications of the EHDS Regulation as lex specialis for secondary use introducing dedicated governance bodies, access authorization mechanisms, and cross-border infrastructures are only sporadically addressed. This creates uncertainty regarding how blockchain-based consent models can integrate with emerging European data space architectures.

Accordingly, this study addresses these gaps by providing a PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses)–based systematic review of literature published between 2020 and 2025, applying a structured

XSL•FO
RenderX

analytical framework and quality assessment to evaluate blockchain-based dynamic consent architectures for secondary use of health data. By focusing on consent life cycle management, auditability, usability evidence, and legal-ethical alignment, this review consolidates fragmented evidence and identifies the technical, evaluative, and governance limitations constraining the operational maturity of existing approaches.

Related Work and Critical Comparison With Existing Reviews

Several recent reviews and surveys have examined blockchain and consent in health care from complementary but partial perspectives. However, none provide a unified analysis of dynamic and revocable consent life cycles for secondary health data use, grounded simultaneously in blockchain-based enforcement mechanisms and emerging European regulatory requirements.

For instance, Hang et al [6] reviewed blockchain applications in clinical trials, emphasizing transparency and traceability, but treated consent primarily as a supporting mechanism rather than as a programmable life cycle with explicit revocation semantics. Similarly, Baysal et al [7] and other broad surveys map blockchain-based health care systems across diverse use cases, yet do not isolate consent management for secondary use as a distinct analytical focus, nor do they assess the enforceability or governance implications in depth.

From the consent-oriented literature, Schmidt et al [8] presented a scoping review of informed consent in digital health, identifying challenges related to consent acquisition and management. However, this work does not engage with blockchain architectures, smart contracts, or decentralized enforcement mechanisms. Likewise, Kassam et al [9] and Cumyn et al [10] synthesized patient and public perspectives on digital consent and transparency in secondary data use, offering valuable socioethical insights but without examining technical design choices or system-level trade-offs.

Other recent surveys, including Phuyal et al [1], provide comprehensive overviews of blockchain in health care but do not analyze consent life cycles, revocation propagation, or patient-controlled secondary use governance. Across these reviews, regulatory considerations are typically limited to high-level discussions of GDPR compliance, with minimal treatment of the EHDS Regulation and its implications for secondary use authorization, governance bodies, and cross-border interoperability.

To situate this review within this landscape, Table 1 provides a structured comparison of recent review and survey papers intersecting blockchain, digital consent, and secondary use of health data. As summarized, existing reviews either focus broadly on blockchain applications without analyzing consent life cycle enforceability or examine digital consent without addressing blockchain-based technical enforcement and secondary use governance. In contrast, this review uniquely integrates (1) smart contract–based consent life cycle management, (2) auditability and traceability mechanisms, (3) usability and empirical evaluation evidence, and (4) legal alignment with both GDPR and the EHDS Regulation, supported by a PRISMA methodology and formal quality assessment across 55 studies.

This comparative analysis demonstrates that this review does not duplicate prior surveys but instead provides an integrative assessment of consent life cycle enforceability and governance readiness for secondary health data use, which has not been systematically examined in earlier secondary studies.

Taken together, prior reviews reflect the gradual evolution of consent research from static, paper-based authorization toward digital and dynamic consent models and more recently toward decentralized and blockchain-enabled infrastructures. Early work on dynamic consent primarily emphasized ethical engagement, communication, and patient trust, while blockchain-focused health care surveys concentrated on data integrity, traceability, and access control. However, these strands have largely developed in parallel. As a result, the technical enforceability of dynamic and revocable consent across distributed systems, particularly for secondary use of health data, has remained insufficiently synthesized in the literature.

Table . Comparison of this review with recent related surveys.

Author, year	Scope	Blockchain focus	Dynamic or revocable consent	Secondary use focus	EHDS[a] or GDPR[b] analysis	Usability and empirical evaluation	Quality assessment	This review's added value
Hang et al (2022) [6]	Blockchain in clinical trials	Yes	Yes	Focused on trials	GDPR only	No	No	Lacks life cycle and revocation analysis
Baysal et al (2023) [7]	Multivocal blockchain in health care	Yes	Yes	Broad	No	No	Yes	Broad mapping, no consent depth
Schmidt et al (2025) [8]	Digital health consent (scoping)	Partial	Yes	Yes	GDPR only	No	No	No blockchain architecture analysis
Kassam et al (2023) [9]	Patient perspectives on digital consent	No	Yes	Yes	No	Yes	No	Human factors only
Cumyn et al (2023) [10]	Transparency in secondary use	No	Partially	Yes	Yes	Yes	No	Governance without technology
Phuyal et al (2025) [1]	Blockchain in health care (survey)	Yes	No	No	Yes	No	No	No consent life cycle or revocation
This review	Blockchain+dynamic consent for secondary use	Yes	Yes	Yes	Yes	Yes	Yes	End-to-end life cycle, revocation propagation, auditability, EHDS focus

[a]EHDS: European Health Data Space.

[b]GDPR: General Data Protection Regulation.

Scope and Contribution of the Review

The purpose of this review is to deliver a thorough and systematic examination of blockchain-based frameworks that support dynamic, auditable, and revocable consent for the secondary use of health data. It adds to current studies by investigating how these systems manage the full life cycle of consent in health care using blockchain and decentralized identity technologies. It also evaluates the system's technical reliability, usability, and compliance with regulatory standards. In bringing these findings together, this review highlights common design approaches and enduring challenges across these separate studies. By integrating findings from technological, ethical, and governance perspectives, it explains how blockchain can enable patient-centric consent systems. It also makes practical recommendations for researchers, system developers, health care providers, and policymakers.

More specifically, this review makes 4 key contributions. First, it provides a PRISMA 2020–compliant synthesis of recent literature published between 2020 and 2025, focusing explicitly on blockchain-enabled dynamic and revocable consent for the secondary use of health data. Second, it applies a multidimensional analytical framework, encompassing consent life cycle management, auditability, usability, and legal-ethical alignment, complemented by a structured quality assessment of the included studies. Third, it identifies recurring architectural patterns such as hybrid on-chain or off-chain designs and the use of DIDs and VCs and analyzes their implications for interoperability, revocation enforcement, and compliance with GDPR and the emerging EHDS framework. Finally, it highlights critical gaps and future research directions required to advance these systems from conceptual prototypes toward operational health care infrastructures.

Objectives and Aims of the Review

The aim of this systematic review was to synthesize and critically evaluate blockchain-based frameworks that support dynamic, auditable, and revocable consent for the secondary use of health data. Specifically, the review seeks to (1) characterize the architectural and operational approaches used to model and enforce consent life cycles; (2) assess how auditability, provenance, and accountability are implemented across distributed systems; and (3) evaluate the extent to which proposed solutions address usability, interoperability, and regulatory alignment, including compliance with the GDPR and the emerging EHDS.

Together, these objectives frame the review's analytical focus on both technical maturity and practical readiness for real-world deployment.

RenderX

Methods

Overview

This systematic review was conducted to identify, analyze, and synthesize peer-reviewed literature on blockchain-based frameworks that enable dynamic, auditable, and revocable consent for the secondary use of health data. The review followed the PRISMA guidelines (Checklist 1) to ensure transparency and reproducibility. The methodological steps included defining eligibility criteria, developing a comprehensive search strategy, screening and selecting studies, extracting and synthesizing data, performing a structured quality assessment, and classifying findings according to a conceptual analytical framework.

Review Design

A systematic literature review approach was selected to provide a comprehensive and structured overview of the current research landscape. This design supports evidence-based synthesis by integrating findings from diverse studies that address similar research questions across technical, ethical, and regulatory dimensions. The review focused on primary research papers, system proposals, prototypes, and evaluations that describe blockchain-based consent management models relevant to health care data reuse. Conceptual papers were included only if they contributed a defined architectural or governance model. The review protocol was defined in advance to minimize selection bias and ensure consistency across screening, data extraction, and synthesis phases.

Eligibility Criteria

Eligibility criteria were established using the PICOS (population, intervention, comparison, outcome, and study type) framework, which ensures a consistent and unbiased selection process.

Inclusion criteria were as follows:

- Studies proposing or evaluating blockchain or distributed ledger–based consent systems within health care contexts
- Systems explicitly supporting dynamic consent, including granular, time-bound, or revocable authorization
- Studies addressing secondary use of health data, such as in research, AI model development, clinical trials, or data analytics
- Peer-reviewed journal publications between January 2020 and October 2025
- Publications written in English

To improve clarity and reproducibility, the inclusion criteria were operationalized as follows:

- Population: health care stakeholders and patient data contexts
- Intervention: blockchain or DLT-based consent management mechanisms
- Comparison: not mandatory, as most studies proposed novel frameworks
- Outcomes: support for dynamic, auditable, and revocable consent and/or reported technical or usability evaluation and
- Study type: peer-reviewed empirical, prototype, or architectural studies

Likewise, the research was set with the following exclusion criteria to filter out the irrelevant articles:

- Studies unrelated to health care or consent management
- Solutions limited to static, one-time consent without revocation or modification features
- Opinion pieces, editorials, or commentaries without technical or empirical contribution
- Duplicates or non–peer-reviewed materials such as white papers and theses or dissertations
- Conference papers were excluded unless extended journal versions were available to ensure sufficient methodological detail and maturity of the included studies.

Information Sources and Search Strategy

The literature search was performed across 3 major electronic databases known for health informatics and blockchain research: PubMed, Scopus, and Web of Science. A Boolean search string was developed and adapted to each database's syntax, combining key terms related to consent management, blockchain, and health data reuse. The core search expression used was as follows:

("dynamic consent" OR "revocable consent" OR "granular consent") AND

("blockchain" OR "distributed ledger" OR "DLT") AND

("health" OR "healthcare" OR "medical data") AND

("secondary use" OR "research" OR "data sharing" OR "AI training")

The core Boolean search strategy was adapted to the syntax and indexing mechanisms of each database. In PubMed, the search was applied to title and abstract fields and supplemented with relevant Medical Subject Headings (MeSH) where available. In Scopus and Web of Science, the search was executed using title, abstract, and keyword fields, with database-specific field tags and operators applied to preserve semantic equivalence across platforms. Truncation and phrase matching were used where supported. These adaptations ensured comprehensive retrieval while maintaining consistency in search intent across databases. The complete database-specific query formulations are available from the authors upon request to support reproducibility.

The final searches were conducted in October 2025, and the results were limited to publications between January 2020 and October 2025. Search fields included titles, abstracts, and keywords where supported by the databases.

Reference lists of included studies were manually screened to identify additional relevant publications not captured by database queries. All records retrieved from the search were exported to a Zotero citation manager [22] for deduplication and structured screening. The complete search strategy and database-specific query adaptations are available upon request to support reproducibility.

Study Selection Process

The selection process was conducted in 2 main stages:

XSL•FO
RenderX

- Title and abstract screening: Each record was independently reviewed to assess relevance against inclusion criteria. Articles clearly outside the health care or blockchain domain were excluded at this stage.
- Full-text review: Potentially relevant studies were examined in full to confirm eligibility and to ensure that they met the review's focus on dynamic and revocable consent mechanisms.

Any discrepancies in inclusion decisions were resolved by discussion among authors to reach consensus. The entire process was documented using a PRISMA 2020 flow diagram, which summarizes the number of records identified, screened, excluded, and included in the final analysis.

Specifically, 2 authors (SP and MB) independently screened all titles and abstracts, and disagreements were resolved through discussion, consulting with the authors RB and JCF when consensus could not be reached. The same procedure was applied during full-text assessment.

Interrater agreement between the 2 reviewers was assessed to evaluate screening consistency. Agreement was substantial, with a Cohen κ coefficient of 0.78 during title and abstract screening and κ of 0.81 during the full-text eligibility assessment, indicating a high level of concordance. Discrepancies were resolved through discussion and, where necessary, consultation with senior authors to reach consensus.

Data Extraction and Coding

A standardized data extraction form was designed to ensure consistency in collecting relevant details from each study. The following key attributes were extracted:

- Bibliographic details: authors, publication year, source, and country of origin
- Use case: health care domain, population, and purpose of data sharing
- Blockchain architecture: platform, consensus model, and smart contract use
- Identity management: use of DIDs, VCs, or public key infrastructure
- Consent features: life cycle stages supported (grant, modify, and revoke), granularity, and enforcement mechanisms
- Auditability mechanisms: on-chain logging, event tracking, hash anchoring, or hybrid verification models
- Usability aspects: interface design, patient engagement, and evaluation methods
- Compliance and ethics: references to GDPR, EHDS, or ethical principles
- Reported challenges: technical, organizational, or legal barriers to implementation

Additional fields were included to capture blockchain deployment models (public, permissioned, or consortium), hybrid on-chain or off-chain designs, and any mechanisms for automated revocation propagation or integration with clinical systems (eg, HL7 [Health Level 7] FHIR [Fast Healthcare Interoperability Resources]).

Extracted data were entered into a structured spreadsheet and cross-verified for accuracy and completeness. Data extraction was performed independently by 2 reviewers on a subset of studies to validate consistency, with disagreements resolved through discussion.

Analytical Framework and Data Synthesis

The synthesis process combined quantitative description with qualitative thematic analysis to identify design patterns and conceptual trends across studies. The analysis was guided by four key conceptual dimensions derived from the literature and regulatory frameworks:

1. Consent life cycle management: how systems model, enforce, and update consent states, including mechanisms for revocation
2. Auditability and traceability: the extent to which systems provide immutable and verifiable records of consent and data access
3. Usability and patient empowerment: the user-facing design and degree of patient control supported by interfaces or wallets
4. Legal and ethical alignment: compliance with data protection laws and ethical requirements related to transparency, purpose limitation, and revocability

Studies were coded against these dimensions and grouped into thematic clusters to highlight common technical approaches, gaps, and best practices. Where relevant, architectural diagrams and comparative tables were used to illustrate design similarities and differences.

Quantitative findings, such as the prevalence of blockchain platforms or identity mechanisms, were summarized using descriptive statistics, while qualitative findings were narratively synthesized to contextualize patterns and highlight challenges. The combined synthesis enabled cross-dimensional analysis, for example, linking architectural choices to observed usability or compliance limitations.

Quality Assessment

To ensure methodological rigor, each included study was evaluated for quality using a set of predefined criteria adapted from digital health and software engineering review frameworks. These criteria assessed the following:

- Clarity of objectives and problem definition
- Transparency in describing the system's architecture or implementation
- Explicit discussion of consent mechanisms and revocation of support
- Alignment with privacy or regulatory standards
- Evidence of validation, testing, or pilot evaluation

Each criterion was scored as 0 (not met), 0.5 (partially met), or 1 (fully met). Scores were summed and normalized to a 0 to 1 scale to derive an overall quality improvement (QI) score for each study. All criteria were equally weighted, as the review aimed to balance architectural transparency, consent life cycle enforceability, regulatory alignment, and empirical maturity. While no studies were excluded solely based on quality, the assessment was used to weight the interpretation of results, identify recurring methodological limitations, and contextualize the strength of the evidence base. Quality assessment was

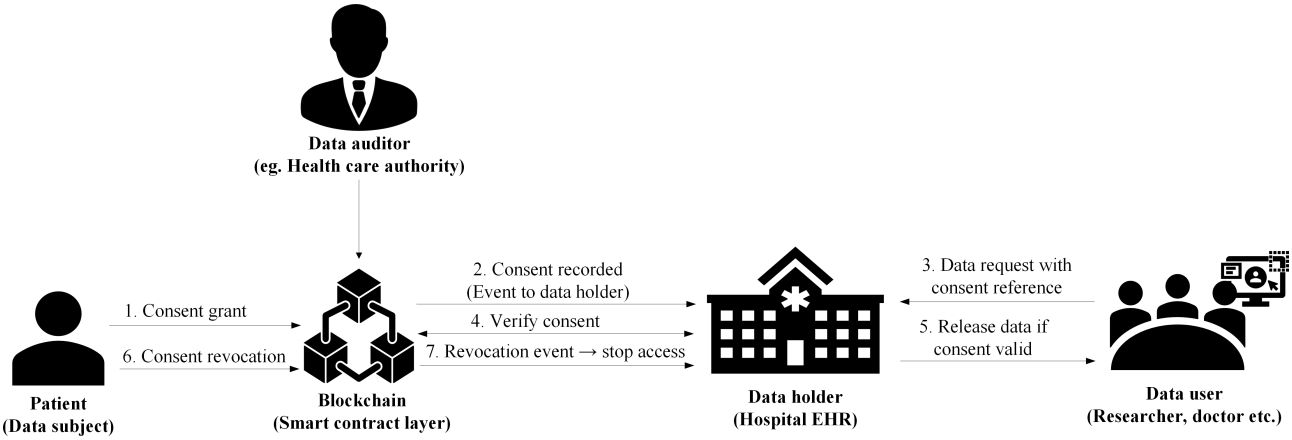
XSL•FO
RenderX

performed independently by the authors SP and MB on all included studies, with disagreements resolved through a collective discussion to ensure consistency.

Aggregate quality trends were later analyzed to distinguish between conceptual proposals and empirically validated implementations and to support sensitivity analysis in the synthesis of results.

As part of this sensitivity analysis, findings were reexamined by restricting the synthesis to studies with QI ≥0.75. This analysis showed that while high-level architectural patterns (eg, hybrid on-chain or off-chain designs and smart contract–based consent modeling) remained consistent, claims related to automated revocation propagation, usability validation, and enforcement assurance were supported by only a small subset of higher-quality studies. No study reported quantitative latency or completeness guarantees for revocation enforcement across distributed data custodians.

Results



Overview

This section presents the findings of the systematic review based on the analysis of 55 peer-reviewed studies that explore blockchain-based consent management frameworks for health care data sharing and secondary data use. The results are structured following the PRISMA process and analyzed according to the 4 conceptual dimensions defined earlier: consent life cycle management, auditability and traceability, usability and patient empowerment, and legal and ethical alignment.

Conceptual Overview

Before presenting the results of the systematic analysis, Figure 1 illustrates a generalized conceptual architecture reflecting the most common consent workflow patterns identified across the reviewed studies. The model summarizes how blockchain-based infrastructures support consent granting, verification, revocation, and audit logging for the secondary use of health data and serves as a reference architecture for the subsequent thematic analysis.

Figure 1. Conceptual architecture of blockchain-based consent management for secondary use of health data. EHR: electronic health record.

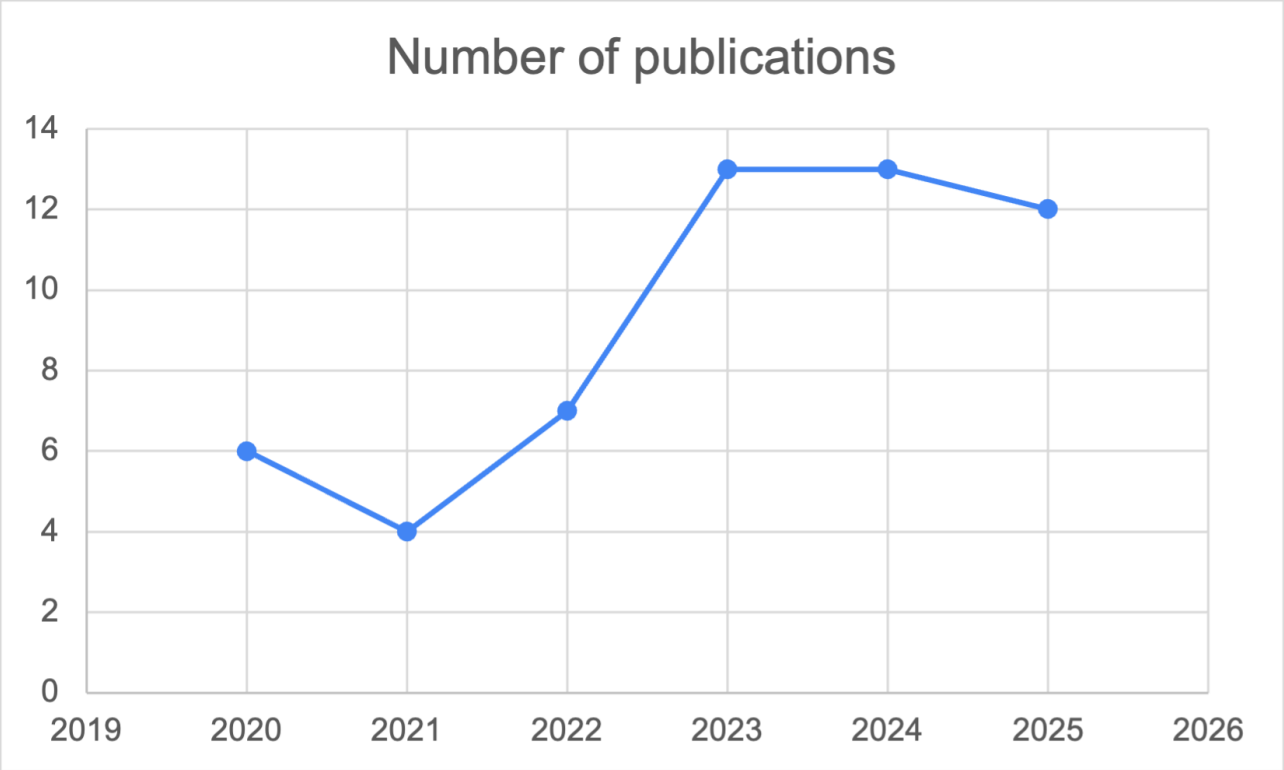
This conceptual model is not derived from a single implementation but represents an abstraction of recurring architectural elements observed across the literature, including hybrid on-chain or off-chain designs, smart contract–based consent logic, DIDs, and off-chain policy enforcement components. In line with the majority of reviewed frameworks, the model assumes a permissioned or consortium blockchain environment, in which participating health care and research institutions operate trusted nodes under defined governance and access control policies.

As shown in Figure 1, the consent workflow proceeds through the following steps.

- Step 1 begins when the data subject grants consent through a patient-facing application or digital identity wallet. This consent action is submitted to the blockchain via a smart contract, which records the consent state immutably on-chain.
- Step 2 propagates the consent creation or update event from the blockchain to the data holder, enabling synchronization of local access control and enforcement mechanisms.
- Step 3 occurs when a data requester submits a request for secondary use of health data, including a reference to the relevant consent identifier.
- Step 4 represents a bidirectional interaction between the data requester or data holder and the blockchain, in which the smart contract verifies the current consent state and returns an acknowledgment indicating whether access conditions are satisfied.
- Step 5 allows the data holder to release the requested data if consent has been verified and all access conditions are met. Sensitive health data remain off-chain throughout this process and are accessed only through controlled institutional interfaces.
- Step 6 enables the data subject to revoke previously granted consent, with the revocation recorded on-chain through a smart contract transaction.
- Step 7 disseminates the revocation event to subscribed data holders, ensuring that local enforcement mechanisms are promptly updated and that subsequent access requests are denied in accordance with the updated consent state.

XSL•FO
RenderX

Although the blockchain serves as the authoritative record of consent, data holders maintain a synchronized local enforcement state to support low-latency access control, auditing, and operational continuity. This local state is derived from on-chain consent events (steps 2 and 7) and does not replace blockchain-based verification.



Overall, blockchain functions primarily as a coordination and audit layer, anchoring consent events and access proofs rather than storing personal health data. This baseline hybrid architecture underpins the subsequent analysis of consent life cycle management, auditability, usability, and legal-ethical alignment across the reviewed studies.

Study Selection

The comprehensive search across 3 academic databases (PubMed, Scopus, and Web of Science) initially yielded 205 records. After duplicate removal and screening for relevance, 55 (26.8%) studies met all inclusion criteria.

The included studies were published between 2020 and 2025, indicating that blockchain-enabled consent management is a relatively recent and rapidly expanding area of research. The number of publications peaked in 2023, reflecting the growing maturity and convergence of blockchain and health care data sharing technologies. Figure 2 shows the publication trend of the articles across the years.

Figure 2. Publication trend of blockchain-based consent management studies (2020 - 2025).

The PRISMA 2020 flow diagram presented in Figure 3 illustrates the identification, screening, eligibility assessment, and final inclusion of studies, while a detailed summary of all included studies is provided in Table 2.

Specifically, 205 records were identified through database searching. After removal of 20 (9.8%) duplicates, 185 (90.2%) records were screened by title and abstract, of which 94 (45.9%) were excluded. Ninety-one (44.4%) full-text articles were sought for retrieval, 11 (5.4%) could not be accessed, and 80 (39%) reports were assessed for eligibility. Of these, 25 (12.2%) were excluded for not meeting the inclusion criteria, resulting in 55 (26.8%) studies included in the final synthesis.

Table . Overview of quantitative characteristics of included studies.

Category	Dominant themes or counts
Total studies included	55
Year range	2020 - 2025
Most active publication year	2023 - 2024
Blockchain-based systems	43
Dynamic or revocable consent	39
Health care–related applications	52
Privacy or security addressed	55
Leading application areas	Clinical trials, PHRs[a], digital health research

[a]PHR: personal health record.

Descriptive Summary of Included Studies

Among the 55 papers, 43 (78%) explicitly implemented or proposed blockchain-based consent management frameworks, and 39 (71%) studies incorporated features of dynamic or revocable consent. Fifty-two (95%) studies addressed health care data sharing scenarios, and every study engaged with data security and privacy considerations.

The reviewed studies were thematically classified based on their primary analytical focus. Although several studies address multiple themes (as reflected in Table 2), each paper was assigned to one dominant category for the purpose of aggregation. The dominant category was determined based on the main contribution emphasized in the study's objectives, system design, and evaluation. While this classification assigns a single dominant theme per study for summary purposes, Table 2 provides a multilabel thematic mapping, allowing studies to be associated with multiple categories. The category "Blockchain" refers to studies whose primary contribution lies in the design or analysis of blockchain-based systems or infrastructures, rather than in consent mechanisms or

XSL•FO
RenderX

application-level workflows. Across the reviewed corpus, the largest proportion of studies addressed data security and privacy (n=55, 21.7%), followed by health care data sharing (n=52, 20.6%) and consent management (n=50, 19.8%). Blockchain-focused studies accounted for 17.0% (n=43), while dynamic consent represented 15.4% (n=39). Review articles constituted the smallest share at 5.5% (n=14).

In terms of domain focus, clinical trials accounted for the largest application area, followed by PHRs and digital health research environments. Fewer studies focused on biomedical research governance, genomic data sharing, or cross-institutional interoperability pilots.

Table 2 summarizes the quantitative characteristics of the included studies. The majority of works were published between 2022 and 2024, reflecting the rapid growth of interest in blockchain-enabled consent management. Ethereum and Hyperledger Fabric were the most frequently used blockchain platforms, while Quorum and Polygon appeared in several experimental prototypes, where the majority of reviewed systems were deployed on permissioned or consortium blockchains, reflecting governance and access control requirements in regulated health care environments.

Influence of Application Domain, Platform Choice, and System Maturity

The reviewed studies exhibited substantial heterogeneity in application domain, blockchain platform, and implementation maturity, which influenced the nature and strength of reported findings. Studies focused on clinical trials and biomedical research more frequently implemented dynamic consent and auditability mechanisms, reflecting established governance requirements and sponsor accountability. In contrast, frameworks targeting EHRs and health information exchange more often emphasized access control and interoperability but provided less detail on consent life cycle enforcement.

Platform choice also affected system design. Permissioned and consortium blockchains, particularly Hyperledger Fabric, were predominantly used in health care–specific deployments and pilot studies, enabling finer governance control and alignment with regulatory requirements. Public blockchain–based proposals, often built on Ethereum, were more common in conceptual or proof-of-concept studies and tended to focus on smart contract expressiveness rather than operational compliance.

Finally, implementation maturity strongly shaped reported outcomes. Conceptual and prototype-level studies frequently claimed support for revocation and patient empowerment, whereas deployed or pilot systems more often reported constraints related to latency, institutional integration, and usability. As a result, higher-maturity implementations demonstrated narrower but more realistic functionality, while lower-maturity studies reported broader capabilities with limited empirical validation.

Thematic Classification

The selected studies were systematically analyzed according to the 4 conceptual dimensions defined in the analytical framework: (1) consent life cycle management, (2) auditability and traceability, (3) usability and patient empowerment, and (4) legal and ethical alignment. This thematic synthesis reveals both the convergence of design strategies across studies and the heterogeneity in their technical maturity, regulatory focus, and evaluation depth.

Consent Life Cycle Management

Across the dataset, most frameworks supported dynamic consent flows allowing users to grant, modify, and revoke consent at multiple stages of data sharing. Smart contracts were widely used to represent consent states, recording events such as *ConsentGranted*, *ConsentUpdated*, and *ConsentRevoked*, *which represent the consent states as the programmable states within the smart contracts, and they are automatically triggered based on predefined conditions*. Dynamic and revocable consent was the most frequently addressed theme across the dataset. Approximately two-thirds of the selected papers implemented explicit revocation mechanisms, with 35 (64%) of 55 studies distinguishing between active revocation (initiated by the data subject) and 6 (11%) of 55 papers adopting time-based or condition-based revocation (automatically triggered by contract logic). However, only 3 (5%) of 55 studies relied on administrator-initiated withdrawal.

To provide an overview of how consent life cycle management is addressed across the literature, Table 3 summarizes the studies that explicitly support dynamic consent features, including mechanisms for granting, modifying, and revoking consent. The table highlights the diversity of application domains and technical approaches through which life cycle control is operationalized in blockchain-enabled frameworks.

To examine revocation propagation mechanisms in greater depth, Table 4 presents a focused analysis of representative frameworks, detailing their propagation mechanisms, enforcement layers, operational scope, and evaluation evidence.

For example, DynamiChain [34] enabled real-time consent expiry via time stamp validation, and the works presented by [5,32,40] also used Solidity contracts to encode purpose-specific permissions and time-bound access. While some other works, such as [25,34], represented consent through chaincode with endorsement policies ensuring institutional accountability. The works such as METORY [52] and BEST [25] demonstrated practical synchronization between blockchain and off-chain access control layers. While few works, such as [20,29], explored how consent withdrawal could automatically cascade to all data custodians through event listeners or application programming interfaces. Overall, most studies successfully demonstrated programmable consent logic at a conceptual or prototype level, but large-scale validation in production environments remained limited.

XSL•FO
RenderX

Table . Revocation propagation: mechanism, scope, and evidence.

Study	Propagation mechanism	Enforcement layer	Scope	Evaluation	Latency or assurance reported	Notes
DynamiChain (Kim et al, 2021) [34]	NR[a] (conceptual time-bound expiry; no explicit listener or API[b] described)	On-chain check (time stamp validation)	NR (likely single site or conceptual)	Sim or laboratory (conceptual prototype)	NR	Implements consent expiry via time stamps; propagation beyond a single relying party appears conceptual only
BEST (Dong et al, 2023) [25]	Event listener or API integration to off-chain access control (described)	Hybrid (blockchain audit+off-chain PDP[c]/PEP[d])	Single site (NR for cross-institution)	Laboratory prototype	NR	Demonstrates synchronization between ledger events and PHR[e] sharing controllers; no explicit latency benchmarks
METORY (Huh et al, 2022) [52]	Event listener or API (NR for exact pattern)	Hybrid (smart contract status+site controllers)	Multisite (clinical trial settings)	Pilot (multicenter)	NR	Operational deployment in multicenter trials; improved transparency or retention reported; no latency numbers
Roman-Martinez et al, 2023 [29]	Service orchestration or API gateway (conceptual)	Hybrid (on-chain state+off-chain services)	Cross-institution (conceptual)	Conceptual or laboratory	NR	Architecture-level description; propagation pathways proposed but not benchmarked (conceptual only)
Can et al, 2024 [20]	Event listeners or APIs (described; implementation depth NR)	Hybrid (auditable consent with on-/off-chain)	Multisite (NR for real deployment)	Laboratory or prototype	NNR	Hybrid auditable consent; propagation discussed; evidence suggests prototype-level implementation without latency metrics

[a]NR: not reported.

[b]API: application programming interface.

[c]PDP: policy decision point.

[d]PEP: policy enforcement point.

[e]PHR: personal health record.

Only 5 (9%) of the 55 reviewed studies described any mechanism intended to propagate consent revocation beyond the blockchain layer. Among these, only 3 (5%) studies implemented or evaluated such propagation beyond a purely conceptual design. None quantified propagation latency. After sensitivity analysis (QI ≥0.75), this reduced to 0 studies, underscoring the critical gap in real-world implementation of revocable consent (Table 4).

Beyond the low prevalence of revocation propagation mechanisms, the reviewed studies provide limited insight into the underlying reasons for this gap. Across the literature, revocation is typically modeled as a smart-contract state transition, while downstream enforcement across distributed off-chain systems is left implicit. This suggests unresolved technical challenges in synchronizing on-chain consent states with heterogeneous institutional PEPs. In addition, regulatory uncertainty regarding the interpretation of “logical deletion” under GDPR Article 17, combined with the absence of performance benchmarks and certification incentives, appears to discourage implementation beyond proof-of-concept designs.

Auditability and Traceability

Auditability was one of the most consistent themes across the corpus. Blockchain’s immutability and append-only structure make it a natural foundation for verifiable audit trails. Among the reviewed studies, 27 (49%) of the 55 studies leveraged blockchain’s immutable ledger to maintain verifiable audit trails of consent and data access events, as summarized in Table 5.

XSL•FO
RenderX

Table . Studies focusing on auditability and traceability.

Authors and year	Audit or trace contribution	Application area
Can et al (2024) [20]	Hybrid architecture with consent management and introduced auditing mechanisms	Consent management
Dong et al (2023) [25]	Immutable logs in the proposed BEST platform	PHRs[a]
Peyrone and Wichadakul (2023) [27]	Supported consent withdrawal, renewal, and audit logs	General health care data sharing
Hang et al (2022) [6]	Comprehensive survey of blockchain in clinical trials, consent traceability, monitoring, data management	Clinical trials
Baysal et al (2023) [7]	Conducted multivocal literature review mapping blockchain applications in health care	General health domain
Garcia et al (2022) [53]	Proposed a blockchain-based privacy-preserving data governance framework ensuring accountability, transparency, and compliance across multiple stakeholders	Multistakeholder data governance
Daudén-Esmel et al (2024) [28]	Proposed a blockchain-based access control system for health care consent management; emphasized efficiency, scalability, and secure patient-controlled access to medical records	Health care consent and access control
Roman-Martinez et al (2023) [29]	Proposed blockchain architecture integrating consent management, access control, and auditing for compliance and interoperability	Health care data sharing or consent management
Ali et al (2023) [54]	Proposed a hybrid blockchain–deep learning architecture for secure and scalable health care data management	General health care systems
Kim et al (2021) [30]	Built a patient-consent blockchain platform (PHR) using hyperledger fabric with on/off-chain data storage; immutable PHR logs	PHRs
Pham et al (2024) [32]	Demonstrated feasibility of immutability in access logs	Clinical research
Albanese et al (2020) [15]	Auditability in clinical trials	Clinical trials
Kim et al (2021) [34]	Designed Dynamichain, a blockchain-based health care ecosystem integrating dynamic consent for medical data sharing; demonstrated system architecture and use cases	Health care data ecosystem
Hovorushchenko et al (2023) [51]	Surveyed blockchain-based approaches for medical data management; proposed classification of methods, highlighting challenges in scalability, privacy, and interoperability	General health care data management
Huh et al (2022) [52]	Designed METORY platform, a blockchain-based DCMS[b] tailored for clinical trials, supporting dynamic consent updates, secure auditability, and decentralized governance	Clinical trials
Tith et al (2020) [40]	Developed purpose-based access control model for patient consent, implemented hyperledger fabric audit trials	EHRs[c] or biobanking
Goint et al (2023) [55]	Proposed a framework for securing off-chain data storage in blockchain-based consent systems	Health care data sharing or off-chain storage
Rohini et al (2024) [43]	Introduced a blockchain-based immutable logging	Health information exchange
Castro et al (2024) [44]	Demonstrates blockchain's role in enhancing transparency, data integrity, traceability, and reproducibility of clinical trial data	Transparent and auditable clinical trial

XSL•FO
RenderX

Authors and year	Audit or trace contribution	Application area
Gondode et al (2025) [45]	Shows how blockchain enables tamper-proof EHRs, immutable audit trails, and transparent data sharing in ICUs[d]	Auditable EHR management
Gupta et al (2024) [46]	Synthesizes cross-industry evidence showing blockchain's role in enabling immutable audit trails and end-to-end traceability	Auditable supply chain management
Kasyapa and Vanmathi (2024) [47]	Systematically synthesizes how blockchain enables immutable audit trails, data integrity, and end-to-end traceability across health care use cases	Auditable EHR systems
Merlec and In (2024) [56]	Analyzes how blockchain-integrated decentralized storage ensures immutable records, verifiable data transactions, cryptographic integrity	Auditable decentralized storage
Nguyen et al (2025) [48]	Demonstrates how immutable ledgers and encrypted on-chain access tickets provide tamper-proof audit trails	Auditable genomic data sharing
Righi et al (2025) [49]	Proposes a hierarchical edge-fog-cloud architecture with data traceability services, sharding-based storage, and immutable logging of vital sign data paths	Auditable remote health monitoring
Felemban et al (2025) [50]	Synthesizes current and emerging uses of blockchain for immutable audit trails and traceability in health care	Auditable EHR systems
Hovorushchenko et al (2023) [51]	Proposes blockchain-based methods for medical data management that ensure immutable storage, provenance, and tamper-proof audit trail	Auditable EHR management

[a]PHR: personal health record.

[b]DCMS: Dynamic Consent Management System.

[c]EHR: electronic health record.

[d]ICU: intensive care unit.

Three dominant audit models emerged:

1. On-chain logging, where all consent transactions are recorded directly on the ledger for maximum transparency.
2. Hybrid anchoring, where detailed logs are stored off-chain but cryptographically hashed and referenced on-chain.
3. Smart-contract state verification, where consent status is queryable through verifiable contract variables.

While these models enhance transparency, several studies noted that blockchain audit logs remain technically complex and not easily interpretable by patients or regulators. Only a small subset provided visual audit dashboards or user-readable verification tools, such as the works presented in METORY [52], BEST [25], and SmartDataTrust [27], which provided graphical summaries of consent events. However, most systems exposed raw transaction logs or hashes, which are not easily interpretable by patients or auditors. This indicates that technical auditability does not always translate to practical accountability.

A small subset, 7 (13%) of 55 studies such as [29,43], implemented FHIR AuditEvent resources to bridge blockchain logs with clinical systems. Some recent works, such as [41], are experimenting with zero-knowledge proofs to verify data access without revealing identifiers, which preserves the privacy of data accessors while exposing only the minimum information required for audit and compliance.

Usability and Patient Empowerment

Usability remains a significant bottleneck in real-world adoption, and findings in this literature study were also mixed. Many systems incorporated patient-facing interfaces or portals that allowed individuals to view and adjust consent preferences. Altogether, 19 (35%) of 55 studies proposed some form of user interface for managing consent, yet only 11 (20%) of 55 studies conducted formal usability or acceptance testing, as summarized in Table 6. Most systems targeted patients via mobile or web dashboards, but interactions often required manual cryptographic signing or wallet operations beyond typical health literacy levels. Approximately one-third of the studies integrated decentralized identity wallets supporting DIDs and VCs to give users more direct control. Technical interactions, such as cryptographic signing and blockchain transactions, were often found to be too complex for typical patients. Where formal usability studies were conducted, results showed improved trust and willingness to share data when transparency and visual feedback mechanisms were present. Overall, patient empowerment was widely emphasized but poorly operationalized, revealing a significant gap between conceptual ideals and deployable user experiences.

XSL•FO
RenderX

Table . Studies emphasizing usability and patient empowerment.

Authors and date	Usability or empowerment focus	Application area
Kim et al (2022) [23]	Developed and tested a blockchain-applied mobile PHR[a] app with usability validation (System Usability Scale score 74.0)	PHR
Charles et al (2024) [19]	Presented blockchain-based dynamic consent model for patient-centric research, clinical trials, and health informatics applications	Patient-centric research or clinical trials
Dewan et al (2025) [57]	Co-designed a decentralized mobile app ("debi") with patients with breast cancer, enabling transparency and engagement in biobank specimen use	Biobanking or patient engagement
Schmidt et al (2025) [8]	Scoping review mapping technical implementations of informed consent in digital health; identified challenges (obtain, prove, retrace, and manage)	Digital health or mobile health consent
Kim et al (2021) [30]	Hyperledger Fabric with on/off-chain data storage; empowered patients with ownership of PHRs, dynamic consent, and secure sharing across hospitals	PHRs
Mishra and Mehra (2025) [31]	Proposed DiabeticChain, a blockchain framework for patient-controlled diabetes data sharing	Diabetes or chronic disease management
Muller et al (2023) [14]	Survey-based study showing patients prefer dynamic consent and continuous communication in large-scale data reuse; emphasized patient-centric governance	Large-Scale Health Data Reuse
Dankar et al (2020) [33]	Highlighted ethical challenges in sequencing and proposed dynamic consent as a solution for transparency and patient control	Genomics or population sequencing
Barnes et al (2025) [35]	Introduced "demonstrated consent": a hybrid model combining blockchain (NFTs[b] tied to samples) and generative AI[c] (LLMs[d]) for interactive, transparent communication in biobanking	Biobanking
Despotou et al (2020) [38]	Surveyed patient attitudes on blockchain-based digital consent for dynamic health data sharing; found patients valued transparency, control, and security	Digital health or patient perception
Lee et al (2023) [39]	Empirical study identifying organizational, technical, and social factors that promote or hinder adoption of dynamic consent in digital health ecosystems	Digital health
Baines et al (2024) [58]	Systematic review on public willingness for secondary data use; found conditional support based on privacy, trust, dynamic consent, and clear benefit communication	Secondary use or public attitudes
Kassam et al (2023) [9]	State-of-the-art literature review on digital health consent from patient perspectives; found preferences for transparency, dynamic consent, and control over protected health information	Digital health
Cumyn et al (2023) [10]	Surveyed public preferences for transparency in secondary data use; highlighted demand for clear communication, control, and ethical oversight	Secondary use of health data
Rohini et al (2024) [43]	Introduced a blockchain-based consent model for HIE[e], ensuring immutable logging, patient control, and streamlined data access	Health information exchange

XSL•FO
RenderX

Authors and date	Usability or empowerment focus	Application area
Lee and Lee (2022) [18]	Conceptual framework for applying dynamic consent in pervasive health care, focusing on privacy-aware IoT[f] and ubiquitous computing environments	Pervasive health care or IoT
Kazemzadeh (2025) [59]	Highlights patient-centered integration of AI by emphasizing informed consent and patient autonomy	Clinical workflows in ophthalmology
Malakar et al (2024) [60]	Explores patient empowerment through data ownership and control by assessing professionals' views on patients' rights to own, control, and decide use of their genomic data, emphasizing dynamic consent	Patient-centric genomic data management
Merlec and In (2024) [56]	Blockchain and smart contracts enable data self-sovereignty by giving users full ownership, control over access, sharing, and portability of their data, supporting user-centric and censorship-resistant data management	Self-sovereign decentralized storage

[a]PHR: personal health record.

[b]NFT: nonfungible token.

[c]AI: artificial intelligence.

[d]LLM: large language model.

[e]HIE: health information exchange.

[f]IoT: internet of things.

Of the studied articles, the mobile PHR app presented by Kim et al [23] achieved a System Usability Scale score of 74, while Dewan et al [57] co-designed the "de-bi," biobanking app with patients, which resulted in enhanced trust and engagement, and the METORY platform by Huh et al [52] was found to have increased transparency and participant retention in multicenter trials.

Furthermore, 18 (33%) of 55 studies integrated DID or VC mechanisms for self-sovereign consent representation [19,41]. These frameworks aligned with emerging EUDI (European Digital Identity) Wallet specifications to enable portable, user-controlled consent tokens. Only a few works addressed multilanguage interfaces, visual consent explainers, or voice assistant features vital for inclusive health data governance. Studies that did incorporate co-design or participatory approaches [38,57] reported higher user trust and perceived autonomy. Collectively, while patient empowerment is a recurrent objective, the translation of this principle into intuitive design remains emerging. Human-centered and iterative design methods remain underused in this domain.

Legal and Ethical Alignment

Compliance with privacy regulations such as GDPR and the EHDS was discussed in 19 of 55 (35%) studies. Most frameworks aimed to align with GDPR principles of informed and revocable consent (Article 7) and data minimization (Article 5). A recurring challenge was the conflict between blockchain immutability and GDPR's right to erasure (Article 17). To address this, several systems used privacy-preserving designs, recording only hashed references or using off-chain pointers to revocable consent states. Only 9 of 55 (16%) studies addressed the "right to erasure" (Article 17) directly, highlighting the continuing tension between blockchain immutability and deletion requirements. Specifically, 12 of 55 (22%) studies used off-chain storage of personal data and on-chain hash references; 6 of 55 (11%) studies adopted revocable credentials or tokenized pseudonyms to enable logical deletion; and 3 of 55 (5%) studies explored zero-knowledge proofs to verify consent without revealing personal data [41], although these remained largely experimental.

The works presented in [19,49] linked blockchain consent to EHDS and EUDI wallet frameworks, indicating an emerging policy-driven research direction. Nonetheless, ethical analysis remained superficial in most papers, only 8 of 55 (15%) studies explicitly referenced bioethical principles, such as autonomy, justice, or beneficence.

Beyond such high-level alignment claims, concrete operational guidance for EHDS is now emerging. The TEHDAS guidelines for Health Data Access Bodies provide detailed recommendations on implementing opt-out from secondary use, including the establishment of national opt-out registries, citizen-facing portals, and cross-border recognition of opt-out choices. This underscores that EHDS compliance for blockchain-based consent systems requires integration with Health Data Access Bodies governance and institutional workflows, not only on-chain auditability or consent logic [3].

Furthermore, studies by van Drumpt [61] and Forster et al [62] provide a comprehensive legal analysis revealing that existing European Union (EU) data protection frameworks, including the GDPR and the EHDS Regulation, inadequately support the lawful and harmonized secondary use of health and genetic data across borders, and it advocates for new EU-level legislative measures to establish consistent legal bases for such data reuse. The work by Barnes et al [35] introduces the novel concept of "demonstrated consent," a blockchain- and generative AI–based

XSL•FO
RenderX

framework that uses nonfungible tokens (NFTs) and large language models to create a transparent, participant-centered system for managing, tracking, and communicating biobanking consent. In addition, a study by Zafar [63] provides a comprehensive analysis of the conflicts between blockchain's immutability and data protection requirements, proposing a hybrid legal-technical framework that leverages off-chain storage, encryption, and privacy-enhancing technologies to achieve regulatory compliance while preserving blockchain's core functionalities.

Thus, while legal alignment is widely acknowledged, comprehensive ethical governance and juridical interpretation of blockchain consent remain underdeveloped. Table 7 summarizes the studies that explicitly address legal and ethical alignment across these dimensions.

XSL•FO
RenderX

Table . Studies addressing legal and ethical alignment.

Authors and year	Legal or ethical focus	Application area
Alhajri et al (2022) [24]	Proposed a GDPR[a]-compliant, decentralized consent system for wearable fitness data using blockchain and smart contracts	Wearable fitness data or health care
Can et al (2024) [20]	Proposed a GDPR-compliant hybrid architecture with a "purpose tree" for consent management	General GDPR consent management (applied to health care)
Qu et al (2025) [64]	Proposed a blockchain-based EMR[b] sharing method with ring signatures and off-chain storage; ensured security, privacy, transparency, and compliance with China's PIPL[c]	EMR
Garcia et al (2022) [53]	Proposed a blockchain-based privacy-preserving data governance framework ensuring accountability, transparency, and compliance across multiple stakeholders	Multistakeholder data governance (health +cross-domain)
Schmidt et al (2025) [8]	Scoping review mapping technical implementations of informed consent in digital health; identified challenges (obtain, prove, retrace, manage), highlighted blockchain and dynamic consent as promising but underevaluated	Digital health or mHealth[d] consent
Minssen et al (2020) [65]	Analyzed regulatory and legal challenges of data sharing in clinical trials under GDPR; focused on compliance, transparency, and secondary use of data	Clinical trials or legal and GDPR compliance
Pina et al (2024) [66]	Provided best practices for data minimization, anonymization, pseudonymization, encryption, and retention; applied case study in health care dataset; highlighted ethical and regulatory compliance	Database management and health care dataset
Vlahou et al (2021) [67]	Review of GDPR impacts on biomedical research and consent; called for harmonization of law and ethics, clarification of broad consent, and roadmap for secondary data use	Biomedical research governance
Muller et al (2023) [14]	Survey-based study showing patients prefer dynamic consent and continuous communication in large-scale data reuse; emphasized patient-centric governance	Large-scale health data reuse
Dankar et al (2020) [33]	Introduced dynamic informed consent for large-scale genomics; highlighted ethical challenges in sequencing and proposed dynamic consent as a solution for transparency and patient control	Genomics or population sequencing
Barnes et al (2025) [35]	Introduced "demonstrated consent": a hybrid model combining blockchain (NFTs[e] tied to samples) and generative AI[f] (LLMs[g]) for interactive, transparent communication in biobanking	Biobanking
Khalid et al (2023) [36]	Proposed a formal security model for DCMS[h]; introduced definitions of confidentiality, availability, unforgeability, auditability; suggested integrating blockchain, differential privacy, and ZKPs[i] to strengthen privacy-by-design	Dynamic consent in eHealth care
Becker et al (2024) [68]	Legal analysis of EU[j] data protection law and ethical issues for secondary use of health or genetic data; argued current GDPR framework insufficient, recommending new legislation	Secondary use of health and genetic data
Baines et al (2024) [58]	Systematic review on public willingness for secondary data use; found conditional support based on privacy, trust, dynamic consent, and clear benefit communication	Secondary use or public attitudes

[f]AI: artificial intelligence.
[g]LLM: large language model.
[h]DCMS: Dynamic Consent Management System.
[i]ZKP: zero-knowledge proofs.
[j]EU: European Union.

Summary of Thematic Prevalence

To consolidate the thematic findings across the 55 reviewed studies, Table 8 summarizes the dominant design approaches, associated methodological characteristics, and proportional representation across the 4 analytical dimensions examined earlier. The purpose of this synthesis is to provide a holistic overview of how blockchain-based dynamic consent systems distribute their priorities between technical, usability, and regulatory domains and to indicate areas where further development and evaluation are needed.

Table . Summary of thematic prevalence across the reviewed studies.

Analytical dimension	Predominant approach	Studies, n (%)
Consent life cycle management	Smart contract–based grant/modify/revoke models	35 (64)
Auditability and traceability	Hybrid on/off-chain hash anchoring systems	27 (49)
Usability and empowerment	Web or mobile interfaces (with limited testing)	19 (35)
Legal and ethical alignment	GDPR[a]-compliant off-chain designs	19 (35)

[a]GDPR: General Data Protection Regulation.

These findings reflect a rapidly converging landscape in which blockchain technologies are increasingly adopted as trust anchors for consent tracking, audit logging, and integrity assurance. However, striking divergences remain in how thoroughly these patterns are implemented and evaluated. Most studies incorporate blockchain for immutable auditability, but fewer extend the evaluation to human-centered usability or cross-system enforcement of consent withdrawal. As detailed in the consent life cycle management analysis, revocation propagation beyond on-chain state updates remains rarely implemented and largely unvalidated in current blockchain-based consent frameworks.

To further clarify how recurring technical mechanisms align with European regulatory frameworks, Tables 9-11 disaggregate the previously consolidated analysis into goal-specific comparisons, focusing on data storage, consent and access enforcement, and auditability and interoperability, respectively. This restructuring enables direct comparison of how the same functional objectives are implemented across different blockchain-based consent frameworks and addresses the overlapping nature of design choices observed in the literature.

XSL•FO
RenderX

Table . Data storage and persistence strategies in blockchain-based consent frameworks.

Strategy	On-chain data	Typical use	Regulatory alignment	Key risk
Off-chain+hash anchoring	No	Integrity, audit	High	Hash linkage
Encrypted on-chain storage	Yes	PoC[a] designs	Low	Erasure impossible

[a]PoC: proof of concept.

Table . Consent and access enforcement mechanisms for secondary use of health data.

Mechanism	Revocable	Enforcement scope	Limitation
Smart contracts+PEP[a]	Yes	Partial	Latency
Token-based consent	Yes	Weak	Cache staleness

[a]PEP: policy enforcement point.

Table . Auditability and interoperability approaches in blockchain-enabled consent systems.

Approach	Human readable	Standards aligned	Limitation
On-chain logs	No	Low	Poor usability
FHIR[a] AuditEvent anchoring	Yes	High	Early adoption

[a]FHIR: Fast Healthcare Interoperability Resources.

Table 9 compares data storage and persistence strategies adopted by the reviewed studies. A clear convergence emerges toward off-chain storage combined with on-chain hash anchoring, which enables integrity verification and auditability while supporting data minimization and erasure requirements under GDPR Articles 5 and 17. Nevertheless, a small subset of studies, primarily proof-of-concept designs, propose storing encrypted health data or metadata directly on-chain. Such approaches raise significant regulatory and security concerns, particularly with respect to the right to erasure and long-term exposure risks, and remain misaligned with GDPR and EHDS expectations.

