Abstract

Background: Acute chest pain (ACP) is one of the most common chief complaints in the emergency department (ED), accounting for approximately 8% of all ED visits. However, among patients presenting with chest pain suggestive of cardiac origin, fewer than 10% are ultimately diagnosed with acute coronary syndrome (ACS).

Objective: AI models were developed to support clinical decision-making for triage level-2 ED patients presenting with ACP. These models aim to accurately detect ACS and reliably identify low-risk patients based on a single high-sensitivity cardiac troponin T test result. By integrating this AI-assisted strategy into clinical workflows, we aim to reduce ED length of stay, alleviate crowding, and improve health care efficiency while maintaining high safety standards.

Methods: We conducted a retrospective study using single-center data from a tertiary teaching hospital between January 2016 and December 2022. Models based on artificial neural networks (ANNs) were trained to classify patients with ACP at triage level 2 into 3 clinical classes: critical patients with ACS (subgroup GA), critical patients without ACS (subgroup GB1), and low-risk patients (subgroup GB2). The models were trained and internally validated via a 5-fold cross-validation protocol using data from 2016 to 2020. Model performance was then evaluated on the hold-out testing data (2021 - 2022) using area under the receiver operating characteristic curve, area under the precision-recall curve, and subgroup-specific metrics. Feature selection methods and the Shapley Additive Explanations value analysis were applied to identify features that drive the model's predictive power. The study was approved by the institutional review board of the National Cheng Kung University Hospital, Tainan, Taiwan (A-ER-111 - 199).

Results: After excluding ED visits with missing triage data, incomplete medical histories, or unsuitable dispositions, 17,935 visits were included, with 1209 GA, 3873 GB1, and 12,853 GB2. Rendering prediction based on 24 feature variables (2 demographics, 6 vital signs, 4 blood test results, and 12 medical history), all ANN models demonstrated strong testing AUROC (95% CI) performance of 0.942 (0.920 - 0.965) for GA classification, 0.824 (0.808 - 0.841) for GB1, and 0.893 (0.884 - 0.902) for GB2. Regarding multiclassification, ANN-S3 achieved balanced performance, with ACS sensitivity of 0.941 (95% CI 0.908 - 0.973) and low-risk positive predictive value and sensitivity of 0.911 (95% CI 0.9 - 0.921) and 0.837 (95% CI 0.824 - 0.85), respectively. A sensitivity-prioritized variant, ANN-S3-L, increased ACS sensitivity to 0.966 (95% CI 0.94 - 0.991) and negative predictive value to 0.998 (95% CI 0.996 - 0.999), but at the cost of lower specificity and reduced low-risk sensitivity, indicating a safety-efficiency trade-off.

Conclusions: These findings suggest that ANN-based classifiers can effectively support clinical risk stratification and disposition decision-making in ACP care for patients presenting ≥3 hours after symptom onset. However, because even the sensitivity-prioritized ANN-S3-L variant falls short of the stringent sensitivity threshold (>0.99) typically required for a standalone ED rule-out tool, this system should be interpreted as a clinical decision-support aid rather than an independent rule-out strategy.

Introduction

Acute chest pain (ACP) is one of the most common chief complaints in the emergency department (ED), accounting for approximately 8% of all ED visits. However, among patients presenting with chest pain suggestive of cardiac origin, fewer than 10% are ultimately diagnosed with acute coronary syndrome (ACS) [1]. Despite this low diagnostic yield, current clinical practice often necessitates multiple measurements of high-sensitivity cardiac troponin T (hs-TnT) and prolonged observation in the ED to safely rule out ACS before discharge decisions can be made [2]. Although this approach enhances diagnostic sensitivity, it also prolongs the patient's length of stay (LoS) in the ED. This extended stay is recognized as one of the major contributing factors to ED crowding [3]. ED crowding is widely acknowledged to negatively impact patient safety and overall quality of care [4]. It also imposes significant burdens on health care providers, leading to increased workload and elevated stress levels [5]. In general, ED crowding not only reduces health care system efficiency but also poses substantial risks to patient safety [6].

To reduce the LoS for patients with ACP, previous studies have proposed the single test rule-out strategy, which aims to expedite ACS exclusion by combining a single hs-TnT measurement with clinical assessment [7]. However, the successful implementation of this strategy remains limited in practice [8]. One of the primary challenges is that clinicians must rely heavily on clinical experience and judgment to accurately identify low-risk patients, in order to avoid premature discharge and associated adverse outcomes [9].

The objective of this study is to develop an AI model, whose predictive power is medically interpretable, to support clinical decision-making in the initial management of patients presenting to the ED with ACP. This is in line with several recent studies that applied explainable AI techniques to enhance interpretability and clinician trust in emergency care-focused models [10,11]. This model is designed not only to accurately detect ACS but also to rapidly and reliably identify low-risk patients based on a single hs-TnT test. By integrating this AI-assisted strategy into clinical workflows, we aim to reduce ED LoS, alleviate crowding, and ultimately improve health care efficiency while lowering medical expenditures.

Methods

Study Design and Setting

This study retrospectively collects data from the ED of a tertiary teaching hospital located in Tainan City, Taiwan, between January 1, 2016, and December 31, 2022. The hospital comprises 783 general ward beds and 136 intensive care unit beds, and on average, receives approximately 100,000 ED visits annually. Adult patients presenting with chest pain and triaged as level 2 (urgent) were included [12]. Inclusion required complete triage data, medical history, examination results, and documented disposition. Patients were categorized into 3 groups: group GA (ACS), group GB1 (non-ACS but requiring acute care or hospitalization), and group GB2 (noncritical, discharged after short observation). Visits with missing or indeterminate data were all excluded, which was the only exclusion criterion. As such, all included visits have no missing data. The dataset was divided chronologically: records from January 1, 2016, to December 31, 2020, were used for training and from January 1, 2021, to December 31, 2022, for testing (75/25 split). Repeat visits were all included unless with missing or indeterminate data.

To maintain the clinical integrity and analytical precision required for this pilot research, we prioritized our institutional dataset over open ED datasets, such as Medical Information Mart for Intensive Care IV Emergency Department and Multimodal Clinical Monitoring in the Emergency Department.

Data Collection and Processing

In total, 27 variables were used for data analysis and model development. These included 3 response variables, 2 demographic variables (age and sex), and 22 clinical variables. The clinical variables consisted of 6 vital signs, 4 blood test results, and history of 12 diseases and medical conditions. Among the 27 variables, the response, sex, and medical history were categorical, while the remaining variables were quantitative (Textbox 1).

Quantitative variables were used in their raw form without prior scaling, standardization, or log-transformation. Instead, potential disparities in numerical scales were (partially) mitigated via batch normalization integrated directly within the artificial neural network (ANN) architectures. Because batch normalization primarily addresses internal covariate shift rather than correcting highly skewed raw input distributions (such as hs-TnT), a sensitivity analysis was conducted by using instead the "log-transformed hs-TnT" as an alternative input.

In alignment with Good Machine Learning Practice principles [13] regarding the clinical workflow context, we defined a precise index time anchor to prevent data leakage. The model's prediction shall be executed at the exact moment the first laboratory panel (including hs-TnT, creatinine, and complete blood count) is reported, which typically occurs within 60 minutes of patient arrival. Only features available at or before this timestamp were used as model inputs. By anchoring the prediction at this specific decision window—after initial laboratory results are available but before final disposition or serial testing is initiated—we ensure the model functions as a true clinical decision support (CDS) tool within the intended use environment.

Textbox 1. Definitions of variables.

- Response variables: Each visit was linked to 3 mutually exclusive binary variables indicating group assignment (GA, GB1, or GB2), with only one variable coded as 1 per patient.
- Vital signs: Six vital signs were measured and recorded by triage nurses, including temperature, heart rate, respiratory rate, systolic and diastolic blood pressure, and peripheral oxygen saturation.
- Blood test: Four blood tests—creatinine, platelet count, white blood cell count, and high-sensitivity cardiac troponin T (measured by Elecsys assay; Roche Diagnostics)—were used for prediction. Serum high-sensitivity cardiac troponin T concentrations were measured using the Elecsys Troponin T hs STAT immunoassay on the cobas e analyzer (Roche Diagnostics). All assay results were reported in nanograms per liter. The assay is characterized by a limit of detection of 5 ng/L and an upper reference limit (99th percentile) of 14 (95% CI 12.7-24.9) ng/L. The clinical sampling protocol used in this study supports both immediate sampling (0 hours) for rapid rule-out and serial sampling at appropriate time intervals (eg, 0-3 hours or longer) to detect the characteristic rise and/or fall of troponin levels required for clinical adjudication. This approach and the associated diagnostic algorithms mirror several established international clinical guidelines, including the 2011 and 2015 European Society of Cardiology 0 hours and 1 hour and 0 hours and 3 hours algorithms, the 2014 National Institute for Health and Care Excellence guidelines for the early rule-out of non–ST-segment elevation myocardial infarction, the Third Universal Definition of Myocardial Infarction, the World Health Organization (WHO) criteria for the definition of acute myocardial infarction, and the Joint American College of Cardiology Foundation/American Heart Association/World Heart Federation task force recommendations for clinical diagnosis.
- Medical history: Twelve conditions were included as binary variables: coronary artery disease, connective tissue disease, peripheral vascular disease, peptic ulcer disease, liver disease, chronic obstructive pulmonary disease, diabetes mellitus (DM), malignancy, AIDS, congestive heart failure, cerebrovascular accident or transient ischemic attack, and dementia. All of the medical conditions considered refer strictly to the patient's preexisting medical history (comorbidity) recorded prior to the corresponding index ED visit.

Definition of Groups GA, GB1, and GB2

Patients diagnosed with ACS were classified as GA. Those without ACS were further categorized as GB1 if they had other serious conditions requiring hospitalization, transfer, or died in the ED, and as GB2 if they were discharged after ED care.

To ensure the safety and validity of the ground truth labels, we established a rigorous adjudication process for ACS, specifically focusing on type 1 myocardial infarction (MI) in accordance with the Fourth Universal Definition of MI [14]. To maintain high specificity and provide a fit-for-purpose reference standard, cases of unstable angina and type 2 MI were intentionally excluded from the target outcome group GA.

The diagnostic adjudication was a multidisciplinary effort. Initial clinical assessments were performed by board-certified emergency physicians, with definitive diagnosis and type 1 versus type 2 MI distinction determined by consulting cardiologists based on clinical presentation, serial electrocardiogram (ECG) changes, and biomarker trajectories. To further minimize label noise and information bias, we implemented a dual-referencing verification strategy: a visit was only labeled as GA if the corresponding *International Classification of Diseases, 10th Revision* (ICD-10 codes; I21.0-I21.4, I22.x) were documented in both the initial ED record and the final hospital discharge summary [15]. This methodology ensures that the model learns from confirmed ischemic events while excluding initial ED misdiagnoses or secondary events occurring after the index visit.

Model Development, Fitting, and Evaluation

ANNs were developed in Python to predict patients' categorical outcomes (GA, GB1, or GB2) [16]. Three submodels—ANN-GA, ANN-GB1, and ANN-GB2—were trained to estimate the probability of each respective group. Their outputs were integrated via a multiclassifier for final prediction. All submodels shared the same architecture, with training parameters tailored to their respective targets; therefore, only the development of ANN-GA is detailed below. The first, second, and third response variables were used to train ANN-GA, ANN-GB1, and ANN-GB2, respectively. To address the imbalance among GA, GB1, and GB2 cohorts, the approach of assigning different weights to different patient groups, or down-sampling the dominating cohort, was adopted when training our models. We did not apply the synthetic minority oversampling technique. We used the scikit-learn (0.23.2) and the tensorflow (2.8.0) libraries for training our models.

The ANN-GA model was developed following a procedure similar to our previous work [17]. A 5-fold cross-validation protocol [18] was applied to the training dataset, dividing it into 5 equal subsets. In the ith iteration (i=1, 2, ... , 5), the ith subset was held out for internal validation, while a model $M_i(x)$ of the form:

(1)Mi(x)=11+efi(x)

(where x represents the input vector of 24 decision variables) was trained on the remaining 4 subsets. Central to the model $M_i(x)$ is the nonlinear function $f_i(x)$, which was obtained by training a fully connected ANN consisting of 4 layers. Each hidden layer (except the last) comprises batch normalization [19], affine transformation, and nonlinear activation. The batch normalization recenters and scales the input to stabilize and accelerate training, the affine transformation applies weights and biases to the input, and the activation introduces nonlinearity. This represents a standard layer structure of the ANNs [16]. The final layer of the network omitted a nonlinear activation, instead passing its output to a standard sigmoid function to generate the final outcome. The input dimensions of layers 1 to 4 were 24, m_2, m_3, and m_4, while the output dimensions were m_2, m_3, m_4, and 1, where m_2, m_3, and m_4 are network design parameters that were set between 5 and 50. The first 3 layers used hyperbolic tangent activations. Each model had fewer than 10,000 trainable parameters. These parameters were optimized based on minimizing the binary cross-entropy function, and the Adam optimizer [20] with recommended

XSL•FO
RenderX

settings was used for the optimization procedure. Finally, the ANN-GA model, $M_{GA}(x)$, was taken as the average of the 5 models; that is, MGA(x):=15∑i=15Mi(x). As the values of $M_{GA}(x)$ are always between 0 and 1, the output of $M_{GA}(x)$ is viewed as the predicted probability of belonging to group GA.

In the next step, the outputs of the 3 uncalibrated ANN models were jointly normalized so that their predicted probabilities for a given event summed to unity. Each model then underwent separate calibration using isotonic regression [21] to align the individual binary predictions with observed event rates. Because this independent calibration generally breaks the sum-to-unity property, a final softmax function with optimized temperature scaling was applied to the joint postisotonic outputs to restore coherent multiclass probabilities. Specifically, let p_A, p_{B1}, and p_{B2} be the postisotonic probabilities for GA, GB1, and GB2 classification, respectively. In the final step, these probabilities are modified as follows:

(2)pi′=eln (pi)T∑i∈ {A,B1,B2}eln (pi)T,i∈ {A,B1,B2}

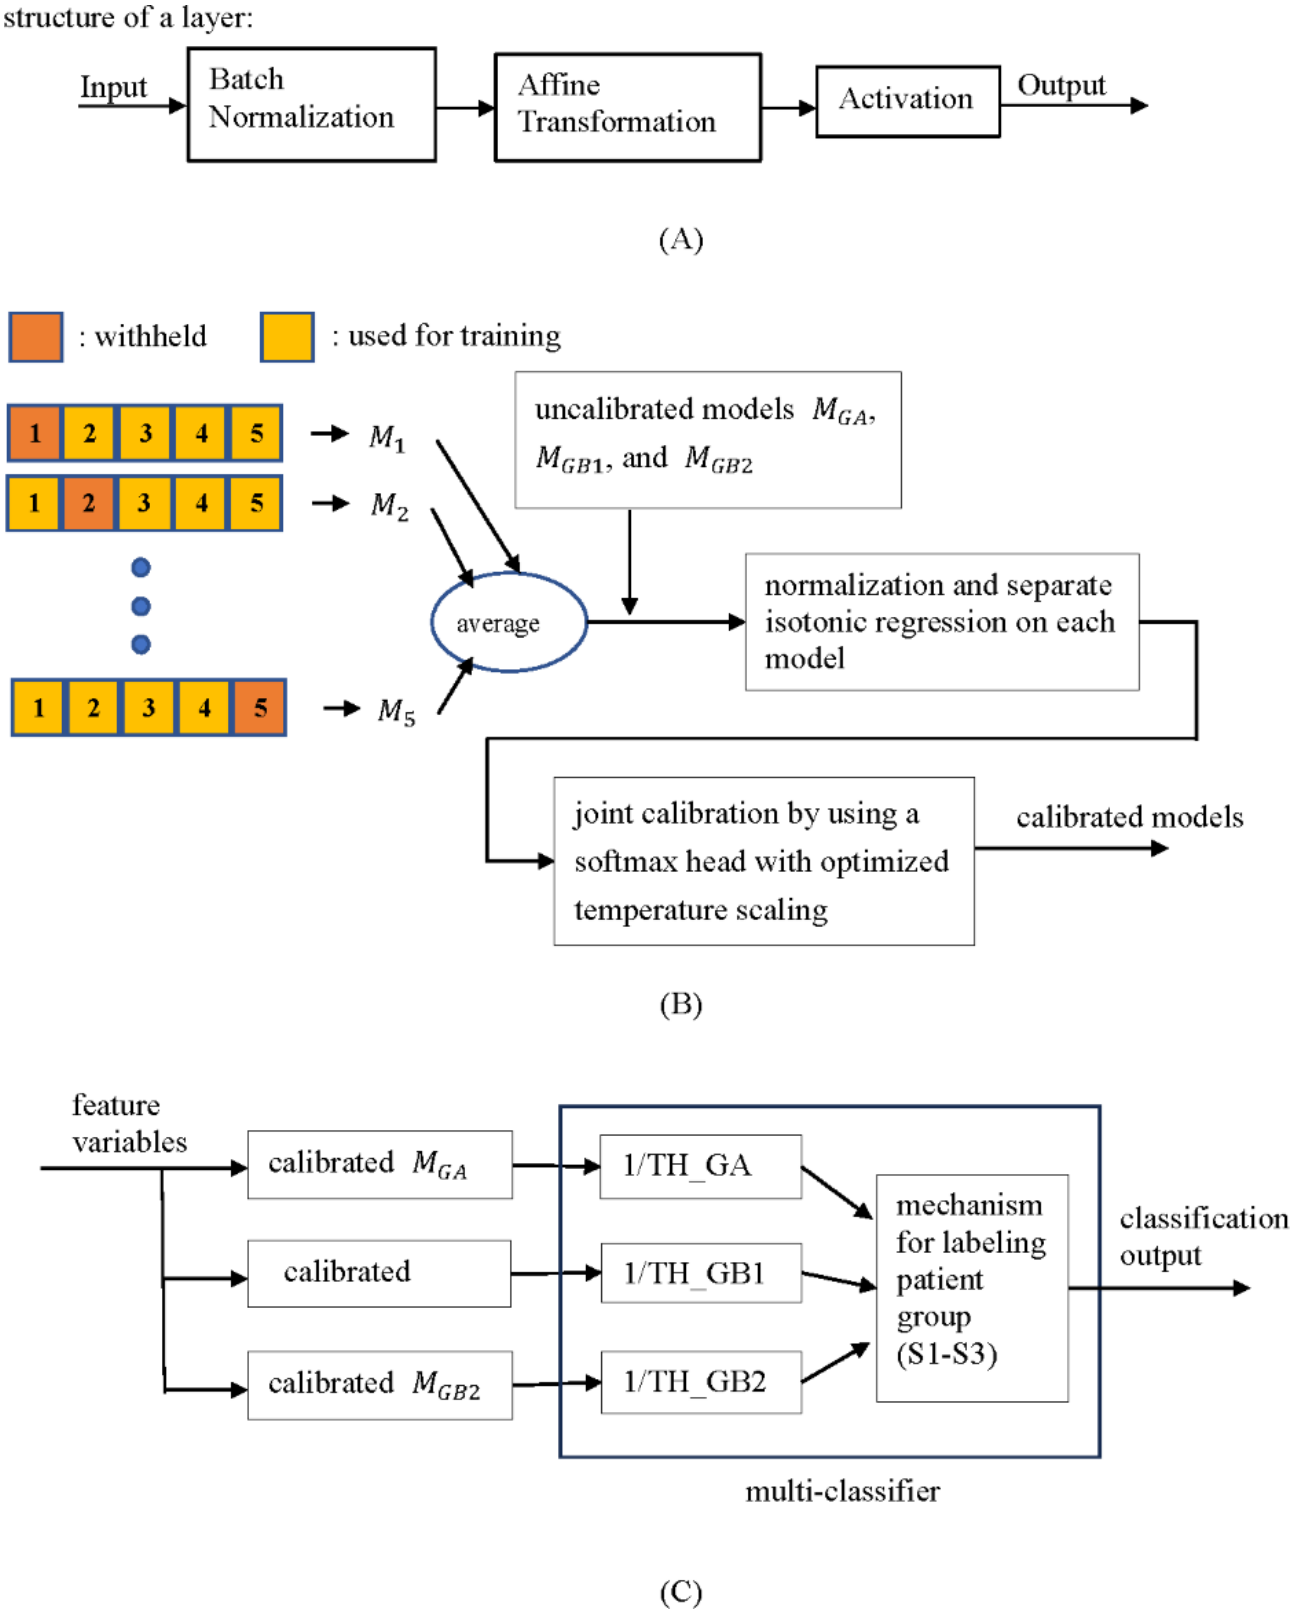
where T denotes the temperature scaling factor, which is optimized to minimize the binary cross-entropy loss of the recalibrated probabilities. The optimized temperature scaling factor T is 0.935. Figure 1A and B illustrate the layer structure and the flow for constructing the ANN models, including the 2-step calibration pipeline. The hyperparameter configurations used for model training are summarized in Table 1.

To verify the similarity between training and testing datasets, we compared feature distributions by calculating category percentages for categorical variables and means with SDs for quantitative variables. Performance evaluation was conducted based on the 2-step calibrated probabilities obtained by applying (calibrated) models to the testing set, with the area under the receiver operating characteristic curve (AUROC) serving as the primary metric. Optimal classification thresholds were derived from the training set's receiver operating characteristic (ROC) curves by maximizing the Youden index calculated from the calibrated probabilities [22]. These thresholds were then applied to evaluate model sensitivity (recall), specificity, positive predictive value (PPV, or precision), negative predictive value (NPV), and F_1-score. Precision-recall (PR) curves and the areas under the precision-recall curves (AUPRC) were also analyzed. Finally, to evaluate clinical utility, decision curve analysis was applied to the 2-step calibrated ANN models, benchmarking their performance against traditional "treat-all" and "treat-none" strategies.

Furthermore, to evaluate whether the ANN architecture offers superior predictive power, we benchmarked the ANN models against their logistic regression (LR) counterparts (LR-GA, LR-GB1, and LR-GB2). Note that by restricting function $f_i(x)$ to be affine, the model $M_i(x)$ becomes an LR model. To ensure a rigorous comparison, the LR models were constructed as ANN models with such a specific architectural constraint, optimized, and calibrated via the same computational process. As their ANN counterparts, the LR models were trained using the same training data by optimizing the same loss function, following the same data imbalance strategies, and using the same hyperparameters for the optimization engine. Furthermore, they were tested on the identical testing datasets and evaluated using the same performance metrics as the ANN models.

Moreover, in order to assess potential performance disparity between different patient groups, subgroup analysis with respect to age, sex, and kidney function was performed. The kidney function was evaluated based on estimated glomerular filtration rate (eGFR), which was calculated using the 2021 Chronic Kidney Disease Epidemiology Collaboration formula [23]. The model's performance on different subgroups was compared based on their ROC curves and the corresponding AUROCs.

Multiclassifiers were constructed for the final prediction using the 2-step calibrated outputs of the 3 ANN models. Each model output was first divided by the respective optimal threshold for binary classification, yielding the scores o_{GA}, o_{GB1}, and o_{GB2} for each patient. By dividing the respective optimal threshold, the scores o_{GA}, o_{GB1}, and o_{GB2} measure a patient's "distance" to the clinically accepted risk requirement for each classification. Three classification rules were evaluated for making the final classification prediction:



- S1: Assign the patient to the group with the highest score.
- S2: Assign to GA if $o_{GA}≥1$; otherwise, to GB2 if $o_{GB2}≥1$; remaining patients to GB1.
- S3: Assign to GA if $o_{GA}≥1$; otherwise to GB2 if $o_{GB2}≥o_{GB1}$, or to GB1 if $o_{GB2}<o_{GB1}$.

Figure 1C illustrates the multiclassification process. Each multiclassifier was applied to the testing data, and their performance was evaluated by comparing miss rates, sensitivity, specificity, PPV, NPV, and F_1-score.

Finally, we benchmark a multiclassifier based on ANN models with Youden optimal thresholds against that based on the LR models to evaluate the performance gains afforded by the ANN architecture. We further conducted sensitivity analyses by varying the GA-classification threshold, allowing us to explore the inherent trade-off between identifying high-risk ACS (GA) and low-risk (GB2) cases.

Table . Hyperparameter configurations used for model training[a,b].

	Nodes (layer 1 to 4)	Learning rate	Batch size	Total epochs	Class weights	
					Positive	Negative
ANN[c]-GA[d] model	(15, 10, 3, 1)	0.002	8267	2000	9	1
ANN-GB1[e] model	(15, 10, 3, 1)	0.01	8267	2000	7	1
ANN-GB2[f] model	(15, 10, 3, 1)	0.01	8267	2000	1	1

[a]Any parameters not explicitly listed in the table were kept at their default settings as specified by the respective programs.

[b]Batch normalization (for all models): momentum=0.8; epsilon=0.001. Early stop criteria (for all models): none. Joint postisotonic recalibration using softmax function (for all models): the temperature scaling factor T=0.935.

[c]ANN: artificial neural network.

[d]GA: critical patients with acute coronary syndrome.

[e]GB1: critical patients without acute coronary syndrome.

[f]GB2: low-risk patients.

Potential Improvement on the Patient Flow

To evaluate the potential of ANN models in reducing ED overcrowding, we analyzed GB2 patient records from the testing dataset, focusing on ED LoS and the number of hs-TnT tests received. While 2 tests are typically required before discharge, some patients were released after 1 test. By identifying such cases, we estimated the average time saved if GB2 patients were discharged earlier based on model predictions, thereby assessing the model's impact on improving patient flow.

Importance of Feature Variables and Model Interpretability

To evaluate the contribution of each feature variable to the predictive power of the models, Gini diversity indices [24] were calculated for classifying patients into GA, GB1, and GB2. Variables with notably high importance were selected, and ANN models were trained and calibrated using only these variables or the remaining ones. The performance of these models was compared to that of the full-variable models to assess whether key features alone provided sufficient predictive power. Furthermore, the Shapley Additive Explanations (SHAP) value analysis [25] was conducted on the ANN models to clarify the impact of each feature variable on the model's output. The results were examined to seek a clinical explanation of the model's predictive power.

Statistical Analyses

Statistical analyses were conducted with SPSS for Windows (version 24.0; IBM Corp). Categorical variables were compared with the chi-square test, and continuous variables (means and SD) with the independent 2-tailed t test.

Ethical Considerations

A formal study protocol was not prospectively prepared for this retrospective analysis. Additionally, the study was not registered in a public clinical trial database, as it used existing electronic health records for model development and evaluation. The study was approved by the institutional review board of the National Cheng Kung University Hospital, Tainan, Taiwan (A-ER-111‐199). The study was conducted following the principles set forth in the Declaration of Helsinki. The requirement for informed consent was waived due to the retrospective nature of the study. Study data were deidentified before processing to protect the privacy of the participants. Patients or the public were not involved in the design, conduct, reporting, or dissemination plans of this research. This study was reported according to the TRIPOD+AI (Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis Or Diagnosis Using Artificial Intelligence) guidelines, and the completed checklist is provided in Checklist 1.

Results

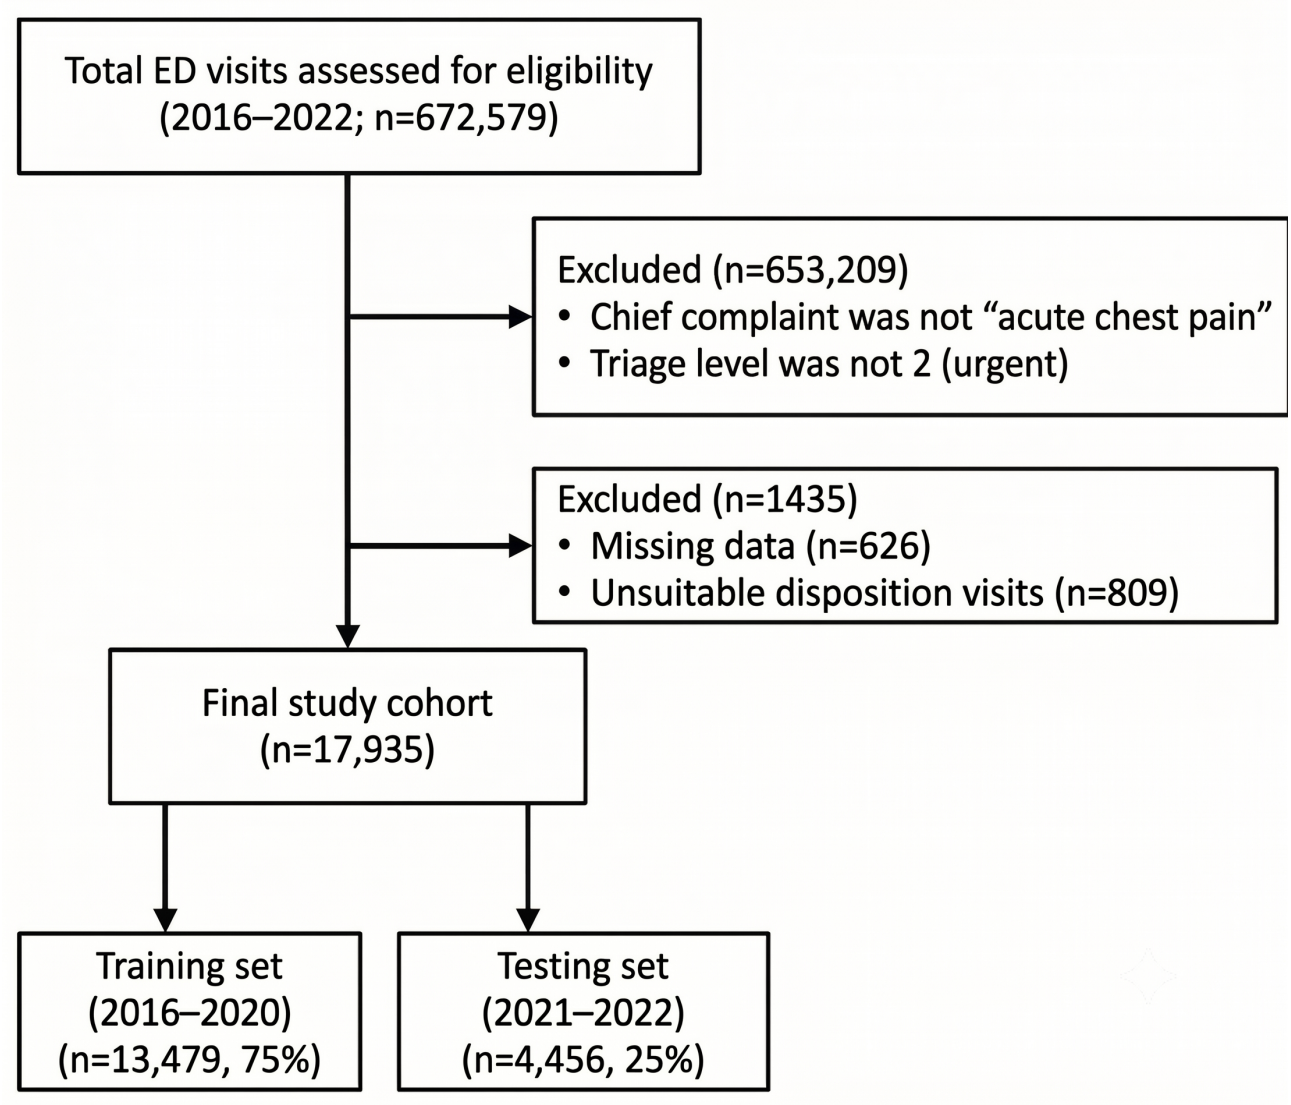
Characteristics of Study Samples

Overview of the Study Population

From the initial 672,579 total visits between January 2016 and December 2022, 653,209 visits were excluded, as they did not meet the inclusion criteria of adult patients presenting with ACP triaged as level 2 (urgent). Of the remaining potential visits, 809 visits were excluded due to unsuitable dispositions (eg, discharge against medical advice and disposition undocumented), while 626 were excluded due to missing triage data, missing examination results, or incomplete medical histories. This resulted in a final study cohort of 17,935 eligible visits. A CONSORT (Consolidated Standards of Reporting Trials)-style patient flow diagram detailing the number of patients excluded is shown in Figure 2.

The total of 17,935 visits were recorded from 13,618 unique patients. Among these, 2384 individuals contributed multiple visits, and 1802 made repeat visits within the same category. Within this latter group, 36 patients made repeat visits in group GA, 321 in group GB1, and 1537 in group GB2, with mean visit frequencies of 2.1 (SD 0.28), 2.3 (SD 0.85), and 2.8 (SD 2.13) per patient, respectively. High-frequency use (over 5 visits) was rare, occurring in only 4 patients in GB1 and 88 in GB2, with no such cases in GA. Of the total visits, 6.74% (1209/17,935) were categorized as GA, 21.59% (3873/17,935) as GB1, and 71.67% (12,853/17,935) as GB2. Furthermore, we identified that 523 patients had separate visits across the training and testing cohorts, with 142 patients (contributing 151 of 4456

XSL•FO
RenderX



visits in the testing dataset) overlapping between the adjacent years of 2020 and 2021. We have reviewed these instances and confirm that they represent unique, independent clinical events separated by significant time intervals; none of them are duplicate records. Furthermore, no short-term revisits (within 72 hours) crossed the temporal split. Because these visits represent different physiological data points, they do not constitute data leakage and were retained to maintain a realistic representation of clinical practice.

Patient characteristics for the training and testing datasets are detailed in Tables S1-S6 in Multimedia Appendix 1. For each patient group, both datasets demonstrated statistical parity across all feature variable distributions. Furthermore, significant differences (*P* value <.01) were observed in many feature variables when comparing each group against all others (eg, GA vs non-GA).

Among the 1435 excluded visits, the average age was 60.6 (SD 17.04) years, 61.67% (885/1453) were male, 38.32% (550/1435) were female, 7.46% (107/1435) are with a history of coronary artery disease (CAD), and 12.13% (174/1435) were with a history of congestive heart failure. These numbers are in line with those of the study cohort.

To further substantiate the clinical grounding of our study labels, we performed a post-hoc analysis of the clinical profiles and follow-up outcomes for both the low-risk surrogate group (GB2) and the non-ACS urgent illness group (GB1).

Figure 2. Participant flow diagram detailing the numbers of patients excluded. ED: emergency department.

Validation of Using “Discharged After Short Observation” as Low-Risk Surrogate to Define GB2

To validate the clinical safety of the ground-truth labeling for the low-risk group (GB2), we conducted a comprehensive post-hoc analysis of all 12,853 visits in this category. Short-term safety was confirmed by a 72-hour ED revisit rate for chest pain of 2.16% (277/12,853) and a negligible 72-hour hospitalization rate for non-ACS urgent illnesses of 0.05% (7/12,853).

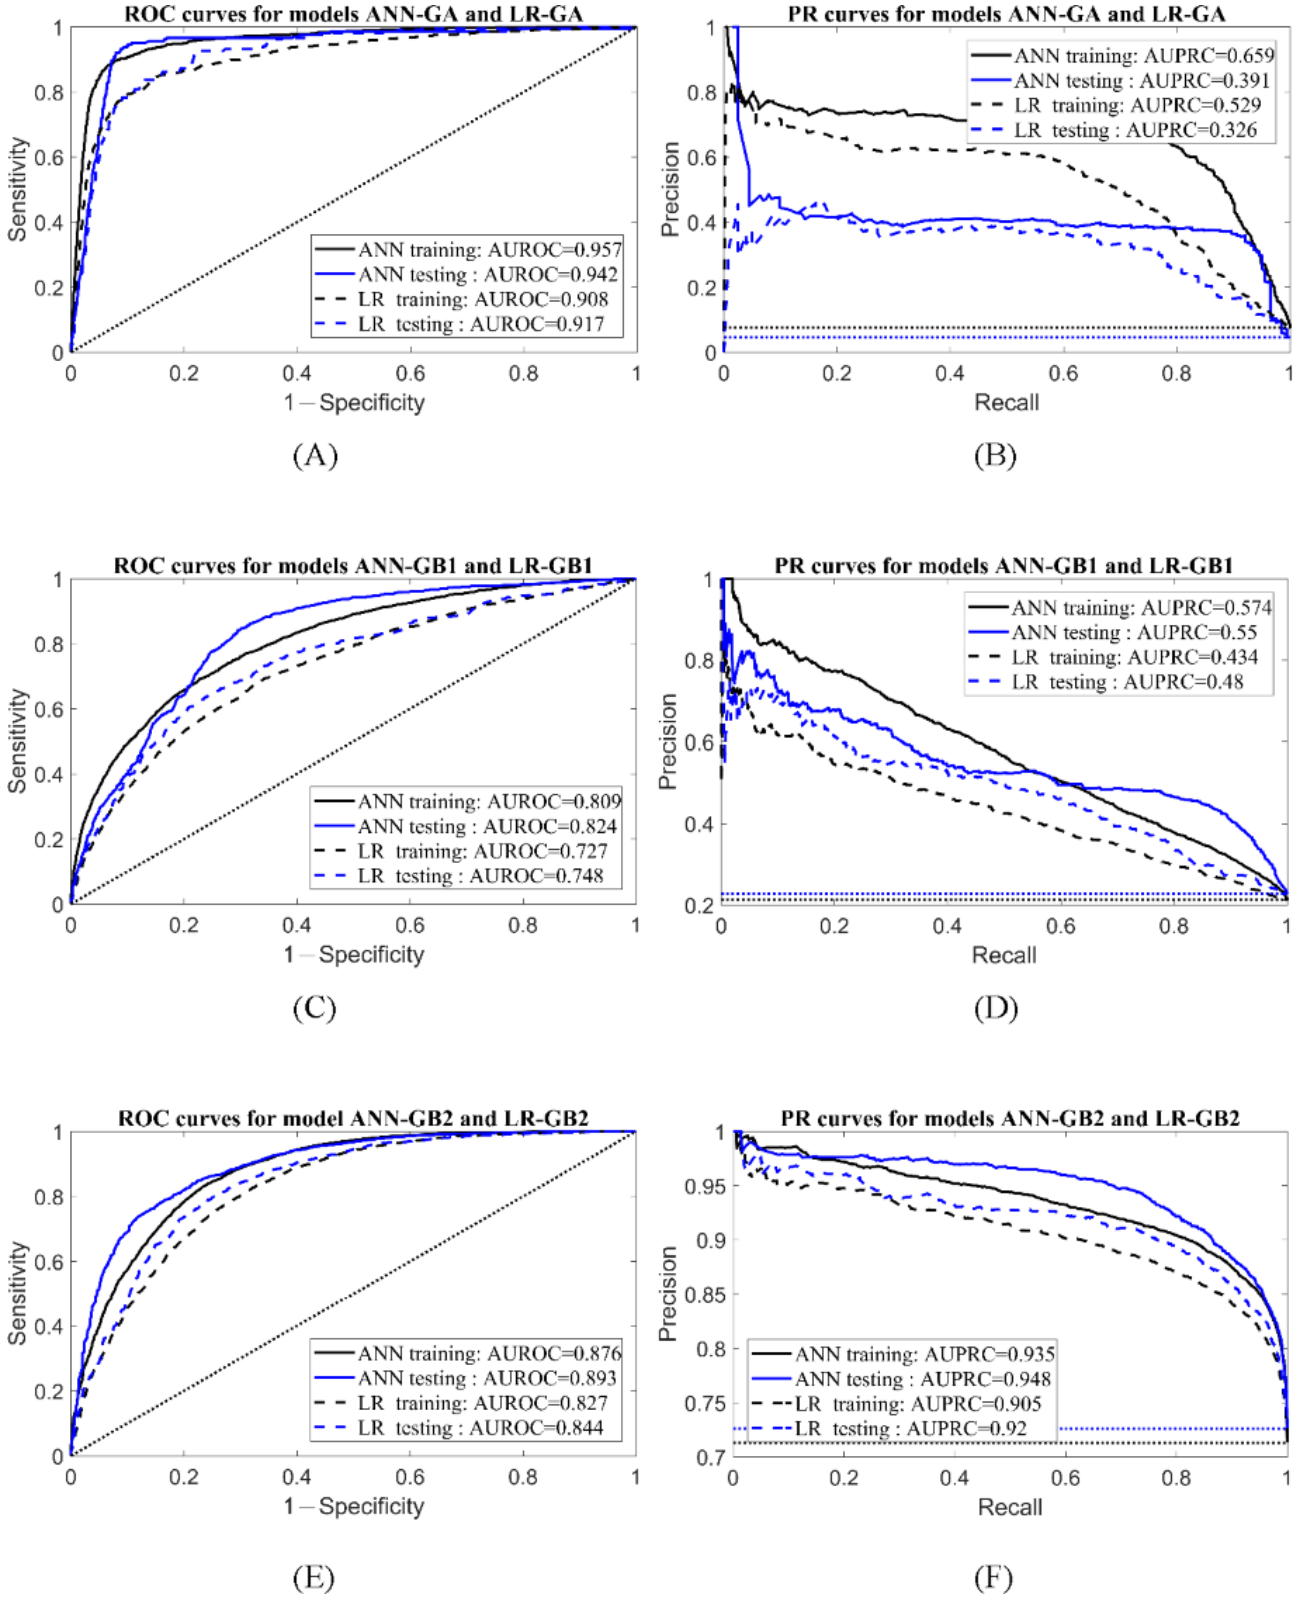
Over a 30-day follow-up period, the cumulative major adverse cardiac event (MACE) rate—comprising ACS and out-of-hospital cardiac arrest (OHCA)—was 0.20% (25/12,853), with a 30-day hospitalization rate of 0.19% (24/12,853). Formal adjudication of these 25 MACE cases identified 21 ACS

XSL•FO
RenderX

diagnoses and 4 OHCAs. The 4 OHCAs occurred 7 to 16 days after discharge. The 21 ACS included 7 ST-elevation myocardial infarctions (STEMIs). Notably, all 7 STEMI cases presented 3 to 29 days after discharge and exhibited significant new changes on follow-up ECGs compared to their index visits. These findings suggest that such events likely reflect late disease progression rather than initial diagnostic failure.

Furthermore, we evaluated the risk of missed lethal noncardiac conditions. Among the 897 (6.98%) patients who revisited the ED within 30 days, we identified only 3 cases of pulmonary embolism and 1 aortic dissection (AD). Within the testing cohort specifically, there was only 1 case of pulmonary embolism and no case of AD. This represents a remarkably low combined incidence of 0.03% (4/12,853 total; 1/3237 testing) for these critical events. Collectively, these results substantiate that using "ED discharge" as a surrogate for low-risk status is both safe and clinically robust.