Table 10 focuses on consent and access enforcement mechanisms. Most reviewed frameworks rely on smart contracts combined with off-chain PEPs or token-based authorization to enable revocable and fine-grained access control. While these mechanisms support logical revocation under GDPR Article 7, enforcement is often partial and dependent on timely synchronization between the on-chain consent state and off-chain systems. As a result, revocation propagation delays and stale authorization caches remain recurring limitations across implementations.

Table 11 summarizes approaches to auditability and interoperability. Immutable on-chain logs are widely used to ensure nonrepudiation and traceability but are rarely human-readable or directly usable by regulators or patients. Emerging approaches that bridge blockchain events with health care standards such as HL7 FHIR Consent and AuditEvent resources demonstrate greater potential for institutional governance and EHDS-aligned interoperability, although adoption remains limited and implementations are still evolving.

Taken together, this goal-based analysis reinforces that blockchain is not inherently compliant or sufficient on its own. Regulatory alignment depends on how architectural components operationalize principles such as data minimization, revocability, accountability, and interoperability. Although architectural convergence is evident across storage and audit patterns, substantial gaps remain in enforcement assurance, usability validation, and governance integration.

Quantitative Summary, Quality Assessment, and Emerging Trends

This section synthesizes the core quantitative findings from the 55 studies, evaluates their methodological quality, and highlights emerging architectures and research trajectories in blockchain-based dynamic consent for secondary health data use, with particular attention to how study quality influences the strength of reported design claims.

As discussed in the Consent Life Cycle Management analysis, sensitivity analysis restricted to higher-quality studies (QI ≥0.75) further confirms that operational revocation propagation beyond on-chain state changes remains rarely implemented and empirically unvalidated. Similarly, the proportion of studies reporting formal usability evaluation remained below 25%. Core architectural trends, such as hybrid on-chain or off-chain storage and smart contract–based consent modeling, remained consistent across quality thresholds. This indicates that while foundational design patterns are robust, claims related to operational enforceability and real-world readiness are supported by a limited subset of higher-quality studies.

Quantitative Overview

A structured synthesis of the extracted data reveals strong convergence on several foundational design patterns for blockchain-based consent management. Table 12 presents the operational definitions and associated aggregate counts derived during quantitative coding.

XSL•FO
RenderX

Table . Operational definitions and counts used in the quantitative synthesis.

Metric	Operational definition	Count (n/N)	Percent
Blockchain consent system	Paper proposes or evaluates a consent framework implemented on blockchain or DLT[a] with executable consent logic or on-chain logging.	43/55	78.2
Dynamic or revocable consent	Framework allows post hoc modification and/or withdrawal of consent enforced by smart contracts or off-chain controllers (not merely discussed conceptually).	39/55	70.9
User interface present	Prototype or product UI[b] shown for patients/stakeholders to manage consent.	16/55	29.1
Formal usability testing	Reports a recognized method (eg, SUS[c]/UEQ[d]/think-aloud) with N and procedure.	11/55	20
Auditability implemented	On-chain or hybrid logging built, not only proposed.	18/55	32.7

[a]DLT: distributed ledger technology.

[b]UI: user interface.

[c]SUS: System Usability Scale.

[d]UEQ: user experience questionnaire.

These proportions reflect a strong trend toward technical feasibility and decentralized audit trails, with less attention to user-facing evaluative studies. In particular, fewer than 1 in 5 studies (<20%) report user experience validation, despite claims of user empowerment and transparency.

Publication trends from 2020 to 2025 show an accelerating interest in the topic, with a marked surge beginning in 2022. This aligns with regulatory movement around the EHDS and the maturation of decentralized identity standards, such as W3C DIDs and VCs.

Quality and Agreement Assessment

To evaluate the reliability and robustness of the reviewed studies, a 5-item QI was applied across all papers, scoring on clarity of objectives, architectural transparency, consent life cycle coverage, privacy or regulatory alignment, and empirical validation. The resulting QI scores ranged from 0.35 to 0.95, with a median of 0.68 (IQR 0.54 - 0.82), indicating overall moderate to high methodological quality.

- Interrater agreement was substantial (κ=0.78, range 0.71 - 0.85).
- Excluding studies with QI <0.50 slightly reduced thematic counts (eg, dynamic consent: from 39 to 33) but did not reverse key trends.
- Notably, automated revocation propagation across system boundaries remains rare and empirically unvalidated, with no studies reporting latency or enforcement assurance metrics, representing an operational gap with direct implications for GDPR compliance (Article 7).

Beyond reporting agreement, the quality assessment provides critical interpretive context for the thematic synthesis. Studies with higher QI scores consistently offered clearer architectural descriptions, explicit consent-state models, and at least partial empirical validation, whereas lower-QI studies were more likely to present conceptual frameworks without implementation detail or reproducible evaluation.

When restricting the analysis to studies with QI ≥0.75, several commonly reported capabilities, particularly around real-time revocation propagation and user empowerment, were supported by only a very small subset of works, indicating that these features remain largely aspirational rather than operationally demonstrated in the current literature.

Similarly, claims of GDPR or EHDS compliance in lower-QI studies were often based on high-level alignment statements rather than concrete legal-technical mechanisms (eg, explicit handling of Article 17 erasure or cross-system enforcement), whereas higher-QI studies more frequently implemented hybrid storage, revocable credentials, or auditable consent-state transitions.

Taken together, these results emphasize that while the foundational architectural patterns for blockchain-enabled dynamic consent are maturing, the empirical depth needed to substantiate performance, usability, and regulatory enforcement remains limited. Evaluation rigor, latency benchmarking, and cross-institutional enforcement assurance therefore represent critical priorities for advancing from conceptual feasibility toward operational readiness.

Overall, the QI analysis suggests that the field is characterized by strong architectural innovation but uneven methodological maturity and that future research must prioritize reproducible implementations, measurable performance indicators, and user-centered validation to strengthen the evidence base for blockchain-based consent systems in real health care settings.

XSL•FO
RenderX

Emerging Research and Technical Trends

Several emergent clusters signal the evolving priorities and directions in the field.

Self-Sovereign Consent With DIDs and VCs

There is increasing adoption of decentralized identity credentials to enable user-controlled consent traces and cross-domain portability, especially in cross-border care scenarios [49].

This trend reflects a shift from institution-centric consent registries toward patient-held, cryptographically verifiable consent artifacts, aligning with emerging EUDI Wallet and W3C VC ecosystems. However, only a limited subset of studies demonstrated live wallet integration or interoperability across domains, indicating that most implementations remain at prototype or conceptual stages.

FHIR and HL7-Aligned Interoperability

There is an increasing emphasis on bridging blockchain with clinical standards (eg, FHIR Consent and AuditEvent), in preparation for EHDS and HealthData@EU infrastructures [69].

Recent works explicitly map smart-contract consent states to FHIR Consent resources and expose blockchain audit events as FHIR AuditEvent records, signaling a growing recognition that blockchain layers must integrate with existing health IT workflows rather than operate as parallel infrastructures. Nonetheless, most proposals stop short of demonstrating production-grade interoperability or conformance testing against national FHIR profiles.

Privacy-Preserving Cryptography

There is experimental use of zero-knowledge proofs and selective disclosure schemes for authorization without identifier exposure, aligned with GDPR Article 25.

These approaches aim to reconcile blockchain transparency with data minimization by enabling verification of consent or access rights without revealing identities or attributes. However, implementations remain limited to proof-of-concept circuits, with unresolved challenges around computational overhead, verifier scalability, and standardization across platforms.

Hybrid Blockchain Architectures

The use of off-chain storage with on-chain hashes or audit indices to balance GDPR erasure rights with audit integrity has been a dominant architectural pattern since early blockchain-based health data exchange systems. Rather than an emerging trend, recent studies refine this baseline by introducing richer metadata anchoring, revocable pointers, and tighter coupling with off-chain PEPs, reflecting a shift from architectural choice toward operational optimization.

Policy-Driven Design

Many systems explicitly frame their architecture in terms of GDPR and EHDS compliance, emphasizing revocability, auditability, and patient agency.

This has led to architectures that embed legal concepts such as purpose limitation, consent expiry, and accountability directly into smart-contract logic. Nevertheless, legal alignment is often asserted rather than empirically validated, and few studies evaluate whether implemented mechanisms would satisfy regulatory scrutiny in real enforcement scenarios.

Across these trends, a common pattern emerges: architectural sophistication is increasing, but empirical validation and cross-system interoperability lag behind. Higher-quality studies (QI ≥0.75) are more likely to integrate multiple trends simultaneously, such as DIDs with FHIR bridging and hybrid storage, suggesting that technical convergence is occurring primarily in the most methodologically mature works. Together, these trends indicate a gradual transition from conceptual feasibility toward policy-aware and interoperability-oriented design. However, significant gaps persist in enforcement interoperability, large-scale deployment evidence, usability testing, and latency assurance, underscoring that most frameworks remain preoperational despite increasing architectural convergence.

Discussion

Summary of Main Findings

This systematic review analyzed 55 peer-reviewed studies published between 2020 and 2025 that proposed or evaluated blockchain-based frameworks for dynamic and revocable consent in the secondary use of health data. The findings indicate that most proposed systems leverage smart contracts and hybrid on-chain or off-chain architectures to support consent life cycle management and immutable auditability. While dynamic consent and revocation are frequently claimed features, only a small subset of studies provided architectural detail or empirical evidence demonstrating automated revocation propagation across distributed systems. Usability evaluation and real-world deployment remain limited, with fewer than one-fifth of studies reporting formal user testing. Furthermore, although GDPR alignment is commonly asserted, explicit consideration of the EHDS governance model and operational opt-out mechanisms is still sparse.

Sensitivity analysis based on methodological quality (QI ≥0.75) confirmed that high-level architectural patterns remain stable, whereas evidence for automated revocation propagation, usability validation, and enforcement assurance is limited to a small subset of higher-quality studies.

Dynamic and Revocable Consent Life Cycle Management

In relation to the first objective of this review, characterizing architectural and operational approaches to dynamic and revocable consent, blockchain was widely adopted as an enabling infrastructure for managing dynamic and revocable consent life cycles in health care. Most frameworks used smart contracts to automate consent processes, recording events such as consent granting, modification, and revocation, and defining granular access conditions including time-bound or purpose-specific authorizations. By encoding consent states on-chain, these systems leveraged blockchain's immutability to maintain verifiable histories of consent actions, conceptually aligning with principles of patient autonomy and ongoing informational self-determination.

XSL•FO
RenderX

However, despite frequent claims of revocability, the practical realization of dynamic consent remained limited. Only a small fraction of studies operationalized real-time revocation propagation across distributed data custodians, and many implementations relied on simulated environments rather than live data sharing scenarios. Even among higher-quality studies, revocation was typically enforced through local policy decision points querying on-chain consent state, rather than through end-to-end automated propagation across institutional boundaries. As a result, most frameworks achieved logical revocability at the ledger level but did not demonstrate effective enforcement across heterogeneous, off-chain data environments.

The increasing integration of DIDs and VCs reflects a broader shift toward self-sovereign consent models, enabling individuals to assert and manage permissions independently of central authorities. Nevertheless, most DID- and VC-enabled systems stopped short of demonstrating cross-domain portability or wallet-to-wallet interoperability, indicating that self-sovereign consent remains largely aspirational. From a regulatory perspective, this gap is significant, as both the GDPR and the EHDS require not only the possibility of consent withdrawal but also its practical and timely effect on ongoing and future data processing.

The limited operationalization of revocation propagation observed in this review reflects a combination of technical, regulatory, and organizational factors rather than a lack of conceptual awareness. From a technical perspective, propagating consent withdrawal across distributed data custodians requires reliable event dissemination, low-latency synchronization, and tight coupling between blockchain layers and off-chain access control systems, capabilities that are difficult to implement and evaluate in academic prototypes. From a regulatory standpoint, uncertainty persists regarding how blockchain-based “logical deletion” mechanisms are interpreted under GDPR Article 17 and how these mechanisms will align with the EHDS governance model, particularly in federated infrastructures such as HealthData@EU. Organizationally, many proposed systems lack clear institutional incentives or compliance drivers to validate revocation enforcement beyond the ledger level, resulting in designs that prioritize auditability over enforceability. Together, these factors help explain why revocation is widely claimed but rarely demonstrated as an end-to-end operational capability.

Auditability, Provenance, and Accountability

Addressing the second objective of assessing auditability and accountability mechanisms, auditability and provenance tracking emerged as among the most consistently addressed features of blockchain-based consent frameworks. Many studies capitalized on blockchain’s tamper-evident recordkeeping to provide verifiable logs of consent events and data access transactions, underpinning accountability in multi-institutional and cross-border data reuse scenarios. Three dominant design patterns were observed: direct on-chain audit logging, hybrid architectures anchoring off-chain logs on-chain, and smart contract state verification through read-only queries.

Hybrid audit models were the most prevalent, reflecting a balance between transparency, privacy, and scalability. These approaches typically stored detailed audit metadata off-chain while anchoring cryptographic proofs on-chain, allowing integrity and nonrepudiation without exposing sensitive identifiers. Such configurations are particularly relevant in GDPR and EHDS contexts, where data minimization and controlled disclosure are essential. Architecturally, this trend also coincides with a move away from public, permissionless blockchains toward permissioned or consortium-based ledgers governed by trusted health care or research institutions.

Despite strong technical guarantees, auditability often did not translate into practical accountability. Only a limited number of studies provided user-facing audit dashboards or regulator-oriented reporting tools, leaving audit data opaque to nontechnical stakeholders. In many cases, audit logs were verifiable by machines but inaccessible or unintelligible to patients, ethics committees, or oversight authorities. This highlights that accountability is not solely a cryptographic property but a sociotechnical one, requiring human-readable representations and institutional governance interfaces.

Emerging efforts to integrate blockchain logs with established health care standards, such as HL7 FHIR AuditEvent resources, represent a promising direction. However, these remain early-stage, and standardized frameworks for consent provenance visualization and regulatory reporting are still under development.

Usability, Interoperability, and Operational Constraints

With respect to the objective of evaluating usability, interoperability, and implementation maturity, usability and real-world adoption remain persistent challenges. Only a minority of studies reported formal usability testing or user experience evaluation, and many systems required interactions with cryptographic wallets, private keys, or blockchain transactions that exceed typical patient or clinician digital literacy. These challenge assumptions underlying self-sovereign models and underscore the need for human-centered design approaches.

Frameworks incorporating mobile-friendly consent dashboards or DID wallets demonstrated greater potential for user acceptance, yet accessibility barriers such as limited multilingual support, unclear consent visualization, and insufficient mobile optimization were common. Studies with higher methodological quality were more likely to report participatory design or usability validation, reinforcing the link between technical maturity and user-centered evaluation.

Interoperability with existing health information systems also emerged as a critical bottleneck. Although several studies referenced integration with EHRs or HL7 FHIR resources, few described concrete mechanisms for synchronizing blockchain-based consent states with institutional access control systems or cross-border infrastructures. Without standardized interfaces and data models, blockchain-based consent solutions risk operating in isolation from clinical and research workflows, limiting their production viability. Increasingly, blockchain appears best positioned as a coordination and trust layer rather than a replacement for established health IT systems.

XSL•FO
RenderX

Scalability and performance concerns further constrain deployment. Most frameworks adopted permissioned ledgers or layer-2 solutions to address throughput and cost limitations, yet latency in consent updates and revocation propagation remains largely unmeasured. The near absence of reported performance benchmarks suggests that scalability is often assumed rather than empirically validated.

Regulatory Alignment and Ethical Governance

Most reviewed studies explicitly referenced compliance with the GDPR, particularly requirements for informed and revocable consent. However, alignment was more often asserted than operationalized. The tension between blockchain immutability and rights such as erasure remains unresolved in many designs, with mitigation strategies such as off-chain storage, revocable credentials, or zero-knowledge proofs still largely experimental.

With the EHDS Regulation establishing dedicated governance structures for secondary use of health data in the EU, future consent architectures must increasingly move beyond GDPR-centric interpretations. Compliance under the EHDS depends not only on technical design but also on integration with HealthData@EU infrastructures, certification schemes, and institutional access bodies. Ethical governance was comparatively underdeveloped across the literature, with limited engagement with principles such as justice, beneficence, or the ethical implications of automated consent enforcement.

Comparison With Existing Reviews

Several prior reviews have examined blockchain applications in health care or digital consent from complementary perspectives; however, their analytical scope differs substantially from that of this review. Surveys focusing on blockchain in health care have primarily emphasized data security, interoperability, or application domains such as clinical trials and supply chains, without systematically analyzing consent as a dynamic and revocable life cycle with enforceable propagation mechanisms. Conversely, reviews of digital or dynamic consent have largely centered on ethical, legal, or usability considerations, often without examining the underlying technical architectures required to ensure verifiable auditability and distributed enforcement.

In contrast to these earlier works, this review explicitly integrates architectural, operational, and regulatory dimensions by examining how blockchain-based frameworks implement consent life cycle management, auditability, usability, and legal alignment for secondary use of health data. By synthesizing evidence from 55 peer-reviewed studies published between 2020 and 2025, this review advances prior literature in 3 key ways. First, it systematically analyzes revocation enforcement and propagation mechanisms, revealing that revocability is frequently asserted but rarely operationalized across distributed data custodians. Second, it evaluates auditability not only as a cryptographic property but also as a sociotechnical capability requiring interpretability and governance integration. Third, it situates blockchain-based consent frameworks within the emerging EHDS regulatory context, which has been largely absent from previous reviews.

By consolidating fragmented evidence across technical, usability, and regulatory dimensions, this review moves beyond descriptive surveys and provides an integrative assessment of the operational maturity of blockchain-enabled consent systems. This positioning clarifies both the current limitations of existing approaches and the concrete design and governance challenges that must be addressed to enable real-world deployment for secondary use of health data.

Positioning this review within the broader consent literature reveals a clear progression in research focus. Reviews of dynamic consent outside blockchain contexts have predominantly examined ethical acceptability, user engagement, and governance models, often assuming centralized infrastructures and institutional enforcement. Conversely, surveys of blockchain in health care have focused on data security, provenance, and interoperability, treating consent as a secondary or implicit function rather than as a programmable life cycle.

This review differs by explicitly integrating these trajectories. By analyzing consent as an enforceable life cycle implemented through blockchain-based architectures, the review links ethical expectations of dynamic consent with the technical mechanisms required to operationalize revocation, auditability, and accountability in distributed secondary-use settings. In doing so, it exposes a persistent gap between conceptual consent models and their technical realization, particularly in relation to revocation propagation and cross-institutional enforcement, an aspect not systematically examined in earlier reviews.

Implications for Design, Governance, and Policy

The findings suggest that future progress depends less on novel blockchain primitives and more on integrative system design. Blockchain should be treated primarily as a coordination and accountability layer rather than as a data repository. Effective systems must tightly couple on-chain consent states with off-chain PEPs, adopt interoperable standards such as HL7 FHIR for consent and audit representation, and embed legal interpretation into system governance.

From an institutional perspective, consortium-based deployments with clear roles and accountability mechanisms are better aligned with secondary-use contexts than public infrastructures. For policymakers and standards bodies, clearer guidance is needed on how blockchain-enabled consent can interoperate with EHDS governance models, including HealthData@EU and Health Data Access Bodies.

The observed variation across application domains, blockchain platforms, and system maturity suggests that blockchain-enabled consent solutions are not uniform and should not be evaluated as a single class of systems. Design trade-offs that are acceptable in clinical trial environments, such as controlled participation and sponsor oversight, may not translate directly to large-scale EHR or population health infrastructures. Similarly, while public blockchains support rapid prototyping and transparency, permissioned and consortium deployments appear more compatible with regulated secondary-use contexts under GDPR and the EHDS. These differences underscore the need for

XSL•FO
RenderX

domain-sensitive evaluation rather than one-size-fits-all architectural assumptions.

Toward an Operational Research Agenda for Blockchain-Based Dynamic Consent

To move beyond high-level design principles, the findings of this review motivate a concrete research agenda focused on operational validation rather than architectural novelty. First, future work should prioritize the design and evaluation of a multisite revocation propagation protocol, in which consent withdrawal events recorded on-chain are automatically disseminated to heterogeneous off-chain policy PEPs operated by independent institutions. Such a protocol should explicitly define event subscription mechanisms, enforcement acknowledgment semantics, and failure-handling procedures, enabling revocation to be evaluated as a measurable system property rather than a conceptual claim.

Second, pilot studies should report quantitative enforcement metrics, including revocation propagation latency, completeness of enforcement across data custodians, and system behavior under partial network or service failures. These metrics are directly relevant to GDPR Article 7 and EHDS requirements that withdrawal of consent have a timely and practical effect, yet they are absent from current implementations.

Third, human-centered design should be operationalized through participatory pilot deployments rather than interface descriptions alone. For example, wallet-based consent systems could be evaluated through longitudinal studies assessing user comprehension of consent states, revocation confidence, and perceived control when consent decisions have observable downstream effects.

Finally, interoperability claims should be validated through standards-based integration pilots, mapping smart-contract consent states to HL7 FHIR Consent and AuditEvent resources and testing end-to-end workflows within EHDS-aligned infrastructures such as HealthData@EU. Together, these directions define a transition from conceptual feasibility toward deployment-ready, regulatorily meaningful consent infrastructures.

Future Research Directions

Future research should prioritize end-to-end revocation enforcement as a measurable system property, rather than treating revocation solely as an on-chain state transition. This includes the explicit design and evaluation of revocation propagation protocols that disseminate withdrawal events from blockchain ledgers to heterogeneous off-chain PEPs operated by independent data custodians. Such protocols should be evaluated using quantitative metrics, including propagation latency, enforcement completeness, and system behavior under partial failures.

In parallel, interoperability with EHDS-aligned infrastructures should move beyond architectural claims toward standards-based validation. Future studies should assess how blockchain-based consent states and audit events can be mapped to HL7 FHIR Consent and AuditEvent resources and exercised within cross-institutional workflows anticipated by HealthData@EU. These evaluations are essential to demonstrate regulatory readiness under the EHDS governance model.

Usability and patient empowerment should likewise be examined through longitudinal, user-centered evaluations rather than interface descriptions alone. In particular, future work should assess whether patients can meaningfully understand, manage, and trust consent withdrawal when revocation has observable downstream effects on data access. Wallet-based and credential-based consent models warrant participatory studies that measure comprehension, confidence, and perceived control over time.

Finally, advancing blockchain-enabled consent from prototype to practice will require interdisciplinary pilot deployments involving technologists, clinicians, legal scholars, ethicists, and policymakers. Such collaborations are necessary to align technical enforcement mechanisms with legal interpretation, institutional governance, and real-world operational constraints.

Conclusions

This systematic review examined 55 peer-reviewed studies (2020 - 2025) that propose or evaluate blockchain-enabled approaches to dynamic, auditable, and revocable consent for the secondary use of health data. The synthesis demonstrates clear architectural convergence: most systems rely on hybrid on-chain or off-chain designs, use smart contracts or equivalent logic to represent consent states, and use blockchain primarily as an integrity, coordination, and audit layer rather than as a storage substrate for sensitive health information. Many frameworks further integrate DIDs and VCs to bind consent states to portable identities and attributes, reinforcing the shift toward self-sovereign yet auditable consent artifacts.

Beyond documenting these trends, this review contributes novel insight by systematically evaluating consent as an enforceable life cycle rather than as a static design feature, linking architectural choices to revocation propagation, usability evidence, and regulatory readiness for secondary-use governance under the GDPR and the EHDS.

The evidence indicates that blockchain can substantively strengthen 2 aspects of secondary-use governance. First, it provides a shared, tamper-evident ledger for recording consent decisions and access events, improving verifiability and accountability across organizational boundaries. Second, it enables programmable consent modeling, granular permissions, time-bound authorizations, and policy-driven transitions, supporting the core intent of dynamic consent.

However, the review identifies a decisive gap between architectural feasibility and operational readiness. While revocation is widely claimed, most implementations demonstrate revocation only as an on-chain state transition or token invalidation, without validated propagation and enforcement across distributed off-chain systems. Sensitivity analysis restricted to higher-quality studies (QI ≥0.75) confirms that operational revocation enforcement is demonstrated by only a small subset of works, with none reporting quantitative guarantees for revocation latency or completeness across data custodians. From a regulatory standpoint, this is material: both GDPR and the EHDS framework require withdrawal to have

XSL•FO
RenderX

practical and timely effect, not merely representational status, particularly in federated secondary-use infrastructures such as HealthData@EU.

A further cross-cutting finding is that technical auditability does not automatically translate into practical accountability. Many systems provide cryptographic proofs and transaction logs that are difficult for patients, auditors, and regulators to interpret. Moreover, despite frequent claims of patient empowerment, formal usability validation remains limited, and the cognitive burden associated with wallets, signing flows, and key custody continues to pose a barrier to real-world deployment.

Overall, this review demonstrates that while blockchain is a promising trust anchor for consent life cycle tracking and auditability in secondary use of health data, it is not inherently compliant or sufficient on its own. Regulatory alignment depends on the broader sociotechnical system, including enforcement mechanisms, interoperability with health IT infrastructures, governance arrangements, and user experience. Achieving operational maturity will therefore require governance-oriented design, quantitative evaluation of enforcement properties, and close integration with emerging European health data infrastructures.

This review advances the consent literature by reframing blockchain-based consent from a static compliance artifact to an enforceable, distributed life cycle subject to measurable system properties such as revocation latency, propagation completeness, and governance integration. Unlike prior surveys, it systematically links architectural design choices to operational enforceability and emerging EHDS governance requirements, revealing that most existing systems remain at a proof-of-concept stage with limited real-world assurance.

Funding

This work was funded by national funds through FCT - Fundação para a Ciência e a Tecnologia, I.P., under projects/supports UID/6486/2025 [70] and UID/PRR/6486/2025 [71]. It was also supported by the Blockchain.PT (PRR—RE-C05-i01.02: AGENDAS/ALIANÇAS VERDES PARA A INOVAÇÃO EMPRESARIAL) and EDU-CARE projects.

Data Availability

The data supporting this systematic review are derived from published literature identified through a structured database search. No primary or experimental data were generated. The literature search details are provided in Multimedia Appendix 1.

Authors' Contributions

JCF conceptualized the work. SP and MB conducted data extraction, formal analysis, synthesis, and initial draft preparation. RB and JCF supervised and revised the original draft. JCF funding acquisition and resources.

Abstract

Background: There is increasing research on machine learning in predicting venous thromboembolism after joint arthroplasty, but the quality and clinical applicability of these models remain uncertain.

Objective: This systematic review aims to evaluate the predictive performance and methodological quality of machine learning models for venous thromboembolism risk after joint replacement surgery.

Methods: Web of Science, Embase, Scopus, CNKI, Wanfang, Vipro, and PubMed were searched until December 15, 2024. The risk of bias and applicability were evaluated using the PROBAST (Prediction Model Risk of Bias Assessment Tool) checklist. A qualitative comprehensive analysis was conducted to extract and describe the data related to the model's characteristics and performance.

Results: This review encompassed 34 prediction models from 9 studies. The most frequently used machine learning models were extreme gradient boosting and logistic regression. The results showed that all studies had significant heterogeneity and high risk of bias. Although some models reported nearly flawless area under the curve (>0.9), they lacked external validation and may have overfitted. The models tested on large external datasets demonstrated more conservative performance.

Conclusions: The predictive performance of machine learning models varied greatly. Although the reported area under the curve values indicated that some models have good discriminative ability, this performance varied greatly and was inconsistent among the included studies. These models have a high risk of bias, and it is necessary to take this into account when they are used in clinical practice. Future studies should adopt a prospective study design, ensure appropriate data handling, and use external validation to improve model robustness and applicability.

KEYWORDS

joint arthroplasty; venous thromboembolism; machine learning; meta-analysis; systematic review

Introduction

Joint replacement surgery is one of the main treatment methods for severe joint injuries, which can alleviate patients' pain and improve joint function [1,2]. In recent years, due to the aging population and the advancement of medical technology, more and more patients have undergone joint replacement surgery. But surgical complications are a big risk that can change how well joint replacement surgery works. Venous thromboembolism (VTE), including deep vein thrombosis (DVT) and pulmonary embolism (PE), is a serious postoperative complication that significantly affects the prognosis of patients [3,4].

Studies have shown that for patients who did not receive preventive medication before undergoing major orthopedic surgeries, such as total hip arthroplasty (THA) or total knee arthroplasty (TKA), the incidence of postoperative VTE can be as high as 26.6% to 60.8% [5]. Asymptomatic VTE may not present any obvious clinical symptoms but can be detected through ultrasound examination or other diagnostic techniques. Some patients with VTE may experience discomfort and swelling in the affected limb, and their functional condition may be poor, which may even affect their postoperative recovery [6,7]. Furthermore, PE also has a significant impact on patients'

XSL•FO
RenderX

lives and prognosis. Studies have shown that up to 34% of postoperative deaths may be caused by PE [8,9].

Being able to accurately identify which patients are at high risk of VTE is of great significance for the prognosis of these patients. Accurate predictions can maximize the effectiveness of anticoagulant drugs and reduce side effects, such as bleeding [10,11]. Through the analysis of vast volumes of high-dimensional data, machine learning (ML) may uncover hidden patterns and intricate nonlinear relationships, aiding illness early warning [12,13]. In recent studies, ML models have been developed to predict the incidence of postoperative VTE. The most commonly used algorithms include extreme gradient boosting (XGB), random forest (RF), and support vector machine (SVM) [14]. In the prediction of VTE, ML technology exhibits many advantages. For instance, compared to traditional approaches, it can provide superior predictions by combining several types of information, such as imaging data, biomarkers, and clinical data [15,16]. Although these studies provide new methods for the field, there are some uncertainties in the consistency and reliability of the results in the existing literature owing to the single data source, small sample size, and the model's limited capacity for generalization. In addition, there are justified concerns about bias, explainability, and applicability [17]. Therefore, this study aimed to assess the effectiveness and methodological quality of ML models in predicting VTE following joint replacement through a systematic review in order to provide evidence-based support for their clinical application, identify current research gaps, and offer guidance for future high-quality studies.

Methods

Registration of the Study

This study adheres to PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses; Checklist 1) guidelines for conducting systematic reviews [18]. The study protocol was registered on PROSPERO (International Prospective Register of Systematic Reviews; registration number: CRD42024625842).

Data Sources and Search Strategy

A comprehensive search was conducted in both Chinese and English databases, including Web of Science, Embase, Scopus, CNKI, Wanfang, Vipro, and PubMed, from the time of their formation until December 15, 2024. The following search terms were applied: "joint arthroplasty," "venous thromboembolism," "machine learning," "risk prediction," "prediction models," and their synonyms and variant terms. A manual search of reference lists containing studies to find related publications was conducted. For detailed search strategies, see Multimedia Appendix 1, which includes keyword combinations and database settings.

Inclusion or Exclusion Criteria

The following were the inclusion criteria: (1) studies on patients after joint replacement; (2) observational studies, case-control studies, cohort studies, and randomized controlled trials; (3) postoperative VTE risk was predicted using an ML model; (4) studies that provide performance evaluation metrics (eg, accuracy, sensitivity, specificity, area under the curve [AUC]) for the model and give clear statistical analysis results; and (5) studies published in English or Chinese.

The following were the exclusion criteria: (1) review articles, case reports, opinion pieces, commentaries, conference abstracts, and other nonoriginal research; (2) studies that do not mention particular kinds of ML models or algorithms; (3) animal experiments, simulation studies, and other nonclinical research; and (4) studies for which the entire text was not retrievable.

Study Selection and Data Synthesis

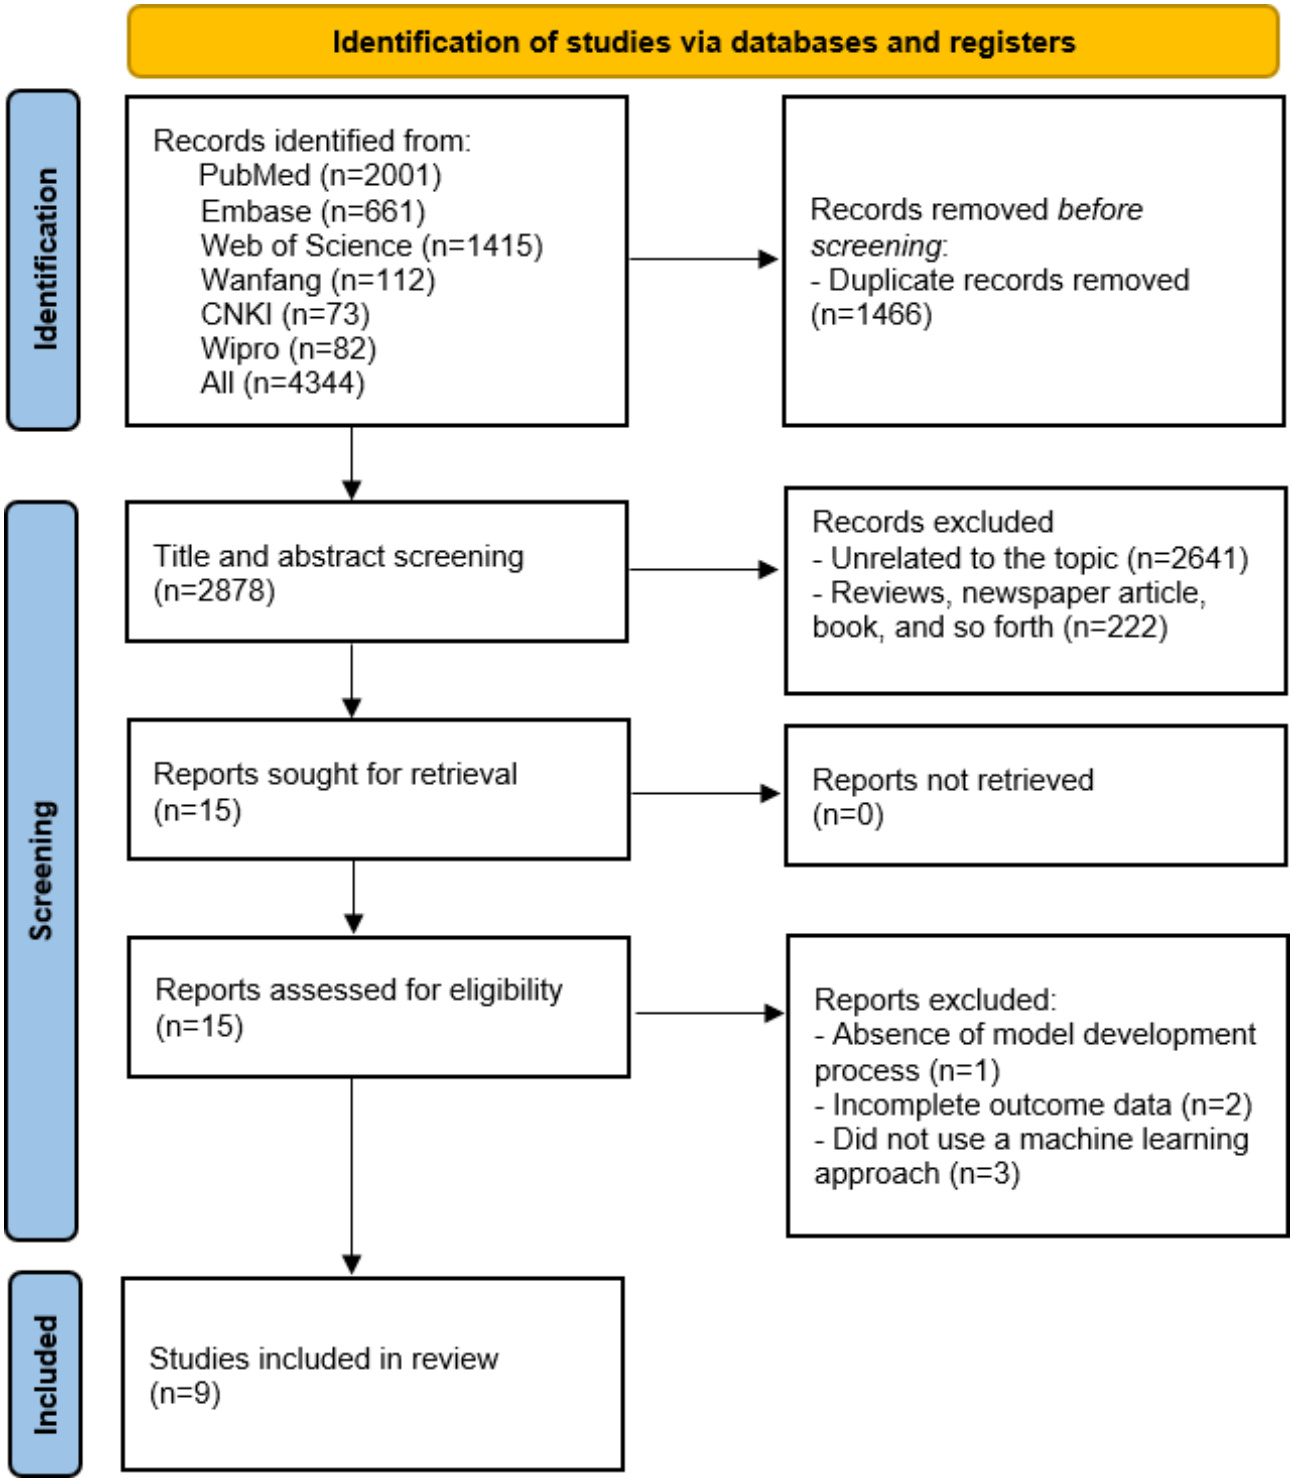
The retrieved results were imported into EndNote 21, and duplicates were eliminated. Two researchers trained in systematic evaluation techniques independently conducted the study selection process based on preestablished eligibility criteria. First, the titles and abstracts of the literature were screened, and the studies failing to meet the eligibility criteria were initially excluded. Second, it was filtered through full-text reading, and if 2 researchers disagreed, a third researcher stepped in to reach an agreement.

The data extraction process was also performed independently by 2 researchers following CHARMS (Critical Appraisal and Data Extraction for Systematic Reviews of Prediction) guidelines [19], and a third researcher settled any discrepancies. There are 2 groups into which the data taken from the chosen studies are separated: (1) basic information: author, year of publication, country, study design, participants, data source, clinical outcome, and sample size and (2) model information: missing data handling, candidate predictors, screening variable methods, prediction timepoint, prediction horizon, model development, internal verification, external verification, model performance, number of variates, calibration, and method of visualization.

Risk of Bias Assessment

The included studies' applicability and bias risk were evaluated using the PROBAST (Prediction Model Risk of Bias Assessment Tool) tool. The assessment has 20 questions, including 4 basic areas: participants, predictors, outcomes, and analysis. There are answers to the questions in each domain: "yes/probably" (low risk of bias), "no/probably not" (high risk of bias), and "no information" (unclear). A domain was deemed to have a high risk of bias if its answer contained "no/probably not." If every question had a "yes/probably yes" response, the domain was deemed to have a low risk of bias. When there is "no information," it is deemed to be highly biased if it cannot be explained by the original or additional material. If each domain was considered low risk, then the total bias risk was considered low. Furthermore, the total risk of bias was deemed high if any domains were deemed to be at high risk.

The bias risk in each model is assessed independently by 2 researchers, and if there are differences, they will be discussed to reach an agreement. Due to the majority of research using various models or having several outcomes, the bias risk is evaluated independently for each model and outcome. Finally, since there are no differences in the risk of bias between models in a single study, each study only shows the result once.



XSL•FO
RenderX

Results

Results of Literature Screening

The study selection process is detailed in the PRISMA flow diagram (Figure 1). A total of 4344 records were initially identified from 6 electronic databases (PubMed, n=2001; Embase, n=661; Web of Science, n=1415; Wanfang, n=112; CNKI, n=73; and Wipro, n=82). After removing 1466 duplicates, 2878 unique records remained for screening. During the title and abstract screening phase, 2863 records were excluded because they were either unrelated to the topic (n=2,641) or were nonoriginal research, such as reviews and newspaper articles. This left 15 reports to be sought for full-text retrieval. The subsequent critical appraisal excluded 6 studies based on predefined criteria: 3 did not use an ML approach, 2 had incomplete outcome data, and 1 did not involve a model development process. Ultimately, 9 studies met the full inclusion criteria and were included in this systematic review.

General Study Characteristics

Table 1 shows the basic characteristics of the 9 studies. These studies were published from 2018 to 2024 and included 1 prospective study [3] and 8 retrospective studies [20-27]. Among them, 4 studies [3,20,21,25] were conducted in China; 3 studies [22-24] were from the United States; 1 was conducted in the Netherlands; and 1 transnational study used data from the Netherlands, the United Kingdom, and Denmark. In terms of study population, 2 studies [3,20] focused on patients with THA, 1 study [21] targeted patients with TKA, and the remaining studies [22-27] focused on both THA and TKA. In terms of clinical outcomes, 2 studies [20,21] concentrated solely on DVT, while the remaining 7 studies [3,22-27] evaluated both DVT and PE. In addition, the studies' sample sizes ranged from 60 to 3,92,661. Cases of VTE ranged from 24 to 4042, with an incidence of 0.9% to 40%.

Table . Basic characteristics of the included studies.

Author (year)	Country	Research type	Data source	Participants	Clinical outcome	Cases/sample size
Ding et al (2023) [3]	China	Prospective study	Shanghai Changzheng Hospital	THA[a]	VTE[b]	76/1481
Chen and Jiang (2022) [21]	China	Retrospective study	Clinical database of a hospital in Chongqing	TKA[c]	DVT[d]	24/60

Wang et al (2023) [25]	China	Retrospective study	A health system	TKA, THA	VTE	1161/6897
Xu et al (2024) [20]	China	Retrospective study	A hospital in Wenzhou, China	THA	DVT	92/333
Sweerts et al (2022) [26]	Netherlands	Retrospective study	Multiple databases from the Dutch	TKA, THA	VTE	26/3776
Nemeth et al (2024) [27]	Netherlands, Denmark, England	Retrospective study	Multiple databases from the United Kingdom, the Netherlands, and Denmark	TKA, THA	VTE	897/64,032

[a]THA: total hip arthroplasty.

[b]VTE: venous thromboembolism.

[c]TKA: total knee arthroplasty.

[d]DVT: deep vein thrombosis.

[e]PE: pulmonary embolism.

Characteristics and Performance of ML Models

Table 2 provides a detailed summary of the methodological design and data characteristics of the included studies. Table 3 presents a summary of the performance of the model development, validation, and inclusion of the studies. Among the 9 studies included, 5 studies [3,20,23-25] evaluated multiple ML algorithms, and 4 studies [21,22,26,27] used a single algorithm. Across these studies, 15 kinds of ML algorithms were used to develop 34 predictive models, and each study developed 1-5 models. Logistic regression (LR) and XGB were the most common algorithms, appearing in 5 studies (5/9, 56%) each. This is followed by RF (3/9, 33%) [23-25] and SVM (3/9, 33%) [20,24,25]. In particular, the XGB model showed strong performance in predicting DVT and PE, with an AUC range of 0.71 - 0.982. Figure 2 details the frequency of the model used.

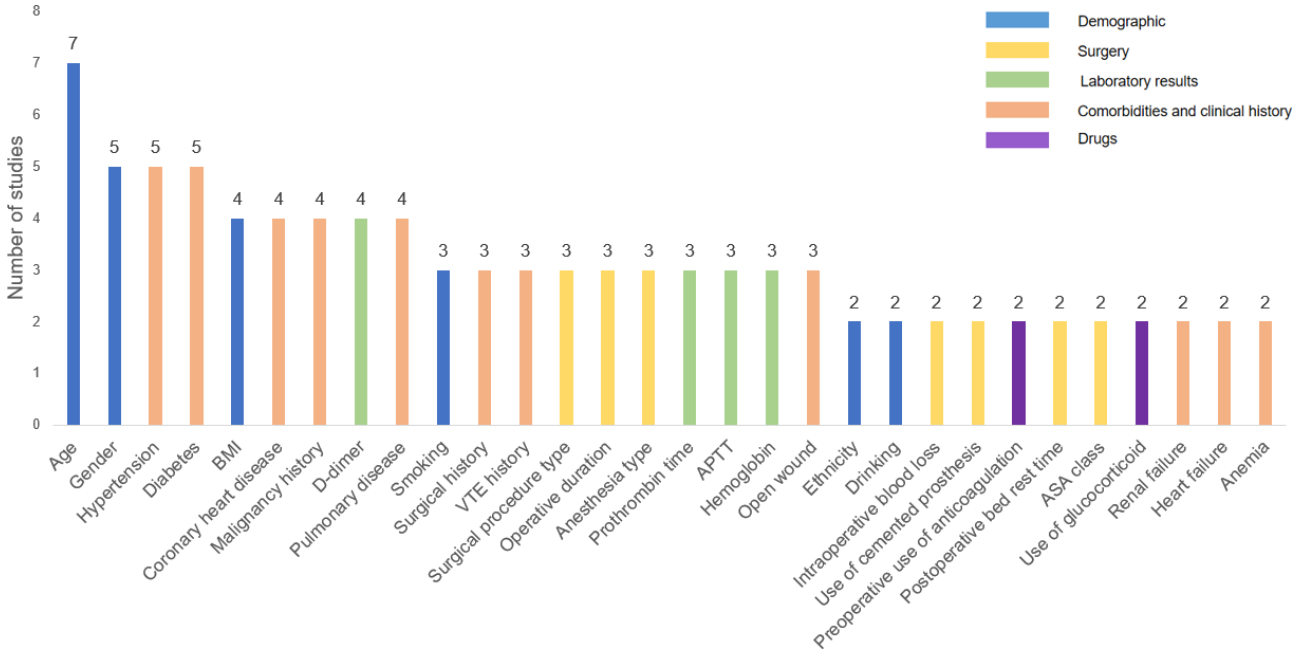
The included studies used a variety of metrics to evaluate ML models, of which AUC was the most common (8/9, 89%). The predicted AUC range for DVT and PE was 0.579 - 0.982. One study did not report AUC but reported C-statistic [22]. XGB, popularized by Chen and Guestrin [28] in 2016, is a widely adopted ML algorithm on the basis of gradient boosting [29,30]. The included XGB studies [3,20,21,24,25] reported AUC ranging from 0.71 to 0.982, demonstrating strong model performance. LR estimates the association of one or more independent variables with binary dependent variables [31,32]. The included LR studies [3,20,25-27] reported AUC ranging from 0.579 to 0.944. RF is a widely used ML algorithm that helps mitigate overfitting and improves the model's stability and accuracy by aggregating the outcomes from various decision trees [33]. It functions as a modeling algorithm as well as a variable selection technique. Three studies [23-25] used RF, with reported AUC ranging from 0.698 to 0.907. In addition, calibration plots were provided in 3 studies [22,24,27]; Brier scores were provided in 1 study [20]; and 1 study [26] also provided Hosmer-Lemeshow, calibration plot, and Brier score. The other 4 studies did not include data on calibration performance. Additional reported metrics encompass accuracy, sensitivity, and specificity.



These 9 studies differ in terms of the optimal timing for risk assessment. Six studies have created preoperative prediction models [3,22,23,25-27] to identify high-risk individuals before surgery. The last 3 studies focused on postoperative prediction, assessing immediate risks using postoperative data [20,21,24]. Additionally, there is diversity in the risk assessment's predictive horizon. Its duration ranges from a brief period following the procedure, such as "within 3 - 5 days after surgery" or "during the postoperative hospital stay" [3,20], to a lengthy risk assessment that might continue for up to a year following the procedure [26]. Common time horizons include 30 days [22,23] and 90 days [24,27].

From a low of 5 [26] to a high of 66 [25], the number of predictor variables that ultimately made it into the model varied

XSL•FO
RenderX

widely. The descriptive analysis of the predictive factors used in each study (as shown in Figure 3) shows that a constant core set of variables is regularly utilized, despite the wide variations in the number of predictive factors used in each investigation. These variables can be broadly classified into four categories: (1) demographic and biological characteristics of the patients (such as age, gender, BMI); (2) major comorbidities (such as hypertension, diabetes, coronary heart disease, and malignant tumors); (3) specific VTE risk histories (such as previous VTE); and (4) key laboratory indicators (such as D-dimer).

Figure 3. Frequency of the predictors. APTT: activated partial thrombin time; ASA: American Society of Anesthesiologists; VTE: venous thromboembolism.

Model Validation

All of the models in the included studies underwent internal validation; however, only 2 studies [22,27] used external validation and reported the AUC value of external validation. The main methods used for internal validation were k-fold cross-validation and random-split validation. External validation plays a key role in confirming whether a model can maintain good performance in different populations and clinical settings. The absence of external validation will limit the generalization and clinical application of these models.

Assessing Risk of Bias

According to the PROBAST evaluation, all models had a high risk of bias (Table 4). The assessment results showed that the main sources of bias were concentrated in the “participants” and “analysis” domains. In the participants domain, 8 studies had a high risk of bias, mainly because these studies relied on retrospective data. In the analysis domain, all models had a high risk of bias. The PROBAST assessment pointed out several specific methodological issues: 4 studies [21,23-25] did not perform model calibration, 4 studies [3,21,23,25] did not report the handling of missing data, and 2 studies [21,23] were insufficient in measures to prevent model overfitting. In contrast, the outcome domain was rated as having a low bias risk level in all studies. In terms of applicability assessment, only 1 study [25] had poor applicability because the model was overly complex and required 66 predictor variables.

Discussion

Principal Findings

VTE is a common and serious postoperative complication that is preventable [10]. Risk assessment and management-based strategies can help prevent or reduce the occurrence of VTE [34]. Therefore, selecting an appropriate predictive model for VTE is crucial. This systematic review examined the methodological quality and clinical applicability of ML methods in predicting VTE after joint replacement surgery. Among the reviewed studies, 15 ML algorithms were utilized to construct 34 predictive models. XGB and LR were the most used model types, followed by RF and SVM. The AUC values of the models ranged from 0.579 to 0.982, indicating that the discrimination ability of the models varied greatly, and some of the models showed excellent performance. Two research [1,6] reports demonstrated extremely high discrimination ability, with their AUC values exceeding 0.9. Such high performance often raises concerns about overfitting, where the model learns specific statistical noise specific to the training data rather than the generalizable underlying biological signals, leading to an optimistically biased performance estimate. Moreover, these models have not yet undergone external validation. This deficiency is a major limitation. In the clinical environment of joint replacement, there may be significant differences among patients, and surgical techniques as well as VTE prevention protocols may also vary among different medical institutions. Models trained based on data from a single hospital are likely to learn the specific treatment patterns of that hospital rather than a universally applicable VTE prediction signature. This may lead to unreliable prediction results when the model is applied to different patient groups. The risk of overfitting and the lack of reliable external validation seriously undermine the clinical value of these highly performing models. These models can only be considered for practical application after undergoing extensive external validation.

Another finding is that the XGB model demonstrates superior predictive performance compared to other models. For instance, 2 studies [3,20] compared the XGB and SVM models with the LR models, and the results showed that the XGB and SVM models outperformed the LR model. This supremacy is probably due to the smart way the algorithm was made. First, XGB has strong built-in features (such as regularization) that keep the model from overfitting when working with small datasets, making it stable even when the data are noisy. Second, XGB is very good at identifying the most important risk factors on its own. It can also capture complicated nonlinear interaction relationships, which typical linear models cannot do. Furthermore, the fact that XGB functions so effectively most likely indicates that the research team spent a great deal of time and energy optimizing the hyperparameters and determining the ideal configurations for their particular dataset. However, research has indicated that LR models may be more successful and easier to apply in some situations, whereas XGB and SVM models may not necessarily perform better. LR's fundamental structure makes it simple to comprehend and analyze. Additionally, it produces dependable findings and has strong convergence, particularly when used for small datasets [35]. The Caprini score is a clinically prevalent instrument utilized to evaluate VTE risk by analyzing many clinical risk factors, including age, surgical history, malignancy, and obesity [36]. One study [25] compared the Caprini Score to ML models and showed that the ML models were better at predicting VTE risk. Although the predictive performance of most models ranged

XSL•FO
RenderX

from moderate to good, the risk of bias in all studies restricted the applicability of these models in clinical practice.

Related Work

The PROBAST assessment results indicate that all the models have a high risk of bias, suggesting that their predictive performance in practical applications may be lower than the reported levels. This widespread bias is mainly due to the flaws in the research design and the statistical analysis methods adopted by the models. In terms of the research design, most studies rely on retrospective data, which increases the risk of selecting an unrepresentative patient population, thereby weakening the generalization ability of the models beyond the original dataset. Additionally, there are numerous flaws in the analysis aspects of the model construction and testing processes. The main issues are that some studies did not check the calibration process. This makes it impossible for us to determine whether the "30% risk of venous thrombosis" predicted by the model truly means a 30% probability in reality, thus preventing its use in clinical decision-making. Some studies also failed to provide enough protections against the "overfitting" problem, in which the model just remembered the noise in the training data instead of identifying the true risk patterns, while others did not provide solutions for handling missing patient data. These analytical flaws make these models likely to perform poorly when applied to new patients. Furthermore, the actual usability is also an issue. One model used an excessive 66 predictive variables, making it overly complex and unsuitable for clinical use. To raise the accuracy and clinical application of predictive models, future studies should apply more rigorous methodological methods. Moreover, the significant bias risk indicates inconsistency in the development and validation of current models, which could influence their widespread application. Future studies should give priority to enhancements in a number of important domains, including the research design (ie, cohort or case-control study design), the number of events, the method for predictor selection, the processing of complicated data, and the processes of model calibration and fitting.

One serious and widespread flaw in these studies is the absence of model calibration reports. Although most of the included studies reported high discrimination metrics such as AUC, the discrimination does not guarantee that the predicted probabilities are accurate. Calibration addresses a more fundamental clinical question: Does the predicted "30% risk of venous thrombosis" really mean that there will be a 30% incidence rate among a group of similar patients? Inaccurate calibration might have very harmful consequences. For example, a model that consistently overestimates risks may incorrectly identify patients with low risks as having high risks [37]. This may lead to the improper use of potent anticoagulant drugs, thereby exposing patients to a serious risk of bleeding, a risk that could have been avoided. However, if the model underestimates the risks, it may prevent doctors from taking necessary preventive measures to ensure the safety of patients with high risk. This could lead to potentially fatal thrombosis incidents [38]. Consequently, owing to the absence of calibration data, most of these models are unreliable for informing individual patient decisions, irrespective of their quoted AUC values. Future research must prioritize calibration as the principal measure of model performance. We strongly urge that studies include both visual calibration plots and quantitative indicators (such as the Brier Score) at the same time to make sure their predictions are accurate in the actual world. Additionally, most of the included studies did not provide reports on the sensitivity and specificity of their models. This affects the overall assessment of model performance, as the reported AUC values may not fully reflect its clinical applicability. Future research should follow standardized reporting guidelines to evaluate its model performance.

External validation is critical to confirm the generalizability of the model's performance and its applicability to different populations [39,40]. However, all the studies used internal validation methods, such as K-fold cross-validation or random split validation, and only 2 studies conducted external validation. Most of these models lack external validation, further increasing the challenge of clinical implementation. In such a sensitive sector as health care, where predictive models are finally meant to be employed in real-world situations, these ML models may not accurately reflect their applicability and dependability without outside validation [41]. Future studies should incorporate external validation where possible, such as in different hospitals or using publicly accessible databases, to optimize the model generalization through data synthesis and larger datasets [42]. Additionally, we advise temporal validation to assess the model's resilience at different points in time.

The ML model's predictive variables found in this study have a number of important effects on clinical practice. First, the predictive factors frequently used in these models play a very important role in current clinical practice and future research. For instance, D-dimer is a well-known clinically validated biomarker for VTE. Studies have shown that it is highly sensitive in predicting the risk of VTE. Prothrombin time, activated partial thromboplastin time, and international normalized ratio are a few other markers that may assist physicians better understand the risk of blood clots and quickly identify and treat patients with high risk [43]. Another established risk factor for VTE is age. Research has indicated that the risk of VTE rises with age. People over the age of 60 years account for around 70% of occurrences of VTE [44]. Considering age while evaluating patients before surgery may enhance outcomes and diminish complication rates. Common chronic disorders, such as diabetes and hypertension, were also among recurring factors. Research has shown that these disorders can raise VTE incidence. A personalized anticoagulant treatment strategy might help those with past histories of these disorders lower their VTE risk even more [45]. Second, the results of the 9 studies on the predictors can guide the development of future predictive models and contribute to later studies on related risk elements. For instance, 1 study [20] included bone cement prosthesis as a predictor in the model, although further study is required to confirm its association with VTE. However, variance in the choosing and reporting of predictors in these studies may affect the comparability and practical utility of the models in different clinical settings.

Limitations

To our knowledge, this is the first study to evaluate ML in predicting VTE in patients undergoing joint replacement

XSL•FO
RenderX

surgery. Nevertheless, the study had certain limitations. First, most of the included studies have been conducted in China and the United States. This geographical concentration restricts the general applicability of the model to different areas. Second, numerous studies focused solely on developing predictive models without considering external validation or practical application of the model. The absence of external validation may affect the credibility of our pooled estimates. Third, since the traditional methods used to assess publication bias (such as funnel plots and Egger or Begg tests) are not applicable to AUC data, no quantitative assessment of publication bias was conducted for the included studies. However, the risk of publication bias remains: “positive” studies (eg, high AUC values) are more likely to be published than “negative” or inconclusive ones. Therefore, the studies included in this review may overestimate the true performance of these models. Finally, the included studies exhibited a high risk of bias and insufficient transparency. These methodological shortcomings could affect the accuracy of model predictions, therefore reducing the dependability and application of the conclusions.

Conclusions

The study identified 9 studies with a total of 34 ML models for predicting VTE after joint replacement. Most studies have modest to good discriminative ability from their AUC values. However, among these 9 studies, only 2 of them underwent effective external validation. The widespread neglect of external validation has left the generalization capabilities of these models, which performed well on the original dataset, completely unknown. In addition, these studies also show a high risk of bias and significant heterogeneity. Most of the studies had significant methodological shortcomings, including a lack of rigorous study design and absence of calibration measurements. These deficiencies will affect the reliability of the model in clinical applications and reduce the promotion value of the model. To improve the prediction capabilities of ML models, future research must closely follow the PROBAST criteria, which place a strong emphasis on meticulous study design and quality control. External validation is also necessary to improve the generalization and applicability of ML models in clinical settings.

Abstract

Background: Individual-level behavioral interventions are designed to improve health behaviors and manage noncommunicable diseases. Neighborhood geo-referenced contexts (NGRCs) significantly impact the success of these interventions. Integrating NGRC data into health information systems (HISs), including electronic medical records (EMRs), electronic health records (EHRs), and personal health records (PHRs), can enhance personalized NGRC-focused behavioral interventions and improve health outcomes. Despite the potential benefits, there is a notable gap in the literature about NGRC-focused behavioral interventions using HISs.

Objective: This scoping review aims to review the current status and stakeholder insights of NGRC-focused behavioral interventions using HISs.

Methods: Two reviewers examined publications indexed by MEDLINE (Ovid) and Scopus. Publications reporting on NGRC-focused behavioral interventions using HISs were included. We extracted data on study characteristics, population attributes, diseases, health setting characteristics, HISs, NGRCs, behavioral interventions, outcomes, and conclusions, with suggestions for future research.

Results: The literature search identified 24 studies for inclusion. Of these, EHRs or EMRs were mostly used in 20 studies, with limited focus on PHRs. HISs were not used in the entire process of NGRC-focused behavioral interventions in 23 studies. Behavioral interventions in 21 studies focused exclusively on social needs interventions, with comparatively limited attention given to lifestyle change interventions. NGRCs mainly focused on built environments (n=24), with less attention to natural (n=1) and social (n=4) environments. The spatiotemporal characteristics of NGRCs were described in limited detail. “Destination accessibility” was the main focus within built environments. Other characteristics (“density,” “design,” “diversity,” and “distance”) were less studied. Stakeholders’ perspectives highlighted the value, convenience, patient autonomy, and privacy of integrating content (NGRCs) and/or technology (HISs) into behavioral interventions, despite the persistence of certain social concerns. We summarized 15 recommendations in terms of NGRC-focused behavioral interventions using HISs.

Conclusions: PHRs have the potential to actively integrate more diverse, dynamic, and/or high-resolution NGRCs. Additionally, PHRs can participate in the entire process of NGRC-focused behavioral interventions, particularly in outpatient lifestyle change interventions. Health care providers can support these interventions to help achieve public health goals and advance health equity.

Introduction

Behavioral interventions are strategies and techniques to influence health-related behaviors at the personal, community, and public policy levels [1]. They may encourage individuals to quit smoking or to exercise regularly. At the community level, behavioral interventions aim to change behaviors by modifying the environments that support them [1]. For example, enhancing existing sidewalks with improved lighting, repainting bike lane markings, and adding benches can create a more enjoyable experience that encourages walking and cycling. At the public policy level, the government or private groups can share health information to encourage behavioral change [1]. The absence of individual-level behavioral interventions poses a significant challenge in managing noncommunicable diseases (NCDs), which account for 70% of global deaths annually [2], as effective interventions for NCDs require long-term engagement and multiple follow-ups to detect relapses or late effects as soon as possible [3].

Neighborhood geo-referenced contexts (NGRCs) have been identified as barriers or facilitators to the acceptance of, participation in, and adherence to individual-level behavioral interventions [4]. NGRCs refer to the physical and social environments of a location or locations along one's daily activities, and they influence people's health-related behaviors [5-8]. NGRCs are a spatial manifestation of the social determinants of health (SDoH), which refer to the conditions in which people are born, grow, live, work, and age, as well as the broader systems and forces that shape these daily life conditions [9]. Beyond the social and natural environments in NGRCs, the built environment is characterized using the 5D framework, which includes *density*, *diversity*, *design*, *distance*, and *destination accessibility*. The failure to address NGRCs is evident from the focus on limited prevention programs or resources in health care settings aimed at addressing individual attitudes and behaviors, along with the limited resources for preventive care [10]. NGRC-focused behavioral interventions allow health care providers to tailor interventions to specific contexts, offering a more personalized approach. These interventions can be categorized into social needs interventions (eg, arranging transportation) and individual lifestyle change interventions (eg, walking in a nearby park). To achieve NGRC-focused behavioral interventions, studying the interaction between NGRCs and modifiable health-related behaviors is essential [11-13].

Health information system (HIS) data have been used to investigate the relationships between NGRCs and health behaviors among health providers, HIS vendors, payers, and researchers [14-24]. A HIS is a system for collecting and processing data, information, and knowledge in health care settings [25]. The category includes (1) provider-centric electronic medical record (EMR) systems used within a single health care setting, (2) electronic health record (EHR) systems spanning multiple settings, and (3) patient-centric personal health record (PHR) systems. Among PHRs, standalone PHRs are not integrated with EMRs or EHRs, whereas tethered and interconnected PHRs are linked to EMRs or EHRs [25-27]. These systems enable various stakeholders, such as health providers, patients, and caregivers, to access and process multimodal data, such as diagnoses, medication use, treatments, NGRCs, and behavioral information.

At the individual level, HISs can enhance NGRC-focused behavioral intervention via comprehensive NGRC data capture and effective intervention prescription, monitoring, and assessment [3]. HISs can help collect NGRC data during routine clinical care, supplemented by patient-reported information, or through linkage with publicly available external data sources like geographic information systems. At the community and policy levels, HISs can support cost-effective, large-volume, and time-efficient assessments of large-scale public health efforts, such as environmental interventions to support behavioral changes, compared with traditional surveys [28].

Although integrating NGRCs with HISs is not new [29], many reviews on the functionalities and features of EHRs, EMRs, and PHRs lack clarity regarding NGRCs [30-44]. Additionally, several systematic reviews have investigated the linkage between NGRC data and clinical data sources (eg, EHRs) for population health research, but they lack specifics regarding behavioral interventions [45,46]. Recent systematic reviews on SDoH screening, linkage, extraction, analysis, and interventions within HISs, especially EHRs, similarly show limited attention to NGRCs and/or intervention-based approaches [47-50]. Given the increasing interest and existing research gap in using HISs to prepare, prescribe, monitor, and assess NGRC-focused behavioral interventions, we conducted, to our knowledge, the first scoping review of the literature in this field to distinguish it from broader SDoH-focused reviews and those lacking an intervention-based approach [46,50]. This review excluded standalone PHRs, as they are independent of provider-centric EHRs or EMRs.

This scoping review aimed to answer the following questions:

1. To what extent and what types of HISs have been used in NGRC data capture, intervention prescriptions, monitoring, and assessments of NGRC-focused behavioral interventions, and across the 4 stages?
2. What types, spatiotemporal characteristics, and databases of NGRCs have been utilized in each type of behavioral intervention supported by HISs?
3. What are stakeholders' insights regarding the use of HISs and/or NGRCs in behavioral interventions?
4. What are the gaps in research on the use of NGRCs and HISs in behavioral interventions?

Methods

Checklist

The analysis adhered to the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) checklist (Checklist 1) [51].

Search for Relevant Research

An information specialist from the Amsterdam Medical Center library (JGD) was consulted to help define key concepts and establish the evaluation framework, which included selecting the appropriate databases, relevant keywords, and MeSH terms.

XSL•FO
RenderX

MEDLINE (Ovid) and Scopus were searched from inception on April 29, 2024, to include studies up to the search date.

The search strategy could be conceptually summarized as follows: ([GRCs] AND (([neighborhoods] AND ([chronic care model] OR ([HISs] AND [health behaviors]))) OR ([community health facilities] AND [health behaviors]))), involving the following four elements related to our research questions: (1) HISs, (2) geo-referenced contexts (GRCs), (3) neighborhoods, and (4) health behaviors. Detailed information regarding the search terms in Scopus is shown in Textbox 1. The inclusion and exclusion criteria are presented in Textbox 2. For search terms in MEDLINE, refer to Table S2 in Multimedia Appendix 1.

Textbox 1. Search terms in Scopus.

Textbox 2. Inclusion and exclusion criteria.

Inclusion criteria

- Study type: Original empirical research studies.
- Health information systems (HISs) and behavioral interventions: Used HISs to prepare, prescribe, monitor, and/or assess behavioral interventions.
- Neighborhood geo-referenced contexts (NGRCs): Used one or more NGRC attributes about the outside world to assist and/or adjust behavioral interventions.
- NGRCs and behavioral interventions: Studies in which NGRC and intervention data pertain to concurrent or longitudinal periods. Studies in which NGRC attributes and intervention attributes use either objective or subjective measurements.

Exclusion criteria

- Study type: Study protocols without substantive findings and studies without results (eg, experimental descriptions and commentaries).
- HISs: Studies for which it cannot be confirmed whether the records are part of an HIS due to an unspecified format (electronic or paper), or it is not explicitly stated whether these data are connected to HISs. Studies on standalone personal health records managed solely by patients and/or caregivers without the integration of data in medical settings (eg, hospitals). Studies using an HIS that was not focused on interventions but was used as a database to identify participants for empirical studies.
- NGRCs: Studies focusing only on broad geographic categories (eg, county, city, region, nation, and urban/rural), using sensors without specific attributes, NGRCs about health services, or economic factors (eg, transportation reimbursement). Studies for which it cannot be determined whether NGRCs were involved due to a lack of specific details on social determinants of health screening tools and interventions.

Results

Search Term Coverage and Rationale

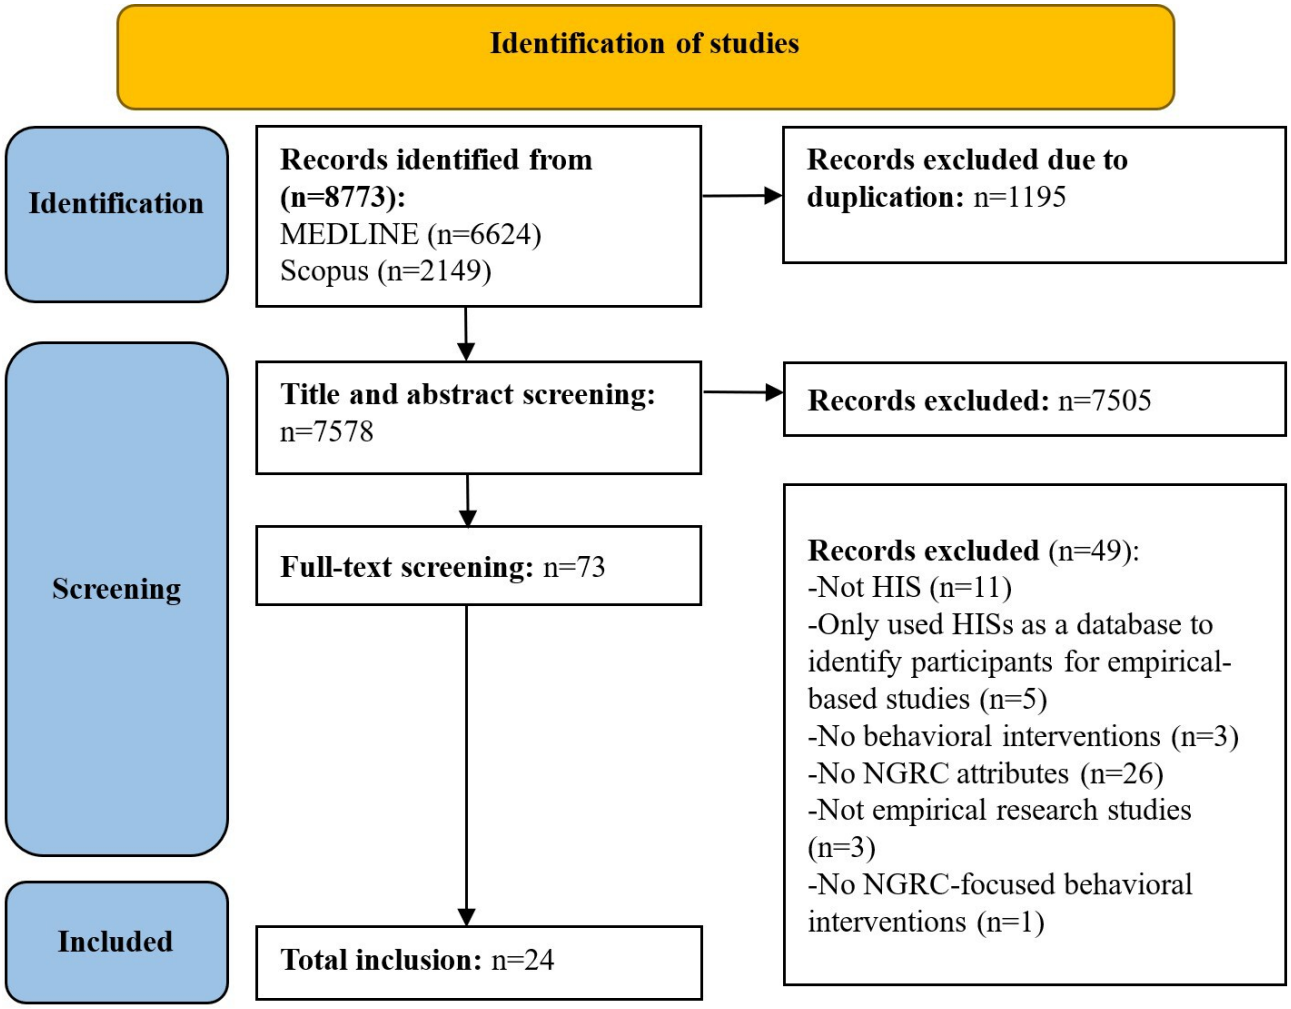
GRCs include (1) built environments from the 5D dimensions (density, diversity, design, distance, and destination accessibility); (2) natural environments; and (3) social environments, which encompass neighborhood socioeconomic status and neighborhood social relationships. Neighborhoods include (1) static administrative areas, (2) various delineations surrounding each participant's address, (3) perceived neighborhoods, and (4) geographic areas encompassing all locations visited by an individual in their daily activities. For the definitions and examples of NGRCs and neighborhoods, see Table S1 in Multimedia Appendix 1 [1,9,26,52-76]. We used 3 different search strategies because some concepts can be merged and replaced by related ones. For example, HISs and health behaviors are 2 critical elements of the chronic care model, which is a valuable framework for patient empowerment, supporting self-management and enhancing health outcomes [53-56]. Consequently, substituting HISs and health behaviors with search terms pertinent to the chronic care model while connecting them with GRCs and neighborhoods constituted the second part of the search strategy. Additionally, community health facility workers may use HISs to address neighborhood-related issues. Therefore, replacing HISs and neighborhoods with search terms relevant to community health facilities (eg, community health centers and community data) while linking these terms with GRCs and health behaviors formed the third part of our search strategy.

Eligibility Criteria

All original peer-reviewed scientific studies in English indexed up to April 29, 2024, were included, while non–peer-reviewed studies and gray literature were excluded. Textbox 2 outlines the inclusion and exclusion criteria.

Selection Process

First, we screened titles and abstracts and excluded studies according to the inclusion and exclusion criteria. When uncertainty arose, studies were retained for the full-text screening stage. Second, XY and MD independently conducted a full-text review and extracted the relevant NGRCs, HISs, and behavioral interventions from the potentially included papers. Any disagreements were first addressed by referring to a predefined inclusion/exclusion checklist. If consensus was not reached using the checklist, the reviewers discussed each case, and, if necessary, a third reviewer (RC) made the final decision. Although interrater reliability was not calculated, this structured approach ensured consistent and transparent decision-making.



Data Extraction

We extracted data from the included studies using a 7-item table. These seven items included: (1) study attributes; (2) population attributes, diseases, and health setting characteristics; (3) HISs; (4) NGRCs; (5) behavioral interventions; (6) results; and (7) conclusions and future studies. Table S3 in Multimedia Appendix 1 provides further details.

Figure 1 presents the PRISMA flowchart, which includes the identification, screening, and selection process. A total of 24 peer-reviewed studies were finally included.

XSL•FO
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic reviews and Meta-Analyses) flowchart. HIS: health information system; NGRC: neighborhood geo-referenced context.

Study Characteristics

We reviewed the descriptive characteristics of all 24 included papers. Basic characteristics of the studies are presented in Table S4 in Multimedia Appendix 1, including information on (1) the type, number, gender, age distributions, and language of participants, and (2) the study type and year of publication. The characteristics with appropriate properties for summarization include (1) the type, NCD, and health and computer literacy of participants, and (2) health settings. All studies were conducted in the United States. Details are provided in Table S5 in Multimedia Appendix 1.

We divided the studies by participant type as follows: 2 studies [29,77] focused solely on providers, 4 studies concentrated on caregivers [78-81], 13 studies examined patients only [10,82-93], and 5 studies involved both health providers and patients [93-97]. Among patients, most studies focused on adults.

Summarization of the Results

Overview

In this section, we aim to summarize the findings from the 24 included articles to address the first 3 research questions. Each of these themes is explored in detail in the subsections that follow.

Question 1: Question Regarding HISs

We summarized whether HISs were used and the types of HISs used. Table 1 presents HIS usage across all stages, while Table S5 in Multimedia Appendix 1 lists the types of HISs. Table S4 in Multimedia Appendix 1 provides the specific names of the HISs.

Table 2 details the stage 1 NGRC data capture, including the settings (eg, health care settings, such as hospitals, and non–health care settings, such as homes), those collecting data (eg, patients, providers, and systems), and those documenting it (systems or providers).

Question 2: Question Regarding NGRCs

We summarized the reviewed studies in terms of behavioral intervention types as follows: (1) social needs interventions, (2) lifestyle change interventions, and (3) whole care without specifying the behavioral intervention type. This categorization agrees with the information in Table S1 in Multimedia Appendix 1. Table 3 summarizes the types and spatiotemporal characteristics of NGRC attributes.

[h]PN: perceived neighborhood.

[i]RD: residential address.

[j]Not available.

We specified substructures for the categorization of social needs interventions, lifestyle change interventions, and whole care. Social needs interventions used actively collected, subjective, and static measures of perceived neighborhood social and built environments. Lifestyle change interventions included (1) actively collected, subjective, and static measures of perceived neighborhood social, natural, and built environments at residential addresses, and (2) passively collected, objective, real-time, and location-based distances to high-risk areas (eg, bars). Whole care included passively collected, objective, and static social and built environment indicators derived from the census tract of residential addresses.

In social needs interventions, actively collected, subjective, and static measures of perceived transportation barriers and neighborhood safety were the only 2 assessed NGRCs (21/24, 88%). These were assessed using electronic or paper-based surveys [29,78-82,84-98]. The focus on transportation barriers (21/24, 88%) may reflect their relative ease of mitigation through interventions (eg, door-to-door transportation to medical appointments [8,92]). These interventions were shaped by specific health service settings and available community resources. Similarly, transportation barriers were assessed using a variety of question formats, time frames, destination types, and SDoH screening tools. Despite these efforts, detailed information, such as transport mode, distance, travel time, and the locations of perceived neighborhoods, was generally rarely collected. Additional details are presented in Table 4.

By the way, we have this new resource team that can help with things not related to health care, like food, housing, and transportation. Is this something you want to talk about?	—	Weekly	—	[97]

[a]NGRC: neighborhood geo-referenced context.

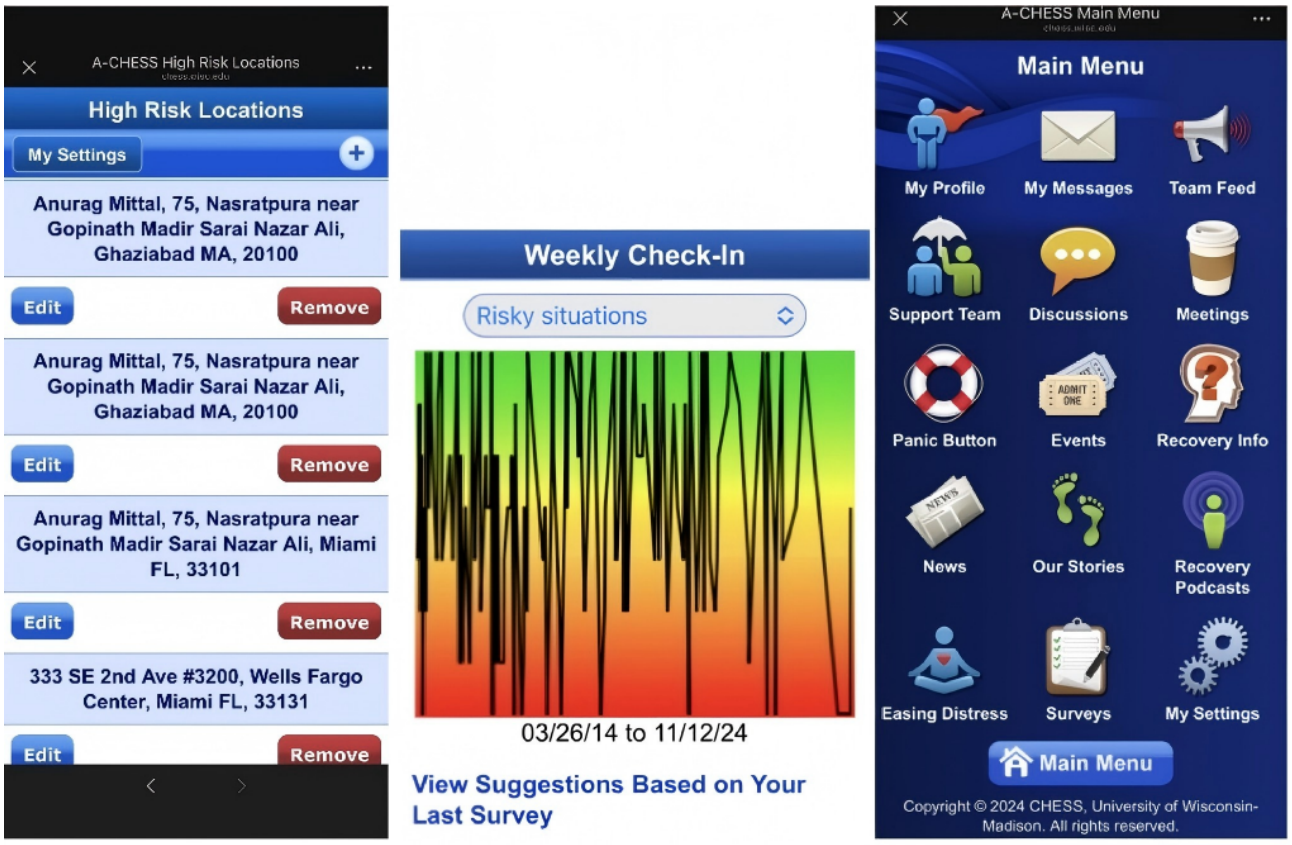
[b]SDoH: social determinants of health.

[c]CRC: colorectal cancer.

[d]Information not available.

[e]NICU: neonatal intensive care unit.

[f]CT: computed tomography.



Lifestyle change interventions assessed actively collected, subjective, and static measures of social, natural, and built environments at participants' perceived residential neighborhoods. These were assessed with "neighborhood assessment" during follow-up visits [10]. These assessments showed the multifaceted interplay between NGRCs and lifestyle behaviors. The environmental barriers to healthy eating and physical activity included air quality, food environment density, physical activity facility density, streetlight design, and neighborhood safety (Table 3). The absence of subsequent similar studies highlights the practical challenges of consistently partnering with community groups and agencies to address environmental barriers to lifestyle change.

In addition, passively collected, objective, real-time, and location-based distances to high-risk areas (eg, bars) were assessed using GPS data from the A-CHESS (Addiction Comprehensive Health Enhancement Support System) app [83] (Figure 2). Unlike approaches that depend on community-level resources of residential addresses, A-CHESS optimizes users' daily routes. This suggests that leveraging existing environments along these routes—not just around residential areas—can be practical without requiring extensive organizational collaboration. A-CHESS also supports weekly surveys to actively assess participants' perceived alcohol use in their residential neighborhoods [83]. While transportation barriers are relatively stable, neighborhood social cultures, such as drinking behaviors, fluctuate rapidly, requiring active and higher-resolution data collection to capture their health effects.

In whole care, passively collected, objective, and static social and built environment indicators based on the census tract level of the residential address were displayed in the Envirome Web Service [77]. Integrated with the Cerner Millennium EHR, this service displays socioeconomic data, food desert status, and contextual information at the census tract level using public datasets (eg, the US Department of Agriculture and the 2010 Decennial Census). Compared with A-CHESS, the Envirome Web Service offers broader, population-level coverage of social and built environment factors through passive data collection but lacks dynamic, route-specific, or nonresidential contextual information.

XSL•FO
RenderX

Figure 2. The A-CHESS (Addiction Comprehensive Health Enhancement Support System) app [83] supports recovery from alcohol use disorder by providing 24/7 smartphone access to services such as cognitive-behavioral therapy, addiction-related resources, and alcohol-free events. The left panel displays a list of identified high-risk locations, the middle panel summarizes risky situations based on weekly surveys, and the right panel shows the app's homepage. Using GPS, A-CHESS monitors when users approach predesignated high-risk locations, such as bars, and sends an alert asking whether they intend to be there. No alert is issued if the user is not near a high-risk location. The screenshots were captured from the app link [99].

Question 3: Question Regarding Stakeholders' Insights

We summarized stakeholders' insights on the use of NGRCs and/or HISs in social needs interventions and whole care from 10 included studies. The details are shown in Table S6 in Multimedia Appendix 1.

Seven studies mentioned attitudes toward NGRC integration. Six out of the seven studies on social needs interventions found that patients, caregivers, and providers valued addressing transportation barriers for comfort and convenience [84,93,96,97]. However, challenges remain in addressing patients' concerns about potential discrimination, such as reduced courtesy or respect, as well as providers' discomfort with stigmatizing questions [81,86,93,96,97]. At the core, the challenge lies in balancing actionable social needs interventions and sensitive care. The last study [77] examined providers' views on NGRC data needs, clinical usefulness, and data visualizations in whole care. Providers emphasized the need for clear definitions and simple visualizations to make complex data more actionable in practice [77].

Nine studies examined HIS integrations from 3 aspects: value and convenience, patient autonomy, and privacy. The efficiency and convenience of electronic NGRC capture tools were recognized by providers, patients, and caregivers, particularly when patients completed them before visits [29,77,86,95-97]. However, providers also expressed concerns about increased workload, time constraints, unfitness to the workflow, and the possibility of raising unmet patient expectations [29,86,94-96]. These concerns underscore the need to integrate NGRC-focused behavioral interventions seamlessly into clinical workflows to avoid a higher administrative burden. Patient autonomy and engagement were enhanced [77,86,95-97]. Improved autonomy can support person-centered and team-based care. However, the absence of data on patients' digital literacy could lead to misinterpretation of patients' attitudes (eg, acceptability, adoption, and usage of HISs), especially for those with low literacy levels, as higher digital literacy can alleviate social concerns [29,84]. Privacy was improved by reducing patients' feelings of judgment and promoting greater honesty in disclosure [84,86,95]. Improved privacy suggests that well-designed digital systems can mitigate stigma associated with sensitive NGRCs.

Discussion

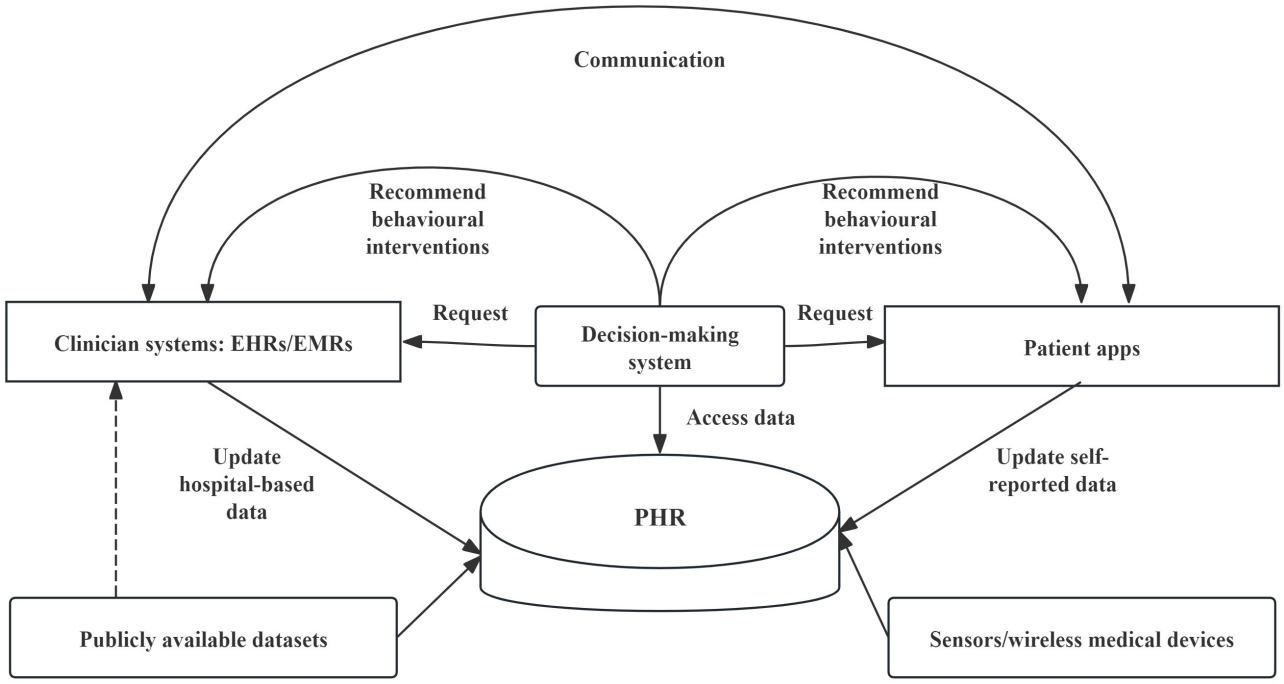
Principal Findings and Recommendations

In this scoping review, we reviewed the current state of NGRC-focused behavioral interventions using HISs in order to propose recommendations for future studies. We included 24 studies, and nearly half of the studies (11/24, 46%) were conducted in 2023 or later (Table S4 in Multimedia Appendix 1). Due to unstructured reporting in many of the included studies, reliably extracting data was difficult. We organized our findings and recommendations according to the 4 research questions.

XSL•FO
RenderX

Question 1: Question Regarding HISs

The predominant reliance on provider-centric EHRs/EMRs and the limited and inconsistently described use of HISs across the entire NGRC-focused behavioral intervention cycle significantly constrain the integration of NGRCs into behavioral interventions. Apart from the unspecified type of HIS in 1 study [10], most included studies relied on provider-centric EHRs/EMRs (20/24, 83%), with limited use of more patient-empowered PHRs. Only 3 studies used tethered PHRs, and none utilized interconnected PHRs (Table S5 in Multimedia Appendix 1). The reliance on provider-centric EHRs/EMRs may lead to difficulties in monitoring and assessment. Therefore, most studies (23/24, 96%) did not apply HISs in the entire process (NGRC data capture, intervention prescription, monitoring, and assessment). HISs were mainly used for (1) NGRC data capture (18/24, 75%), with limited patient-led (5/24, 21%) or system-led (1/24, 4%) cases; (2) intervention prescriptions (13/24, 54%); and (3) assessments (11/24, 46%) focusing on health care utilization, with minimal use in monitoring (2/24, 8%). Limited monitoring and a narrow focus on health care utilization data for assessments leave the sustainability of behavior change largely unaddressed. Given its critical role in improving long-term health outcomes, future research should aim to establish integrated frameworks that embed tethered or interconnected PHRs consistently across the 4 phases. Furthermore, the lack of details on HIS functionalities limits the ability to synthesize evidence and derive practical design recommendations for future interventions. Future studies should provide sufficient details to ensure reproducibility.



Although HISs have been used frequently in NGRC data capture, the dominance of active collection (eg, patient-administered or provider-administered surveys; 22/24, 92%) and the underuse of passive collection (eg, linkage with public datasets; 1/24, 4%) and GPS data (1/24, 4%) have left existing data underutilized, and active collection may cause user information to be unclear. On one hand, the majority of studies (17/24, 71%) relied on manual NGRC collection and documentation into EHRs/EMRs by stakeholders (Table S6 in Multimedia Appendix 1). Active data collection likely contributes to negative provider attitudes due to increased workload and limited consultation time. This potentially hinders the integration of NGRCs into routine care. Self-completed assessments using tethered or interconnected PHRs may address providers' concerns, and both patients and providers hold positive attitudes toward them (Table S6 in Multimedia Appendix 1). However, tethered or interconnected PHRs were underutilized in the included studies. The gap between positive stakeholder attitudes and practice suggests missed opportunities to reduce provider burden and engage patients more actively in their care using PHRs. On the other hand, although the A-CHESS app achieved passive data collection, it relied solely on HISs as assessment tools and had limited provider access to behavioral data, which constrained the understanding of how HISs and providers influence behavior change and its sustainability. Similarly, the Envirome Web Service [77] passively collected NGRC data via public dataset linkages. However, the lack of detailed descriptions of the use of HISs in subsequent steps (eg, monitoring and assessment) further limited insights into their role in supporting sustained behavior change.

The complexity of provider types and roles in the entire process of NGRC-focused behavioral interventions (Table 1) further complicates implementation in clinical settings. Future studies should clearly define the responsibilities of every provider to enhance coordination across care teams, thereby improving intervention fidelity and consistency.

In summary, implementing tethered or interconnected PHRs throughout the intervention process, particularly in outpatient settings, is recommended (Figure 3). Connection with EHRs/EMRs can also achieve provider support. By ensuring privacy, security, and controlled access, PHRs can enhance user acceptance and usage [100]. Secure data exchange among patient apps, public datasets, sensors, and EMRs/EHRs can enable tailored interventions, timely issue detection, improved communication, greater engagement and adherence, better care coordination, higher satisfaction, and reduced treatment burden [86,101]. We have summarized 3 recommendations in Textbox 3.

Textbox 3. Recommendations.

Recommendations regarding the types and roles of health information systems (HISs) in the entire process of neighborhood geo-referenced context (NGRC)–focused behavioral interventions

1. Consider tethered or interconnected personal health records (PHRs), especially in outpatient settings, in the entire process of NGRC-focused behavioral interventions.
    - Use tethered or interconnected PHRs to actively or passively collect multiple NGRCs and generate a more comprehensive view of patients' NGRCs [84]. PHRs can passively obtain location-related NGRCs through connections with electronic health records (EHRs)/electronic medical records (EMRs), public datasets (eg, government data and cohorts), sensors, and wireless medical devices. The locations can include not only the residential address but also regularly visited places or GPS-derived data. On the other hand, PHRs can also embed patient- or caregiver-completed surveys to actively collect perceived NGRCs. Determining the optimal timing and frequency of data capture is essential to balance user burden and data quality [82,84,102,103].
    - Clinical decision support systems (CDSSs) can use NGRC data from PHRs to personalize behavioral interventions, delivering recommendations to patients via apps and to providers via EHRs/EMRs. For instance, real-time CDSS alerts sent at optimal intervals can support providers in adjusting NGRC-focused interventions.
    - Consider integrating PHRs with other portable devices (eg, patient apps, sensors, and wireless medical devices) to allow real-time monitoring through surveys, GPS, and sensors.
    - Integrating PHRs with EHRs/EMRs and other portable devices can provide sufficient long-term follow-up data. CDSSs can then use these data to assess and adapt NGRC-focused behavioral interventions [46,85,104], allowing the evaluation of the sustainability of outcomes and the identification of interventions that produce lasting effects.
2. Incorporate the support of health care providers throughout NGRC-focused behavioral interventions. This support can be provided through (1) providers' guidance on CDSS recommendations and (2) direct patient-provider communication.
    - Explore the roles of various health care providers in the entire process of NGRC-focused behavioral interventions.
3. Balance active and passive NGRC data collection to achieve higher acceptability, feasibility, and effectiveness of NGRC-focused behavioral interventions [24,84,86].

Recommendations regarding the types, spatiotemporal characteristics, and datasets of NGRCs in each type of behavioral intervention

1. Accommodate NGRC-focused social needs interventions with lifestyle change interventions.
2. Include a broader range of NGRCs with detailed spatiotemporal information for different behavioral interventions.
    - Expand the focus beyond influential built environments to also include key natural and social environments for specific behaviors.
    - Incorporate a comprehensive 5D (density, diversity, design, distance, and destination accessibility) framework of built environments.
    - Optimize NGRC spatiotemporal resolution using an evolutionary approach. Apply high-resolution or real-time data when available for precise interventions; otherwise, use static or coarse data (eg, administrative datasets) to capture neighborhood influences. Combining dynamic and static NGRCs can mitigate challenges such as the modifiable areal unit problem, the uncertain geographic context problem, and neighborhood effect averaging.
    - Prioritize key subjective and objective NGRCs for specific behaviors (eg, cycling and walking) and standardize their definitions, spatiotemporal attributes, and measurements through multidisciplinary collaboration. Such efforts should leverage and expand existing terminologies (eg, "community details" in Systematized Nomenclature of Medicine—Clinical Terms [SNOMED CT] and Logical Observation Identifiers Names and Codes [LOINC]) and ontologies (Social Determinants of Health Ontology [SOHO] [105] and social determinants of health ontology [SDoHO] [106]) [24].
    - Assess the availability of influential objective NGRCs in existing datasets and explore opportunities to collect missing objective and subjective data through passive methods (eg, sensors). When certain NGRCs cannot be captured passively, develop self-administered questionnaires to obtain the remaining information. Finally, evaluate the quality, usability, and improvement potential of patient-completed data.
3. Address both technical and social considerations (eg, ethical issues) in NGRC data collection [92].

Recommendations regarding stakeholders' insights on the use of HISs and/or NGRCs in behavioral interventions

1. Assess stakeholder acceptance, attitude, and preferred interactive features for various NGRC-focused behavioral interventions using HISs, particularly those targeting lifestyle changes. For example, evaluate patients' willingness and desired features in PHR-based self-management tools, and design EHR/EMR features that fit providers' workflows to mitigate concerns like time constraints and workload.
2. Develop and iteratively test efficient, user-friendly data visualization tools for stakeholders [33,107-111].
3. Explore stakeholders' perspectives on integrating diverse and/or real-time NGRCs into behavioral interventions, extending beyond transportation barriers to broader applications. Future research should identify which NGRCs stakeholders consider most actionable and relevant for specific interventions, and determine effective, nonstigmatizing data collection methods. For example, assess patient willingness to share GPS data when they can control access to their information.
4. Consider stakeholders' computer and health literacy when evaluating their attitudes toward NGRC-focused behavioral interventions using HISs.

XSL•FO
RenderX

5. Iteratively build support systems, responding to negative feedback by aligning patient expectations and addressing stakeholders' social concerns.

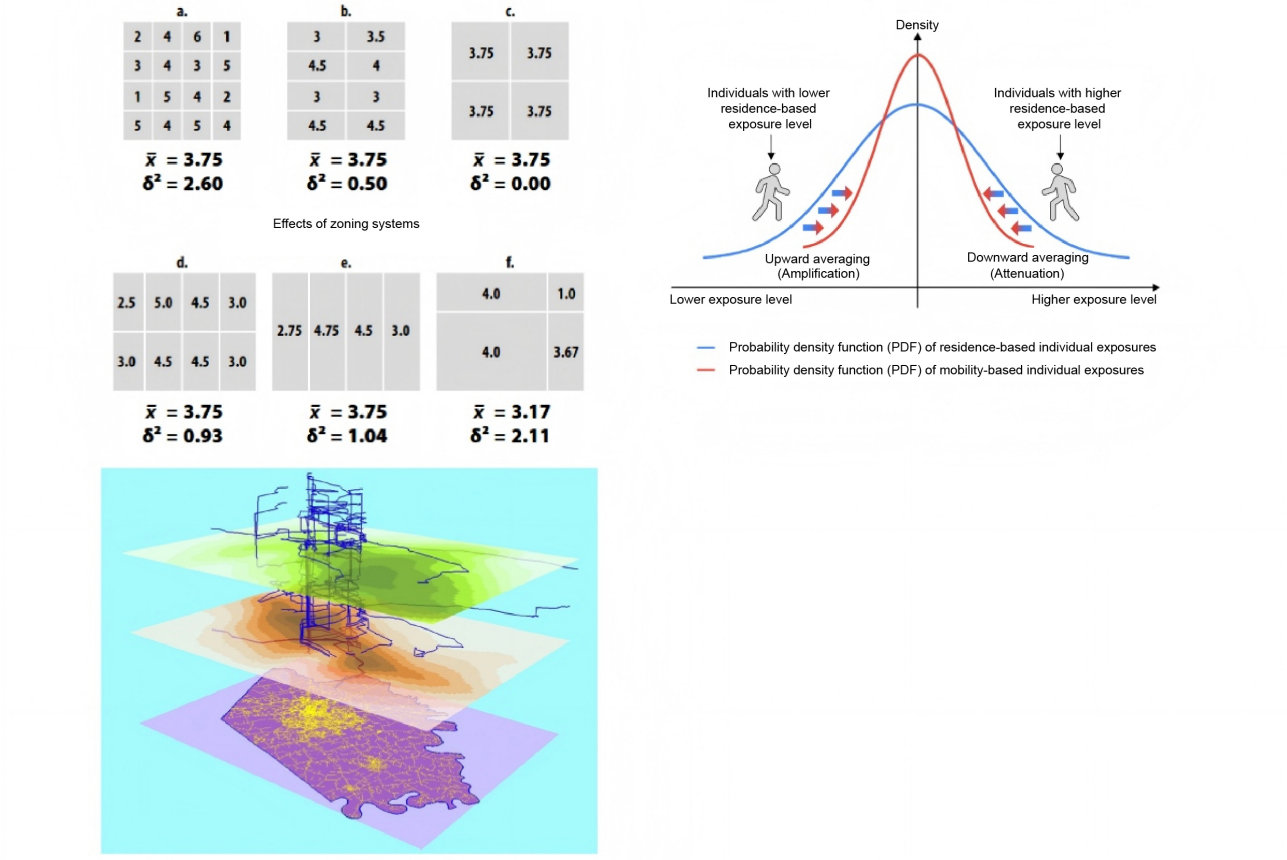
Recommendations regarding research designs

1. Adopt standardized and detailed descriptions of NGRCs [24], HIS functionalities, intervention designs, and relevant disease contexts—ideally guided by common metadata standards or consensus-based frameworks—to enhance transparency, comparability, and collaboration across studies.
2. Evaluate the feasibility, acceptability, adoption, sustainability, effectiveness, cost-effectiveness, ethics issues, and mechanisms of change of NGRC-focused behavioral interventions using HISs, with detailed descriptions of research design for reproduction, testing, and comparison. For example, in research design, the only difference between the intervention and control groups should be whether the intervention is NGRC-focused, in order to isolate the effect of NGRCs.
3. Initiate comparative studies examining how different NGRCs and HIS functionalities influence specific intervention effectiveness, which would further inform the design of evidence-based interventions.

Generalizability

1. Explore the unique challenges and context-specific solutions relevant to countries outside the United States.

Question 2: Question Regarding NGRCs



The dominance of structured, measurable social needs interventions in the involved studies likely reflects that health care prioritizes short-term outcomes. In contrast, long-term lifestyle change interventions are overlooked. This may be due to operational challenges, including reimbursement constraints, lower adherence, long-term evaluation, etc [112-115]. However, lifestyle change interventions are crucial for preventing NCDs. To raise attention on lifestyle change interventions, incorporating NGRCs is beneficial for improving adherence and effectiveness. Future studies should focus on leveraging NGRC data to design and evaluate personalized, NGRC-focused lifestyle interventions aiming at advancing patient-centered and preventive care.

Current research has largely overlooked NGRCs beyond transportation barriers within the "destination accessibility" dimension of built environments. Neglecting other 4D elements, as well as social (eg, community crime, neighborhood safety, and socioeconomic data; included in 4 studies) and natural environments (specifically air pollution; included in 1 study), may limit our understanding of how specific NGRCs can inform behavioral interventions. Within the built environment domain, the exploration of "density," "distance," and "design" in the "5D" framework was limited, and "diversity" was not addressed. Future studies should systematically explore other less-studied NGRCs, such as social, natural, and other built NGRCs, to inform more holistic solutions of behavioral interventions using HISs.

Insufficient attention to objective, dynamic, and/or high-resolution NGRCs has left several key methodological challenges largely unaddressed. These include the modifiable areal unit problem, uncertain geographic context problem, neighborhood effect averaging problem, and problem of temporal variations in NGRCs (Figure 4) [60,116-120]. One likely reason is that 22 studies (92%) relied on actively collected, subjective, and static NGRC data, which require substantial participant effort and are therefore difficult to scale for capturing dynamic and/or high-resolution NGRCs. Passive data collection methods (eg, GPS tracking and linkage with public datasets) could help overcome these limitations by enabling more dynamic and/or high-resolution NGRC measurement. However, passive approaches alone cannot capture all real-time and/or high-resolution NGRCs, particularly those related to individual perceptions. Therefore, active data collection remains essential for assessing perceived NGRCs. While some studies have focused exclusively on perceived measures, others have underscored the added value of combining subjective and objective NGRCs to more comprehensively understand their associations with behavioral outcomes [121-124]. When collecting perceived dynamic and/or high-resolution NGRCs, issues, such as user vagueness and the quality of self-reported data, must be carefully considered. Future work should prioritize developing optimized and balanced approaches that integrate active and passive data collection, thereby leveraging dynamic and/or high-resolution NGRC measures to advance behavioral intervention research.

XSL•FO
RenderX

Figure 4. The top-left figure displays the modifiable areal unit problem. The mean value does not change with aggregation, but the variance declines [118,119]. The top-right figure presents how the neighborhood effect averaging problem operates in individual air pollution exposures [116,120]. The bottom figure shows the uncertain geographic context problem, which arises because of the spatial uncertainty in the actual areas that exert contextual influences on the individuals being studied, and the temporal uncertainty in the timing and duration in which individuals experienced these contextual influences [60,117].

Furthermore, all involved studies illustrated the ongoing challenges of balancing granularity and comprehensiveness in assessing NGRCs. On the one hand, actively collected, subjective NGRC measures provide individualized insights but are limited in granularity and comprehensiveness. On the other hand, passively collected, objective indicators offer broad coverage but often lack individual insights and granularity, potentially due to existing dataset constraints. This trade-off underscores the need for integrated approaches that combine active and passive data to capture the complex, dynamic interplay between NGRCs and health behaviors.

To improve the granularity and comprehensiveness of NGRCs in various behavioral interventions, especially lifestyle change interventions, HISs—preferably tethered or interconnected PHRs in outpatient settings—should be considered. We have summarized 3 recommendations in Textbox 3.

Question 3: Question Regarding Stakeholders' Insights

Improved perceived value, convenience, patient autonomy, and privacy were consistently reported as outcomes of integrating technological (HISs) and content (NGRCs) innovations into behavioral interventions in all 10 included studies. On the other hand, social concerns persisted, including provider workload and the potential for discrimination. These benefits and concerns could be influenced by participants' computer literacy, which was rarely reported in the studies. Given this gap, future research should explore how to balance technological and content innovations with unresolved social concerns, accounting for variations in computer literacy.

The NGRC information needs of providers, the clinical usefulness of NGRC data, and the usefulness of NGRC-related data visualizations are not yet well supported by existing evidence. Future studies should investigate which NGRCs should be presented in HISs, how they should be used in practice, and which interactive features best support their use.

Stakeholders' insights into the integration of NGRCs and/or HISs into lifestyle interventions were not explored in the included studies. This highlights a critical gap in both technological and content innovations, as well as in addressing social concerns and in the integration of HISs and NGRCs into lifestyle change interventions.

We have summarized 5 recommendations focusing on enhancing NGRC and/or HIS integrations in behavioral interventions in Textbox 3.