Composition of the Non-ACS Urgent Illness Group GB1



The GB1 category was established to encompass acute conditions requiring medical intervention or hospitalization other than ACS. Analysis of the primary diagnoses within this group revealed a diverse spectrum of clinically significant conditions: congestive heart failure (746/3873, 19.26%), acute pulmonary edema (666/3873, 17.20%), cardiac arrhythmia (585/3873, 15.10%), pneumonia (454/3873, 11.72%), AD (194/3873, 5.01%), and pneumothorax (39/3873, 1.01%). Additionally, 28.53% (1105/3873) of cases in GB1 were hospitalized for intensive clinical observation of chest pain. These findings indicate that a broad range of urgent medical states beyond coronary events have been taken into account in the model training process.

Model Performance

Figure 3 presents the ROC and PR curves of the 3 ANN and the 3 LR models for both training and testing datasets. The full confusion matrices and class-wise performance metrics, including AUROC, accuracy, sensitivity, specificity, PPV, NPV, F_1-score, and AUPRC at respective optimal cutoff thresholds, are summarized in Tables 2 and 3. For multiclass classification, full confusion matrices and performance metrics under 3 decision mechanisms (S1-S3) are summarized in Tables 4 and 5. The ANN-based multiclassifiers (thereafter referred to as ANN-S1, ANN-S2, and ANN-S3) were able to achieve high sensitivity in identifying GA patients and high PPV and high sensitivity in identifying GB2 patients. Notably, ANN-S3 yielded 0.941 sensitivity (95% CI 0.908 - 0.973) for GA and 0.837 sensitivity (95% CI 0.824 - 0.850) and 0.911 PPV (95% CI 0.900 - 0.921) for GB2.

Furthermore, Tables 6 and 7 provide the complete confusion matrices and performance metrics for multiclassifiers using the S3 mechanism. These summaries compare the multiclassifiers based on ANN and LR models (referred to as ANN-S3 and LR-S3, respectively)—both using Youden-optimal thresholds—alongside an ANN variant with a reduced GA classification threshold (referred to as ANN-S3-L). For ANN-S3-L, the GA classification threshold was set at 0.0167 (significantly lower compared to 0.0744 for ANN-S3 and 0.0553 for LR-S3). This value was determined by identifying the maximum threshold at which the ANN-GA model achieved a sensitivity exceeding 0.95 on the training data, a conservative approach intended to prioritize clinical safety and minimize false negatives.

Calibration curves with Brier scores (95% CIs) for ANN-GA, ANN-GB1, ANN-GB2 models on the training and testing datasets are presented in Figure 4. The results indicate that the calibrated models render predicted probabilities more aligning with the observed risk. ANN-GB2 appears to be very well calibrated on both datasets, while ANN-GB1 somewhat underestimates and ANN-GA overestimates the risk. The results of the decision curve analysis are illustrated in Figure 5. The

XSL•FO
RenderX

decision curves show that across a broad range of probability thresholds, all models demonstrated superior clinical utility compared to the traditional "treat-all" and "treat-none" baseline strategies. Notably, for the GB1 and GB2 models, this improved net benefit was maintained across almost the full range of probability thresholds.

Analysis of subgroup performance was based on the ROC curves of the calibrated ANN models on different subgroups (testing) data. Specifically, we consider 3 age bands (below 65, 65 - 85, and above 85 years), male and female sexes, and 4 eGFR strata (below 30, 30 - 60, 60 - 90, and above 90). The results are presented in Figure 6. Figure 6D-F shows that the ROC curves for male and female subgroups closely align with those of the full dataset, indicating negligible disparity of the model's predictive power among different sex subgroups. However, notable disparities exist regarding age and eGFR. Specifically, the model underperformed in older-age and low-eGFR subgroups, which exhibited both lower AUROC scores and ROC curves that fell substantially below the aggregate baseline.

Figure 6. Results of ANN-GA, ANN-GB1, and ANN-GB2 models on different subgroups testing data. (A-C) Comparison among different age groups, (D-F) comparison between male and female sex groups, and (G-I) comparison among different eGFR strata. ANN: artificial neural network; AUROC: area under the receiver operating characteristic curve; eGFR: estimated glomerular filtration rate; GA: critical patients with acute coronary syndrome; GB1: critical patients without acute coronary syndrome; GB2: low-risk patients.

Sensitivity Analysis

To ensure that the 142 patients overlap between the adjacent years of 2020 (belonging to the training cohort) and 2021 (belonging to the testing cohort) did not bias our findings via static baseline variables (eg, age, sex, and comorbidities), a sensitivity analysis was performed by excluding the 151 testing visits by these individuals. The resulting performance metrics remained tightly aligned with the primary analysis. In particular, the AUROC, sensitivity, and PPV for both GA and GB2 classifications remained well within the original 95% CIs. This confirms that cohort overlap did not artificially inflate model performance. A comprehensive comparison is detailed in Tables S7 and S8 in Multimedia Appendix 1.

Furthermore, to evaluate whether the heavy positive skew of the raw hs-TnT data impacted model performance, we performed a sensitivity analysis by retraining and calibrating the ANN models under identical conditions and replacing the raw hs-TnT

XSL•FO
RenderX

values with their log-transformed counterparts. Models trained with log-transformed hs-TnT showed slightly lower performance; yet, their results remained tightly aligned with our primary architecture, as reflected by heavily overlapping 95% CIs. Specifically, the training AUROC scores for the primary vs log-transformed ("-T") models were ANN-GA: 0.957 (95% CI 0.948 - 0.965) vs ANN-GA-T: 0.951 (95% CI 0.941 - 0.960), ANN-GB1: 0.809 (95% CI 0.799 - 0.819) vs ANN-GB1-T: 0.794 (95% CI 0.784 - 0.804), and ANN-GB2: 0.876 (95% CI 0.870 - 0.881) vs ANN-GB2-T: 0.869 (95% CI 0.864 - 0.875). This demonstrates that while batch normalization primarily stabilizes mini-batch activations, the neural network's architecture was robust to the empirical distribution and skewness of the raw cardiac biomarker data. A comprehensive performance comparison, including AUPRC scores, is provided in Table S9 in Multimedia Appendix 1.

Potential Improvement of the Patient Flow

In the testing dataset, 3237 patients were categorized as GB2, indicating noncritical conditions. Among them, 3087 had complete data for ED length-of-stay analysis. Of these patients, 1247 received a single hs-TnT test (T1 subgroup, consistent with a single-sample rule-out strategy [26]; median ED LoS 139, IQR 108-195 minutes), whereas 1840 received 2 hs-TnT tests (T2 subgroup, consistent with an every-3-hour serial testing strategy [27]; median ED LoS 285, IQR 251-366 minutes). Based on the clinical variables available at the time of the initial laboratory panel, the ANN-S3 multiclassifier identified 2653 patients as GB2, while 434 GB2 patients were classified as non-GB2.

Among the model-identified GB2 patients, 1170 were from the T1 subgroup, representing 93.83% (1170/1247) of patients who were discharged after a single hs-TnT test in actual clinical practice. This high concordance suggests that the model frequently aligned with physicians' real-world decisions to manage selected low-risk patients using a single-sample strategy. In addition, 1483 model-identified GB2 patients were from the T2 subgroup, representing 80.60% (1483/1840) of patients who underwent serial hs-TnT testing. These patients represent a retrospectively identified subgroup who might have been considered eligible for a single-sample protocol based on the risk-assessment model, although they were managed with serial testing in actual practice.

The longer median LoS observed in the T2 subgroup compared with the T1 subgroup suggests that serial hs-TnT testing was associated with longer ED stays in this retrospective cohort. However, these observational differences should not be interpreted as direct evidence that model implementation would reduce LoS by the same magnitude, because the original decision to perform single versus serial testing was likely influenced by physician-perceived risk and other clinical workflow factors. Therefore, our findings, as illustrated in Figure 7, should be interpreted as demonstrating the model's potential to enhance ED throughput by identifying additional low-risk candidates for a single-sample strategy, rather than as definitive evidence of actual operational improvement. The actual impact on ED LoS, discharge timing, and patient flow will require prospective evaluation in real-world clinical workflows.

RenderX

Figure 7. (A) Number of GB2 patients identified based on “single sample rule-out” (green) and “Q3H strategy” (blue) protocols. With the assistance of the ML model, the number of GB2 patients identified by the “single sample rule-out” protocol could be more than doubled compared to the number by physician judgment. (B) Comparison between physician decision and ML model prediction on “single sample rule-out” and “Q3H strategy” protocols. The model highly agreed with the physician decision on “single sample rule-out” (1170/1247 or 93.8%), while in addition correctly identified 1483 more GB2 patients who went through the “Q3H strategy” protocol based on the “single sample rule-out” protocol. GB2: low-risk patients; LoS: length of stay; ML: machine learning; Q3H: every 3 hours.

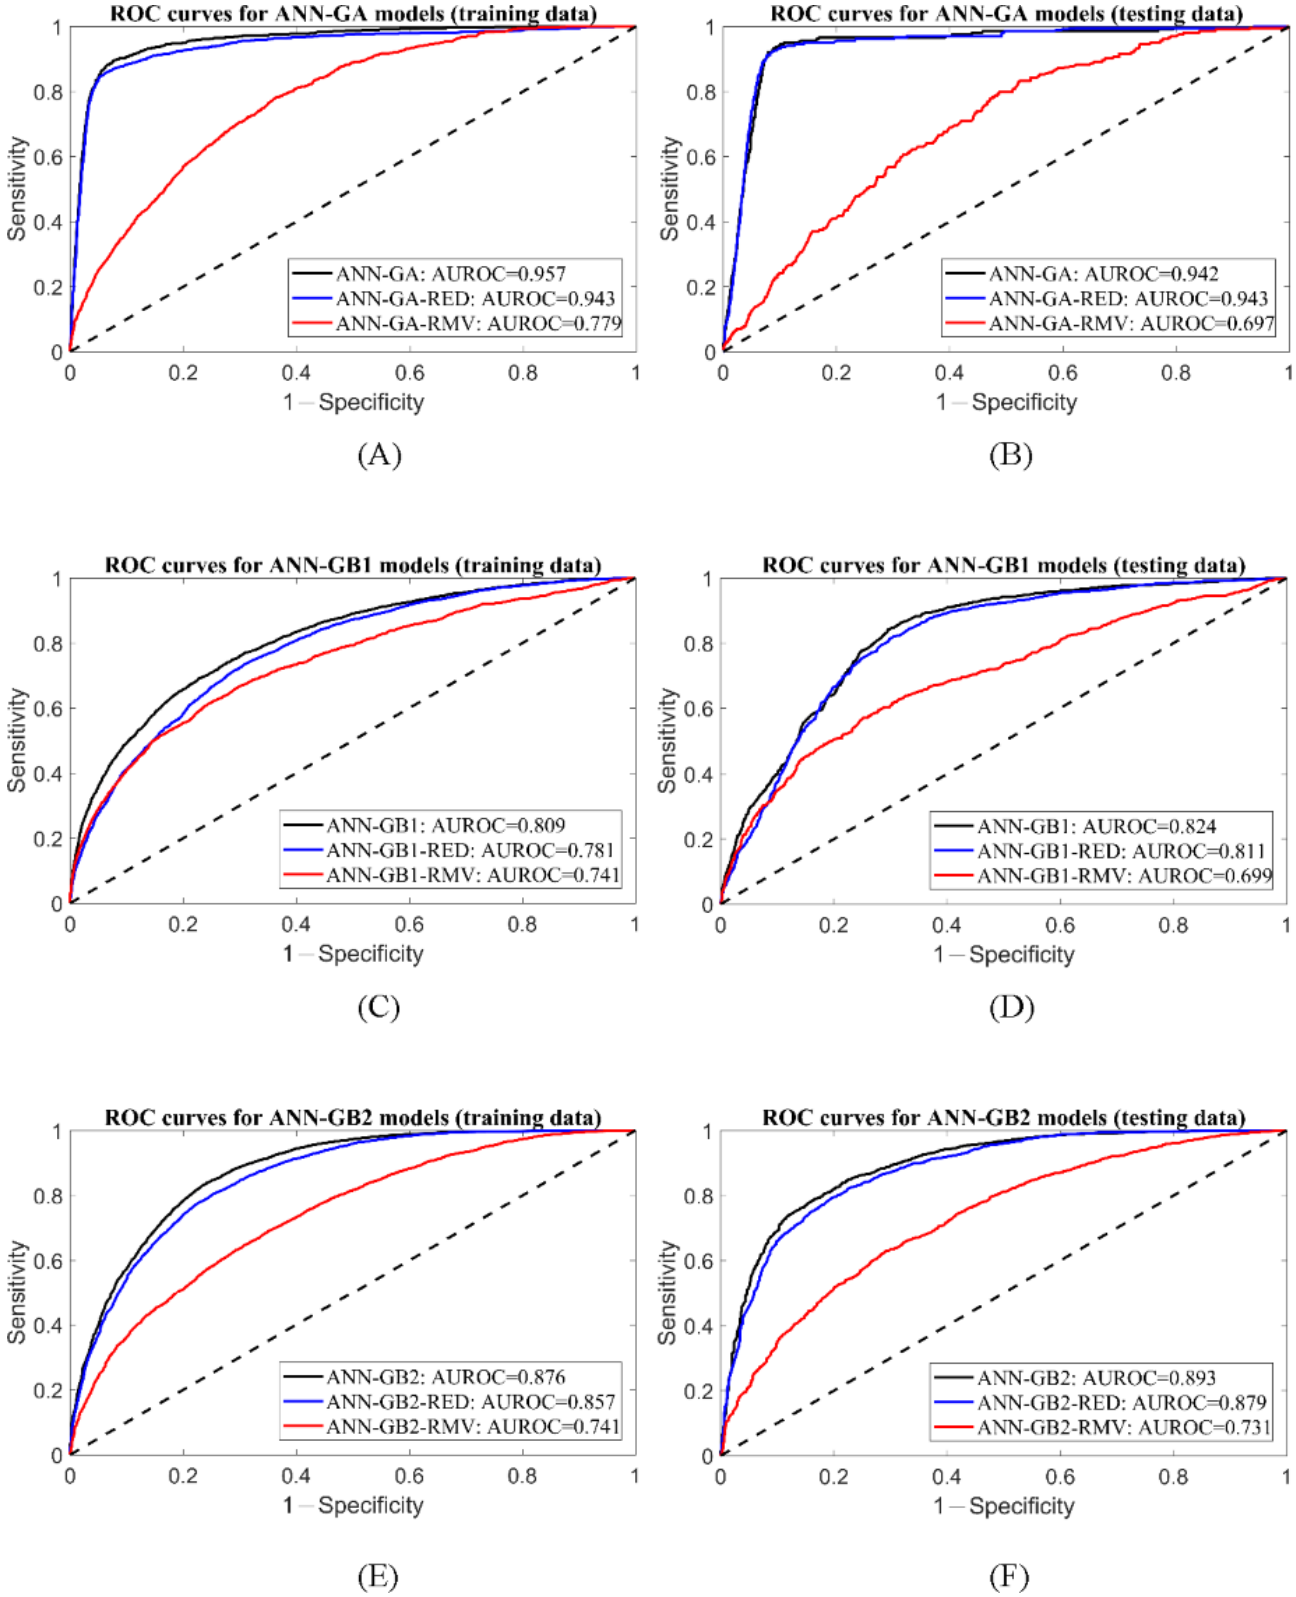
Importance of Feature Variables and Model Interpretability



For each group classification, the 7 most important feature variables (referred to as "key feature variables") identified by Gini diversity analysis are as follows:

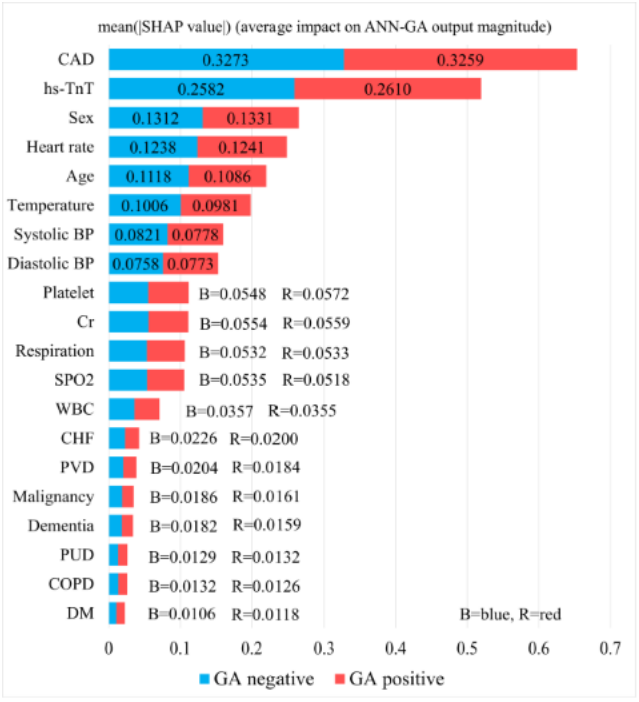
- For group GA: the 4 blood test results, CAD, and diastolic and systolic blood pressures (BPs).
- For group GB1: the 4 blood test results, CAD, age, and heart rate.
- For group GB2: the 4 blood test results, CAD, age, and systolic BP.

The ANN models trained using only key feature variables were referred to as ANN-GA-RED, ANN-GB1-RED, and ANN-GB2-RED, respectively. Models trained using all features except the key feature variables were named ANN-GA-RMV, ANN-GB1-RMV, and ANN-GB2-RMV, respectively. Figure 8 displays the ROC curves of these models, along with those of ANN-GA, ANN-GB1, and ANN-GB2. The detailed performance metrics of these models on the testing data are summarized in Table S10 in Multimedia Appendix 1.

XSL•FO
RenderX

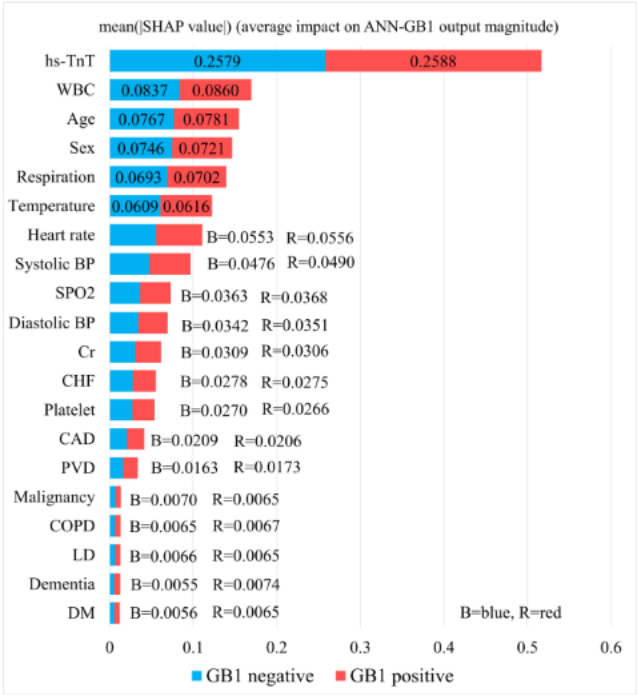
Figure 8. ROC curves of the ANN-GA, ANN-GB1, ANN-GB2 models trained with or with only or without key feature variables. (A and B) Curves of ANN-GA models on training and testing data, (C and D) curves of ANN-GB1 models on training and testing data, and (E and F) curves of ANN-GB2 models on training and testing data. ANN: artificial neural network; AUROC: area under the receiver operating characteristic curve; GA: critical patients with acute coronary syndrome; GB1: critical patients without acute coronary syndrome; GB2: low-risk patients; RED: models trained using only key feature variables; ROC: receiver operating characteristic; RMV: models trained using all but key feature variables.

Regarding the impact of each feature variable on the model's output, the results of SHAP value analysis are presented in Figure 9. For each model, the top 7 "high impact" feature variables are as follows:



- For model ANN-GA: CAD, hs-TnT, sex, heart rate, age, temperature, and systolic BPs.
- For model ANN-GB1: hs-TnT, white blood cell (WBC), age, sex, respiration, temperature, and heart rate.

XSL•FO
RenderX



- For model ANN-GB2: hs-TnT, CAD, WBC, age, respiration, temperature, and sex.

Apparently, the predicted probabilities rendered by ANN-GA and ANN-GB2 models are driven by 5 common feature variables: CAD, hs-TnT, age, sex, and temperature. In addition, the output of the ANN-GB1 model is predominantly driven by the hs-TnT variable, whose impact is tripled compared to those of other variables.

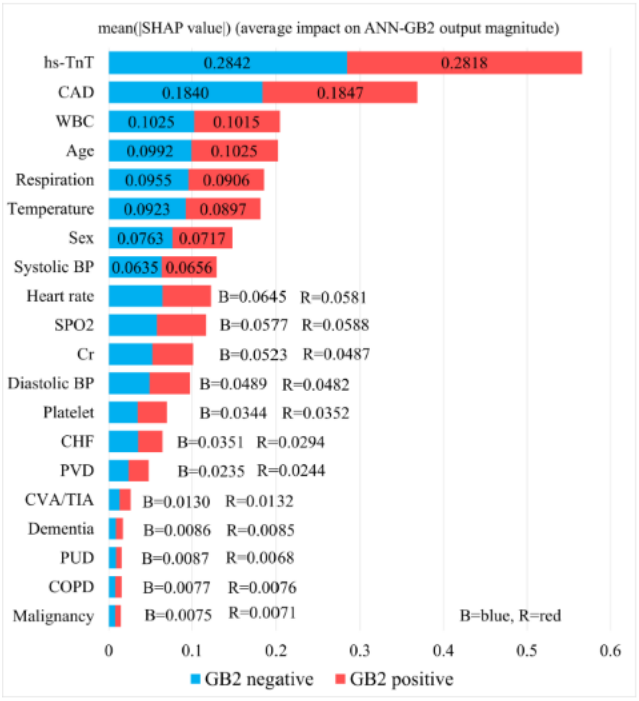


Figure 9. Results of the SHAP value analysis for ANN-GA, ANN-GB1, and ANN-GB2 models. (A) Average impact of each feature variable on the ANN-GA model output, (B) average impact of each feature variable on the ANN-GB1 model output, and (C) average impact of each feature variable on the ANN-GB2 model output. ANN: artificial neural network; BP: blood pressure; CAD: coronary artery disease; CHF: congestive heart failure; COPD: chronic obstructive pulmonary disease; Cr: creatinine; CVA/TIA: cerebrovascular accident/transient ischemic attack; DM: diabetes mellitus; GA: critical patients with acute coronary syndrome; GB1: critical patients without acute coronary syndrome; GB2: low-risk patients; hs-TnT: high-sensitivity cardiac troponin T; LD: liver disease; PUD: peptic ulcer disease; PVD: peripheral vascular disease; SHAP: Shapley Additive Explanations; SPO_2: peripheral oxygen saturation; WBC: white blood cell.

Discussion

Principal Findings

In this study, machine learning models were developed to assist in identifying patients with ACS (GA), those without ACS but with other severe illness (GB1), and low-risk patients (GB2). The individual ANN classification models—ANN-GA, ANN-GB1, and ANN-GB2—all demonstrated impressive performance based on testing AUROC scores: ANN-GA and ANN-GB2 achieved scores close to or greater than 0.9, while ANN-GB1 achieved 0.824. In terms of AUPRC scores, ANN-GB1 and ANN-GB2 achieved 0.55 and 0.948, respectively, indicating a good balance between precision and recall. ANN-GA performed relatively poorly on the AUPRC score, achieving only 0.391. However, this is still a significant improvement compared to a no-skill classifier, for which the AUPRC score would be less than 0.05. The superior predictive powers of the ANN models are evidenced by their significant performance gains over their LR counterparts. This margin is clearly demonstrated by the ROC curves in Figure 3, and the comprehensive metrics are summarized in Tables 2 and 3.

The primary objectives for multiclassification are two-fold: (1) maximizing sensitivity for patients with ACS (GA) due to the life-threatening nature of the condition and (2) ensuring high sensitivity and PPV for low-risk patients (GB2) to streamline the ED patient flow. Among the models evaluated, the ANN-S3 classifier emerged as the superior choice. While ANN-S2 matched its sensitivity for GA, it experienced a lower PPV for GB2 patients. ANN-S1 achieved (almost) identical GB2 performance but exhibited notably lower sensitivity for GA cases. The LR counterpart, LR-S3, proved inferior due to prohibitively low GA and GB2 sensitivities (0.808 and 0.672, respectively). To prioritize clinical safety, the ANN-S3-L variant was developed by lowering the GA classification threshold from 0.0744 to 0.0167. This adjustment resulted in a much higher GA sensitivity (0.966) and NPV (0.998), though it reduced GA specificity from 0.902 to 0.797, as well as GB2 sensitivity from 0.837 to 0.787. This shift ultimately diminished the model's ability to identify low-risk patients, highlighting the inherent trade-off between clinical safety and operational efficiency.

The S3 multiclassifier uses adjusted scores to differentiate between GB1 (requiring acute care) and GB2 (suitable for discharge after observation) classifications. To prioritize patient safety, the GB1 adjustment factor is nearly 3 times larger than that of GB2 (1/0.2441 vs 1/0.7069). This scaling biases borderline decisions against the GB2 classification, favoring clinical caution over statistical parity. These adjusted scores essentially measure a patient's "distance" from the clinically accepted risk requirement for respective classification. For example, if a patient's risk profile exceeds the GB1 threshold (adjusted score>1) but remains below the GB2 threshold (adjusted score<1), the mechanism defaults to GB1. This design is based on the principle that meeting a specific "required" risk level is a more significant clinical milestone than achieving a high raw score that fails to cross a safety threshold. While we acknowledge that this lack of statistical parity may reduce GB2 sensitivity, we view this as a necessary trade-off to enhance the safety of high-risk patients.

Notably, the ANN-based multiclassifier S3 misclassified 5 ACS (GA) cases as "low-risk" (GB2), as shown in Table 6. We have conducted a detailed review of the 5 ACS cases to identify specific failure modes. The misclassified cohort shared a specific "low-risk" profile: (1) a lack of prior CAD history, (2) a relatively young age (median<65 years), (3) hemodynamic and respiratory stability, and (4) initial hs-TnT levels below the 99th percentile URL of 14 ng/L (with 6 of 7 cases<11 ng/L). Identifying ACS in patients who lack traditional risk factors, present as physiologically stable, and maintain "normal" biomarkers represents a significant diagnostic boundary for the model. Such cases remain a formidable challenge even for experienced clinicians [26]. Recognizing these failure patterns is vital for the responsible integration of AI in the ED, ensuring that the model serves as an objective support tool while physician judgment remains the primary safeguard for atypical or early presentations.

Regarding subgroup performance, our analysis revealed that model predictive power decreases in older populations and in patients with lower eGFRs. These results reflect the inherent complexity of diagnosing acute conditions among the older patients in the ED, where they often present with atypical symptoms and multiple comorbidities that obscure traditional clinical signals [27,28]. The observed performance drop suggests that ACS-associated multivariable patterns are significantly more heterogeneous in older cohorts than in younger ones. Moreover, while hs-TnT was a high-impact variable across all classification groups, renal impairment acts as a known confounder. Chronically elevated baseline hs-TnT levels in patients with renal disease complicate the distinction between acute myocardial injury and chronic cardiac strain [29]. Consequently, the diagnostic utility of hs-TnT diminishes as eGFR declines, leading to the observed degradation in model performance. These findings underscore that a "one-size-fits-all" model may be insufficient for high-risk, complex populations. To ensure the responsible deployment of AI in clinical settings, our future work will focus on developing specialized models tailored to the unique physiological and biomarker profiles of older patients and patients who are renally impaired.

Furthermore, the observed performance disparities may stem from the underrepresentation of specific subgroups during training. For instance, patients older than 85 years of age constitute only 7.8% of the training dataset, while those with an eGFR of 30 - 60 mL/minute/1.73 m^2 and below 30 mL/minute/1.73 m^2 represent just 13% and 11%, respectively. To mitigate this training bias in future iterations, oversampling strategies such as the synthetic minority oversampling technique could be used to better balance these cohorts.

The current 2021 American Heart Association (AHA) and American College of Cardiology (ACC) and 2023 European Society of Cardiology guidelines emphasize serial high-sensitivity troponin testing as the primary standard of care for the evaluation of ACP. Our findings are not intended to supersede these class I recommendations; rather, they explore the potential of AI to support existing "single-sample rule-out"

XSL•FO
RenderX

concepts for specific low-risk populations, as discussed in the 2021 AHA and ACC guidelines for patients with prolonged symptom onset. By integrating hs-TnT with 23 other demographic and clinical feature variables, our ANN model offers a multidimensional risk assessment that may help clinicians interpret "gray-zone" troponin levels in older or comorbid patients. This approach serves as a CDS tool, providing an additional layer of evidence to assist physicians in their disposition decisions while remaining within the safety boundaries established by contemporary clinical practice.

While clinical guidelines such as the European Society of Cardiology 0/1 hour or 0/2 hour algorithms are established standards for ruling out ACS, their impact on operational efficiency in real-world practice is often limited. Findings from the European Society of Cardiology 0h/1h Troponin Rule-Out Protocol trial suggest that implementing the 0/1 hour protocol may not significantly reduce ED LoS or increase early discharge rates compared to standard care [30]. This discrepancy exists because actual clinical workflows are fundamentally driven by physician judgment, which synthesizes patient history and multifaceted clinical assessments rather than relying solely on serial laboratory values. Our ANN model addresses this gap by integrating 24 decision variables, including renal function (creatinine), hematological parameters (WBC and platelet counts), vital signs, and extensive medical history. By using this multidimensional approach, the model identifies low-risk features more comprehensively than simple heuristics—such as isolated troponin thresholds—and more closely mirrors the integrative nature of expert clinical reasoning. Furthermore, the objective risk stratification provided by the AI model serves as a reliable "second opinion." This decision support is particularly valuable in high-pressure ED environments, where it can mitigate decision fatigue and cognitive burden among emergency physicians. By enhancing the confidence of clinicians in early discharge decisions, the model has the potential to optimize patient flow and alleviate ED overcrowding without compromising the established safety standards of current practice.

Our findings suggest that while point-of-care testing is invaluable for rapid, lean evaluations, an AI-augmented strategy may provide a distinct, complementary pathway for deeper risk stratification. Rather than imposing a "one-size-fits-all" mandate, this model offers an objective decision-support tool that reinforces the physician's initial clinical suspicion. For patients already requiring a standard laboratory workup, the model leverages 24 variables to facilitate a confident, single-sample disposition, which may achieve a substantial reduction in ED LoS compared to traditional serial testing protocols. In our retrospective cohort, patients managed with a single-sample strategy had a median LoS of 139 (IQR 108-195) minutes, compared with 285 (IQR 251-366) minutes among those who underwent serial testing. The difference suggests the potential operational relevance of identifying additional candidates for a single-sample protocol. One should not, however, interpret this difference as a predicted reduction in LoS after model implementation, as the comparison is observational and subject to confounding by indication. Prospective evaluation is required to determine the actual operational impact of a model-driven decision support tool on ED throughput.

The predictive power of each ANN model was primarily driven by a set of key feature variables, as demonstrated by the performance variance in models trained with, with only, and without these variables. These essential features—detailed in the Importance of Feature Variables and Model Interpretability section—encompass patient age, triage blood pressure, prior history of CAD, WBC count, platelet count, serum creatinine, and hs-TnT. The inclusion of age, hypertension, and prior CAD history aligns with traditional cardiovascular risk profiles [31-33]. Models' reliance on serum creatinine mirrors the documented association between the severity of chronic kidney disease and an increased likelihood of cardiovascular events [34]. Moreover, the predictive weight of WBC and platelet counts reflects the systemic inflammation and platelet activation inherently linked to atherothrombotic processes often observed in patients with ACS [35]. Finally, the inclusion of hs-TnT, the cornerstone biomarker for myocardial injury, reinforces the medical relevance of our feature selection. These key features contribute the primary diagnostic weight. Notably, the "reduced" models—trained exclusively on these high-impact variables—occasionally outperformed the 24-variate "full" models in specific test settings. Furthermore, for categories GB1 and GB2, performance was slightly higher on the testing data than on the training data. This phenomenon likely results from the random fluctuations of low-contributory variables in the training set, which can lead to overfitting. By focusing on high-impact features, the reduced models achieve a form of "implicit regularization," effectively filtering out stochastic noise. Consequently, these parsimonious models may offer superior operational robustness for real-world clinical deployment, as the marginal utility of the remaining variables is offset by the risk of overfitting to cohort-specific noise.

SHAP value analysis demonstrates high consistency and medical interpretability across both high-risk (GA) and low-risk (GB2) classifications. The most influential variables—specifically hs-TnT, age, sex, and a history of CAD—are firmly grounded in established clinical evidence [36]. In particular, the dominant role of hs-TnT as a fundamental biomarker for myocardial injury aligns perfectly with current diagnostic standards for ACS. Notably, these findings underscore that the model's predictive power is derived from medically plausible features rather than mere statistical correlation. This alignment between model-identified variables and clinical intuition supports the causal relevance of the model, distinguishing it from conventional "black-box" approaches. Such interpretability is essential for fostering clinician trust and ensuring the responsible integration of AI into medical decision-making.

Most existing studies have focused primarily on the diagnostic performance of AI models in identifying or ruling out ACS [37]. However, relatively few have proposed robust methodologies to evaluate whether the implementation of such models in real-world clinical workflows could yield tangible benefits. In this study, we conducted a retrospective analysis using historical data to quantitatively assess the potential impact of incorporating an AI-based CDS system into the emergency management of patients presenting with ACP. In the high-risk patient subgroup,

XSL•FO
RenderX

our model may facilitate earlier recognition of non-STEMI and unstable angina, thus enabling more timely intervention and potentially improving patient outcomes. For low-risk patients, our findings suggest that, compared to physicians' original clinical decisions, the AI model could safely identify a greater proportion of patients eligible for the single-sample rule-out protocol [38]. This may reduce unnecessary serial blood testing and prolonged ED observation, thereby lowering health care costs and alleviating ED crowding [3].

Furthermore, the integration of AI models into clinical workflow for decision-making support may help mitigate cognitive burden and decision fatigue among emergency physicians, ultimately reducing the risk of burnout [39]. On the other hand, while our ANN model demonstrates high classification performance in a retrospective setting, we acknowledge that significant barriers remain before it can be integrated into routine emergency care. These include sociotechnical challenges such as clinician acceptance, workflow integration, and the medical-legal implications of deviating from serial troponin testing protocols. Our findings should be interpreted as a preliminary step in exploring AI-augmented risk stratification. Future research must focus on prospective validation and implementation science to ensure that such models provide tangible clinical benefits without compromising patient safety or increasing the cognitive load on ED staff.

To ensure the safe and responsible implementation of our model, we emphasize that the AI system is designed as a CDS tool intended to function within a human-AI team framework. Rather than replacing physician judgment, the model provides context-specific risk assessments that emergency physicians can integrate into their clinical workflow. For high-risk cases (GA and GB1), the system can actively alert clinicians, whereas for low-risk patients, it serves as a passive supportive resource. To mitigate risks such as overreliance or user error, clinicians are provided with the basis for model outputs and informed of the system's limitations. Furthermore, in alignment with Good Machine Learning Practice principles, we acknowledge that the performance of deployed models must be subject to ongoing monitoring in "real-world" use. Our planned future work includes establishing a dedicated monitoring platform to detect dataset drift or performance degradation over time. This framework will include strict controls for retraining and model updates to manage risks such as overfitting or unintended bias, ensuring the model's safety and effectiveness throughout its total product life cycle.

Limitation

This study has several limitations. First, this study's single-center, retrospective design inherently limits the geographic and ethnic generalizability of our findings. We acknowledge that some key baseline characteristics—such as cardiovascular risk profiles, BMI thresholds, and renal function—vary significantly across diverse populations and health care systems. Consequently, the model's performance may reflect our specific local cohort and might not be immediately applicable to other clinical settings. External validation using larger, multicenter datasets is a mandatory prerequisite before this model can be considered for universal clinical implementation.

Second, our study used ED disposition as the primary surrogate for the "low-risk" (GB2) ground truth, which may not capture adverse events occurring outside the hospital. Although we confirmed the 30-day survival of 8556 patients through subsequent clinical records, remaining patients had no further follow-up in our ED, limiting our ability to definitively confirm their survival status. This is again a characteristic limitation of single-center retrospective designs. However, given the negligible 30-day MACE rate of 0.2%, the GB2 label remains a clinically reliable benchmark for training and evaluating our AI models.

Third, the absence of symptom-onset timing in our dataset represents a significant constraint. The 2021 AHA and ACC Chest Pain Guidelines mandate that single-sample rule-out strategies apply only to patients presenting more than 3 hours after symptoms begin. Since our dataset lacks this temporal data, the model's clinical use should be limited to late-presenting cohorts to maintain diagnostic safety. Future research will focus on safely extending the model's utility to early presenters while preserving a high NPV.

Fourth, a notable limitation of this study is that the model does not use raw ECG waveforms, structured ECG interpretations, or qualitative clinical descriptors (eg, specific chest pain characteristics) as direct inputs. These variables are core components of established risk stratification tools such as the History, ECG, Age, Risk factors, Troponin score, or Emergency Department Assessment of Chest Pain Score; their absence in a structured format within our retrospective dataset precluded a direct comparison with these traditional heuristics. However, because our unselected study population included all eligible ED visits regardless of ECG presentation, and since our ground-truth labels were derived from final clinical diagnoses—which inherently incorporate ECG and semiological findings—the model effectively learned to correlate its 24 clinical variables with outcomes already influenced by these factors. While our SHAP analysis highlights the importance of traditional risk factors, the ANN architecture was specifically leveraged to capture complex, multidimensional interactions across the available parameters. Currently, the model is intended to augment, rather than replace, initial physician ECG screening. Future prospective work aims to integrate digitized ECG signal analysis and granular clinical descriptors to further strengthen diagnostic safety and benchmark the model's additive value against established clinical scores.

Fifth, this model may be subject to spectrum bias, as the inclusion criteria were limited to patients triaged as level-2 (urgent). While this prioritized a high-acuity cohort with the most immediate clinical need, it excludes patients undertriaged to lower levels who may still harbor high-risk pathology. This reliance on triage levels partly stems from a lack of granular, structured chest pain data—such as pain radiation, quality, or alleviating factors—which was primarily captured as unstructured narrative text. Although our current variables align with the standard of care, the absence of these qualitative descriptors might lead to the omission of atypical presentations.

XSL•FO
RenderX

Future integration of natural language processing to extract clinical features from nursing notes could mitigate this bias, allowing for a broader patient spectrum and improved differentiation between ACS and other critical conditions across all triage categories.

Sixth, a potential selection bias exists due to the exclusion of 1435 visits with missing or indeterminate data, such as incomplete triage records, examination results, or medical histories. While our analysis shows that the final cohort of 17,935 visits remains highly representative of our institution's urgent chest pain population, these exclusions may slightly impact the generalizability of our findings. The potential bias can be mitigated when the models are retrained with more available data in the future. Moreover, to minimize predictive uncertainty, we deliberately avoided data imputation, ensuring that no prediction is rendered unless all required feature values are present to inform the physician's judgment. The system was designed to issue error or warning messages when it encounters missing data or unstructured entries that do not meet the input specifications. However, we recognize that this "complete-case" requirement may limit the real-world utility of our models in clinical settings with less structured data entry. To address this, future iterations will explore multivariate imputation by chained equations, enabling the model to have robust performance in the presence of missing data and mitigating current utility restrictions while maintaining diagnostic reliability.

Seventh, the inferred time savings associated with the model are based on a retrospective comparison of median LoS. These findings are subject to confounding by indication, as the single-test cohort likely represented patients with lower perceived clinical risk. While the results suggest a trend toward improved efficiency through reduced repeat testing, they should be interpreted as the theoretical potential of a single-sample strategy. The actual impact on LoS in prospective deployment may vary depending on clinical judgment, ED crowding, and institutional protocols [40], and cannot be definitively predicted from this observational data.

Eighth, the assessment of potential improvements in ED workflow following model implementation was based on retrospective data. Future prospective studies, ideally incorporating collaboration with experts in operations research, are needed to evaluate the real-world impact of integrating the model into clinical practice.

Finally, the testing AUPRC for the high-risk (GA) group was only 0.391. Given the GA prevalence of only 4.6% in our test cohort, this performance represents a significant improvement over random classification; however, it also reflects a lower PR balance for this rare but critical class. While our model prioritizes a high NPV (>99.5%) to ensure patient safety, this emphasis may result in a higher rate of false positives. This conservative bias could potentially lead to increased resource use and diagnostic observation in the ED. Future work will focus on incorporating dynamic clinical features to enhance precision without compromising the model's high safety threshold.

Conclusions

The AI models developed in this study serve as a preliminary proof-of-concept for providing CDS to physicians managing ACP. The multiclassification model we developed achieved 0.941 sensitivity for identifying patients with ACS and 0.837 sensitivity and 0.911 PPV for identifying nonsevere patients. Despite many limitations, these results suggest that integrating AI-based multiclassification algorithms into ED workflows has the potential to enhance risk stratification and optimize resource use. However, we recognize that translating these findings into real-world practice involves significant sociotechnical, medical-legal, and workflow challenges. Ultimately, the objective of this work is to develop tools for supporting ED physicians to accurately evaluate ACP within a broad range of clinical guidelines. To enhance predictive performance and broaden model utility, future iterations will focus on four key areas: (1) retraining models using symptom-onset timing and high-impact features, which may include descriptors extracted from digitized ECG signals and nursing notes; (2) integrating data imputation strategies, such as multivariate imputation by chained equations, to handle missing data; (3) developing dedicated models tailored to specific biomarker profiles, such as patients with low eGFR due to renal failure; and (4) validating the models using larger, diverse, multicenter datasets.

Acknowledgments

Abstract

Background: Transfusion thresholds in upper gastrointestinal bleeding are debated; hemoglobin cutoffs of 70‐80 g/L are widely cited yet inconsistently applied. Common risk scores offer limited individualized guidance and rarely provide calibrated, interpretable predictions for transfusion decisions.

Objective: This study aimed to develop and validate a two-stage, clinically constrained gradient-boosting framework (Medically Constrained Gradient Boosting [MCGB]) that predicts transfusion need and estimates transfusion dose with quantified uncertainty and to implement a prototype recommendation system for clinical use.