Question 4: Question Regarding Research Design

We found limited coverage and inconsistent health outcomes of NGRC-focused behavioral interventions using HISs. Health outcomes focused mainly on health care utilization (eg, emergency visits), with limited coverage of clinical indicators, including medication adherence [97], asthma control [92], cancer screening [98], and blood pressure [87]. This limited coverage of clinical health outcomes limits the understanding of long-term

XSL•FO
RenderX

behavior change and highlights the need for more comprehensive assessments. Moreover, the inconsistent health care utilization outcomes [88,91] may be caused by the inconsistent and/or insufficient reporting of 5 aspects. These aspects include (1) NGRC attributes (eg, definitions and spatiotemporal characteristics), (2) HIS types and functionalities, (3) assessment methods (eg, clinical metrics [eg, HbA_{1c}] and health care utilization), (4) stakeholders (eg, only HISs or various health providers), and (5) targeted diseases. Such heterogeneity causes low interstudy comparability and reproducibility. It also limits the ability to determine which behavioral interventions, leveraging specific NGRCs via particular HIS functions, are most effective, thereby complicating the translation of findings into evidence-based practice.

No studies have addressed key issues such as cost-effectiveness and ethical considerations. Future research should examine these critical factors to ensure successful implementation.

To develop evidence, we have summarized 3 recommendations in Textbox 3.

Generalizability of the Results

Our objective was to synthesize global literature on NGRC-focused behavioral interventions supported by HISs. However, we were unable to identify published, peer-reviewed studies conducted outside of the United States. Initiatives, such as the European Health Data Space (EHDS) [125] and China's Healthy China Initiative [126], reflect growing efforts to integrate SDoH, including NGRCs, into HISs. On one hand, contextual differences do not preclude transferability. The contextual differences include cultural norms, socioeconomic conditions, and geographic contexts. With appropriate localization and system-level adaptation, the core principles identified in United States–based studies can be effectively applied in diverse settings. However, the limited diversity of study settings may obscure unique challenges and solutions relevant to low-resource or non-Western countries. Addressing these gaps is essential, and future research should ensure that context-specific NGRC-focused behavioral interventions using HISs are inclusive, adaptable, and globally relevant (Table 3). On the other hand, technological and political differences across the world do not influence the generalizability of our study. These differences include (1) HIS infrastructure, architecture, and integration capabilities, and (2) data standards, privacy regulations (eg, the European General Data Protection Regulation [127]), and governance policies. The commonalities of these differences help support the generalizability of the findings [128].

Strengths and Limitations

Our review has 4 key strengths. First, this article reviews the current state of NGRC-focused behavioral interventions using HISs. This provides a comprehensive analysis from 3 perspectives: technology, NGRC content, and stakeholders' insights. Second, we searched a wide range of databases, leading to publications from diverse disciplines, including medical journals, environmental journals, and computer science conferences. Third, we consulted a library information specialist to develop the search strategy, ensuring its comprehensiveness and accuracy, which thus enhanced the research's quality and credibility. Finally, to provide readers with sufficient context and allow them to assess the reliability of the evidence, we extracted and reported descriptive information, including study type, publication year, and sample size (Table S4 in Multimedia Appendix 1). We did not conduct a critical appraisal of the included studies, as it is not mandatory in scoping reviews. According to the Joanna Briggs Institute (JBI) methodology for scoping reviews [129], a critical appraisal is generally unnecessary unless it is directly relevant to the review objectives. Additionally, most quality assessment tools, including the Mixed Methods Appraisal Tool (MMAT) [130], primarily evaluate study design, data collection, and methodological rigor. Therefore, applying such tools would not provide meaningful information for our objectives (eg, HIS functionalities and NGRC indicators).

Our study also has several limitations that should be considered. First, NGRCs are ambiguous, suggesting that they are open to multiple interpretations or are vague. For example, in various studies, neighborhood safety may refer to different things, but there are no clear details of this concept in the studies. However, resolving this ambiguity is challenging because of the lack of standardized definitions and the context-dependent characteristics of NGRCs. Therefore, future studies should adopt detailed and consistent definitions of NGRCs, ideally guided by standardized terminologies or ontologies. These terminologies or ontologies can leverage and expand existing terminologies (eg, "community details" in Systematized Nomenclature of Medicine—Clinical Terms [SNOMED CT] and Logical Observation Identifiers Names and Codes [LOINC]) and SDoH ontologies [24].

Possible Mechanisms and Implications for Clinicians or Policymakers

HISs are often seen as passive recorders of health data. However, tethered or interconnected PHRs can actively participate in the entire process of NGRC-focused behavioral interventions, especially in outpatient lifestyle change interventions, with the relatively limited help of health care providers. For example, platforms like the iManageCancer platform for cancer patients and the iManageMyHealth app for their physicians provide personalized content from reliable public resources on cancer. However, these platforms do not currently consider NGRC factors and focus on behavioral interventions [3]. This underscores the importance for providers and policymakers to utilize tethered or interconnected PHRs to collect comprehensive, dynamic, and static NGRCs; deliver timely behavioral interventions in outpatient settings; monitor behaviors and the health status; and assess interventions. By doing so, they can achieve public health goals and promote health equity.

Conclusion

In this study, we found that most NGRC-focused behavioral interventions utilized transportation barriers to support social needs interventions. Meanwhile, HISs were involved only in specific aspects of the NGRC-focused behavioral intervention process. To achieve comprehensive dynamic and/or

XSL•FO
RenderX

high-resolution NGRC considerations and the full integration of HISs throughout the behavioral intervention process, given the limited and heterogeneous evidence, further research is needed to determine how tethered or interconnected PHRs can effectively support NGRC-focused interventions, especially lifestyle change interventions. During implementation, it is essential to address social concerns alongside technological (eg, HIS integration) and content innovations (eg, NGRC integration). We compiled a list of 15 recommendations for future research. These recommendations are likely to accelerate the integration of tethered or interconnected PHRs in NGRC-focused behavioral interventions.

Acknowledgments

Abstract

Background: Nursing care systems face significant challenges due to demographic changes, a workforce shortage, and rising demand for care services. Digital assistive technologies offer potential to address these challenges, but systematic and standardized nursing data are essential to evaluate both innovations and broader care processes. The Nursing Minimum Data Set (NMDS) provides a foundational framework for capturing structured information on nursing care, yet there is no international consensus on its core content, development, and practical use.

Objective: This scoping review aims to map current international literature regarding (1) the core content elements of NMDS, (2) methodological approaches used in NMDS development, and (3) implementation and use of NMDS in different nursing settings.

Methods: Following the JBI (Joanna Briggs Institute) methodology and Arksey and O'Malley framework, a systematic search was conducted on July 2, 2025, in the MEDLINE (via PubMed) and CINAHL (via EBSCO) databases using the term "nursing minimum data set." Inclusion was restricted to studies in English or German focusing on the content, development, or implementation of the NMDS. The research team reviewed studies in an independent and double-blinded fashion for eligibility based on predefined criteria, with discrepancies resolved by consensus. Eligible studies were narratively summarized, with extraction structured into categories based on the review's research questions.

Results: From 1908 initially identified articles, 26 (1.4%) studies met the inclusion criteria. Considerable heterogeneity was found in the structure and scope of the NMDS, with datasets comprising 16 to 145 items. Despite variation, 4 central domains consistently emerged: patient demographics, medical care information, nursing care elements, and institutional or organizational data. NMDS development typically followed a participatory, multistage approach involving literature analysis, stakeholder consensus building, and validation through pretesting and real-world application. Implementation and use of the NMDS serve multiple functions, including documenting nursing care processes, supporting workload measurement and resource planning, quality assurance, benchmarking, and demonstrating nursing's contribution to patient outcomes. However, successful implementation depends on technical, legal, organizational, and educational strategies. Core challenges include a lack of standardized terminology, inconsistent legal frameworks, and varying levels of staff training and acceptance.

Conclusions: The NMDS provides a robust basis for standardized nursing documentation, quality assurance, and health system planning, but international variability and ongoing challenges in harmonization, integration, and acceptability persist. Advancing the NMDS requires collaborative efforts for interoperability, investment in digital infrastructure, and targeted education. Further research should focus on comparative effectiveness, cross-context validation, and strategies to reduce documentation burden while maximizing data utility.

(JMIR Med Inform 2026;14:e84281) doi:10.2196/84281

Introduction

The nursing care system in Germany is confronted with significant challenges, including demographic shifts, a shortage of nursing personnel, and increasing demand for care services [1]. From 2014 to 2021, expenditures on long-term care insurance increased more than 2-fold, rising from €25.5 billion (US $30 billion) to €53.9 billion (US $63.4 billion) [2]. To ensure the sustainability of care provision, there is a need for innovative digital solutions. Digital assistive technologies have been shown to have considerable potential in promoting participation and autonomy, as well as reducing care dependency [3]. However, research focusing on the etiology and progression of care needs, as well as the ramifications of digital innovations, has been disproportionately underrepresented to date [4].

Robust and standardized nursing data are essential to evaluate these innovations and their impact on care. The Nursing Minimum Data Set (NMDS) is defined as "a minimum set of items of information with uniform definitions and categories concerning the specific dimension of nursing which meets the information needs of multiple data users in the health care system" [5]. The NMDS provides a structured basis for capturing nursing care across populations, settings, and regions. It facilitates the monitoring of trends in care delivery and resource use, serves as a foundational element for research by establishing connections with broader health information systems, and contributes to the formulation of health policy, thereby ensuring the visibility of nursing contributions in health care planning and decision-making [6]. With a focus on influencing factors and opportunities to prevent or reduce care dependency, the NMDS can also serve as a framework for assessing the impact of digital innovations.

Despite its potential, there is a lack of clarity regarding which elements should be included in a core nursing dataset, how such elements are developed, and what barriers or success factors influence its implementation in practice. The objective of this scoping review is to map the current state of the literature by addressing the following research questions:

1. Which content elements comprise a nursing minimum dataset?
2. Which methodological approaches have been used in its development?
3. What is the implementation and use of such a dataset in different nursing settings?

Methods

This scoping review was conducted in accordance with the JBI (Joanna Briggs Institute) methodology [7] and guided by the framework of Arksey and O'Malley [8], which structures the process into the following phases: identifying relevant studies, study selection, data presentation, and synthesis of results. To enhance rigor and transparency, the reporting process adhered to the PRISMA-ScR checklist (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews; Checklist 1) [9].

Search Strategy

A systematic search was conducted on July 2, 2025, in the MEDLINE (via PubMed) and CINAHL (via EBSCO) databases using the search term "nursing minimum data set," applied identically in both databases. "Nursing minimum data set" is an internationally established and unambiguous term for the concept of interest. Preliminary searches using broader terms such as "nursing data" or "nursing data set" yielded numerous irrelevant results, mostly referring to general medical datasets including nursing-related variables but not specifically designed for nursing care. Searches in other databases (eg, Google Scholar and Europe PMC) produced even more irrelevant hits.

Using the precise term "nursing minimum data set" maximized specificity and relevance. PubMed's Automatic Term Mapping further captured synonyms and MeSH (Medical Subject Headings) terms. This focused approach aligns with Freguia et al [10] but extends their work by also analyzing the development and implementation of the NMDS. The MEDLINE and CINAHL databases were selected due to their comprehensive coverage of peer-reviewed nursing and health services research. No date restrictions were applied, and reference lists of the included articles were manually screened to minimize the risk of missing eligible studies.

The detailed inclusion and exclusion criteria are enumerated in Textbox 1. Exclusion criteria were based on our aim to map the conceptual, methodological, and implementation aspects of the NMDS rather than secondary applications or specialized derivatives. Studies focusing solely on specific clinical conditions, measurement tools, isolated settings (eg, palliative care), or context (eg, quality management) were excluded. Publications on other datasets (eg, the Minimum Data Set Resident Assessment Instrument [11]) or nursing classifications were also excluded. Language was restricted to English and German to ensure reliable screening and data extraction. Although this may introduce language bias, the majority of conceptual NMDS literature is published in these languages.

XSL•FO
RenderX

Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria

- Primary and secondary studies with abstracts available
- Language: German or English
- Description of content, development, implementation, and use in practical applications of the Nursing Minimum Data Set

Exclusion criteria

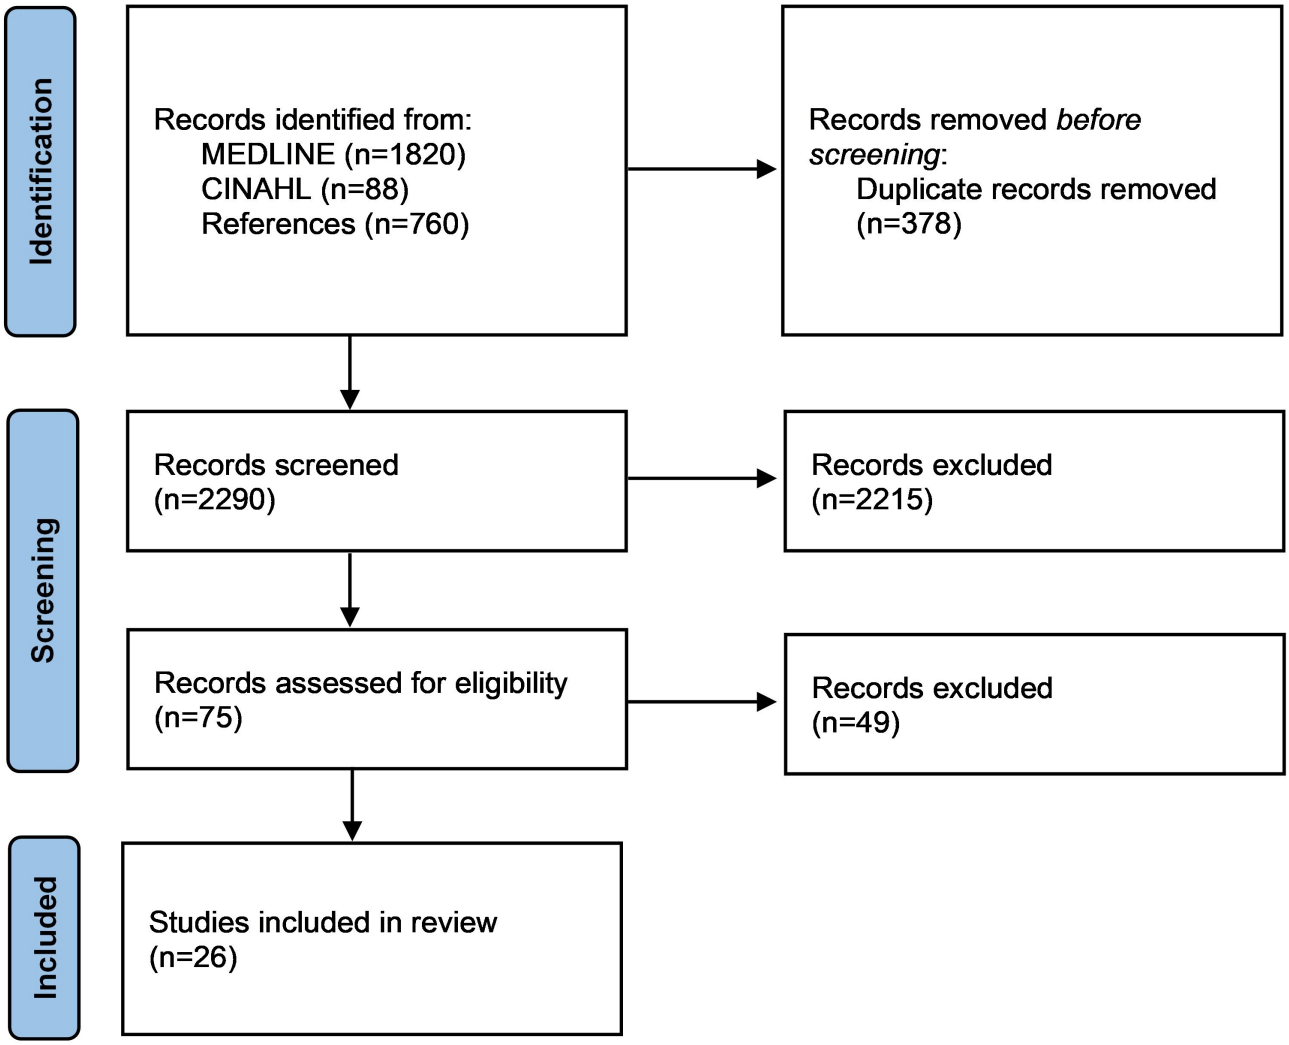
- Secondary analyses of the Nursing Minimum Data Set
- Reference to interventions, specific clinical pictures, or medications
- Reference to quality management, personnel indicators, or specific settings
- Comparison of measurement instruments
- In cases of duplicate publication, only the most comprehensive or earliest version was included to avoid double-counting

Study Selection and Data Extraction

The study selection followed the JBI methodology for transparency and reproducibility. Duplicate removal and screening were conducted using Rayyan (Rayyan Systems, Inc) [12], a web-based collaborative platform enabling independent and blinded review. Duplicates were first removed automatically using the software's matching algorithms based on title, author, DOI, journal, and year and then manually checked to resolve partial matches or inconsistent metadata.

Titles and abstracts of remaining records were independently screened by 2 reviewers (PM and AG) using Rayyan's blinded mode. Records identified as potentially eligible by at least 1 reviewer proceeded to full-text review. Discrepancies were resolved through discussion, with a third reviewer (KG) consulted if consensus could not be reached. The process was independent of study design and focused on studies addressing the conceptualization, development, or implementation of the NMDS. The number of records at each stage is presented in the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram. Reference lists of the included studies were manually screened to identify further eligible studies.

To systematically extract and present relevant information, included studies were narratively summarized in a data-charting form. The studies were categorized and analyzed according to the following classifications: "overview" (eg, definition and elements); "development" (eg, methods and processes); and "implementation" (eg, evaluation, availability, reliability, and validity). The primary categories were derived deductively from the review questions. Subcategories were subject to refinement and expansion in an iterative manner as novel themes and patterns emerged from the included studies. This framework enabled the synthesis of structured and flexible approaches, capturing the breadth of the research field.



Results

Study Selection

The database search conducted in July 2025 yielded 1908 results (PubMed: n=1820, 95.4%; CINAHL: n=88, 4.6%). After removing duplicates, 1869 (N=1908, 98%) records remained for title and abstract screening. Of these, 1823 (N=1869, 98%) were excluded due to unavailability of full texts or because they focused on data infrastructure, storage, or evaluation frameworks unrelated to NMDS content, development, or implementation. A total of 36 (N=1869, 2%) articles underwent double-blind full-text review. After applying all eligibility criteria, 23 (N=1869, 1.2%) articles were included. Screening reference lists added 3 more studies, resulting in a total of 26 included studies. No conflicts occurred among independent reviewers. The selection process is presented in the PRISMA flowchart [13] (Figure 1). A comprehensive list of the included studies and the data extraction table are provided in Multimedia Appendix 1 [6,10,14-37].

XSL•FO

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart illustrating the study selection process.

Main Characteristics of the Included Studies

The 26 studies originated from 9 countries. Most were from the Netherlands (n=6, 23.1%), the United States (n=4, 15.4%), Austria (n=4, 15.4%), Belgium (n=4, 15.4%), and Ireland (n=3, 11.5%). Additional studies were conducted in Finland (n=2, 7.7%), and 1 (3.8%) each from Italy, Germany, and Thailand. The majority of reported NMDS initiatives have their origins in the United States [10,16,19,25,29], Belgium [10,19,25,29,32-34,36], Canada [10,19,25,29], Thailand [10,25,27,29,37], Switzerland [25,29], and the Netherlands [18,20-23,25,29]. Additional origins including Ireland [14,26,29], Germany [17,29], Finland [24,25,29,35], Australia [19,25,29], Sweden [25], Brazil [25], Japan [25], Austria [28,30,31], and Scotland [19] were mentioned in several studies, which also referenced a European [10,19,25] and an international NMDS [19,25]. Most of the studies focused on universal nursing settings. However, there have also been investigations of specific settings such as hospitals, long-term care facilities, nursing homes, home health care agencies, and public health contexts.

The articles encompassed a period from 1988 to 2022. The predominant language of publication was English (n=24, 92.3%), with 2 (7.7%) articles published in German. The study designs exhibited heterogeneity, encompassing theoretical papers (n=9, 34.6%), mixed methods studies (n=7, 26.9%), quantitative studies (n=9, 34.6%), and a single qualitative study. The predominant focus was the development of the NMDS [14,17,21,27,28,30,33-36], followed by evaluation [16,20,22,31] and implementation [24,26,32]. A subset of these studies was also partially cited in the included systematic review [29] and umbrella review [10].

Data Elements

The datasets have been designed to capture comprehensive and comparable information on nursing practice, patient status, and care context. This facilitates the monitoring, evaluation, and enhancement of nursing care delivery at both the individual and system levels. A review of the existing literature revealed a considerable variation in the number of elements comprising an NMDS, ranging from 16 to 145 items per dataset. Despite this variation, 4 key categories consistently emerged: patient demographics, medical care information, core nursing care elements, and institutional or organizational data (Textbox 2).

The patient's demographic information is typically documented on an initial admission to the health care facility and subsequently serves as a foundational reference point for the patient's characteristics. The medical care items in question prioritize crucial medical information. While certain elements are documented on a single occasion during the patient's hospital

XSL•FO
RenderX

stay, details concerning medical procedures and medications are frequently recorded throughout the patient's stay. Core nursing care elements are typically collected continuously throughout the duration of hospitalization. The exception to this is nursing outcomes, which are generally assessed at discharge. Risk assessments and nursing diagnoses, on the other hand, are updated as the patient's status changes. Institutional or organizational data link patient- and care-level information with structural and organizational attributes, thereby supporting contextual analysis of care processes.

Textbox 2. The datasets are designed to capture information on nursing practice, patient status, and care context.

Patient demographics (3-8 items)

- Personal identification (pseudonymized)
- Date of birth and age
- Gender
- Race and ethnicity
- Place of residence
- Address and phone number

Medical care information (4-7 items)

- *International Classification of Diseases* codes
- Medical history (patient and family)
- Drug allergies or other allergies
- Procedures
- Laboratory tests
- Medication
- Dead or alive codes and resuscitation status
- Admission or encounter date
- Discharge information (date and summary)
- Length and progression of stay
- Health status (stability, severity, complications, and critical events)

Nursing care elements

- Nursing diagnosis (17-48 items)
- Nursing interventions (8-170 items)
- Nursing outcome (4-40 items)
- Intensity of nursing care (3-4 items)
- Nursing process (10 items)
- Client status (activities of daily living)
- Discharge plan
- Care planning (goals of the shift and goals of nursing care)
- Medical instruments' use before discharge

Institutional or organizational data

- Health care setting (4-5 items): type of institution, main point of service, type of nursing delivery system, and other disposition point
- Resource allocation (4 items): number and qualification of available nurses, number of nursing hours available, number of beds, and nurse-to-patient ratios
- Institutional or provider identifiers: service or agency number, health record number, nurse identifier, and physician identifier
- Expected payer of the bills or health insurance

XSL•FO
RenderX

NMDS Development

The development of the NMDS generally follows a three-stage process: (1) selection and definition of relevant data elements based on literature analysis, document analysis, and interdisciplinary consensus; (2) validation and consensus building through expert rounds, pretesting, and reliability assessments; and (3) application and testing the feasibility in real-world settings.

Selection and Definition of Data Elements

Potential items were chosen for clinical relevance and feasibility through literature reviews, analysis of clinical records (n=15-45 per study), and collaborative expert panels or Delphi processes. Participants included field nurses, nurse managers, nursing scientists, informatics specialists, and policy representatives (n=22-287 per study). Semistructured interviews and questionnaires were central, supported by focus groups and multiple rounds of expert panels (up to 11 with n=5-88 participants). The goal was to ensure that the items reflected actual practice, captured the diversity of nursing activities, and could be coded in a feasible manner. Critical decisions included choosing terminology and coding schemes, unit of data collection (eg, patient day or episode of care), and timing of data entry.

Refinement and Validation

The refinement of items and structures was achieved through consensus-building methods, such as repeated Delphi rounds and focus groups, along with pretests and reliability assessments, including Cohen κ and intraclass correlation coefficient. These methods often incorporated interdisciplinary and practice-based feedback, facilitating the continuous improvement and refinement of the research instruments. In the preliminary phase, the expert participants engaged in deliberations concerning the relevance, frequency, and practical feasibility of each item. In addition, they addressed the conceptualization, frequency, and relevance of the items, along with the data that were routinely collected. Lists of nursing diagnoses, interventions, and outcomes were developed and discussed for clarity and practicality. Subsequent rounds entailed the refinement and evaluation of the wording and definitions for their usefulness and feasibility, as well as the systematic testing of the definitions and coding rules. The resulting data collection instruments provided multiple response options for each item, thereby generating a broad range of analyzable variables. Each data element was carefully defined and accompanied by specific operational instructions, including scoring schemes that frequently used 5-point Likert scales to evaluate interventions and diagnoses.

The documentation of nursing care is typically implemented through the use of standardized classification systems. However, a universal system has yet to be established across all NMDS implementations. Instead, a variety of established frameworks are used, including the International Classification of Nursing Practice [38], the North American Nursing Diagnosis Association-I classification [39], the Omaha System [40], and the Home Health Care Classification [41], among others. The NMDS has been designed to either specify a preferred system or permit cross-mapping between local and international standards. The ability to exchange data and information seamlessly across different systems and between different countries is paramount for the comparability of data at both the national and international levels.

Reliability and validity testing constituted a fundamental component of the second stage. Pretests were conducted using samples ranging from 4 to 214 participants, often comparing the extracted information from patient records (n=20 to nearly n=300,000) by pairs of raters (research staff and clinical nurses). The coding agreement was subsequently quantified. The validity of the content was determined through its alignment with existing literature and user evaluations.

Feasibility Testing and Application

The final development stage focused on evaluating the usability and practical implementation of the NMDS. This included structured pilot applications in real nursing settings, such as hospitals, nursing homes, ambulatory care, and home health agencies. Typically, a longitudinal design with repeated measurements over a defined observation period (eg, 7 d or 1 admission episode) was selected. Consequently, the NMDS demonstrated its efficacy in the domains of care process description, workload measurement, resource planning support, benchmarking, and quality improvement across diverse nursing settings.

One such function is to systematically describe the diversity of nursing care and patient populations through frequency analyses of nursing diagnoses, interventions, and outcomes. The application of advanced analytical approaches, such as relative to an identified distribution analysis, has been demonstrated to facilitate the illustration of variations in nursing practice and complexity across a variety of settings, age groups, and medical diagnoses. In addition, the NMDS is instrumental in evaluating the intensity of nursing care. By establishing a correlation between the implementation of each nursing intervention and the temporal and experiential parameters of the nursing personnel involved, health care institutions can facilitate a quantitative assessment of the workload associated with each patient or unit of care. Classification systems such as the nursing diagnosis index or patient dependency models (eg, the San Joaquin classification) are used to establish a correlation between patient needs and staffing requirements, thereby facilitating evidence-based staffing decisions and resource allocation.

A further central benefit of the NMDS is its ability to demonstrate nursing's contribution to patient outcomes. For instance, path analysis can be used to examine the relationship between nursing interventions and patient progress, as illustrated by improvements in functional indices (eg, the Barthel index) during hospitalization. In the context of quality management and patient safety, outcome indicators facilitate the identification of care problems and the evaluation of improvement strategies through the integration of validated assessment instruments. The longitudinal use of these tools adds further value by enabling the tracking of care trends and patient outcomes over extended periods. These analyses are valuable for clinical managers and policymakers in the context of epidemiological

XSL•FO
RenderX

analysis, benchmarking institutions, highlighting areas of best practice, and supporting the dissemination of evidence-based interventions. This facilitates the formulation of strategic decisions regarding care processes and resource distribution.

A comprehensive implementation strategy must encompass not only technical solutions, such as increasing automation and electronic data collection, but also legal, organizational, and educational strategies. For instance, the implementation of the NMDS in specific contexts was terminated due to the absence of a legal foundation or inadequate institutional endorsement. The quality and utility of collected data are contingent on nurses' familiarity with the NMDS content and vocabulary. Educational initiatives are required to enhance nurses' comprehension of the significance of structured data collection and its pertinence for clinical decision-making, quality assurance, and the development of interoperable hospital information systems. To reduce the workload associated with NMDS documentation, it may be necessary to minimize the scope of collected variables, with a push toward electronic and automated data collection.

Discussion

Principal Findings

This scoping review offers a comprehensive mapping of the extant literature on the NMDS with regard to content elements, methodological development processes, and implementation and use across nursing settings. Synthesizing evidence from diverse international contexts and research designs, this review addresses the critical knowledge gaps identified in the introduction and provides an informed basis for further research and policy development in the field of standardized nursing data.

A salient finding of this review is the substantial heterogeneity observed in the structure and length of reported NMDSs, which vary from 16 to 145 items. Nevertheless, 4 core domains consistently emerged: patient demographics, medical care information, nursing care elements, and institutional or organizational data. This convergence on key domains, despite variation in the level of detail and specific items, underscores both the complexity of capturing nursing care and the international consensus on the essential pillars of nursing-relevant information. The comprehensive integration of nursing diagnoses, interventions, and outcomes signifies a worldwide transition toward outcome-oriented, evidence-based nursing practice. However, the absence of a universally adopted classification system for these categories—variously using systems such as the North American Nursing Diagnosis Association-I classification, the International Classification of Nursing Practice, or local taxonomies—continues to challenge the comparability of nursing data both within and across countries. This diversity underscores the necessity for enhanced harmonization to facilitate broader benchmarking, interoperability, and secondary data use.

The development of the NMDS is characterized by rigorous, iterative, and participatory processes. Most of the studies used a 3-stage approach: first, systematic identification and selection of content elements (frequently drawing from the literature, expert consultations, and clinical record analyses); second, consensus building and validation (frequently relying on Delphi processes, focus groups, and pretesting); and third, pilot implementation in real-world settings. The consistent engagement of field nurses, managers, scientific experts, and policy stakeholders supports both the clinical relevance and the practical feasibility of the resulting datasets. However, methodological diversity—particularly in the degree of stakeholder inclusion, the criteria for item selection, and the approach to validation—limits the extent to which the results can be compared and generalized. A fundamental finding is that consensus and interdisciplinary involvement significantly enhance acceptance and operationalization. However, disparities in contextual adaptation and infrastructure availability necessitate context-sensitive approaches, superseding the notion of a universally optimal solution.

The review demonstrates a wide range of applications of the NMDS, encompassing care process documentation, workload measurement, resource planning, quality assurance, benchmarking, and outcome evaluation. Analytical techniques such as frequency analysis, relative to an identified distribution analysis, and path analysis facilitate the sophisticated use of NMDS data. This includes the identification of care trends and variations, the mapping of nursing workload, and the demonstration of the impact of nursing care on patient outcomes. NMDS data have demonstrated their relevance for supporting clinical management, health policy, and epidemiological surveillance in multiple health care systems.

However, the implementation of NMDS is not without challenges. Achieving success in this endeavor necessitates the implementation of a multifaceted approach, encompassing not only technical solutions such as electronic and automated data collection but also legal, organizational, and particularly educational strategies. In certain settings, the discontinuation of NMDS initiatives was attributed to a lack of legal foundation, inadequate institutional support, or suboptimal integration into health information systems. The collection of consistent and high-quality data is contingent upon nurses' familiarity with the terminology and documentation standards. Consequently, training and change management are imperative. Furthermore, the balancing of data comprehensiveness with feasibility, as well as the minimization of documentation burden, emerges as a recurring theme in the pursuit of long-term sustainability.

Strengths and Limitations

A central strength of this review is its comprehensive and systematic approach, which adheres to established methodological frameworks (JBI and PRISMA-ScR) and uses a transparent, replicable search and data extraction process. The program's emphasis on international literature and a diverse array of study types contributes to the generalizability and relevance of the findings. The use of independent, blinded screening and iterative data charting enhances the rigor and credibility of the synthesis.

Several limitations of this review should be acknowledged. First, only 2 databases and a single search term were used. Preliminary scoping checks indicated that broader terms or additional databases yielded mostly irrelevant results, suggesting

XSL•FO
RenderX

a low likelihood of missing studies specifically addressing the NMDS. As NMDS initiatives are sometimes embedded in national health IT programs, relevant reports may appear in gray literature or regional journals not indexed in the MEDLINE or CINAHL databases. Nevertheless, the potential remains that studies using alternative terminology or published outside the MEDLINE and CINAHL databases were not captured. This structural publication bias should be considered when interpreting the findings. Second, the exclusion criteria may limit the mapping breadth by underrepresenting NMDS adaptations in non–English-speaking and non–German-speaking countries or highly specialized settings. This potential exclusion could introduce publication bias and limit the capture of ongoing or context-specific innovations. Third, as is typical for scoping reviews, no formal quality appraisal of included studies was conducted, which may have affected the weight assigned to individual findings. Fourth, the heterogeneity of study designs, settings, and health care systems complicates a direct comparison and synthesis of findings. To conclude, while this review identifies fundamental content and process elements, as well as prevalent barriers and success factors, it does not provide a meta-analytic estimate of the impact of the NMDS on patient or system outcomes.

Conclusions

This scoping review highlights the heterogeneity and evolving consensus on the structure, development, and implementation of the NMDS. Despite international variations, 4 core domains consistently emerged: patient demographics, medical care information, nursing care elements, and institutional or organizational data. The NMDS can enhance the visibility, quality, and effectiveness of nursing care across health care systems, provided that challenges related to standardization, interoperability, and acceptance are addressed.

To translate these findings into practice, policymakers and health care managers should prioritize the standardization of nursing documentation through appropriate legal frameworks, investment in digital infrastructure, and targeted educational initiatives for nursing staff. Practical steps include establishing interoperable digital nursing records; providing structured training on NMDS use; and implementing pilot programs to assess the feasibility, usability, and data utility. Researchers are encouraged to evaluate the NMDS across diverse settings, conduct comparative effectiveness studies, and explore strategies to reduce documentation burden while maximizing actionable insights for care management, resource planning, and policy decisions. Overall, the review underscores that advancing the NMDS requires interdisciplinary collaboration, context-sensitive implementation, and ongoing evaluation to ensure that standardized nursing data meaningfully inform clinical practice and health system planning.

Funding

This research was funded by the Federal Ministry of Research, Technology, and Space (grant 01ZZ2401A). The study has been funded for a 5-year period, starting in November 2024. The study was funded for €4,559,301.88 (US $5,369,253.83). The funder had no involvement in the study design, data collection, analysis, interpretation, or the writing of the manuscript. The authors acknowledge the financial support of the Open Access Publication Fund of the Martin-Luther University Halle-Wittenberg.

Abstract

Background: Technology has improved patient care in hospitals, enhancing the overall patient experience. However, digitalization raises questions on effectively integrating technological strategies to ensure assertive communication of information during emergency department (ED) journeys. Keeping patients well-informed boosts their service perception and satisfaction, a factor often neglected by institutions in EDs.

Objective: This paper analyzes relevant studies on technological strategies designed for EDs aimed at improving patient experience, focusing on communication and information access. We analyze the technologies, outcomes, impacts, and challenges of the strategies.

Methods: A scoping review was conducted using the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) guidelines and CADIMA tool. Searches were performed in Scopus, PubMed, IEEE Xplore, and CINAHL databases. Articles published from January 2018 to December 2024 were included. Quality appraisal was performed using the Crowe Critical Appraisal Tool version 1.4. Three reviewers independently examined the title and abstract for eligibility based on the inclusion and exclusion criteria.

Results: Sixteen eligible studies were included. Four technological strategy categories were identified: artificial intelligence−based, simulation-based, infrastructure and hardware technologies, and interfaces and information systems. Mobile and web applications were the main technologies adopted in the studies.

Conclusions: Technological strategies hold significant potential to enhance patient experiences in EDs by providing real-time updates on medical status and care progress. However, their effectiveness depends on usability, literacy, and system design. Existing literature highlights the impact and challenges of deploying and using these strategies in EDs. However, no studies have systematically evaluated long-term outcomes or cost-effectiveness across diverse ED settings.

(JMIR Med Inform 2026;14:e79782) doi:10.2196/79782

KEYWORDS

scoping review; PRISMA-ScR framework; emergency department; patient journey; communication technology; patient experience

Introduction

The emergency department (ED) constitutes the gateway to health care for many people, being the place where treatment begins for a wide spectrum of diseases, some of which are life-threatening and require immediate attention [1]. The typical patient journey in the ED involves triage classification, medical evaluation, necessary examinations, medications, or procedures, reevaluation, and finally discharge or observation [2]. However, challenges such as overcrowding, uncomfortable facilities, and poor communication continue to hinder timely and efficient ED patient care, negatively impacting both patient experience and institutional performance [3]. In fact, effective and assertive communication of information about the ED patient journey has been found to be associated with patient satisfaction; thus, studies indicated that the lack of information on the progress and delays has a greater effect on patient satisfaction than perceived waiting times while visiting the ED [4]. In addition, it leads to feelings of powerlessness for patients and their family members [5]. Patients who feel well informed tend to have a better perception of the service [6], leading to higher satisfaction with the care and reduced anxiety [7], which in turn contributes to greater institutional efficiency [8].

XSL•FO
RenderX

With recent technological innovations, the potential to address communication challenges in EDs has increased significantly. Technologies that enhance communication and improve information accessibility have shown promise in improving the patient experience in the ED [9]. However, due to the rapid pace of technological advancement and the growing use of digital solutions in health care, there is an urgent need to review existing evidence to guide future implementation efforts.

This scoping review aims to analyze relevant studies and describe the evidence on technological strategies implemented in EDs worldwide that enhance patients' experiences during their journey in the ED. A technological strategy refers to the approach and implementation of technologies and supporting infrastructure within ED workflows to improve patient experience throughout their journey. Regarding the ED patient experience, the review focuses on two dimensions: communication and access to information. Communication refers to the exchange of timely, accurate, and comprehensible information between health care providers and patients or family members regarding medical status and progress updates during the ED visit. Access to information refers to patients' ability to obtain and understand relevant details about their journey in the ED. The following research questions (RQ) were addressed:

- What technological strategies exist to improve patient experience in EDs, considering dimensions such as communication and information accessibility?
- What infrastructure and technologies support technological strategies?

The scoping review offers a comprehensive and interdisciplinary perspective, integrating insights from clinical, technological, and human-centered design domains. The primary innovation of this study lies in its integrative and multidimensional approach to evaluating technological interventions in EDs, specifically through the lens of patient communication and information accessibility—dimensions often underrepresented in prior reviews. Unlike earlier works that focus predominantly on clinical outcomes or operational efficiency, this review foregrounds the patient experience and satisfaction as central evaluative criteria. It also identifies a critical knowledge gap: the lack of standardized frameworks for evaluating the long-term effectiveness, cost-efficiency, and scalability of these technologies across diverse health care settings. Additionally, the review highlights the insufficient attention given to the adaptability of these tools for vulnerable populations, such as those with low digital literacy or disabilities, and the need for participatory design approaches to ensure equitable and sustainable implementation.

Methods

Databases and Search Keywords

To analyze the current and future landscape of technological strategies in EDs, a scoping review was conducted following the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) guidelines [10]. Studies were retrieved from Scopus, PubMed, IEEE Xplore, and CINAHL in January 2025. The inclusion of CINAHL and PubMed ensures coverage of nursing and clinical perspectives that are highly relevant to patient care and workflow improvements, complementing the technical focus of IEEE Xplore and the multidisciplinary scope of Scopus. The keywords used in the search queries included technology, strategy, ED, communication, and access to information. The complete search strategy was as follows: ("Technolog*") AND ("Strateg*" OR "Approach*" OR "Solution*" OR "Framework*" OR "System*" OR "Model*") AND ("Emergency Department*" OR "Emergency Service, Hospital" OR "Emergency Room*" OR "Emergency Medical Service*") AND ("Communication" OR "Access to Information"). The final database search queries for the period January 2018 to December 2024 are summarized in Multimedia Appendix 1.

Inclusion and Exclusion Criteria

To ensure the quality of the articles, only those that met the inclusion and exclusion criteria presented in Textbox 1 were considered in the review process. These criteria were chosen to focus on studies that specifically examine technological strategies designed for EDs and their impact on patient experience, particularly in the dimensions of communication and information accessibility. Three reviewers independently applied the criteria to refine the list of eligible articles. In cases of uncertainty, the decision was made collectively after discussion.

XSL•FO
RenderX

Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria

- Documents published between 2018 and 2024 (including both years)
- Documents published in peer-reviewed journals or conference proceedings
- Full-text articles available in English
- The research setting is at least a hospital or an emergency department (ED), regardless of the age or sex of the patients who have used the ED
- Technological strategies specifically designed for EDs aimed at improving the patient's experience during their ED journey, focusing on communication and access to information
- Studies reporting on at least one patient-centered outcome (satisfaction, experience, or well-being)

Exclusion criteria

- Technological strategies outside the health care sector or those presented as telemedicine, remote medicine, or prehospital solutions
- Patients who have not used hospital or ED services
- Articles that do not present a descriptive evaluation, case study, or empirical evidence regarding the design, implementation, or impact of technological interventions on patient experiences in EDs
- Protocol-only studies or incomplete data reports

Study Selection

A 3-step filtering process was implemented to refine the selection of studies relevant to our RQ:

- In the first filter, *identification*, duplicates were removed. This process ensured the uniqueness of each record for accuracy and to avoid redundancy.
- The second filter involved *screening* by title and abstract, which significantly narrowed down the selection, based on our inclusion and exclusion criteria. This step focuses on identifying papers that are most relevant to ED's technological advancements.
- The third filter involved a full-text review to assess the *eligibility* of studies that addressed our RQ, culminating in the final selection of studies included in the review.

CADIMA was used for both the first and second filtering stages. CADIMA is an open-access online tool developed by the Julius Kühn-Institut during the EU-funded Global Response Against Child Exploitation project to support the conduct of systematic reviews [11].

Data Charting

The data charting process for the studies included in this review was structured into three rigorous rounds to explore the categories of technological strategies in EDs comprehensively. In the first round, we extracted fundamental attributes from each study, such as the authors, publication year, journal, and keywords. This process allowed us to understand the distribution of research over time and identify key categories within the field. A standardized data charting form was jointly developed in Microsoft Excel by three reviewers and piloted on a subset of studies to ensure consistency and clarity before full data extraction.

In the second round, we delved deeper into technological strategies applied in the studies. The charting form included variables such as the affected dimension (communication or access to information), technology and infrastructure used, impact on patient experience, measurement tools for usability or satisfaction, preferred information by patients, implementation details (approach, settings, challenges), and implementation outcomes.

Finally, in the third round, each paper was independently reviewed by three reviewers to ensure consistency and reduce bias in the analytical process. Any discrepancies were discussed and resolved by consensus. The charting process was iterative, and adjustments were made to the Excel form when new variables or categories emerged.

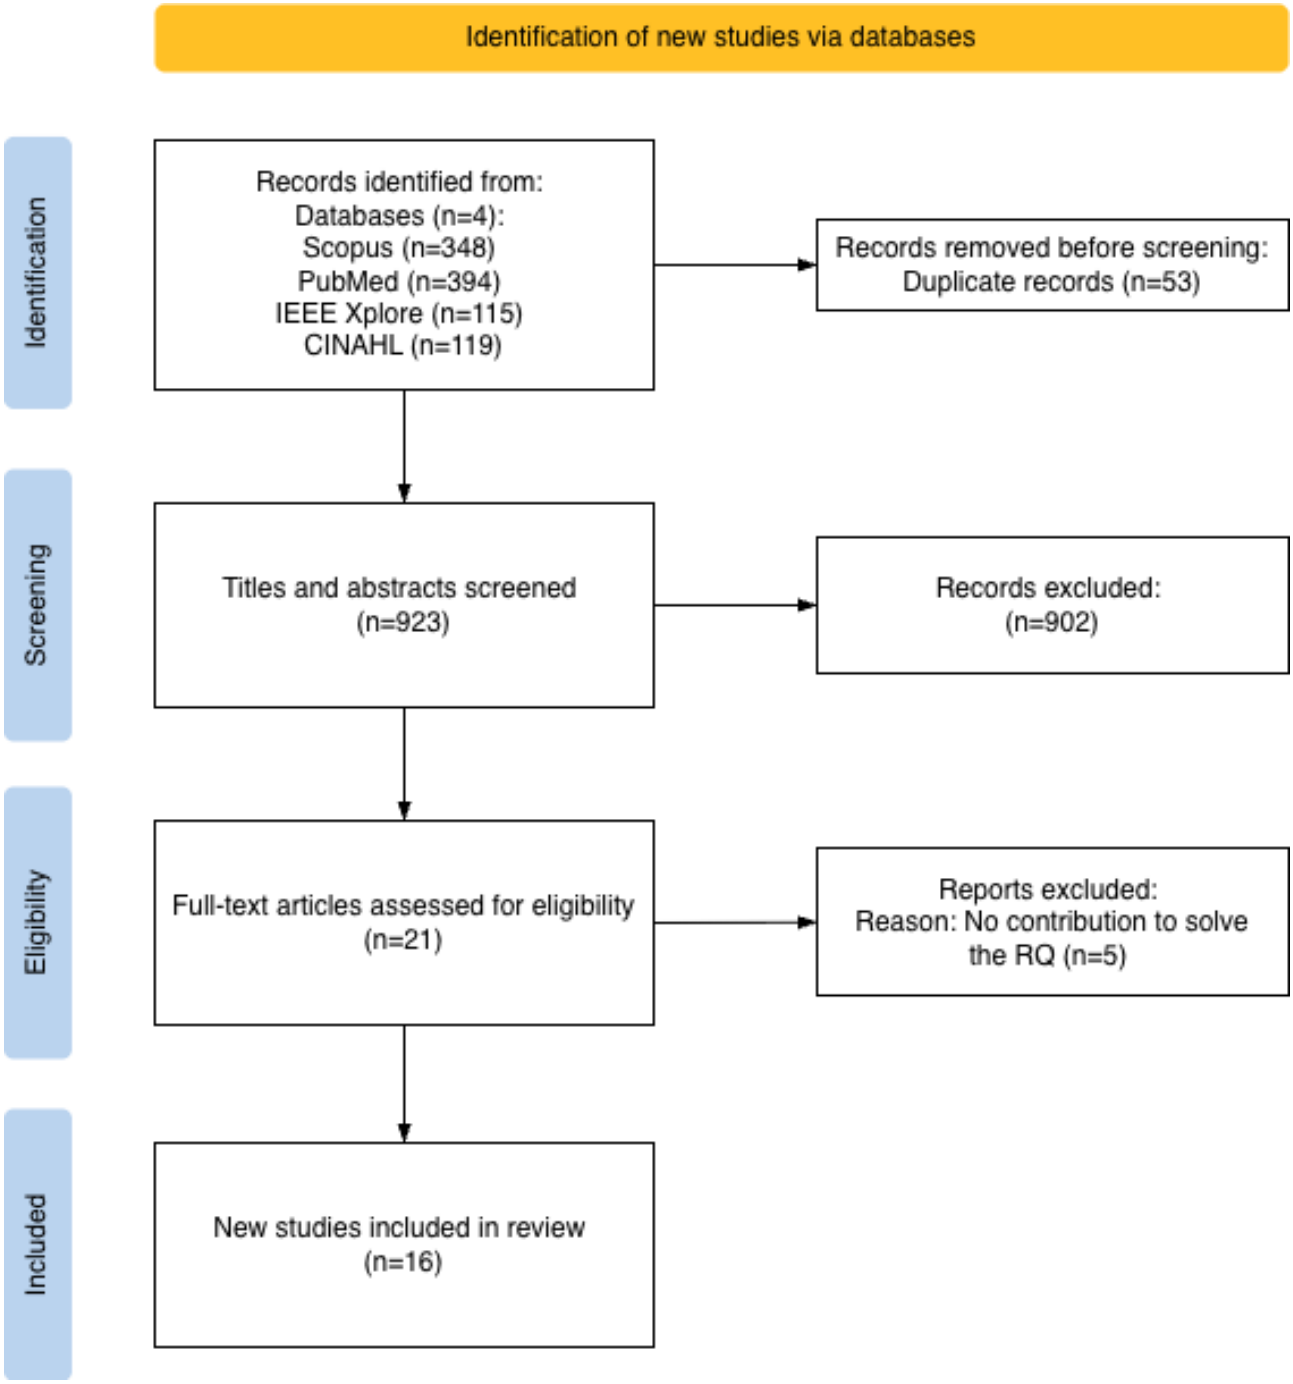
Quality Appraisal

Each selected paper underwent a quality appraisal conducted independently by two reviewers using the Crowe Critical Appraisal Tool version 1.4 (CCAT) [12]. This step was undertaken to assess the methodological rigor and credibility of the included evidence, supporting a more reliable interpretation of the findings in relation to our research questions. The CCAT is a widely used instrument recognized for its high reliability in evaluating research papers [13]. This instrument is organized into 8 categories comprising 22 items. Each category is scored on a 6-point scale ranging from 0 (lowest) to 5 (highest). The overall score is calculated as a percentage, and we arbitrarily considered acceptable a score above 60%. Prior to the appraisal, both reviewers were familiarized with the CCAT manual to ensure consistent interpretation of criteria. In cases of discrepancies between the reviewers' assessments, consensus was reached through discussion of the arguments and evidence.

Synthesis of Results

We grouped the studies by technological strategy category and summarized their associated challenges, as well as related patient experience outcomes and impacts. The strategy categories were defined using a content-based grouping approach: we reviewed all included studies, examined the technologies and their stated purposes, and clustered similar technologies based on their primary function and orientation toward improving ED patient

XSL•FO
RenderX



experience. The synthesis mapped the relationship between each strategy and its impact on communication and access to information, highlighting key outcomes, impacts, and challenges. Technologies and IT infrastructures were tabulated by strategy category, while patients' preferred information and satisfaction improvements were synthesized narratively.

Results

Flow Diagram and Number of Studies

The scoping review process is detailed in the flow diagram shown in Figure 1, presenting the stepwise filtering and the number of studies included at each step. In the *identification* step, 976 papers were identified and selected. Papers were imported into the CADIMA, where duplicates were removed, resulting in 923 papers. These papers were *screened*, applying the defined inclusion and exclusion criteria, where 21 papers were classified as eligible. Finally, after *full-text* reading, 16 papers were selected for further analysis; 5 articles did not contribute to the RQ.

Figure 1. Flow diagram of the scoping review process. RQ: research question.

General Description and Characteristics of Studies

The set of 16 studies, published between 2018 and 2024 in journals such as *Journal of Medical Internet Research* and *Applied Clinical Informatics*, examines a range of technological strategies designed to improve patient experience in EDs. These studies address key aspects, including the design and implementation of solutions, the technological and infrastructural components that support them, patients' preferences for information delivery, system usability, and the assessment of their impact on patient satisfaction and overall experience. Methodologically, the articles include qualitative evaluations, observational pilot studies, and mixed methods research, reflecting a diversity of approaches (see Multimedia Appendix 2).

The reviewed literature reveals an interdisciplinary orientation, with collaborations among computer scientists, clinicians, designers, and data analysts. Notably, studies originate from diverse regions, including the United States [14-19], the United Kingdom [20], Italy [21], Israel [22,23], Denmark [5], Australia [24], Thailand [25], Malaysia [26], South Korea [27], and Greece [28]. Finally, the quality appraisal of the 16 studies revealed that 87.5% (n=14) were of high quality and 12.5% (n=2) of medium quality (see Multimedia Appendix 2).

Key Findings on Technological Strategies

Technological Strategies

Based on revised studies and following the process described in the Synthesis of Results subsection, we categorized the technological strategies that help to enhance patient journey experiences in EDs into four primary categories, as outlined below.

1. Interfaces and information systems: This category encompasses tools and information systems designed to provide access to comprehensive patient medical information and ED stage updates, enhancing patients' understanding of their journeys through the ED and facilitating communication with medical staff.
2. Infrastructure and hardware technologies: This category includes strategies focused on the underlying IT infrastructure necessary for ED operations. It encompasses advanced computing systems, integration devices, and hardware that are critical for patient care and tracking.
3. Artificial intelligence (AI)–based strategy: This category includes strategies that utilize machine learning (ML) and deep learning models for predictive analytics and pattern recognition in EDs.
4. Simulation-based strategy: This category encompasses simulation strategies, which are essential for evaluating the performance of health care operations, analyzing patient flow, and modeling complex interactions within ED settings.

Figure 2 illustrates the distribution of these strategy categories by dimension within the reviewed literature. Interfaces and information systems strategies were the most frequently cited, appearing in 14 studies, followed by infrastructure and hardware technologies and AI-based strategies, each appearing in 3 studies, and the simulation-based category, appearing in 2 studies. All categories addressed both dimensions, except the simulation-based category. These findings indicate a clear preference for integrated solutions and reveal a gap in studies dedicated exclusively to communication strategies.

XSL•FO
RenderX

Figure 2. Distribution of articles by technological strategy category and dimension focus.

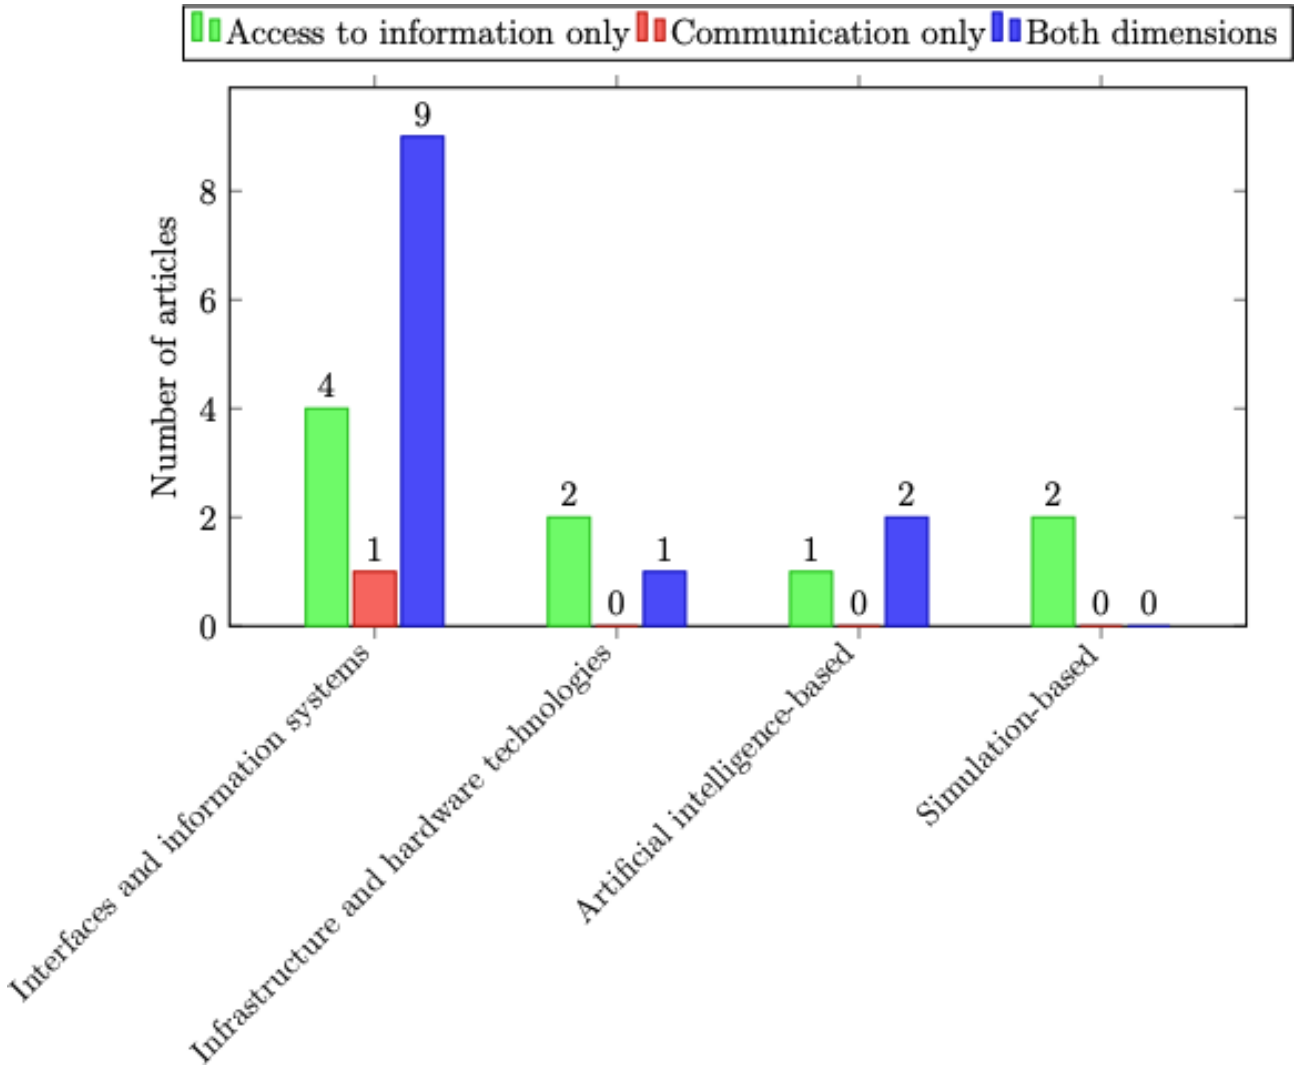

Table 1 provides a comprehensive overview of the key technological strategies implemented in EDs to enhance patient experience. For each strategy, the table details the specific dimension(s) addressed (communication and access to information), the implementation approach used and the target population (patients, family members, or health care staff), the measurement methods used to assess outcomes, the observed outcomes and their impact on patient experience and satisfaction, and the implementation challenges encountered. The results reveal a strong emphasis on systems that integrate both communication and access to information, particularly through interfaces and information systems such as digital whiteboards [16], clinical logic platforms [5], and discharge tools [17,24]. These solutions consistently aim to enhance patient and family engagement, improve satisfaction, and streamline information flow during care transitions [22].

Jaafar et al [26]	Comm and ATI	I&H[i]	• Patient Tracking System (TrackMe): Mobile app with wireless wristbands for real-time updates on patient location • Target population: staff, family	Satisfaction surveys (Likert)	Enhanced family engagement; decreased anxiety through real-time updates about patient status and location; high user satisfaction (mean >4.0)	Resistance to adoption among staff; training needs; connectivity and infrastructure requirements

[a]Comm: communication.

[b]ATI: access to information.

[c]Int & IS: interfaces and information systems.

[d]ED: emergency department.

[e]EHR: electronic health record.

[f]SUS: System Usability Scale.

[g]PETS: Parent Engagement Through Technology Solutions.

[h]REDCap: Research Electronic Data Capture.

[i]I&H: infrastructure and hardware.

Common measurement methods include satisfaction surveys, usability scales, and structured interviews, reflecting a focus on patient-centered evaluation (see the *Measuring Usability, Patient Experience, and Satisfaction Improvement* subsection for more information). Reported outcomes and impact generally include improved understanding of care processes [22], reduced anxiety [5,26], and better communication with health care professionals [5], although challenges persist, such as technical limitations [17], integration with existing systems [16], and resistance to adoption [26]. Notably, infrastructure-based tools such as patient tracking systems [26] complement these efforts by supporting real-time updates, but they face barriers related to cost and implementation complexity. Overall, the evidence suggests a trend toward multidimensional strategies that prioritize transparency and communication while highlighting gaps in scalability and interoperability. In addition, the literature provides limited discussion on how these strategies can adapt to dynamic changes in ED protocols [22], ensure equity among diverse patient populations—including individuals with disabilities or lower digital literacy [5,18,24]—and effectively support digitally underserved or vulnerable groups [16,17].

Technologies and IT Infrastructures

Table 2 provides an overview of the main technologies and IT infrastructures used in ED settings, grouped by strategy category.

XSL•FO
RenderX

Table . Overview of technologies and IT infrastructures used in EDs, grouped by strategy category.

Strategy category and technology/infrastructure	Description and outcome	References
Interfaces and information systems		
Mobile app	Provides a patient-friendly health information and communication interface through a smartphone app, designed to deliver real-time and comprehensive medical data—such as health status, triage classification, vital signs, discharge instructions, and location within the ED[a] journey—while also enabling communication with patients' next of kin and supporting guidance for effective illness management, thereby improving health care services and enhancing patient satisfaction.	[17,20,26-28]
Web dashboard	Delivers a user-friendly, graphical web interface that provides real-time updates on patients' medical status—including triage classification, clinical conditions, and vital signs—along with their ED treatment progression, open clinical note access, care pathways, and discharge instructions. This interface enhances transparency and patient engagement during the ED stay.	[5,14,18,19,22-25,28]
Digital whiteboard	Provides an electronic paper interface via a digital whiteboard that communicates relevant real-time clinical information to ED patients, including status updates, orientation details, care team assignments, safety alerts, patient orders, and disposition information. This interface enhances patient understanding of their journey through the ED.	[16]
Patient-centered information system	Provides an information system accessible across various devices and interfaces (web and desktop applications), designed to deliver real-time updates and detailed information—including procedures, treatments, associated waiting times, nurse and physician responsible for care, and current and upcoming stages—directly to patients and their family members. This enhances patients' understanding of their individual journeys through the ED and supports informed decision-making and communication.	[5,22]
Infrastructure and hardware technologies		
Internet of Medical Things	Includes IoT[b] devices (eg, wearables) for real-time monitoring of ED patients, providing vital insights into their health status, vital signs, patient stratification for special services, and physical location within the ED. This information supports clinical decision-making and enhances communication by delivering timely and essential updates to both medical staff and patients' families about the health care process.	[26-28]
Computing infrastructure	Covers advanced computing infrastructures, such as cloud computing, that support real-time data storage, processing, and analysis in EDs.	[26,28]
Artificial intelligence–based		
ML[c] algorithms	Encompasses ML algorithms like random forest for predictive analytics in EDs, providing insights into patient treatment, stratification, and predicting waiting times based on workload and patient characteristics.	[14,15,22]
Simulation-based		

XSL•FO
RenderX

Strategy category and technology/infrastructure	Description and outcome	References
Discrete-event simulation	Provides a simulation-based model in R to estimate individual treatment times from aggregated ED data, aiming to assess delays, improve waiting time estimates, and enhance understanding of patient flow.	[21]
Petri net model	Comprises a simulation-based model in Python using Colored Petri Nets to model and analyze ED processes and workflows, supporting improvements in patient flow across treatment paths and enhancing decision-making efficiency.	[15]

[a]ED: emergency department.

[b]IoT: Internet of Things.

[c]ML: machine learning.

Interfaces and information systems emerge as the most significant strategy category for directly improving patient experience through enhanced communication and transparency (14 studies). Within this category, *mobile* and *web dashboard applications* are the most widely adopted technologies (5 and 9 studies, respectively). For example, the Parent Engagement Through Technology Solutions (PETS) [24] and MyEDCare [17] mobile apps support patients and caregivers during discharge by improving comprehension and reinforcing key information about the ED journey. Complementing these mobile tools, the MyED system [22] and the Cetrea Clinical Logistics (CCL) dashboard for patients [5] were designed as web dashboard applications to enhance patients' understanding of their care trajectory by displaying completed, ongoing, and anticipated procedures, as well as identifying the clinicians responsible for their care. Additionally, digital whiteboards, leveraging E-paper technology, deliver real-time notifications on delays and post-discharge instructions, functioning as integral components of the IT infrastructure [16].

Building on these interface-focused solutions, *infrastructure and hardware technologies* provide the foundation for real-time monitoring and data exchange. This category integrates *Internet of Medical Things* (*IoMT*) components with robust *computing infrastructure*. IoMT technologies enable real-time sensing and location tracking through dedicated hardware: beacon devices worn as patient bracelets and beacon readers (gateways) enable continuous wireless monitoring of patient location and status [26]; wearable biosensors capture physiological signals such as heart rate and oxygen saturation, supported by real-time location devices, Wi-Fi hotspots, and Bluetooth-to–Wi-Fi gateways for data transmission [28]; and near-field communication (NFC) tags paired with mobile electronic medical record (EMR) devices (eg, smartphones) allow location-based access to patient information [27]. Computing infrastructure complements these technologies by offering backend systems for secure data storage, processing, and decision support, including cloud-based databases and local servers operating within private networks [26,28]. Examples of strategies include TrackMe [26], which combines beacon-enabled bracelets with a mobile app and a 3-tier architecture for real-time updates; the NFC-integrated Mobile EMR System [27], which accelerates access to patient records; and IntelTriage [28], which uses wearable biosensors and LAN-based communication to monitor vital signs and geo-location, supported by a decision-support subsystem for dynamic prioritization.

Building on these physical infrastructures, *AI-based* strategies leverage computational techniques to enhance decision-making and operational efficiency. Predictive models such as *machine learning algorithms* [14,15] and random forest [22] approaches analyze EMR data—including length of stay, procedures, and clinical notes—to generate actionable insights. For example, the AI-enabled non-English language preference prioritization strategy [14] computes complexity scores for patients with a non-English language preference, while the AI/ML model presented in Gehlot et al [15] provides deeper insights into treatment details and patient experiences, thereby supporting more accurate patient routing based on acuity. Similarly, the MyED strategy [22] combines random forest models with operations research techniques, such as process discovery and queue mining, to predict waiting times for specific procedures and deliver real-time updates to patients through a responsive mobile interface.

Finally, *simulation-based* approaches complement predictive analytics by modeling complex ED workflows to optimize patient flow. Techniques such as *discrete-event simulation* and *Petri Net models* are used to estimate waiting times, identify bottlenecks, and validate algorithms for time-to-treatment predictions. These models support more reliable and equitable resource allocation. Reported strategies use these models to simulate care pathways and assess workflow constraints, enabling validation of predictive algorithms for waiting time and treatment prioritization [21]. A notable example is presented in Gehlot et al [15], where a Colored Petri Net–based simulation is integrated with Python-based AI/ML components to evaluate and refine triage processes, aiming to improve clinical outcomes and enhance patient experience.

Further details on usability, patient experience, and satisfaction impacts are provided in Table 1 and discussed in the subsection *Measuring Usability, Patient Experience, and Satisfaction Improvement*.

Patient's Preferred Information

The selected studies displayed a wide variety of topics that patients preferred on their journey through the ED. Specifically, patients preferred detailed information on their medical status

XSL•FO
RenderX

and progress updates [18,26], including triage status [15,28], treatment, and discharge instructions [17,19,24]. Additionally, patients valued comprehensive medical information related to their vital signs [18,25,28], laboratory results [27] and medical orders [16,18], nursing care plans [15,25,28], and the nurse and physician responsible for care [5,16]. Patients also appreciated personalized medical information and updates on procedures, associated waiting times [5,21], as well as current and upcoming stages of their ED stay [16,22]. They also favored precise tracking of their location in the ED [26,27], safety, and disposition information [16]. These preferences highlight a significant trend toward personalized health care information, underscoring the need for technological strategies to focus on delivering precise, individualized health data and highlighting the importance of accuracy and clarity in the patient communication tools of the ED.

Measuring Usability, Patient Experience, and Satisfaction Improvement

Usability evaluations are essential in health care technology to identify design flaws early and prevent ineffective implementations [24]. Among reviewed studies, the System Usability Scale (SUS) was the most frequently used instrument [5,18,24,27]. SUS is a 10-item Likert questionnaire that generates a score from 0 to 100, interpreted using a grading scheme (eg, >90: "A" [excellent]; <60: "F" [poor]). To illustrate, the PETS mobile discharge tool scored 94/100 (A grade—Excellent), indicating superior design and strong patient acceptance [24]. Similarly, the CCL patient information system achieved near-excellent usability with a mean SUS score of 83.6/100 (B+ grade—Acceptable) [5]. In contrast, NFC-integrated mobile EMR and REDCap eConsent interfaces scored 71.9/100 and 78/100 (B grade—acceptable), reflecting moderate usability and less direct impact on patient experience [24,27]. The electronic health record display for ED patient health status and care plan progress received a mean SUS score of 69.6 out of 100 (C grade—marginally acceptable) [18], suggesting limited effectiveness in improving patient experience.

While SUS provides a standardized measure, complementary approaches are often necessary to capture user perceptions more comprehensively. Likert-scale satisfaction surveys (typically 5- or 10-point) are commonly used to assess design quality, content relevance, and overall user-friendliness [16,25,26]. For example, the web application for emergency trauma patients, using a 10-point Likert scale, reported a mean usability score of 4.09 (SD 0.74) [25]. Similarly, the TrackMe patient-tracking system, using a 5-point Likert scale, reported a mean usability score of 4.0 (SD 1.2) and a mean satisfaction score of 4.4 (SD 1.0), indicating a generally positive user experience during ED waiting periods [26]. These findings reinforce that usability and satisfaction are interrelated but distinct constructs, underscoring the need for multidimensional assessment.

Patient experience and satisfaction are closely linked to usability, which strongly influences technology acceptance in clinical settings. In ED environments, these areas are typically assessed using mixed methods that combine SUS scores, Likert-scale measures, and validated instruments such as Hospital Consumer Assessment of Health Care Providers and Systems (CAHPS) and ED-CAHPS [16,17], complemented by semistructured interviews for contextual insights into patient perceptions [5,22,24]. For example, semistructured interviews in the MyED study showed that patients who used the solution demonstrated significantly better understanding of their ED journey compared with nonusers ($F_{8,299}$=2.519; P=.01) [22]. Using satisfaction surveys, the digital whiteboards intervention improved patient-reported communication about delays (1.96 vs 2.48; P=.03) and clarity of post-discharge instructions (2.41 vs 2.83; P=.02), and users were more likely to recommend the facility (9.66 vs 9.22; P=.05) [16]. Operational benefits were also reported in the MyEDCare study: patients receiving digital discharge instructions had significantly fewer unscheduled ED returns at 72 hours and 30 days compared with those receiving standard paper-based discharge (P=.003 and P<.001) and higher ED-CAHPS scores in nursing communication domains (eg, "Nurses explain in a way you understand": 86.5 vs 81.9; P=.03) [17].

Collectively, these findings underscore that usability is not merely a design metric but a critical driver of patient experience, satisfaction, and even clinical outcomes in ED technology implementations. In addition, the evidence shows that *Interfaces and Information Systems*—particularly *mobile and web applications*—provide the greatest added value for improving patient experience, primarily by enhancing communication, transparency, and comprehension.

Discussion

Principal Findings

The integration of advanced digital technologies in EDs represents a rapidly evolving but still unstructured field. Among the 16 studies included in this review, 9 reported interventions that achieved measurable improvements in communication, patient satisfaction, or reductions in service fragmentation [5,16-18,22,24-27]. Despite the promising results (see subsection *Measuring Usability, Patient Experience, and Satisfaction Improvement*), the absence of standardized frameworks, definitions, and evaluation models limits comparability and scalability across settings [29]. Developing a shared conceptual and operational framework is essential to ensure consistency in research and guide technology implementation within ED systems.

Patient-facing technologies such as mobile apps, real-time dashboards, and web-based platforms have enabled patients to access individualized health information, often in real time, enhancing their sense of involvement in emergency care [22]. Some tools demonstrated significant benefits—for example, MyEDCare improved patient comprehension and experience (86.5 vs 81.9; P=.03) [17], and digital whiteboards reduced perceived uncertainty (2.41 vs 2.83; P=.02) [16]. However, implementation challenges were common. The MyED system faced difficulties synchronizing live data from hospital databases, and short ED visits limited patient engagement [22]. Usability issues were also reported among older adults, who requested simplified functions [5]. These findings underscore the need for participatory design approaches that incorporate patient perspectives prior to implementation [30]. Ultimately,

XSL•FO
RenderX

usability remains a critical determinant of successful adoption and effective use [31].

Technological impact extends beyond patient interaction to clinical workflows. Real-time data systems and mobile-based discharge tools require adjustments in routines, new training protocols, and additional coordination. While these tools can enhance communication and data accuracy, they often introduce extra responsibilities, increasing cognitive and operational burden on health care professionals [24]. This tension—between intended benefits such as efficiency and the reality of added workload—has been documented in multiple studies [32,33]. Understanding nursing staff perceptions and acceptance is therefore essential for successful adoption [34]. Policymakers and ED managers must consider these trade-offs when planning technological strategies to avoid overburdening staff while pursuing efficiency goals [16].

Additionally, the integration of wearable devices (eg, TrackMe, IntelTriage) and patient-facing platforms (eg, CCL, MyED) is reshaping care dynamics by fostering patient autonomy [5] and involvement in decision-making [20,23]. Although these innovations hold promise for improved outcomes and satisfaction [16,17,23], they raise concerns regarding workflow implications (eg, TrackMe increased nurses' workload [26]; fears of delays with MyED [22]), digital literacy barriers (eg, limited access to Open Notes among non-English speakers [23]; usability issues for older users of CCL [5]), and communication norms (eg, risks of patients viewing information before staff [22]; potential reduction in nurse/physician time) [5]). These factors must be addressed to ensure equitable and safe implementation.

Finally, the economic cost required for the investment, implementation, and maintenance of advanced technologies in EDs must be carefully considered. These expenses may include infrastructure upgrades, software development, technical support, and training for health care personnel [19]. Given the potential financial implications, future studies should explore the cost-benefit relationship of these technological strategies, assessing their feasibility, sustainability, and overall value in diverse health care settings [17].

Strengths and Limitations

A key strength of this study is its multidimensional approach, which provides a holistic view by examining various facets of ED care, including communication and information accessibility. This comprehensive perspective was achieved by focusing on emerging technologies, such as AI and IoT, which represent the forefront of operational efficiency and diagnostic accuracy in EDs. The recent literature (2018 - 2024) grounds the study's findings in current technological trends, ensuring relevance. However, limitations include a focus on English articles, which may have excluded relevant studies in other languages, potentially restricting generalization. Furthermore, since many technologies analyzed are relatively new (eg, IoMT, AI), few studies directly address their long-term impacts. Variability in environments where these technologies are implemented can also affect reproducibility, especially in resource-limited settings. The recent temporal range may not capture emerging trends or long-term effects, highlighting the need for ongoing research to understand their sustained impact.

Conclusions

This scoping review synthesized current technological strategies designed to enhance patient experiences in EDs, primarily through improved communication and access to information. The limited number of studies identified (n=16, published between 2018 and 2024) underscores the nascent and fragmented nature of this research area. Existing evidence suggests that patient-facing tools—such as mobile apps, real-time dashboards, and web-based platforms—can improve information transparency and engagement, while clinical workflow solutions, including digital whiteboards and mobile discharge systems, support communication accuracy and care coordination. Emerging innovations like IoT-wearable monitoring devices further demonstrate potential for promoting patient autonomy and continuous observation. However, these benefits are tempered by persistent implementation challenges. Usability barriers among older adults, technical integration issues, and increased workload for health care professionals remain significant obstacles. Equity concerns related to digital literacy and language accessibility further complicate adoption, raising questions about inclusiveness and fairness in technology-driven care. Importantly, none of the reviewed studies conducted systematic evaluations of long-term outcomes or cost-effectiveness across diverse ED contexts, limiting the evidence base for sustainable integration. Future research should move beyond descriptive assessments toward rigorous, standardized evaluation frameworks that capture clinical, economic, and experiential outcomes. Participatory and inclusive design approaches are essential to address usability and equity gaps, while comprehensive cost-effectiveness analyses will inform scalability and resource allocation. Advancing this agenda is critical to ensure that technological innovations in EDs are not only effective but also equitable, sustainable, and adaptable across varied health care settings.

Acknowledgments

Abstract

Background: Large language models (LLMs), such as GPT-3.5 and GPT-4 (OpenAI), have been transforming virtual patient systems in medical education by providing scalable and cost-effective alternatives to standardized patients. However, systematic evaluations of their performance, particularly for multimorbidity scenarios involving multiple coexisting diseases, are still limited.

Objective: This systematic review aimed to evaluate LLM-based virtual patient systems for medical history-taking, addressing four research questions: (1) simulated patient types and disease scope, (2) performance-enhancing techniques, (3) experimental designs and evaluation metrics, and (4) dataset characteristics and availability.

Methods: Following PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020, 9 databases were searched (January 1, 2020, to August 18, 2025). Nontransformer LLMs and non–history-taking tasks were excluded. Multidimensional quality and bias assessments were conducted.

Results: A total of 39 studies were included, screened by one computer science researcher under supervision. LLM-based virtual patient systems mainly simulated internal medicine and mental health disorders, with many addressing distinct single disease types but few covering multimorbidity or rare conditions. Techniques like role-based prompts, few-shot learning, multiagent frameworks, knowledge graph (KG) integration (top-k accuracy 16.02%), and fine-tuning enhanced dialogue and diagnostic accuracy. Multimodal inputs (eg, speech and imaging) improved immersion and realism. Evaluations, typically involving 10-50 students and 3-10 experts, demonstrated strong performance (top-k accuracy: 0.45-0.98, hallucination rate: 0.31%–5%, System Usability Scale [SUS] ≥80). However, small samples, inconsistent metrics, and limited controls restricted generalizability. Common datasets such as MIMIC-III (Medical Information Mart for Intensive Care-III) exhibited intensive care unit (ICU) bias and lacked diversity, affecting reproducibility and external validity.

Conclusions: Included studies showed moderate risk of bias, inconsistent metrics, small cohorts, and limited dataset transparency. LLM-based virtual patient systems excel in simulating multiple disease types but lack multimorbidity patient representation. KGs improve top-k accuracy and support structured disease representation and reasoning. Future research should prioritize hybrid KG-chain-of-thought architectures integrated with open-source KGs (eg, UMLS [Unified Medical Language System] and SNOMED-CT [Systematized Nomenclature of Medicine - Clinical Terms]), parameter-efficient fine-tuning, dialogue compression, multimodal LLMs, standardized metrics, larger cohorts, and open-access multimodal datasets to further enhance realism, diagnostic accuracy, fairness, and educational utility.

KEYWORDS

large language model; virtual patient; medical education; history-taking; simulated patients

Introduction

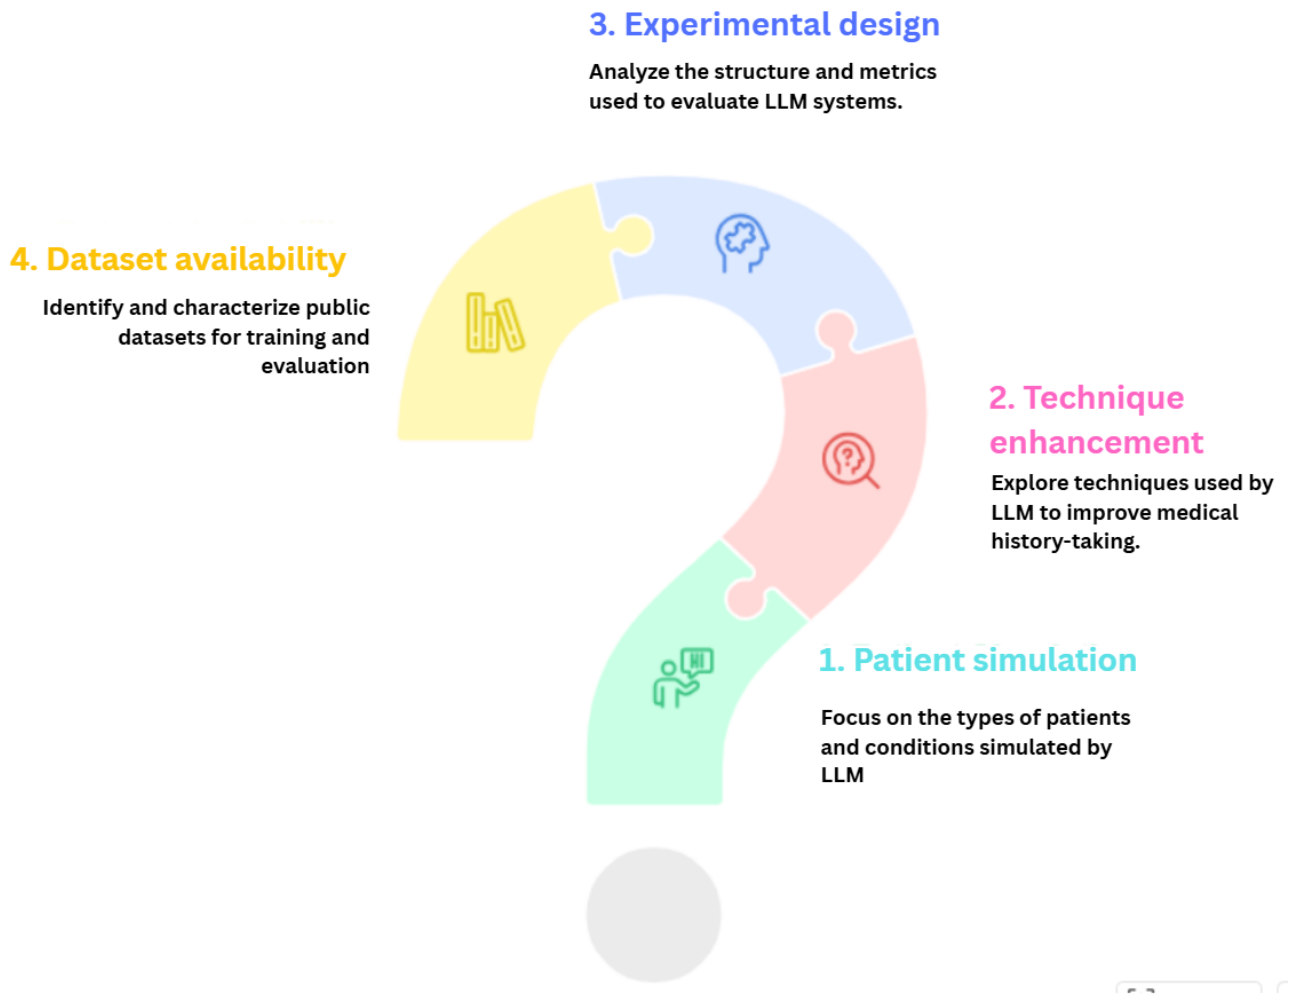
Since 2020, large language models (LLMs) such as GPT-3.5 (OpenAI) [1] and GPT-4 (OpenAI) [2] have significantly enhanced virtual patient systems in medical education. Unlike traditional methods relying on resource-intensive standardized patients or high-fidelity simulators [3], LLMs provide scalable, low-risk, and cost-effective solutions by simulating realistic patient interactions across a wide range of clinical scenarios, including internal medicine, mental health disorders, and surgical and orthopedic cases [4]. This capability addresses key challenges in medical education, such as limited exposure to diverse clinical cases and the high costs of traditional simulation approaches.

Early virtual patient systems, often based on models like BERT (Bidirectional Encoder Representations from Transformers), struggled to generate natural dialogues and adapt to complex clinical scenarios, limiting their effectiveness in medical training [5,6]. In contrast, modern LLMs, leveraging prompt-based techniques for role and scenario customization, demonstrate improved contextual understanding, enabling clinically relevant responses. However, these systems still face challenges with hallucination, defined as the generation of factually incorrect or contextually irrelevant content, which may compromise the accuracy of medical history-taking in virtual patient simulations [7,8].

To ensure effective clinical training, continuous improvement and validation of LLMs are essential to mitigate hallucination rate and ensure the reliability of generated information [7]. Recent studies have incorporated techniques such as Supervised Fine-Tuning (SFT) [9] and Retrieval-Augmented Generation (RAG) [10] to enhance contextual adaptability and diagnostic accuracy, as measured by metrics like top-k accuracy and GTPA@k. However, the specific disease types simulated by LLMs, such as such as neurological and rheumatological or rare multiple disease types and potential gaps in simulation capabilities remain underexplored partly due to variations in experimental design and datasets.

Despite progress, systematic comparative evaluations of these techniques in virtual patient systems are lacking. Existing literature reviews often broadly discuss LLMs in medical education without focusing on virtual patient history-taking, limiting insights into domain-specific challenges [11]. Thus, a systematic literature review is critical to consolidate fragmented research, identify challenges, and guide future work.

Previous systematic reviews have explored LLMs in medical education but lack specificity. For instance, Lucas et al [11] reviewed LLMs' implications for teaching effectiveness, ethics, and reliability but did not focus on virtual patient history-taking. García-Torres et al [12] used a hybrid human-LLM methodology to evaluate virtual patients' impact on clinical reasoning but provided limited technical details on prompt design, knowledge graph (KG) integration, or fine-tuning. Similarly, Fatima et al [13] conducted a cross-disciplinary review of ChatGPT in research, clinical practice, education, and patient interaction but did not systematically analyze virtual patient history-taking. Recent empirical studies on LLM-powered virtual patients with automated feedback have prioritized educational outcomes over methodological comparisons [8].



In contrast, this review specifically examines LLM-based virtual patient systems for clinical history-taking. It systematically analyzes prompt engineering, external knowledge integration, model fine-tuning, and evaluation strategies, synthesizing their implications for medical education and effective clinical training. By adopting this methodological focus, this work addresses gaps in prior reviews, which were either too broad or lacked technical depth.

Given this research gap, a systematic literature review is essential to consolidate fragmented research and guide future studies. This paper addresses four core research questions (RQs), as outlined in Figure 1:

- RQ1: what types of patients, conditions, or diseases, such as internal medicine or rare and multiple disease types, are simulated in LLM-based virtual patient systems?
- RQ2: what techniques do LLMs use to enhance medical history-taking capabilities in clinical interviews?
- RQ3: how are experimental designs structured to evaluate LLM-based virtual patient systems, and what evaluation metrics, such as top-k accuracy or System Usability Scale (SUS), are used?
- RQ4: what public datasets are available, and what are their characteristics for training, simulating, and evaluating medical history–taking in virtual patient systems?

XSL•FO
RenderX

Figure 1. Overview of 4 research questions on large language model–based virtual patient systems, covering simulation types, enhancement techniques, evaluation strategies, and datasets.

This systematic literature review addresses these questions to guide researchers in understanding the potential, limitations, and ethical challenges of LLMs in virtual patient systems. It is critical for advancing effective clinical training tools in medical education. The paper is structured as follows, the first section introduces the background of virtual patient systems and LLM applications; the second section describes the literature search methodology and evaluation criteria; the third section presents results, analyzing effectiveness and challenges; the fourth section discusses findings in the context of existing literature; and the fifth section concludes with key findings and recommendations for future research.

Methods

Overview

This study conducted a systematic literature review adhering to PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 guidelines. The research topic and target population were clearly defined, a comprehensive search strategy was formulated, and key search terms were identified. Search results were exported as CSV files via Mendeley (Mendeley Ltd) and Zotero (Corporation for Digital Scholarship) and manually screened. Abstracts were initially evaluated, followed by a comprehensive full-text assessment to confirm relevance and quality.

Eligibility Criteria

Population

The population includes medical students and physicians engaged in medical history–taking. Artificial intelligence (AI)–based virtual patients refer to LLM-based systems simulating patients for training in history-taking. Only transformer-based LLMs (eg, GPT series) are included, excluding older models like BERT (Google AI) or pre-Transformer architectures. Studies focusing on anesthesia, emergency procedures, or intraoperative scenarios are excluded, as these are nontraditional history-taking contexts. Preoperative history-taking for surgical and orthopedic patients is included. This ensures a focus on transformer-based LLMs for history-taking, emphasizing educational and clinical skill development while excluding irrelevant clinical settings. Only studies where LLMs serve as virtual patients for active history-taking and patient communication are included, excluding those focused solely on medical interviews without history-taking.

XSL•FO
RenderX

Intervention

The intervention involves transformer-based LLM technologies applied to medical history-taking, including prompt design, model fine-tuning, KG integration, and other LLM-related techniques. These aim to enhance diagnostic accuracy, interaction quality, and overall performance in virtual patient systems.

Outcomes

Outcomes include performance metrics such as top-k accuracy (eg, top-1 accuracy), empathy scores, readability, system stability (eg, response consistency), user experience (eg, SUS, Chatbot Usability Questionnaire [CUQ]), and other relevant indicators, such as κ (Cohen κ) and *P* value. These metrics evaluate the effectiveness of transformer-based LLM virtual patient systems in medical history–taking.

Inclusion and Exclusion Criteria

Inclusion and exclusion criteria were established to ensure relevance and quality, as shown in Textbox 1. Inclusion criteria prioritize studies with technical depth, validated outcomes, recent publication, and a focus on Transformer-based LLM virtual patients for history-taking, excluding nontransformer models.

Textbox 1. Inclusion and exclusion criteria for transformer-based large language model (LLM) virtual patient studies.

Inclusion criteria:

- IC1: the study population included medical students or physicians involved in medical history–taking or communication training.
- IC2: the intervention involved Transformer-based LLMs (eg, GPT series) used as virtual patients for history-taking or communication training in traditional consultation settings.
- IC3: the study was published between January 1, 2020, and August 18, 2025, including peer-reviewed articles and preprints.
- IC4: the study reported measurable outcomes related to diagnostic performance, communication effectiveness, empathy, readability, or user experience.
- IC5: preoperative history-taking scenarios (eg, surgical or orthopedic patients) were included if they involved conventional patient–clinician consultation processes.

Exclusion Criteria:

- EC1: based on earlier or nongenerative transformer models (eg, BERT [Bidirectional Encoder Representations from Transformers] and GPT-2) rather than modern LLMs.
- EC2: focused solely on medical interviews without explicit medical history–taking.
- EC3: published before January 2020.
- EC4: duplicate titles or redundant publications.
- EC5: review or commentary papers.
- EC6: non-English language studies.
- EC7: focused on anesthesia, emergency procedures, or intraoperative contexts (except preoperative consultations).

Information Sources

A systematic literature search was conducted across 9 authoritative databases PubMed, Scopus, Web of Science, IEEE Xplore, ACM Digital Library, SpringerLink, ERIC, arXiv, and ACL Anthology, covering studies published between January 2020 and August 18, 2025, in medicine, AI, education, and virtual technologies. A secondary search used a snowballing strategy, identifying additional sources from 15 initial articles and relevant publications, including theses from ProQuest. Including peer-reviewed articles and grey literature (eg, preprints from arXiv and theses) ensured comprehensive coverage of the rapidly evolving fields of AI and medical education.

Search Strategy

Two search strategies were used for this systematic review. The first query combined virtual patient terms (eg, virtual patient, simulated patient, AI patient, conversational patient, chatbot patient, intelligent virtual agent, and dialogue agent) with LLM-related keywords (eg, LLM, ChatGPT, GPT-4, GPT, transformer model, generative AI, AI-powered tutor, and natural language generation) and was applied to structured databases including PubMed, Scopus, Web of Science, IEEE Xplore, and ACM Digital Library. The second, simplified query included only virtual patient terms and was applied to broader repositories, namely SpringerLink, ERIC, arXiv, and ACL Anthology, to ensure comprehensive coverage, as strict LLM keywords reduced results in these databases (see Multimedia Appendix 1 for more details).

Selection Process and Data Collection

The literature screening and data collection process followed PRISMA 2020 guidelines [14] (checklist provided in Multimedia Appendix 2). Titles and abstracts were manually screened for relevance to LLM-based virtual patient history-taking, with GPT-3.5 Turbo used for auxiliary verification. Full-text evaluations were conducted for studies meeting preliminary inclusion criteria. A multidimensional quality assessment form recorded key study characteristics and outcomes, as detailed in Multimedia Appendices 3 and 4. The ChatPDF tool was used to cross-check content, and final inclusion decisions were made with the supervising researcher's input.

XSL•FO
RenderX

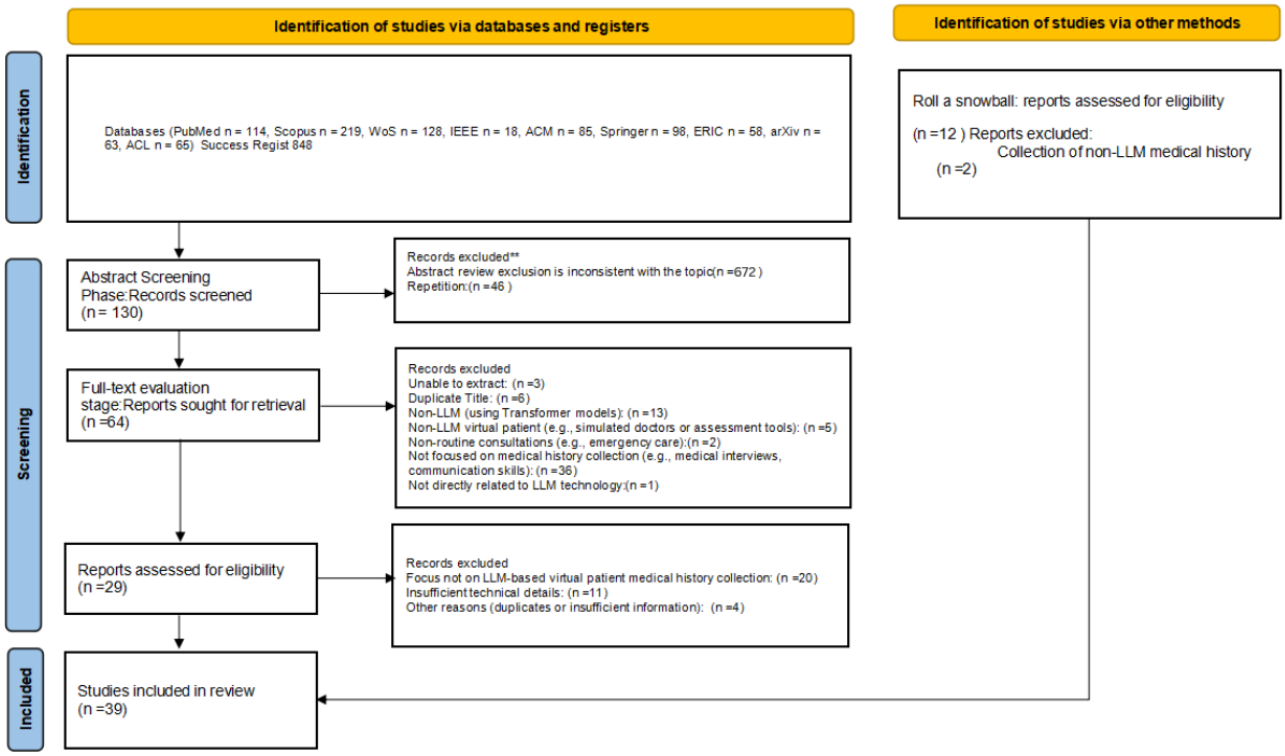
Quality and Risk of Bias Assessment

A reviewer with a computer science background, under the supervision of an experienced research advisor, conducted the quality assessment. A customized multidimensional assessment framework was developed to evaluate the technical quality of the included studies, as described in Multimedia Appendices 3 and 4. Conventional appraisal tools such as the Joanna Briggs Institute Critical Appraisal Checklist (2020) were adapted because they were not fully suitable for LLM-based virtual patient research. The framework incorporated 6 evaluation dimensions methodology clarity, dataset transparency, completeness of system evaluation, innovation or integration level, reproducibility and openness, and the presence of control or baseline comparisons. Each dimension was rated on a 3-point scale ranging from 0 to 2, with 2 indicating the highest quality. The total score for each study, therefore, ranged from 0 to 12. Based on the overall score, studies were categorized into 3 quality levels, high (9-12 points), medium (5-8 points), and low (0-4 points). This classification ensured a consistent and transparent interpretation of the technical quality across studies. The assessment emphasized methodological rigor, technical implementation, system architecture, model training strategies, multimodal integration, and evaluation methods to identify potential sources of bias.

Risk of bias was also assessed across 5 domains—selection or reporting bias, implementation bias, evaluation bias, data bias, and reporting completeness bias—to capture variations in study design, data transparency, technical implementation, and reporting quality. This combined approach ensured a systematic evaluation of both methodological soundness and potential bias in LLM-based virtual patient studies.

Based on the aforementioned screening and evaluation methods, the research results will be presented in detail in the next section.

Results



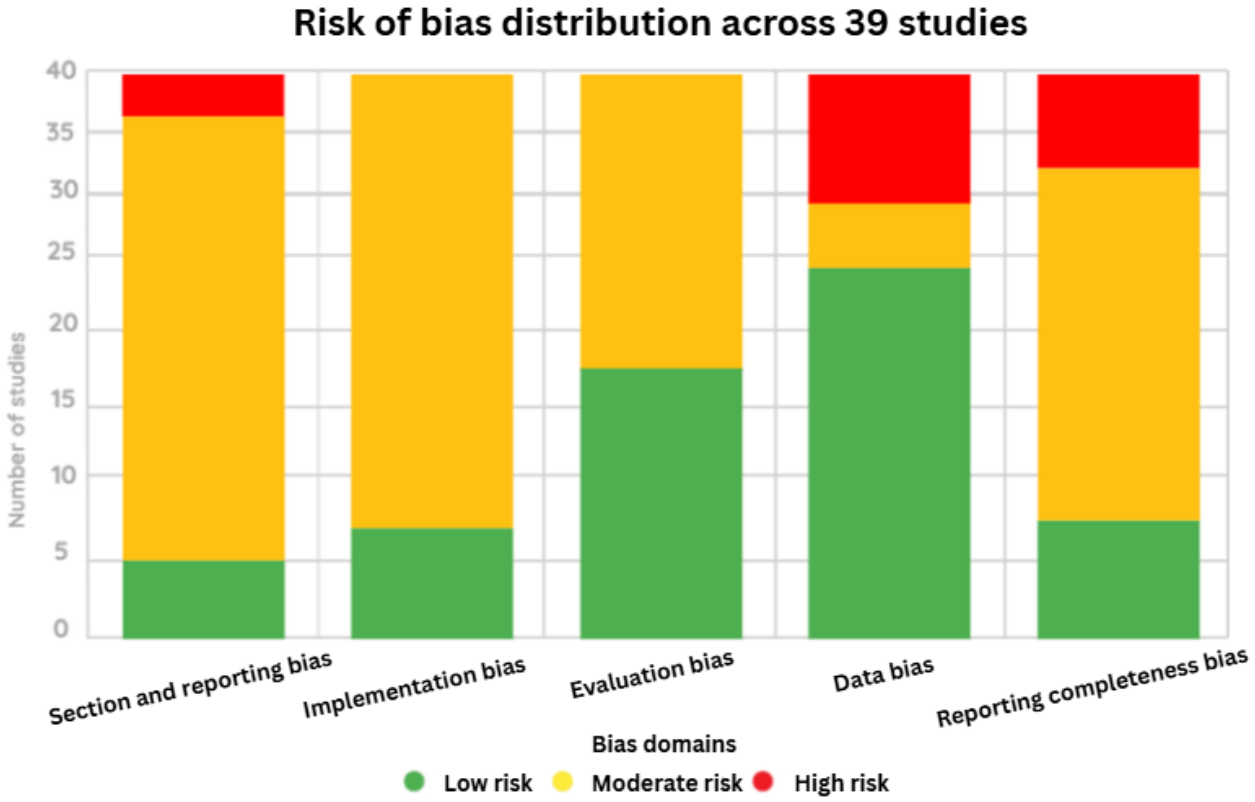
Overview

This section reports the results of literature selection, study characteristics, and findings related to the 4 RQs, avoiding interpretive discussion.

Study Selection Results

During identification (see Figure 2 for the 2020 flow diagram for systematic reviews, including database and register searches), 848 records were retrieved from 10 databases. During abstract screening, 672 records were excluded, and after removing 46 duplicates, 130 unique full-text articles were assessed. Of these, 66 were excluded for reasons including lack of extractable data (n=3), duplicate content (n=6), non-LLM models (n=13), focus not on LLM applications (n=5), nonroutine clinical settings (n=2), no history-taking focus (n=36), or nonrelevance to LLM technologies (n=1), leaving 64 eligible articles. During multidimensional evaluation, 20 studies were excluded for limited relevance, 11 for insufficient technical detail, and 4 for other reasons, yielding 29 articles from database searches. An additional 12 articles were identified through snowballing, of which 2 were excluded as irrelevant, resulting in 10 included snowballed studies. The final synthesis comprised a total of 39 studies [8,10,15-51] (6 high-quality, 33 moderate-quality) (see Multimedia Appendix 5).

Figure 2. PRISMA flow diagram.



XSL•FO
RenderX

Quality and Risk of Bias Assessment Results

Most studies achieved the highest rating (2 points) for methodological clarity, indicating well-defined research procedures and consistent experimental designs. Scores for dataset transparency and system evaluation completeness varied considerably, with approximately 45%-55% of studies receiving moderate ratings (1 point) due to insufficient details regarding data sources or evaluation frameworks. Innovation and integration levels were generally high, with about 80% of studies receiving high ratings (2 points), reflecting notable progress in multimodal integration and technological creativity. Reproducibility and openness received moderate ratings (1 point) in approximately 60% of studies, as some provided replication details whereas others lacked information on model configurations or training strategies. Control or baseline comparison obtained the lowest scores (0-1 point), with only 25%-30% of studies incorporating explicit comparative or controlled analyses. Overall, 6/39 (15%) studies were rated as "high quality," and 33/39 (85%) as "moderate quality," suggesting strong methodological design and innovation but highlighting the need for improved dataset transparency, evaluation completeness, and reproducibility (see Multimedia Appendix 5 for details).

Risk of bias was assessed across five domains—selection and reporting bias, implementation bias, evaluation bias, data bias, and reporting completeness bias—as illustrated in Figure 3.

Figure 3. Overview of risk of bias distribution across studies.

Selection and reporting bias was evident in disease coverage. Approximately 95% (37/39) of studies simulated specific disease types (eg, internal medicine or mental health disorders), but only 50% (20/39) addressed multiple disease stages, thereby limiting generalizability to multimorbidity contexts.

Implementation bias was observed in the limited reporting of model development details. While 80% (31/39) of studies described model types, only 35% (14/39) provided information on training procedures, fine-tuning processes, prompt engineering, reinforcement learning with human feedback (RLHF), domain-specific adaptation, or multimodal integration. This resulted in high technical heterogeneity.

Evaluation bias was reflected in the uneven assessment of educational and user experience outcomes. Approximately 70% (27/39) of studies evaluated educational outcomes, and 65% (25/39) assessed user experience using instruments such as the SUS or the Chatbot Usability Questionnaire (CUQ). However, only 30% (12/39) of studies conducted comparative or controlled evaluations, which limited the interpretability of effectiveness findings.

Data bias stemmed from moderate dataset transparency. Fewer than half of the studies (18/39, 45%) explicitly identified data sources or quality control procedures, constraining reproducibility.

Reporting completeness bias was identified in the limited documentation of personalization mechanisms and quality control for generated outputs, reported in only 25%-30% (10-12/39) of studies, suggesting incomplete methodological reporting.

In summary, this multidimensional quality and bias assessment systematically examined the technical features, methodological design, and potential biases of LLM-based virtual patient research. The findings highlight the need to improve dataset

XSL•FO
RenderX

transparency, enhance the comprehensiveness of system evaluation, and include controlled comparative studies to strengthen reproducibility and scientific validity. Details of the screening results and full bias assessment are provided in Multimedia Appendix 6.

Finding for RQ1: What Types of Patients Are Simulated in LLM-Based Virtual Patient Systems?

This section presents a descriptive statistical analysis and classification of patient types simulated by LLMs in virtual patient history-taking systems, based on a systematic literature review. The classification uses disease categories from Table 1, grouping similar disease types (eg, internal medicine and mental health disorders). For each category, the number of studies, specific simulation scenarios, disease complexity (eg, low: single symptom; medium: multisystem involvement; high: rare or complex interactions), number of simulated cases (if specified), and disease stage (eg, acute and chronic) are summarized.

Table 1. Classification of patient types simulated in virtual patient systems.

Disease category	Simulation scenarios	Complexity	Number of cases	Stage	References
Internal medicine	Chest/abdominal pain, diabetes, COPD[a], COVID-19, hypertension, multisymptom	Medium-high	3-500+	Acute-chronic	12 studies [15,20-30]
Mental health disorders	Depression, PTSD[b], ADHD[c], TRD[d], CBT[e] models	High	1-106	Acute-chronic	8 studies [18,31-35,37]
Surgical/orthopedic	Plastic surgery, hand surgery, joint pain	Medium	3-10	Acute–chronic	4 studies [16,20,24,38]
Neurological/rheumatological	Stroke, meningitis, concussion, polymyositis, brain hemorrhage	High	1-4	Acute	6 studies [20,21,36,39-41]
Ophthalmological	Eye conditions, pain with redness/photophobia	Medium	1-24	Acute	3 studies [17,20,42]
Dermatological	Ear cyst, telogen effluvium, skin conditions	Medium	1-394	Acute-chronic	4 studies [19,25,43,44]
Rare/multiple disease types[f]	Rare diseases, unspecified conditions, broad patient scenarios	High	8-5230	Diverse	10 studies [8,10,25,45-51]

[a]COPD: chronic obstructive pulmonary disease.

[b]PTSD: posttraumatic stress disorder.

[c]ADHD: attention deficit hyperactivity disorder.

[d]TRD: treatment-resistant depression.

[e]CBT: cognitive behavioral therapy.

[f]Only [25] involves rare disease simulation, using the RareBench dataset with 421 rare disease cases. Other references in the "rare/multiple disease types" category focus on multiple disease types or unspecified/broad patient scenarios.

Summary of Research Focus and Coverage

A systematic descriptive analysis of the literature indicates that research primarily focuses on internal medicine, particularly gastrointestinal (eg, abdominal pain, heartburn, hematemesis [20-23,27,28]), respiratory (eg, cough, chronic obstructive pulmonary disease, COVID [20,21,23,29,30]), cardiovascular (eg, chest pain, hypertension [20-22,30]), metabolic and endocrine (eg, diabetes [10,23,24]), and fatigue-related conditions (eg, chronic fatigue [15,26]). These conditions are well-suited for effective clinical training, with LLMs effectively simulating both acute and chronic management scenarios, though vague symptoms like fatigue remain underexplored.

Mental health disorders are a significant focus, including depression and related disorders (eg, suicidal ideation and treatment-resistant depression) [15,32-35], posttraumatic stress disorder (posttraumatic stress disorder; eg, combat trauma) [18,31], attention-deficit/hyperactivity disorder [31], and other mental health conditions (eg, cognitive impairment, cognitive behavioral therapy [CBT] models) [32,37]. These simulations emphasize emotional and psychological complexity, suitable for empathy and CBT training, though behavioral disorders like attention-deficit/hyperactivity disorder are less explored.