Methods: We analyzed a retrospective multicenter cohort of 849 adults with endoscopically confirmed upper gastrointestinal bleeding admitted to 3 hospitals in Chongqing, China (January 2019 to August 2025). Predictors available before the transfusion decision included demographics, first recorded vital signs, initial laboratory indices, and clinician-adjudicated etiology. Stage 1 used a calibrated classifier with prespecified monotonic constraints and stability-screened, clinically justified interactions. Stage 2 modeled transfusion dose via quantile predictions with conformal adjustment to generate 95% prediction intervals. Performance was assessed using a cross-site hold-out design. Overall, 2 hospitals were used as the development cohort, within which stratified 5-fold cross-validation was performed for model development, hyperparameter tuning, interaction screening, and calibration. The remaining hospital was held out as an independent test cohort for final evaluation. Hospital-wise alternating external testing was further conducted as a supplementary robustness analysis to assess performance stability across institutions. Classification performance was evaluated using discrimination metrics (area under the receiver operating characteristic curve and area under the precision-recall curve), calibration metrics, and decision-curve analysis; regression performance was evaluated using R^2, mean absolute error, and prediction-interval coverage. A graphical user interface was implemented to enable clinicians to input patient data and obtain calibrated predictions of transfusion probability and corresponding dose recommendations.

Results: MCGB achieved strong discrimination and good calibration across subgroups (area under the receiver operating characteristic curve=0.97 and area under the precision-recall curve=0.91). At a reference probability threshold of .50, sensitivity, specificity, and F_1-scores were 0.99, 0.87, and 0.85, respectively, providing a representative operating point for comparison. For dose prediction among transfused patients, MCGB achieved R^2 of 0.95 and mean absolute error 0.04; 95% prediction-interval coverage was 0.94, indicating accurate point estimates with reliable uncertainty quantification. The software prototype further demonstrated feasibility of real-time decision support at the bedside.

Conclusions: MCGB provides calibrated, interpretable predictions of transfusion need and individualized dose in upper gastrointestinal bleeding and may support bedside decision-making and blood-bank planning, with a prototype interface demonstrating potential for clinical deployment. External validation in additional settings is warranted to confirm generalizability.

Introduction

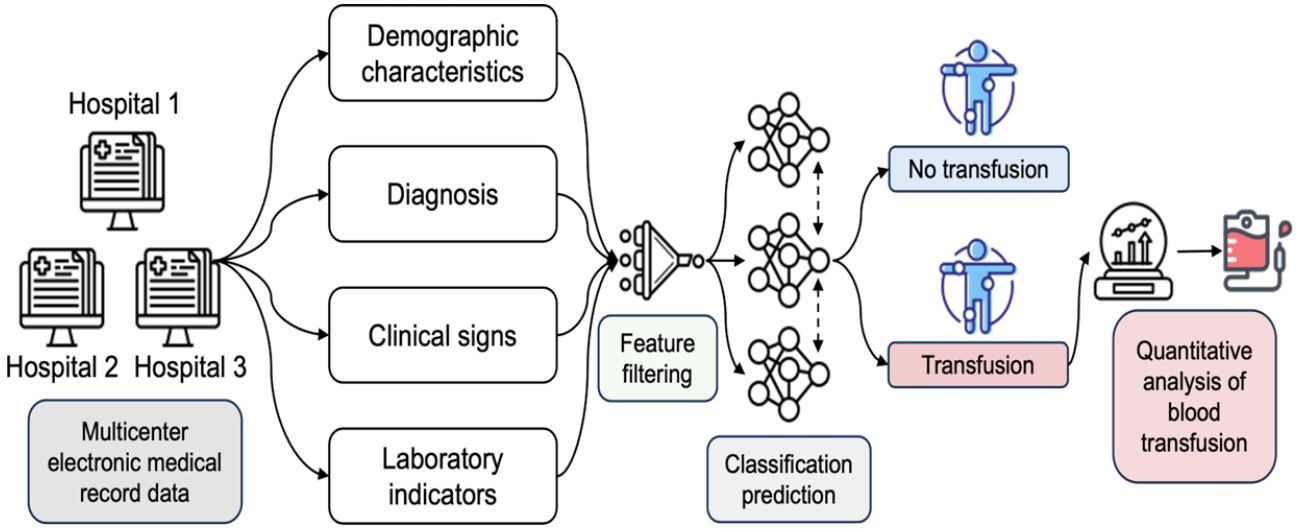
Upper gastrointestinal bleeding (UGIB) is a frequent emergency in gastroenterology and acute care [1]. Common etiologies include rupture of esophageal or gastric varices in cirrhosis, peptic ulcer disease, erosive hemorrhagic gastritis, and malignant tumors [2]. Rapid blood loss can precipitate hypotension and coagulopathy with peripheral circulatory failure, progressing to shock and death without timely resuscitation and blood transfusion [3-5]. Although hemoglobin thresholds of 70 - 80 g/L are widely cited, clinical application varies across centers and patient profiles [6,7], reflecting differences in comorbidity burden, cardiopulmonary reserve, ongoing hemorrhage risk, and the rate and dose of bleeding [8,9]. These realities motivate decision support that is both individualized and reproducible.

Risk scores such as Glasgow-Blatchford, admission Rockall, and AIMS65 are widely used for early triage in UGIB [10-12]. They stratify short-term risk but do not provide calibrated, individualized probabilities of transfusion or quantitative guidance on transfusion dose. Fixed cutoffs may be sensitive to local practice and case mix and can underperform when clinical heterogeneity is high [13,14]. From a systems perspective, uncertainty about transfusion need and dose complicates blood-bank operations, cross-matching, and inventory management during busy endoscopy schedules or resource-constrained periods. A tool that yields reliable risk estimates and dose guidance could improve bedside decision-making while supporting operational planning.

Machine learning has improved discrimination in many clinical prediction tasks and sometimes outperforms traditional scores [15,16]. However, prior work on transfusion decision support has several limitations that hinder clinical uptake. First, models are often difficult to interpret, which impedes bedside discussion and auditability [17]. Second, probability calibration is inconsistent, limiting safe threshold selection and net-benefit optimization [18,19]. Third, performance can degrade across hospitals and etiologies due to distributional shift. Fourth, preprocessing pipelines sometimes use the full dataset rather than being refit within cross-validation folds, increasing the risk of information leakage and optimistic estimates [20,21]. Finally, most studies stop at binary classification and do not estimate transfusion dose or communicate uncertainty for resource allocation. These gaps suggest that methodological choices should encode clinical directionality, preserve interpretability, control information flow during training, and report both discrimination and calibration alongside clinical utility [22,23].

Electronic health records (EHRs) capture the measurements typically available before a transfusion decision, including demographics, initial vital signs, key laboratory indices, and clinician-adjudicated etiology [24]. Leveraging these data for actionable decision support requires models that map to clinical reasoning while remaining robust across centers [25]. Monotonic constraints can encode established relationships such as higher international normalized ratio (INR) or longer prothrombin time (PT) increasing transfusion risk, and higher hemoglobin, hematocrit, or blood pressure decreasing risk. Curating a small, clinically justified set of feature interactions can improve fit without sacrificing transparency. Calibration methods can align predicted probabilities with observed risks, enabling thresholds derived from decision-curve analysis to reflect clinical utility [26].

This study develops and validates a 2-stage, clinically constrained framework—Medically Constrained Gradient Boosting (MCGB)—for transfusion decision support in UGIB using multicenter EHR data. Stage 1 produces calibrated, interpretable probabilities of transfusion need by imposing monotonic clinical directionality and retaining a stability-screened set of clinically justified interactions. Stage 2 estimates transfusion dose using quantile predictions with conformal adjustment to provide 95% prediction intervals, communicating uncertainty for blood-bank planning. The aim is to deliver a reproducible, well-calibrated, and robust tool that supports bedside decisions and operational workflows across heterogeneous hospitals and etiologies.



Methods

Overview

The transfusion decision system used a 2-stage framework termed MCGB. A calibrated classifier first estimates the probability of transfusion using monotonic constraints on prespecified laboratory and physiological variables to encode clinically consistent directionality, together with a stability-screened interaction allowlist. To enhance robustness across settings, training optimizes a group distributionally robust objective over hospital, etiology, and admission-period strata; predicted probabilities are calibrated by temperature scaling, and the operating threshold is selected with decision-curve analysis to align classification with clinical utility [27,28]. Patients predicted to require transfusion are then modeled with a regression component that estimates blood units via quantile predictions with conformal adjustment, yielding 95% prediction intervals to communicate uncertainty for blood-allocation planning [29,30]. All preprocessing—Winsorization at the first and 99th percentiles, median imputation, indicator encoding, and interaction construction—is confined to cross-validation folds and applied only to the corresponding calibration and test splits to prevent information leakage. Candidate interactions arise from continuous-by-etiology and continuous-by-continuous pairs, are filtered for high correlation, ranked by mutual information and distance correlation, and retained when they meet prespecified stability criteria, following a screen-in principle that preserves interpretability, reproducibility, and transparency; the overall workflow is shown in Figure 1.

Ethical Considerations

The study protocol was reviewed and approved by the institutional ethics committees of Daping Hospital, Army Medical Center of PLA, Army Medical University; the Third People's Hospital of Chongqing; and the 13th People's Hospital of Chongqing. The requirement for individual informed consent was waived because the analysis used routinely collected EHR data that were deidentified before analysis and posed minimal risk to participants. Data were handled in secure, access-controlled environments under institutional data-use agreements; only coded study identifiers were used, and direct personal identifiers were not accessible to investigators. All procedures complied with the Declaration of Helsinki and applicable local regulations. The project did not involve any prospective intervention and was not registered as a clinical trial.

Data and Dataset

Routinely collected data were retrieved from the clinical data warehouses of 3 hospitals in Chongqing, China. Consecutive adults with endoscopically confirmed UGIB between January 2019 and August 2025 were screened. A total of 849 patients met the inclusion criteria, including 655 nontransfusion cases and 194 transfusion cases. The cohort comprised 264 patients from the Third Affiliated Hospital of the Third Military Medical University, 326 patients from the Third People's Hospital of Chongqing, and 259 patients from the 13th People's Hospital of Chongqing. Exclusion criteria included insufficient clinical data, non-UGIB bleeding, incomplete diagnostic or therapeutic care, self-discharge, transfusion before the index decision, and missing key variables required for model development. The study was approved by the institutional ethics committees of all 3 hospitals, with a waiver of informed consent due to the retrospective design.

Predictors available within 24 hours before the transfusion decision were extracted from the EHR and included demographics, first recorded vital signs at presentation, and initial laboratory results obtained prior to the transfusion decision (covering hematology, coagulation, renal function, albumin, and electrolytes), as well as clinician-adjudicated bleeding etiology encoded as 5 binary indicators. Units were harmonized across centers, and variables not available before the transfusion decision were excluded to prevent data leakage. Patients with missing key variables required for modeling were excluded during cohort construction, resulting in a largely complete analytic dataset. Continuous variables were processed using a median imputation strategy as part of a standardized preprocessing pipeline, although imputation was rarely required in practice due to the near-complete nature of the data. Categorical variables were one-hot encoded, and missingness indicators for selected laboratory tests were constructed to preserve compatibility with potential real-world scenarios in which data may be incomplete. Pairwise correlations were summarized to characterize relationships among predictors while preserving clinically relevant variables. For descriptive comparisons, transfused and nontransfused groups were analyzed using Student *t* tests or nonparametric equivalents for continuous variables and chi-square or Fisher exact tests for categorical variables; 2-sided *P* values are reported in Table 1.

To further characterize the relationships among predictors and enhance transparency in model interpretation, pairwise correlations were first examined using a heat map Figure 2A, providing an overview of feature dependencies while retaining clinically relevant variables. Building on this analysis, model outputs were subsequently examined using Shapley additive explanations (SHAP), as illustrated in Figure 2B. Each point represents an individual patient from the evaluation set, and the horizontal axis indicates the SHAP value, which quantifies the contribution of each feature to the predicted probability of

XSL•FO
RenderX

transfusion [31,32]. Positive SHAP values indicate an increased predicted risk, whereas negative values indicate a decreased risk, and the color represents the original feature value, with red denoting higher values and blue denoting lower values. Key predictors showed clinically coherent patterns: lower hemoglobin and hematocrit levels were associated with a higher predicted probability of transfusion, whereas higher values shifted predictions toward lower risk. Coagulation-related indices and hemodynamic variables also exhibited consistent directional effects that aligned with established clinical understanding of bleeding severity and transfusion requirements. Overall, these findings indicate that the model captures clinically meaningful and plausible relationships among predictors, supporting the interpretability and reliability of the MCGB classifier.

Figure 2. (A) Variable correlation heat map. (B) SHAP summary for transfusion predictors: each dot=patient; x-axis=SHAP value (positive → higher probability, negative → lower); color=feature value (red high, blue low). AG: acute erosive gastritis; Alb: albumin; APTT: activated partial thromboplastin time; BUN: blood urea nitrogen; Ca: calcium; DBP: diastolic blood pressure; Fib: fibrinogen; Hb: hemoglobin; Hct: hematocrit; INR: international normalized ratio; K: potassium; MT: malignant tumor; P: pulse; Plt: platelets; PT: prothrombin time; PU: peptic ulcer; R: respiratory rate; REV: rupture of esophageal varices; SBP: systolic blood pressure; Scr: serum creatinine; SHAP: Shapley additive explanations; T: temperature.

Model Building

In this study, the MCGB framework is proposed to extend standard gradient boosting by integrating 3 clinically motivated components: (1) monotonic constraints to enforce clinically consistent relationships, (2) interaction whitelisting to restrict feature interactions to stable and interpretable pairs, and (3) subgroup-aware reweighting to improve robustness across heterogeneous populations. These extensions are designed to improve both predictive performance and clinical reliability.

The dataset is represented as D=(xi,yi), where xi∈ Rm denotes the input features, yi∈ R denotes the corresponding outcome, and i=1,2,…,n indexes the samples. Following the standard gradient boosting formulation, the boosted predictor after T rounds can be expressed as:

(1) FT(x)=∑t=1Tft(x), ft∈ F,

where F denotes the space of regression trees mapping Rm to R. Each tree partitions the data into leaves and assigns a score wj. The boosting procedure iteratively refines predictions through stage-wise optimization, while the proposed extensions introduce clinically informed constraints and reweighting mechanisms to enhance robustness and consistency. The optimization objective at iteration *t* is expressed as:

(2)Objt=∑i=1nl(yi, Ft−1(xi)+ft(xi))+γTt+λ2∑j=1Ttwj2,

where γ controls model complexity by penalizing the number of leaves, and λ is an L2 regularization parameter on leaf weights.

A second-order Taylor expansion is applied around Ft-1(xi). With first- and second-order derivatives defined asgi=∂y^l(yi,y^)|y^=Ft-1(xi) and hi=∂y^2l(yi,y^)|y^=Ft-1(xi), the approximated loss becomes:

(3)l(yi, Ft−1(xi)+ft(xi))≈l(yi, Ft−1(xi))+ yi ft(xi)+12 hi ft(xi)2

To improve robustness across heterogeneous subgroups, MCGB introduces subgroup-aware reweighting of gradients. Specifically, for each predefined subgroup g, a softmax-based weighting scheme is defined as:

(4)πg(η)=exp (ηLg)∑g´exp (ηLg´),#

where Lg denotes the loss associated with group g, and η§amp;gt;0 is a temperature parameter that controls the sharpness of the weighting distribution. For each sample i, let g(i) denote the group to which the sample belongs. The reweighted derivatives are then defined as g~i=πg(i)(η)giand h~i=πg(i)(η)hi, where gi and hi are the original first- and second-order derivatives. This design prevents the model from being dominated by majority subgroups and reduces overfitting to site-specific patterns.

At the tree level, gradients are aggregated within each leaf node. For a leaf *j* with the instance set Ij, the sufficient statistics are

XSL•FO
RenderX

defined as Gj=∑i∈ Ijg~i and Hj=∑i∈ Ijh~i. The quadratic surrogate objective is then approximated as:

(5)Obj(t)~= ∑j=1Tt(Gjwj+12(Hj+λ)wj2)+γTt.#

The unconstrained optimal leaf weight is given by w^j=-GjHj+λ. In MCGB, this solution is further adjusted to satisfy clinical monotonicity constraints of the form ∂FT(x)∂xkσk≥0, where k∈ M denotes features subject to monotonic constraints and σk∈ {-1,+1} specifies the expected direction. The feasible solution is obtained by projecting w^onto the isotonic cone:

(6)w∗=argminAw≤b12||w−w^||22,

ensuring that model predictions follow clinically expected trends and preventing implausible extrapolations, thereby improving generalization and trustworthiness.

The reduction in the surrogate objective when splitting a node into left and right children is quantified by the gain, defined as:

(7)Gain=12(GL2HL+λ+GR2HR+λ−(GL+GR)2HL+HR+λ)−γ

To further enhance interpretability and reproducibility, MCGB restricts candidate splits using an interaction whitelist W. To construct this whitelist, a stability-driven selection procedure is employed. Candidate feature pairs are first evaluated using the Friedman *H*-statistic to quantify interaction strength. Pairs with a median *H*-statistic greater than 0.10 across cross-validation folds are retained. To ensure robustness, only interactions that rank among the top five strongest interactions in at least four out of five folds are selected. This process ensures that retained interactions are both statistically stable and clinically plausible. If a node path already includes feature p, then a split on feature q is admissible only if (p,q)∈ W. The whitelist itself is defined by a reproducibility criterion,

(8)1{(p, q)∈ W=1{medianr Hpq(r)>0.10 ∧Top5pq ≥4}},#

Where Hpq(r) is the Friedman H-statistic in fold r and Top5pq is the number of folds in which (p,q) ranks among the 5 strongest interactions. This stability-based selection ensures robustness and reproducibility.

In summary, the MCGB framework extends classical gradient boosting by incorporating 3 clinically motivated components: monotonicity constraints to enforce clinically consistent relationships, interaction whitelisting to restrict feature interactions to stable and interpretable pairs, and group-wise loss reweighting to improve robustness across heterogeneous clinical subgroups. Together, these components enable the model to achieve not only strong predictive performance but also improved interpretability and stability in real-world clinical settings.

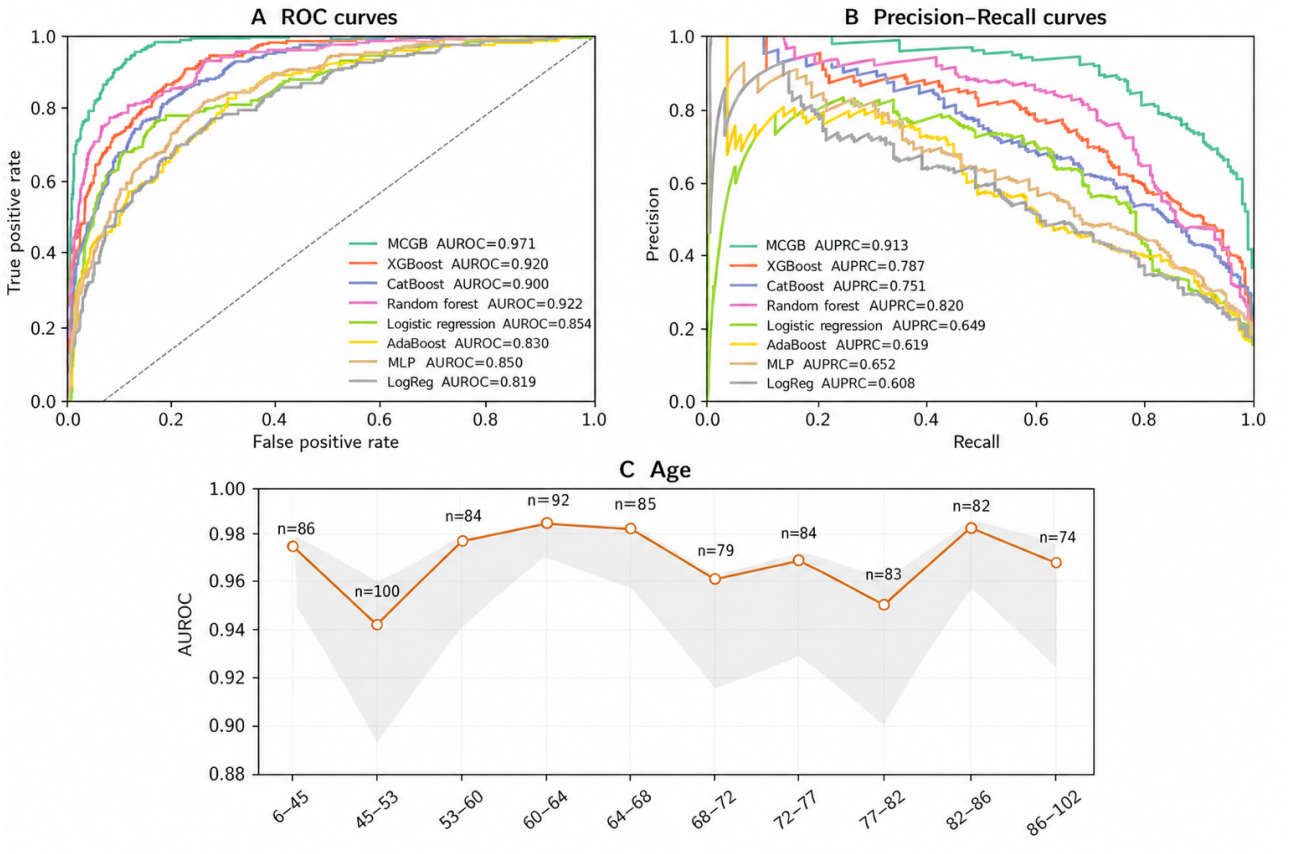
To evaluate the effectiveness of the proposed framework, all comparator models were implemented using standard libraries (scikit-learn, extreme gradient boosting [XGBoost], and categorical boosting [CatBoost]) and evaluated under the same cross-site hold-out design as the proposed MCGB model. Within the development cohort, each comparator was trained using the same stratified 5-fold cross-validation splits and fold-specific preprocessing pipeline, and the resulting cross-validation–derived models were subsequently applied to the independent test cohort. This design ensured a fair comparison while maintaining consistent separation between model development and final evaluation. For the classification task, the compared models included logistic regression (LogReg), multilayer perceptron (MLP), random forest (RF), adaptive boosting (AdaBoost), XGBoost [32], and CatBoost [33]; for the regression task, the compared models included linear regression (LR), MLP [34], RF, AdaBoost, XGBoost, and CatBoost. Hyperparameters for all baseline models were tuned via grid search within the training folds only, with model selection based on validation performance.

Model Training

Model development and validation were conducted using a predefined cross-site hold-out design to assess generalizability. Data from the Third People's Hospital of Chongqing and the 13th People's Hospital of Chongqing were combined as the development cohort, whereas data from the Third Affiliated Hospital of the Third Military Medical University were held out as an independent test cohort. The independent test cohort was not used for preprocessing fitting, feature interaction screening, hyperparameter tuning, calibration, threshold selection, or model selection. Within the development cohort, stratified 5-fold cross-validation was used to preserve the transfusion event rate across folds and to perform model development and internal validation. In each fold, preprocessing steps, including median imputation, one-hot encoding, and interaction construction, were fitted exclusively on the training split and then applied to the corresponding validation fold and the independent test cohort, ensuring strict separation and preventing information leakage. Each fold yielded a cross-validation–derived model, and final performance on the independent test cohort was summarized as the mean (SD) across the 5 models. To further examine cross-site robustness, hospital-wise alternating external testing was conducted as a supplementary analysis, in which each hospital was alternately treated as the external test cohort and the remaining 2 hospitals were used for model development. This supplementary analysis was used only to evaluate institutional stability and was not mixed with the primary independent test evaluation.

Given the moderate class imbalance (655 nontransfusion vs 194 transfusion cases), no explicit resampling was performed in order to preserve the original clinical distribution. Model evaluation therefore emphasized metrics robust to class imbalance, including the area under the precision-recall curve (AUPRC) alongside the area under the receiver operating characteristic curve (AUROC). Predicted probabilities were calibrated using temperature scaling within the development cohort, and the learned calibration parameters were then applied unchanged to the independent test cohort. Model performance was primarily assessed across a range of clinically relevant threshold probabilities using decision curve analysis to reflect potential clinical utility. Results at a reference threshold of 0.50 were additionally reported as a conventional operating point for comparison with prior binary prediction studies. For the interaction ablation analysis, net benefit was additionally evaluated at a threshold probability of 0.20 because this value lies within the low-to-moderate risk range in which clinicians may consider early preparation, closer monitoring, or cross-matching rather than immediate transfusion. Therefore, ΔNB@0.20 was used to assess whether the retained interactions

XSL•FO
RenderX



improved clinical utility in an early decision-support setting and was not intended to replace the 0.50 reference threshold used for reporting primary classification performance. Primary discrimination metrics included AUROC and AUPRC, whereas secondary metrics included sensitivity, specificity, positive predictive value, negative predictive value, accuracy, F_1-score, and expected calibration error.

For the regression component among transfused patients, predictive accuracy was evaluated using mean absolute error (MAE) and root-mean-square error, explanatory performance using R^2, and uncertainty using empirical coverage and interval width of 95% prediction intervals derived from conformalized quantile prediction. Agreement between predicted and observed transfusion dose was further assessed using Bland–Altman analysis.

Results

As shown in Figures 3A and 3B, MCGB achieved the best discrimination across all models with an AUROC of mean 0.971 (SD 0.008) and an AUPRC of mean 0.913 (SD 0.022). Relative to the strongest baseline, RF, MCGB improved AUROC by 0.049 (0.971 vs 0.922) and AUPRC by 0.093 (0.913 vs 0.820); gains were larger versus XGBoost (ΔAUROC 0.051; ΔAUPRC 0.126) and CatBoost (ΔAUROC 0.071; ΔAUPRC 0.162). The receiver operating characteristic (ROC) and precision–recall curves for MCGB dominate the comparators across clinically relevant thresholds, with the precision–recall separation indicating sustained precision at high recall under class imbalance. For AUROC, the 95% bootstrap intervals do not overlap between MCGB (mean 0.971, SD 0.008) and the leading baselines (RF mean 0.922, SD 0.031; XGBoost mean 0.920, SD 0.020); CatBoost mean 0.900 (SD 0.025), supporting a statistically meaningful improvement. AUPRC intervals are largely separated as well, with only marginal overlap relative to RF.

Figure 3. Discrimination and subgroup robustness of MCGB (Medically Constrained Gradient Boosting). (A) ROC curves on the independent test cohort. (B) Precision–recall curves on the independent test cohort. (C) AUROC stratified by hospital in the supplementary hospital-wise alternating external testing analysis. AdaBoost: adaptive boosting; AUPRC: area under the precision-recall curve; AUROC: area under the receiver operating characteristic curve; CatBoost: categorical boosting; MLP: multilayer perceptron; ROC: receiver operating characteristic; XGBoost: extreme gradient boosting.

As shown in Figures 3A and 3B, MCGB achieved the best discrimination across all models with an AUROC of mean 0.971 (SD 0.008) and an AUPRC of mean 0.913 (SD 0.022). Relative to the strongest baseline, RF, MCGB improved AUROC by 0.049 (0.971 vs 0.922) and AUPRC by 0.093 (0.913 vs 0.820); gains were larger versus XGBoost (ΔAUROC 0.051; ΔAUPRC 0.126) and CatBoost (ΔAUROC 0.071; ΔAUPRC 0.162). The ROC and precision–recall curves for MCGB dominate the comparators across clinically relevant thresholds, with the precision–recall separation indicating sustained precision at high recall under class imbalance. For AUROC, the 95% bootstrap intervals do not overlap between MCGB (mean 0.971,

XSL•FO
RenderX

SD 0.008) and the leading baselines (RF mean 0.922, SD 0.031; XGBoost mean 0.920, SD 0.020); CatBoost mean 0.900 (SD 0.025), supporting a statistically meaningful improvement. AUPRC intervals are largely separated as well, with only marginal overlap relative to RF.

Table 2 summarizes classification performance on the independent test cohort. Values are reported as the mean (SD) across the 5 cross-validation–derived models trained within the development cohort. MCGB achieves the best overall performance, with the highest AUROC mean 0.971 (SD 0.008) and AUPRC mean 0.913 (SD 0.022), indicating strong discriminative ability under class imbalance. It also attains the highest accuracy mean 0.922 (SD 0.026) and F_1-score mean 0.847 (SD 0.041), reflecting a favorable balance between precision and recall. Notably, MCGB achieves near-perfect sensitivity mean 0.990 (SD 0.013) while maintaining relatively high specificity mean 0.873 (SD 0.032), suggesting effective identification of patients requiring transfusion with acceptable false-positive rates. Tree-based baselines such as RF and XGBoost show competitive discrimination but consistently lower composite performance, whereas linear and shallow models exhibit reduced recall and F_1-score despite reasonable AUROC. Overall, MCGB provides a more favorable error profile, which is desirable in safety-critical clinical settings.

Table . Classification performance.

Model	AUROC[a], mean (SD)	AUPRC[b], mean (SD)	Accuracy, mean (SD)	Sensitivity, mean (SD)	Specificity, mean (SD)	F_1-score, mean (SD)

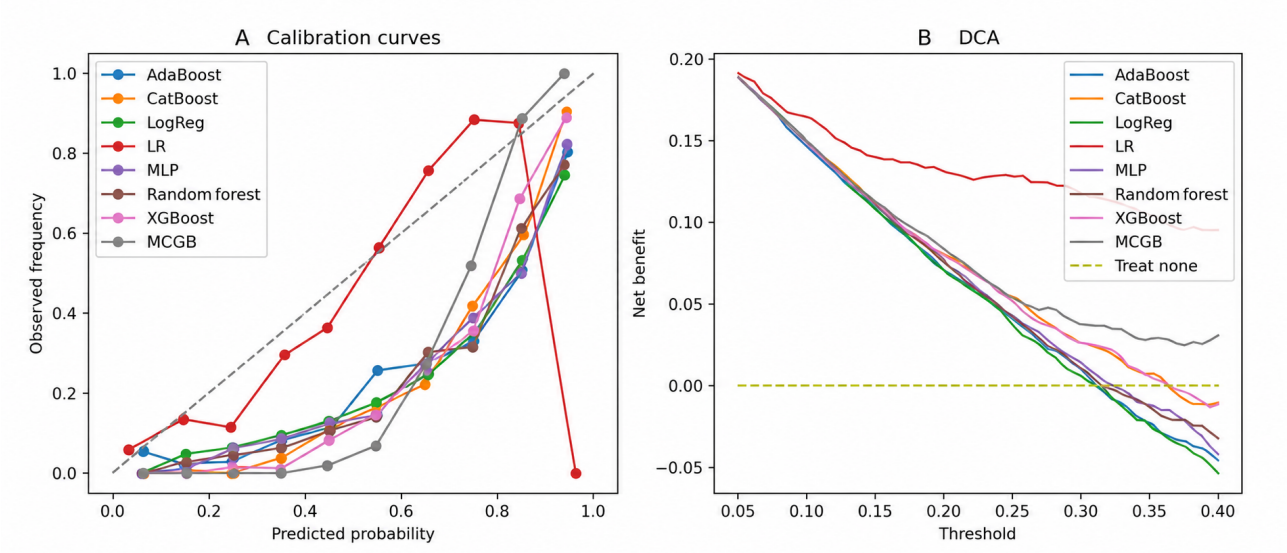

Figure 3C presents model performance stratified by hospital, etiology, and age. Across all strata, MCGB maintained consistently high AUROC with relatively narrow 95% CIs estimated via bootstrapping, indicating stable performance despite variation in subgroup sample sizes (eg, n≈264/326/259 across hospitals). Although some strata contained fewer samples, the corresponding CIs did not show substantial widening, suggesting that performance estimates remain reliable. As a supplementary robustness analysis, hospital-wise alternating external testing was conducted by alternately holding out each institution as the external test cohort and using the remaining 2 institutions for model development. This analysis was separate from the primary independent test evaluation and was intended to examine cross-site stability under institutional heterogeneity. In contrast, comparator models exhibited greater variability across strata, with more pronounced performance fluctuations in smaller subgroups. This stability of MCGB is consistent with its design, including monotonic constraints that encode clinically plausible relationships and a curated interaction structure that reduces overfitting to site-specific patterns. Overall, these results indicate that MCGB achieves not only strong discrimination but also robust and consistent performance across demographic and clinical subgroups, supporting its applicability in multicenter settings.

In addition to discrimination and subgroup robustness, the calibration and clinical usability of the proposed MCGB model were further evaluated. As shown in Figure 2, the reliability curves illustrate the agreement between predicted probabilities and observed outcomes across models. MCGB achieves the lowest Brier score, indicating superior overall probabilistic accuracy, although its calibration slope and intercept suggest a degree of overconfidence, which is commonly observed in high-capacity models. To address this, temperature scaling was applied as a post hoc calibration method, resulting in improved probability reliability. Furthermore, decision curve analysis demonstrates that MCGB provides competitive or superior net benefit across most clinically relevant threshold ranges. While RF shows slightly higher net benefit in certain threshold intervals, this difference does not persist across clinically relevant ranges, where MCGB demonstrates consistently strong clinical utility.

XSL•FO
RenderX

To move beyond aggregate discrimination, we evaluated whether MCGB captures clinically meaningful interactions as shown in Figure 4. A stability-based screen-in rule combined the Friedman *H*-statistic across folds with mean SHAP interaction values and retained reproducible pairs such as INR × PT and systolic blood pressure × pulse, while interactions including blood urea nitrogen × serum creatinine and age × etiology were discarded. Paired ablation on out-of-fold predictions showed reductions in Brier score and gains in net clinical benefit at a decision threshold of 0.20, and the corresponding 95% CIs did not cross zero. Because the interaction analysis was designed to evaluate whether the retained interaction terms improved clinical utility in the early decision-support range, net benefit was assessed at a threshold probability of 0.20. This threshold corresponds to a low-to-moderate predicted risk level at which clinicians may initiate closer monitoring, prepare blood products, or consider cross-matching, whereas the 0.50 threshold was retained as the conventional reference operating point for reporting primary classification performance. Paired ablation on out-of-fold predictions showed reductions in Brier score and gains in net clinical benefit at this threshold, and the corresponding 95% CIs did not cross zero. These findings indicate that MCGB encodes physiologically plausible structure, with INR × PT reflecting coagulation synergy and systolic blood pressure × pulse capturing hemodynamic coupling, which enhances robustness and interpretability beyond overall discrimination.

Figure 4. Calibration and decision curve analysis of different models. (A) calibration curves comparing predicted probabilities with observed outcomes. The dashed line represents perfect calibration. (B) Decision curve analysis (DCA) showing the net benefit of each model across threshold probabilities. AdaBoost: adaptive boosting; CatBoost: categorical boosting; DCA: decision curve analysis; LR: linear regression; LogReg: logistic regression; MCGB: Medically Constrained Gradient Boosting; MLP: multilayer perceptron; XGBoost: extreme gradient boosting.

Among transfused patients, MCGB achieved the lowest prediction error and the highest explanatory power, with a mean MAE of 0.038 (SD 0.016), mean RMSE of 0.099 (SD 0.042), and a mean R^2 of 0.95 (SD 0.024). Because the transfusion dose was normalized during model training, these error values represent deviations on a relative scale; in practical terms, such small deviations indicate that predicted doses are closely aligned with clinician-determined transfusion decisions, typically differing only by a small margin that is unlikely to alter clinical management or blood allocation planning. Compared with the strongest baseline (RF), MCGB substantially reduced MAE (0.128-0.038) and RMSE (0.245-0.099), while improving R^2 (0.88-0.95), with consistent gains across evaluation metrics, suggesting improved predictive accuracy and stability rather than metric-specific improvements. For uncertainty estimation, conformalized quantile prediction achieved a 95% prediction-interval coverage of mean 0.943 (SD 0.021), which is close to the nominal level while maintaining practically useful interval widths; from a clinical perspective, these prediction intervals provide an interpretable range of likely transfusion requirements, supporting communication between clinicians and blood-bank services and facilitating more informed resource planning. In contrast, baseline models showed either under-coverage or less stable interval performance across folds. Overall, these findings indicate that MCGB not only achieves high statistical accuracy but also produces dose estimates that are clinically meaningful, reliable, and directly applicable to transfusion decision-making and operational planning, as summarized in Table 3.

XSL•FO

As illustrated in Figure 5, the MCGB regression model demonstrated a close alignment between predicted and true transfusion dose across all 5 cross-validation folds. The predicted curves (blue) consistently tracked the observed transfusion doses (red) with minimal deviation, yielding low MAE and RMSE, alongside a high coefficient of determination. These results indicate that MCGB was able to capture the fine-grained dose-response relationship while maintaining robustness across heterogeneous patient subgroups. The stability of the predictions across folds further suggests that the model generalizes well and avoids overfitting, making it potentially reliable for practical deployment in transfusion planning and blood inventory management.

Figure 5. Screening and ablation of feature interactions in MCGB (Medically Constrained Gradient Boosting). (A) Stability-based screen-in rule using the Friedman H-statistic and Shapley additive explanations.

Comparison with clinical risk scores. To further assess clinical relevance, the proposed MCGB model was compared with established clinical risk scores, including AIMS65, Glasgow-Blatchford Score, and Rockall. As shown in Table 4, these conventional scoring systems demonstrated modest discrimination, with AUROC values ranging from 0.613 to 0.693 and AUPRC from 0.310 to 0.377, whereas MCGB achieved substantially higher performance (AUROC: mean 0.971, SD 0.008; AUPRC: mean 0.913, SD 0.022). Notably, a marked discrepancy between AUROC and AUPRC was observed for the clinical scores. This pattern is consistent with the class imbalance of the cohort and indicates that, although these rule-based scores retain some ability to rank patients by risk, they have limited precision in identifying patients who truly require transfusion, resulting in a higher proportion of false-positive predictions at the individual level. In contrast, MCGB maintained consistently high values across both AUROC and AUPRC, suggesting not only strong global discrimination

XSL•FO
RenderX

but also improved precision in detecting clinically relevant cases. This distinction is of particular importance in clinical practice, where AUPRC provides a more informative assessment of a model's ability to correctly identify patients requiring intervention. The observed differences may be attributed to the design of traditional scores, which rely on a small set of predefined variables and are primarily intended for coarse risk stratification, thereby limiting their capacity to capture complex and nonlinear relationships underlying transfusion decisions. By comparison, MCGB incorporates data-driven modeling with clinically informed constraints, enabling more individualized and reliable predictions. Collectively, these findings suggest that, while established clinical scores remain useful for general risk assessment, they may be insufficient for precise transfusion prediction, and the proposed approach offers potential advantages for supporting clinical decision-making in upper gastrointestinal bleeding.

Table . Performance of established clinical risk scores for transfusion prediction under stratified five-fold cross-validation.

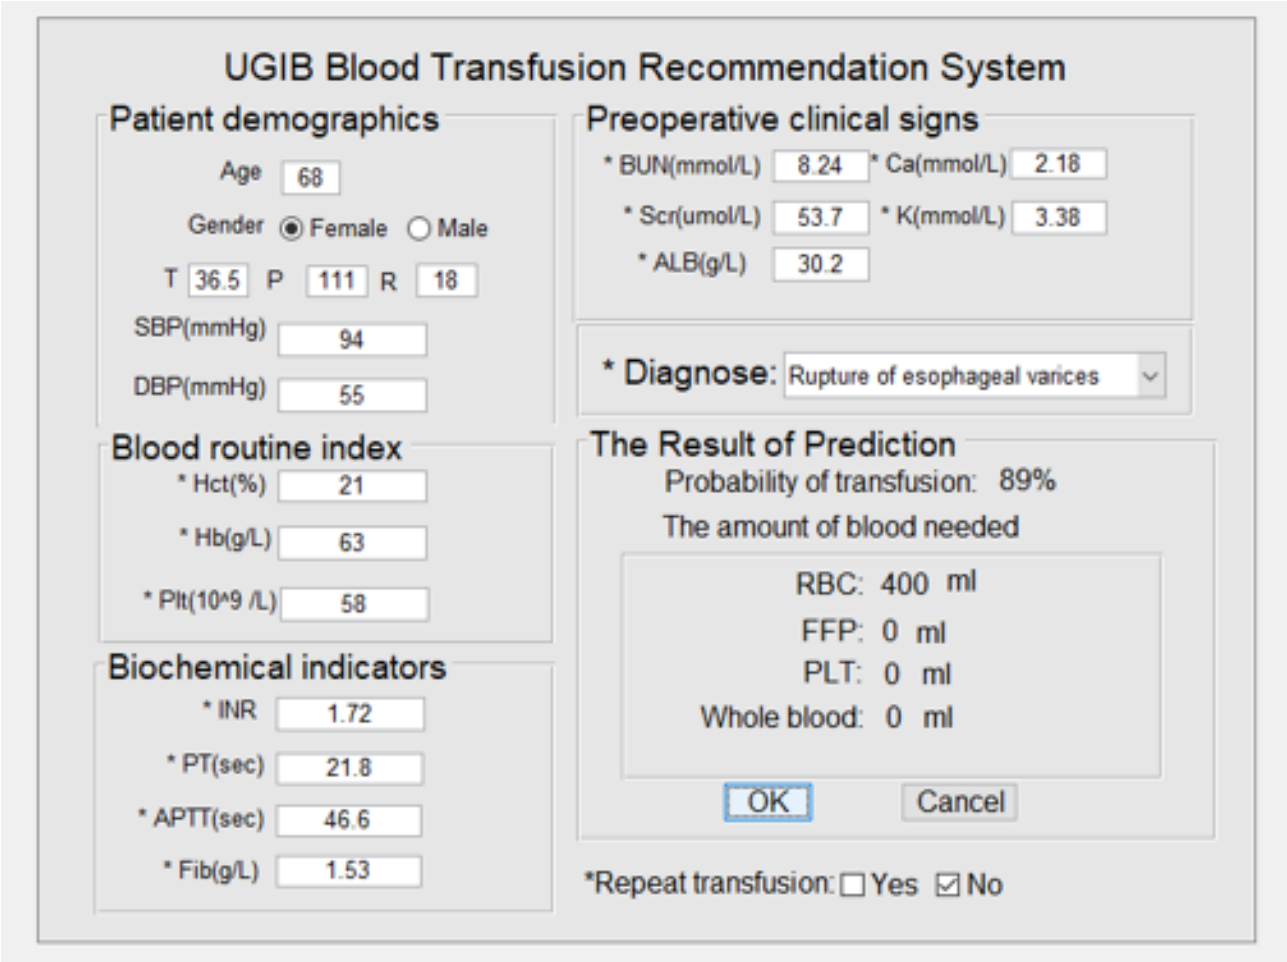
Through the preceding analyses, the MCGB model demonstrated strong performance in predicting transfusion requirements among patients with UGIB. To facilitate clinical translation, an interactive transfusion recommendation system was developed based on the MCGB model. This system functions as a user-oriented calculator that enables clinicians to estimate the probability of transfusion by inputting routinely available demographic and clinical variables. For patients predicted to require transfusion, the system additionally provides an individualized estimate of the recommended blood dose, thereby supporting both decision-making and treatment planning.