Rare and multiple disease types are well represented, focusing on heterogeneous case collections and electronic health record (EHR)–driven simulations [8,46-51], as well as rare disease modeling (eg, 421 rare diseases [10,25,45]). These studies highlight the scalability and diversity of LLMs in simulating complex and varied clinical conditions.

Less studied areas include neurological and rheumatological diseases (eg, stroke, meningitis, and polymyositis [20,21,36,39-41]), dermatological diseases (eg, ear cyst, telogen effluvium, and skin conditions [19,25,43,44]), surgical and orthopedic diseases (eg, joint pain, plastic surgery, and hand surgery [16,20,24,38]), and ophthalmological diseases (eg, eye pain, photophobia, and multiple eye conditions [17,20,42]). These areas, due to specialized or visual simulation requirements, have received less attention, revealing significant research gaps.

XSL•FO
RenderX

Overall, research focuses on internal medicine and mental health disorders due to their prevalence and clinical relevance. Rare and multiple disease types demonstrate LLMs' scalability and generalization potential. In contrast, specialized domains such as surgical and orthopedic, neurological and rheumatological, dermatological, and ophthalmological diseases remain underexplored, presenting opportunities for further innovation in simulation-based medical education.

Finding for RQ2: What Techniques do LLMs Use to Enhance Medical History–Taking Capabilities in Clinical Interviews?

To address RQ2, LLMs use advanced techniques to enable realistic, dynamic, and accurate virtual patient simulations for medical history-taking, providing medical students and professionals with effective clinical training platforms that closely resemble real-world scenarios. The following sections categorize core LLM technologies for history-taking into prompt engineering, KGs and structured data, model fine-tuning and training, and speech interaction, as summarized in Table 2.

Table 2. Technical metrics, evaluation scores, and key strengths and limitations of LLM virtual patient techniques.

Category and technique (source)[a]	Top-k accuracy (%)	Hallucination rate (%)	IRR[b] (%)	AS[c] (%)	Strengths	Limitations
Prompt design						
Role-based prompts [10,23]	81.4	4.97	2.08	28	Realistic role-play; multiagent;	Long prompts inconsistent; complex cases limited
Few-shot [25]	Not used: 25%, used: 52%				Simple, effective;	Limited depth
Multiagent prompt frameworks [21,24]	—[d]	—	—	—	Consistent dialogue	Higher computation
KG[e]						
Entity-relation triples [17]	—	—	—	—	Structured triples	Small-scale realism
Entity layering [10]	97.42	—	—	—	High diagnostic accuracy and interpretability	Limited semantic layers
KG+history and few-shot [10]	97.85	—	—	—	Role continuity	Context overflow
KG+multiagent prompts [10]	97.85	—	—	—	Modular roles	High cost
Fine-tuning						
SFT[f] [17]	—	(Before fine-tuning 3.71%, after fine-tuning 0.31%)	4.79	87.00	Reduces hallucination rate; better reasoning	Limited turn validation
LoRA[g] [17]	—	—	—	—	Efficient tuning	Limited scalability evidence
Speech interaction						
TTS[h] [28,51]	—	—	—	—	Realistic voice; multimodal input	Recognition errors possible

[a]All techniques listed are LLM-based Transformer architectures.

[b]IRR: information-related response rate.

[c]AS: Anthropomorphism Score.

[d]Not available.

[e]KG: knowledge graph.

[f]SFT: supervised fine-tuning.

[g]LoRA: low-rank adaptation.

[h]TTS: text-to-speech.

Prompt Design for Realistic Patient Simulation

1. Role-based prompt design: detailed prompts embed patient demographics, personality traits (eg, Big Five), and clinical symptoms to simulate authentic patient behavior. For instance, Borg et al [41] developed virtual patient cases with approximately 2000 tokens per prompt, including detailed medical histories and contextual information, occupying a significant portion of the LLM's 4096-token context window. Implementations include structured prompts with role context, medical history, and behavioral constraints [16-20,22,24-29,31,33-41,43-46,51]. For

XSL•FO
RenderX

example, Bodonhelyi et al [37] used Satir model roles (eg, "accuser"') to achieve up to 95% dialogue consistency. This ensures consistent role-playing but requires instructor oversight to maintain medical accuracy [36].

2. Few-shot and dialogue history–based prompting: prompts incorporate dialogue history and few-shot examples to maintain conversational coherence and mimic gradual information disclosure. MEDDxAgent uses structured examples to guide diagnostic reasoning, improving top-k accuracy from 25% to 52% in complex cases [25]. Limitations include token constraints, which may restrict handling of intricate scenarios.
3. Multiagent prompt frameworks: multiple agents (eg, patient agent, doctor agent, and behavior controller) collaborate to generate realistic and personalized clinical dialogues, reducing reliance on single prompts and minimizing hallucination rate. For example, EvoPatient, developed by Du et al [18], uses a patient–doctor dual-agent system for natural dialogue via unsupervised learning. LLM-based generative agents integrate memory flows, retrievers, and cognitive mechanisms to enhance dialogue realism and training effectiveness [24]. Additionally, AI self-play agents such as AMIE simulate diagnostic conversations through internal and external self-play loops, applying multirole strategies within a single model to improve diversity and dialogue adaptation [21].

Knowledge Graphs and Structured Data

1. Dynamic KG retrieval: MedDiT uses KG agents to retrieve relevant subgraphs via SPARQL queries, linearizing them into natural language prompts to reduce token load and context loss, achieving significant token reduction [47].
2. Hierarchical KG modeling: AI Patient integrates layered KG with a Reasoning RAG multiagent framework, boosting accuracy from 68.94% to 94.15%. For the difficult "family and social history" category, accuracy improved from 13.33% to 85.56%, showing the value of structured KG reasoning. Compared to role-based prompts, the KG-based method performs better in multiclass tasks. With entity layering [10], accuracy rose by 16.02% (81.4% to 97.42%) in challenging categories such as allergy and social history.

Model Fine-Tuning and Training

1. Instruction fine-tuning and self-play: AMIE uses real and simulated medical dialogues with self-play loops (inner and outer) to optimize diagnostic performance, outperforming primary care physicians (PCPs) [19,45].
2. SFT and LoRA (Low-Rank Adaptation): Liu et al [17] fine-tuned Qwen2.5-72B-Instruct on MedDialog, reducing the hallucination rate from 3.71% to 0.31% [17]. At the same time, in terms of information-related response rate and Anthropomorphism Score (AS).
3. Chain-of-thought (CoT) and RLAIF+MoM: CureFun uses CoT and RAG, while Kumar et al's [26] RLAIF+MoM framework structures ambiguous symptoms, achieving up to 95% output clarity [23].

Speech Interaction

1. TTS and STT integration: Takata et al [28] use Google application programming interface (API) and Unity for synchronized speech [51] and emotional facial expressions, outperforming traditional platforms in interaction realism. Thesen et al [51] leverage Whisper-3 for immersive speech processing, achieving high student satisfaction.
2. Multimodal enhancements: AMIE integrates image uploads (eg, skin photos) to support history-taking, outperforming PCPs in diagnostic accuracy [19]. Ryu et al [35] enhances realism with patient image uploads.

In conclusion, LLM technologies achieve consistent and realistic virtual patient dialogues through multilevel prompt design, few-shot examples, and multiagent mechanisms. The use of KGs and structured data enhances information retrieval and medical history modeling, improving classification and recognition accuracy. Model fine-tuning techniques (SFT, LoRA, self-play, CoT, RLAIF+MoM) effectively reduce hallucination rate, optimize reasoning, and enhance diagnostic performance. Furthermore, speech interaction and multimodal integration improve interaction immersion and provide diagnostic support.

Findings for RQ3: How Are Experimental Designs Structured to Evaluate LLM-Based Virtual Patient Systems, and What Evaluation Metrics Are Used?

To address RQ3, this review synthesized 32 studies listed in Table 3 to examine the experimental design, evaluation methods, and metrics of LLM-based virtual patient systems, focusing on medical education, high diagnostic accuracy, and effective clinical training. Of the 39 identified studies (see Multimedia Appendix 5), 7 were excluded due to the absence of formal evaluations (eg, Takata et al [28] described planned behavioral experiments without data collection; Rodrigo et al [46] outlined testing plans but reported no results; Geer [31] focused on design without providing quantitative outcomes; Li et al [47] emphasized system architecture but lacked performance metrics; Staples et al [34] relied solely on qualitative feedback; Kumar et al [26] discussed workflow but lacked quantified results; Lee et al [15] provided expert Likert scores without statistical analysis). Due to high heterogeneity in evaluation metrics (eg, top-k accuracy, hallucination rate, CUQ, inconsistent scales and dimensions, lack of statistical information such as SDs or confidence intervals in many studies, and large variations in sample sizes that could bias pooled analyses), a meta-analysis was not performed. Instead, a structured narrative synthesis was adopted, supplemented with tabular summaries in Tables 2 and 3, which present the technical approaches and corresponding evaluation metrics.

[a]AI: artificial intelligence.

[b]Stats: statistical analysis.

[c]Q: Quantitative.

[d]κ: Cohen κ.

[e]PCP: primary care physician.

[f]t and MWU: *t* test/Mann-Whitney *U* test.

[g]Likert: Likert scale.

[h]*P*: Objective Structured Clinical Examination performance comparison between AI-trained and traditionally trained students showed a difference of 28.1 vs 27.1, respectively (Mann–Whitney *U* test, *P*=.01).

[i]M: Mixed.

[j]ICC: intraclass correlation coefficient.

[k]*P*: Feedback group scored 3.60 on CRI-HTI vs 3.02 in control group (ANOVA, ICC=0.924, *P*=.049).

[l]*P*: Robot vs virtual patient authenticity ratings were 4.5 vs 3.9 (*t* test; *P*=.04).

[m]*P*: Students receiving feedback showed higher Likert-scale scores compared to control (*t* test; *P*=.04).

[n]*P*: LLMDP-trained students scored 78.13 (SD 8.35) on history acquisition; traditional group scored 67.08 (SD 7.21), with a mean difference of 11.05 points (*P*<.001).

[o]*P*: Comfort scores improved from 61% to 76% after intervention (*t* test; *P*<.001).

[p]CUQ: Chatbot Usability Questionnaire.

[q]Descr: Descriptive.

[r]QL: Qualitative.

[s]*P*: Robot vs VIC comparison yielded authenticity ratings of 4.47 vs 3.93 (Wilcoxon test; *P*=.035).

[t]Acc: Accuracy.

[u]*P*: Original article did not provide comparative statistical values such as means or test statistics, only reported model accuracy with significance levels.

[v]*P*: Among the 8 evaluated cases, exact *P* values for comparisons 1 and 2 were *P*<.001 and *P*=.04, respectively; the remaining 6 ranged from *P*=.003 to *P*=.011. As per reporting guidelines, *P*=.000 was converted to *P*<.001.

Commonalities and Specificities in Experimental Design

Commonalities

Most studies involved medical or health professional students, typically 10-50 participants, with some including residents or practicing physicians as evaluators (usually 3-5 experts) [10,19,36]. A few studies used AI agents for large-scale automated testing [18,25]. Tasks primarily covered core clinical competencies, including history-taking accuracy [10,36], diagnostic reasoning [45], role-playing [37], and multiturn dialogues [41].

Evaluation paradigms were categorized into 3 types quantitative (18 studies) using randomized controlled trials (RCTs) or comparative experiments with statistical tests (eg, ANOVA, *t* tests, and correlation) [39,45]; qualitative (1 study) using expert interviews, thematic analysis, or questionnaires [32]; and mixed (13 studies) integrating objective metrics (eg, top-k accuracy, and F_1-score) with subjective scales (eg, Likert, CUQ) [36,40]. Comparative baselines included model comparisons (GPT-4 and 4o, Claude, and Gemini) [16], AI versus human physicians [19,45], with or without feedback or platform comparisons [40,41], and variations in prompt strategies, multimodality, or RAG and KG [49]. Most studies applied blinding and reported rater consistency (eg, κ) [8,39]. Details of each study's evaluation type are provided in Table 3 (Evaluation type column).

Specificities

Some studies implemented AI self-play for scalability [18], or AI doctor-AI patient automated evaluation [16]. Social robot-LLM hybrids were used to enhance realism [40,41]. Comparative baselines varied, including direct AI versus human physician comparisons [19,45], modular and hybrid architecture comparisons (eg, RASA or KG or LLM) [49], and multimodel comparisons (GPT-4.5 and 4o, Claude 3.7, and Gemini 2.5)

XSL•FO
RenderX

showing nonsignificant differences, indicating a high performance baseline [16].

Evaluation Metrics: Commonalities and Specificities

Evaluation metrics in LLM-based virtual patient systems generally fall into 5 categories: clinical accuracy and knowledge, communication and interaction quality, robustness and stability, training efficacy and feedback quality, and system performance. Clinical accuracy and knowledge were assessed using metrics such as top-k accuracy [19], GTPA@k [25], information coverage [43], hallucination rate [17,19], and fidelity and relevance [18], evaluating diagnostic and information-gathering capabilities. Communication and interaction quality were measured through readability (Flesch and Flesch–Kincaid) [10], CUQ [22], and Anthropomorphism Score [17,37], reflecting language clarity and interaction naturalness. Robustness and stability were evaluated via paraphrase robustness [10], leak resistance [18], and rater consistency metrics, including κ [8] and intraclass correlation coefficient (ICC) [39]. Training efficacy and feedback quality focused on learning outcomes and user experience, assessed through Objective Structured Clinical Examination (OSCE) score improvements [39], and usability scales (such as CUQ). System performance metrics, including latency, failure rate [49], and confusion or clarification rates [49], captured efficiency and reliability. Specificities included unique metrics such as span-level F_1-score [10] for knowledge extraction, cosine similarity-based fidelity and relevance [18], weighted F_1-score or fuzzy labels for professionalism and ethics [39], and system-level confusion, clarification, or failure rates. Automated evaluation metrics such as GTPA@k [25] provided standardized measures for diagnosis, while expert ratings revealed realism biases, including underestimation by GPT-4. Usability was further examined through instruments such as the CUQ (score of 77/100), 7-dimensional Likert scales combined with ANOVA for accuracy, realism, and empathy, and system latency and confusion reporting (0.5%). These metrics collectively enable comprehensive assessment of both the technical performance and experiential quality of LLM-based virtual patient systems. The calculation formula for the indicators is detailed in Multimedia Appendix 7.

Evaluation Results

The synthesis of evaluation results from the 32 included studies indicates that LLM-based virtual patient systems demonstrate high diagnostic accuracy across key metrics. Quantitative results showed top-k accuracy ranging from 0.45 to 0.98 (based on 34 models and 300 patient cases); Saab et al [19] reported that AMIE achieved a Top-1 Accuracy of 0.65, compared to 0.53 for PCPs, with $P<.001$. Information coverage averaged 33.89% to 94.4% (eg, Liao et al [43] reported 33.89%, based on 150 cases; Holderried et al [22] reported 94.4%, based on 502 questions explicitly covered in case scripts, with a total of 826 answers), while hallucination rate remained low, ranging from 0.31% to 5% (eg, Liu et al [17] conducted experiments with up to 5 dialogue rounds, achieving a hallucination rate of 0.31%).

In terms of communication quality, CUQ scores ranging from 77 to 86.25 (eg, Laverde et al [24] reported 86.25). Training effectiveness was evident in OSCE performance (eg, Yamamoto et al [20] reported posttraining 28.1 vs pretraining 27.1, $P=.01$; Luo et al [42] reported that medical students trained using the LLM-based digital patient system (LLMDP) achieved a medical history acquisition score of 78.13 (SD 8.35), while the control group trained with traditional real patients scored 67.08 (SD 7.21). The difference between groups was 11.05 points, with $P<.001$, indicating a highly statistically significant difference). Robustness metrics such as κ ranged from 0.74 to 0.832 (eg, Holderried et al [8] reported 0.832; Rashidian et al [30] reported 0.74).

Mixed methods studies reported improvements in authenticity (eg, Borg et al [40] reported postuse 4.5 vs preuse 3.9; $P=.04$) and comfort (Thesen et al [51] reported that among 69 participants, average preuse comfort was 61%, increasing to 76% postuse, indicating higher student-reported comfort after training; $P<.001$). Automated baseline systems, such as EvoPatient, achieved a relevance of 0.7589 and a faithfulness of 0.8786 (Du et al [18]), while multimodel comparisons showed no significant differences among top LLMs (Haider et al [16]).

These results highlight the effectiveness of LLM-based systems in simulating realistic interactions, although specific metrics—such as the low failure rate of 2.0% reported by Ng et al [49] (based on 200 dialogue trials) and the high ICC of 0.924 reported by Brugge et al [39]—indicate that further standardization is needed.

The reviewed studies exhibit consistent commonalities in participant composition, task objectives, and evaluation paradigms, typically involving small to medium student samples and multisource evaluations with experts and AI, focusing on history-taking and diagnostic reasoning. Specificities are evident in comparative settings (AI vs humans, multimodel comparisons) and statistical methods such as bootstrap, false discovery rate (FDR), and ICC. Across studies, 5 key evaluation aspects were assessed using objective metrics. Clinical accuracy and knowledge were measured using top-k accuracy [19,21], GTPA@k [25], information coverage [22,43], and span-level F_1-score [18], capturing high diagnostic accuracy and knowledge acquisition. Authenticity was evaluated using hallucination rate [17] and fidelity metrics [18]. Interaction experience was assessed via CUQ [24] and Anthropomorphism Score [17], reflecting communication quality and user perception. Robustness and consistency were quantified using κ [30] and ICC [39]. System performance was captured through latency, failure rate, and confusion rate [21,49]. These categories collectively enable a comprehensive assessment of both technical and experiential quality, highlighting the systems' effectiveness while indicating areas for further standardization and evaluation refinement.

Finding for RQ4: What Public Datasets Are Available, and What Are Their Characteristics for Training, Simulating, and Evaluating Medical History-Taking in Virtual Patient Systems?

A variety of datasets support the development and evaluation of virtual patient systems, ranging from real-world EHRs to structured synthetic clinical scenarios. Table 4 summarizes key datasets used in recent studies, which are either publicly

XSL•FO
RenderX

available or accessible through formal application processes. These datasets provide diverse clinical data resources for effective clinical training and evaluation.

MIMIC-III (Medical Information Mart for Intensive Care-III) is a comprehensive publicly available medical dataset, containing detailed EHR data from over 40,000 intensive care unit (ICU) patients [10]. It covers multiple disease types, including internal medicine and neurological and rheumatological conditions, serving as a critical resource for virtual patient system development. However, its ICU-focused nature, primarily reflecting acute or severe diseases, limits its applicability to noncritical care scenarios, such as outpatient consultations, mental health disorders, or chronic disease management [10].

DDxPlus provides clinical dialogue data for respiratory diseases [25], suitable for training virtual patient systems in specific domains within internal medicine. The iCraft-MD dataset focuses on dermatological cases [25], and RareBench contains region-specific subsets of rare and multiple disease types [25]. While valuable for specialized applications, their scope is limited for building generalized, multitask virtual patient systems.

The medical-NLP corpus provides a broad range of clinical dialogues and records [18], while CCKS 2019 offers a Chinese medical KG dataset, enabling multilingual history-taking simulations [17,56]. The Open-i dataset includes multimodal chest X-ray images and textual descriptions, supporting dynamic image generation alongside history-taking [47]. MedQA provides multiple-choice and long-form medical question-answering data, useful for fine-tuning LLMs for diagnostic dialogues [45]. These datasets enhance multimodal and question-answering capabilities, though their coverage is narrower than MIMIC-III.

In summary, current datasets primarily focus on critical care or specific medical domains, with limited publicly available, diverse resources. These datasets have limitations in generalizability, multitask applicability, and multilingual support for virtual patient systems. Combining MIMIC-III (broad coverage) [10], DDxPlus and iCraft-MD (specialized domains) [25], and CCKS 2019 (multilingual support) [17,56] provides partial coverage. However, further development of diverse, emotionally annotated, and non-English datasets is needed to enhance system generalizability and conversational fidelity.

Table 4. Datasets used in virtual patient systems.

Dataset Name	Index	Description	Access requirements
MIMIC-III[a]	[10]	EHR[b] database from Beth Israel Deaconess Medical Center, over 40,000 ICU[c] patients (2001-2012), including vital signs, medications, laboratory results, diagnostic codes.	Access via PhysioNet; requires CITI training and DUA [52].
DDxPlus	[25]	Synthetic dataset for respiratory diseases, with clinical dialogues and diagnoses.	CC-BY[d]; publicly available, allows commercial use with attribution [53].
iCraft-MD	[25]	Synthetic dermatology dataset from public medical question banks and expert cases.	MIT License; publicly available [54].
RareBench	[25]	Rare disease dataset with regional subsets (Europe, Canada, and China).	Apache-2.0; publicly available [55].
medical-nlp	[18]	Medical NLP[e] corpus with clinical dialogues and records.	GNU General Public License v3.0; publicly available on GitHub [18].
CCKS 2019	[17]	Chinese medical knowledge graph dataset with entity recognition, relation extraction, QA[f] tasks.	Research use only; cite source [56].
Open-i	[47]	Multimodal dataset with 3314 chest x-ray images and textual descriptions.	Open Data Commons Open Database License; publicly available via NIH Open-i project [57].
MedQA	[45]	Multiple-choice and long-form medical QA dataset for diagnostics.	Publicly available via GitHub [45].

[a]MIMIC-III: Medical Information Mart for Intensive Care-III.

[b]EHR: electronic health record.

[c]ICU: intensive care unit.

[d]CC-BY: Creative Commons Attribution.

[e]NLP: natural language processing.

[f]QA: question-answering.

Discussion

Principal Findings

Current LLM-based virtual patient systems exhibit significant limitations in disease coverage, complex case simulation, multimorbidity representation, specialty applicability, multimodal capabilities, and standardization of evaluation metrics, indicating a need for systematic optimization to enhance clinical fidelity, educational adaptability, and interaction quality.

XSL•FO
RenderX

Limitations and Future Directions in Virtual Patient Type Simulation Research

The systematic review reveals several limitations in current virtual patient systems regarding disease coverage, case complexity modeling, and support across medical specialties [20,32]. First, research is heavily concentrated on internal medicine (eg, gastrointestinal, respiratory, and metabolic disorders) and mental health disorders, accounting for over half of the studies [15,32]. This focus reflects the strengths of LLMs in language-driven tasks and the availability of relevant data, but it highlights significant gaps in surgical and orthopedic, ophthalmological, and dermatological domains. Scenarios requiring procedural operations, image recognition, or multimodal interactions are underrepresented, with current systems lacking effective modeling mechanisms [16,43]. This finding aligns with RQ1, indicating that most simulations focus on specific disease categories, leaving certain specialty areas insufficiently covered.

Although some studies involve multiple disease types, current virtual patient systems mainly use single-disease trajectories, with each virtual patient representing only one disease [21,25]. multimorbidity simulations—patients with 2 or more coexisting chronic or acute diseases—are limited. Clinical multimorbidity requires complex decisions, including drug interactions, overlapping symptoms, and conflicting management priorities. Dataset analysis for RQ4 shows most datasets focus on a single primary disease, lacking comprehensive multimorbidity cases. Without simulating this complexity, virtual patient systems have limited use in advanced medical education and clinical reasoning. Future research should emphasize role construction and dialogue design for multimorbidity scenarios to support integrated management across multiple diseases.

Furthermore, current systems exhibit instability in simulating vague or atypical symptoms (eg, chronic fatigue, low mood, attention deficits), demonstrating weak extraction of unstructured chief complaints and incoherent reasoning processes, which limits support for comprehensive clinical assessments [10,31]. Incorporating KGs and CoT reasoning mechanisms may improve knowledge organization and causal chain construction, enhancing models' reasoning and response capabilities in complex clinical scenarios [58,59]. Open-source KGs, such as UMLS (Unified Medical Language System) [60], SNOMED-CT (Systematized Nomenclature of Medicine - Clinical Terms) [61] can be integrated to provide structured, high-coverage medical knowledge. Leveraging these KGs allows LLMs to reference verified entities and relationships during dialogue generation, reducing hallucinations and enhancing reasoning in multimorbidity or complex symptom scenarios.

Additionally, coverage of specialty domains remains limited, particularly in surgical and orthopedic, ophthalmological, and dermatological contexts requiring procedural or visual recognition skills. These fields show constraints in case complexity, multimodal interaction support, and procedural training, limiting educational adaptability and clinical fidelity [43]. This observation is consistent with findings from RQ1 and RQ4, indicating that certain specialty cases and complex patient scenarios remain underrepresented.

In summary, current virtual patient systems require systematic optimization in disease coverage balance, case complexity, multimorbidity simulation, specialty applicability, multimodal capabilities, and interaction depth. These improvements are expected to enhance clinical fidelity, educational adaptability, and natural human-computer interaction, providing a foundation for advancing intelligent medical education and clinical decision support systems.

Technical Challenges and Solutions of LLM-Based Virtual Patient Simulation

In virtual patient simulation, prompts guide LLMs to generate dialogues conforming to specific role characteristics. However, overly long prompts lead to information loss, affecting dialogue quality and coherence. Specifically, GPT-style models based on autoregressive decoder architectures process prompts sequentially from left to right, prioritizing information at the beginning (primacy effect) and end (recency effect), while middle information may be ignored or inadequately processed, impacting content completeness and accuracy [62]. Additionally, few-shot learning maintains role settings using limited historical dialogues, but balancing information completeness and avoiding overload in multiturn complex dialogues remains challenging. To address this, core information should be prioritized at the prompt's beginning and end, with emotional content placed in the middle to ensure accurate and consistent information transmission.

Compared to single-prompt methods, multiagent frameworks decompose dialogue generation into modular components, with agents handling specific functions such as patient history or simulated emotions, or leveraging adversarial training to enhance dialogue quality [18,21,24]. However, multiagent systems increase computational costs, as each agent independently calls APIs, leading to higher financial burdens. Additionally, fine-tuning using older APIs may cause "memory loss," affecting dialogue context continuity. Dialogue saving and restoration mechanisms are necessary to ensure information consistency. To reduce costs and improve efficiency, dialogue compression and summarization mechanisms can simplify context input, and noncritical tasks can be assigned to lower-cost APIs to balance performance and expense.

Research on fine-tuning GPT-style models and integrating KGs remains limited. Liu et al [17] proposed a SFT strategy using synthetic medical records and manually annotated dialogues, significantly enhancing the realism and anthropomorphism of patient history collection dialogues on the Qwen-72B model (Alibaba Cloud), reducing Hallucination Rate from 3.71% to 0.31%. However, their training process did not explicitly embed disease names into the Transformer model, limiting specific disease knowledge mastery. Prior studies indicate that incorporating disease names as labels or input features improves semantic understanding and generalization, particularly for simulating patient histories for specific diseases [58,59]. Combining CoT methods with fine-tuning to guide step-by-step reasoning for complex medical knowledge is underexplored and presents a potential direction for medical dialogue systems.

KGs systematically represent structured medical knowledge, but there is a lack of studies comparing disease embeddings

XSL•FO
RenderX

trained by LLMs with KG embeddings to evaluate differences in knowledge representation and reasoning capabilities. KGs' clear entity and relation structures complement LLMs' limitations in sparse knowledge or verification, while LLM-trained embeddings as a baseline reveal constraints in semantic understanding and improvements from KG enhancement. Future research should establish a unified evaluation framework integrating supervised fine-tuning, LoRA, and CoT reasoning to explore the complementary roles of KG and LLM embeddings, advancing medical dialogue models in logical reasoning and knowledge accuracy.

Evaluation Design Suggestions and Summary of Metrics

Evaluation methods and metrics in LLM-based virtual patient systems are diverse, reflecting the multidimensional nature of performance and educational outcomes. However, the lack of standardized frameworks hinders cross-study comparison and generalizability. Diagnostic accuracy is often measured by top-k accuracy (eg, 65% [19]) and GTPA@k [25], though these coarse metrics may not capture system capabilities. Information Coverage and Hallucination Rate assess retrieval fidelity but usually rely on manual verification. Interaction quality metrics—such as semantic similarity (0.7589 [18]) and user scores (eg, CUQ=77 [22])—highlight interactivity but are limited by subjectivity and small samples. External studies also report high usability, such as SUS=88.1[31], a 10-item scale measuring ease of use, confidence, and learnability, reinforcing the systems' educational value despite inconsistent evaluation standards.

Moreover, system performance assessment remains insufficient. Some studies report response delays affecting conversation naturalness, but lack quantitative measures or systematic evaluations. The absence of standardized key performance indicators exacerbates framework fragmentation, hindering effective implementation and broader application in medical education and effective clinical training [41].

To address fragmented metrics, a unified and scientifically grounded evaluation framework is necessary. Key performance indicators with recommended thresholds are proposed to guide system design and assessment:

- Top-1 accuracy (≥0.80): AMIE achieved a top-1 accuracy of 0.65, outperforming primary care physicians (0.53) [19], while *GTPA*@1 reached 0.96 [25]. A threshold of 0.80 ensures reliable diagnostic performance.
- Hallucination rate (≤0.05): GPT-4o demonstrated a Hallucination Rate of 0.31% [17], with rates below 5% reported in [19], supporting medical safety standards.
- Information coverage (≥0.50): coverage of critical history items was 33.89% [43], indicating room for improvement. A 50% threshold ensures adequate information capture.
- Empathy and Anthropomorphism Score (≥0.75, standardized 0-1 scale): GPT-4o scored 0.87 [17], and [37] reported approximately 0.76, indicating desired human-like interaction and empathy.
- Usability (SUS≥80, CUQ≥75): SUS of 88.1 [59] and CUQ of 77 [22] meet standards for satisfactory usability.
- Robustness (leak resistance≥0.90): a value of 0.9412 was reported in [18], indicating compliance with privacy and ethical requirements.
- Rater consistency (κ and ICC≥0.80): high interrater reliability was observed, with ICC=0.924 [39] and κ=0.832 [8].

Challenges of Data Diversity: Limitations in Corpus Coverage and Adaptability

Existing datasets for training and evaluating LLM-based virtual patient systems are diverse, encompassing real-world EHRs, synthetic clinical scenarios, and multimodal or multilingual resources [10,17,18,25,45,47,56]. Table 4 summarizes key datasets, which are either publicly available or accessible through formal application processes. Analysis reveals several limitations impacting system development.

Mainstream datasets like MIMIC-III primarily reflect intensive care scenarios, containing records from ICU patients with acute or critical conditions, often within internal medicine or neurological and rheumatological categories [10]. This bias limits generalizability to nonacute settings, such as outpatient consultations, mental health disorders, or chronic disease management. Specialized datasets, including DDxPlus (internal medicine), iCraft-MD (dermatological), and RareBench (rare and multiple disease types), provide tailored resources [25]. While valuable for specific domains, their narrow coverage limits suitability for general-purpose or multitask system training.

Linguistic and cultural diversity is limited, as most corpora are English-based and originate from Western health care systems [17,18,45,47,56]. The lack of datasets in other languages, such as Chinese [17,56], and integration with local KGs or region-specific disease contexts constrains performance in multilingual and cross-cultural environments. Modality limitations are evident; most datasets provide textual information and lack multimodal inputs like images, speech, or physiological signals [47], restricting interaction realism and diagnostic reasoning.

Data accessibility and format heterogeneity affect usability. Access requirements, annotation styles, field definitions, and dialogue formats vary [10,17,18,25,45,47,56], hindering integration and comprehensive training. Standardization of data formats and unified interfaces is necessary to reduce development costs and support broader adoption. Additionally, task alignment poses challenges, as datasets like MedQA [45] are structured for multiple-choice or question-answering tasks, requiring extensive adaptation for dialogue generation.

Combining broadly covering datasets like MIMIC-III [10] with domain-specific (DDxPlus, iCraft-MD, RareBench) [25] and multilingual or multimodal datasets (CCKS 2019 [17,56], Open-i [47], medical-nlp [18], MedQA [45]) can partially address gaps. However, developing diverse, emotionally annotated, non-English, and multimodal datasets is essential to enhance generalizability, robustness, and interaction fidelity.

Conclusion

This systematic review, conducted per PRISMA 2020 guidelines, evaluated studies (January 2020-August 18, 2025) on LLM-based virtual patient systems for medical history collection, sourced from 9 databases PubMed, Scopus, Web of Science, IEEE Xplore, ACM Digital Library, Springer, ERIC, arXiv, and ACL Anthology. Following rigorous screening, deduplication, and quality appraisal, 6 high-quality and 33 moderate-quality studies were included, addressing 4 research questions, simulated patient types, performance-enhancing technologies, experimental designs, and evaluation metrics.

Key findings include (1) systems primarily simulate internal medicine and mental health disorders (acute and chronic), with limited coverage of rare and multiple disease types, multimorbidity, and specialties like surgical and orthopedic, neurological and rheumatological, dermatological, and ophthalmological, restricting applicability in complex clinical reasoning and education [15,16,32,43]. (2) Technologies such as role-based prompts, few-shot learning, multiagent frameworks, KGs, and fine-tuning (eg, SFT, LoRA, CoT, RLAIF+MoM) enhance dialogue coherence, retrieval accuracy (+16.02% with KGs) [10], and high diagnostic accuracy, while multimodal integration (eg, speech) improves immersion [18,25]. (3) Evaluations involved medical students and practitioners, using mixed methods (top-k accuracy, F_1-score, SUS, CUQ, and expert ratings) with comparisons across AI models, physicians, or prompt variations; small sample sizes (10-50 students and 3-10 experts) and inconsistent metrics limit generalizability [19,40]. (4) Systems demonstrated high diagnostic accuracy: top-k accuracy 0.45-0.98, information coverage 33.89%-94.4%, Hallucination Rate 0.31%-5%, and high usability (SUS≥80), often outperforming junior physicians [18,43]. Dataset limitations (eg, MIMIC-III ICU bias, restricted access, low multilingual and multimodal diversity) hinder cross-study comparability [10,17,25].

The key discussion points are summarized: (1) Disease coverage is imbalanced, favoring internal medicine and mental health disorders over surgical and orthopedic, dermatological, ophthalmological, and multimorbidity scenarios, limiting effective clinical training [16,43]. Future systems should prioritize multimorbidity and diverse patient populations (cultural and linguistic) to enhance realism [17,56]. (2) Prompt design endures information loss in long prompts; placing critical information at prompt ends and using dialogue compression or multiagent frameworks can mitigate this [18,60]. KG-LLM integration and fine-tuning improve performance, with potential for further gains via hybrid KG-CoT approaches [58,59]. (3) Fragmented evaluation frameworks, inconsistent metrics, and small participant pools reduce reliability. A standardized framework with thresholds (eg, top-1 accuracy≥0.80, hallucination rate≤0.05, SUS≥80, CUQ≥75,κ and ICC≥0.80) and larger samples (50-100 students, 5-10 experts) is needed [19,39]. (4) Dataset biases (eg, ICU focus), format heterogeneity, and privacy restrictions limit inclusivity. Open-access, ethically compliant, multimodal, and multilingual datasets are essential for equitable systems [10,45,47].

Future research should focus on large-scale longitudinal studies, standardized evaluation metrics, diverse open-access datasets (eg, UMLS [60] and SNOMED-CT [61]), and advanced integration of KGs, multimodal training, and optimized prompts to enhance the realism, high diagnostic accuracy, and fairness of LLM-based virtual patient systems in medical education [17,18,59].

Abstract

Background: Observational data are fundamental to medical research but present formidable challenges for causal inference. Machine learning–based causal discovery algorithms have emerged as a promising solution to identify causal structures directly from such data. However, the current literature is skewed toward theoretical and methodological innovations, with a critical gap in systematic assessments of performance in medical research settings and a lack of practical guidance for clinicians and researchers on selecting and applying these algorithms in specific medical contexts.

Objective: This study aimed to systematically map and synthesize the application of causal discovery methods in observational medical research, detailing the methodologies used, their application domains, the robustness of the findings, and the practical challenges encountered.

Methods: Following the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) guidelines, we conducted a systematic search of Scopus, Web of Science, PubMed, MEDLINE, Embase, and CINAHL from inception to May 2025. We included studies that applied any causal discovery algorithms within a medical research context, encompassing both analyses of real-world observational data and method-validation studies using synthetic or benchmark datasets with a clear medical focus. Purely methodological papers and studies based solely on experimental data were excluded. Data were extracted and synthesized using a descriptive analysis focused on study characteristics, algorithm types, application domains, reported numerical results, and implementation challenges.

Results: Out of 2296 identified publications, 72 (3.1%) met the inclusion criteria. Our synthesis revealed three key themes. The first theme was methodological landscape, where constraint-based algorithms were the most prevalent (38/72, 52.8%), with the fast causal inference (10/72, 13.9%) and Peter-Clark algorithms (9/72, 12.5%) being most common. Score-based (19/72, 26.4%) and hybrid (14/72, 19.4%) methods also represented significant and growing segments (methods were not mutually exclusive). The second theme was application domains and findings, where the majority of studies (54/72, 75%) were in clinical research, with a strong focus on mental health (19/72, 26.4%; eg, identifying symptom networks in schizophrenia and posttraumatic stress disorder) and chronic diseases (19/72, 26.4%; eg, elucidating progression pathways in Alzheimer and diabetes). Etiological research was the primary objective (28/72, 38.9%). Public health applications (18/72, 25%) frequently assessed the causal impacts of behavioral interventions. The third theme was implementation challenges and innovations, where common challenges included pervasive unmeasured confounding, limited sample sizes (noted in more than 20% of studies), and reliance on unvalidated causal assumptions. Emerging innovations focused on longitudinal data frameworks and the integration of multimodal data sources to strengthen causal claims.

XSL•FO
RenderX

Conclusions: This review underscores the growing application of causal discovery algorithms in medical research while also highlighting challenges such as the lack of standardized validation frameworks and persistent confounding. Future efforts must focus on developing evaluation standards and fostering interdisciplinary collaboration to translate these powerful computational techniques into reliable tools for medical research and practice.

KEYWORDS

causal discovery; medical research; observational data; algorithm; scoping review

Introduction

The advent of big data has driven significant advances in machine learning (ML), yet current methodologies often focus on identifying correlations rather than uncovering underlying causal relationships [1]. This limitation is particularly critical in medicine, where understanding causality is essential for effective clinical decision-making. Contemporary causal research addresses 2 interrelated challenges: causal discovery (identifying causal structures and directions between variables) and causal inference (quantifying effects within predefined causal frameworks) [2-5]. Causal discovery is concerned with deducing the causal structure and directionality among variables from data, with the primary objective of elucidating direct and indirect causal pathways by constructing causal graphs. Typically, it relies on statistical principles such as conditional independence tests to discern potential causal structures from correlational patterns. In contrast, causal inference focuses on quantifying the magnitude of the effect of specific interventions on an outcome variable, presuming a known or assumed causal structure. Therefore, inferring causal relationships, that is, causal discovery, from observational medical data is critical for advancing precision and personalized medicine. A central class of computational methods developed for causal discovery, such as the Peter-Clark (PC) algorithm and fast causal inference (FCI), aims to learn a causal graph that represents the underlying data-generating mechanism. The growing scale and accessibility of diverse medical data resources, encompassing real-world records, such as surgical, therapeutic, and diagnostic information, as well as genetic, lifestyle, and environmental data, have become invaluable for such research [6]. However, these data are often affected by confounding, selection bias, and missing data, posing substantial challenges to deriving reliable causal conclusions. Although randomized controlled trials (RCTs) remain the gold standard for medical decision-making [7], the limits of RCTs and the growing abundance of observational data underscore an urgent need for more robust causal discovery methodologies.

Observational datasets, particularly those derived from real-world settings, offer significant advantages for medical research, including large sample sizes, accessibility, and the ability to reflect real-world clinical scenarios. Previous studies have demonstrated their potential to elucidate disease etiology [8-10], optimize treatment strategies [11,12], and refine prognostic models [13,14]. However, the specific application of causal discovery methods to harness these datasets remains particularly challenging and fragmented. Key barriers include unmeasured confounding, complex data structures, and a lack of consensus on methodological best practices. As a result, there is an insufficient synthesis of how these methods can be robustly applied, validated, and translated into clinical insights. This scoping review aims to fill this gap by systematically analyzing causal discovery methods applied to observational medical studies. Specifically, we critically assess: (1) The evolving methodological landscape and algorithm suitability across clinical contexts; (2) High-impact application domains and translational outcomes; (3) Persistent implementation challenges, such as unmeasured confounding and sample limitations. By mapping these dimensions, we provide a foundation for advancing causal discovery in digital health and precision medicine.

Methods

Study Design

This scoping review adhered to Arksey and O'Malley's framework for scoping review [15] and the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) guidelines [16] (Multimedia Appendix 1). Our primary research question was: "What are the methodologies, clinical applications, and implementation challenges of causal discovery in observational medical research?" The aim was to synthesize evidence to guide future methodological development and clinical translation. Given the rapidly evolving nature of this field, no temporal restrictions were applied.

Search Strategy

To comprehensively review studies of causal discovery algorithms in medical research and its subtypes, 2 researchers (XY and ZH) performed a systematic literature search of Scopus, Web of Science, PubMed, MEDLINE, Embase, and CINAHL in May 2025 and was restricted to studies published in English, using the following search strategies: "causal discovery/causal structure discovery/causal structure learning/causal graph discovery/learning causal models." The search was focused on biomedical databases (PubMed, Embase, etc) as this review aims to map applications in medical research. While computer science–focused databases, such as IEEE Xplore or ACM Digital Library, include methodological developments, they primarily emphasize algorithmic innovation; seminal methodological papers with medical applications are typically also indexed within the selected biomedical sources. The search strategy was designed in consultation with an information specialist. The entire search strategy for the 6 databases is displayed in Multimedia Appendix 2.

XSL•FO
RenderX

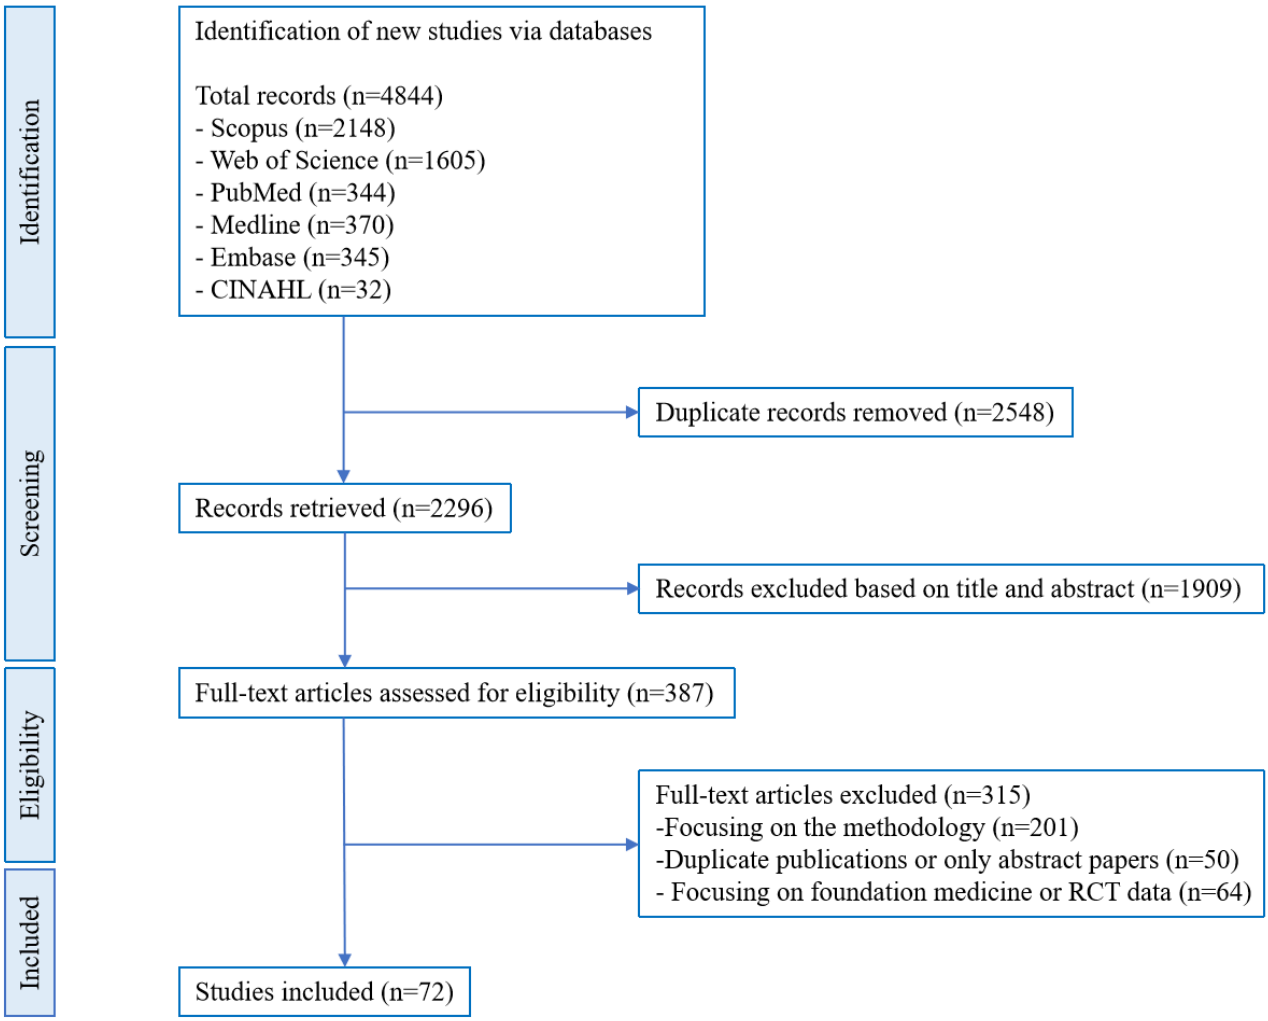
Eligibility Criteria

Two researchers (HM and JM) independently screened studies based on predefined inclusion and exclusion criteria by examining their titles, abstracts, and full texts. Studies met the following inclusion criteria: (1) application focus: empirical implementation of causal discovery algorithms in medical or health contexts. (2) Data and methodology: the study applied a causal discovery approach within the observational research paradigm. This included analyses of real-world observational medical data as well as method-validation studies that used synthetic or benchmark datasets to address a medical research question or simulate a medical data environment. (3) Output: the study generated an explicit causal graph or causal structure. (4) Language: English-language publications. The exclusion criteria were: (1) The study purely focused on methodological or theoretical papers without medical applications. (2) Experimental (RCT) or basic science studies. (3) Duplicate publications, brief abstracts, or conference summaries lacking full methodological and results sections. (4) Studies where causal discovery was not the primary methodology. Discrepancies in study eligibility were resolved through consensus between 2 independent reviewers (JK and JL).

Data Extraction and Synthesis

Screening was performed using Rayyan [17], with dual-reviewer verification at all stages. A standardized electronic form was used to extract the following data items: (1) study characteristics: year of publication, country or region of corresponding author affiliation, study design, and sample size; (2) causal discovery methods: specific algorithms, methodological category, and the primary software or package used for implementation; (3) data properties: data type, dimensionality, and temporal features; (4) application domain and specific clinical or public health objectives; and (5) validation approaches and key reported limitations.

Data synthesis was conducted in 2 complementary ways to align with the scoping review's descriptive aims. First, a descriptive quantitative analysis summarized structured characteristics (eg, causal discovery algorithms, software tools, and application domains) using frequencies and percentages. Second, for textual data on reported methodological considerations and challenges, an inductive content summary was performed. Two reviewers (ZL and TL) independently identified recurrent issues and patterns, which were then discussed, consolidated, and organized into overarching descriptive themes (eg, methodological landscape and challenges). This process ensured the results reflected both the quantitative distribution and qualitative substance of the included literature. While this scoping review did not undertake a formal critical appraisal of individual studies using standardized quality assessment or risk-of-bias tools, we systematically extracted study-reported methodological limitations and implementation challenges as a prespecified data item during full-text screening. These author-reported limitations were subsequently subjected to inductive qualitative synthesis, alongside other extracted textual data, to identify recurrent patterns and to develop the descriptive themes presented in the "Challenges" section. This approach was intended to map commonly reported methodological issues in the literature rather than to appraise or grade the quality of individual studies.



Results

Article Selection

After the removal of duplicates, 2296 unique records were identified for screening. Of these, 72 studies [8-14,18-82] (3.1%) met the inclusion criteria and were included in the final synthesis (Figure 1). After eliminating 2548 duplicates (52.6%), title or abstract screening excluded 1909 records (39.4%). A full-text review of 387 articles led to the exclusion of 315 (81.4%) due to reasons such as a methodological focus (201/315, 63.8%), duplicate publications or abstracts (50/315, 15.9%), and basic research or experimental designs (64/315, 20.3%).

Figure 1. PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) flowchart for the study selection process. RCT: randomized controlled trial.

Characteristics of the Articles

The characteristics of the included studies (N=72) [8-14,18-82] are summarized in Table 1, covering publication year, country or region, and document type. The number of annual publications progressively increased from 2017 to 2025, with the years 2023-2025 accounting for the majority (46/72, 63.9%). Publications peaked in 2023 and 2024. The majority of studies were peer-reviewed journal articles (64/72, 88.9%), with the remaining studies being conference proceedings. The studies originated from 18 distinct countries or regions, with the United States contributing the largest proportion (25/72, 34.7%), followed by China (8/72, 11.1%), the Netherlands (6/72, 8.3%), and Japan (4/72, 5.6%), accounting for a combined total of 59.7% of publications. Three primary themes emerged from the analysis: (1) methodological landscape, that is, dominant causal discovery approaches and typologies in medical research; (2) application domains, that is, multidimensional implementation scenarios across observational studies; and (3) challenges, that is, methodological limitations and barriers to clinical translation.

Country of publication		
United States	25 (34.7)	[18,20,22,23,26,28,36,38,43,46,47,51,56-58,60,61,63,65-67,70,73,74,79]
China	8 (11.1)	[19,29,33,42,52,69,77,78]
Netherlands	6 (8.3)	[9,27,59,71,80,81]
Japan	4 (5.6)	[39,40,49,75]
Other countries	29 (40.3)	[8,10-14,21,24,25,30-32,34,35,37,41,44,45,48,50,53-55,62,64,68,72,76,82]

Themes

Theme 1: Methodological Landscape

Causal discovery methodologies are broadly divided into several major categories: constraint-based, score-based, continuous optimization, functional causal models, and hybrid methods. It should be noted that these categories are not mutually exclusive; a single study could use methods from more than one category. Thus, the percentages reported below are calculated based on the total number of included studies (N=72) [8-14,18-82] and may sum to more than 100%. Among the 72 studies analyzed, constraint-based methods constituted the predominant approach (38/72, 52.8%) [8-10,12,14,18,24,25,27,29-32,34-38,43,45,48,52,53,55,57-59,63,64,68,70,71,73,74,77,79-81], followed by score-based (19/72, 26.4%) [8,11,18-20,23,24,26,28,32,33,35,39,42,61,67,73,74,82], hybrid (14/72, 19.4%) [8,13,22,23,33,41,46,47,51,56,60,63,65,69], continuous optimization (9/72, 12.5%) [29,33,36,40,44,49,50,54,62], and functional causal models (5/72, 6.9%) [21,32,66,75,78]. At the algorithmic level, FCI (10/72, 13.9%) [10,18,29,34,38,43,58,63,73,74] and PC (9/72, 12.5%) [12,18,25,27,29,35,36,53,70] algorithms were the most implemented constraint-based methods, whereas greedy fast causal inference (GFCI) (10/72, 13.9%) [13,22,23,41,46,47,51,60,63,65] and Non-combinatorial Optimization via Trace Exponential and Augmented Lagrangian for Structure learning (6/72, 8.3%) [36,40,49,50,54,62] demonstrated notable dominance within the hybrid and continuous optimization categories, respectively. Additionally, time-series causal discovery (eg, Peter-Clark momentary conditional independence) was actively explored in 11 studies [32,44,48,55,64,66,68,72,76,77,82]. These findings highlight a clear trajectory toward the adoption of more integrated, scalable, and nonparametric causal discovery frameworks. The reviewed studies used methodologies from 2 distinct conceptual frameworks. The majority used structural causal discovery algorithms (eg, PC, FCI, and NOTEARS) to learn causal graphs or networks. An analysis of implementation tools revealed the software landscape for causal discovery (Table 2). Of the 72 included studies, 45 (62.5%) [8-10,12,13,18-22,24,26-28,30,32,36-39,41,43,44,46-48,50,51,54,55,57,60-63,65,68-71,74,75,77,79] explicitly specified the software or package used. Among these, R was the most prevalent environment, used in 22 studies [8-10,12,18,20,22,24,26-28,30,37,38,48,55,57,60,61,68,74,82] (22/45, 48.9% of reporting studies, or 22/72, 30.6% of all studies), with the *pcalg* package being the most frequently cited. The standalone Tetrad suite was used in 10 studies [13,18,41,43,46,47,51,63,65,74] (10/45, 22.2% of reporting studies, or 10/72, 13.9% overall). Out of 45 studies, Python and MATLAB were implemented in 7 [9,21,32,36,50,54,62] (15.5%) and 8 [32,44,69-71,75,77,79] (17.7%) of the software-reporting studies, respectively. A notable finding regarding transparency was that 27 studies [11,14,23,25,29,31,33-35,40,42,45,49,52,53,56,58,59,64,66,67,72,73,76,78,80,81] (37.5% of the total) did not report any software details, posing a significant barrier to reproducibility. For details, refer to Table 2.

[a]PC: Peter-Clark algorithm.
[b]FCI: fast causal inference.
[c]FGES: fast greedy equivalence search.
[d]GRaSP: greedy relaxation of the sparsest permutation.
[e]PC-stable: Peter-Clark stable.
[f]Inter-IAMB: interleaved incremental association Markov blanket.
[g]HC: hill climbing.
[h]Tabu: tabu search.
[i]MMHC: max-min hill climbing.
[j]H2PC: hybrid of HPC and PC.
[k]GES: greedy equivalence search.
[l]BCCD: Bayesian Constraint-based Causal Discovery.
[m]LiNGAM: linear non-Gaussian acyclic model.
[n]GFCI: greedy fast causal inference.
[o]MGM: mixed graphical model.
[p]GraSP-FCI: greedy relaxation of the sparsest permutation fast causal inference.
[q]ARACNE: algorithm for the reconstruction of accurate cellular networks.
[r]iMIIC: interpretable multivariate information-based inductive causation.
[s]GGES: greedy generalized equivalence search.
[t]GAE: graph autoencoder.
[u]Modified PC: modified Peter-Clark algorithm.
[v]AnchorFCI: anchor fast causal inference.
[w]RDCM: regression dynamic causal modeling.
[x]MVGC: multivariate Granger causality.
[y]PCMCI: Peter-Clark momentary conditional independence.
[z]VarLINGAM: vector autoregressive linear non-Gaussian acyclic model.
[aa]CBAMN: cycle-breaking algorithm based on modified NOTEARS.
[ab]SEM: structural expectation-maximization.
[ac]RL: reinforcement learning.
[ad]IIE: inverse information entropy strength.
[ae]CABG: isolated coronary artery bypass grafting.
[af]AVR: isolated aortic valve replacement.
[ag]DYNOTEARS: dynamic noncombinatorial optimization via trace exponential and augmented lagrangian for structure learning.
[ah]SAM: structural agnostic modeling.
[ai]IAMB: incremental association Markov blanket.
[aj]GS: grow-shrink.
[ak]PTSD: posttraumatic stress disorder.
[al]ANM: additive noise model.
[am]PKCL: prior-knowledge-driven local causal structure learning.
[an]T2DM: type 2 diabetes mellitus.
[ao]GLL-PC: global-local learning Peter-Clark algorithm.
[ap]TPC: temporal Peter-Clark algorithm.
[aq]ADHD: attention-deficit/hyperactivity disorder.
[ar]PCDSD: probabilistic causal discovery in sequential datasets.
[as]LSTM: long short-term memory.
[at]McDSL: multiple-cause discovery combined with structure learning.
[au]SVM: support vector machine.
[av]LGMM: latent growth mixture modeling.
[aw]HITON-PC: HITON-PC algorithm.
[ax]ASD: autism spectrum disorder.

[bi]CD-SF: causal discovery based on the streaming feature.

[bj]CD-SU-SF: causal discovery with symmetrical uncertainty based on the streaming feature.

[bk]LiNGAM: linear non-Gaussian acyclic model.

Theme 2: Application Domains

Examination of the 72 studies [8-14,18-82] indicated that causal discovery applications were dominated by clinical research (54/72, 75%), with public health comprising the remainder (18/72, 25%). Etiological investigation emerged as the predominant focus within clinical research, followed by predictive modeling, highlighting the method's central role in elucidating disease mechanisms and enabling clinical prognosis. This application profile demonstrated the adaptability of causal discovery methodologies across the spectrum from individual-level clinical research to population health studies.

Causal Discovery Methodological Approaches to Disease Categories

Among the 54 clinical studies [8-14,18,19,21-23,25-29,31-34,36,38,39,42-46,51-54,58-61,63-65,67,69-81], mental health represented the most extensively examined area (19/72, 26.4%) [13,22,23,27,29,32,45,46,51,53,59,60,65,70,71,75,79-81], with significant attention to schizophrenia (3/72, 4.2%) [13,32,51], posttraumatic stress disorder (3/72, 4.2%) [46,70,79], autism spectrum disorder (2/72, 2.8%) [22,80], and attention-deficit/hyperactivity disorder (2/72, 2.8%) [71,80]. Chronic disease investigations equally comprised 26.4% (19/72) of studies [9-12,14,19,21,26,28,31,36,38,42,52,69,72-74,76], spanning neurodegenerative diseases [10,19,26,72-74,76] (particularly Alzheimer disease [10,19,26,74] and amyotrophic lateral sclerosis [72,76]), malignancies [11,14,28,36,52], diabetes [21,42], and other chronic conditions [9,12,31,38,69]. Additional clinical applications included acute illnesses [8,33,78], pharmacological research [18,63], and other various specialized clinical scenarios [25,34,39,43,44,54,58,61,64,67,77], collectively demonstrating the extensive penetration of causal discovery methodologies in clinical research. For details, refer to Table 2.

Research Focus and Clinical Applications

The 54 clinical studies [8-14,18,19,21-23,25-29,31-34,36,38,39,42-46,51-54,58-61,63-65,67,69-81] showed a distinct concentration in research aims. Etiological exploration represented the predominant focus (28/72, 38.9%) [8-10,18,22,23,25,27,29,31,39,42-46,51,54,60,61,63,65,69-71,74,75,80], establishing causal discovery as a core methodology for investigating disease mechanisms. Predictive modeling constituted the second major application area (13/72, 18.1%) [19,21,26,33,34,58,64,72,73,76-79], while prognostic evaluation [13,14,28,52] and disease diagnosis [32,36,38,53] each accounted for 4 studies respectively. Collectively, these 4 domains accounted for 49 investigations (49/72, 68.1%), underscoring the method's primary use in addressing fundamental clinical questions from causation to outcome assessment.

For example, in a study by Zhang et al [63], causal discovery methods were applied to construct causal networks of COVID-related acute kidney injury using longitudinal electronic health record (EHR) data. Specifically, the FCI and GFCI algorithms were used to automatically identify the development of COVID-19–related acute kidney injury with minimal prior assumptions about pathway connectivity. The results provided a more refined understanding of how remdesivir and other risk factors contribute to acute kidney injury, identifying critical time points for potential intervention and offering valuable insights for clinical decision-making [63]. Similarly, Sokolova et al [80] demonstrated the application of the Bayesian constraint-based causal discovery algorithm to cross-sectional phenotypic data, which revealed directional relationships between attention-deficit/hyperactivity disorder and autism spectrum disorder symptom domains that traditional correlational methods failed to elucidate, generating novel hypotheses regarding the etiological mechanisms underlying their comorbidity [80].

However, the limited applications in clinical decision support development (1/72, 1.4%) [67] and measurement scale implementation (2/72, 2.8%) [59,81] suggested that the translation of causal discovery into practical clinical tools remained underdeveloped, highlighting substantial potential for future research and implementation in real-world health care settings.

Public Health Research Applications

Public health domains were addressed in 25% (18/72) of studies [20,24,30,35,37,40,41,47-50,55-57,62,66,68,82], demonstrating the expanding relevance of causal discovery beyond clinical settings. Health behavior interventions constituted the largest subgroup (8/72, 11.1%) [30,35,37,40,41,49,56,62], primarily focusing on lifestyle quantification and health promotion. Disease management decision-making and health care optimization strategies were examined in 9.7% (7/72) of studies [20,24,47,50,66,68,82], encompassing social determinants of

XSL•FO
RenderX

health, health care use patterns, and nursing home hospitalization reduction. The remaining studies addressed infectious disease transmission research [57,66] and life-course epidemiology [55]. These applications collectively demonstrated the methodological versatility of causal discovery in tackling population-level health challenges and informing public health policy.

Theme 3: Challenges

Common Observational Study Challenges

Medical observational studies using causal discovery methods consistently faced several fundamental limitations. Unmeasured confounding represented the most prevalent challenge (32/72, 44.4%) [11,12,18,20,21,25-27,29,37,38,41,43,44,52-57,59,62,63,65,66,70,71,73,75,82-84], potentially introducing spurious discoveries and biased effect estimates. Sample size limitations were reported in 29.2% (21/72) of studies [9,10,23,24,27,30,31,35,38,40,41,49,55,61,63,69,71,73,78,81,85], restricting statistical power and generalizability. Data quality issues emerged across multiple investigations, including substantial missing data and discretization-induced biases [10,12,30,33,47,49,54,77]. The absence of longitudinal designs in several studies further hindered the verification of temporal directionality in causal relationships [10,13,19,29,54,74,86].

Causal Discovery-Specific Methodological Issues

The application of causal discovery algorithms revealed distinct methodological challenges. Unvalidated algorithmic assumptions were identified in 18.1% (13/72) of studies [8,9,37,43,44,48,52,57,61,71,82,87,88], compromising validity when core assumptions such as causal sufficiency and the Markov property were violated. Limited cross-disease validation [21] and insufficient external validation [59] constrained the broader applicability of findings. Additionally, overreliance on prior knowledge introduced subjectivity into the discovery process, potentially influencing causal structure learning and interpretation [24,36,74,89,90].

Proposed Methodological Improvements

To address these challenges, future research should focus on the following. First, developing confounder-robust algorithms, as demonstrated by AnchorFCI in cardiometabolic disease research [31], and integrating domain knowledge in neurodegenerative studies [10]. Second, advancing longitudinal causal discovery frameworks for irregularly sampled temporal data in EHRs, as seen in nephrotoxicity and intensive care unit studies [63,64]. Third, enabling multimodal data integration strategies, such as coupling neuroimaging with EHRs or synthesizing wearable data with clinical assessments to explore lifestyle diseases [40,49,61]. Finally, incorporating artificial intelligence (AI) architectures like large language models, deep learning, and reinforcement learning to enhance clinical interpretability and model transferability across institutions [21,25,36,42,58,67].

Discussion

Principal Findings

This scoping review represents the first systematic mapping of causal discovery algorithms in observational medical research. It synthesizes key methodological, translational, and implementation gaps across clinical and public health domains. Despite the field's nascent stage, research momentum has accelerated markedly, reflecting growing translational potential. The scarcity of qualifying studies (72 of 2296 screened) underscores both the emergent nature of these methods and the novelty of this review. Our integration of fragmented evidence establishes a foundational framework for interdisciplinary refinement, advancing beyond traditional observational research limitations and supporting the causal discovery's role in medical settings.

Translational Gaps in Application Domains

Clinical research concentrates on etiological exploration, leveraging causal graphs to deconstruct complex diseases (eg, mental health and chronic conditions). However, a severe imbalance exists between mechanism discovery and clinical decision support development (1/72, 1.4%), revealing a critical mechanism-application dissociation. This translational gap primarily stems from 4 interconnected barriers: most methods remain at the proof-of-concept stage without large-scale clinical validation, creating a fundamental trust deficit; existing tools lack seamless integration with clinical workflows and EHR systems; real-world data quality issues and computational demands hinder practical implementation; and crucially, statistically robust findings often fail to translate into clinically actionable recommendations that clinicians can readily understand and apply at the point of care. Public health applications focus on behavior interventions (eg, lifestyle-outcome linkages) and system optimization (eg, health care use patterns), but face domain-specific confounders (eg, policy shifts). Cross-domain translation requires context-adapted methodological frameworks.

Methodological Challenges to Practical Translation

Causal discovery in observational medical research remains dominated by constraint-based (eg, PC and FCI) and score-based methods (eg, GES and FGES), valued for their reliability in exploratory analysis and high-dimensional data, as well as their inherent interpretability; their graphical outputs and testable assumptions align well with clinical reasoning. However, their limitations in identifying causal directions, handling unmeasured confounding, and computational efficiency have spurred new approaches: continuous optimization (eg, NOTEARS) enhances scalability, although often at the cost of transparency; hybrid methods (eg, GFCI) improve robustness; functional models (eg, LiNGAM) enable direction identification; and time-series approaches (eg, PCMCI) capture dynamic causality. This interpretability-scalability trade-off critically guides model selection in clinical settings, where trust and actionable insight depend on understandable outputs. This evolution marks a transition toward more robust, scalable, and temporally-aware causal inference.

XSL•FO
RenderX

Unmeasured confounding remains fundamental, distorting effect estimates and causal structures. Partial ancestral graph algorithms (eg, FCI and RFCI [91]) and negative control designs [92] offer partial solutions but lack universal robustness. Small-sample limitations undermine statistical power and generalizability, particularly in rare diseases or early-phase studies. Transfer learning [93], multimodal data fusion (eg, Cov-Pneum dataset [94]), and cross-disease validation mitigate data scarcity [95], while embedding expert knowledge (eg, in Bayesian networks) reduces model uncertainty. Beyond these challenges, translating causal discovery into practice requires concerted action on 2 fronts: establishing benchmark datasets and implementing a rigorous, explainable, multitiered validation framework. We strongly recommend the curation of medical benchmark datasets derived from gold-standard sources, such as large-scale RCTs or well-validated longitudinal cohorts, to provide a critical foundation for fairly evaluating and comparing algorithms. For instance, the study by Gururaghavendran and Murray [18] used a zero placebo effect as the benchmark to compare multiple causal discovery algorithms, demonstrating that guidance from expert insight and prior knowledge significantly enhances their performance.

Explainable artificial intelligence techniques hold significant potential for improving the causal discovery process. Hasan and Gani [96] introduced a knowledge-guided causal AI system that integrates domain-specific prior knowledge as structural constraints with observational data to refine causal graph discovery. The results show that this approach also lowers computational demands while improving reliability [96]. One study introduced a new causal discovery approach, called REX, leveraging ML models coupled with interpretability techniques, showing REX's effectiveness and robustness in accurately recovering true causal structures, along with its applicability to real-world problems [97]. In addition, moving beyond theoretical sensitivity analyses, a robust validation strategy must integrate internal validation (eg, using bootstrap to assess graph stability), external validation on independent datasets, and most importantly, rigorous evaluation of biological and clinical plausibility against established knowledge or new experimental findings. This comprehensive approach is essential for bridging the current trust gap and generating clinically actionable insights.

Future Directions

To propel the field beyond current methodological constraints and accelerate clinical translation, the following strategic advancements warrant prioritized investigation:

1. Advancing temporal causal inference: integrate time-series data (eg, EHRs) with target trial emulation frameworks to resolve temporal ambiguity, mitigate time-varying confounding, and strengthen causal directionality inference [98].
2. Enabling multimodal data integration: leverage causal ML methodologies to unify heterogeneous data sources (eg, EHRs, genomics, and behavioral data), thereby facilitating robust estimation of individualized treatment effects and bridging critical evidence gaps [10,36,99].
3. Developing AI-enhanced causal discovery: synthesize deep learning (for high-dimensional feature extraction), reinforcement learning (for adaptive decision-making), and causal representation learning to enhance the accuracy, scalability, and interpretability of causal inference in complex biomedical systems [21,25,42,100].
4. Accelerating clinical translation: it is imperative to establish reproducible benchmarking frameworks and standardized reporting guidelines. We encourage journals to adopt policies that actively promote code and data availability, thereby enhancing transparency and reproducibility. The integration of sensitivity analyses into routine methodological reporting should be considered essential for evaluating the robustness of inferred causal relationships. Furthermore, the development of cross-institutional validation protocols and standardized tools that facilitate the incorporation of clinical domain knowledge into causal discovery pipelines will be critical for fostering broader clinical adoption.
5. Enhancing interpretability: improving the interpretability of causal discovery outputs and building clinical trust requires heightened methodological transparency and consistent reporting standards. The field should move toward developing domain-specific reporting guidelines for causal discovery in medicine, which would detail the algorithms used, parameter settings, and evaluation metrics. Systematically embedding interpretability-focused techniques, such as feature importance analysis or causal pathway explanation, can help bridge inferred causal structures with established clinical evidence.

Ultimately, the real-world impact of causal discovery hinges on its ability to deliver comprehensible and actionable insights that resonate with clinical researchers and practitioners. However, whether causal discovery can genuinely drive scientific progress, generate novel insights, and inform scholarly discourse in fields can ultimately be determined only through its repeated application in practice, coupled with rigorous and transparent reporting of the results [101].

Strengths and Limitations

This review provides a timely, comprehensive synthesis of causal discovery algorithms across diverse medical domains. Nevertheless, limitations exist: First, restricting the search to English-language publications may have excluded valuable non-English evidence. Second, our review reveals a pronounced geographic concentration of research, with the majority of studies originating from the United States and China. This likely reflects disparities in access to large-scale digital health infrastructure, advanced computational resources, and targeted research funding. Consequently, the current evidence base and its associated methodological trends may not be fully representative of global research activity or directly generalizable to health care settings in other regions. Third, the search was conducted within biomedical databases and relied on a core set of terms centered on "causal discovery." While this approach efficiently captured studies self-identifying with this paradigm, it is possible that some relevant applications published under different terminology (eg, "Bayesian network structure learning") in computational science venues were not retrieved. Finally, while we mapped application breadth, a formal assessment of reporting quality or bias risk was not

XSL•FO
RenderX

conducted; future work should implement standardized appraisal tools to systematically evaluate methodological rigor.

Conclusions

Causal discovery is emerging as a pivotal approach in medical observational research, offering transformative potential for etiological exploration and clinical decision-making. However, critical barriers impede clinical translation, notably the absence of standardized validation frameworks and persistent confounding. Future progress necessitates rigorous evaluation standards and AI-causal methodology integration to enable robust, generalizable real-world decision support.

Acknowledgments

In accordance with journal policy, we confirm that no generative artificial intelligence tools were used in the writing of this manuscript or in the generation of its scientific content. Artificial intelligence–assisted tools were used solely for minor language polishing and proofreading. All conceptualization, analysis, intellectual interpretation, and authorship of the final manuscript are solely attributable to the human authors.

Data Availability

All data generated or analyzed during this study are included in this published article and Multimedia Appendices 1-2.

Funding

This study was supported by the National Natural Science Foundation of China (grant numbers 82360667 and 82160645), the Natural Science Foundation of Jiangxi Province (grant number 20212BAB206091), and the National Undergraduate Training Program for Innovation and Entrepreneurship (grant number 202510403077).

Authors' Contributions

JK and JL were involved in the concept and design of the review. ZL, TL, HM, JM, XY, and ZH made major contributions to literature search, data collection, data analysis, and data interpretation. ZL and JK wrote and edited the manuscript. All authors read and approved the final manuscript.

Abstract

Background: Machine learning is increasingly used to develop prognostic prediction models for spinal cord injury. Nevertheless, current studies exhibit heterogeneity in outcome measures, predictors, modeling strategies, and validation methods. Moreover, the reporting quality, risk of bias, and clinical applicability of these models have not been systematically evaluated using assessment tools specific to prediction models.

Objective: This review aimed to assess the reporting quality and risk of bias of machine learning–based prognostic models for spinal cord injury, and evaluate their clinical applicability, model features, validation, and implementation barriers.

Methods: We searched the China National Knowledge Infrastructure (CNKI), Wanfang Data, VIP Database, Sinomed, PubMed, Web of Science, Embase, and Scopus databases from their inception up to May 14, 2025. Two investigators independently screened studies, extracted data, and assessed risk of bias. Reporting quality and risk of bias were evaluated using the Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis (TRIPOD) statement and the Prediction Model Risk of Bias Assessment Tool (PROBAST). Descriptive statistics and narrative synthesis were used to summarize the findings.

Results: In total, 19 cohort studies were included. TRIPOD adherence ranged from 54.8% (17/31) to 81.1% (30/37), with a median of 74.2% (IQR 64.5%-77.4%). Overall, all 19 studies were judged to have a high risk of bias, mainly because of limitations in the analysis domain. Only 1 (5.3%) study included external validation, while 16 (84.2%) studies used internal validation and 2 (10.5%) studies reported model development only. No study justified the sample size; 6 (31.6%) studies reported imputation or other methods for handling missing data, and calibration was rarely reported.

Conclusions: Machine learning shows potential for spinal cord injury prognostic modeling, especially when complex clinical or imaging data are available. However, existing evidence is limited by incomplete reporting, high risk of bias, substantial heterogeneity, and limited external validation. Larger, methodologically robust studies with standardized outcomes, external validation, and evaluation of clinical usefulness are necessary before these models can be implemented in routine clinical practice.

Introduction

Background

Spinal cord injury (SCI) is a serious central nervous system disorder caused by trauma, tumors, or inflammation. It results in varying degrees of motor and sensory impairments, along with autonomic nervous system dysfunction [1,2]. Globally, SCI affects 40 to 80 individuals per million, mainly male individuals aged 15 to 35 years [3,4]. Treatment options include surgery, medications, new technologies, and rehabilitation with assistive devices [1,5-8]. However, differences in injury severity, neurological symptoms, treatments, and recovery make individualized prognosis challenging [9,10]. Therefore, reliable prediction models are crucial for early risk assessment, goal setting, rehabilitation planning, and communication with patients and families [11,12].

Machine learning (ML), a branch of artificial intelligence (AI), develops predictive models by identifying inherent patterns in clinical data. Its significance in supporting clinical decisions has led to cross-disciplinary research endeavors [13,14]. Recently, ML models have been developed to predict outcomes in patients with SCI, including neurological recovery, functional independence, walking ability, daily activity performance, and postoperative recovery [15-17]. The included studies show considerable variation in outcome measures, such as the American Spinal Injury Association Impairment Scale (AIS) [18], Spinal Cord Independence Measure (SCIM) [19], Functional Independence Measure (FIM) [20], Functional Ambulation Category at discharge (FAC-DC) [21], and activities of daily living (ADL) [22]. The modeling approaches also varied greatly, from logistic regression [23] and support vector machines [24] to random forests, Extreme Gradient Boosting (XGBoost) [18], Light Gradient Boosting Machine (LightGBM) [25], convolutional neural networks [26], and ensemble methods. This diversity indicates considerable methodological innovation but also makes it challenging to compare models across studies and assess their clinical applicability.

Although ML has been widely used for SCI diagnosis and prognosis, its practical application encounters some limitations. The variability in patient characteristics, treatment approaches, and imaging features presents challenges in creating reliable neurofunctional outcome prediction models [15]. Furthermore, differences in prediction targets and the lack of standardized evaluation methods hinder effective model comparison. In 2024, Habibi et al [27] conducted a systematic review on ML in SCI that covered diagnostic, prognostic, and management studies. Of the 21 included studies, 5 focused on diagnostic accuracy, whereas 16 addressed prognostic factors or management strategies. In addition, methodological quality was assessed using the Quality Assessment of Diagnostic Accuracy Studies 2 (QUADAS-2), which is intended for diagnostic accuracy studies rather than prediction model research [28]. Therefore, many studies included in that review were not eligible for this review, which focused specifically on cohort-based prognostic prediction models for functional outcomes in SCI. As a result, important issues relevant to prognostic prediction models—such as reporting completeness, risk of bias in model development and validation, handling of missing data, sample size adequacy, distinction between internal and external validation, and implications for model applicability—were not sufficiently evaluated.

Aims

Therefore, a targeted review of ML-based prognostic prediction models for SCI is needed. This systematic review aimed to evaluate the reporting quality and risk of bias of existing ML-based prognostic prediction models for SCI using Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis (TRIPOD) and Prediction Model Risk of Bias Assessment Tool (PROBAST) and secondarily to examine their clinical applicability, model characteristics, validation strategies, and barriers to clinical implementation.

Methods

Study Design and Registration

This review was conducted in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) statement [29]. The study protocol was registered prospectively with PROSPERO, the International Prospective Register of Systematic Reviews, under registration number CRD420251071502.

Search Strategy

Systematic searches were performed in the China National Knowledge Infrastructure (CNKI), Wanfang Data, VIP Database, Chinese Biomedical Literature Service System (Sinomed), PubMed, Web of Science, Embase, and Scopus databases. The search strategy combined MeSH (Medical Subject Headings) terms and free-text terms such as “Spinal Cord Injuries/Myelopathy, Traumatic/Cord Traumas, Spinal/Post Traumatic Myelopathy,” “Machine Learning/Learning, Deep/Artificial Intelligence/Machine Intelligence,” and “predictive model/prediction/forecasting/risk assessment/risk prediction/models.” The searches covered all records from each database’s start date up to May 14, 2025.

Eligibility Criteria and Study Selection

Two trained reviewers independently screened records and full texts according to predefined criteria. Screening decisions were cross-verified, and disagreements were resolved by discussion with a third reviewer.

Eligible studies met the following criteria: (1) population: individuals diagnosed with SCI who were aged 18 years or older, regardless of treatment methods (eg, surgery or rehabilitation) [30]; (2) intervention: development, validation, or both of prognostic models; (3) outcomes: metrics assessing the model’s predictive validity and accuracy; (4) study designs: cohort studies, including retrospective and prospective studies; (5) language: publications in Chinese or English. Studies were excluded if they only analyzed prognostic factors without building a prediction model, provided insufficient details on model development, or were nonoriginal publications, such as reviews, systematic reviews, meta-analyses, case reports, commentaries, or conference abstracts.

XSL•FO
RenderX

Data Extraction and Model Characteristics

A structured data extraction form was developed following the CHARMS (Critical Appraisal and Data Extraction for Systematic Reviews of Prediction Modeling Studies) checklist for systematic reviews of prediction models [31] and subsequently verified for accuracy. The included studies provided the following information: author, publication year, country, study design, outcome incidence, data source, predictors, model type, sample size, predictor selection methods, key predictors, missing data handling techniques, modeling approaches, model presentation format, performance metrics, and validation type (development only, internal validation, or external validation). Two reviewers independently extracted the data, cross-checked all entries, and resolved discrepancies through discussion with a third investigator.

Reporting Quality Assessment

Two researchers with methodological training independently evaluated the reporting quality of the included studies using the TRIPOD statement [32,33]. This guideline covers 22 items spanning the title and abstract, introduction, methods, results, and discussion sections. In this review, each TRIPOD item was categorized as either reported, partially reported, or not reported. An item was considered reported if all key elements specified by TRIPOD were clearly described in the article, partially reported if only some elements were included or the description was incomplete, and not reported if the information was missing.

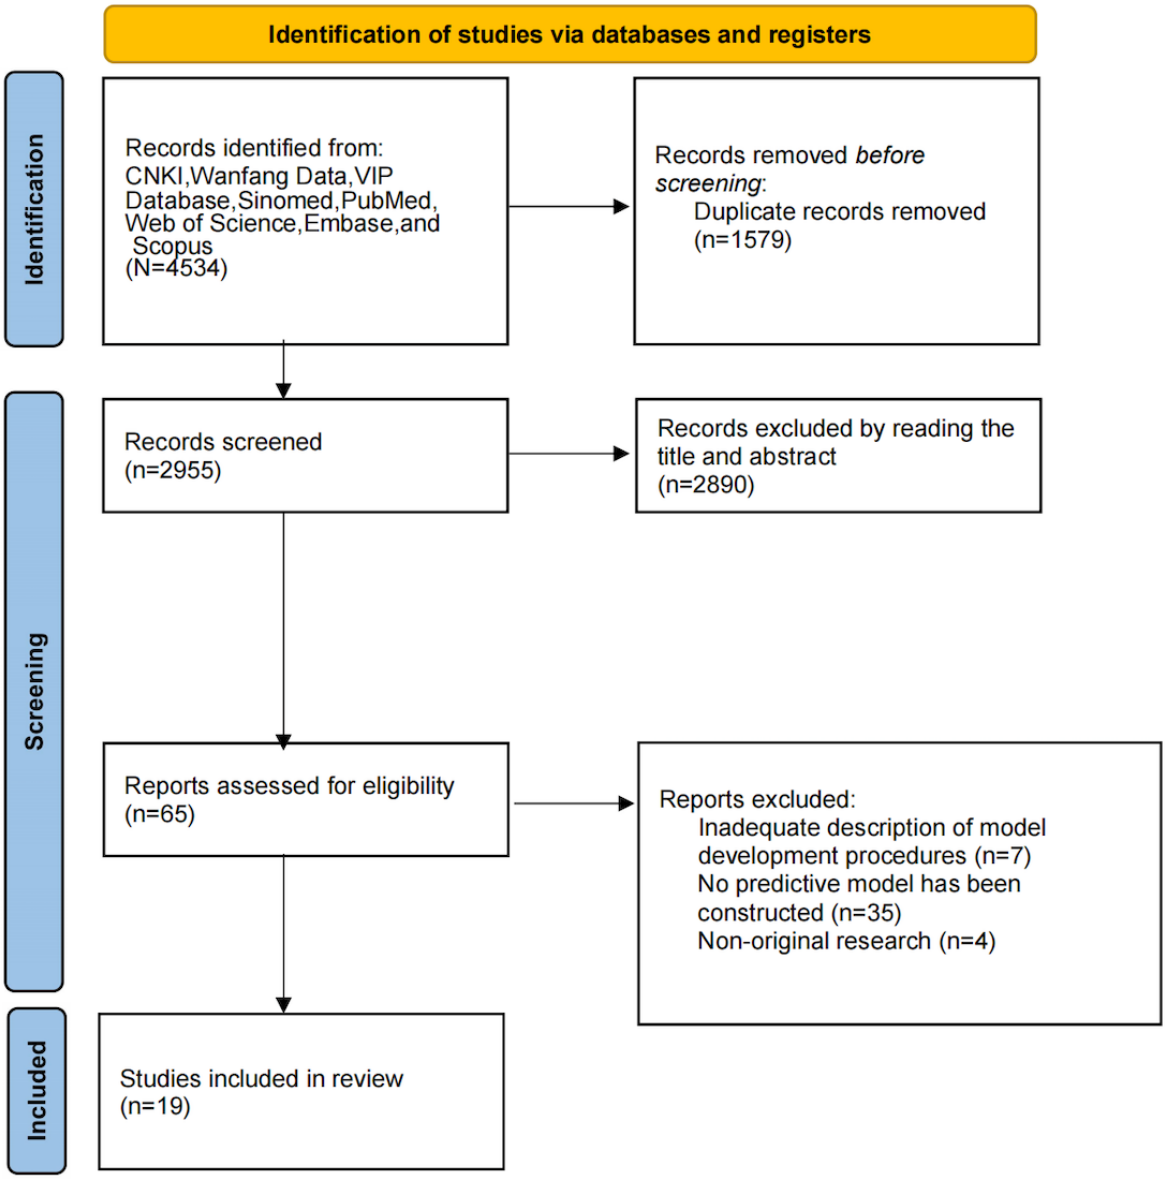
Risk of Bias and Applicability Assessment

Two reviewers independently assessed the risk of bias using the PROBAST [34]. PROBAST comprises 4 domains—participants, predictors, outcome, and analysis—each with 20 signaling questions. Domain-level judgments were based on the responses to these questions. The overall risk of bias was rated as high if at least one domain was rated high risk, unclear if at least one domain was rated unclear and no domain was rated high risk, and low only when all domains were rated low risk [35]. Disagreements regarding TRIPOD or PROBAST were resolved through discussion, with a third reviewer acting as an arbitrator if needed. Interrater reliability statistics were not calculated because the independent preconsensus ratings were unavailable for analysis.

Data Synthesis and Cross-Study Pattern Analysis

Given the substantial heterogeneity among the included studies, along with various biases and differences in modeling approaches, descriptive analyses and graphical representations were used to summarize the results. Adherence rates for each TRIPOD item were determined by dividing the number of studies meeting that specific item by the total number of studies for which the item was relevant. Overall adherence for each study was measured in a similar way. If a specific item was marked as “not applicable” for a study—such as the 6 items related to external validation (items 10c, 10e, 12, 13c, 17, and 19a), the 3 conditional items for model development (items 5c, 11, and 14b), or the 2 conditional items for model validation (items 10e and 17)—that item was excluded from the calculation of the TRIPOD compliance score. Additionally, since direct quantitative pooling of performance metrics was unsuitable due to heterogeneity in outcomes, modeling approaches, and validation strategies, model features and performance were summarized narratively using a structured comparison framework. Furthermore, cross-study patterns were examined narratively by categorizing studies based on predictor types, outcome domains, algorithm groups, validation approaches, and calibration metric reporting.

Because no meta-analysis of predictive performance was conducted and the included studies were highly diverse in outcomes, modeling approaches, and validation strategies, a formal statistical assessment of publication bias (eg, funnel plots or regression asymmetry tests) was not suitable. Instead, we qualitatively examined the possibility of reporting and dissemination bias by analyzing study characteristics, the completeness of reporting, and whether external validation and calibration assessments were present or absent.



Results

Study Selection

Initial searches across 8 databases yielded 4534 records. After removing duplicates, 2955 (65.2%) records remained. Title and abstract screening excluded 2890 (63.7%) records, leaving 65 (1.4%) articles for full-text review. After a comprehensive review of the full text, 19 (29.2%) studies were found to meet the inclusion criteria [18-26,36-45]. The study selection process is presented in Figure 1.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram.

Study and Model Characteristics

Overview

The characteristics of the included studies and models are summarized in Table 1, and detailed model characteristics are provided in Multimedia Appendix 1 [18-26,36-45]. Out of these 19 studies, only 1 (5.3%) [43] conducted external validation, using an independent prospective cohort (n=34) from a later period (July 2023-November 2023) as a temporal external validation set, distinct from the retrospective development dataset (January 2018-June 2023). A total of 16 (84.2%) studies [18,20-26,36,38-42,44,45] involved both model development and internal validation, while 2 (10.5%) studies [19,37] focused solely on model development. Nine (47.4%) studies included both surgical and conservative management approaches [19,22,24,26,37,41,43-45], whereas 3 (15.8%) studies modeled outcomes following anterior or posterior cervical approaches [18,23,43]. Additionally, 4 (21.1%) studies [20,36,38,40] did not specify treatment methods. All studies used more than 5 predictors. Regarding modeling algorithms, Maki et al [41] used 16 ML methods, Kitagawa et al [44] used 15, Zhang et al [25,43] applied 11 algorithms across 2 studies, and other studies used between 1 and 8 algorithms. These algorithms included CatBoost, LightGBM, random forest, gradient boosting, Extra Trees, XGBoost, k-nearest neighbors, Adaptive Boosting (AdaBoost), decision trees, and various regression methods (linear, ridge, least-angle, Bayesian ridge, lasso, Huber, and elastic net), along with support vector machines. Due to marked differences in prediction targets, modeling algorithms, sample sizes, and validation methods among the studies, a comparative analysis of model features and performance was performed in the following section.

[a]ST: surgical treatment.

[b]CT: conservative treatment.

[c]AIS: American Spinal Injury Association Impairment Scale.

[d]FIM: Functional Independence Measure.

[e]IANR: International Association of Neurorestoratology.

[f]FAC-DC: Functional Ambulation Category at discharge.

[g]SCIM: Spinal Cord Independence Measure.

[h]NR: not reported.

[i]ADL: activities of daily living.

Considering the considerable variability among the included studies, we conducted a structured narrative synthesis to uncover patterns rather than merely summarizing each model's performance. Our cross-study comparison centered on predictor categories, outcome domains, algorithm families, validation methods, and the reporting of performance metrics, including calibration.

Predictor Groups

The predictors used in various studies can be generally categorized into four groups: (1) demographic and baseline patient attributes, such as age and sex; (2) indicators of neurological and clinical severity, including AIS grade and functional status at the start; (3) treatment-related factors such as surgical versus conservative management and perioperative

XSL•FO
RenderX

details; and (4) features derived from imaging or other high-dimensional data, especially radiomics-based variables. Most (13/19, 68.4%) studies [18-22,24,36-41,44] used multivariable predictor sets that combined demographic and clinical factors, while a smaller number (5/19, 26.3%) [23,25,26,43,45] included imaging features or multimodal data. This pattern suggests that current SCI prognostic models primarily rely on routinely collected clinical data, whereas imaging-focused models constitute a more specialized subset.

Variability in Outcomes

There was considerable heterogeneity in the predicted outcomes, including neurological recovery, functional independence, gait recovery, ADL, discharge walking ability, and postoperative recovery. The studies used various measures, including AIS, SCIM, FIM, Functional Ambulation Category at discharge (FAC-DC), ADL, walking ability, and International Association of Neurorestoratology (IANR) score, as their primary outcomes. Outcomes related to AIS were the most frequently reported, followed by SCIM and FIM. Besides differences in outcome scales, the timing and clinical relevance of these outcomes varied, ranging from short-term neurological improvements to functional status at discharge and beyond. This variability complicates direct comparisons of model performance across different studies.

Algorithm Families

The studies also showed distinct clustering based on algorithm family. One group [21,23,42] mainly used regression-based or traditional statistical models, such as logistic regression, linear regression, ridge regression, and lasso. A second group [18,21,25,43] used ML methods based on trees or kernels, including random forest, decision trees, support vector machines, XGBoost, LightGBM, gradient boosting, and related ensemble techniques. A third group [19,20,26,37,40] used neural network or deep learning approaches, such as artificial neural networks, convolutional neural networks, recurrent neural networks, and deep learning–based radiomics. Tree-based and ensemble algorithms were among the most frequently tested, often compared with regression methods within the same dataset. Nonetheless, no single algorithm family consistently outperformed others in all studies, due to notable variations in outcomes, predictor sets, and validation protocols.

Validation Patterns

Validation strategies varied across the studies. Of the 19 studies, 2 (10.5%) [19,37] focused solely on model development, while most (16/19, 84.2%) combined model development with internal validation methods, such as data partitioning or cross-validation [18,20-26,36,38-42,44,45]. Only 1 (5.3%) study [43] performed external validation using an independent temporal dataset. Consequently, the evidence base is mainly composed of internally validated studies, with limited evaluation of how well these models generalize to other settings.

Patterns in Performance Reporting

The evaluation of model performance primarily focused on discrimination metrics. Most classification studies reported measures such as area under the receiver operating characteristic curve, accuracy, sensitivity, and specificity, whereas regression studies reported root mean square error, mean absolute error, coefficient of determination (R^2), mean squared error, or root mean squared logarithmic error more frequently. Conversely, calibration was seldom reported in a structured way, with formal calibration metrics or plots largely absent. Only 5.3% (1/19) of study [23] used decision curve analysis, but these do not replace calibration assessment. This pattern suggests that the current literature emphasizes discrimination over agreement between predicted and observed outcomes, thereby hampering the assessment of clinical usefulness.

Overall, these cross-study patterns indicate that the literature on ML-based SCI prognostic models is marked by both methodological variety and common structural imbalances. These include frequent use of mixed clinical predictors, marked variability in outcome definitions, a focus on tree-based and ensemble algorithms, reliance on internal validation, and limited calibration reporting. These patterns are important to consider when evaluating differences in model performance. A structured comparison of study features is provided in Table 1 and Multimedia Appendix 1 [18-26,36-45].

Reporting Quality

Overview

Regarding reporting completeness, of the 19 studies, 7 (36.8%) [21,23-25,37,40,41] achieved at least 70% adherence across all TRIPOD domains, including title and abstract, background and objectives, methods, results, discussion, and supplementary information. Conversely, 2 (10.5%) studies [36,45] reported adherence of less than 60%. The adherence rates for each TRIPOD item are detailed in Multimedia Appendix 2. Overall, adherence per study ranged from 54.8% (17/31) to 81.1% (30/37), with a median of 74.2% (IQR 64.5%-77.4%). Additionally, 7 (36.8%) studies [18,20,22,26,38,39,42] met or exceeded the 60% adherence threshold.

Title and Abstract (Items 1-2) and Background and Objectives (Items 3)

Of the 19 studies, 14 (73.7%) [18-21,23,24,36-38,40,42-45] fully reported the requirements for titles and abstracts. Five (26.3%) studies [25,26,39,41,43] did not explicitly clarify whether they focused on model development, validation, or both, although most (14/19, 73.7%) included target populations and outcomes in their titles. A minority of the descriptions included predictors in the abstracts. All studies provided detailed descriptions of their research backgrounds.

Methods (Items 4-12)

All studies reported data sources, outcome definitions, assessment methods, timing for predictors, and model performance metrics. A total of 14 (73.7%) studies [19-21,23-25,36-41,44,45] specified key study dates; 13 (68.4%) studies [19,20,23-26,37-41,43,45] detailed participant inclusion and exclusion criteria. Treatment information was provided in 5 (26.3%) studies [19,23,42-44]. Only 2 (10.5%) studies [41,44] described procedures for blinded outcome assessment unaffected by predictor knowledge. Blinded predictor assessment was used in 4 (21.1%) studies [18,21,43,44]. Six (31.6%) studies [22,24,25,38,39,41] documented the handling of missing data

XSL•FO
RenderX

using imputation methods. Risk stratification criteria were clearly defined in 4 (21.1%) studies [23,40,42,43]. One (5.3%) study [45] did not report critical setting elements and predictor preprocessing. Another [18] omitted details on full model development procedures. None of the studies justified their sample size. Zhang et al [43], in an external validation study, reported the calculation methods for predictors and noted discrepancies in settings, eligibility criteria, outcomes, and predictors compared with the development dataset, but did not include details on model updating.

Results (Items 13-17)

All studies (19/19, 100%) presented performance metrics for the prediction models. Participant flow diagrams were included in 16 (84.2%) studies [19-26,36-41,43,44]. Sixteen (84.2%) studies [18-26,37-41,44,45] provided details on the number of participants and outcome events. Seven (36.8%) studies [19,21-23,37,42,43] reported unadjusted associations between potential predictors and outcomes. Full model specifications were available in 10 (52.6%) studies [18,19,21,22,25,26,37,41,43,44], while instructions for applying the models were given in 10 (52.6%) studies [18,19,21,22,25,26,41-44]. Only 1 (5.3%) study [42] lacked basic demographic information. Although Zhang et al [43] performed external validation, they did not specify any results related to model updating.

Discussion (Items 18-20) and Supplementary Information (Items 21-22)

All studies acknowledged limitations and provided overall interpretations of their findings, covering study objectives, limitations, results from similar research, and other relevant evidence. In total, 12 (63.2%) studies [18-21,24,37,38,40-43,45] addressed clinical applicability and implications for future research. Supplementary resource availability was noted in 7 (36.8%) studies [23-25,40,43-45]. Funding sources and the roles of funders were disclosed in 13 (68.4%) studies [18-20,23,24,26,37,39-44]. Zhang et al [43] reported results based on development data and other validation datasets.

Risk of Bias and Applicability Assessment

The risk of bias and applicability of the included studies were assessed using PROBAST, with detailed results shown in Table 2. All 19 studies were rated as having a high overall risk of bias. In PROBAST, judgments were based on domain-specific signaling questions and the overall pattern of methodological limitations across studies. In the participants' domain, concerns mainly focused on the use of retrospectively assembled cohorts with limited reporting of eligibility criteria, patient selection procedures, or data source consistency, rather than on the retrospective design itself. For predictors, 10 (52.6%) studies [19,20,22,23,36-40,42] were rated as high risk due to possible inconsistencies in predictor assessment and data collection methods across centers, as well as the risk of bias from outcome awareness during measurement. In the outcome domain, 17 (89.5%) studies [19,20,22-26,36-45] were judged to be at high risk of bias because outcome assessment procedures were insufficiently reported and may have been influenced by knowledge of predictor information. In the analysis domain, some studies (n=2, 10.5%) did not meet commonly used sample size rules of thumb for prediction model research, such as ≥20 events per variable during model development [46] and at least 100 events and 100 nonevents for external validation [47]. Two (10.5%) studies [23,40] had insufficient modeling samples, and 4 (21.1%) studies [25,39,40,43] had validation samples below 100. Predictor selection was based solely on literature or clinical experience in 5 (26.3%) studies [21,23,36,41,42], while selection methods were unreported in 2 (10.5%) studies [26,45]. Missing data handling was inadequate in 13 (68.4%) studies [18-21,23,26,36,37,40,42-45]. Overall applicability concerns were deemed low across the included studies, consistent with Table 2, indicating that the review questions, target populations, predictors, and outcomes of the included studies broadly align with the scope of this review.

Discussion

Principal Findings

This systematic review found that ML-based prognostic prediction models for adults with SCI remain methodologically promising but clinically immature. Across 19 studies, TRIPOD adherence was incomplete, with a median of 15 of 22 TRIPOD items (74.2%) completed, and all studies were judged to have a high overall risk of bias. The main weaknesses were insufficient justification of sample size, incomplete handling of missing data, limited reporting of blinded predictor and outcome assessment, scarce calibration assessment, and very limited external validation. Only 1 (5.3%) of 19 studies externally validated a model. These findings indicate that most models should be viewed as exploratory rather than ready for routine clinical implementation, which is consistent with recent SCI-focused evidence showing that, although ML models may predict SCI prognosis with relative accuracy, larger datasets, stronger validation, and more rigorous model development remain necessary before clinical implementation [48,49].

Methodological and Reporting Limitations

The high overall risk of bias observed in this review should not be interpreted as meaning that retrospective prediction model studies are inherently unreliable. Rather, the PROBAST judgments reflected multiple modifiable methodological limitations, particularly in the analysis domain. None of the included studies justified their sample size, 13 (68.4%) of 19 studies had inadequate handling of missing data, and several (n=4, 21.1%) studies tested multiple algorithms without sufficient evidence that overfitting was adequately controlled. In several (n=4, 21.1%) studies [20,22,36,38], concerns also arose from insufficiently described participant selection procedures or limited data sources, which may have reduced representativeness and increased the risk of selection bias.

Prospective studies require standardized, multidimensional clinical data collected over clinically meaningful follow-up periods, which is resource-intensive and difficult to implement in SCI prognostic modeling [48,50,51]. As a result, most included studies relied on retrospective datasets. Although retrospective data can be useful for early model development, they are often affected by small sample sizes, heterogeneous treatment pathways, incomplete follow-up, and missing baseline or outcome data. For example, Lin et al [23] included only 82 eligible patients, and Kishikawa et al [40] enrolled 80 patients without clearly defined inclusion or exclusion criteria, both of which may have increased the risk of biased or unstable model estimates.

XSL•FO
RenderX

Incomplete adherence to prediction model reporting and appraisal standards was another important limitation, particularly considering recent PROBAST+AI guidance, which emphasizes quality, risk of bias, and applicability assessment for prediction models developed using regression or AI methods [52]. The included studies did not fully follow TRIPOD and PROBAST recommendations. Common problems included insufficient reporting of treatment details, lack of blinded predictor or outcome assessment, incomplete description of missing-data methods, unclear risk stratification criteria, inadequate reporting of unadjusted predictor-outcome associations, and limited availability of model implementation details or supplementary materials. Similar problems have been reported in other reviews of clinical prediction models, in which most included studies were judged to have a high risk of bias because of methodological flaws, incomplete outcome reporting, or small sample sizes [53,54]. These findings suggest that the methodological limitations identified in this review are not unique to SCI but reflect broader challenges in ML-based prediction research.

External validation was particularly limited. Only one included study [43] conducted external validation using an independent temporal cohort. This is problematic because internal validation alone cannot fully assess whether a model will generalize to different institutions, patient populations, rehabilitation pathways, or clinical settings [50,55]. Models without external validation may show optimistic performance in the development dataset but perform less well when applied in real-world clinical practice. Therefore, the current evidence base remains insufficient to support broad implementation of these models, particularly because clinical prediction models generally require external validation, model updating when performance changes across settings, and implementation evaluation before routine clinical use [51].

Substantial Interstudy Heterogeneity

Substantial heterogeneity was observed across studies in outcome measures, predictor selection, modeling algorithms, validation strategies, and performance metrics. The predicted outcomes included neurological recovery, functional independence, gait recovery, ADL, discharge walking ability, and postoperative recovery. Different studies used different outcome scales, including AIS, SCIM, FIM, FAC-DC, ADL, walking ability, and IANR. The timing of outcome assessment also varied, ranging from short-term neurological improvement to functional status at discharge or later follow-up. This heterogeneity prevents direct quantitative comparison of model performance and limits the ability to identify which modeling approach is most suitable for SCI prognosis.

Algorithm selection also varied widely. Some studies used traditional regression-based models, whereas others used tree-based methods, ensemble algorithms, neural networks, deep learning, or radiomics-based approaches. Several studies [41,44] tested 15 to 16 algorithms, which may increase the risk of overfitting or selective emphasis on the best-performing model, particularly when sample sizes are limited. At present, no single algorithm family can be considered consistently superior across SCI prognostic tasks because the available studies differ substantially in clinical context, outcome definitions, predictor sets, and validation methods.

Clinical Applicability and Implementation Barriers

Beyond methodological quality, the clinical usefulness of current SCI prognostic models remains limited. For a model to be clinically valuable, it should answer a clearly defined clinical question, use predictors available at the time of decision-making, provide outputs that clinicians can interpret, and demonstrate acceptable performance beyond the original development dataset [50,56-59]. Most included studies did not fully meet these conditions.

First, many models were developed using retrospective data from single centers or limited multicenter datasets, raising concerns about generalizability across different health care systems, rehabilitation pathways, and patient populations [60]. Second, some models relied on complex pipelines, imaging-derived features, or multiple algorithms without clearly demonstrating bedside feasibility. A model may perform well internally but still have limited practical value if it depends on specialized software, uncommon image-processing procedures, or predictors that are not routinely available in daily clinical care.

Third, interpretability is especially important in SCI care. Prognostic predictions are used not only to support clinicians' decisions but also to communicate expected neurological recovery, functional prognosis, rehabilitation goals, and discharge planning to patients and families [61-63]. Models that lack clear explanations may have limited acceptance, even if they show good discrimination. Fourth, prediction errors may have meaningful clinical consequences. Overly optimistic predictions could misguide rehabilitation planning and patient counseling, whereas overly pessimistic predictions could lead to unnecessary restrictions in therapy intensity or referral decisions [64]. Therefore, clinical implementation requires not only discrimination or accuracy but also calibration, transparency, interpretability, robustness, usability, and assessment of decision consequences [65].

Comparison Between ML and Traditional Models

Although some included studies reported better discrimination or accuracy for certain ML models than for conventional statistical approaches, the current evidence does not support a general conclusion that ML consistently outperforms traditional models in SCI prognostic prediction. Direct comparisons were limited, and when available, they were usually based on individual datasets with different outcomes, predictor sets, preprocessing methods, and validation strategies. Because most studies relied only on internal validation and all were judged to have a high overall risk of bias, any apparent performance advantage of ML should be interpreted cautiously.

A more balanced interpretation is that ML may be useful in specific scenarios, particularly when modeling complex nonlinear relationships, high-dimensional predictors, imaging-derived features, or multimodal clinical data. For example, radiomics-based or ensemble techniques may be promising for selected postoperative or imaging-focused prediction tasks [25,43]. However, traditional regression models

XSL•FO
RenderX

may remain appropriate when sample sizes are small, predictor sets are limited, and interpretability is a priority. Nomogram-based approaches may also offer practical value because they can translate complex statistical models into visual tools that support individualized risk estimation [25]. Future studies should conduct transparent and predefined comparisons between ML and conventional models within the same clinical context, using rigorous external validation, calibration assessment, and clinical utility evaluation [66].

Implications for Future Research

Future research should prioritize the development of streamlined, clinically meaningful, and externally validated prediction models. This review examined 42 prediction models using diverse predictors, including demographic characteristics, disease-related variables, imaging features, and treatment-related factors, reflecting the multifactorial nature of SCI prognosis. However, adding too many predictors can increase computational burden, reduce model stability, and make clinical implementation more difficult [50,67]. Future models should therefore use careful variable selection, simpler model structures when appropriate, regularization methods to reduce overfitting, and validation protocols that reflect real clinical settings [67,68].

Standardization is also essential. Future studies should develop core outcome sets for SCI prognostic modeling, clearly define outcome timing, and consider more granular outcomes, such as segmental motor recovery when clinically appropriate, rather than relying only on broad functional scales or aggregate motor scores [69]. Multicenter prospective cohorts are needed to increase sample size, improve representativeness, and reduce the effect of single-center practice patterns. Researchers should justify sample size requirements, report missing-data methods with clear methodological reasoning, assess calibration, and provide full model specifications or accessible implementation tools. External validation should include temporal, geographic, or multicenter validation, and model updating should be considered when performance changes across settings or over time.

Study Limitations

This review has several limitations. First, substantial heterogeneity in predictors, modeling algorithms, outcome measures, follow-up times, and performance metrics prevented quantitative pooling or direct comparison of model performance. Second, although we used TRIPOD and PROBAST to systematically assess reporting quality and risk of bias, these assessments depended on the information reported in the original studies; therefore, some judgments may have been influenced by incomplete reporting rather than by confirmed methodological flaws. Third, although TRIPOD and PROBAST assessments were conducted independently by 2 reviewers and disagreements were resolved by consensus, interrater reliability measures, such as Cohen kappa, were not calculated because the independent preconsensus ratings were unavailable. This may limit the transparency of the assessment process. Finally, we did not formally evaluate publication bias because quantitative pooling was not performed and the included studies were highly heterogeneous; however, reporting and dissemination bias may still exist and should be considered when interpreting the findings.