The graphical user interface, implemented using the QT Designer platform (Trolltech), is designed to be intuitive and easy to operate, allowing real-time interaction within clinical workflows. As illustrated in Figure 6, for a representative patient, the system estimated a transfusion probability of 89% and recommended a red blood cell dose of 400 mL. By integrating predictive modeling into a practical interface, the proposed system provides a feasible pathway for incorporating data-driven decision support into routine clinical practice. In this setting, clinicians can obtain rapid, standardized predictions without additional computational burden, which may contribute to more consistent and timely transfusion decision-making (Figure 7).

Figure 6. Cross-validation performance of MCGB (Medically Constrained Gradient Boosting) regression model. Comparison of predicted versus true transfusion dose across five cross-validation folds. Red lines denote true transfusion doses and blue lines denote MCGB predictions. Shaded background regions indicate fold partition. Figure 7. Interface of the UGIB blood transfusion recommendation system. The system integrates patient demographic information, vital signs, laboratory measurements, and clinical diagnosis as inputs, and provides individualized predictions of transfusion probability along with estimated blood component requirements. The interface enables clinicians to obtain real-time decision support for transfusion need assessment and dosage planning, facilitating standardized and interpretable clinical decision-making. ALB: albumin; APPT: activated partial thromboplastin time; BUN: blood urea nitrogen; Ca: calcium; DBP: diastolic blood pressure; FFP: fresh frozen plasma; Fib: fibrinogen; Hb: hemoglobin; Hct: hematocrit; INR: international normalization ratio; K: potassium; Plt: platelet; PT: prothrombin time; RBC: red blood cell; SBP: systolic blood pressure; Scr: serum creatinine.

Discussion

Principal Findings

This study shows that a clinically constrained, 2-stage framework can provide end-to-end decision support for transfusion in UGIB. The classifier delivered very high discrimination together with good calibration, and it maintained performance across hospitals, etiologies, and age strata. These characteristics matter more than a single accuracy number: calibration enables risk thresholds to be interpreted as probabilities, subgroup stability reduces the chance that performance collapses when case mix shifts, and explicit operating thresholds translate model output into consistent actions. In addition, calibration performance is reflected not only in visual agreement but also in quantitative metrics such as expected calibration error and Brier score, which are critical for clinical decision-making [35]. The innovation is not only the use of gradient boosting but the way clinical knowledge is built into the learning process. Monotonic constraints encode clinically expected relationships, and interaction constraints improve interpretability. In the second stage, dose regression provides point estimates with uncertainty, enabling actionable planning rather than binary decisions. In the primary cross-site hold-out evaluation, MCGB maintained strong discrimination and calibration when applied to an independent institutional test cohort.

Comparison With Prior Work

Traditional UGIB scores are useful for triage but do not provide patient-level probabilities of transfusion or quantitative guidance on dose. Many machine-learning studies report high AUROC yet give little attention to calibration, interpretability, or robustness across sites, and most stop at binary classification [36]. The present work addresses those gaps through several design choices. First, clinical constraints are imposed at training time rather than post hoc, which prevents clinically nonsensical relationships from emerging and reduces the need for manual rule fixes later. Second, interaction curation is principled: interactions such as INR × PT and systolic blood pressure × pulse are retained because they are stable across folds and supported by domain knowledge, and ablation confirms that they improve both calibration and net benefit. Third, evaluation extends beyond global curves to threshold performance, decision-curve analysis, and subgroup reporting, which are the quantities clinicians use when deciding whether and how to act.

XSL•FO
RenderX

Finally, the dose module elevates the scope of decision support by estimating the quantity of blood required with explicit uncertainty, which is rarely attempted and directly relevant to operations [37,38].

Clinical Implications and Workflow

The proposed MCGB framework is designed to support bedside and blood-bank decision-making using routinely collected clinical data. At presentation, the calibrated classifier provides an individualized probability of transfusion need, and a prespecified threshold derived from decision curve analysis encodes the trade-off between missed transfusion and unnecessary cross-matching, enabling standardized triage and reducing subjective variability [39]. For patients exceeding this threshold, the dose model generates both a unit estimate and a 95% prediction interval, supporting clinical communication, cross-matching, and inventory planning [40]. These outputs can be delivered through the interactive UGIB transfusion recommendation system (Figure 6) and integrated into electronic health record systems to enable automated data extraction and real-time risk assessment without disrupting existing workflows. To support safe use, model outputs are intended as decision support rather than definitive recommendations, with probability estimates and uncertainty information provided to assist clinician interpretation and reduce the risk of automation bias. In practice, implementation also requires careful configuration of thresholds and alerts to align with clinical pathways and avoid alert fatigue [41]. Finally, as a clinical decision support tool, MCGB would require prospective validation, external evaluation, and compliance with relevant regulatory frameworks prior to deployment, with clinician oversight and transparent documentation to ensure accountability and safe integration into routine care.

Limitations and Future Directions

The analysis is retrospective and limited to 3 hospitals within a single regional health care system, which may restrict generalizability to other settings and populations; external and temporal validation is needed to assess transportability and inform recalibration strategies. The dataset is imbalanced with fewer transfusion events, and larger, more balanced cohorts are warranted. Some subgroup strata are relatively small, increasing uncertainty in stratum-specific estimates, although CIs suggest overall stability. In addition, patients with missing key variables were excluded during cohort construction, resulting in model development and validation on a largely complete analytic dataset. While this improves internal consistency, it may not fully reflect real-world deployment conditions, where laboratory measurements may be delayed, unavailable, or selectively ordered at the time of decision-making, requiring explicit strategies for incomplete inputs such as minimum-data requirements or clinician review. Furthermore, thromboelastography and other advanced coagulation indices were not included because they are not routinely available across centers. While such variables may provide additional physiological information, the model was intentionally developed using routinely collected clinical features to enhance generalizability and real-world applicability, and the strong performance observed suggests that commonly available variables capture the majority of clinically relevant signals for transfusion decision-making [42]. Future work should evaluate whether incorporating advanced coagulation markers can further improve performance in settings where such data are available. Although conformal prediction achieved near-nominal coverage, the clinical utility of interval width requires prospective validation. Finally, deployment will require human-in-the-loop safeguards, appropriate alert configuration, and attention to automation bias to ensure safe and effective clinical use.

Conclusions

This study developed a clinically constrained, 2-stage framework MCGB—to support transfusion decisions in UGIB. By incorporating monotonic constraints that encode established clinical directionality and retaining only stability-screened, clinically plausible interactions, MCGB achieved superior discrimination, reliable calibration, and interpretable predictions. Beyond classification of transfusion need, the framework extends to individualized dose estimation with well-calibrated prediction intervals, offering actionable guidance for both bedside decision-making and blood-bank resource planning. These results demonstrate that MCGB can bridge methodological advances in machine learning with clinical requirements for transparency, robustness, and operational relevance, highlighting its potential as a practical decision-support tool for UGIB management.

Abstract

Background: Accurate preanesthetic assessment is essential for perioperative risk stratification, but conventional tools such as the American Society of Anesthesiologists (ASA) physical status classification and postoperative nausea and vomiting (PONV) risk scores may be affected by subjective judgment, incomplete documentation, and fragmented clinical data. Large language models may support preanesthetic assessment by integrating structured and unstructured clinical information.

Objective: This study aimed to develop and retrospectively validate a GPT-4o (OpenAI)–powered AI system for preanesthetic assessment. The primary validation focus was the agreement between AI-generated and clinician-assigned ASA physical status classifications. PONV risk stratification was evaluated as an additional clinically relevant performance outcome. A secondary objective was to assess the incremental contribution of National Health Insurance (NHI) cloud data to model performance.

Methods: This single-center retrospective validation study included 600 adult surgical patients randomly sampled from 4404 eligible inpatient surgical patients between January and May 2025. The system processed structured and unstructured electronic health record data, with and without NHI cloud data, to generate preanesthetic assessment outputs. ASA agreement was assessed using Cohen κ with 95% CIs. PONV prediction was evaluated using sensitivity, specificity, overall accuracy, positive predictive value, negative predictive value, confusion matrix analysis, the 2-sided Fisher-Freeman-Halton exact test, and Cramér V.

Results: Among the 600 patients, clinician-assigned ASA classifications were ASA I in 39 patients, ASA II in 498 patients, ASA III in 57 patients, and ASA IV in 6 patients. Agreement between AI-generated and clinician-assigned ASA classifications was high when NHI data were incorporated (κ=0.883, 95% CI 0.841 - 0.946), whereas agreement was lower without NHI data (κ=0.518, 95% CI 0.412 - 0.691). A total of 49 (8.2%) patients experienced documented PONV within 24 hours after surgery. Using the high-risk category as the primary test-positive threshold, the model achieved a sensitivity of 34.7% (95% CI 22.9 - 48.7), a specificity of 99.1% (95% CI 97.9 - 99.6), a positive predictive value of 77.3%, and a negative predictive value of 94.5%. The association between the model-assigned PONV risk categories and observed PONV outcomes was statistically significant (P<.001, Cramér V=0.531).

Conclusions: The GPT-4o–powered preanesthetic assessment system demonstrated feasibility and high agreement with clinician-assigned ASA classifications when NHI cloud data were incorporated. For PONV risk stratification, the system showed high specificity and a high negative predictive value but modest sensitivity, indicating that it identified a small high-risk subgroup with a high observed PONV incidence but did not capture all patients who developed PONV. These findings support the use of large language model–based decision-support tools as adjuncts to, rather than replacements for, anesthesiologist judgment.

Introduction

Accurate preanesthetic assessment is fundamental to perioperative safety because it supports early identification of patients at increased risk for anesthesia-related complications and informs appropriate perioperative planning. In routine practice, the American Society of Anesthesiologists (ASA) physical status classification system and the Apfel risk score for postoperative nausea and vomiting (PONV) are among the most commonly used tools for preoperative risk stratification. Despite their widespread use, both instruments have important limitations that may affect their consistency and scalability in contemporary clinical workflows.

The ASA classification system remains clinically useful but is inherently dependent on clinician judgment. Prior studies have shown substantial variability in ASA assignment across providers, even when similar clinical information is available [1,2]. This variability is not limited to anesthesiologists. In procedure-based specialties, surgeons may assign lower ASA classes than AI-assisted or anesthesia-based assessments, suggesting that risk may be underestimated when classification is performed outside a dedicated anesthetic context [3]. Likewise, the Apfel score is practical and well established, but its predictive performance depends on the availability of a small set of clinical risk factors, including nonsmoking status, prior PONV, and motion sickness history, which may be incompletely documented in routine electronic records [4]. Together, these limitations illustrate a broader challenge in perioperative medicine: clinically important preanesthetic judgments are often made using fragmented data, subjective interpretation, or both.

AI offers a potential solution to this problem by enabling more standardized and data-driven preoperative assessment. In recent years, machine learning and natural language processing approaches have demonstrated promising performance in perioperative risk modeling, including postoperative mortality prediction and automated ASA-related classification using preoperative electronic health record (EHR) data [1,5]. Beyond anesthesia-specific applications, AI-based models have also shown feasibility for preoperative risk stratification in other clinical domains, such as computed tomography–based risk classification of gastrointestinal stromal tumors [6]. More recently, large language models (LLMs) have emerged as particularly attractive tools because they can process not only structured variables but also unstructured clinical narratives, which are abundant in real-world perioperative documentation. This capacity is especially relevant in anesthesiology, where clinically meaningful information is frequently embedded in free-text records such as admission notes, consultation summaries, medication histories, and operative documentation.

Among current LLMs, GPT-4o (OpenAI) has shown strong performance across medical reasoning tasks. Published evaluations have reported variable GPT-4o performance across medical reasoning tasks, including radiology diagnostic quiz cases and high-stakes anesthesiology examination settings [7-9]. These findings suggest that model performance varies with task structure and domain specificity and may be sufficient to support clinically relevant reasoning under controlled conditions. At the same time, these studies also highlight an important caution: high overall performance does not eliminate the possibility of clinically meaningful error. In anesthesiology-focused benchmarking, unsupported medical claims were a frequent error type among incorrect responses, underscoring the need for careful validation before clinical deployment [8].

Several strategies have been proposed to improve the reliability of LLM-based medical systems. Retrieval-augmented generation, for example, can anchor model outputs to external knowledge sources and has been shown to improve accuracy in preoperative fitness assessments [10]. In parallel, conventional machine learning models for PONV prediction have outperformed traditional clinical scores in some datasets [11]. However, many existing predictive systems remain limited by their dependence on structured inputs and may not fully exploit the rich narrative content available in EHRs. LLMs may offer an advantage in this respect, but their real-world clinical validity in perianesthetic workflows remains insufficiently studied.

Another unresolved issue concerns how clinicians interact with AI-generated recommendations. Human-AI collaboration can improve diagnostic performance when AI is used to augment rather than replace expert judgment [12]. However, clinician acceptance of AI outputs should not be interpreted as evidence of correctness. Recent work has shown that physician satisfaction with LLM responses does not necessarily correlate with response accuracy, raising concerns that automation bias may obscure clinically important errors if human oversight is weak [13]. For this reason, evaluating LLMs in real clinical environments requires not only accuracy testing but also careful attention to workflow integration and the preservation of clinician accountability.

The objective of this study was to develop and retrospectively validate a GPT-4o–powered AI-assisted preanesthetic assessment system. The primary validation focus was the agreement between AI-generated and clinician-assigned ASA physical status classifications. PONV risk stratification was evaluated as an additional clinically relevant performance outcome. A secondary objective was to quantify the incremental effect of incorporating National Health Insurance (NHI) cloud data on model performance. This study is reported in accordance with the TRIPOD (Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis)-LLM guidance for studies using LLMs, with additional consideration of the broader TRIPOD+AI reporting framework for prediction model studies [14,15].

Methods

Study Design and Setting

This was a single-center retrospective validation study conducted at Far Eastern Memorial Hospital. The study evaluated a GPT-4o–enabled preanesthetic assessment system using existing clinical records from surgical patients who underwent preanesthetic consultation during the study period. The system integrated structured and unstructured data from hospital information systems and NHI cloud records to generate preanesthetic assessment outputs, including ASA physical status classification and PONV risk stratification.

Ethical Considerations

This study was reviewed and approved by the Institutional Review Board of Far Eastern Memorial Hospital (IRB 114151-E). Because this was a retrospective study using existing clinical records, the requirement for additional study-specific informed consent was waived by the Institutional Review Board. At admission, all patients provided written consent for the institutional use of their personal and medical data for purposes including clinical care, research, automated data processing, and related quality improvement activities, in accordance with institutional policy.

To protect privacy and confidentiality, direct identifiers, including patient names, were removed or replaced with generic placeholders before transmission to the cloud-based AI service. The field labeled “date of birth” contained only the patient’s year of birth; the month and day were not transmitted. Limited demographic variables, including age, sex, blood type, and year of birth, were retained in the transmitted data. AI-generated outputs were mapped back to identifiable clinical records only within the hospital’s secure local database.

No compensation was provided to participants because the study was retrospective, involved no direct participant contact, and used existing clinical data. Figures and supplementary materials were prepared using system architecture diagrams and workflow diagrams. No identifiable individual participant images or personal information is included in the manuscript or supplementary materials.

Data Privacy and Security

To protect patient privacy and support regulatory compliance, a multilayered security framework was implemented. First, direct patient identifiers were removed or replaced with generic placeholders on-premises before transmission to the cloud-based AI service. Patient names were replaced with generic placeholders, and the birth-date field contained only the year of birth; the month and day were excluded. Limited demographic variables required for clinical assessment, including age, sex, blood type, and year of birth, were retained. Second, transmitted data were protected using encryption mechanisms during data transfer. Third, the hospital maintained a formal contractual agreement, with the AI service provider prohibiting the use of institutional data for external model training or third-party purposes. Fourth, AI-generated results were mapped back to identifiable clinical records exclusively within the hospital’s secure local database after retrieval.

System Architecture and Workflow

The AI system comprised three functional layers: (1) a hospital data input layer, (2) a GPT-4o prediction engine, and (3) an output module. As depicted in Figure 1, the system collected structured and unstructured inputs from hospital information systems, including the hospital information system, nursing information system, laboratory information system, and anesthesia information management system, as well as NHI cloud data, preoperative clinical documentation, and historical summaries from prior hospital encounters when available.

All model inputs were restricted to information available before the index surgery and before the clinician completed the preanesthetic evaluation. Historical summaries from prior hospital encounters could be included as part of the longitudinal medical history when available. However, the discharge summary and postoperative documentation from the index surgical encounter were not available at the time of inference and were not provided to the model.

To prevent circularity and label leakage in the ASA agreement analysis, the anesthesiologist’s preanesthetic evaluation note and the signed anesthesia consultation record from the index surgical encounter were excluded from the model input. Additionally, any explicit clinician-assigned ASA physical status classification contained in structured fields or unstructured clinical text was excluded or masked before inference. The clinician-assigned ASA classification used as the reference standard was retrieved separately only after AI inference had been completed and was used solely for the subsequent agreement analysis.

XSL•FO
RenderX

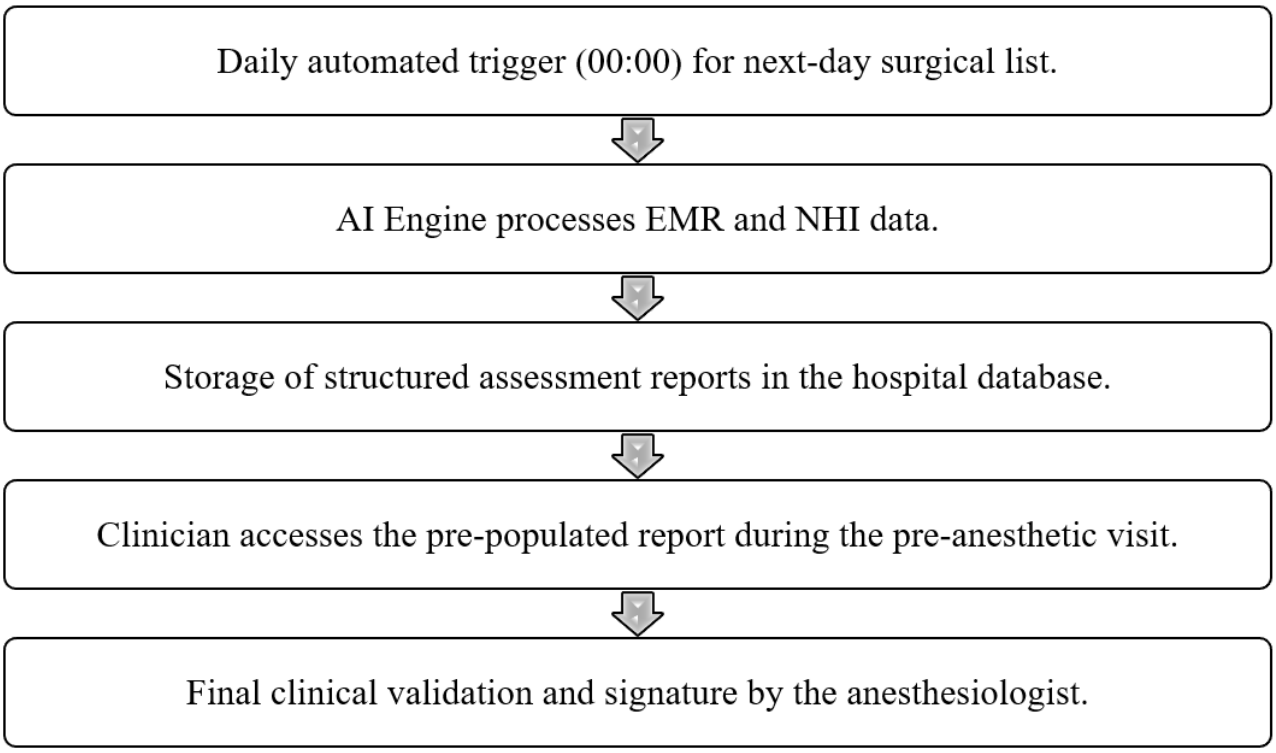

Figure 1. The system architecture supports GPT-4o–enabled preanesthetic assessment. The model integrates structured and unstructured preoperative data from the hospital information system, nursing information system, laboratory information system, and anesthesia information management system, as well as National Health Insurance (NHI) cloud data. Unstructured inputs included preoperative clinical documentation and historical summaries from prior hospital encounters. The discharge summary and postoperative documentation from the index surgical encounter were not available at the time of model inference and were not provided to the model. These inputs were processed by the GPT-4o–based AI engine to generate American Society of Anesthesiologists (ASA) physical status classifications and postoperative nausea and vomiting risk predictions for clinician review. PACS: picture archiving and communication system.

XSL•FO
RenderX

To optimize clinical efficiency and minimize latency, the system followed an automated batch-processing and clinical retrieval workflow (Figure 2):

1. Automated daily trigger: The system was triggered automatically at midnight each day to retrieve the surgical schedule for the following day.
2. Batch analysis: The GPT-4o engine processed the deidentified longitudinal data to generate preanesthetic assessments.
3. Secure storage: The structured reports were stored in the hospital database.
4. Clinical interaction: During the preanesthetic visit, anesthesiologists accessed the prepopulated reports as an auxiliary clinical decision-support tool.
5. Human-in-the-loop validation: All AI-generated outputs required clinical verification and a final electronic signature by the anesthesiologist before formal integration into the medical record.

Figure 2. The system used an automated batch-processing and clinical retrieval workflow. The system automatically retrieves the next-day surgical schedule, processes deidentified electronic medical record (EMR) and National Health Insurance (NHI) cloud data through the GPT-4o engine, stores structured assessment reports in the hospital database, and enables anesthesiologists to review and validate the prepopulated report during the preanesthetic visit before final approval and integration into the medical record.

Sampling and Data Collection

During January to May 2025, a total of 11,817 surgical records were screened. After removing 100 duplicate records related to combined procedures, 11,717 unique surgical records remained. These records included 3815 emergency surgeries, 3403 outpatient or day-surgery encounters, and 4499 inpatient surgical patients. Emergency surgeries and outpatient or day-surgery encounters were excluded because the present study focused on inpatient surgical patients undergoing standard preanesthetic consultation. At our institution, cases planned for local anesthesia alone do not undergo routine preanesthetic consultation and are not included in the preanesthetic consultation workflow. Therefore, local-anesthesia-only cases were not part of the sampling frame for this validation study. In accordance with the Institutional Review Board–approved study protocol, only adult patients aged 18 years or older at the time of surgery were eligible for inclusion. Pediatric patients were not included because individuals younger than 18 years were outside the approved study population and were considered a vulnerable population. Among the 4499 inpatient surgical patients, 95 patients classified as ASA physical status V or VI were further excluded because the study system was designed to validate routine preanesthetic assessment for ASA I-IV surgical patients rather than moribund patients or organ donors. The final eligible sampling frame, therefore, consisted of 4404 inpatient surgical patients. From this sampling frame, 600 adult patients were selected using stratified simple random sampling, with 120 patients randomly selected from each month between January and May 2025. All patients included in the final analytic cohort had a completed clinician-assigned ASA classification available for comparison with the AI-generated ASA classification.

Sample Size Justification

Because this was a retrospective validation study, the sample size was determined by feasibility and temporal balancing rather than by a formal a priori power calculation. A total of 600 patients were selected from the eligible inpatient surgical cohort, with 120 patients randomly sampled from each month between January and May 2025. This sampling strategy was used to

XSL•FO
RenderX

provide balanced temporal representation and to reduce the influence of month-specific workflow or case-mix variation.

The primary validation focus was agreement between AI-generated and clinician-assigned ASA physical status classifications. The PONV analysis was treated as a secondary performance evaluation. Because PONV occurred in 49 of 600 patients, estimates of sensitivity for PONV prediction were subject to greater statistical uncertainty and were therefore interpreted cautiously.

Prompt Development and Validation

The prompting strategy was developed through an iterative refinement process from July to December 2024. A multidisciplinary expert panel consisting of board-certified anesthesiologists and certified registered nurse anesthetists conducted multiple cycles of testing, evaluation, and refinement to optimize the model's clinical reasoning and output structure. These iterations specifically addressed inconsistencies in extracting unstructured narratives, including smoking status and motion sickness history, and refined the logic for prioritizing objective electronic medical record (EMR) documentation over subjective patient-reported information when discrepancies were identified. The final prompt template reached expert consensus after demonstrating stable performance across diverse clinical scenarios.

For the study period, the final version was implemented with the model temperature fixed at 0 to support highly reproducible outputs. The final structured prompt template used for the GPT-4o–enabled preanesthetic assessment system is provided in Multimedia Appendix 1. Because the prompt was implemented in Traditional Chinese in the actual clinical workflow, the appendix includes the verbatim Traditional Chinese prompt and an English translation for editorial and reviewer reference. The English translation is provided for reviewer reference only and was not the version used during system execution.

Foundation Model and Deployment Configuration

The AI engine used GPT-4o through a hospital-integrated, vendor-managed cloud deployment rather than a locally hosted model or a directly researcher-controlled API account. During the study period, the model was accessed through the same institutional deployment environment for all cases. The final prompt template, input preprocessing logic, output format requirements, and inference workflow were fixed throughout the study period and were applied identically to both the NHI-enabled and NHI-withheld conditions.

Temperature was fixed at 0 to support highly reproducible outputs. Other generation parameters, including top_p, maximum output tokens, frequency penalty, presence penalty, and system-level safety or routing parameters, were managed by the vendor deployment environment and were not directly exposed in the retrospective research dataset. No fine-tuning, local model training, or model-weight modification was performed by the study team.

Because the system was operated through a hospital-integrated deployment, the exact underlying model snapshot string and some deployment-level hyperparameters were not directly available to the investigators at the time of retrospective analysis. This limitation is reported to ensure transparency. Future prospective validation studies should retain deployment-level metadata, including model snapshot, API version, deployment version, and generation parameters, to improve reproducibility.

Model Functionality and Outputs

The GPT-4o–enabled system processed both structured and unstructured EMR data to generate two primary outputs: (1) ASA physical status classification and (2) prediction of PONV risk (low, moderate, or high).

To simulate expert-level clinical reasoning, a structured prompt was created to guide GPT-4o's behavior. This prompt was constructed based on a combination of institutional anesthesia practice guidelines and evidence-based criteria from the published literature.

The prompting logic was designed to:

1. Identify comorbidities based on the patient's history, medication records, and diagnostic codes.
2. Interpret unstructured data elements, including clinical notes and surgical reports.
3. Assign ASA class II or higher if any chronic systemic disease is present.
4. Perform PONV risk stratification using an Apfel-informed prompt that instructed the model to consider 4 Apfel-related factors: female sex, nonsmoking status, history of PONV or motion sickness, and expected postoperative opioid use.
5. Generate a final model-assigned PONV risk category as low, moderate, or high risk based on available documentation and the model's prompt-guided clinical judgment.
6. Produce a structured, tabulated output that includes the following: (1) patient demographics, (2) comorbidities with justification, (3) ASA classification with rationale, (4) the suggested anesthesia plan, (5) optional self-pay items, (6) perioperative mortality risk estimation, and (7) clinical recommendations.

To improve clinical interpretability, the structured reports were rendered through the hospital's front-end clinical application rather than being displayed as raw model output. The GPT-4o engine generated structured text with predefined formatting markers, including Markdown bold syntax and HTML color tags for clinically significant findings. These formatting markers were parsed and rendered by the application layer to display high-risk findings in bold text or red font where supported by the interface. In plain-text or unsupported environments, the system retained bold formatting only.

Primary Outcome and Threshold

PONV within 24 hours after surgery was classified as a binary outcome based on documentation in postoperative nursing notes, recovery records, physician progress notes, or medication records indicating nausea, vomiting, or the administration of rescue antiemetic therapy. Because the outcome was retrospectively ascertained from routine clinical documentation,

XSL•FO
RenderX

undocumented mild or transient PONV episodes may not have been captured.

Evaluation of AI Performance

The performance of the AI system was evaluated by comparing ASA physical status classifications from three sources: (1) clinician-assigned ASA classification, (2) AI-generated ASA classification without NHI data, and (3) AI-generated ASA classification with NHI data. The clinician-assigned ASA classification was used as the clinical reference classification for agreement analysis.

To evaluate the incremental contribution of NHI cloud data, each of the same 600 patients was processed under 2 input conditions. In the NHI-enabled condition, the model input included institutional EMR data and the NHI cloud data block. In the NHI-withheld condition, the NHI cloud data block was completely removed before model inference, while all other institutional EMR inputs, prompt instructions, model settings, and output requirements were kept identical. Therefore, the comparison between AI-generated ASA classifications with and without NHI data was based on paired outputs from the same patients rather than on different patient cohorts.

Agreement between AI-generated and clinician-assigned ASA classifications was assessed using Cohen κ coefficient with 95% CIs. Differences in model performance with and without NHI data were summarized descriptively.

For PONV risk prediction, the AI system generated a final risk category of low, moderate, or high risk. The PONV component was implemented as an Apfel-informed, prompt-based clinical risk stratification task rather than as a deterministic recalculation of the conventional Apfel score by the investigators. The prompt instructed the model to consider 4 Apfel-related factors: female sex, nonsmoking status, history of PONV or motion sickness, and expected postoperative opioid use. However, the risk category analyzed in this study was extracted directly from the model-generated output rather than recalculated after inference by rule-based criterion counting.

These predicted risk levels were compared with actual postoperative PONV events documented in clinical records within 24 hours after surgery. Diagnostic performance was evaluated using sensitivity, specificity, overall accuracy, positive predictive value, negative predictive value, and confusion matrix analysis. The relationship between the model-assigned PONV risk group and observed PONV outcome was analyzed using the 2-sided Fisher-Freeman-Halton exact test because the expected cell-count assumption for the Pearson chi-square test was not satisfied. The strength of the association was summarized using Cramér V.

Because the GPT-4o system generated ordinal PONV risk categories rather than calibrated continuous probability scores, receiver operating characteristic (ROC) and precision-recall plots were constructed using the available categorical thresholds. The primary threshold defined high risk as test-positive, whereas the sensitivity analysis defined moderate and high risk as test-positive. These analyses were interpreted as categorical threshold–based performance summaries rather than a formal optimization of a continuous probability threshold. The supplementary ROC and precision-recall plots are provided in Multimedia Appendix 2.

Statistical Analysis

Data management, data checking, variable coding, descriptive summaries, and tabulation were performed using Microsoft Excel 365. Inferential statistical analyses were conducted using SPSS Statistics (version 29.0.1.1; IBM Corp). Agreement between AI-generated and clinician-assigned ASA classifications was assessed using Cohen κ coefficient with 95% CIs. The association between model-assigned PONV risk categories and observed PONV outcomes was evaluated using the 2-sided Fisher-Freeman-Halton exact test because more than 20% of the contingency-table cells had expected counts below 5. The strength of the association was summarized using Cramér V. Diagnostic performance for PONV prediction was summarized using sensitivity, specificity, overall accuracy, positive predictive value, negative predictive value, and confusion matrix analysis. All hypothesis tests were 2-tailed, and a $P<.05$ was considered statistically significant. Descriptive statistics were used to summarize categorical variables and classification outputs. No imputation was performed for missing outcome or classification data.

Structured Prompt Logic for GPT-4o–Enabled Preanesthetic Assessment

Prompt Design Objectives

To emulate the clinical reasoning of an experienced anesthesiologist, we developed a structured prompt to guide the behavior of the GPT-4o LLM. The prompt was constructed using institution-specific clinical heuristics, guideline-derived decision rules, and explicit formatting instructions. Its purpose was to enable the model to generate a complete, clinically relevant preanesthetic assessment based on both structured and unstructured data retrieved from the EMR.

The prompt was designed to perform the following functions: (1) evaluate comorbidities and clinical history based on EMR data, (2) derive the ASA physical status classification in accordance with ASA guidelines, (3) stratify PONV risk using an Apfel-informed, prompt-based approach, (4) recommend appropriate anesthesia modalities and procedural interventions (eg, an arterial line and a central venous catheter placement), (5) assess the feasibility of optional self-pay anesthesia services, (6) estimate the perioperative mortality risk, and (7) suggest referrals for additional preoperative consultations when clinically indicated.

Clinical Reasoning Logic

Comorbidity Recognition

When discrepancies were found between patient self-reports and EMR data (such as *International Classification of Diseases, 10th Revision* [*ICD-10*] codes, medication history, or laboratory abnormalities), the model prioritized objective documentation. If any chronic systemic disease was identified, the system defaulted to assigning an ASA classification of at least class II, consistent with ASA definitions.

XSL•FO
RenderX

PONV Risk Stratification

The PONV component was designed as an Apfel-informed prompt-based risk stratification task. The prompt instructed the model to consider 4 Apfel-related factors associated with PONV: female sex, nonsmoking status, history of motion sickness or previous PONV, and expected postoperative opioid use. Additionally, the prompt asked the model to generate a final low-risk, moderate-risk, or high-risk classification according to the expected clinical incidence and to provide reasons for high-risk factors.

Because the implemented prompt contained both Apfel-related factor instructions and an incidence-based risk classification instruction, the final PONV risk category was treated as a model-assigned ordinal risk category rather than as a deterministic recalculation of the conventional Apfel score. Accordingly, the low, moderate, and high categories in this study should be interpreted as prompt-defined clinical decision-support categories rather than as standard Apfel score categories.

Clinical Output Structure

The model was configured to return structured, tabulated summaries across the following clinical domains:

1. Demographics: Includes blood type, sex, age, and year of birth.
2. Comorbidities and surgical history: Includes conditions such as diabetes, cardiovascular disease, thromboembolism, respiratory illnesses, hepatic or renal dysfunction, prior surgeries, substance use, allergies, psychiatric disorders, and a family history of malignant hyperthermia.
3. ASA classification: Displays the assigned ASA physical status along with the supporting rationale.
4. Anesthesia plan: Recommends an anesthesia modality (eg, endotracheal tube general anesthesia, intravenous general anesthesia, spinal anesthesia, epidural anesthesia, and local anesthesia) and flags indications for invasive monitoring (eg, arterial line and central venous catheter), intensive care unit admission, or fiberoptic airway evaluation.
5. Optional patient-pay services: Suggests nonreimbursed perioperative options (eg, BIS monitor, patient-controlled analgesia, and warming devices), based on surgical type, patient age, and comorbidity profile.
6. Perioperative mortality estimation: Provides a risk estimate based on cumulative clinical factors.
7. Referral suggestions: Identifies cases requiring additional evaluation or a specialty consultation (eg, cardiology).

Formatting Protocol

To enhance interpretability, clinically significant findings (eg, positive comorbidities or high-risk status) are rendered in bold text. In environments that support HTML or rich-text formatting, such findings are also highlighted in red font using a texttag. In plain-text contexts (eg, terminal or PDF output), only bold formatting is applied.

Results

Baseline Characteristics and Binary-Coded Apfel-Related Factors

A total of 600 adult surgical patients were included in the analysis. The results are presented in two parts: (1) the agreement between clinician-assigned and AI-generated ASA physical status classifications and (2) the performance of AI-based risk stratification for PONV.

Baseline characteristics and binary-coded Apfel-related factors are shown in Table 1. The cohort included adults aged 18 to 80 years. Apfel-related factors were coded as positive when identified from the model input or the preoperative clinical record review and as not positive when they were not identified in the available preoperative records. Among the 600 patients, 161 (26.8%) were female, 26 (4.3%) had nonsmoking status documented, 20 (3.3%) had a documented history of previous PONV or motion sickness, and 20 (3.3%) had expected postoperative opioid use documented. The relatively low coded frequencies of nonsmoking status, previous PONV or motion sickness, and expected postoperative opioid use likely reflect incomplete or nonexplicit documentation in the available preoperative records rather than their true prevalence in the study cohort.

XSL•FO
RenderX

Table . Baseline characteristics and binary-coded Apfel-related factors of the study cohort[a].

Characteristic	Overall cohort (N=600)
Age (y), mean (SD)	42.8 (16.2)
Age (y), median (IQR)	41.0 (30.0 - 53.0)
Age range (y)	18 - 80
Age group (y), n (%)	
<18	0 (0)
18 - 64	526 (87.7)
≥65	74 (12.3)
Sex, n (%)	
Male	439 (73.2)
Female	161 (26.8)
Binary-coded Apfel-related positive factors, n (%)	
Female sex	161 (26.8)
Nonsmoking status	26 (4.3)
History of PONV[b] or motion sickness	20 (3.3)
Expected postoperative opioid use	20 (3.3)
Number of binary-coded Apfel-related positive factors, n (%)	
0	422 (70.3)
1	151 (25.2)
2	6 (1)
3	20 (3.3)
4	1 (0.2)

[a]Apfel-related factors were coded as binary variables based on information available in the model input and preoperative clinical record review. A value of 1 indicated that the factor was identified as positive, whereas a value of 0 indicated that the factor was not identified as positive in the available preoperative records. The number of binary-coded Apfel-related positive factors is reported descriptively and was not used by the investigators to recalculate the AI-generated PONV risk category after inference.

[b]PONV: postoperative nausea and vomiting.

ASA Classification Agreement

Table 2 summarizes the distribution of ASA classifications across 3 sources: clinician-assigned ASA classifications, AI-generated classifications with NHI data, and AI-generated classifications without NHI data. Among the 600 patients, the majority of clinician-assigned ASA classifications were ASA II (n=498 patients, 83%), followed by ASA III (n=57 patients, 9.5%), ASA I (n=39 patients, 6.5%), and ASA IV (n=6 patients, 1%).

Table . Distribution of American Society of Anesthesiologists (ASA) classifications by clinicians and AI models with and without National Health Insurance (NHI) data.

ASA grade	Clinician-assigned ASA	AI with NHI	AI without NHI
1	39	37	140
2	498	497	409
3	57	62	48
4	6	4	3
Total patient number	600	600	600

The AI system incorporating NHI data closely matched clinicians' assessments, assigning ASA I to 37 patients and ASA II to 497 patients. In contrast, the AI system without NHI data substantially overestimated ASA I classifications (140 vs 39 patients; +101) and underestimated ASA II classifications (409 vs 498 patients; –89), indicating a systematic underestimation of preoperative physical status severity when NHI cloud data were unavailable.

As shown in Table 3, agreement between AI-generated and clinician-assigned ASA classifications was high when NHI data

XSL•FO
RenderX

were incorporated, with a Cohen κ of 0.883 (95% CI 0.841 - 0.946). In contrast, agreement was lower when NHI data were not incorporated, with a Cohen κ of 0.518 (95% CI 0.412 - 0.691), indicating moderate agreement. The difference in κ values (Δκ=0.365) suggests that incorporating NHI cloud data improved consistency between AI-generated and clinician-assigned ASA classifications.

Table . Agreement between AI-generated and clinician-assigned ASA[a] classifications.

Comparison	Cohen κ	95% CI[b]
AI with NHI[c] vs clinician-assigned ASA	0.883	0.841 - 0.946
AI without NHI vs clinician-assigned ASA	0.518	0.412 - 0.691
Difference in κ	0.365	—[d]

[a]ASA: American Society of Anesthesiologists.

[b]The 95% CI was calculated for each Cohen κ estimate. A 95% CI for the difference in κ was not calculated.

[c]NHI: National Health Insurance.

[d]Not applicable.

PONV Risk Prediction Performance

The performance of the AI system in predicting PONV is shown in Table 4. A total of 8.2% (49/600) patients experienced PONV. The AI model stratified patients into 3 risk levels: low, moderate, and high. These risk groups represented the final AI-generated, Apfel-informed, prompt-based classifications and were not recalculated by the investigators using deterministic Apfel criterion counting after model inference.

Table . PONV[a] prediction vs actual outcomes (primary threshold: high risk=test-positive)[b].

PONV outcome	Low risk	Moderate risk	High risk	Total
No PONV	540	6	5	551
PONV	27	5	17	49
Total	567	11	22	600

[a]PONV: postoperative nausea and vomiting.

[b]The association between the 3 model-assigned PONV risk categories and observed PONV outcomes was evaluated using the 2-sided Fisher-Freeman-Halton exact test (P<.001) because more than 20% of the contingency-table cells had expected counts below 5. Cramér V was used to summarize the strength of the association (V=0.531). The primary diagnostic-performance analysis counted high risk as test-positive, whereas the sensitivity analysis counted moderate and high risk as test-positive. In the sensitivity analysis, sensitivity was 44.9%, specificity was 98.0%, positive predictive value was 66.7%, and negative predictive value was 95.2%.

Among the 49 patients who developed PONV, the model classified 17 as high risk, 5 as moderate risk, and 27 as low risk. Among the 551 patients who did not develop PONV, the model classified 540 as low risk, 6 as moderate risk, and 5 as high risk.

Using high-risk as the primary test-positive threshold, the model achieved a sensitivity of 34.7% (95% CI 22.9 - 48.7), specificity of 99.1% (95% CI 97.9 - 99.6), positive predictive value of 77.3%, and negative predictive value of 94.5%. The observed incidence of PONV differed significantly across the 3 model-assigned risk categories (2-sided Fisher-Freeman-Halton exact test, P<.001), with a large association as indicated by Cramér V of 0.531. The incidence of PONV was 4.8% (27/567) in the low-risk group, 45.5% (5/11) in the moderate-risk group, and 77.3% (17/22) in the high-risk group.

In the sensitivity analysis counting the moderate-risk and high-risk categories as test-positive, sensitivity increased to 44.9% (95% CI 31.9 - 58.7), while specificity was 98.0% (95% CI 96.5 - 98.9), positive predictive value was 66.7%, and negative predictive value was 95.2%. Supplementary ROC and precision-recall plots based on ordinal PONV risk thresholds are provided in Multimedia Appendix 2. Because the model generated categorical low-risk, moderate-risk, and high-risk levels rather than calibrated continuous probabilities, these plots were constructed using the available categorical thresholds.

Discussion

Principal Findings

This retrospective validation study showed that a GPT-4o–enabled preanesthetic assessment system can generate clinically meaningful ASA physical status classifications and PONV risk predictions using both structured and unstructured clinical data. The primary validation focus was agreement between AI-generated and clinician-assigned ASA physical status classifications. The most important finding was that agreement between AI-generated ASA classifications and anesthesiologist-assigned classifications was high when NHI cloud data were incorporated (κ=0.883, 95% CI 0.841 - 0.946), whereas agreement was lower without NHI data (κ=0.518, 95% CI 0.412 - 0.691). The observed reduction in agreement (Δκ=0.365) highlights the importance of comprehensive and longitudinal patient information in AI-assisted perioperative risk assessment.