Conclusions

ML shows methodological promise for prognostic prediction in SCI, particularly when complex clinical, imaging, or high-dimensional data are available. However, current evidence remains exploratory because of incomplete reporting, high risk of bias, heterogeneous outcomes, limited calibration assessment, and scarce external validation. Future studies should use standardized SCI-specific outcome frameworks, transparent reporting, appropriate sample size justification, robust external validation, and explicit assessment of clinical usefulness before these models are implemented in routine practice.

Abstract

Ambient AI scribes have been rapidly adopted across health care organizations to mitigate documentation burden and burnout. Initial single-system reports described substantial time savings, but more recent multisite evaluations and meta-analyses describe modest, heterogeneous effects with generally low methodological quality. Most evaluations emphasize efficiency and satisfaction, leaving potential effects on communication quality, narrative preservation, cognitive performance, and equity largely unmeasured. This viewpoint aimed to characterize evaluation patterns in prominent ambient AI scribe implementations, explain why unmeasured domains warrant investigation for patient safety and care quality, and propose an expanded framework with feasible research priorities. This analytic viewpoint mapped evaluation domain coverage in a purposive, illustrative sample of prominent implementation reports published through April 2026, then synthesized findings with literature on clinical communication, narrative medicine, automation effects, and health equity. Reporting was guided by Scale for the Assessment of Narrative Review Articles (SANRA) principles for narrative reviews; PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) was not used because the work is a domain-coverage characterization rather than an evidence synthesis estimating effects. A single reviewer (VSME) performed selection and extraction, consistent with the viewpoint's illustrative intent. Across the included implementations, evaluation consistently measured documentation time, after-hours work, and clinician satisfaction. Within this illustrative sample of 6 independently peer-reviewed real-world implementation evaluations, we did not identify any that reported systematic assessment of patient-clinician communication using validated instruments, structured comparison of AI-generated against human-generated notes for narrative fidelity, longitudinal evaluation of cognitive or educational effects, or equity analyses stratified by language and demographic group. The absence in this purposive sample reflects an absence of public reporting rather than proof that no organization has measured these dimensions internally. Limited error analyses found frequent omissions, with accuracy declining as encounter complexity increased. Evidence from multilingual and interpreter-mediated encounters was notably sparse. Current evidence supports continued implementation with quality safeguards in settings where benefits are demonstrated locally rather than universal adoption on the strength of early single-system reports. Organizations implementing ambient AI scribes should consider embedding prospective evaluation across 4 domains: validated communication quality measurement, structured narrative content comparison, longitudinal cognitive and training studies, and equity analyses across languages and demographics. Three near-term priorities offer immediate feasibility for organizations with evaluation capacity: (1) deploying validated communication instruments such as the Communication Assessment Tool or Consumer Assessment of Health Care Providers and Systems (CAHPS) within ongoing rollouts; (2) launching multisite longitudinal trainee cohorts comparing programs with and without ambient AI exposure; and (3) oversampling multilingual and interpreter-mediated encounters for stratified equity analyses. Narrative preservation requires foundational methodological work before implementation-ready measures exist. Editors, implementers, and vendors can each act now: editors by requiring domain-coverage reporting; implementers by preregistering evaluation plans before rollout; vendors by publishing stratified performance data as a routine condition of deployment. The goal is to preserve documented efficiency gains while generating evidence about communication, narrative, reasoning, and equity dimensions that current evaluations leave unmeasured.

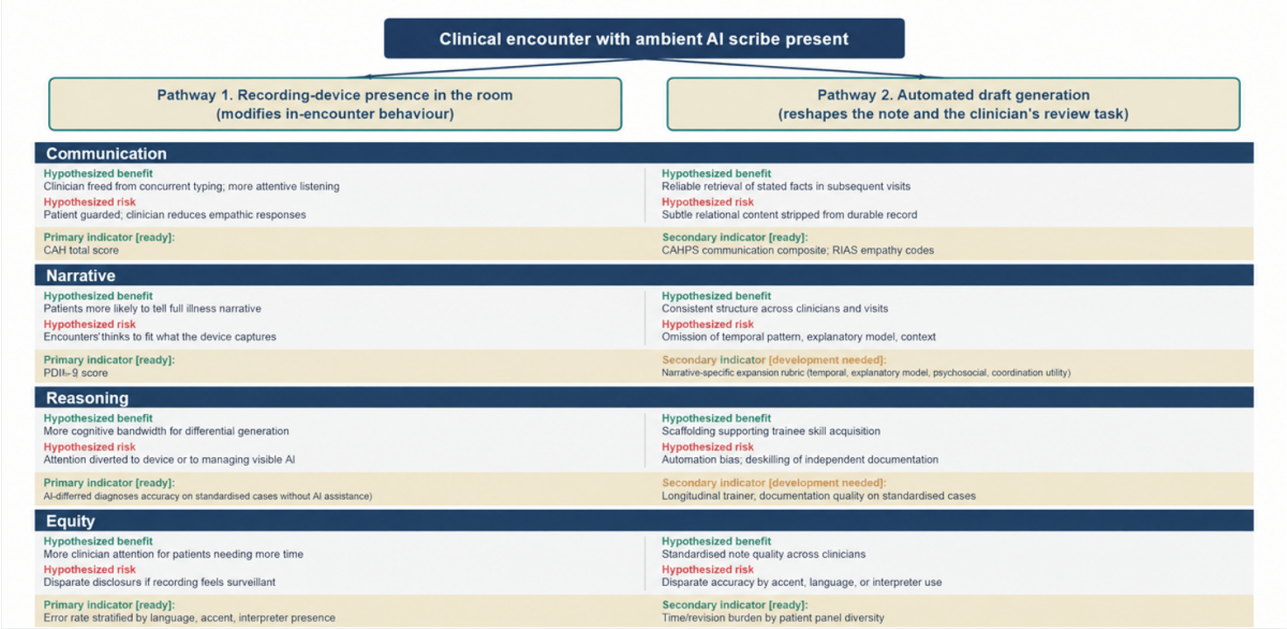
Introduction

Clinical documentation burden represents a significant workforce crisis in modern medicine. Nearly half of US physicians report burnout symptoms, contributing an estimated US $4.6 billion annually in costs from turnover and reduced clinical hours [1]. Physicians spend approximately 2 hours on electronic health record tasks for every hour of direct patient care [2], often extending 1 to 2 hours into evenings [3]. This burden links directly to patient safety, as burnout correlates with higher self-reported medical errors [4] and poor electronic health record usability independently associates with increased burnout [5].

Ambient AI scribes have been rapidly adopted to address this crisis [6]. Initial reports described substantial efficiency and well-being gains, with reductions in documentation time and burnout rates [7]. More recent evidence is more measured. A multisite study found only modest decreases in total electronic health record time and documentation time alongside a modest increase in weekly visit volume [8], and a systematic review and meta-analysis of 23 studies [9] demonstrated a moderate pooled reduction in documentation workload across 14 studies (standardized mean difference −0.71; 95% CI −0.93 to −0.49) but considerable heterogeneity across studies and generally low methodological quality. The effect of ambient AI scribes on documentation workload appears real but variable, setting-dependent, and supported by an evidence base in which study quality remains an important limitation. Current evaluation frameworks focus predominantly on these efficiency metrics, creating evidence gaps concerning domains central to patient safety and care quality.



Systematic error analyses remain rare. One instrument-validation study comparing AI-generated drafts against reference standards found errors that must be evaluated to mitigate safety risks [10]. Accuracy degrades as clinical complexity increases [11]. Evidence is largely absent for performance in multilingual or interpreter-mediated encounters. Ambient AI scribes combine automatic speech recognition, speaker diarization, and large-language-model summarization [12,13], and inequities may arise at any of these stages. Underlying automatic speech recognition components alone show significant accuracy disparities across racial and dialect groups [14]. These are component-level findings, not direct evidence of ambient-scribe inequity; the downstream note reflects compounded effects from across the pipeline. A staged audit that follows the pipeline—word error rates by language, accent, and dialect group first; speaker attribution accuracy second; clinical-concept and narrative-relevant omission third—is feasible with existing tools and is the analytic foundation for equity claims about full ambient-scribe systems. Documentation automation bias is the analogous concern at the synthesis stage: clinicians may accept an AI-generated narrative that then shapes downstream reasoning, coding, orders, and the medico-legal record. Plausible failure modes include a missed red-flag symptom in the history of present illness, an inflated problem list, or an incorrect speaker attribution that quietly redirects the differential. The mechanism is well characterized in the health care automation bias literature for decision support [15]; how it translates when the AI output is the encounter narrative rather than a discrete recommendation is an open empirical question. Direct measures of patient experience remain largely absent from this literature [16]. Errors and omissions in clinical documentation propagate through downstream care: notes guide handoffs, coding, continuity decisions, and the medicolegal record on which subsequent clinicians depend [17].

Given documented time savings and reduced burnout, ambient AI scribes rank among the most swiftly adopted clinical AI technologies [7,18]. At this scale, failing to systematically assess impacts on care quality leaves a set of plausible, testable risks unexamined: that patient-clinician communication may be subtly altered, that clinical narratives important for care coordination may be degraded, and that documentation accuracy may differ across patient populations [19,20]. We do not claim these harms are established for ambient scribes; we argue they are plausible and measurable using existing instruments, on the strength of adjacent evidence on clinical communication, automation effects, electronic health record narrative quality, and speech-recognition equity.

This viewpoint characterizes current evaluation patterns in prominent ambient AI scribe implementations, explains why unmeasured domains warrant investigation for care quality, and proposes an expanded assessment framework guiding future research and responsible adoption. To organize the analysis, we present a conceptual model (Figure 1) describing how ambient AI scribes may affect care quality through 2 parallel pathways: the presence of a recording device in the clinical encounter, which modifies in-encounter behavior, and automated draft generation, which reshapes the resulting note and the clinician's review task. Each pathway has plausible benefits and risks across the 4 evaluation domains we consider, communication, narrative, reasoning, and equity, with example measurable indicators that anchor the proposals that follow.

Scope and Analytic Approach

We conducted a purposive, analytic review characterizing evaluation patterns in ambient AI scribe implementations rather than a systematic review. The aim was to map evaluation domain coverage in a purposive, illustrative sample of independently peer-reviewed real-world implementations, not to estimate intervention effects or to summarize the totality of available evidence. We chose Scale for the Assessment of Narrative Review Articles (SANRA) over PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) because the work is a domain-coverage characterization rather than an evidence synthesis; structured-review reporting standards would imply dual screening, formal risk-of-bias appraisal, and exhaustive searching that we did not perform. Reporting was guided by the Scale for the Assessment of Narrative Review Articles (SANRA) [21], and abstraction of implementation features drew on DECIDE-AI (Developmental and Exploratory Clinical Investigations of Decision Support Systems Driven by Artificial Intelligence) guidance for the early-stage evaluation of decision-support systems driven by AI [22]. DECIDE-AI was developed for AI decision-support systems rather than documentation tools; we adopt its abstraction items because ambient AI scribes share the implementation features for which DECIDE-AI was designed—live clinical use, iterative product changes during deployment, embedded human-AI workflow, and the need for safety monitoring under real-world conditions. We do not import DECIDE-AI's outcome categories wholesale, since its decision-support emphasis on diagnostic accuracy does not map directly onto documentation evaluation. Throughout, we use "prominent implementation reports" to mean publicly available, independently peer-reviewed evaluations of real-world ambient AI scribe deployments meeting all of the following: (i) deployment at a named health system or large practice (operationalized here as a multiclinic group or a named practice with a defined minimum number of clinicians, a threshold chosen to exclude micropilots and single-clinic demonstrations while retaining such practices, rather than a single-site pilot without organizational identification; where clinician count was not reported, multiclinic or enterprise-deployment language served as a proxy); (ii) reporting of at least 1 quantitative outcome relevant to documentation burden, after-hours work, clinician burnout or satisfaction, note quality, or error profile; and (iii) sufficient methodological detail to permit characterization of evaluation domain coverage. This definition is operationalized by the selection criteria for illustrative implementations below.

We searched PubMed, Google Scholar, and Scopus on several occasions, with the final search for this revision completed in April 2026. Search terms combined the concept of ambient AI scribes ("ambient AI scribe", "digital scribe," "AI-powered scribe," "ambient documentation," "generative AI documentation") with the concepts of clinician outcomes (clinician OR physician OR "health professional"), evaluation ("implementation," "evaluation," "documentation time," and "burnout"), and clinical setting ("health system," "health care," "primary care," and "specialty care"). Searches were limited to English-language items published through April 2026. Results were supplemented by hand-searching reference lists of included articles, organizational websites of major health systems publicly reporting deployments, and independent evidence scans. Selection criteria for illustrative implementations required (i) a real-world implementation of an ambient AI scribe in clinical practice; (ii) reporting of at least 1 quantitative outcome relevant to documentation burden, after-hours work, clinician burnout or satisfaction, note quality, or error profile; and (iii) sufficient methodological detail to permit characterization of evaluation domain coverage. We excluded purely simulation-based studies, vendor case studies without independent peer review, and editorial commentary without primary data. Searches identified records after deduplication; these underwent full-text screening, and 6 met all selection criteria. The smaller number reflects

XSL•FO
RenderX

strict requirements for independent peer review and detailed outcome reporting; a larger pool of studies cited elsewhere in this viewpoint informed the synthesis but did not meet criteria for inclusion in Table 1. A single reviewer (VSME) performed selection and extraction without dual screening or formal quality assessment. Because the goal was to illustrate evaluation patterns rather than estimate effects, we used single-reviewer screening with conservative selection criteria and a prespecified structured extraction grid; we describe operational definitions in the next paragraph and provide the full extraction grid as Supplementary Material. Missed studies remain possible and this is acknowledged as a methodological limitation.

Table . Evaluation domains assessed in major ambient AI scribe implementations[a].

Implementation	Setting, scale, and duration	Efficiency	Satisfaction	Communication	Narrative	Reasoning	Equity
Tierney (Permanente) 2024 [23]	Integrated delivery system	Yes[b]	Yes	Subj.[c]	No[d]	No	No
Tierney (Permanente) 2025 [24]	Integrated delivery system; approx. 2.5 million encounters; approx. 12 months	Yes	Yes	Subj.	Subj.	No	No
Olson et al 2025 [7]	Multicenter quality improvement study in ambulatory settings	Yes	Yes	No	No	No	No
Liu et al. 2024 [25]	Nonrandomized clinical trial	Yes	Yes	No	Subj.	No	No
Davis et al. 2026 [26]	University of Rochester large academic medical center, outpatient care, 49 providers across 9 departments	No	No	Subj.	No	No	No
Evans et al (Australian Allied Health) 2025 [27]	Australian allied health private practice; clinician and patient perspectives	Yes	Yes	No	No	No	No

[a] The threshold for Yes (systematically assessed) is the use of a validated patient-reported instrument, an objective system-derived measure, or a structured audit against reference notes or transcripts. For Communication, this means the Communication Assessment Tool, the Consumer Assessment of Health Care Providers and Systems (CAHPS) Clinician and Group communication composite, or Roter Interaction Analysis System-coded analysis; for Satisfaction, the Maslach Burnout Inventory, Mini-Z, or the Stanford Professional Fulfillment Index; for Narrative, the Physician Documentation Quality Instrument (PDQI-9) or a structured audit; for Efficiency, the electronic health record audit-log time-on-documentation. Subj. denotes subjective perceptions reported through clinician self-report, single-item questions, or open-ended comments without instrumented measurement. No denotes absence of public reporting and does not prove absence of unaffected performance or of internal evaluation. General patient experience measures (overall satisfaction, perceptions of physician computer use during visits) are reported separately in the Documented Benefits text and should be distinguished from validated communication assessment; the latter is what the Communication column captures. Borderline cases were classified conservatively: unvalidated local surveys were classified Subj.; proprietary vendor scores without disclosed rubric were classified No; ambiguous instrument provenance was classified Subj. Full classification rules are detailed in Methods and in the Supplementary Material.

[b]Yes: systematically assessed with validated instruments or objective measures.

[c]Subj: subjectively assessed through unstructured self-report or single-item perceptions.

[d]No: not assessed in published reports.

We categorized reported outcomes in each domain according to operational definitions established before Table 1 was populated. An outcome was classified as systematically assessed when measured using a validated instrument (such as the Communication Assessment Tool, Consumer Assessment of Health care Providers and Systems (CAHPS) communication composite, Maslach Burnout Inventory, or Mini-Z), an objective electronic health record-derived measure (such as audit-log documentation time), or a structured audit against reference notes or transcripts. An outcome was classified as subjectively assessed when reported through unstructured clinician self-report, single-item perceptions, or open-ended comments without instrumented measurement. An outcome was classified as not assessed in published reports where the publication did not report any measure of that domain. Borderline cases were classified conservatively: a locally developed 3-item survey without published psychometric properties was classified as subjective rather than systematic; a vendor-dashboard “note quality score” without disclosed scoring rubric was classified as not assessed for the relevant domain, since absence of

XSL•FO
RenderX

methodology prevented interpretation; where instrument provenance was unclear, the outcome was classified as subjective. Absence of public reporting does not prove absence of internal evaluation by implementing organizations. A second reviewer was not available for adjudication; this limitation is acknowledged.

Implementation features were abstracted to inform a design and reporting features table (Table 2) detailing study design, comparator, follow-up duration, vendor, setting, outcome ascertainment method, and whether patient-level data were collected. We do not claim to apply a formal risk-of-bias instrument; the table summarizes design and reporting characteristics relevant to interpretability. Abstraction items drew specifically from DECIDE-AI guidance on context of use, workflow integration, human factors, and safety monitoring under live clinical conditions, and outcome ascertainment, providing a structured basis for interpreting the evaluation domain coverage shown in Table 1 [22]. To motivate an expanded evaluation framework, we synthesized these implementation patterns with established literature on clinician burnout [28], patient-clinician communication measurement [29], narrative medicine, automation bias [15], and health equity in speech recognition [30]. This integrative approach aimed to identify systematic measurement gaps, explain why unmeasured domains may affect patient safety and care quality, and propose feasible research priorities for active deployments.

Table . Design and reporting features for the studies in Table 1.[a]

Implementation	Study design	Comparator	Follow-up	Vendor	Data source	Patient-level data
Tierney (Permanente) 2024 [23]	Pre- and postimplementation cohort	Predeployment baseline	10 weeks	Abridge (proprietary)	EHR[b] audit logs; clinician survey	No
Tierney (Permanente) 2025 [24]	Longitudinal observational cohort	Predeployment baseline	Approximately 12 months	Abridge (proprietary)	EHR audit logs; clinician survey	No
Olson et al 2025 [7]	Multicenter quality improvement study	Preimplementation baseline	1 month	Multiple (mixed)	Clinician survey	No
Liu et al 2024 [25]	Nonrandomized clinical trial	Predeployment baseline	5 weeks	Single proprietary	EHR audit logs; clinician survey	No
Davis et al 2026 [26]	Retrospective provider-level pre- and postcohort	Each provider's pre-DAX[c] baseline; no concurrent control	Variable postuse period from first use in March–July 2024 through December 2024	Nuance Dragon Ambient eXperience	Epic Signal encounter counts and provider-level aggregate Press Ganey data	No
Evans et al (Australian Allied Health) 2025 [27]	Mixed methods (survey and interviews)	Within-clinician comparison	Several months	Proprietary AI scribe	Clinician survey; patient interviews	Limited

[a]Vendor names are reported as published; some implementations involved multiple vendors or do not name a vendor publicly. "Patient-level data" indicates whether outcomes were measured at the patient encounter level (Yes), only at the clinician level (No), or partially (Limited—eg, subset of patient interviews). All included studies are at moderate-to-high risk of bias for clinical effectiveness conclusions because of pre-post or single-arm design, absence of blinding, and short follow-up; this risk profile is associated with early-stage implementation evaluation [31] and is consistent with the generally low methodological quality identified by the recent systematic review and meta-analysis of AI documentation tools [9].

[b]EHR: electronic health record.

[c]DAX: Dragon Ambient Experience.

Documented Benefits

Implementation studies report efficiency benefits across diverse settings, although effect sizes vary. Table 1 summarizes evaluation patterns across 6 implementation studies [7,23-27] published between 2024 and 2026. Table 2 reports the corresponding design and reporting features—study design, comparator, follow-up duration, vendor, setting, and data source—enabling readers to judge whether absent domain coverage reflects absent measurement or absent reporting.

Reported magnitudes are heterogeneous. Kaiser Permanente's deployment across more than 7000 physicians reportedly saved nearly 16,000 documentation hours over 10 weeks, with 70 percent of users reporting reduced burnout [23]. A multisite study across 5 US academic health systems, by contrast, reportedly found modest reductions in total electronic health record time and documentation time alongside a slight increase in weekly visit volume after AI scribe adoption [8], an effect size more in line with the moderate pooled estimates of recent meta-analytic synthesis [9]. Other systems reported significant decreases in burnout measures, with substantial methodological heterogeneity in instrumentation: studies used the Maslach Burnout Inventory, the Mini-Z single-item burnout question, the Stanford Professional Fulfillment Index, and ad hoc single-item measures, and reported a mix of absolute and relative changes. Cross-study numeric comparison should accordingly be made with caution [7]. These findings replicate across organizations, specialties, and practice types, with reproducibility and modest-to-moderate effects more consistent than uniform large benefits [32]. Patient experience data indicated modest benefit. Patient satisfaction scores showed small improvements in some studies [26].

Evidence quality varies substantially by clinical setting. Peer-reviewed evaluations are concentrated in ambulatory settings, with many in primary care and outpatient internal

XSL•FO
RenderX

medicine [32], where encounter structure tends to be predictable and information transfer is a substantial proportion of documentation work. Evidence from specialty care is mixed and considerably thinner, with implementations in pediatrics, oncology, and allied health practice reporting more variable benefits and identifying specialty-specific challenges including management of psychosocial complexity [33-35]. The case for evaluating communication and narrative outcomes is strongest in specialties where lifestyle counseling, chronic disease management, and emotional or psychosocial content occupy the center of the encounter rather than its margins.

Taken together, these reports describe efficiency gains that are real but heterogeneous, modest to moderate in pooled magnitude, and supported by an evidence base in which study quality remains a notable limitation. The case for continued implementation rests on this evidence; the case for systematic evaluation rests on the same evidence and on the question of whether the additional domains addressed below remain unmeasured at scale.

Systematic Measurement Gaps

Tables 1 and 2 reveal a consistent pattern in evaluation approaches across the included publicly reported implementations. All 6 studies [7,23-27] systematically measured time savings or clinician satisfaction, establishing consistent evidence for efficiency and well-being benefits within their methodological constraints. Within this illustrative sample of 6 independently peer-reviewed, real-world implementation evaluations, none systematically assessed communication quality using validated instruments such as the Communication Assessment Tool or CAHPS communication composites. None evaluated narrative content preservation through structured comparison of AI-generated versus human documentation. None examined clinical reasoning effects through longitudinal tracking or automation bias assessment. None stratified performance by patient primary language, demographic characteristics, or encounter complexity. These observations are bounded by our selection criteria and definitions and should not be read as field-wide empirical claims; absence in this sample reflects absence of public reporting in independently peer-reviewed, real-world implementation evaluations meeting our criteria, rather than proof that no implementing organization has measured these dimensions internally.

While some studies report clinicians feeling “more present” or note modest gains in patient satisfaction, these subjective, self-reported impressions are not a substitute for rigorous assessment, given that clinician and patient ratings of communication often show poor agreement [36]. They may represent valuable preliminary signals suggesting positive communication effects. However, subjective impressions without structured assessment provide limited evidence about whether the specific communication dimensions that predict adherence, outcomes [37], and malpractice risk are preserved or affected. Two studies reported subjective perceptions of documentation quality or noted high retention rates of AI-generated content in final notes [20,38], but these assessments differ from a structured comparison examining whether narrative elements essential for care coordination and clinical reasoning are consistently preserved.

Error analyses were provided concerning preliminary data. Biro et al [10] conducted an instrument-validation study comparing AI-generated drafts against reference standards under controlled conditions; this is not a real-world implementation study and findings are not directly generalizable to active clinical practice. Within those constraints, the audit found that AI-generated drafts contained errors that must be evaluated to mitigate safety risks. The meta-analytic synthesis reported that note quality was at least comparable to that of manually prepared notes [9], indicating that aggregated comparison may attenuate the per-note error rates seen in instrument-validation work. Evidence from multilingual encounters, family-mediated consultations, and interpreter-assisted visits was notably absent across both implementation studies and the broader meta-analytic literature.

Why Additional Domains Warrant Investigation

Communication Quality as Foundation of Clinical Effectiveness

Patient-clinician communication fundamentally shapes health care quality. Communication affects diagnostic accuracy through information disclosure completeness [39], treatment adherence through shared decision-making quality [40], and patient satisfaction through perceived caring and partnership [37]. Meta-analyses demonstrate that better communication correlates with improved adherence, improved health outcomes, and higher satisfaction [29,41]. The Joint Commission identifies communication failures among the leading causes of sentinel events [42].

No implementation study in our included sample measured communication quality using validated instruments capable of detecting effects in either direction, leaving this question unresolved within the evidence base most directly relevant to active deployments. In non-AI contexts, evidence regarding recording effects is mixed. Studies examining video recording for research purposes found both minimal impact and meaningful changes in interaction patterns, with effects varying by context [43].

The presence of recording might degrade communication if patients become guarded in disclosure or if clinicians reduce empathic responses knowing these typically do not require documentation. Conversely, recording might improve communication if clinicians, freed from the mental load of concurrent documentation, provide more attentive listening and empathic responses. Patient experience data showing increased perception of physician attention suggests this positive pathway may predominate in many encounters [44]. However, preliminary positive signals from satisfaction surveys, though valuable, differ from systematic assessment using instruments designed to detect subtle changes in communication dimensions that predict clinical outcomes.

The tools exist and are feasible to deploy. Validated measurement of patient-clinician communication operates at 3 levels: multi-item patient-reported scales (the Communication Assessment Tool, a 14-item patient-rated measure of physician

XSL•FO
RenderX

communication developed and tested by Makoul et al [45]; the CAHPS Clinician and Group communication composite, the canonical patient-reported measure for interorganization benchmarking, maintained by the Agency for Health Care Research and Quality [46,47]); observational coding such as the Roter Interaction Analysis System [48]; and encounter-level behavioral proxies derived from audit logs or recordings. The Communication Assessment Tool produces clinician-specific feedback at the visit level and is well suited to local quality improvement [49]; the CAHPS CG communication composite serves as the standard for system-level benchmarking and is distinct from CAHPS general-satisfaction items [50]; observational coding captures interactional patterns invisible to either patient-reported instrument. Local short-form instruments and conversation-analytic methods have a place but produce data less suited to interorganization comparison. The point is not that only the Communication Assessment Tool or CAHPS counts; it is that subjective single-item perception is not equivalent to validated communication measurement, and that pragmatic, deployable instruments already exist. These instruments could be incorporated into ongoing implementations to determine whether preliminary positive signals reflect actual communication quality preservation or improvement, or whether they coexist with subtle degradation in dimensions that general satisfaction questions do not capture.

Narrative Preservation and Care Coordination

Clinical documentation preserves more than discrete biomedical facts. It captures temporal symptom patterns, patient explanatory models, psychosocial context, and narrative coherence, enabling subsequent providers to understand what documented information means for patient care [51]. Research on electronic health record effects found that structured templates, while improving data capture, often degraded narrative coherence, with clinicians reporting that template-driven documentation obstructed building the patient's story [52].

Error analyses indicating frequent omissions in AI-generated drafts under instrument-validation conditions [53] raise concerns about what narrative elements may be systematically lost at scale. Measurement of narrative preservation can proceed in stages. The Physician Documentation Quality Instrument (PDQI-9) provides a starting point: it assesses note quality across 9 dimensions including up-to-date accuracy, thoroughness, usefulness, organization, comprehensibility, succinctness, synthesis, and internal consistency [54] and has been used in prior studies of electronic health record note quality [55]. PDQI-9 fits best as a baseline tool for outpatient consultation notes and is less well suited to high-tempo settings: a study in emergency medicine found that PDQI-9 did not adequately discriminate scribe-note quality, suggesting that adaptation or complementary instruments may be needed for emergency documentation, structured discharge summaries, and consult-to-transfer notes [56]. PDQI-9 does not, in addition, capture the narrative-specific features most at risk under automated documentation, temporal coherence, patient explanatory model, psychosocial context, and care-coordination utility, each of which would benefit from a validated extension or a supplementary scale developed for this purpose. A staged research program would therefore: first, deploy PDQI-9 in comparative studies of AI-generated and pre-AI clinician documentation to establish baseline note-quality differences using existing validated tools; second, develop and validate narrative-specific extensions for the 4 features above; and third, conduct large-scale comparative evaluations using the combined instrument set.

Methodological development must address the comparator problem directly. The relevant question is not whether AI-generated documentation matches an idealized researcher transcript, but whether it preserves narrative content as well as, or better than, the manual documentation it replaces. Manual documentation has its own well-documented gaps, including omissions and inconsistent documentation [57], and equity-relevant disparities in how patients of different backgrounds are described [58]. Validated rubrics should accordingly compare AI output against multiple references, pre-AI manual documentation by the same clinician, peer-clinician documentation, and verbatim transcripts, to distinguish AI-specific failure modes from baseline documentation limitations.

Cognitive Engagement and Skill Development

Documentation differs from clinical decision support in important respects. Decision-support automation bias concerns clinicians accepting an AI recommendation about a discrete clinical decision; documentation automation bias concerns clinicians accepting an AI synthesis of an encounter that itself shapes downstream clinical reasoning. The translation between domains is not trivial: documentation produces a narrative artifact rather than a discrete recommendation; the time-pressure under which review occurs differs; and the failure modes (omission and silent restructuring) are qualitatively unlike an incorrect alert. Even so, the underlying cognitive mechanisms—reliance, overtrust, and reduced critical engagement with an authoritative-looking automated output—plausibly generalize. Evidence from the decision-support context, while not directly transferable, illuminates the mechanism. An empirical study of prescribing decision support reports that clinicians overrode correct initial judgments in approximately 5% of prescribing cases when presented with erroneous automated advice [59]. Recent evidence from large language model diagnostic assistance found physicians using ChatGPT (OpenAI) performed no better than those without AI access despite ChatGPT alone outperforming physicians on the same cases, suggesting superficial engagement with AI outputs [60].

Skill degradation with prolonged automation reliance appears in aviation, surgery, and other domains [61,62]. A multicenter observational study of physicians using AI assistance showed performance degradation when AI was withdrawn, suggesting dependence development rather than skill augmentation [63]. Documentation represents more than transcription—it is where clinical reasoning crystallizes from observations into coherent assessments. If clinicians accept AI documentation outputs without comparable engagement, 3 specific outcomes would demonstrate cognitive offloading rather than helpful scaffolding: trainee-generated notes on standardized cases of lower quality than those of historical comparator cohorts; declining

XSL•FO
RenderX

diagnostic-reasoning performance when AI assistance is withdrawn (the AI-off probe used in adjacent literature [64]); and inverse correlation between AI exposure intensity and standardized reasoning assessments at program exit. Conversely, if AI assistance supports skill development, the same instruments would show preserved or improved performance.

The balance between helpful scaffolding and harmful cognitive offloading likely depends on implementation approach, supervision structures, and whether learners are taught critical engagement with AI outputs. No longitudinal studies compare skill trajectories of trainees with varying AI exposure [65,66], warranting prospective assessment in institutions recently adopting AI scribes.

Performance Equity Across Populations

Equity in clinical documentation is not a problem ambient AI scribes introduce. Studies of manual documentation have revealed disparities, with patients from minority backgrounds more likely to be described in stigmatizing terms [58]. The relevant question for AI scribes is therefore whether they amplify, attenuate, or shift these existing patterns, and whether efficiency gains generalize across populations or accrue disproportionately to some.

Most published AI scribe evaluations have examined primarily English-speaking patients in straightforward encounters [67,68]. Performance in multilingual consultations, interpreter-mediated encounters, and family-involved decision-making remains only partially examined despite these being common in diverse health care settings globally. In Asian health care contexts, including Singapore, multilingual encounters involving Mandarin, Cantonese, Tamil, Malay, and English code-switching represent normative practice rather than exceptional circumstances [69], with family members routinely participating in medical decision-making across generations [70]. Clinical experience in such settings reveals specific challenges when AI systems must accurately attribute speaker identity among multiple family members, distinguish patient speech from interpreter or family translation, handle mid-sentence language switching, and preserve interactional patterns containing diagnostic information about family dynamics and care preferences.

Algorithmic bias and disparate performance across demographic groups are well documented in other health AI applications [71]. Speech recognition systems demonstrate lower accuracy for speakers with nonstandard accents, minority racial and ethnic groups, and non-English languages [72,73]; in the flagship analysis, Koenecke et al [30] reported substantial racial disparities in word error rates across the 5 major commercial automatic speech recognition (ASR) systems. This is component-level evidence about the front end of the ambient-scribe pipeline rather than direct evidence of inequity in the final note. The downstream artifact reflects compounded effects from ASR, diarization, and summarization; the staged audit proposed earlier—word error rates first, speaker-attribution accuracy second, clinical concept and narrative-relevant omission third—is the analytic foundation for equity claims about full ambient-scribe systems. If AI scribes exhibit similar biases, documented benefits may not generalize to all populations and may come at the cost of disparate impacts for specific groups. When AI systems struggle with speaker attribution in family consultations involving multiple languages, attribution errors create documentation inaccuracy or require extensive clinician revision time, effectively reducing benefits for clinicians serving diverse populations.

Few published studies have stratified ambient AI scribe error rates by patient primary language, accent characteristics [74], interpreter presence, or demographic characteristics. Equity assessment can begin while methods for narrative preservation are still being developed; performance heterogeneity by language, accent, interpreter presence, and family-mediated speech can be measured with extant transcription accuracy and information extraction methods, and need not wait on the more demanding work of narrative-fidelity rubrics. Sequencing equity work after narrative methodology risks entrenching disparities during the period of fastest deployment.

Proposed Evaluation Framework and Research Priorities

An expanded evaluation framework assessing 4 additional domains would complement rather than replace current efficiency and satisfaction metrics: communication quality measurement using validated instruments; narrative content preservation requiring methodological development as a longer-term priority; cognitive and skill development effects, particularly in training contexts; and equity across languages and demographics. Three research priorities offer immediate feasibility for organizations with evaluation capacity, while narrative assessment requires foundational methodological work before implementation-ready tools exist. The 4 domains are parallel rather than sequential: communication, cognitive and skill development, and equity work can proceed using extant instruments, and findings in any one domain inform the others.

Priority 1: Communication Quality Assessment

Communication quality assessment offers the highest immediate feasibility, given existing validated instruments and that many organizations already collect relevant data. Organizations implementing AI scribes could begin assessment using the Communication Assessment Tool or the Consumer Assessment of Health care Providers and Systems Clinician and Group (CAHPS CG) communication composite, both of which have established reliability and validity [75,76] for measuring dimensions of patient-clinician interaction that predict clinical outcomes [41]. The 2 instruments serve complementary purposes and can be deployed together. The Communication Assessment Tool is administered at the visit level and produces clinician-specific feedback well suited to local quality improvement [49]. The CAHPS CG communication composite is standardized for interorganization benchmarking and is a widely used patient-reported measure for system-level comparison [46]. Organizations seeking both internal improvement and external benchmarking can use both with limited additional patient burden.

Study designs should include cluster randomized trials comparing departments randomized to implement AI scribes versus traditional documentation, with communication measured at baseline and follow-up intervals. Alternatively, interrupted time series analyses can track communication scores before and

XSL•FO
RenderX

after implementation using statistical controls for temporal trends and patient characteristics. Organizations already collecting patient experience data can add validated communication items, although achieving meaningful results requires biostatistical expertise that academic centers possess more readily than community settings [77]. Collaborative approaches in which academic centers lead multisite studies including community hospitals would distribute measurement burden while ensuring findings generalize across practice contexts. We propose 2 tiers for organizations with evaluation capacity. Baseline feasible: a single patient-reported communication item (eg, one CAHPS CG composite question [78]) added to existing patient experience surveys, with pre- and postimplementation comparison at clinic level, no clinician-level benchmarking required and achievable wherever an existing CAHPS or equivalent infrastructure operates. Ideal: a patient-reported Communication Assessment Tool or full CAHPS CG communication composite at the visit-level [78] with clinician-level reporting; an interrupted-time-series design at clinic-level, or—where multiple clinics roll out sequentially—a stepped-wedge design; baseline and follow-up assessments aligned with the rollout calendar; analysis adjusted for temporal trends, clinician, and patient case mix. Clinician-level sample-size targets (for example, 50 patients per clinician per evaluation period) are appropriate for benchmarking studies [79] but are not a prerequisite for system-level effect detection.

Priority 2: Longitudinal Trainee Cohort Studies

These designs are hypothesis-testing investigations motivated by plausible mechanisms identified in the adjacent literature on documentation, decision support, and skill acquisition, rather than being responses to known safety concerns regarding accuracy and omissions in ambient-scribe practice [80]. Longitudinal skill development assessment merits high priority despite requiring extended commitment and substantial resources. Enrollment should begin immediately in training programs recently adopting AI scribes, recognizing that cohorts must progress through multiyear training before graduation outcomes can be assessed. Implementation should compare programs recently adopting AI scribes with matched programs delaying implementation, with baseline assessment at program entry establishing incoming capabilities prior to AI exposure.

Outcome measurement should include independently generated documentation quality on standardized cases (using PDQI-9 and narrative extensions where available), diagnostic reasoning capacity using validated instruments, and clinical knowledge assessment, with periodic AI-off probes to test whether reasoning performance is preserved when AI assistance is withdrawn. This approach would determine whether trainees exposed to routine AI assistance develop documentation and reasoning competencies differently from those trained without such assistance, and whether experienced clinicians maintain independent documentation skills when using AI regularly. Collaborative approaches in which multiple organizations jointly fund research would distribute costs while ensuring findings generalize across practice contexts and training environments. We propose 2 tiers for organizations with evaluation capacity. Baseline feasible: a single-program cohort enrolling trainees at program entry, with PDQI-9-scored documentation on 1 or 2 standardized cases at program entry, mid-training, and exit, AI-on assessment only; this is achievable within most academic programs without interinstitutional coordination. Ideal: prospective cohort enrolling trainees at program entry now, AI-exposed cohort versus matched programs delaying implementation; outcomes include PDQI-9-scored documentation on standardized cases and validated diagnostic-reasoning probes administered AI-on and AI-off at program entry, mid-training, and exit; follow-up to graduation, with longer-term extension where feasible. We acknowledge that a five- to seven-year follow-up horizon is unrealistic for many programs [81]; partial follow-up to early postgraduate practice is informative even where graduation-plus follow-up is not feasible.

Priority 3: Equity and Performance Heterogeneity Analysis

Equity analysis merits immediate priority given both feasibility and ethical urgency. Implementation should focus on health care organizations serving diverse patient populations with substantial proportions of non-English encounters, interpreter-assisted visits, and patients from communities experiencing health care disparities. Primary stratifiers are: (1) patient primary language; (2) interpreter status (none, professional, family, or ad hoc); (3) accent or dialect group where feasibly identifiable; and (4) demographic categories defined by self-reported race, ethnicity, age, and gender. The minimum reporting standard for equity-aware evaluations is stratified ASR-level and content-level error rates, stratified efficiency benefits (time savings and revision burden), and stratified patient-reported experience, each accompanied by per-stratum sample sizes and confidence intervals. The study design uses deliberate oversampling ensuring adequate representation of diverse populations rather than sampling proportionate to frequency in organizational caseloads.

Blinded expert raters review AI-generated documentation, identifying errors including omissions, misattributions, and narrative gaps. Comparators should include both verbatim transcripts and pre-AI manual documentation by the same clinician and peer clinicians, so that AI-specific failure modes can be distinguished from baseline documentation limitations. Analysis is stratified by patient language, interpreter presence, and demographic characteristics, examining whether error rates differ across strata after adjusting for clinical complexity. Additionally, the assessment examines whether efficiency benefits are equitably distributed by analyzing time savings and revision burden across clinicians serving patient panels with varying diversity characteristics. Organizations serving multicultural communities could conduct such analyses with results emerging in reasonable timeframes, providing essential evidence about whether documented benefits generalize across populations or mask disparate impacts.

Community engagement with patient advisory councils and representatives from affected communities should begin before study implementation and continue throughout evaluation, ensuring that equity assessment addresses community priorities rather than only researcher-defined outcomes. Minimum

XSL•FO
RenderX

specification for organizations with evaluation capacity and a diverse local catchment: deliberate oversampling targeting at least 30% non-English encounters where the catchment supports this; stratified ASR-level and content-level error rates; comparators including both verbatim transcripts and pre-AI manual documentation by the same and peer clinicians; blinded expert audit; results reported with per-stratum sample sizes and CI; community engagement throughout. Organizations without a sufficiently diverse caseload to support stratified analysis can contribute through pooled sentinel surveillance described in practical guidance.

Practical Guidance for Implementation

Implementation with Embedded Evaluation

Organizations currently implementing or considering ambient AI scribes should adopt them where benefits are demonstrated locally and where implementation can be paired with prospective evaluation from initial deployment. This means establishing baseline measurement across relevant outcome domains before deployment begins, enabling before-and-after comparison or control-period data for analysis. Organizations should select evaluation priorities based on context: safety-net hospitals and practices serving diverse populations should prioritize equity validation; academic medical centers with training programs should establish trainee cohort studies; and all organizations with evaluation capacity should, at a minimum, assess communication quality given its feasibility and centrality to care quality [82].

Large academic medical centers and integrated delivery systems possess resources for comprehensive evaluation across multiple domains and should view evaluation capacity as an essential component of responsible implementation. Allocating a portion of implementation budgets for systematic evaluation ensures deployment decisions are evidence-based. Community hospitals and mid-sized practices with limited research infrastructure should focus on feasible priorities, particularly communication quality assessment using existing patient experience survey infrastructure, and participation in collaborative multisite studies that distribute research burden while contributing to field-wide evidence.

Small ambulatory practices and solo practitioners typically lack capacity for formal evaluation and should not be expected to generate independent statistical findings on quality dimensions [83]. Their contribution lies in routine ongoing monitoring (described below) and in participation in pooled or sentinel surveillance led by specialty societies and learned colleges. Organizations should commit to disseminating findings, including negative results and implementation challenges, through peer-reviewed journals, presentations at national meetings, and collaborative networks. This transparency ensures that field-wide evidence generation reflects both successful implementations and problematic patterns, enabling other organizations to make more informed deployment decisions.

Ongoing Monitoring in Practice

Formal evaluation studies operate on multiyear timelines [84]. Clinicians and organizations using ambient AI scribes today need lighter-weight tactics for monitoring quality between research findings, and several can be adopted with minimal infrastructure. These tactics complement rather than substitute for formal research; they give clinicians a way to maintain situational awareness of their AI tools in the years before validated outcome measures and longitudinal cohorts mature.

The first tactic is periodic side-by-side comparison. Clinicians can sample a small proportion of their own encounters—a feasible target is 1 in 20 notes—and dictate or write a brief independent version of the note before reviewing the AI output. The comparison surfaces systematic omissions and stylistic drifts that pass unnoticed in routine review, particularly the subtle erosion of psychosocial context and patient explanatory models [85].

The second is targeted spot-checking. Encounters with high information density or psychosocial weight—initial consultations, disclosures of significant diagnoses, complex shared decision-making, conversations involving family members—warrant routine review of AI output against the clinician's own recall of the conversation. These are the encounters in which omissions matter most and in which AI performance is least studied [67].

The third is structured patient feedback. Brief items added to existing patient experience surveys can capture comfort with recording technology and perceived effects on the encounter, providing a real-time signal to clinicians and managers about whether implementation is progressing effectively.

The fourth is participation in pooled surveillance. Small ambulatory practices and solo practitioners cannot generate statistically meaningful internal evaluations, but specialty societies and learned colleges can convene sentinel surveillance networks. Member practices contribute anonymized samples of AI-generated notes for centralized review by trained raters, generating system-level evidence that no single practice could produce.

Regulatory Considerations

Current regulatory frameworks treating ambient AI scribes primarily as administrative tools [86] may inadequately address their influence on clinical documentation quality, diagnostic reasoning, and care coordination. Documentation is clinically consequential rather than purely administrative: it preserves diagnostic reasoning, enables care coordination, and provides the medical record on which subsequent decisions depend [87]. Technologies transforming documentation processes warrant regulatory attention proportionate to their potential impact on care quality and patient safety. Two reporting expectations are tractable across jurisdictions and would generate the evidence currently absent from voluntary disclosure. The first is stratified predeployment performance reporting: word error rate, speaker attribution accuracy, and clinical concept omission rates reported separately by patient primary language, demographic group, encounter complexity, and, where feasible, accent or dialect group, rather than aggregate accuracy alone. The second is postmarket monitoring with disclosure: ongoing reporting of revision burden, vendor-side updates to underlying models, and signal-level performance changes following retraining or model swap. Both expectations sit at the vendor level, where data are

XSL•FO
RenderX

routinely collected; equivalent requirements on individual clinicians' documentation practices would not be feasible and would not generate the systematic evidence the field requires.

Regulatory taxonomies differ materially across jurisdictions in how the administrative-tool versus clinical-decision-support boundary is drawn [88] and in the instruments through which postmarket surveillance is required [89]. The principles above are portable; the regulatory instruments through which they are applied—United States Food and Drug Administration software-as-a-medical-device pathways, the European Union AI Act, the United Kingdom Medicines and Health Care Products Regulatory Agency framework, Singapore's Health Sciences Authority guidance, and other regional regimes [90],—are not. Regulation must balance evaluation requirements against genuine workforce sustainability benefits, avoiding overly restrictive approaches that would harm clinician well-being and health care delivery capacity.

Discussion

Ambient AI scribes deliver generally promising but heterogeneous efficiency and clinician well-being benefits [91]. Pooled effect sizes from recent meta-analytic synthesis are moderate; multisite evaluation describes modest reductions in electronic health record and documentation time, and study quality across the underlying evidence base is generally low [9]. These benefits are real, replicated across diverse settings, and clinically meaningful for workforce sustainability; they are also smaller and more variable than initial single-system reports suggested. Current evaluations focus narrowly on time savings and satisfaction [92], leaving critical domains unmeasured. This analysis identified systematic evaluation gaps concerning patient-clinician communication, narrative content preservation, cognitive effects on clinical reasoning, and equity. We frame these as plausible, measurable hypotheses warranting investigation, not as harms established for ambient scribes; the case for evaluation rests on adjacent evidence and on the scale of deployment, not on demonstrated harms specific to these systems.

This evaluation pattern may be appropriate for early-stage technology assessment, with efficiency and satisfaction metrics correctly prioritizing the establishment of feasibility and user acceptance as a foundation for broader deployment. However, as adoption scales from pilot projects to enterprise-wide deployment and integration into training programs, evaluation frameworks must mature to encompass comprehensive care quality assessment. The question is not whether documented benefits justify initial adoption but whether continued rapid expansion should proceed with or without evidence regarding additional care quality dimensions.

The conceptual framework (Figure 1) clarifies how ambient AI scribes may produce both positive and negative effects through 2 primary pathways: recording-device presence during encounters and automated draft generation. Each pathway has plausible benefits and risks for communication, narrative, reasoning, and equity. Recognition of competing pathways emphasizes that neither universally positive nor universally negative conclusions are likely accurate and that effects probably vary by context, implementation approach, and population.

For clinicians and health systems, demonstrated well-being benefits support continued adoption in settings where they are observable locally [7], paired with quality safeguards including structured audits of AI-generated notes, measuring patient-clinician communication with validated instruments where feasible, and developing protocols for use in complex or multilingual encounters. For medical education, the critical challenge is balancing efficiency gains for trainees with developing independent documentation and reasoning competencies. Documentation differs from clinical decision support: the AI-off probe used in adjacent literature provides a concrete way to detect skill degradation in trainees and would be a productive endpoint for prospective trainee studies [93]. Policymakers and developers must prioritize equitable performance across patient populations, evaluating ambient AI scribes against both transcript reference standards and preAI clinician documentation, because speech-recognition disparities may interact with preexisting inequities in clinical documentation and patient description [19,94].

This work has several strengths, including synthesizing findings from prominent, large-scale, recent ambient AI scribe implementations and integrating recent multisite and meta-analytic evidence on the magnitude and quality of efficiency benefits. By drawing upon established literature from communication science, medical education, automation psychology, and health equity, it provides robust conceptual grounding for proposed evaluation frameworks. The research agenda is pragmatic, leveraging existing validated instruments and feasible study designs integrable into current implementations.

However, limitations warrant acknowledgment. As an analytic viewpoint rather than a systematic review, this analysis is subject to selection bias and may not capture the entirety of rapidly evolving literature; reporting was guided by SANRA principles to maximize transparency within these constraints, but selection and extraction were performed by a single reviewer (VSME). Conclusions rest on studies with often short follow-up periods and generally low methodological quality, limiting insight into potential long-term effects. Critically, concerns raised about automation bias, deskilling, and narrative degradation remain plausible risks grounded in adjacent literature rather than demonstrated harms of ambient AI scribes specifically. This analysis proposes hypotheses requiring testing rather than documenting established harms that necessitate immediate intervention. Empirical investigation may reveal that theoretical concerns do not manifest clinically or that positive pathways predominate.

The path forward involves launching rigorous communication quality studies, establishing longitudinal cohorts assessing cognitive and educational impacts, and conducting dedicated audits ensuring equitable performance. By embracing broader evaluation frameworks, the field can ensure ambient AI scribes not only restore time to clinicians but also robustly support the quality and humanity of patient care. The opportunity to generate

XSL•FO
RenderX

this evidence is time-limited, as adoption expands and practice patterns develop [95].

Conclusions

Ambient AI scribes show efficiency and some clinician well-being benefits, but evidence remains limited, heterogeneous, and context-dependent [7,91]. Current evidence supports continued implementation with quality safeguards in settings where benefits are demonstrated locally, rather than uniform adoption justified by early single-system reports. Existing evaluation frameworks focus narrowly on time savings and satisfaction while leaving questions about quality of care, equity, and other downstream impacts systematically unmeasured [6].

An expanded framework would complement existing approaches with 3 near-term priorities: validated communication measurement deployable within ongoing rollouts; longitudinal trainee cohort studies launched at programs recently adopting AI scribes, including AI-off probes to test for skill degradation; and stratified equity analyses oversampling multilingual and interpreter-mediated encounters, with comparators including both verbatim transcripts and preAI manual documentation. Narrative preservation can advance in stages, beginning with PDQI-9 and progressing to validated narrative-specific extensions [54,96]. In parallel, organizations and clinicians can adopt lighter-weight monitoring tactics—periodic side-by-side comparison, targeted spot-checking, structured patient feedback, and pooled sentinel surveillance—to maintain situational awareness during the years before formal evidence matures.

The goal is not to slow adoption but to ensure that it proceeds with evidence commensurate with scale. The window for generating that evidence is narrowing as adoption expands and practice patterns develop [97]. Three audiences have specific next steps. Editors and reviewers can require consistent domain coverage reporting for ambient AI scribe evaluations submitted for publication. Implementing organizations can preregister evaluation plans across the 4 domains before rollout, select priorities according to local context and patient populations served, and commit to publishing findings including negative results. Vendors can publish stratified performance data and postmarket monitoring signals as a routine condition of deployment.

Acknowledgments

The author used Claude (Anthropic) during preparation of this manuscript. It was used to draft and improve the flow of the text across successive versions. All references and numerical claims were verified against the primary sources by the named author, who takes full responsibility for the content of this article, including any part influenced by AI.

Funding

The author declared no financial support was received for this work.

Data Availability

This viewpoint article synthesizes published implementation reports and literature. No original data were collected. All sources cited are publicly accessible through academic databases or organizational websites. The search strings, dates, and selection criteria are reported in the Methods section.

Authors' Contributions

VSME conceptualized the study, conducted the literature review, performed the analysis, drafted the manuscript, and approved the final version. As sole author, VSME takes responsibility for all aspects of the work and accuracy of content.

Conflicts of Interest

The author has used AI documentation tools developed by SingHealth in clinical practice since 2024. Experience has been mixed, with clear efficiency benefits for straightforward encounters in English, but observed challenges in multilingual consultations involving Mandarin and Cantonese code-switching, family-mediated decision-making with multiple speakers, and complex cases involving substantial emotional or psychosocial context requiring nuanced narrative preservation. Specific clinical encounters where AI systems struggled with speaker attribution in family consultations involving elderly patients, adult children, and the author simultaneously, and instances where AI-generated summaries omitted emotional context about patient fears regarding familial cancer patterns that were relevant to shared decision-making about screening intensity, motivated attention toward equity and narrative preservation concerns in this analysis.

These observations are subjective clinical impressions from a tertiary gastroenterology practice serving diverse immigrant populations and may not represent typical patterns across other clinical settings. The author’s institution has not conducted a formal internal evaluation informing this work beyond routine clinical quality review processes. No financial relationships with AI vendors or parent companies exist. This viewpoint reflects the author’s personal analysis and does not represent the institutional positions of Singapore General Hospital or SingHealth Duke-NUS Medical Humanities Institute.