XSL•FO
RenderX

For PONV prediction, the model showed a different performance profile. Using the high-risk category as the primary positive threshold, specificity was very high (99.1%), whereas sensitivity was modest (34.7%). The primary threshold also yielded a positive predictive value of 77.3% and a negative predictive value of 94.5%. When the test-positive threshold was broadened to include both moderate and high-risk categories, sensitivity increased to 44.9%, but the positive predictive value decreased to 66.7%, illustrating the tradeoff between identifying more potential PONV cases and preserving prediction precision. Because the system produced categorical low, moderate, and high PONV risk outputs rather than calibrated probability scores, the ROC and precision-recall plots should be interpreted as ordinal threshold–based performance summaries rather than as continuous probability–based threshold optimization. Accordingly, the PONV component should be interpreted as an ordinal risk stratification tool that identified a small high-risk subgroup with a high observed PONV incidence, rather than as a stand-alone screening system for all patients who may develop PONV.

Taken together, these findings suggest that LLM-based systems can approximate local clinicians' reasoning in preanesthetic evaluation, particularly for ASA classification, but their performance is strongly influenced by the completeness of the underlying data environment.

Comparison With Prior Work

The high concordance observed in ASA classification is consistent with prior work showing that AI and machine learning approaches can support or approximate ASA assignment using EHR-derived data. Previous studies have reported moderate agreement between a machine learning–derived ASA score and anesthesiologist ratings, as well as strong agreement between ChatGPT-4 (OpenAI) and expert anesthesiologists in a prospective multicenter evaluation [1,2].

Human-to-human agreement provides an important benchmark for interpreting AI-clinician agreement in ASA physical status classification. Prior studies have reported only fair-to-moderate agreement among clinicians. Riley et al [16] reported a κ value of 0.40 among 151 anesthetists assigning ASA classifications to standardized hypothetical adult patient histories. In a large clinical-practice cohort, Sankar et al [17] reported a weighted κ of 0.61 when comparing ASA physical status ratings assigned in the preoperative assessment clinic and operating theater, with 67.0% (7279/10864) of patients assigned the same ASA physical status class. Kwa et al [18] reported moderate concordance between surgeon-assigned and anesthesiologist-assigned ASA classifications in 46,284 elective surgical patients, with a weighted Cohen κ of 0.53. In this context, the agreement observed between the GPT-4o system using NHI data and anesthesiologist-assigned ASA classifications in the present study (κ=0.883) appears high relative to previously reported human-to-human agreement benchmarks. However, this comparison should be interpreted cautiously because the prior studies differed in rater design, case mix, clinical setting, and the use of weighted vs unweighted κ. Therefore, our finding should not be interpreted as evidence that AI outperforms clinicians, but rather as suggesting that comprehensive longitudinal data integration may support more consistent and standardized ASA classification.

Our findings extend this prior work in 2 ways. First, the present system was designed to function within a real clinical workflow using both structured and narrative data, rather than relying solely on predefined structured inputs. Second, the marked improvement observed after incorporation of NHI cloud data suggests that data integration, rather than model architecture alone, may be a major determinant of clinical utility.

This interpretation is further supported by the observed distributional shift in ASA predictions without NHI data. In the absence of cloud-based information, the system overassigned ASA I and underassigned ASA II, indicating a tendency to classify patients as healthier when longitudinal comorbidity data were incomplete. From a clinical perspective, this pattern is important because underestimation of ASA status could lead to insufficient preoperative preparation or underrecognition of perioperative risk. The benefit of richer preoperative data is also consistent with prior perioperative AI studies showing that the combination of structured variables and unstructured clinical text can improve prediction performance, particularly for outcomes influenced by complex comorbidity patterns [5].

Several factors may explain the limited sensitivity for PONV prediction. The prompting framework was informed by Apfel-related factors, including female sex, nonsmoking status, history of motion sickness or previous PONV, and postoperative opioid use [4]. However, the final PONV risk category evaluated in this study was the model-assigned ordinal output rather than a deterministic recalculation of the conventional Apfel score. Some of these variables are not consistently or reliably documented in routine EHRs. In particular, motion sickness history, prior PONV, and smoking status may be incompletely captured, leading to systematic underidentification of risk even when the prompt logic is otherwise clinically reasonable.

These findings are consistent with more recent work suggesting that machine learning approaches may outperform classical PONV scores when broader perioperative predictors are available [11]. Accordingly, future improvement in LLM-based PONV prediction may require not only prompt refinement but also broader feature integration, including anesthetic technique, intraoperative medication exposure, recovery-phase variables, and a more complete capture of patient-reported risk factors.

Ethical and Regulatory Considerations

An important feature of this system is that it was developed as a workflow-oriented clinical support tool rather than as an autonomous decision-making system. The model processed deidentified data in batch mode before the preanesthetic visit, generated structured outputs for clinician review, and required final verification and an electronic signature by an anesthesiologist before their formal integration into the medical record. This human-in-the-loop design is essential because clinician acceptance of AI-generated content does not necessarily guarantee correctness [13]. More broadly, the literature on human-AI collaboration suggests that AI is most appropriate when used to augment expert interpretation rather than replace professional judgment [12].

XSL•FO
RenderX

The system also generated additional clinical outputs, including suggested anesthesia plans, indications for invasive monitoring, perioperative mortality estimates, referral suggestions, and optional patient-pay anesthesia services. These outputs were intended to support structured clinical review but were not independently validated in the present study. This distinction is important because recommendations concerning invasive monitoring, referrals, mortality risk, or nonreimbursed services may have clinical, ethical, and financial implications. These outputs should therefore be interpreted as preliminary decision-support suggestions requiring clinician verification rather than as validated automated recommendations.

The inclusion of optional patient-pay anesthesia services requires particular ethical caution. In the present system, AI-generated patient-pay items were not autonomous recommendations, were not automatically prescribed, and were not directly presented to patients without clinician review. The system identified potentially applicable services based on predefined clinical factors, including anesthesia type, surgical procedure, age, and comorbidity profile. Final assessment of clinical appropriateness, discussion with the patient, and any subsequent recommendation remained the responsibility of the anesthesiologist.

The financial-hardship logic functioned as a clinician-facing caution rather than as an automatic exclusion rule. When the medical record contained unpaid medical bills, social work documentation, physician orders, or other information indicating financial difficulty, the system alerted the reviewing clinician to consider the potential financial burden associated with nonreimbursed services. This alert did not remove patient-pay options from the clinical workflow, prohibit clinicians from discussing them, or prevent patients from considering potentially beneficial services.

The intent of this logic was partly protective, aiming to reduce indiscriminate promotion of costly nonreimbursed services to patients experiencing financial difficulty. However, we acknowledge that even a clinician-facing socioeconomic alert could influence whether a potentially beneficial option is discussed and could therefore raise concerns regarding equity and patient autonomy. The decision to introduce a patient-pay option remained based on its clinical relevance and was made by the responsible anesthesiologist after consideration of the patient's clinical condition, preferences, and individual circumstances. When an option was considered clinically appropriate, the clinician could still provide balanced information regarding its rationale, expected benefits, alternatives, risks, and costs, thereby allowing the patient to participate in shared decision-making.

Optional patient-pay suggestions should therefore be treated as preliminary clinical prompts rather than as revenue-oriented recommendations or automatic eligibility determinations. To reduce the risk of systematic disadvantage, appropriate governance should include institutionally approved criteria, multidisciplinary oversight, clinician education, and periodic audits to assess whether patients with financial-risk alerts are systematically less likely to receive information about clinically relevant options. Review of clinician responses to these alerts and documentation of subsequent discussions may further support transparency and accountability. These safeguards are important for preserving equity, patient autonomy, and shared decision-making.

More broadly, to reduce the risk of automation bias, particularly among junior clinicians, AI-supported workflows should be accompanied by appropriate training in AI literacy, information security, and critical interpretation of model outputs. Clinical accountability for final assessment and decision-making should remain with the responsible anesthesiologist.

Limitations

First, this was a single-center retrospective study, and model performance may differ in other hospitals, documentation systems, or patient populations. The present system benefited from the NHI cloud infrastructure in Taiwan, which provides longitudinal claims and medication information beyond a single-institution record. Although the underlying principle of longitudinal data integration is transferable, comparable performance may not be achieved in settings with less complete data interoperability. Future multicenter validation is needed across institutions with different documentation cultures, coding practices, and data completeness.

Second, the comparison between NHI-enabled and NHI-withheld inputs revealed a clinically important default-to-healthy bias when longitudinal NHI data were unavailable. Specifically, when NHI data were withheld, the system classified 140 patients as ASA I, whereas clinicians classified only 39 patients as ASA I. This pattern suggests that, in the absence of longitudinal comorbidity and medication information, the model may underrecognize systemic disease burden and classify patients as healthier than they are. From a patient safety perspective, such underclassification could lead to underrecognition of perioperative risk if clinicians accept AI-generated outputs without careful review. This finding reinforces the need for mandatory anesthesiologist verification, clear labeling of data completeness, and caution when using AI-generated ASA classifications in settings where longitudinal external health data are unavailable.

Third, the reference standard for ASA classification was clinician-assigned ASA status rather than an adjudicated consensus panel. Therefore, the observed agreement reflects concordance with local real-world clinical practice rather than agreement with an objective gold standard. In routine clinical workflow, independent duplicate ASA assessments by multiple anesthesiologists are not systematically performed for the same patient; therefore, an internal human-to-human κ could not be calculated from this retrospective dataset. Because ASA classification is known to vary across providers, the model should be interpreted as approximating local clinician judgment rather than establishing an independent ground truth.

Fourth, the structured prompt included a conservative rule assigning ASA class II or higher when a chronic systemic disease was identified. This rule was intended to reduce the risk of underrecognizing clinically relevant comorbidity during automated preanesthetic assessment. However, it may not fully capture cases in which a prior localized condition has completely resolved or has no current systemic implications. In such cases,

XSL•FO
RenderX

an ASA I classification may still be clinically appropriate. This hardcoded logic therefore represents an algorithmic constraint and may contribute to conservative upward classification at the ASA I-II boundary, particularly when historical diagnoses are not clearly distinguishable from active systemic disease in the source clinical records. Future versions of the prompt should more explicitly distinguish active systemic disease from remote, resolved, or clinically insignificant medical history.

Fifth, the PONV component should be interpreted with caution because it was implemented as an Apfel-informed, prompt-based clinical risk stratification task rather than as a deterministic recalculation of the conventional Apfel score. The prompt instructed the model to consider 4 Apfel-related factors: female sex, nonsmoking status, history of PONV or motion sickness, and expected postoperative opioid use. However, the analyzed PONV risk category was extracted from the model's final low-risk, moderate-risk, or high-risk output rather than recalculated by the investigators using rule-based Apfel criterion counting after inference. Therefore, the PONV results represent the performance of the study system's prompt-defined ordinal risk stratification rather than a validation of standard Apfel score thresholds.

The prompt also contained both Apfel-related factor instructions and an incidence-based risk classification instruction. This prompt-design ambiguity may have contributed to the high proportion of low-risk classifications and should be addressed in future prompt refinement and prospective validation. Additionally, some Apfel-related variables, including smoking status, prior PONV, motion sickness history, and expected postoperative opioid use, may not have been consistently documented in routine EHRs, which may have further limited sensitivity.

PONV events were retrospectively identified from routine clinical records. Mild or transient nausea and vomiting may not have been consistently documented, meaning that the true incidence of PONV may have been higher than the observed 8.2% (49/600). This ascertainment bias may have influenced estimates of diagnostic performance and may have caused some apparent AI false positives to represent undocumented true-positive events.

Sixth, the sample size was determined by feasibility and temporal balancing rather than by a formal a priori power calculation. Although the 600-patient cohort allowed the evaluation of ASA agreement in a temporally balanced retrospective sample, the study was not specifically powered for PONV prediction. Only 49/600 (8.2%) patients experienced documented PONV within 24 hours after surgery. As a result, sensitivity estimates for PONV prediction had wider uncertainty and should be interpreted cautiously. Future studies with larger samples or enriched PONV-positive cohorts are needed to more precisely evaluate model performance for PONV risk prediction.

Seventh, while the temperature parameter was fixed at 0 to improve output consistency, the system was operated through a hospital-integrated, vendor-managed cloud deployment. Therefore, the exact underlying model snapshot string and some deployment-level hyperparameters were not directly available in the retrospective research dataset. LLM outputs may also be influenced by prompt framing, source documentation quality, model updates, deployment configuration, and computational variation. This setting should therefore be described as supporting highly reproducible outputs rather than guaranteeing strict determinism. Future prospective studies should retain deployment-level metadata, including model snapshot, API version, deployment version, and generation parameters, to improve reproducibility.

Eighth, the study evaluated only ASA classification agreement and PONV risk stratification. Other generated outputs, including suggested anesthesia plans, invasive monitoring recommendations, perioperative mortality estimation, referral suggestions, and optional patient-pay anesthesia services, were not independently validated. These outputs should therefore be interpreted as preliminary decision-support prompts requiring anesthesiologist verification rather than validated automated clinical recommendations.

Ninth, although the system was designed to support workflow efficiency through automated batch processing and prepopulated reporting, operational outcomes such as documentation time, assessment completion time, clinician workload, user satisfaction, and downstream decision-making were not directly measured. Therefore, the present findings support diagnostic and workflow feasibility but do not yet demonstrate measurable efficiency gains or improved clinical outcomes.

Future Directions

Future studies should validate this system prospectively and across multiple clinical sites. Particular attention should be paid to improving the sensitivity of PONV prediction by incorporating additional perioperative predictors, including anesthetic technique, intraoperative medication exposure, postoperative opioid use, recovery-room symptoms, and structured patient-reported histories of motion sickness or previous PONV. Future work should also evaluate representative false-negative and false-positive cases in greater detail to identify whether errors are driven primarily by model reasoning, incomplete documentation, or outcome underascertainment.

Additional validation is also needed for clinical outputs beyond ASA and PONV, including suggested anesthesia plans, indications for invasive monitoring, perioperative mortality estimation, referral suggestions, and optional patient-pay service recommendations. Future implementation studies should measure effects on documentation time, clinician workload, assessment consistency, patient safety, prophylaxis decisions, and cost-related ethical outcomes.

Conclusions

This study demonstrated the feasibility of a GPT-4o–powered AI system for preanesthetic assessment using structured and unstructured data from EHRs and NHI cloud records. The system showed high agreement with anesthesiologist-assigned ASA classifications when NHI data were incorporated, supporting the value of comprehensive longitudinal data for AI-assisted surgical risk stratification. For PONV prediction, the model demonstrated high specificity and high negative predictive value but modest sensitivity, indicating that it identified a small high-risk subgroup with a high observed

XSL•FO
RenderX

incidence of PONV but did not capture all patients who developed PONV.

These findings support the use of LLM-based clinical decision-support tools as adjuncts to, rather than replacements for, anesthesiologist judgment. The system may help synthesize heterogeneous clinical information, standardize preliminary assessment, and surface clinically relevant findings for clinician confirmation. Further prospective and multicenter studies are needed to improve PONV sensitivity, validate additional clinical outputs, evaluate ethical safeguards for optional patient-pay recommendations, and quantify real-world effects on workflow efficiency and clinical decision-making.

Acknowledgments

The authors thank the Department of Anesthesiology and the information technology team of Far Eastern Memorial Hospital for their support in system development, data integration, and clinical workflow implementation. The authors also thank the clinical staff involved in preanesthetic consultation and perioperative documentation. The authors used ChatGPT (OpenAI) for English-language editing, manuscript formatting, and assistance in preparing the responses to reviewers. All AI-generated outputs were reviewed and revised by the authors, who take full responsibility for the final content.

Funding

The authors declared no financial support was received for this work.

Data Availability

The data analyzed in this study are not publicly available because they contain sensitive clinical information derived from hospital electronic medical records and National Health Insurance (NHI) cloud data. Deidentified aggregate results are presented in the manuscript. Requests for access to additional deidentified data may be considered by the corresponding author and Far Eastern Memorial Hospital, subject to Institutional Review Board approval, institutional data governance policies, and applicable privacy regulations.

Abstract

Background: Accurate assessment of pulpal status is essential for achieving successful endodontic outcomes. However, direct evaluation remains inherently challenging because the pulp is surrounded by calcified tissue, necessitating reliance on clinical and radiographic examinations for diagnostic and prognostic decision-making. These procedures demand substantial clinical expertise and time, and less-experienced clinicians often face challenges that may lead to errors in diagnosis and treatment planning. Recent advancements in large language models (LLMs) offer promising opportunities to enhance clinical reasoning by facilitating the integration of evidence and supporting methodical diagnostic decision-making.

Objective: This study aimed to evaluate the clinical applicability of LLMs by comparing their text-based clinical screening performance and the clinical validity of their treatment plan responses with those of human evaluators.

Methods: Between January 2011 and December 2022, 100 clinical cases involving primary endodontic disease were randomly selected from the clinical records of outpatients who visited the Department of Conservative Dentistry or Advanced General Dentistry (AGD) at Yonsei University Dental Hospital. Four prompt types, combining 2 variables (language and role), were used as input for 4 LLMs. Both LLMs and human evaluators (AGD specialists, AGD residents, endodontic residents, and senior dental students) assessed the cases using text-based clinical records. Radiographic images were not directly provided. Screening performance was evaluated using a 0-to-2-point concordance scale, and treatment plan validity and relevance were assessed using a 5-point Likert scale.

Results: Among the 4 LLMs evaluated, ChatGPT achieved the highest mean concordance score on Korean-doctor prompts (mean 0.98, SD 0.82). However, this score did not reach the partially correct criterion of 1 on the 0 to 2-point scale. Clova X recorded the lowest mean score on English-patient prompts (mean 0.23, SD 0.63). Across both diagnostic categories, AGD specialists demonstrated the highest diagnostic accuracy (pulpal: 0.70; periapical: 0.65), with higher sensitivity but lower specificity than those exhibited by the other groups. ChatGPT also showed favorable performance among the LLMs, with accuracies of 0.65 (95% CI 0.55 - 0.74) for pulpal disease and 0.57 (95% CI 0.47 - 0.69) for periapical disease, which were comparable to those of AGD and endodontic residents.

Conclusions: Under image-free clinical record review conditions, ChatGPT 4.0 showed relatively higher and more consistent performance in symptom screening and treatment planning compared to the other LLMs evaluated. However, its highest mean score of 0.98 (SD 0.82) did not reach the partially correct criterion of 1 on the 0 to 2-point scale. Hallucinations generated by LLMs and experience-dependent interpretation biases among human evaluators remain key challenges that require attention. Therefore, continuous clinical supervision and comprehensive user training are necessary for the safe and effective clinical application.

Introduction

Accurate diagnosis of pulp pathologies plays a critical role in the success of root canal treatment, with the ultimate objective being the preservation of natural dentition [1,2]. In many clinical situations, root canal treatment is combined with periodontal and prosthodontic procedures, which complicates the process of diagnosis and treatment planning. A thorough evaluation of pulp and periapical tissue conditions, including the assessment of pulp vitality, remains essential before treatment initiation [2]. However, the pulp is surrounded by calcified tissue, which structurally limits direct examination [3]. Consequently, radiographic assessment remains an indispensable diagnostic modality for treatment planning and prognosis evaluation, playing a vital role in the objective confirmation of lesions [4,5].

The integration of imaging findings with clinical data often requires substantial time and expertise. Limited resources and time constraints frequently prevent clinicians from promptly incorporating the latest evidence or clinical guidelines into practice. Less experienced clinicians, in particular, are more vulnerable to diagnostic bias and errors, which may compromise diagnostic accuracy and clinical outcomes [2,6,7]. Recent advances in large language models (LLMs), which can process and generate human-like responses from unstructured patient records, have introduced new possibilities for supporting clinical assessment and treatment planning based on patient information [8,9].

LLMs can facilitate systematic clinical decision-making by integrating recent research findings and clinical guidelines. They may also provide value in complex cases by reconfirming overlooked information, reducing uncertainty, and supporting the development of individualized treatment strategies. This capability enables clinicians to refine diagnostic reasoning and design patient-specific treatment plans [10,11]. Therefore, evaluating the potential of LLMs as auxiliary tools to enhance symptom-based screening performance and treatment planning validity is a priority.

Most existing research on LLMs in conservative dentistry has focused on educational applications, such as responding to patient-related clinical questions or addressing multiple-choice examinations [12-16]. Furthermore, few studies have evaluated LLM performance using real-world clinical cases and compared model outputs with those of human evaluators. To address this gap, this study evaluated the clinical validity and relevance of LLM-generated symptom-based assessments and treatment planning responses using routine clinical records. This study examined how LLMs may function during the initial clinical assessment, where narrative clinical information guides early screening decisions, and compared their outputs with those of clinicians and senior students across different levels of clinical experience. In addition, we provide practical evidence on where LLM support may be clinically useful and where expert oversight remains essential. Therefore, this study aimed to provide clinically validated criteria for different applications of LLMs within the limited context of symptom-based screening in the field of dentistry.

Methods

Ethical Considerations

This retrospective study was approved by the institutional review board of the Dental Hospital of Yonsei University (IRB 2-2024-0075). All procedures were part of standard clinical care, and the committee waived the need for informed consent. To maintain privacy and confidentiality, all data were fully anonymized before analysis. This study did not involve participant compensation.

Data Collection

This retrospective analysis included records of patients who visited the outpatient clinics of the Departments of Advanced General Dentistry (AGD) or Conservative Dentistry between January 2011 and December 2022. Eligible participants were adults aged 19 years or older, who had a recorded chief complaint at the initial visit, and were diagnosed with pulpal or periapical disease by a specialist. Among those who underwent pretreatment periapical radiography with corresponding clinical and radiographic records, 100 cases without previous endodontic treatment were randomly selected. The demographic and clinical characteristics of the included cases are summarized in Table 1. Chief complaints recorded in the clinical records reflect the patient-reported symptom history, whereas objective examination findings reflect the clinical status at the time of presentation.

Study Design

Four LLMs were evaluated, namely ChatGPT (version 4.0, OpenAI Inc), Gemini (version 1.5 Pro, Google), Bing (Microsoft), and Clova X (version Hyper Clova X, Naver Corporation). All LLM queries were conducted between November 30, 2024, and December 7, 2024. Four prompt types were created by combining 2 variables—language (Korean vs English) and role (doctor vs patient): (1) Korean-doctor, (2) Korean-patient, (3) English-doctor, and (4) English-patient (Multimedia Appendix 1). All LLMs were queried using platform-default generation settings, without any manual adjustments. Clinical cases were provided in a narrative clinical record format, including patient age, sex, chief complaint, reason for visit, and clinical symptoms. Radiographic images were not directly provided to either the LLMs or the human evaluators. However, because radiographic interpretations are commonly documented in routine clinical information, summarized radiographic descriptors could be included within the chart text. Screening performance was compared with that of human evaluators using Korean-doctor prompts reflecting the clinical background of the evaluators. All treatment plan responses were reformatted into a narrative format before evaluation to ensure assessor blinding to the source of the response. English prompts were generated from the original Korean prompts using Google Translate (Google LLC) and reviewed by a domain expert for accuracy. To ensure reproducibility, prompt structure and generation settings were standardized. Persona prompts were adopted to reflect differences in clinical communication between clinicians and patients. A zero-shot prompting design was used to allow standardized evaluation without example-based guidance, thereby improving comparability across models and evaluator groups.

Evaluator Groups

A conservative dentistry specialist with more than 20 years of clinical experience initially reviewed and selected suitable clinical cases for this study based on clinical data and radiographic assessments. The same specialist established the reference standard diagnosis using the full clinical and radiographic records and was blinded to the LLM-generated outputs and the diagnostic assessments of all evaluators. Twelve evaluators then independently assessed the cases using the same clinical information in the patient records provided to the LLMs.

XSL•FO
RenderX

The evaluators included 3 AGD specialists with more than 5 years of experience, 3 AGD residents with more than 2 years of experience, 3 endodontic residents with more than 2 years of experience, and 3 senior dental students. Subsequently, the same evaluators assessed the clinical validity and relevance of the treatment plans generated by each LLM.

Evaluation Criteria

Symptom-based screening accuracy was evaluated on a 0 to 2-point scale according to pathological concordance and the criteria of the *ICD-10* (*International Statistical Classification of Diseases, Tenth Revision*) [17]. Two points were assigned for diagnoses fully consistent with the reference standard, whereas 1 point was assigned for identification of the correct disease category with minor discrepancies in diagnostic specificity or terminology (eg, correct classification as pulpal disease with an imprecise subtype). No points were assigned for a complete mismatch (Multimedia Appendix 2). Because the doctor prompts requested *ICD-10*–based diagnoses while the reference standard used American Association of Endodontists terminology, differences in terminology between the 2 systems were handled within the existing assessment criteria, where responses identifying the correct disease category with a minor terminological discrepancy were scored as 1, and those fully consistent with the reference diagnosis were scored as 2. For screening performance analyses, the ordinal scores were binarized, with scores of 1 and 2 classified as positive and a score of 0 classified as negative. Diagnostic metrics were calculated using a one-versus-other scheme, in which pulpal cases (58/100) served as positives and periapical cases (42/100) as negatives for pulpal disease metrics, with the reverse applied for periapical disease metrics. For the human evaluator groups, responses from the 3 evaluators within each group were combined before calculating diagnostic metrics, resulting in an effective observation count of 174 per group for pulpal disease and 126 for periapical disease; 95% CIs reflect this aggregated count. The corresponding 2×2 contingency cell counts (true positive, false negative, false positive, and true negative) for all groups are provided in Multimedia Appendix 3. The clinical validity and relevance of LLM-generated treatment plans were assessed using a 5-point Likert scale [18,19]. Higher scores reflected greater clinical appropriateness and concordance with evidence-based practice. Evaluators independently rated the realism and evidence-based nature of each plan within a real-world clinical context; they were blinded to the LLM outputs (Multimedia Appendix 4).

Statistical Analysis

To analyze differences between groups, the Kruskal-Wallis test was used, with post hoc pairwise comparisons conducted using the Dunn test with Bonferroni correction. Interrater agreement among the 4 evaluator groups was assessed using the intraclass correlation coefficient (ICC). Screening sensitivity, specificity, positive predictive value, negative predictive value, accuracy, and 95% CIs of the LLMs and clinicians were analyzed and compared for each disease. Diagnostic metrics and corresponding 95% CIs were calculated using the MedCalc Diagnostic Test Evaluation Calculator [20]. All statistical analyses were performed using SPSS (version 27, IBM Corp). Statistical significance was set at $P<.05$.

Results

Text-Based Screening Performance by Prompt Type

The case selection and diagnostic classification process is shown in Figure 1. The text-based screening performance of LLMs, measured on a 0 to 2-point scale, was compared across prompt types (doctor vs patient) and languages (Korean vs English; Figure 2). ChatGPT achieved the highest concordance on Korean-doctor prompts (mean 0.98, SD 0.82), with a significant within-model difference between languages ($P<.001$). Conversely, Clova X recorded the lowest agreement on English-patient prompts (mean 0.23, SD 0.63), with a significant within-model difference ($P=.004$).

Evaluation of Treatment Plan Relevance and Validity

Across all evaluator groups, ChatGPT demonstrated higher mean ranks for treatment plan validity than other LLMs, whereas Clova X showed the lowest mean ranks (Figures 3 and 4). Statistically significant differences in both outcomes were observed among LLMs within each evaluator group.

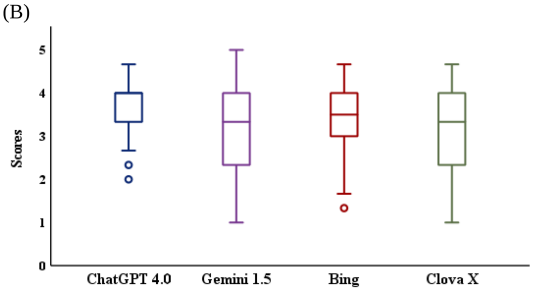

Figure 3. Relevance scores across large language models (LLMs) as evaluated by 4 human evaluator groups: (A) Advanced General Dentistry (AGD) specialists, (B) AGD residents, (C) endodontic residents, and (D) senior students. Box plots show median (IQR) and outliers of relevance scores on a 5-point Likert scale. Relevance reflects how directly LLM responses addressed the clinical questions posed in each prompt.

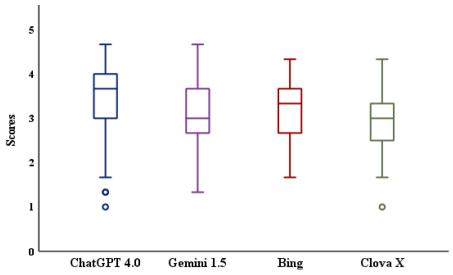
(A)



Group	N	Mean rank	$\chi^2(df)$	*P*
ChatGPT 4.0	100	234.79	13.96 (3)	.003

Comparison of Symptom-Based Assessment Scores

Symptom-based assessment scores on the 0 to 2-point scale were compared between LLMs and human evaluators using the Kruskal-Wallis test. AGD specialists achieved the highest mean rank (mean 1.10, SD 0.71; 466.81), followed by endodontic residents (mean 0.97, SD 0.79; 425.49), ChatGPT (mean 0.98, SD 0.82; 425.21), and AGD residents (mean 0.94, SD 0.78; 416.07). Senior dental students showed intermediate performance (mean 0.90, SD 0.71; 410.20), whereas Bing (mean 0.77, SD 0.90; 361.55), Gemini (mean 0.74, SD 0.79; 357.28), and Clova X (mean 0.68, SD 0.74; 341.40) demonstrated lower mean ranks (Table 2). There was a significant difference in symptom-based assessment scores among the groups (χ^2_7=25.75; *P*<.001).

Table . Comparison of symptom-based assessment scores across large language models and human evaluator groups using the Kruskal-Wallis test (N=100)[a].

Group	Mean (SD)	Mean rank
AGD[b] specialist	1.10 (0.71)	466.81[c]
Endodontic residents	0.97 (0.79)	425.49[d]
ChatGPT 4.0	0.98 (0.82)	425.21[d]
AGD residents	0.94 (0.78)	416.07[d]
Senior student	0.90 (0.71)	410.20[d]
Bing	0.77 (0.90)	361.55
Gemini 1.5	0.74 (0.79)	357.28
Clova X	0.68 (0.74)	341.40

[a]χ^2_7=25.75; *P*<.001.

[b]AGD: Advanced General Dentistry.

[c]Mean ranks of AGD specialist are significantly different from Bing, Gemini 1.5, and Clova X.

[d]Mean ranks of endodontic residents, ChatGPT 4.0, AGD residents, and senior students are not significantly different from either AGD specialists or Bing, Gemini 1.5, and Clova X based on Dunn post hoc test with Bonferroni correction (*P*>.05).

Interrater agreement among the 4 evaluator groups, measured by the ICC, was lowest for AGD specialists (ICC 0.579, 95% CI 0.413 - 0.704; *P*<.001). Moderate agreement was observed for AGD residents (ICC 0.774, 95% CI 0.685 - 0.841; *P*<.001), endodontic residents (ICC 0.793, 95% CI 0.711 - 0.854; *P*<.001), and senior dental students (ICC 0.750, 95% CI 0.651 - 0.824; *P*<.001; Table 3). Post hoc pairwise comparisons using the Dunn test with Bonferroni correction showed that AGD specialists scored significantly higher than Clova X, Gemini, and Bing (Multimedia Appendix 5).

Table . Interrater reliability of diagnostic evaluations across evaluator groups.

Evaluator group	ICC[a], average measure (95% CI)	*F* value (*df*)	*P* value
AGD[b] specialists	0.579 (0.413 - 0.704)	2.377 (99, 198)	<.001
AGD residents	0.774 (0.685 - 0.841)	4.431 (99, 198)	<.001
Endodontic residents	0.793 (0.711 - 0.854)	4.830 (99, 198)	<.001
Senior dental students	0.750 (0.651 - 0.824)	3.995 (99, 198)	<.001

[a]ICC: intraclass correlation coefficient.

Comparative Diagnostic Metrics

Tables 4 and 5 present the diagnostic metrics for pulpal and periapical diseases, respectively. AGD specialists showed the highest diagnostic accuracy among all groups for both pulpal (0.70) and periapical diseases (0.65). Among the LLMs, ChatGPT demonstrated the highest accuracy for pulpal disease (0.65, 95% CI 0.55 - 0.74), whereas Clova X showed the lowest accuracy (0.47, 95% CI 0.37 - 0.57). For periapical disease, the overall diagnostic performance of LLMs was lower, with ChatGPT achieving an accuracy of 0.57 (95% CI 0.47 - 0.69).

[b]AGD: Advanced General Dentistry.

[c]PPV: positive predictive value.

[d]NPV: negative predictive value.

Distribution of Diagnostic Scores

Distribution analysis of diagnostic scores demonstrated that AGD specialists had the highest proportion of correct diagnoses at 48% (48/100), followed by endodontic residents at 43% (43/100), AGD residents at 41% (41/100), and senior dental students at 33% (33/100; Figure 5). Among the LLMs, ChatGPT produced the highest proportion of correct responses at 32% (32/100), surpassing that of senior dental students but remaining lower than that of specialists and residents. Regarding incorrect responses, Bing had the highest proportion at 54% (54/100), followed by Clova X at 48% (48/100). An exploratory subgroup analysis comparing patients aged younger than 60 years and 60 years or older demonstrated no significant difference in diagnostic accuracy between the groups (P=.051).

XSL•FO
RenderX

Figure 5. Distribution of diagnostic accuracy scores among large language models (LLMs) and human evaluator groups. Stacked bar graphs show the proportion (%) of diagnostic accuracy scores (0="incorrect," 1="partially correct," and 2="correct") for 4 LLMs and human evaluator groups. Among all groups, Advanced General Dentistry (AGD) specialists demonstrated the highest proportion of correct responses, followed by endodontic residents and AGD residents. ChatGPT 4.0 outperformed Gemini, Bing, and Clova X in diagnostic accuracy.

Discussion

Principal Findings

This study compared the performance of LLM-generated outputs with that of clinicians and senior dental students, evaluating the clinical validity and relevance of LLM-derived treatment plans. AGD specialists achieved the highest symptom-based screening accuracy and sensitivity. Among the LLMs, ChatGPT consistently showed the highest performance, with screening accuracy and diagnostic metrics comparable to those of AGD and endodontic residents. However, its relatively low sensitivity for pulpal disease diagnosis represents an important safety limitation, indicating that LLM-generated outputs should not be used for independent definitive diagnosis without expert supervision.

The 0 to 2 points scoring system enabled standardized comparison across LLMs and human evaluators. However, partially correct responses included a broad range of diagnostic differences, from minor imprecision to clinically meaningful misclassification. Therefore, the findings should be interpreted with caution, as this simplified scoring may not fully reflect the clinical impact of specific diagnostic errors. Although AGD specialists demonstrated high screening accuracy, their interrater agreement was relatively low, likely reflecting variability in expert interpretation of ambiguous or incomplete clinical information. This variability does not indicate poorer diagnostic ability but highlights the complexity of decision-making under limited clinical information [21,22]. LLMs did not achieve specialist-level performance; however, ChatGPT showed potential as a supportive tool for less experienced clinicians. Post hoc pairwise analysis further showed that AGD specialists scored significantly higher than Clova X, Gemini, and Bing. In contrast, no statistically significant difference was detected between ChatGPT and any of the human evaluator groups. These results are consistent with our overall finding that ChatGPT performed relatively better than the other LLMs evaluated, while overall performance remained modest. Nonetheless, hallucinations were observed, including fabricated clinical details and treatment plans inconsistent with established guidelines (Multimedia Appendix 6).

Comparisons With Prior Work

Although recent studies have investigated the use of LLMs in conservative dentistry, most have focused on educational settings, patient inquiries, or multiple-choice examinations [12-16] (Table 6). In contrast, this study used real-world data under multiple prompting scenarios. Zero-shot prompts and personas were applied to reflect practical clinical use, where optimized prompting cannot be assumed [23].

XSL•FO
RenderX

Table . Comparison of this study with prior large language model (LLM) studies in dentistry.

Study	Data source	Clinical task	Evaluators	Outcomes assessed
Abdulrab et al [12], 2025	Exam-style questions	Knowledge assessment	Students	Accuracy
Aljamani et al [15], 2025	Patient inquiries	Patient information support	None	Response quality
Büker and Mercan [13], 2025	Patient inquiries	Patient information quality assessment	None	Readability, accuracy, and quality
Jalali et al [14], 2025	Board-style exam questions	Board exam performance	None	Accuracy
Arılı Öztürk et al [16], 2025	Endodontic exam-style questions	Knowledge assessment in endodontics	None	Answer accuracy
This study	Text-based clinical records (image-free)	Symptom-based diagnostic screening and treatment planning	Specialists, residents, and students	Diagnostic accuracy, treatment plan validity, and inter-rater reliability

Outputs varied substantially by language and prompt type, underscoring the importance of prompt design in clinical contexts [24,25]. Consistent with prior medical studies, role-specific prompts improved clinical relevance, whereas vague prompts reduced consistency [26,27]. The student group rated the LLM-generated treatment plans more positively than experienced clinicians, likely reflecting differences in error recognition ability based on clinical experience. Tangadulrat et al [28] reported similar findings in medicine, where medical students tended to trust ChatGPT's results more than physicians did. These results suggest that clinical experience is critical for evaluating AI-generated outputs. As summarized in Table 6, this study differs from prior work.

Recent advances in multimodal LLMs, such as GPT-4V and Gemini Pro Vision, demonstrate improved diagnostic performance when radiographic images are incorporated into diagnostic assessments [29,30]. In this study, radiographic images were not directly reviewed, although summarized radiographic findings were available in clinical records. Given the indispensable role of radiographic examination in endodontic diagnosis, limited access to image interpretation may partly explain the lower sensitivity observed for LLMs compared with specialists. Incorporating radiographic image analysis into future dental AI systems may improve diagnostic performance in clinical practice.

Previous studies in conservative dentistry have mainly examined the use of LLMs in educational contexts and multiple-choice examinations. Previous studies by Arılı Öztürk et al [16], Abdulrab et al [12], and Künzle and Paris [31] consistently demonstrated that more advanced models, such as ChatGPT-4 and ChatGPT-4o, showed higher accuracy and stability than earlier versions or other models. Durmazpinar and Ekmekci [32] found that ChatGPT-4o outperformed students in multiple-choice questions. In addition, Nguyen et al [33] observed that ChatGPT performed well in text-based questions but showed lower accuracy in image-based questions.

Similar findings have been reported in studies addressing patients' clinical inquiries. Aljamani et al [15], Baris and Baris [34], and Büker and Mercan [13] showed that several models achieved high accuracy and quality in answering patients' questions related to endodontic treatment. However, these studies consistently highlighted important limitations, including higher reading levels, variability in reliability, and the potential for misinterpretation without expert supervision.

Limitations

This study had several limitations. First, a zero-shot prompting design was used, and follow-up questions were intentionally excluded, which limited the evaluation of iterative clinical reasoning [35]. Consequently, this study could not assess whether multiturn prompting, which allows iterative clarification and the inclusion of additional information, would alter diagnostic accuracy or reasoning performance.

Second, although the English prompts were reviewed by a domain expert, translation nuances may have influenced model interpretation. Notably, *per* (+) was used instead of the standard English shorthand for percussion sensitivity, and *conservative dentist* was used instead of the internationally recognized term *endodontist*. The study was also limited to English and Korean prompts, which may have restricted the generalizability of the findings to other linguistic or cultural contexts.

Third, the analysis relied on clinical record information. Radiographic images were not directly reviewed by LLMs or human evaluators, although summarized radiographic interpretations were available in routine documentation. Diagnostic performance may, therefore, have been underestimated. Accordingly, direct comparability between the reference standard and test conditions was limited. Therefore, it remains unclear whether diagnostic failures reflect limited reasoning capability or simply reflect missing diagnostic data. A single specialist determined the reference diagnosis, and pre-2017 cases were not reclassified under updated criteria. In addition, no formal sample size calculation was performed, as the sample size was determined by the available eligible cases. This may have limited statistical power for some comparisons. Furthermore, 139 of 312 eligible cases were excluded due to multiple concurrent symptoms, which may have resulted in a less clinically diverse set of included cases. Therefore, the diagnostic performance of both LLMs and human evaluators may have been higher than that observed in routine clinical practice, where patients frequently present with overlapping symptoms.

Fourth, doctor and patient prompts differed in both persona and the amount of clinical information provided, as doctor prompts included objective examination findings and radiographic

XSL•FO
RenderX

descriptors, while patient prompts relied solely on subjective symptoms. Therefore, it remains unclear whether the observed performance differences were attributable to persona framing or to the difference in available clinical data. Additionally, the doctor prompts requested *ICD-10*–based diagnoses, while the reference standard used AAE terminology. Where the 2 classification systems do not correspond one-to-one in certain categories, model responses may have been more likely to receive a score of 1 rather than 2, potentially underestimating performance under doctor-prompt conditions.

Fifth, the Kruskal-Wallis test assumes independent samples; however, because all groups assessed the identical set of 100 clinical cases, this assumption is not fully satisfied. This limitation should be considered when interpreting both Table 2 and the post hoc pairwise comparisons in Multimedia Appendix 1. Additionally, the one-versus-other classification scheme assigns each case to a single disease category. It may not fully capture clinically linked dual diagnoses, potentially classifying biologically comprehensive responses as false positives. Furthermore, pooling responses across 3 evaluators within each group may constitute pseudoreplication, potentially narrowing the reported 95% CIs in Tables 4 and 5. In addition, scores of 1 and 2 were both classified as positive in the binary diagnostic performance analysis. Although this approach was intended to reflect clinically meaningful partial agreement, grouping partially correct diagnoses as positive outcomes may have inflated the reported sensitivity and accuracy metrics (Multimedia Appendix 7).

Finally, hallucination and interpretation biases were observed, but qualitative error classification was not performed. Future studies incorporating qualitative analyses and multimodal inputs are warranted for better characterization of safety risks and improved clinical applicability. Despite these limitations, this study provides a comprehensive evaluation using real-world clinical data under diverse prompting conditions.

Future Outlook

Future research should evaluate multimodal LLMs integrating text and imaging data under identical clinical conditions. In addition, advanced prompting strategies—including chain-of-thought and few-shot prompting—should be examined to enhance structured clinical reasoning and diagnostic accuracy. Approaches that constrain model outputs using established clinical guidelines or retrieval-augmented generation may help mitigate hallucinations. Moreover, interactive conversational frameworks that enable clarification of missing information may also enhance clinical reasoning and reliability. From a clinical implementation perspective, a human-in-the-loop workflow may be more appropriate than independent model use. Given the relatively high specificity but limited sensitivity observed, LLMs may be better suited for generating differential diagnosis lists rather than for definitive screening. In this workflow, clinicians review model-generated suggestions and integrate them with clinical examination and radiographic findings before making final decisions.

Conclusions

Compared to other LLMs, ChatGPT provides more stable and reliable responses in endodontic diagnosis, demonstrating potential as a supportive tool for clinicians. However, limitations such as hallucinations, low sensitivity, and variability depending on user expertise remain significant challenges to its use as an independent diagnostic aid. For safe and effective clinical application, the development of standardized prompt templates, the implementation of comprehensive user training, and continued clinical supervision will be essential.

Abstract

Background: Foot orthosis prescription is a complex clinical decision-making process that involves selecting and combining multiple structural, functional, and material components based on heterogeneous biomechanical information. In routine outpatient practice, detailed biomechanical assessments are often incomplete, creating substantial variability in prescription decisions, and limiting the applicability of conventional machine learning (ML) models that assume fixed feature availability.

Objective: This study aimed to develop and evaluate a hierarchical ML-based clinical decision support framework for foot orthosis prescription that accommodates variable clinical information availability, supports multilabel prescription decisions, and incorporates safety-oriented recommendation strategies for routine outpatient practice.

Methods: A retrospective observational study was conducted using 6462 visit-level clinical encounters collected from a single institution between 2015 and 2020. Orthotic prescription was formulated as a multilabel prediction task involving 15 prescription components. A hierarchical modeling framework was implemented, consisting of a basic decision level using routinely available demographic and alignment variables, and an advanced level incorporating subtalar joint inversion and eversion range of motion measurements when available. Tree-based gradient boosting models were evaluated using 5-fold stratified grouped cross-validation. Model performance was assessed using component-wise area under the receiver operating characteristic curve (AUROC), area under the precision-recall curve (AUPRC), positive predictive value (PPV), macro-averaged Hamming loss, Top-K hit, and coverage rates based on probabilities calibrated using internal grouped Platt scaling, and component-specific safety-oriented threshold calibration.

Results: The hierarchical models demonstrated consistent predictive performance across both decision levels, although precision-recall–based analyses indicated greater variability for low-prevalence prescription components. The Level 4 and Level 8 models achieved mean component-wise AUROC values of 0.792 and 0.816, respectively, with macro-averaged Hamming loss of 0.113 and 0.111. Using component-specific Platt scaling within the 5-fold stratified grouped cross-validation framework, Top-K analysis demonstrated a Top-1 hit rate of 86.7% and a Top-3 hit rate of 97.4%. When all prescribed components were considered, Top-K coverage reached 71.7% at Top-3 and increased to 97.0% at Top-8. Safety-oriented threshold calibration was performed separately for each prescription component, selecting the threshold that achieved the highest sensitivity while maintaining a specificity of at least 95%. Under this component-specific calibration strategy, the aggregated operating profile achieved a microaveraged specificity of 96.00% with a microaveraged sensitivity of 28.71%. Age-stratified analyses revealed distinct feature-importance patterns between pediatric and adult populations.

Conclusions: The proposed hierarchical clinical decision support framework supported multicomponent foot orthosis prescription under variable information availability commonly encountered in outpatient practice. By generating ranked component-wise recommendations and high-confidence threshold-calibrated outputs, the framework may support clinician decision-making in routine orthotic practice. Further prospective validation will be required to determine its clinical utility.

KEYWORDS

clinical decision support system; foot orthosis prescription; hierarchical machine learning; multilabel classification; gradient boosting; outpatient clinical data

Introduction

Background and Clinical Motivation

Foot deformities such as pes planus, pes cavus, and in-toeing gait are prevalent across the lifespan and are frequently associated with pain, fatigue, and secondary musculoskeletal complications [1-4]. Customized foot orthoses are widely prescribed as a conservative intervention to support lower-limb alignment and modulate biomechanical loading during gait [5-8]. Through modulation of subtalar joint (STJ) mechanics and redistribution of ground reaction forces, orthoses can reduce excessive pronation, alleviate tendon strain, and mitigate the progression of conditions such as plantar fasciitis and knee osteoarthritis [5,7]. In younger populations, orthotic interventions are also commonly considered to support age-appropriate gait development and functional alignment during growth, further underscoring the need for prescription strategies that account for developmental stage and evolving biomechanical demands [9].

Despite their widespread clinical use, foot orthosis prescriptions remain highly individualized and are largely dependent on clinician experience and heterogeneous biomechanical assessments. Orthotic prescription rarely involves selecting a single standardized device; instead, clinicians typically prescribe combinations of structural modifications, functional components, and material-specific base designs tailored to a patient's biomechanical profile, age, diagnosis, and functional demands [10-12]. This inherent combinatorial complexity makes orthotic prescription difficult to standardize and challenging to support using conventional rule-based or single-output decision frameworks.

In practice, the availability of detailed biomechanical measurements varies substantially in routine outpatient settings. Assessments such as joint range of motion (ROM) testing are often performed selectively based on clinical judgment, time constraints, and patient presentation. As a result, substantial interclinician variability exists in routine outpatient prescription practice, even among patients with similar clinical profiles. This complexity positions orthosis prescription as a multilabel clinical decision-making problem rather than a simple categorical classification task, highlighting the need for clinical decision support systems (CDSS) that can accommodate heterogeneous information availability and reflect routine clinical prescribing workflows [13].

Computational Approaches and Informatics Challenges

Advances in machine learning (ML) have increasingly facilitated data-driven approaches to clinical decision support across diverse medical domains. In the field of foot biomechanics, early computational studies primarily relied on linear regression models and rule-based decision trees to examine associations between anatomical measurements and foot pathologies [14,15]. However, such approaches have limited capacity to capture nonlinear and high-dimensional interactions among biomechanical variables. More recent studies have demonstrated improved performance using ensemble methods and neural network-based classifiers for tasks such as foot type classification based on plantar pressure data, footprint images, or wearable sensor signals [16-18]. Nevertheless, most existing ML-based approaches have focused on automated diagnosis or classification tasks, rather than supporting therapeutic prescription decisions that require explicit selection of treatment components.

From an informatics perspective, orthosis prescription poses additional challenges that extend beyond conventional diagnostic modeling. Prescription decisions involve the concurrent selection of multiple interdependent design elements—including structural modifications, functional components, and material properties—making the problem inherently multilabel in nature. Moreover, orthotic decision-making must operate within the constraints of real-world clinical workflows, where the availability of biomechanical measurements varies substantially across patients and visits. In contrast, most prior ML-based models have been developed using curated datasets with complete and uniformly acquired measurements under standardized protocols [19,20]. These limitations restrict the translational applicability of existing models and underscore the need for decision support frameworks that can accommodate varying levels of clinical information while preserving clinically meaningful prescription patterns.

Routine Outpatient Data Limitations and the Need for Hierarchical Decision Support

In routine outpatient clinical settings, comprehensive biomechanical assessments are often selectively performed or omitted due to time constraints, interrater variability, and institutional differences in outpatient workflows. As a result, electronic health records frequently contain selective measurement availability and partially observed biomechanical information, creating a substantial gap between idealized ML models and the conditions under which clinical decisions are actually made [20,21]. Consequently, a clinically implementable decision support system must not only achieve high predictive performance under controlled conditions but also demonstrate stable, interpretable behavior across varying levels of information availability encountered at the point of care.

To address these challenges, decision support architectures must explicitly account for the hierarchical nature of clinical data acquisition. Fundamental alignment measures, such as resting calcaneal stance position (RCSP), are routinely documented and serve as important considerations in orthotic design decisions [22]. In contrast, more detailed biomechanical assessments, including STJ inversion and eversion ROM, are typically obtained only in selected clinical contexts where additional evaluation is warranted [23,24]. Clinically, RCSP functions as a mandatory baseline assessment during initial

XSL•FO
RenderX

evaluation, whereas STJ ROM represents higher-resolution biomechanical information acquired selectively to refine prescription decisions. This naturally creates a hierarchical structure of information availability in routine practice. Modeling strategies that assume uniform access to a fixed set of clinical variables are therefore poorly aligned with real-world workflows. Instead, approaches capable of adapting to multiple tiers of information availability are required to ensure the practical applicability and scalability of CDSS [25]. Collectively, these considerations motivated the development of the hierarchical modeling framework evaluated in the present study.

Prior Work and Study Rationale

Existing studies have demonstrated the feasibility of computational approaches for supporting orthotic prescription decisions through component-level prediction models [26]. However, most of these studies were developed using relatively small and homogeneous datasets and focused on predicting a single prescription outcome. This simplified formulation does not adequately reflect real-world orthotic design, where multiple components are prescribed simultaneously to address complex biomechanical needs.

Large-scale retrospective analyses of custom foot orthoses have further shown that clinicians commonly prescribe diverse combinations of structural, functional, and material-specific components, with substantial variability associated with individual experience and institutional practice patterns [27]. Despite this complexity, few studies have explicitly formulated orthotic prescription as a multilabel prediction problem. Moreover, the performance of such models under the incomplete and heterogeneous data conditions encountered in routine outpatient practice remains largely unexplored. In particular, most existing models implicitly assume uniform availability of biomechanical measurements or rely on imputation strategies that do not reflect how data are selectively acquired in real-world clinical workflows. Consequently, their applicability is limited when advanced biomechanical assessments are unavailable, which is common in routine outpatient settings. These limitations highlight a critical gap between existing computational approaches and the realities of clinical orthosis prescription.

From a clinical safety perspective, omission of a necessary orthotic component may result in inadequate biomechanical correction and persistent or worsening symptoms [28,29]. Accordingly, decision support systems for orthosis prescription should emphasize high reliability and flexible recommendation strategies that assist rather than replace clinical judgment. Providing ranked recommendation shortlists is particularly important in multicomponent prescription tasks, where clinicians must evaluate multiple potentially relevant orthotic elements while balancing completeness and over-recommendation. In addition, decision support systems should communicate recommendations in a manner that supports clinician oversight and minimizes the risk of unnecessary component suggestions. These considerations highlight the need for clinically deployable decision support frameworks that can learn prescription patterns from routine outpatient data while supporting safe and reliable decision-making in everyday practice.

Objective of This Study

In this study, we propose a hierarchical ML-based CDSS for foot orthosis prescription using a large-scale single-institution outpatient clinical dataset comprising 6462 visit-level clinical encounters collected during routine outpatient care. The system is explicitly designed to reflect variability in clinical information availability by adopting a hierarchical structure, ranging from a basic decision level based on routinely assessed alignment variables to an advanced level incorporating detailed STJ inversion and eversion range of motion measurements. A tree-based gradient boosting framework was employed to accommodate heterogeneous feature distributions and selective measurement availability commonly encountered in routine outpatient data.

The objectives of this study were threefold: (1) to evaluate the performance of hierarchical ML models in predicting 15 orthotic prescription components within a multilabel decision-making framework; (2) to investigate age-dependent differences in the relative importance of clinical variables guiding orthotic prescription; and (3) to evaluate the clinical utility of the proposed system under routine outpatient data conditions using calibrated Top-K analysis and safety-oriented threshold calibration.

Methods

Study Design, Setting, and Data Source

We conducted a retrospective observational study using routine outpatient clinical data collected during foot orthosis prescription at a single clinical institution. The dataset was derived from patients evaluated at a specialized podiatric clinic within the Department of Rehabilitation Medicine at Chungnam National University Hospital (Daejeon, Republic of Korea) between 2015 and 2020. All records originated from usual-care clinical documentation rather than from a controlled research protocol.

The final dataset comprised 6462 visit-level encounters from pediatric and adult patients presenting with foot deformities and lower-extremity alignment abnormalities such as pes planus, pes cavus, and in-toeing gait. Because examinations were performed as part of routine clinical workflows, the availability of detailed biomechanical measurements varied across visits. Demographic variables and core alignment measures were routinely documented, whereas STJ inversion and eversion ROM were obtained selectively based on clinical judgment, time constraints, and patient presentation. This workflow-driven variability in feature availability motivated the hierarchical design of the decision support framework. Each encounter was modeled as an independent decision point, reflecting routine outpatient orthosis prescription practice in which prescription decisions are based on the contemporaneous clinical presentation and available measurements during a single visit. Repeated encounters were identified using combined name, sex, and age information, and only 100 of 6355 patients (1.57%) contributed more than one encounter. Because some individuals contributed multiple encounters, patient-level grouped cross-validation was used during model development and evaluation to ensure that all encounters from the same patient were assigned exclusively to either the training or validation folds. All preprocessing,

XSL•FO
RenderX

feature construction, hyperparameter optimization, model training, and probability calibration steps were confined within the training folds to minimize optimistic bias.

Ethical Considerations

The study protocol was reviewed by the Institutional Review Board of Jeonbuk National University and deemed exempt because it involved secondary analysis of fully deidentified retrospective data (JBNU 2021-08-011). Informed consent was waived by the institutional review board, and all data were anonymized prior to analysis. No identifiable participant images were included in the manuscript or supplementary materials. The study was conducted in accordance with the Declaration of Helsinki and relevant ethical guidelines.

Clinical Variables and Feature Sets

Predictor variables were defined to reflect biomechanical measures commonly used in routine orthosis prescription and were selected based on (1) clinical relevance to orthotic design decisions and (2) feasibility within standard outpatient workflows. Age was treated as a continuous variable, and sex was encoded as a binary categorical variable.

Primary diagnostic categories (eg, pes planus, pes cavus, and in-toeing gait) were not included as predictor variables because the modeling framework was designed to rely on objective biomechanical and alignment features that more directly reflect the functional characteristics relevant to orthotic prescription.

RCSP was selected as the core alignment variable because of its clinical prominence in orthotic decision-making. Bilateral RCSP values (left and right) were recorded in degrees during relaxed weight-bearing examinations and were treated as continuous predictors to preserve laterality. For advanced biomechanical characterization, bilateral STJ inversion and eversion range of motion, measured in degrees, were incorporated when available.

To support robust learning while preserving clinical interpretability, two derived RCSP features were computed within each encounter: RCSP sum (left+right), representing overall hindfoot alignment magnitude, and RCSP difference (absolute left–right difference), representing alignment asymmetry.

Two feature sets were defined a priori based on measurement availability. The Level 4 feature set included sex, age, bilateral RCSP measurements, RCSP sum, and RCSP difference. The Level 8 feature set comprised all Level 4 variables with the addition of bilateral STJ inversion and eversion ROM.

Orthosis Prescription Labels and Multilabel Formulation

Orthosis prescriptions were represented as 15 binary component labels (P1-P15), reflecting routine clinical practice in which multiple orthotic elements are frequently prescribed in combination. Each label was encoded as 1 (prescribed) or 0 (not prescribed). Labels were additionally grouped into clinically meaningful categories (eg, structural modification, functional modification, base material, cushioning, and structural support) to facilitate interpretation, while preserving component-level granularity for modeling.

Because orthotic prescriptions frequently involve combinations of multiple components within a single encounter, prescription was formulated as a multilabel prediction problem. For model development and evaluation, each prescription component was modeled as an independent binary classification task. Overall multilabel performance and clinical utility were assessed by aggregating component-level predictions using appropriate multilabel metrics. The 15 prescription components and their associated clinical categories are summarized in Table 1.

XSL•FO
RenderX

Table . Orthotic prescription components and their clinical categories used as multilabel outcomes.

Label	Orthotic component name	Clinical category
P1	Forefoot extension	Structural modification
P2	Poron base material	Base material
P3	Multidensity foam	Base material
P4	Cork-based foundation	Base material
P5	Polyethylene base material	Base material
P6	Metatarsal dome	Pressure redistribution
P7	Heel Poron cushion	Pressure redistribution
P8	Medial inverted balance posting	Structural support
P9	Medial forefoot flange	Structural modification
P10	Lateral flange	Structural modification
P11	Gait plate	Functional modification
P12	Reverse gait plate	Functional modification
P13	UCBL[a]	Structural support
P14	Navicular support	Structural support
P15	Kinetic wedge	Functional modification

Missing Data Handling and Hierarchical Evaluation Strategy

Missingness in biomechanical variables reflected selective measurement practices in routine clinical care rather than random acquisition failures. In particular, STJ inversion and eversion ROM were not uniformly recorded across encounters because these assessments were performed selectively according to clinical judgment. An overview of the hierarchical clinical decision support framework is illustrated in Figure 1.

XSL•FO
RenderX

Figure 1. Overview of the proposed hierarchical clinical decision support framework for foot orthosis prescription. RCSP: resting calcaneal stance position; ROM: range of motion; STJ: subtalar joint.

A hierarchical evaluation strategy was adopted based on measurement availability. Encounters with available STJ inversion and eversion ROM were evaluated using the Level 8 model, whereas encounters without these measurements were evaluated using the Level 4 model. As a result, Level 8 performance reflects a complete-case subset analysis restricted to encounters with available STJ ROM measurements. For direct comparison between the two hierarchical levels, both Level 4

XSL•FO
RenderX

and Level 8 were additionally evaluated using the same complete-case subset.

Within each predefined feature set, remaining missing values were retained as not a number (NaN) and handled using the native missing-value processing capability of the tree-based algorithms used in this study. This approach avoids ambiguity between missing observations and valid biomechanical measurements.

Model Development and Implementation

To benchmark model performance, several tree-based and ensemble learning algorithms were comparatively evaluated, including HistGradientBoosting (HGB), Extreme Gradient Boosting (XGBoost), Light Gradient Boosting Machine (LightGBM), and a soft-voting ensemble combining the three models. All comparator models were trained using the same feature sets, cross-validation framework, and component-wise binary classification strategy to ensure fair comparison across hierarchical decision levels. Comparative performance was assessed using mean component-wise area under the receiver operating characteristic curve (AUROC) and macro-averaged Hamming loss. HGB was selected as the final architecture because it consistently achieved strong performance across hierarchical levels while naturally accommodating the heterogeneous and partially observed characteristics of the clinical dataset.

For each prescription component (P1—P15), a separate binary classifier was trained within each hierarchical level using the corresponding feature set. Sex was encoded as a binary categorical variable, and continuous predictors were retained in their original scales without normalization, consistent with the properties of tree-based learning methods. No explicit class weighting was applied during model training.

Hyperparameters for each prescription component and hierarchical level were optimized using Optuna with 5-fold stratified grouped cross-validation. Candidate parameter combinations were evaluated according to the mean out-of-fold AUROC obtained from the grouped cross-validation folds, and the configuration achieving the highest mean AUROC was selected as the final component-specific parameter set. Optimization was conducted over predefined search spaces for max_iter, max_depth, learning_rate, l2_regularization, max_bins, and min_samples_leaf, with parameter-specific sampling distributions (Table S3 in Multimedia Appendix 1). The resulting optimized parameter settings are reported in Table S4 in Multimedia Appendix 1. Patient-level grouping was maintained throughout hyperparameter optimization, and a fixed random seed (42) was applied to ensure reproducibility.

Evaluation Metrics and Cross-Validation

Model discrimination was evaluated using AUROC, computed separately for each prescription component. Performance across components was summarized using the mean component-wise AUROC. In addition, the area under the precision-recall curve (AUPRC) and positive predictive value (PPV) were calculated for each prescription component. PPV was calculated using binary predictions generated with the default probability threshold of 0.5 and was included to provide a prevalence-sensitive measure of positive prediction performance.

Evaluation was conducted using 5-fold stratified grouped cross-validation. Patient identifiers were used as grouping variables to ensure that all encounters from the same patient were assigned exclusively to either the training or validation folds, with class distributions preserved within each fold. All preprocessing, feature construction, hyperparameter application, model training, and probability calibration were performed exclusively within the training folds and subsequently applied to the corresponding validation folds to prevent information leakage.

To quantify overall multilabel misclassification, component-wise Hamming loss was calculated using binary predictions generated with the default probability threshold of 0.5 and then macro-averaged across the 15 prescription components. In addition, clinical utility was evaluated using Top-K analysis and safety-oriented threshold calibration.

For safety-oriented threshold calibration, candidate probability thresholds from 0.01 to 0.99 were evaluated separately for each prescription component using out-of-fold predictions. For each classifier, the operating threshold was selected as the value achieving the highest sensitivity while maintaining a specificity of at least 95%.

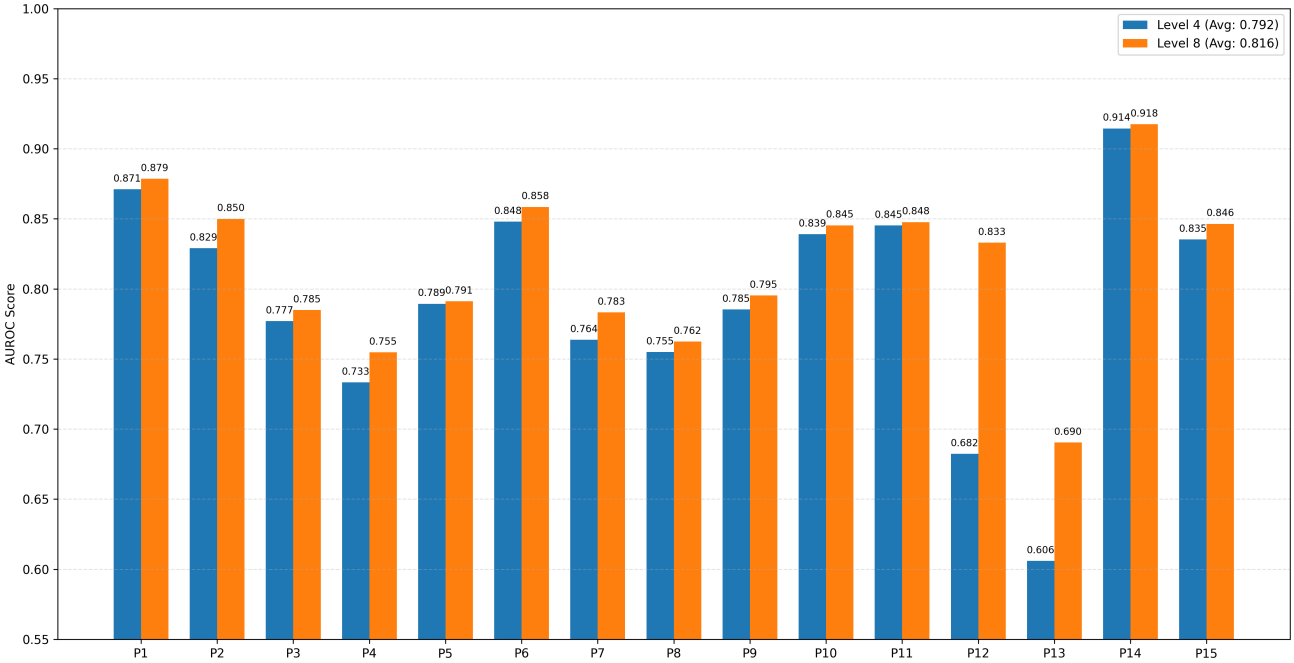
For Top-K analysis, calibrated out-of-fold probabilities were generated within an outer 5-fold stratified grouped cross-validation framework. Within each outer training fold, each component-specific HGB classifier was calibrated using Platt scaling with an additional internal stratified grouped cross-validation procedure. Patient-level grouping was maintained in both the outer and internal cross-validation procedures to ensure that encounters from the same patient were not shared across model-training, calibration, and outer validation subsets. The calibrated model was then applied to the corresponding outer validation fold, and the resulting probabilities were aggregated across folds to obtain complete out-of-fold predictions for all encounters. For each encounter, the calibrated predicted probabilities of the 15 prescription components were ranked in descending order to generate component-level recommendations. Top-K hit rate was defined as the proportion of encounters in which at least one clinician-prescribed component was included among the Top-K recommendations. Top-K coverage was defined as the mean proportion of clinician-prescribed components captured within the Top-K recommendations for each encounter, accounting for encounters with multiple prescribed components. 95% CIs for Top-K metrics were estimated using 1000 bootstrap resamples.

To characterize potential selection bias, baseline characteristics of the full cohort and the Level 8 complete-case subset were compared using independent *t* tests for continuous variables and chi-square tests for categorical variables. A 2-sided $P<.05$ was considered statistically significant.

Feature Importance Analysis

Feature importance was assessed using permutation importance analysis. For each predictor, values were randomly permuted and the resulting change in model performance was calculated

XSL•FO
RenderX



relative to the unpermuted model. Permutation was repeated 5 times, and mean importance values were used for visualization. Positive values indicate that permutation reduced model performance, whereas negative values indicate negligible or unstable predictive contribution and should not be interpreted as evidence of inverse association. Age-stratified feature importance analysis was performed within the Level 8 complete-case subset (n=3717).

Results

Overall Performance of Hierarchical Models (AUROC and Hamming Loss)

Based on model comparison, the Optuna-tuned HGB model was selected for subsequent analyses. To enable a direct comparison between hierarchical levels, both models were evaluated using the same complete-case subset (n=3717). As illustrated in Figure 2, the mean component-wise AUROC increased from 0.792 to 0.816, while the macro-averaged Hamming loss decreased from 0.113 to 0.111. These results indicate that the improved performance of the Level 8 model was associated with the additional STJ inversion and eversion ROM measurements rather than differences in cohort composition.

Figure 2. Component-wise AUROC (area under the receiver operating characteristic curve) comparison between the Level 4 and Level 8 hierarchical gradient boosting–based models evaluated on the same complete-case subsets (n=3717).

Baseline characteristics of the Level 8 complete-case subset compared with the full cohort are provided in Table S2 in Multimedia Appendix 1. The Level 8 subset differed from the full cohort in several demographic, alignment, and prescription characteristics, suggesting that advanced biomechanical measurements were obtained in a clinically selective subgroup.

As summarized in Table 2, component-wise analysis revealed heterogeneous predictive performance across the 15 prescription labels. Structural elements, such as navicular support (P14; AUROC=0.918) and forefoot extension (P1; AUROC=0.879), demonstrated robust discriminative ability in the Level 8 model. Performance improvements were observed for most prescription components following the inclusion of STJ inversion and eversion ROM measurements, whereas gains were limited or absent for a small number of components, particularly those with very low prevalence.

XSL•FO
RenderX

Table . Baseline prevalence and component-wise performance (AUROC[a], AUPRC[b], and PPV[c]) of the Level 4 and Level 8 hierarchical models evaluated using the same complete-case subset (n=3717), together with macro-averaged Hamming loss[d].

Label	Component	N (%)	Level 4, mean (SD)			Level 8, mean (SD)		
			AUROC	AUPRC	PPV	AUROC	AUPRC	PPV
P1	Forefoot extension	3248 (87.4)	0.871 (0.023)	0.972 (0.009)	0.899 (0.015)	0.879 (0.021)	0.974 (0.010)	0.903 (0.014)

[a]AUROC: area under the receiver operating characteristic curve.

[b]AUPRC: area under the precision-recall curve.

[c]PPV: positive predictive value.

[d]PPV was calculated using binary predictions generated with the default probability threshold of 0.5. Values are presented as mean (SD), where SD represents variability across the 5 grouped cross-validation folds. For low-prevalence components, SD values may be large relative to the mean, and point estimates should be interpreted with caution.

[e]UCBL: University of California Biomechanics Laboratory orthosis.

[f]Not applicable.

Within the matched complete-case subset (n=3717), prescription prevalence varied substantially across components, ranging from 12/3717 (0.3%) for P12 to 3248/3717 (87.4%) for P1. To further evaluate performance under class imbalance, AUPRC

XSL•FO
RenderX

and PPV were additionally assessed. Mean component-wise AUPRC increased slightly from 0.414 for the Level 4 model to 0.424 for the Level 8 model, while mean PPV increased from 0.445 to 0.490. Despite acceptable AUROC values, several low-prevalence prescription components exhibited low AUPRC and PPV. For example, P12 achieved an AUROC of 0.833 in the Level 8 model but an AUPRC of only 0.021 and a PPV of 0.000. These findings indicate that discrimination performance should be interpreted alongside prevalence-sensitive metrics, particularly for rare prescription components. Fold-to-fold variability was also greater for several low-prevalence components, especially for PPV estimates.

To quantify overall multilabel misclassification, macro-averaged Hamming loss was calculated across the 15 prescription components. The Level 4 model yielded a macro-averaged Hamming loss of 0.113, which decreased slightly to 0.111 in the Level 8 model, indicating improved overall multilabel prediction performance following the inclusion of STJ measurements.

Model Comparison and Selection

To determine the optimal learning algorithm under a fair matched-cohort comparison, several tree-based ensemble methods were evaluated using the same complete-case subset for both hierarchical levels. Model performance was evaluated using the mean component-wise AUROC across the 15 prescription components for both hierarchical levels within the matched complete-case subset.

As summarized in Table 3, the Optuna-tuned HGB model achieved the highest mean component-wise AUROC among all evaluated algorithms (Level 4: 0.792; SD 0.078; Level 8: 0.816; SD 0.057). Compared with the default HGB model, Optuna-based hyperparameter optimization resulted in modest improvements, particularly for the Level 8 model. Consequently, the Optuna-tuned HGB model was selected for all subsequent analyses.

Table . Comparison of mean component-wise AUROC[a] across learning algorithms for the Level 4 and Level 8 hierarchical models evaluated using the same complete-case subset (n=3717)[b].

Model	Level 4	Level 8
XGBoost[c]	0.790 (0.083)	0.811 (0.064)
LightGBM[d]	0.789 (0.085)	0.808 (0.064)
HGB[e]	0.790 (0.079)	0.809 (0.058)
Soft-voting ensemble (XGBoost + LightGBM + HGB)	0.786 (0.083)	0.806 (0.065)
Optuna-tuned HGB	0.792 (0.078)	0.816 (0.057)

Age-Dependent Predictive Patterns in Orthotic Prescription

To investigate developmental differences in predictive feature importance patterns, the Level 8 complete-case subset was stratified into pediatric (age <18) and adult (age ≥18) groups. While overall predictive performance remained stable, the relative importance of clinical variables exhibited distinct, age-dependent profiles, as illustrated in Figure 3.

XSL•FO
RenderX

Figure 3. Age-stratified variable importance for orthotic prescription components. RCSP: resting calcaneal stance position; STJ: subtalar joint.

In the pediatric subgroup, prediction patterns were primarily associated with alignment-related factors, reflecting the importance of hindfoot correction during developmental stages. Age contributed meaningfully to several components (P1, P3, P7, and P11) but did not uniformly dominate decision-making, with the strongest contributions observed for P7 and P3. Hindfoot alignment measures, particularly RCSP-derived features, showed pronounced importance for alignment-related structural support components, most notably navicular support (P14), where RCSP sum exhibited the highest importance. In contrast, STJ inversion and eversion ROM exhibited generally modest importance across most pediatric components, with measurable contributions limited to select prescriptions such as forefoot extension (P1) and cushioning-related components (P4 and P7). Several low-prevalence components (P2, P5, P6, P12, P13, and P15) showed near-zero importance values across variables, suggesting limited learnable signal within the pediatric subset. Overall, alignment-related variables showed greater predictive importance than STJ mobility measures in the pediatric subgroup.

Adult orthotic prescriptions exhibited a distinct predictive pattern. Age demonstrated a dominant contribution for several prescriptions, most prominently Poron base material (P2), and also contributed meaningfully to selected cushioning and pressure-redistribution components, including the metatarsal dome (P6) and heel Poron cushioning (P7), while alignment- and mobility-related variables provided complementary predictive information across multiple prescription labels. Alignment-related measures (bilateral RCSP and RCSP-derived features) remained important across multiple prescription components. For some labels, their contributions were comparable to those of age (eg, RCSP sum for P6). STJ inversion and eversion ROM demonstrated modest, component-specific contributions rather than broad dominance, with the most visible signals appearing in selected cushioning- and foundation-related prescriptions (P4 and P7). Notably, for heel cushioning (P7), RCSP difference showed a relatively large contribution to model prediction compared with several other variables. Overall, adult prescription patterns were associated with a broader combination of age, alignment, and mobility-related variables.

Clinical Utility of Top-K Analysis and Safety-Oriented Calibration

Clinical utility was evaluated using Top-K analysis and safety-oriented threshold calibration (Figure 4 and Table 4). Unlike traditional categorical accuracy, Top-K analysis evaluates whether clinician-prescribed components are included among the model's highest-ranked recommendations and the extent to which these components are captured within a given recommendation set, reflecting a clinician-in-the-loop workflow.

XSL•FO
RenderX

Figure 4. Top-K hit rate and Top-K coverage rate for clinician-prescribed orthotic components among model-ranked recommendations.

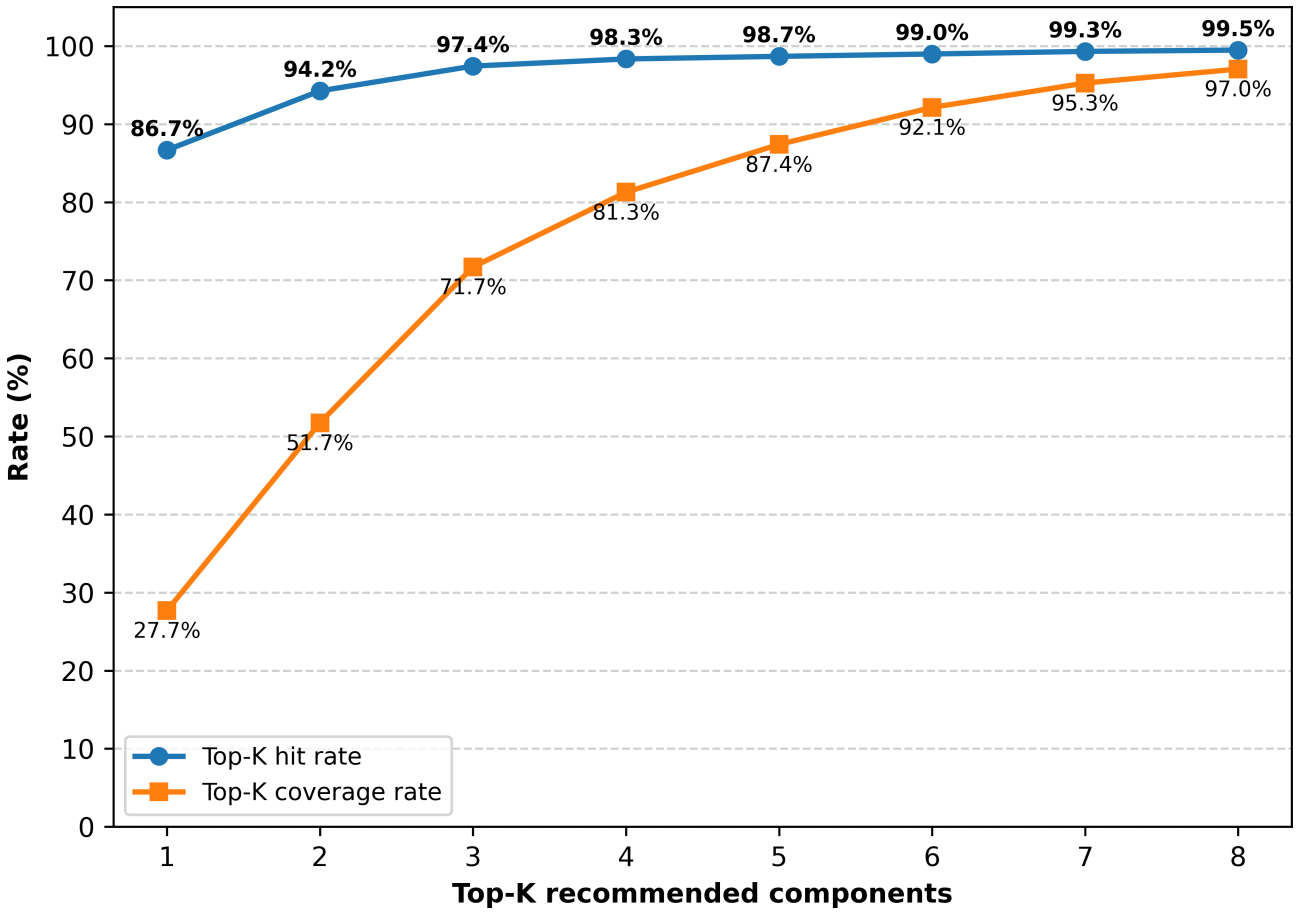

Table . Aggregated confusion matrix obtained using component-specific safety-oriented threshold calibration across the 15 orthotic prescription components[a].

Actual prescription	Predicted no	Predicted yes
No	96.00%	4.00 %
Yes	71.29 %	28.71 %

[a]Values are row-normalized percentages. For each prescription component, the operating threshold was selected to maximize sensitivity while maintaining a specificity of at least 95%. The resulting microaveraged specificity and sensitivity were 96.00% and 28.71%, respectively.

As illustrated in Figure 4, the Top-1 hit rate was 86.7% (95% CI 85.6 - 87.8) and increased to 97.4% (95% CI 96.9 - 97.9) at Top-3, indicating that a compact recommendation set frequently included at least one clinician-prescribed component. The hit rate continued to increase gradually, reaching 99.5% (95% CI 99.2 - 99.7) at Top-8. Top-K coverage increased more gradually, reaching 71.7% (95% CI 70.9 - 72.4) at Top-3 and 97.0% (95% CI 96.7 - 97.4) at Top-8 when all prescribed components were considered. Top-K rankings were generated using probability-calibrated out-of-fold predictions obtained through nested grouped cross-validation, improving comparability across prescription components while avoiding probability calibration on the same data used to train the corresponding base classifiers.

To assess clinical safety, safety-oriented threshold calibration was performed separately for each prescription component. As shown in Table 4, the aggregated confusion matrix demonstrated a microaveraged specificity of 96.00%, corresponding to a false-positive rate of 4.00%. The resulting microaveraged sensitivity of 28.71% reflects the conservative operating profile adopted for safety-oriented decision support. Component-specific thresholds, sensitivities, and specificities for all 15 prescription labels are provided in Multimedia Appendix 1 Table S1. Although several low-prevalence prescription components maintained high specificity, their sensitivities remained relatively low, indicating reduced detection of rare prescription labels under the conservative calibration strategy.

Table 5 summarizes the age-stratified performance of the component-specific safety-oriented threshold calibration strategy in the Level 8 complete-case subset (n=3717). Using the same component-specific thresholds, the pediatric subgroup (Age <18, n=2570) achieved a microaveraged sensitivity of 0.243 and a specificity of 0.967, whereas the adult subgroup (Age ≥18, n=1147) achieved a microaveraged sensitivity of 0.368 and a specificity of 0.943. Although the adult subgroup demonstrated higher sensitivity, both subgroups maintained

XSL•FO
RenderX

specificity above 94%, suggesting that the safety-oriented calibration objective was preserved across age groups.

Table . Age-stratified safety-oriented threshold calibration results for the Level 8 complete-case subset (n=3717).

Age group	Sensitivity	Specificity
Pediatric (Age <18, n=2570)	0.243	0.967
Adult (Age ≥18, n=1147)	0.368	0.943

Discussion

Principal Findings

The proposed hierarchical CDSS demonstrated stable overall performance across both decision levels, though precision-recall–based analyses revealed substantial performance heterogeneity, particularly among low-prevalence prescription components. These results highlight the importance of interpreting AUROC together with prevalence-sensitive metrics when evaluating multilabel clinical prediction models under class imbalance. Overall, the framework appeared more reliable for moderate- and high-prevalence prescription components, whereas predictive performance for rare prescription components remains limited despite acceptable AUROC values in some cases.

Notably, the model achieved a Top-1 hit rate of 86.7% and a Top-3 hit rate of 97.4%, indicating that a compact recommendation shortlist frequently included at least one clinician-prescribed component. Top-K coverage increased more gradually, reaching 71.7% at Top-3 and 97.0% at Top-8 when all prescribed components were considered. This divergence between hit rate and coverage indicates that a concise shortlist may provide efficient initial decision support, whereas capturing the full set of prescribed orthotic components in multicomponent prescriptions may require broader recommendation sets.

The proposed framework was designed to prioritize clinical safety through a conservative operating profile. Component-specific thresholds were selected to maximize sensitivity while maintaining a specificity of at least 95% for each prescription component, thereby reducing the likelihood of unnecessary component recommendations [30,31]. The resulting aggregated operating profile achieved a microaveraged specificity of 96.00%. Although this strategy resulted in a lower microaveraged sensitivity of 28.71%, this trade-off reflects the role of the CDSS as a clinician-supervised decision support tool rather than an autonomous prescription system.

The hierarchical architecture remained robust despite the variability of routine outpatient data. Although advanced biomechanical measurements such as STJ ROM were not consistently available, the framework maintained stable predictive performance by adapting to the information available at the time of prescription. Using the same complete-case subset (n=3717), the mean component-wise AUROC increased from 0.792 in the Level 4 model to 0.816 in the Level 8 model, indicating incremental predictive value from STJ inversion and eversion measurements. This incremental pattern remained consistent under patient-level grouped cross-validation, suggesting that the observed difference was not attributable to repeated patient encounters. Although the magnitude of improvement varied across prescription components, most components showed stable or improved discrimination following the inclusion of STJ measurements. Despite this component-specific variability, the overall findings suggest that the framework may provide clinically useful decision support even when comprehensive biomechanical assessments are not always feasible [32].

Age-stratified analyses identified distinct age-related differences in feature importance patterns. Variable importance profiles differed between pediatric and adult groups, with pediatric prescription patterns showing stronger associations with alignment-related measures, whereas adult prescription patterns demonstrated relatively greater contributions from age for selected prescription components. These patterns should be interpreted as model-derived predictive associations rather than evidence of causal relationships in prescription decision-making and are broadly consistent with clinical expectations [33].

Comparison With Previous Work

Previous studies in foot orthotics and rehabilitation have demonstrated the feasibility of applying ML techniques to biomechanical assessment and gait analysis. However, most prior work has focused on tasks adjacent to prescription, such as diagnostic classification or outcome prediction, rather than directly supporting the complex, multicomponent decision-making process involved in orthotic prescription.

Several studies have explored ML-based insole or footwear recommendation by formulating the task as a single-output classification problem in which each patient is assigned to one predefined insole type or footwear category. For example, Kim et al [34] proposed a deep learning-based framework for prescribing customized insoles for patients with foot pain, demonstrating that convolutional neural network models could map plantar pressure patterns and clinical features to predefined insole categories with promising predictive performance. Similarly, Rajagopal et al [35] developed a ML pipeline that combined automated foot condition detection and classification with subsequent footwear recommendation. Although these studies demonstrated the clinical potential of data-driven insole and footwear recommendation, the prescription task was ultimately reduced to selecting a single mutually exclusive category. This formulation does not reflect routine clinical orthotic practice, where clinicians assemble combinations of multiple structural and material components tailored to individual patient needs [36]. To better reflect routine orthotic practice, the present study formulated prescription as a multilabel decision-making problem involving 15 orthotic components.

XSL•FO
RenderX

Another important body of research has focused on automating biomechanical measurement using ML. For example, Mun and Choi [37], and Liao et al [38] proposed deep learning–based approaches to estimate plantar pressure distributions and derive clinically relevant indices from sensor data, while Dindorf et al [39] developed scalable frameworks for automated plantar pressure analysis across multicenter datasets. Although these studies represent important methodological advances in biomechanical assessment, their primary contribution lies in measurement automation rather than in translating biomechanical information into actionable prescription decisions. Related investigations have emphasized outcome prediction following orthotic intervention, such as predicting gait speed or modeling postintervention pressure changes [40,41]. While clinically meaningful, these approaches focus on downstream effects of intervention rather than the upstream decision of how orthotic components should be selected and combined at the time of prescription [42].

A separate line of research has framed foot-related ML tasks as diagnostic or classification problems. Studies by Agrawal et al [43], Xu et al [44], and Jun et al [45] demonstrated the utility of plantar pressure, inertial, and multimodal data for classifying foot pathology or abnormal gait patterns. However, these models do not address the combinatorial nature of orthotic design, in which multiple interacting components are prescribed simultaneously [46].

In the rehabilitation domain, ML-based studies have also examined ankle-foot orthosis (AFO)–related decision-making. Prior work has focused either on predicting the need for an AFO or on optimizing control strategies for powered AFO systems [47,48]. Although clinically relevant, these approaches primarily address high-level indication or intervention execution rather than supporting detailed configuration of orthotic design elements at the prescription stage.

A notable distinction between the present work and many previous ML studies is the explicit framing of the system as a clinical decision support tool [49,50]. While predictive performance is often emphasized, comparatively less attention has been given to workflow integration, uncertainty communication, and clinician interaction. The Developmental and Exploratory Clinical Investigations of Decision support systems driven by AI (DECIDE-AI) reporting guideline highlights the importance of evaluating AI-enabled decision support not only on discrimination metrics but also on intended use, workflow fit, and early-phase clinical evaluation design [51]. Consistent with this perspective, previous studies have shown that clinician responses to AI recommendations depend strongly on presentation format and explanation style [52-54].

In contrast to these prior approaches, the present study was intentionally designed as a CDSS rather than an automated prescription tool. Orthotic prescription was formulated as a multilabel, component-based decision-making problem because clinical prescription involves combining multiple orthotic elements rather than selecting a single device category. However, each prescription component was modeled as an independent binary classification task, and therefore statistical dependencies among prescription labels were not explicitly modeled. To improve cross-label comparability, probability calibration was applied before generating ranked recommendations. By generating probabilistic, component-wise recommendations, the proposed framework narrows a complex decision space while preserving clinician oversight in the final prescription process.

Another distinguishing feature of this study is its hierarchical architecture, which was designed to reflect routine clinical workflows in which advanced biomechanical measurements are not always available. Rather than requiring a fixed set of inputs, the framework adapts to available clinical information by relying on alignment-based variables when advanced measurements are unavailable and incorporating mobility-related variables when such measurements are present. This flexible structure was intended to accommodate heterogeneous data conditions commonly encountered in outpatient orthotic practice and represents a workflow-oriented alternative to previous biomechanical, diagnostic, and outcome-focused ML approaches.

Clinical Implications

In clinical practice, the proposed CDSS can function as a safety-oriented and workflow-compatible support tool that augments clinician decision-making. By presenting a concise shortlist of high-probability components, the system may reduce cognitive burden and support more consistent prescription practices among clinicians with varying levels of experience. It may also serve as a bridge between junior and experienced clinicians, potentially contributing to more standardized orthotic prescription practices [46,55]. For less experienced clinicians, Top-K recommendations provide structured guidance grounded in historical prescription patterns. For experienced clinicians, the system functions as a safety checklist that helps reduce inadvertent omissions in time-constrained settings while preserving professional autonomy.

A safety-oriented operating profile was adopted because unnecessary orthotic components may impose additional cost, complexity, or burden without clear clinical benefit. Component-specific threshold calibration was therefore applied to minimize the risk of false-positive recommendations. Although this strategy resulted in lower overall sensitivity, the resulting trade-off is consistent with the intended role of the CDSS as a clinician-supervised decision support tool designed to provide high-confidence recommendations rather than autonomous prescription decisions. Threshold-calibrated recommendations and Top-K recommendations serve complementary purposes. Whereas threshold-calibrated outputs emphasize high-confidence recommendations with minimal false positives, the Top-K framework provides a broader ranked shortlist that supports clinician review and decision-making during the prescription process.

Beyond clinician-facing decision support, the proposed CDSS may also function as a communication aid during patient consultations [56]. By providing probabilistic outputs linked to patient-specific clinical variables, the framework may help clinicians explain the rationale for selected orthotic components. For example, clinicians may be able to contextualize recommendations for specific materials or structural supports

XSL•FO
RenderX

using relevant patient characteristics, such as age or alignment-related measures. Such transparency may facilitate patient understanding of prescription decisions and support shared decision-making. The hierarchical architecture further enhances clinical applicability by ensuring continuity of decision support under incomplete data conditions [57]. In routine outpatient settings, advanced biomechanical assessments are often unavailable because of time or resource constraints. By adapting its decision pathway according to information availability, the CDSS maintains usability across diverse clinical environments and may help reduce dependence on specialized biomechanical assessments.

From an interface design perspective, the observed Top-K recommendation patterns have direct implications for how decision support outputs should be presented. A concise ranked shortlist may provide efficient initial guidance while minimizing alert fatigue and supporting clinician trust. At the same time, presenting a broader set of ranked recommendations may help clinicians review additional potentially relevant orthotic components in complex multicomponent prescriptions. In a practical deployment scenario, the CDSS could present clinicians with a ranked shortlist of recommended orthotic components together with component-specific probability estimates, allowing clinicians to review, accept, modify, or reject individual recommendations before final prescription.

Limitations

Several limitations should be considered when interpreting these findings. First, clinician prescriptions in this study were derived from routine outpatient practice rather than from standardized consensus labeling or guideline-based adjudication. As a result, the training data may reflect interclinician variability as well as site-specific prescribing behaviors or implicit institutional biases. The model may therefore reflect prevailing institutional prescribing patterns rather than universally optimal or guideline-based prescription strategies. Future multicenter studies and external validation will be essential to enhance the generalizability and mitigate such effects.

Second, the data were collected over a historical period and may not fully capture temporal changes in orthotic materials, clinical guidelines, or prescribing practices. Longitudinal evaluation and periodic model updating will therefore be necessary to ensure the continued relevance of the CDSS as practice paradigms evolve.

Third, clinician prescriptions were used as a pragmatic reference standard, whereas downstream patient-centered outcomes—such as symptom improvement, functional gains, or long-term adherence—were not directly evaluated. Agreement with historical prescribing patterns does not necessarily imply improved clinical effectiveness. Although the model aligns with current expert practice, prospective studies will be required to determine whether CDSS-assisted prescriptions translate into improved clinical outcomes.

Fourth, although patient-level grouped cross-validation was implemented to prevent information leakage during model development and evaluation, the dataset originated from a single institution. Consequently, patient characteristics, clinical workflows, and prescribing patterns may differ across institutions, potentially limiting external generalizability.

Fifth, advanced biomechanical measurements were obtained selectively according to clinical judgment rather than through a standardized assessment protocol. As a result, the Level 8 complete-case subset may represent a clinically distinct subgroup, potentially limiting the generalizability of findings derived from this subset.

Sixth, imaging data such as radiographs or magnetic resonance imaging were not included in the present modeling framework. In some complex or structural deformities, orthotic prescription decisions may rely on anatomical information that cannot be fully captured through physical examination and biomechanical measurements alone. Therefore, the applicability of the current CDSS may be limited in clinical scenarios requiring imaging-informed decision-making.

Seventh, although missing values were retained as NaN and handled using the native missing-value processing capability of the tree-based models evaluated in this study, the mechanisms underlying missingness were not explicitly modeled. Because advanced biomechanical measurements were obtained selectively according to clinical judgment rather than at random, missingness itself may carry clinically relevant information. In addition, alternative missing-data handling strategies were not systematically evaluated in the present study. Consequently, the potential impact of different missing-data handling approaches on model calibration, feature-importance estimates, and model interpretability remains uncertain. Future studies should investigate whether incorporating explicit missingness indicators or other missingness-aware modeling strategies can further improve predictive performance and interpretability.

Eighth, although the dataset spanned a 6-year period (2015 - 2020), model evaluation relied on cross-validation rather than temporal holdout validation. Therefore, the robustness of the proposed CDSS against time-dependent shifts in clinical practice was not explicitly assessed.

Ninth, several prescription components had extremely low prevalence, which likely contributed to reduced predictive performance and limited clinical utility for minority labels. In particular, some rare prescription components demonstrated very low AUPRC and PPV values despite acceptable AUROC estimates, indicating that discrimination performance alone may overestimate real-world predictive usefulness under severe class imbalance. Therefore, predictions for these components should be interpreted cautiously and are not yet sufficient to support independent clinical decision-making. In addition, several low-prevalence components exhibited substantial variability across cross-validation folds, particularly for PPV estimates. For some labels, the SD was large relative to the mean estimate, indicating limited stability of positive prediction performance. This pattern likely reflects severe class imbalance and the limited number of positive cases available for training and evaluation. Accordingly, performance estimates for these minority-label components should be interpreted together with their variability measures rather than relying solely on mean values. Although prevalence-sensitive metrics such as AUPRC and PPV were included to provide complementary performance assessment,

XSL•FO
RenderX

explicit imbalance mitigation strategies—including resampling, cost-sensitive learning, class weighting, or synthetic minority augmentation—were not evaluated in the present study because the primary objective was to assess model feasibility using real-world prescription distributions across all clinically relevant orthotic components. Whether targeted imbalance mitigation strategies can improve prediction of rare prescription labels while preserving the clinical representativeness of real-world prescribing distributions remains an important area for future investigation.

Tenth, the conservative, safety-oriented threshold calibration strategy adopted in this study used component-specific thresholds to prioritize high specificity and minimize over-recommendation. Although this approach reduced the likelihood of false-positive component recommendations, it also substantially reduced sensitivity for several prescription components and may result in the omission of clinically relevant components in certain contexts. Consequently, threshold-calibrated outputs should be interpreted as high-confidence recommendations rather than comprehensive prescription suggestions. In clinical practice, clinician review remains essential to identify omitted or context-specific components before final prescription decisions. Adaptive or context-specific calibration strategies that balance sensitivity and specificity according to clinical context and prescription risks represent an important direction for future research.

Eleventh, although the hierarchical framework was designed to reflect routine clinical measurement availability, alternative modeling strategies, such as unified models with explicit missingness indicators or probabilistic data fusion approaches, were not systematically benchmarked in the present study. Therefore, although the proposed hierarchical framework demonstrated improved predictive performance when additional biomechanical measurements were available, whether this architecture provides advantages beyond workflow compatibility compared with alternative missing-data modeling strategies remains to be established.

Finally, although feature importance analysis provided clinically interpretable predictive patterns, these findings reflect predictive associations rather than causal relationships. In addition, the current framework provides only aggregate-level explanations and does not yet support case-specific explanation or uncertainty-aware recommendation outputs. Further work is needed to improve transparency and to better characterize how recommendations are generated for individual patients.

Future Directions

Prospective validation of the proposed CDSS within routine clinical workflows remains a critical next step, with particular emphasis on clinician-in-the-loop evaluations and patient-reported outcomes. Whether CDSS-assisted prescriptions translate into sustained functional recovery and symptom relief remains to be established through prospective clinical evaluation.

An important methodological extension involves the development of dynamic clinician–AI interaction frameworks. While the current system demonstrates strong performance using calibrated probability-based Top-K recommendations, future iterations could adopt continual learning paradigms in which clinician overrides or modifications are incorporated as informative feedback signals. Such approaches may enable adaptive decision support that remains aligned with evolving clinical practice patterns. Any deployment of continually updated models would require structured governance mechanisms, including performance monitoring, periodic recalibration, and clinician oversight.

Alternative approaches for handling heterogeneous clinical information, including unified modeling strategies with explicit missingness indicators and probabilistic data fusion frameworks, warrant further evaluation. In addition, the current component-wise modeling strategy could be extended through multilabel architectures that explicitly capture dependencies among prescription components, such as classifier chains, structured output learning, or neural models.

Improving prediction performance for low-prevalence prescription components remains an important methodological challenge. Potential directions include dedicated class imbalance mitigation strategies, such as resampling, cost-sensitive learning, class weighting, or synthetic minority augmentation, as well as calibration approaches that dynamically balance sensitivity and specificity according to component-specific clinical risks and decision contexts. Recent work in gait-related ML has demonstrated that data balancing and generative augmentation strategies can improve classification performance in rare and highly imbalanced clinical datasets [58].

Future work may also investigate approaches for case-specific explanation and uncertainty communication, including instance-level feature attribution methods (eg, Shapley Additive Explanations [SHAP]) or uncertainty-aware recommendation outputs. Such extensions could help clinicians better understand model recommendations and evaluate their reliability in routine orthotic care.

Conclusions

This study developed and evaluated a hierarchical CDSS for foot orthosis prescription using routinely collected outpatient clinical data from a large single-institution cohort. The proposed framework modeled prescription as a multilabel, component-based decision problem and combined probability-calibrated Top-K recommendations with component-specific safety-oriented thresholds. The hierarchical structure enabled decision support under varying levels of information availability in routine clinical practice while demonstrating improved predictive performance when additional biomechanical measurements were available.

The system provides component-wise recommendations intended to support, rather than replace, clinician judgment in routine orthotic care. By combining high-confidence threshold-calibrated recommendations with ranked Top-K outputs, the framework may support clinician-in-the-loop decision-making while reducing the likelihood of unnecessary component recommendations. Further prospective validation is required to establish its clinical utility and evaluate its performance in real-world orthotic care.

Abstract

Background: Systematic strategies to harness electronic health record (EHR) workflows, reduce redundancy, and support decision-making remain limited in acute care surgery (ACS). Understanding how EHR systems and workflows intersect with time-sensitive settings is critical to improving decision-making and outcomes in ACS.

Objective: This study aimed to evaluate how ACS clinicians leverage the EHR for decision-making and to identify opportunities and challenges for EHR-enabled decision support.

Methods: We conducted a qualitative ethnographic study over a 6-month period, combining in-depth interviews with 15 ACS surgeons and providers and 100 hours of "paired fieldwork" observations spanning the entire perioperative arc by a surgical provider and an organizational sociologist. Using constructivist grounded theory, we identified the enablers, challenges, and opportunities for EHR-enabled decision-making in ACS.

Results: Surgeons fell into two groups: (1) those who accepted information overload as inherent to the EHR, relying on generic templates and standard attestations, and (2) others who viewed it as a problem to fix, actively correcting errors and composing individualized summaries. Ambiguity in billing requirements drove overdocumentation, resulting in "note bloat" that obscured high-yield information. EHR use during decision-making focused primarily on risk assessment, though navigation challenges hindered access to critical data. Forecasting key outcomes that alter management or facilitate shared decision-making was seen as valuable. Automated risk stratification, generated from live EHR data while minimizing alert fatigue, was seen as a potential solution.

Conclusions: ACS clinicians use various tactics to navigate EHR challenges and focus on high-value tasks. Streamlined risk assessment using EHR data may strengthen decision-making in critical moments, but solutions must integrate seamlessly within existing workflows to provide rapid and accurate outputs that prioritize meaningful outcomes.

KEYWORDS

acute care surgery; ACS; electronic health records; EHR; decision-making; ethnography; risk assessment

Introduction

Acute care surgery (ACS), which encompasses trauma, emergency general surgery, and surgical critical care, is thematically defined by the notion of surgical rescue, in which ACS teams must maintain a high state of anticipation for unexpected and potentially devastating events [1]. While ACS surgeons find purpose in the care and rescue of critically ill patients, they continue to face burnout at alarming rates as high as 67% [2,3]. A major contributor to this crisis is the escalating burden of administrative tasks, particularly the documentation of complex clinical data. Compared to their peers, ACS surgeons spend 60% more time on electronic health records (EHRs) [4-6]. The resulting cognitive overload undermines high-stakes decision-making while eroding their sense of purpose, ultimately impacting outcomes in rapidly evolving surgical emergencies [7].

Since the introduction of the Health Information Technology for Economic and Clinical Health (HITECH) Act [8] in 2009, EHRs have become the core infrastructure for data-driven technologies in health care. Yet EHR adoption continues to face challenges, including poor data standardization, interoperability issues, and difficulties integrating data into clinical workflows. While EHRs are widely used for documentation and billing, their role in supporting effective decision-making, particularly in acute settings, remains poorly defined. Moreover, few studies

XSL•FO
RenderX

have evaluated the effectiveness of EHR-based tools in comparison to the bureaucratic counterfactual: the existing, nontechnical workflows that shape clinical practice [9,10]. Understanding the clinical and organizational context into which these digital tools are introduced is critical to ensuring they enhance, rather than disrupt, patient care, particularly in busy, high-stakes environments like ACS.

Accordingly, a broader sociotechnical perspective situates EHRs within complex clinical workflows, team interactions, and organizational constraints that shape their real-world use and impact [11,12]. Ethnographic studies have shown that clinical work is inherently distributed, iterative, and context-dependent, with EHR use reflecting adaptation to workflow complexity rather than deviation from intended design [13]. From this view, EHRs function as evolving information infrastructures, shaped over time by policy, institutional priorities, and user adaptation [14]. Ethnographic insights from field observations and stakeholder perspectives may therefore clarify how digital tools are embedded in practice, informing efforts to better support decision-making and surgical rescue.

Given that clinical decisions in ACS often occur in rapid, high-stakes settings without the benefit of preoperative planning, ACS represents a key opportunity to understand how EHRs and related workflows can be optimized [15]. This qualitative, ethnographic study aims to examine how ACS teams interact with EHR systems, focusing on how data are accessed, interpreted, and used in decision-making. By mapping existing workflows and patterns of engagement, we seek to identify barriers and opportunities for future implementation of digital tools that align with the realities of frontline surgical care.

Methods

Ethical Considerations

This study received ethical approval from the institution's research ethics board (IRB-76999), and all participants provided informed consent. The study adhered to the SRQR (Standards for Reporting Qualitative Research) guidelines (Checklist 1) [16].

Setting and Participants

This ethnographic study was conducted over a 6-month period between September 2024 and February 2025 at an academic teaching hospital providing level I trauma services. The institution's ACS section accounts for approximately 11% of the hospital census and serves as a regional hub, coordinating care across 2 primary counties in collaboration with surrounding centers. The hospital uses Epic Hyperspace (Epic, Verona, and WI) as its front-end EHR interface, through which users document care, enter orders, review longitudinal patient data, and support billing workflows, all of which shape how they interact with patient data. Epic Systems has served as the institution's primary EHR since its full implementation in 2008 as part of broader institutional efforts to modernize clinical infrastructure, improve care coordination, and support data-driven quality improvement and regulatory compliance initiatives.

Participants were recruited from the institution's ACS section using a purposeful sampling strategy to capture variation across roles, experience levels, and EHR workflows. Attending surgeons (n=11) who were actively in clinical service during the study period were exhaustively sampled, with all eligible ACS faculty invited and included. Advanced practice providers (APPs; n=3) and one senior resident (n=1), identified during previous attending interviews as exemplary EHR users, were also purposively sampled to provide deeper insight into high-performing documentation practices and workflows within the section. In total, 15 ACS surgeons and providers participated in both semistructured interviews and direct observation of their EHR workflows (Table 1). The broader clinical context was captured through observational inclusion of approximately 20 other rotating residents and 5 fellows, who were not formally interviewed but participated in in situ ethnographic interviews during field observation. These brief targeted interviews were used to clarify observed behaviors and validate interpretations, consistent with established ethnographic methodology [17].

Table . Interview participant characteristics.

Participant group	Value, n	Sex	Years in practice
Attending surgeons	11	6 male, 5 female	0 - 5 years: n=4; 6 - 10 years: n=2; 11 - 20 years: n=3; >20 years: n=2
APPs[a]	3	3 female	6 - 10 years: n=2; 11 - 20 years: n=1
Senior resident	1	1 male	—[b]

[a]APP: advanced practice provider.

[b]Not applicable.

Data Collection

With growing calls from qualitative methodologists to conduct ethnographic fieldwork in interdisciplinary teams [18-20], this study developed and used a novel "pair fieldwork" technique to deepen and enrich our data collection. Specifically, a surgical care provider and an organizational sociologist conducted ethnographic in-depth interviews and field observations together throughout the project, to contrast insider ("emic") and outsider ("etic") perspectives on EHR practices. Each fieldworker focused on asking interview questions and writing ethnographic fieldnotes related to their areas of expertise; the surgical care provider focused on the nuances of clinical decision-making, whereas the organizational sociologist focused on routines, workflows, and broader organizational processes. As a result of these differing emphases, the 2 fieldworkers' notes diverged

XSL•FO
RenderX

significantly even while observing the same phenomenon: the surgeon's notes tended to contain details on how patient data were accessed, discussed, and integrated into real-time clinical decision-making, whereas the sociologist's notes tended to contain details on broader sociotechnical factors (eg, pace of work, division of labor, and the broader spatiotemporal context of clinical encounters) that shaped EHR use. To maximize the analytic value of this variation, the 2 fieldworkers maintained independent fieldnotes and descriptive memos throughout the study, while meeting regularly with the research team to discuss high-level similarities and differences in what was being observed, and to strategize approaches to broaden and deepen data collection. Moreover, since neither fieldworker held clinical or supervisory roles within the section or department, both could move freely in the field and prompt open, candid discussions of EHR practices without appearing to be implicated in the section's organizational hierarchy or reporting structures.

An interview protocol was developed and iterated by the research team a priori, beginning with general questions about participants' daily workflows, and subsequently covering questions about their practices, preferences, and needs related to generating, inputting, analyzing, and interpreting EHR data, as well as general perceptions of EHR workflows and existing systems. Participants were recruited through an internal faculty and staff email list as well as announcements during section meetings. Interviews were conducted either in-person or on a video conference platform (Zoom, version 6.2) depending on participant availability and were voice-recorded with consent for subsequent transcription.

Approximately 100 hours of field observations were conducted during the study period. In keeping with best practices in constructivist (as opposed to purely inductive) grounded theory [21-23], observation scripts were developed to tactically focus fieldwork toward understanding the processes and workflows underlying this study's phenomenon of interest: how ACS clinicians interact with EHR data. First, sites were identified where ACS teams regularly interacted with EHR data when making clinical decisions—most notably, daily handover conferences, patient rounds, clinics, and consultations. The 2 fieldworkers regularly visited these sites over a 6-month period, documenting interactions, actions, and behaviors, as well as broader contextual information surrounding interactions with the EHR. As data collection progressed, observation scripts were refined to also include sites where individual clinicians input and interpret EHR data—attendings' private offices and the ACS resident or APP "team rooms." The diversity of environments, spanning intrasettings and multidisciplinary settings, enabled the capture of workflows and interactions across both hierarchical and nonhierarchical contexts. At these sites, a "think-aloud" protocol was used, whereby individuals were asked to vocalize what they were thinking as they interacted with the EHR, to capture their beliefs, preferences, and attitudes on the role of the EHR in clinical decision-making [24,25]. Throughout our fieldwork, passive observation was interspersed with ethnographic interviews to confirm the accuracy and veracity of our observations, as well as to reflect on specific anomalies and inconsistencies that arose during the observations.

Data Analysis

Data analysis was iterative and proceeded along 3 broad stages [26,27]. The first stage entailed open coding, where the research team stayed close to the textual content of fieldnotes and interview transcripts to identify patterns related to how clinicians recorded, interpreted, and leveraged EHR data. At this stage, multiple phenomena of interest were identified as occurring frequently and/or being putatively important to the study participants. Subsequently, fieldnotes and interview transcripts were reanalyzed with a focus on generating explanations and underlying mechanisms for each phenomenon identified in the previous stage. Finally, in the third stage of theoretical coding, codes that had reached thematic saturation were abstracted and connected with extant literature to identify novel contributions to research on EHR workflows and their impact on clinical decision-making [28]. All analyses were performed using ATLAS.ti (version 25.0; Lumivero).

Results

EHR Use During Clinical Shifts

On average, participants reported spending approximately 3 to 4 hours per 12-hour shift engaged with the EHR, both by reviewing notes on the fly during patient rounds and by more deliberately reviewing and discussing patient information during structured settings such as handover conferences. However, considerable heterogeneity was observed in terms of how this time was spent, reflecting underlying differences in perspectives on how to input, retrieve, and leverage EHR data for clinical decision-making.

Perspectives on Inputting Data Into EHR Systems

Two distinct types of EHR users, in terms of their approach to inputting data into EHR systems, were identified among clinicians (Textbox 1). One group, labeled the "passive acceptors," perceived the EHR as a burdensome task to be efficiently circumvented for clinical work. They tended to use generic templates for documentation and standard attestations, such as writing "as above," while accepting minor errors in notes as is. Passive acceptors were also less likely to provide feedback regarding notes (eg, to trainees). On the other hand, "active editors" viewed the EHR as a systems problem to fix and leverage for clinical work. They often generated individualized summaries and attestations, while identifying and correcting minor errors in the EHR for accurate communication.

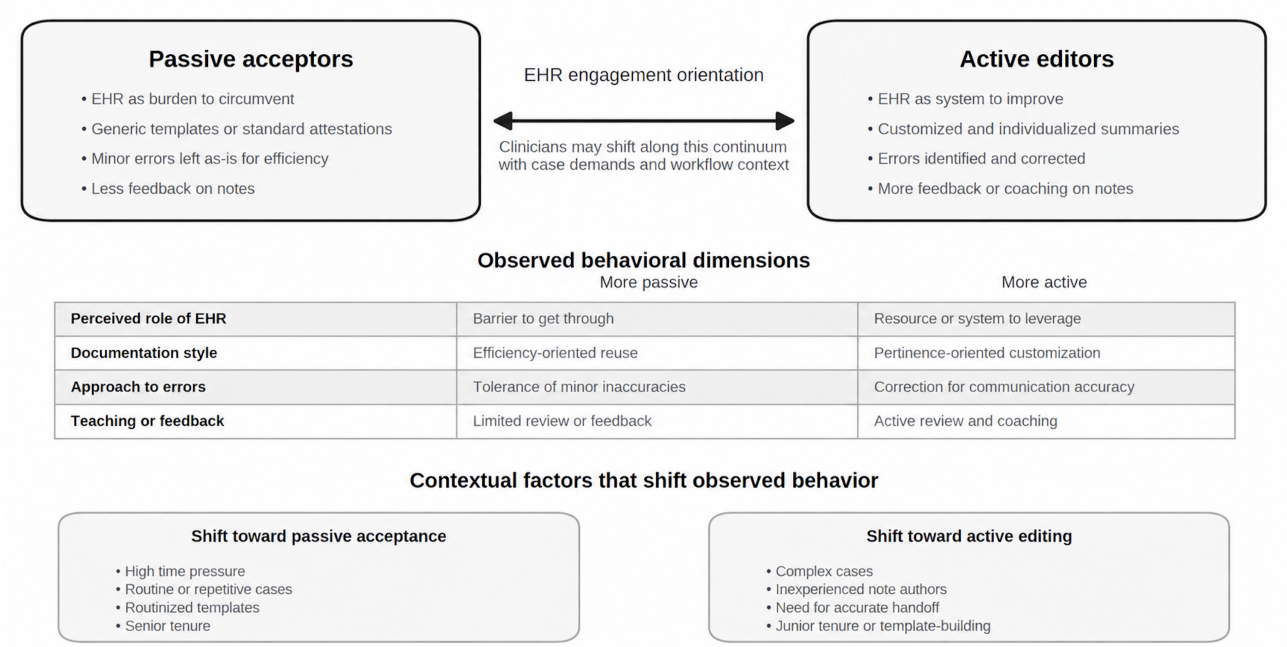
XSL•FO
RenderX

Textbox 1. Illustrative quotes describing key characteristics of electronic health record (EHR) users in acute care surgery (ACS).

Passive acceptors

- EHR is a barrier to circumvent for clinical work
  - **Nurse Practitioner:** "I know that nobody is going to read my note fully, so it really matters more how I present my information during rounds." (Field observation: handover conference)
- Generic templates and standard attestations are preferred
  - **Attending:** "I always click 'moderate [severity]' for most floor patients. ['Moderate' is one of the options for severity required for billing] I always put 'moderate'. Dr XX is really the expert and will show you how to really charge things. I just put 'moderate' all the time." (Field observation: clinic)
- Minor errors are left as is for efficiency
  - "When I close wounds, I'm very particular about how they're closed. I don't use staples on skin … I saw a note … that said 'closed with staples.' I knew for a fact that the skin was not closed with staples, but it was carried over from some other formatted note. But I didn't have time to correct it nor did I tell [the author]." (In-depth interview: attending)
  - "I would say there are some attendings that require more detail. They actually will read the note and then text me about it… they'll give you a little bit of feedback. But for the most part, most attendings don't end up giving you any." (In-depth interview: resident)

Active editors



- EHR is a problem to solve and improve on
  - "I enjoy going on the EHR when I'm reading about patients, making quick decisions, running surgery… That works well in those situations—in terms of accessing notes, labs, x-rays, consultant notes." (In-depth interview: attending)
- Customized, individualized summaries are preferred
  - **Attending:** "Look at the whitespace, the clear headings, and the summary at the end. I don't mean to be biased, but I think this is quite neat, no? I'm quite proud of it … I made a template when I joined, and I've been trying to improve it ever since." (Field observation: clinic)
- Errors are identified and fixed
  - [Attending calls out an error on a note, recognizing an erroneous diagnosis that was recorded] "Make sure this goes into the note, please." (Field observation: patient rounding)
  - "There are things that get missed because things get carried on from prior days and they don't read them. So, I have to go over them … read and make sure there's pertinent information that is relevant to patient care … You go over and make sure it's accurate, make sure it's up to date." (In-depth interview: attending)

Importantly, these 2 categories ("passive acceptors" and "active editors") imply general tendencies, rather than rigid, determinate labels—and, as such, were responsive to broader sociotechnical factors surrounding EHR use (Figure 1). For instance, during particularly busy shifts or when dealing with routine, repetitive cases, surgeons who may otherwise tend to be active editors may, in the interest of time, adopt practices similar to passive acceptors. Similarly, when dealing with particularly complex cases or when reviewing notes written by inexperienced interns or students, ordinarily passive acceptors may adopt practices similar to active editors. Tenure appeared to be another important factor in shaping these tendencies. Senior attendings with more experience writing and reviewing notes tended to have detailed templates and routinized practices to cover a wider range of cases (thus tending toward passive acceptance), whereas junior attendings tended to spend more time customizing their summaries and fussing about minor errors (thus tending toward active editing).

Next, when surgeons were explicitly prompted to reflect on sources of documentation errors and overdocumentation, or "note bloat," opaque billing requirements were identified as a key driver of inaccuracies, cognitive stress, and overall challenges with using the EHR across both groups (Textbox 2, theme 2.1). Strategies to overcome these documentation burdens, such as copying and pasting text from the previous day, further contributed to the vulnerability of information to errors (Textbox 2, theme 2.2).

XSL•FO
RenderX

Figure 1. Continuum of clinician engagement with electronic health record (EHR) documentation in acute care surgery (ACS). Passive acceptors and active editors represent tendencies rather than fixed user types. Clinicians could shift along the continuum depending on contextual factors such as time pressure, case complexity, author experience, handoff needs, and the degree of template routinization.

Textbox 2. Illustrative quotes describing sources of overdocumentation and errors.

Theme 2.1: Opaque billing requirements are a major driver of overdocumentation and note bloat

- "What is a good note? A good note is one that meets billing requirements; no more, no less!" (In-depth interview: attending)
- "When I made the standardized templates for progress notes, I tried to go through all the [financial-legal] requirements and hit them all. That's why the templates are made that way. Like the review: 'you need to have a certain number of physical exam systems'…. It's very odd because none of it is very clinical; they're very arbitrary rules! For instance, you need to add a skin exam as part of a distinct system, otherwise it doesn't count. How does that make sense?" (In-depth interview: attending)
- "For operative notes, now they're making us add all this stuff that I really don't think is necessary. If you do a debridement, you have to say how much you debrided it, how deep did you debride it. I'm pretty sure those aren't requirements, but our coders are convinced that they are. So, we're stuck…. Then you get peppered with additional messages in your inbox." (In-depth interview: attending)

Theme 2.2: Attempts to mitigate documentation burdens (eg, copyforwarding) contribute to documentation errors

- **Observer:** "What happened there? Wasn't it in the note [that the patient's feeding tube was already removed]?" **Resident:** "It was! [Scrolls down the note] I put it here in the assessment and plan, but I think I copied over yesterday's note that still showed the tube was in. It is honestly quite tedious to check and edit that every time." (Field observation: ACS team room)
- "After copying a note, I'll edit the note a little bit, but it's so burdensome…. Having to sift through pages of notes to edit things takes forever, and so it's not worth the time. And so, you''ll find errors [in copy-forwarded notes] compound upon each other. If people tried to edit every note, they would spend exponentially more time on the computer than with patients." (In-depth interview: attending)

Perspectives on Retrieving and Interpreting Data From EHR Systems

Participants noted that, unlike other surgical specialties where surgeons often have the time to review EHR data in detail and plan operative strategies in advance, ACS demanded faster, more reflexive approaches to retrieving and interpreting useful information. Accordingly, a primary motivation for leveraging EHR data in ACS was to support real-time decision-making, often through streamlined risk assessment (Textbox 3, theme 3.1). For instance, observations revealed that attending surgeons frequently raised questions or comments regarding the patient's status and trajectory to decide on operative intervention. During interviews, participants also emphasized the role of EHR data in supporting risk assessment.

XSL•FO
RenderX

Textbox 3. Illustrative quotes describing EHR use for decision-making in ACS.

Theme 3.1: Data from the EHR is frequently leveraged and important for risk assessment

- [The attending mentions using the Emergency Surgery Score to risk stratify each consult. The residents seem to be responsible for these tasks at this time, but the attending states that they are trying to "streamline it using the EHR"] (Field observation: handover conference)
- [Many questions, especially from the attendings, are around patient status and trajectory. "How much pressors are they on," "How are their labs looking like now," "Can we book them for surgery today." These questions lead to decisions around surgery…. Sometimes, the case presenter is wrong on specific laboratory values or medication doses. The presenter tries to find the specific information on the EHR but usually has trouble finding it right away.] (Field observation: handover conference)
- **Attending:** "When we do morning rounds and go through a large number of cases and charts, is there a way we can quickly stratify risk?" [Both residents and attendings respond positively. One attending brings up how even when dealing with similar conditions, [depending on specific patient characteristics], one patient would have "a longer window for rescue" (eg, a young, previously healthy patient) compared to an older or frailer patient.] (Field observation: handover conference)

Theme 3.2: Note bloat limits extraction of high-value information for decision-making

- "In the jumble that is [the EHR], what happens is you have a little bit of narrative at the beginning, then you have some physical findings. Sometimes, you''ll have long streams of laboratory data, investigations, and medications, relevant or not. You can scroll all the way to the bottom and realize it just trails off and there's no summary at the end. Then you scroll back up to find somewhere in there will be the clinical summary for that day." (In-depth interview: attending)
- **Attending:** "Let me find the ICU note…. It's a bit hard to tell which one the ICU note is. Think it's this one." [Clicks on one of the notes] "I don't love the way it looks." [He begins scrolling down, and there is a long list of tests, exams, and summaries of events] "I don't know if human beings are meant to understand data like this! There's no prioritization here, and I don't know what to focus on." [He scrolls to the bottom of the note] "And then it just ends all of a sudden! There's no impression or plan!" (Field observation: patient rounding)
- [The attending asks about the patient's medical history to the resident on the EHR] **Resident:** "Hmm, where is it?" [Scrolls down to the end of the note] "Not here, I think. Ugh, it is so embarrassing to have you all watch me do this!" [She opens up a new note and scrolls to the bottom]. "Not here either." [Grunts in frustration]. **Attending:** "That's fine. We'll look for it in case it comes up during rounds later." (Field observation: handover conference)
- [For the next patient, there was a discrepancy between what was documented and the working diagnosis described by the resident. She originally stated that this patient had a cecal perforation, but on review of the operative note by the attending, the patient actually had a small bowel perforation. The attending calmly corrected this. He asked the team to further review the patient's chart and requested to keep track of the patient's hemodynamics and laboratory trends, establishing clear criteria for when to escalate care.] (Field observation: patient rounding)

Note bloat and errors that propagated through copy-forwarded documentation posed significant challenges for ACS clinicians, making it difficult to identify pertinent information, especially given the rapid pace at which data needed to be reviewed and interpreted (Textbox 3, theme 3.2). While surgeons hoped that EHR-enabled decision support would leverage objective data and mitigate the reliance on maladaptive heuristics, the errors and note bloat pervading the EHR made it difficult to effectively integrate data into decision-making workflows.

Moreover, as risk assessment emerged as a key use of EHR data, several surgeons reported relying on existing risk-stratification systems, including standalone calculators. However, they also pointed to several shortcomings in these tools (Textbox 4, theme 4.1).

Textbox 4. Illustrative quotes describing the use and shortcomings of existing decision support systems.

Theme 4.1: Existing tools are not optimized for electronic health record (EHR) integration

- "I use this NSQIP risk calculator…. It's kind of not ideal for the emergency surgery population. It accounts for a broad-based, more so elective practice. You could look up the literature, but it tends to misestimate emergency surgery patients and [those who] have multiple comorbidities and what not." (In-depth interview: attending)
- "There are calculators out there that help you with decisions. None of them are perfect…. I'm always like, how come these tools aren't embedded into [the EHR] so that I'm able to open patients' charts and click on the [risk calculator] tab. It should be like this – with the calculator saying this, automatically." (In-depth interview: attending)

Perspectives on Future Opportunities for Improving EHR-Enabled Decision Support

When asked to describe the ideal EHR-enabled decision support tool during in-depth interviews, participants conceptualized an embedded risk assessment model that forecasted key ACS outcomes. They emphasized the need for automated data input to eliminate the time-consuming task of manually identifying and entering key information (Textbox 5, theme 5.1). Just as critically, they stressed that model outputs should not increase cognitive burden, for example, by contributing to alert fatigue, but instead should be easily accessible and intuitive (Textbox 5, theme 5.2). Importantly, clinicians underscored that any embedded tools must have clinical utility (Textbox 5, theme 5.3). For instance, the most valuable predictions were those that systematically heightened vigilance and better standardized

XSL•FO
RenderX

escalations in care, as well as those that conveyed overall outcomes that would help guide shared decisions around operation.

Even as ACS surgeons expressed enthusiasm for incorporating specific tools into the EHR, they emphasized that successful development and implementation must align closely with existing workflows. Surgeons highlighted that risk assessment, for example, should be grounded in an understanding of which outcomes may be most useful to predict, the extent to which different risk thresholds may or may not warrant revised management plans, and how these tools can be leveraged to discuss treatment options with patients.

Textbox 5. Illustrative quotes describing electronic health record (EHR)-enabled decision support.

Theme 5.1: EHR-enabled risk assessment should be automated using real-time data

- "I can manually enter data. But it's not useful. It's because of the pace of work, it's not feasible to calculate scores…. For example, for liver failure, there is a score called MELD score which will tell you a lot about that patient's risk. The problem is the MELD score is a bit difficult to calculate." (In-depth interview: attending)
- "I had to pull my phone, do the calculation and then decide. But [the EHR] should be able to make a suggestion to me, right? It has the data that I'm using. It should be doing it automatically. In fact, I feel like it should automatically suggest it and just be like, this is what we decided, do you agree or disagree? All these things can be automated. Why am I doing this manually in 2024?" (In-depth interview: attending)

Theme 5.2: Models should be embedded into the EHR as a dashboard without exacerbating alert fatigue

- "If the data could be displayed in a user-friendly way…. People carry paper notes and lists right now, but [the EHR] is how I see patients and they have these little icons, but I actually don't know what those icons are. If there is a way that I could absorb all the pertinent information quickly, that would be valuable." (In-depth interview: attending)
- "All of these indices, there's that constant tension between being overly sensitive. Sometimes it over triggers. And then you run the risk of alarm fatigue, because people see this, and they just kind of become immune to it." (In-depth interview: attending)

Theme 5.3: Models should be tailored to output relevant and/or actionable outcomes in ACS

- "I think the stakes are high in these patient populations, so mortality immediately comes to mind, but I think organ failure is another important outcome…. I care about their hospital length of stay—it's a marker for how well you care for them. And then, of course, functional outcomes are ultimately the most important thing, but we don't really have much information about that." (In-depth interview: attending)
- "Could we get all of the data from the EHR, use AI to see if we could build a predictive tool based on the information available to predict which patients were going to vomit, which patients were going to breathe it into their lungs, and which ones would wind up in the ICU? That's something that'd be helpful, because you're being very specific, and your [risks] are then actionable." (In-depth interview: attending)
- "Things like discharge to a nursing facility. I think a lot about those longer-term complications that affect people's lives…. People care if they're going to be the same mentally… or what their life is going to look like in 6 months, or something like that. That's what people care about." (In-depth interview: attending)

Discussion

This ethnographic study examined the EHR workflows through which ACS clinicians make data-driven decisions, identifying both opportunities and barriers to implementing digital tools that support surgical care delivery. Opaque billing requirements were a key driver of documentation overload, contributing to note bloat and errors. ACS clinicians responded to this burden either passively or actively. Decision support through risk assessment emerged as a central use of EHR data, with clinical decisions hinging on the timely identification and integration of relevant data points that could facilitate surgical rescue. Clinicians emphasized that digital tools must be designed with attention to data input, output, accuracy, and clinical relevance to augment, rather than impede, effective decision-making. These findings align with broader sociotechnical perspectives on health informatics, showing that system performance emerges from interactions among technical design and the social, organizational, and cognitive contexts of use.

ACS may be viewed as an extreme environment in which high acuity, uncertainty, and time pressure, compounded by worsening workforce shortages, magnify the impact of documentation burden and note bloat [4-6,29]. Yet, prior work suggests that such extreme contexts can serve as revealing cases, exposing latent inefficiencies that might otherwise remain obscured, as constraints of time, uncertainty, and limited resources amplify their effects [30]. In this study, these dynamics were evident in users selectively bypassing bloated notes, relying on synchronous communication, or developing workarounds to rapidly locate high-value information. These behaviors highlight how excessive or poorly structured documentation can hinder information retrieval and clinical decision-making. Although such adaptations may be particularly necessary in ACS, they likely reflect broader, systemic challenges in EHR use, where the consequences of documentation burden may be less immediate but remain consequential.

The competing demands of administrative compliance and clinical care have shaped the evolution of EHRs from single-purpose clinical tools into multipurpose systems. The HITECH Act, for example, catalyzed EHR adoption by strengthening the financial rationale for implementation among hospital administrators [31]. Since then, documentation standards designed to support financial and legal compliance, such as those related to Current Procedural Terminology (CPT) codes and the *International Classification of Diseases* (ICD),

XSL•FO
RenderX

have increasingly influenced digital and clinical workflows alongside persistent interoperability and data fragmentation challenges [32]. Such requirements have further exacerbated misalignment between system-imposed documentation structures and the cognitive and workflow needs of frontline clinicians [12,14].

This is particularly consequential for medically complex patients, where, as Naik and Singh [33] emphasize, asynchronous communication methods such as the EHR are critical for transmitting pertinent information across multiple receivers without interruption. In ACS, there is a natural bias toward synchronous, interruptive communication (eg, face-to-face conversations and phone calls) due to the time-sensitive nature of care. While necessary and efficient in urgent or life-threatening situations, overreliance on synchronous communication alone can lead to cognitive overload, increased dependence on short-term memory, work-related stress, and higher risk of medical errors [34,35]. Ethnographic studies of EHR use have similarly shown that clinicians rely on both formal documentation and informal communication practices to manage complex, time-sensitive care, with breakdowns often occurring when digital systems fail to support this distributed coordination [13]. In ACS, there is thus a strong incentive to develop noninterruptive EHR systems aligned with surgeon workflows to support shared decision-making, with prior work demonstrating that targeted EHR-based redesign can improve timeliness of care [36].

While greater clinical experience and seniority might suggest a shift toward intuitive decision-making over time, previous research shows that surgical judgment, particularly in assessing risks and benefits, remains highly variable regardless of experience level, especially in areas lacking clear guidelines [37,38]. As a result, EHR-enabled decision support tools are increasingly valued for their ability to promote deliberative reflection and counteract maladaptive cognitive biases and heuristics [39]. Harnessing this potential will therefore require documentation practices that balance efficiency with the effective inclusion and retrieval of clinically important information.

A key strategy may be to shift from systems-based to problem-based charting. Interviews revealed that documentation standards for billing are often poorly understood, with some believing that systems-based documentation is required for certain services when it is not. Increasing transparency around billing requirements could help dispel these misconceptions and encourage more focused documentation of high-value information without compromising financial-legal standards. Accordingly, a previous study of problem-based charting demonstrated significant improvements in capturing certain critical care diagnoses for billing purposes [40]. Such a transition would facilitate the identification and use of relevant EHR information to support surgical and perioperative decision-making.

In this study, EHR data were often leveraged for risk assessment, such as to support critical decisions around when and whether to operate. However, the manual search and entry of pertinent information remain significant barriers to adopting EHR-embedded decision support tools, indicating "hidden work" in the form of cognitive and navigational tasks not accounted for in system design [41]. Recent advances in AI, including models capable of generating real-time predictions or recommendations, have made it increasingly feasible to overcome these limitations [42,43]. These insights must also be clinically meaningful or actionable, particularly in settings where decision-making already depends on heterogeneous or uncertain clinical data [44]. For example, predicting specific complications such as postoperative respiratory failure should be coupled with standardized, risk-stratified protocols that align predicted risk with appropriate interventions, such as tailored monitoring and recovery strategies. In contrast, predictions of more general outcomes like mortality or overall morbidity may be most useful in situations of clinical uncertainty, supporting decisions and shared decision-making during equipoise through quantitative data, or serving as a second opinion when clinicians seek additional validation. Analogous decision support frameworks in other high uncertainty domains have used fuzzy multicriteria decision-making models to integrate expert judgment, conflicting criteria, and ambiguous data, illustrating the broader relevance of structured approaches when decisions cannot be reduced to a single quantitative output [45,46].

While there are certain perceptions that clinical gestalt may ultimately override any outputs from EHR-enabled decision-making, there is also general agreement that digital workflows can be better optimized to mitigate human cognitive biases [47]. For example, studies have demonstrated improved predictive accuracy when surgeons are supported by risk calculators, and, in some cases, the tools alone can outperform both unaided and aided surgeons [48,49]. This underscores the importance of educating clinicians to meaningfully integrate decision-making processes into digital workflows without falling into patterns of overreliance or reflexive skepticism. One suggested model is a Bayesian-like approach, where AI output is treated as an informed second opinion from a colleague with a distinct expertise profile, neither overriding nor subservient to clinical judgment, but contributing to a well-calibrated decision [50]. Translating this model of collaboration into routine practice will require prospective validation across dynamic environments, subgroup populations, and ACS care models, with attention to calibration and clinically actionable outcome definitions. Clinician trust will also depend on whether outputs are interpretable, available at the right moment in the workflow, and linked to clear responsibilities and care pathways. To ensure these tools augment care delivery, future implementation should therefore evaluate not only predictive performance, but also effects on alert fatigue, documentation burden, communication patterns, and unintended changes in surgical decision-making.

This study has several limitations. First, as a single-center ethnographic study, findings may not be generalizable to institutions with different EHR systems, workflows, or models of ACS care. Documentation practices are also shaped by local institutional culture, remuneration and billing structures, and national regulatory context, which may further limit transferability. However, several findings likely reflect broader sociotechnical dynamics relevant beyond academic hospitals,

XSL•FO
RenderX

including documentation burden, note bloat, reliance on workarounds, difficulty retrieving high-value information, and the need for decision support tools embedded within existing workflows. In nonacademic hospitals or smaller health systems, these challenges may be amplified by leaner staffing models, fewer APPs or trainees, and less information technology support, although simpler organizational structures may also facilitate more direct communication. Thus, while the specific EHR behaviors observed in this study should be interpreted in context, the broader need to align documentation, information retrieval, and decision support with frontline clinical workflows is likely applicable across diverse acute surgical care settings. Second, the presence of observers may have introduced reactivity or response bias, and any concurrent EHR-related initiatives may have influenced participant perspectives. Third, our purposive sampling strategy may have introduced selection bias and underrepresented certain groups, including those with limited availability (eg, night-shift staff) and early-career providers. In addition, we did not fully capture EHR interactions involving consulting services or bedside nursing staff. Nevertheless, the inclusion of all attending surgeons alongside APPs and trainees, combined with a dual-observer fieldwork approach and in situ ethnographic interviews, supports the breadth and validity of the findings. Finally, while we identified opportunities for EHR-enabled decision support, we did not evaluate the implementation or impact of such tools, which will require future prospective and intervention-based research.

EHR systems are critical parts of the ACS workflow, shaping how information is documented as well as how decisions are made. This study highlights the dual burden of administrative documentation and clinical complexity, demonstrating that EHR practices are both a source of friction and a potential site for innovation. Meaningful improvement will likely require reconsideration of how documentation, communication, and decision-making processes are structured within the broader clinical system. While ACS clinicians vary in their engagement with the EHR, there is broad recognition that better integration of clinically valuable decision support, tailored to the ACS context, could improve surgical workflows and patient outcomes. Aligning EHR design, documentation standards, and digital tools with frontline ACS workflows is essential to advance a more efficient, accurate, and cognitively supportive environment for high-stakes surgical care delivery.

Acknowledgments

The authors would like to thank the participants from the acute care surgery section for their contributions to this study. AI tools (GPT-4o, OpenAI) were used solely to assist with proofreading and editing the manuscript for clarity, grammar, and style. The AI did not generate original content, analyses, or interpretations, and all substantive ideas and conclusions are those of the authors.

Funding

This research did not receive any specific grant from funding agencies in the public, commercial, or not-for-profit sectors.

Data Availability

Data for this qualitative study include interviews and observations of individual health care providers, containing information that could compromise participant confidentiality. Full datasets are not publicly available. Deidentified excerpts, with all identifying information removed, may be made available upon reasonable request to the corresponding author, subject to ethical approval and data use agreements to ensure participant privacy.

Authors' Contributions

AHL and DN contributed to the conceptualization, data curation, formal analysis, and the writing of the study. KS and AKN contributed to the conceptualization, data curation, and the writing of the study. SMH contributed to the conceptualization, data curation, writing, and the supervision of the study.

Conflicts of Interest

SMH is a founder of T6 Health Systems, a health information technology company focusing on data collection and analysis during trauma resuscitation. All other authors declare that they have no competing interests.

Abstract

Background: In recent years, the incidence of cognitive diseases has also risen with the significant increase in population aging. Among these diseases, Alzheimer disease constitutes a substantial proportion, placing a high-cost burden on health care systems. To give early treatment and slow the progression of patient deterioration, it is crucial to diagnose mild cognitive impairment (MCI), a transitional stage.

Objective: In this study, we use autobiographical memory (AM) test speech data to establish a dual-modal longitudinal cognitive detection system for MCI. The AM test is a psychological assessment method that evaluates the cognitive status of subjects as they freely narrate important life experiences.

Methods: Identifying hidden disease-related information in unstructured, spontaneous speech is more difficult than in structured speech. To improve this process, we use both speech and text data, which provide more clues about a person's cognitive state. In addition, to track how cognition changes over time in spontaneous speech, we introduce an aging trajectory module. This module uses local and global alignment loss functions to better learn time-related features by aligning cognitive changes across different time points.

Results: In our experiments on the Chinese dataset, the longitudinal model incorporating the aging trajectory module achieved area under the receiver operating characteristic curve of 0.85 and 0.89 on 2 datasets, respectively, showing significant improvement over cross-sectional, single time point models. We also conducted ablation studies to verify the necessity of the proposed aging trajectory module. To confirm that the model not only applies to AM test data, we used part of the model to evaluate the performance on the ADReSSo dataset, a single time point semistructured data for validation, with results showing an accuracy exceeding 0.88.

Conclusions: This study presents a noninvasive and scalable approach for early MCI detection by leveraging AM speech data across multiple time points. Through dual-modal analysis and the introduction of an aging trajectory module, our system effectively captures cognitive decline trends over time. Experimental results demonstrate the method's robustness and generalizability, highlighting its potential for real-world, long-term cognitive monitoring.

KEYWORDS

mild cognitive impairment; longitudinal speech analysis; multimodal fusion; Alzheimer disease detection; deep learning; autobiographical memory test

Introduction

Alzheimer disease (AD) is a neurodegenerative disorder often associated with memory decline, language impairment, and a diminishing capacity to perform daily activities independently. However, AD remains incurable. Current research indicates that approximately 47 million people were diagnosed with dementia in 2015 [1], and it is expected that the number will triple by 2050 [2]. Such forecasts pose a significant burden on both patients' families and health care systems.

XSL•FO
RenderX

Within the spectrum of cognitive health, an intermediary stage exists between a state of normalcy and the onset of AD, denoted as mild cognitive impairment (MCI). Patients with MCI do not exhibit significant cognitive symptoms compared with those with AD. Those patients are still capable of performing daily activities independently. According to the study by Petersen et al [3], an estimated 16% of individuals with MCI progress to dementia within a year. Therefore, early identification of MCI holds significant value in instigating interventions aimed at impeding the advancement of dementia. However, the detection of MCI presents a notable challenge due to the subtle manifestation of its symptoms.

While biomarkers have demonstrated sensitivity in identifying MCI, such as positron emission tomography and magnetic resonance imaging [4,5], many of them necessitate invasive procedures. The associated costs of data collection for such methods are relatively high. Conversely, leveraging voice data for cognitive assessment offers a simpler and more suitable approach for long-term monitoring of cognitive status. Our approach relies on using autobiographical memory (AM) test data as the primary input [6], wherein interviewers engage participants in a series of questions and answers regarding their life experiences. This method, resembling a casual conversation, is more approachable than other psychological test methods because it reduces the testing stress experienced by participants.

Longitudinal analysis for MCI detection based on speech data remains relatively unexplored compared with other data types, such as magnetic resonance imaging, resulting in a scarcity of research in this area. The research proposed by Al-Hameed et al [7] focuses on extracting solely acoustic features from speech data collected across multiple visits from DementiaBank, which primarily pertains to speech associated with picture description tasks. They aim to predict participants' Mini-Mental State Examination scores and cognitive labels. Following feature selection, they used support vector machine or stochastic gradient descent for prediction. Integrating data from 3 visits achieved a 90% accuracy in distinguishing between healthy control (HC) and MCI in a binary classification task. However, due to label imbalance in the dataset, accuracy as a metric may not be entirely equitable. This study demonstrates that incorporating features from previous visits enhances prediction accuracy for subsequent visits.

Using the same dataset, another survey by Ammar et al [8] concentrates on extracting a wide range of linguistic features related to fluency and richness for Mini-Mental State Examination score prediction. However, unlike the former study, they do not leverage the correlation between previous visits. In the research proposed by Laguarta and Subirana [9], 16 physiological biomarkers were identified from speech data, represented in a personalized subject feature map. This feature map is capable of illustrating and monitoring cognitive changes over time. Achieving 93.6% accuracy in the ADReSS datasets, this study is the only one among them that visually depicts cognitive decline.

Yamada et al [10] used phone calls for long-term participant tracking, manually transcribing the conversations to extract linguistic features. They focused on extracting topic and word repetition features across different calls. Their model achieved an area under the receiver operating characteristic curve (AUROC) of 0.91 in classifying between AD and HC. In our previous work proposed by Chang et al [11], the author first extracted traditional acoustic feature sets, extended Geneva Minimalistic Acoustic Parameter Set [12], from AM audio files collected across multiple visits. The author then used TabNet [13] to learn the cognitive information embedded within these feature sets. To further enhance the model, an aging alignment loss was applied, encouraging cognitive representations in the latent space to be closer to each other. The approach achieved an accuracy of 0.66 and an F_1-score of 0.64.

In this work, we use AM data as the primary input for our model. We analyze the AM data from both linguistic and acoustic perspectives and further establish an aging trajectory module (ATM). By introducing the ATM, which captures cognitive decline across different time points through direction embeddings, our framework provides more representative modeling of longitudinal changes. The key contributions of this work are summarized as follows:

1. Unlike most studies focusing on single time point analysis, this work introduces a longitudinal framework using AM speech data to track cognitive changes over time.
2. The system jointly analyzes linguistic and acoustic features from unstructured AM speech, offering a richer representation of cognitive status than unimodal approaches.
3. Proposed ATM, which models cognitive decline by aligning temporal features across visits through a specially designed alignment loss applied to direction embeddings.

Methods

Problem Setting

There are 2 problem settings in this work: longitudinal type and cross-sectional type. The longitudinal problem setting is our main focus. The cross-sectional problem setting evaluates whether our model is general enough to tackle different tasks of detecting cognitive impairment disease detection tasks.

Longitudinal Problem Setting

In our problem setting, we have the dataset D={D1,D2,…,DV}with the corresponding label set L={L1,L2,…,LV}, where V means the total visit times, and D_k means the dataset at the kth visit. Each D_k is expressed as Dk={x1,k, x2,k, …, xN,k}, where N represents the number of the subjects involved in the test, andxi,k={xi,k1, xi,k2, …,xi,kM} represents the M stories provided by subject i at the kth visit; note that the number of M may vary across different visits. The corresponding labels set Lk={l1,k, l2,k, …, lN,k} shows the cognitive status of each subject, with each $l_{i,k}$ indicating whether the subject is an HC or has MCI.

During the data preprocessing, we extract the feature set {xi,km,a, xi,km,t, xi,km,l} from the raw audio xi,km, where xi,km,a, xi,km,t, xi,km,l represents the acoustic feature set, textual data, and linguistic feature set, respectively. Subsequently, the model input is the sequential visit data defined

XSL•FO
RenderX

in equation 1, where xi,1m1∈ xi,1, xi,2m2∈ xi,2, and xi,VmV∈ xi,V.

(0)m2, . . xmV={xm1m1,xm2m2, . . xmVmV}

It is worth noting that stories from each visit are randomly paired across visits within each subject. This design ensures that the model learns subject-level temporal progression rather than relying on similarities driven by specific story topics or linguistic content. Random pairing is not an arbitrary source of noise but a deliberate mechanism aligned with our longitudinal modeling objective. Because story content varies substantially across visits and participants, enforcing semantic matching or averaging all embeddings within a visit would bias the model toward topic-dependent features, flatten meaningful variability in linguistic complexity, and increase the risk of overfitting to specific story topics. In contrast, random pairing operates strictly within each subject, preserving the temporal order while exposing the model to multiple sampled transitions across training epochs. This provides a richer distribution of temporal transitions, enabling the framework to learn visit-level cognitive progression directions that remain robust to story content and reflect each subject's distribution of linguistic changes over time.

Formally, our model can be viewed as a mapping function fW, where *W* represents the set of learnable parameters. The function fWprojects the input sequence {xi,1m1,xi,2m2,…,xi,vmv} into the label of the last visit l(i,V). In this study, the maximum number of visits per subject, *V*, is 3, following the available structure of the dataset.

Cross-Sectional Problem Setting

In the cross-sectional problem setting, the primary difference from the longitudinal problem setting is that data collected from the same subject at different interview visits are treated as data from independent subjects. Thus, we have the dataset D={x1,x2, …, xCN} with the corresponding label set L={l1,l2, …, lCN}, where CN is the sum of all subjects from all visits, and x_i represents the raw audio for the subject *i* with the cognitive label l_i. The cognitive label l_i indicates that the subject is either an HC or under the targeted condition (MCI or AD). During the data preprocessing, we extract the feature set {xia,xit,xil} from the raw audio x_i. Our cross-sectional model aims to map the model input {xia,xit,xil} into the cognitive label l_i.

Overview

The system overview is shown in Figure 1. The goal of the system is to detect the cognitive condition of subjects, specifically whether they have MCI, using speech data. Before training, the speech data first undergo data preprocessing, which involves converting the audio files to text using automatic speech recognition (ASR), extracting additional linguistic features, and deep learning–based acoustic feature extraction. These steps generate additional text data and acoustic data, which are then intertwined to form dual-modal data pairs serving as the input for the model training. In addition, to effectively capture the features of aging and enhance the detection of potential MCI, the model input should have speech data for this time as well as points of follow-up data. This philosophy leads to our proposed longitudinal analysis for MCI detection.

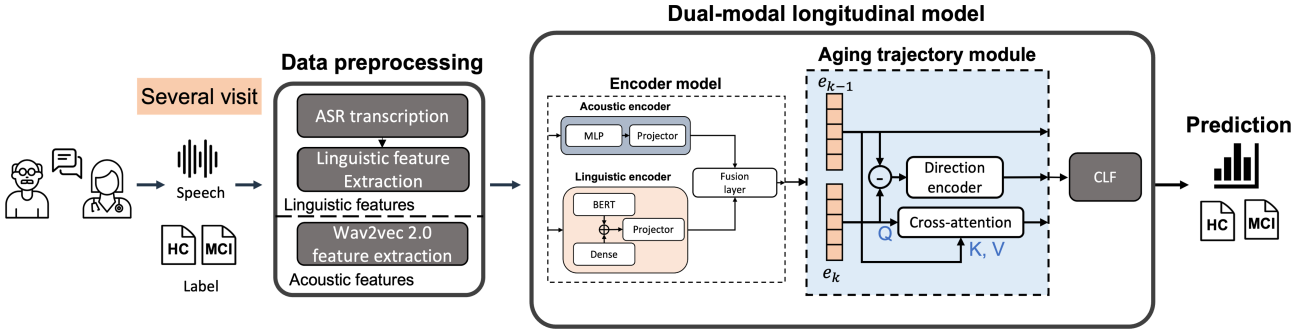

Figure 1. Overall framework of the proposed longitudinal multimodal model. The model consists of two main modules: (1) encoder model, combining a CNN-based acoustic encoder and a BERT-based linguistic encoder to generate fused multimodal embeddings; and (2) aging trajectory module, which models longitudinal changes between consecutive visits using a direction encoder and cross-attention before classification. ASR: automatic speech recognition; BERT: bidirectional encoder representation for transformer; CLF: classifier; CNN: convolutional neural network; HC: healthy control; MCI: mild cognitive impairment.

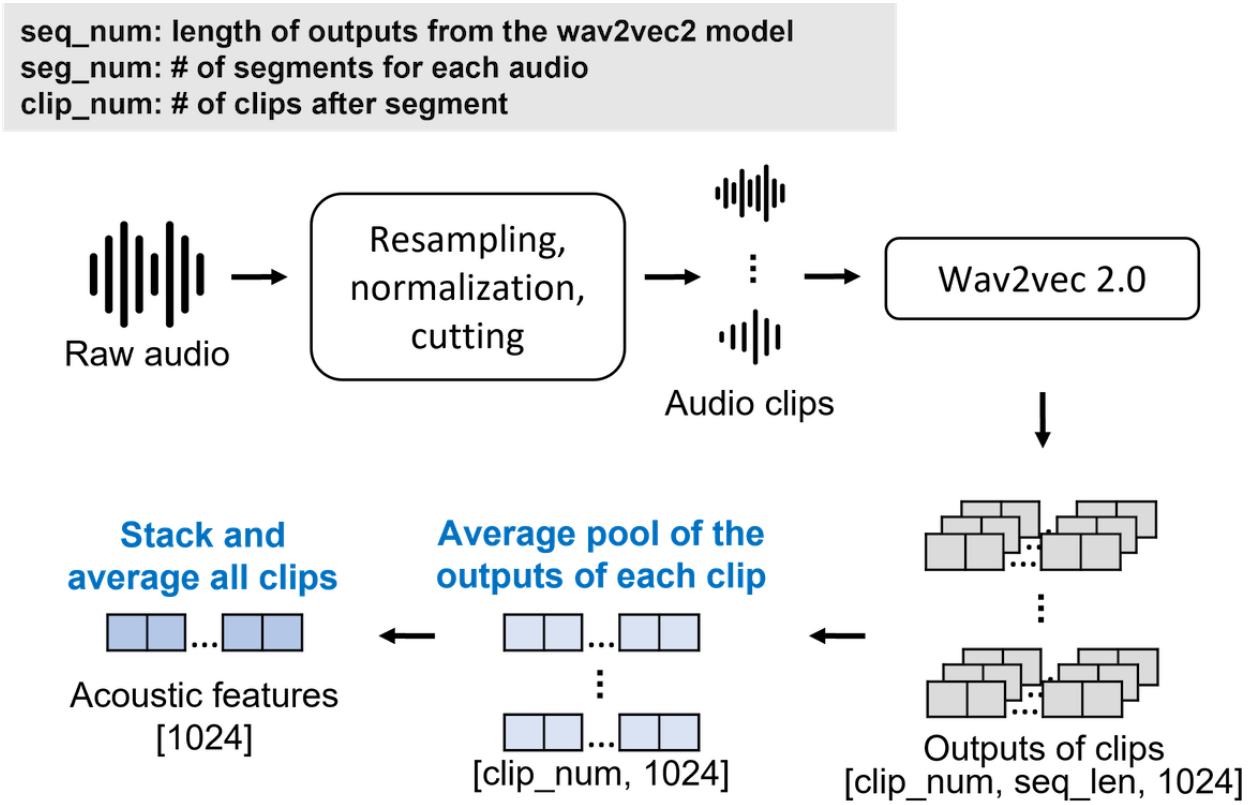
Data Preprocessing



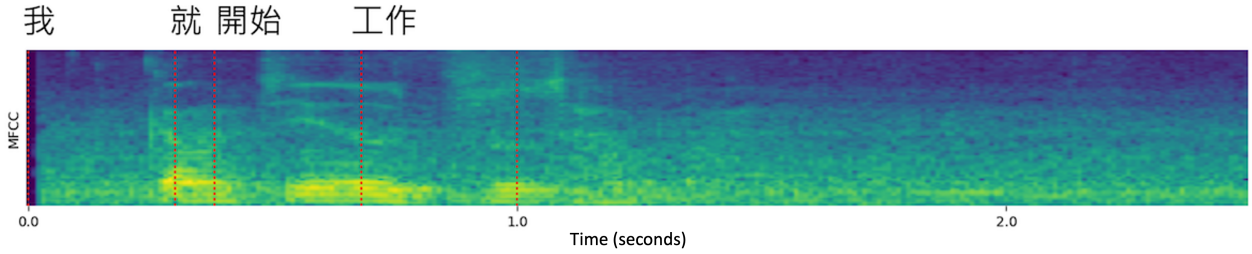
Before the data are input into the model, they need to be preprocessed to ensure data quality and to extract useful features. After data collection is completed, given that the data are based on the entire interview process of each subject during a single visit, we first segment each story recording from the interview. To prepare the audio file of each subject, we segment the audio files based on the story topics provided by the subject, cutting the corresponding recall and probing audio files.

Acoustic Feature Extraction

The preprocessing of audio data is shown in Figure 2. First, the notation xi,km denotes a raw audio waveform, which means the *m*th audio file of the subject *i* collected at the *k*th interview visit undergoes basic processing, including normalization and resampling. Normalization is done using zero-mean unit-variance normalization. Next, the audio is segmented into *t*-second clips with a 5-second overlap. Each audio file can be denoted as xi,km={xi,km,1,xi,km,2,…,xi,km,seg_num}, where seg_num represents the number of clips to which the raw audio file can be divided, and the total number of segments varies for each audio file.

XSL•FO
RenderX

Figure 2. Overview of acoustic preprocessing. Each raw audio recording is divided into multiple fixed-length clips and processed by the wav2vec2.0 feature extractor to obtain frame-level representations. For each segment, the outputs from all clips are stacked and averaged to produce a single clip-level feature. The averaged clip features are then pooled across segments to generate the final visit-level wav2vec2.0 embedding, which is used as input to the acoustic encoder.



In our research, wav2vec 2.0 model [14] is used as an acoustic feature extractor, and we leverage the pretrained model available on Hugging Face. Using the wav2vec 2.0 model in advance to extract deep acoustic representation features offers the advantage of saving memory space and making the subsequent model structure lighter, thereby increasing training efficiency. Each clip is fed into the wav2vec 2.0 model, producing an output with dimensions [seq_len, 1024], where seq_len is determined by the convolution layer in wav2vec 2.0 and the clip length, which is computed by dividing the clip length and the multiplication of the stride length in the convolution layers. After obtaining the output of each clip, the first average pooling is performed, resulting in a 1024-dimensional acoustic feature for each clip. Then, all clip outputs are stacked together, and a final average pooling is conducted to obtain the final acoustic features xi,km,a of the entire raw audio file; hence, the dimension of xi,km,a is 1024.

Linguistic Feature Extraction

The preprocessing of linguistic data can be divided into 2 stages: generating the transcript and extracting features from the generated text. Since not all audio files in the dataset have manual transcripts, we use ASR to generate the transcripts for our research. We use the open-source tool kit "whisper-timestamped," which provides both timestamps and the corresponding text, as illustrated in Figure 3. Previous research [15-17] has confirmed that pauses are an indicator in AD-related diseases, where patients with MCI or AD tend to exhibit more frequent and longer pauses. In our study, we classify pauses based on the interval duration between sentences into 3 types: short pause (duration <0.5 seconds), medium pause (duration between 0.5 and 2 seconds), and long pause (duration >2 seconds) [18]. In addition to pauses, we calculate the mean length of utterance, which is defined as the average number of words spoken in a sentence. In this step, we will generate transcripts with pause information and 4 numerical linguistic features. Besides pause information, we provide additional syntax information to enrich the linguistic features. Previous research [19] has shown that the sentence structures used by individuals with AD and HC are different. Therefore, we use part-of-speech (POS) tagging in this study. After generating the text, we use the open-source tool kit "ckipnlp" for word parsing and POS tagging. The text segments are then categorized into 5 POS types: noun,

XSL•FO
RenderX

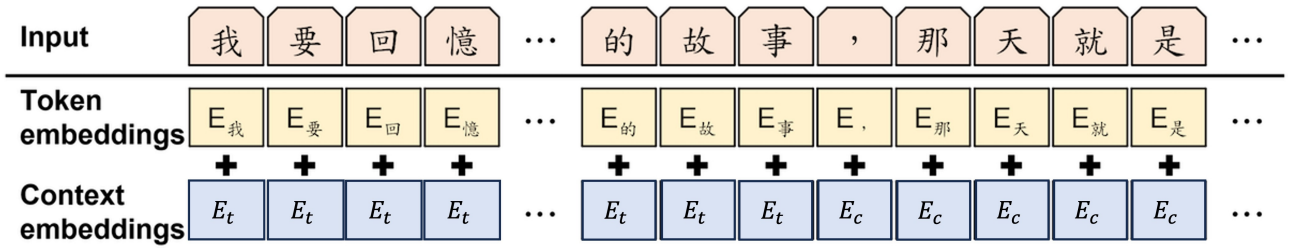
Figure 3. Example of how the result of whisper-timestamped, where the timestamp of the Mandarin speech is aligned with the transcript, is used for the temporal segmentation to extract linguistic features. MFCC: mel frequency cepstral coefficients.

verb, adjective, pronoun, and other. In this step, we count the total number of these POS taggers.

In addition, due to the nature of the AM test, subjects can share stories on unrestricted topics. To facilitate the model to capture more meaningful information from the transcripts, we apply the topic insertion technique proposed by our previous work [11,18]. This technique is to add a sentence with the mentioned topic at the beginning of the transcript, such as “I’m going to share a story of...” The tester specifies the topic during data collection. This step helps ensure that the subsequent transcript is thematic. After the whole preprocessing of linguistic data, from the raw audio xi,km, we finally obtain the transcripts with topics and pauses xi,km,t, along with 9 additional linguistic features xi,km,l, which include mean length of utterance; the number of short, medium, and long pauses; and 5 types of POS tags.

Encoder Module

Acoustic Encoder



During the data preprocessing stage, 1024-dimensional deep learning–based acoustic features, denoted as xi,km,a, were extracted using the wav2vec 2.0 model. These high-level representations were then passed to a lightweight convolutional neural network–based acoustic encoder designed to capture hierarchical temporal-spectral patterns. The encoder consists of three 1D convolutional layers with kernel size 3 and stride 1, each followed by batch normalization, rectified linear unit activation, and max-pooling with a kernel size and stride of 2, progressively reducing the feature resolution by a factor of 8. The convolutional layers use 16, 32, and 64 filters, respectively, to model increasingly abstract local dependencies in the acoustic embedding. The resulting feature maps are flattened and projected through a fully connected layer that maps the representation to a 128-dimensional latent space. This projection enhances computational efficiency, mitigates overfitting, and provides a compact and informative acoustic embedding ai,km for multimodal fusion.

Linguistic Encoder

In the linguistic encoder, the ASR transcript xi,km,t and 9-dimension features xi,km,l generated during data preprocessing are sent to the BERT [20] model and a linear layer, respectively, for initial encoding. During data preprocessing, to ensure that the subjects’ speech has a thematic structure, we add a topic at the beginning of the transcript. In BERT, we borrow the concept of segment embeddings from the original paper [20]. Here, we refer to it as “context embedding” to enhance the model’s understanding of the topic and content. We divide the transcript into 2 parts: topic and context. The topic part is labeled as 0, and the context part as 1. These values are then encoded into context embeddings E_t and E_c through a learning embedding layer. This design helps the model determine whether there is a sufficient correlation between the topic and content. Research in AM tests indicates that episodic memory significantly declines in patients with cognitive impairments [21,22]. Therefore, we can assess the subject’s cognitive state by examining whether the subject’s story contains details related to the topic.

As illustrated in Figure 4, context embeddings are element-wise added to the original BERT token embeddings for further processing. A linear layer is used as a numerical encoder for linguistic features xi,km,l. Finally, the output from BERT and the learned numerical embeddings are concatenated and processed through a projector to obtain the final linguistic embedding ti,km.

Figure 4. Overview of the BERT embedding. Each input token is first mapped to a token embedding, which is combined with additional context embeddings to capture both semantic meaning and conversational context. BERT: bidirectional encoder representation for transformer.

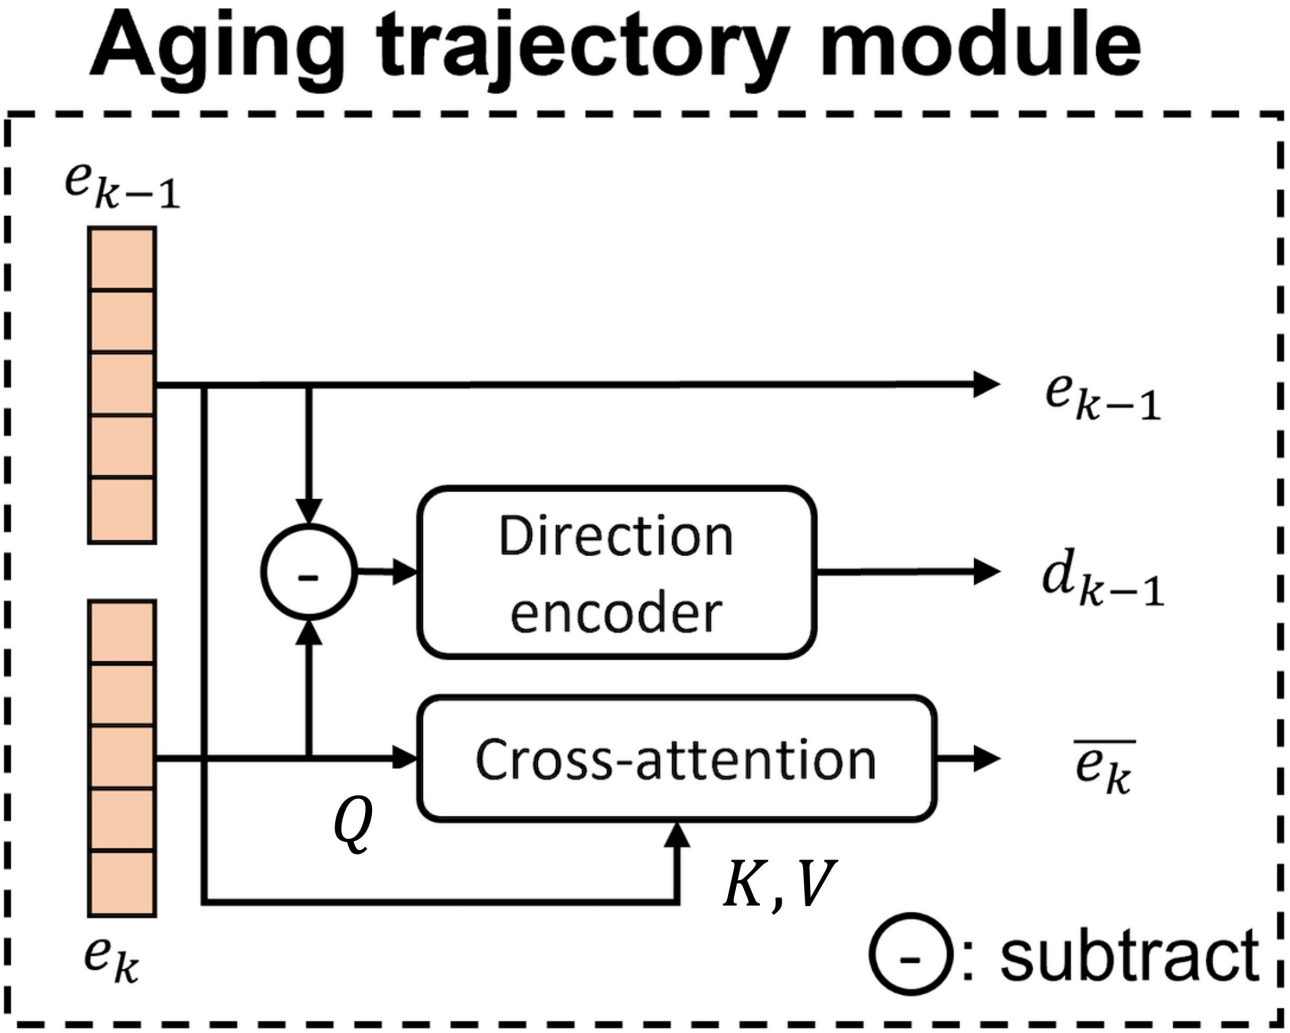
RenderX

Fusion Layer

In this study, we adopt a self-attention fusion method to enable the model to capture information between different modalities more effectively. The concept is illustrated in Figure 5. After obtaining the acoustic embedding ai,km and the linguistic embedding ti,km, these 2 embeddings are added together to form a combined representation, which is then fed into a multihead self-attention layer. Through the calculations of the self-attention layer, we obtain the final integrated embedding ei,km. This design helps the model capture deeper interrelated information between different features.

Figure 5. Overview of the fusion layer. Acoustic and linguistic embeddings are integrated through a multihead attention mechanism, producing a joint embedding that captures cross-modal interactions and complementary cognitive cues.



Aging Trajectory Module

The ATM is a key component of our longitudinal model, designed to capture cognitive changes across multiple visits. The structure is shown in Figure 6. In our study, each subject contributes up to 3 visits. Therefore, the model's initial input is in the form of a triplet, {xi,1m1, xi,2m2,xi,3m3}. After passing them through the encoder model process, this becomes the embedding triplet of the same form, {ei,1m1, ei,2m2,ei,3m3}. In this module stage, the embeddings are fed in pairs, such as {ei,1m1,ei,2m2}or {ei,2m2,ei,3m3}, so that the model focuses on learning the relationship between visits *k* and *k*-1. To model these relationships, we use a cross-attention mechanism, where the embedding from the *k*th visit serves as the query (*Q*), and the embedding from the (*k*-1)th visit serves as the key (*K*) and value (*V*). This mechanism allows us to capture the differences in feature values between 2 visits. The reason for using the *k*th visit embedding as the query and the (*k*-1)th visit embedding as the key and value is that, in practice, we can retrieve information only from the past data and not future data. This approach ensures that the model can access information only from the previous visits, reflecting a realistic scenario where future data are unavailable. By doing so, the model learns to focus on the most relevant past information that can be referenced by the current visit, enabling the tracking of changes and peeking of patterns of cognitive decline over time. This method effectively highlights the differences and similarities between visits, providing a more nuanced understanding of the subject's cognitive progression.

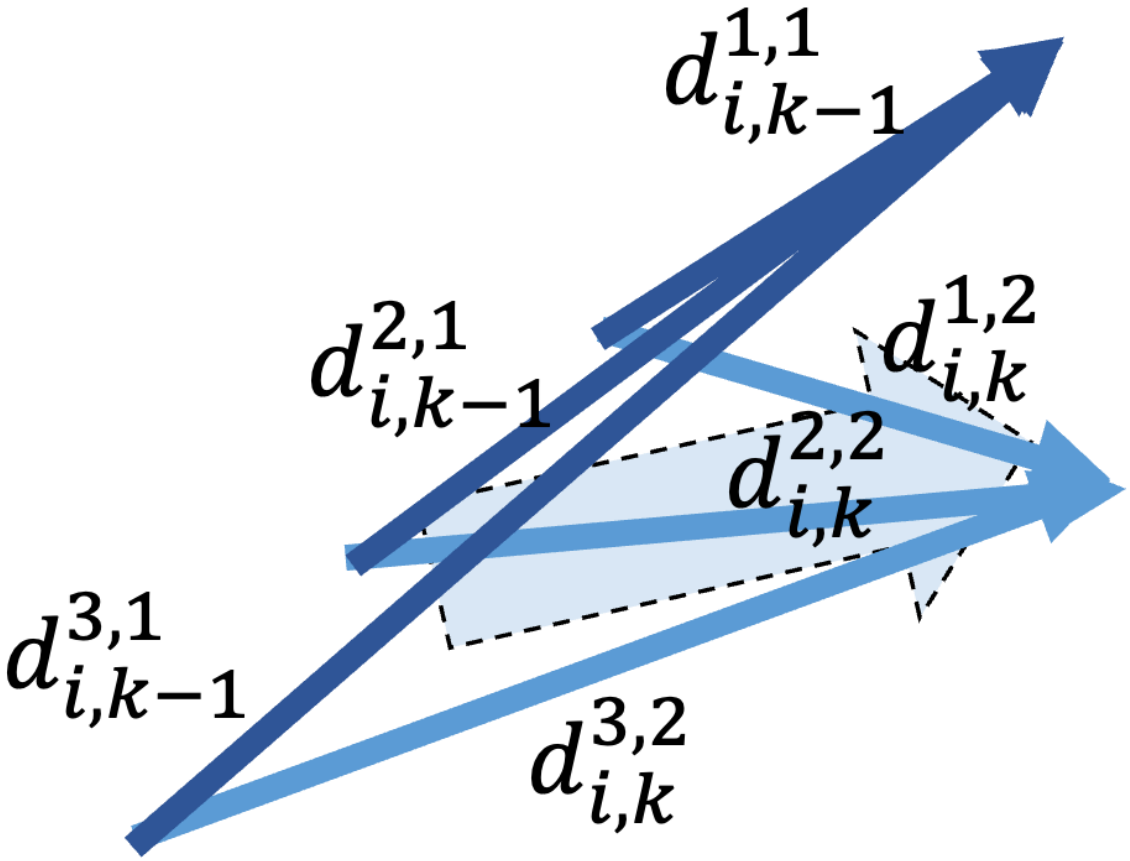
XSL•FO
RenderX

Figure 6. Overview of the aging trajectory module. Consecutive visit embeddings are compared through cross-attention and a direction encoder to capture cognitive differences between visits.

The concept of contrasts is quite straightforward. We aim to explore a deeper understanding of the relationship between the (*k*-1)th and *k*th visits. To achieve this, we use a cross-attention mechanism. In this setup, the embedding from the *k*th visit is used as the query (*Q*), whereas the embedding from the (*k*-1)th visit serves as the key (*K*) and value (*V*). This mechanism allows us to capture the differences in feature values between 2 visits. The reason for using the *k*th visit embedding as the query and the (*k*-1)th visit embedding as the key and value is that, in practice, we can retrieve information only from the past data and not future data. This approach ensures that the model can access information only from the previous visits, reflecting a realistic scenario where future data are unavailable. By doing so, the model learns to focus on the most relevant past information that can be referenced by the current visit, enabling the tracking of changes and peeking of patterns of cognitive decline over time. This method effectively highlights the differences and similarities between visits, providing a more nuanced understanding of the subject's cognitive progression.

To quantify the differences between visits, we introduce a direction encoder f_D, composed of several linear layers. The difference between embeddings is projected into a latent space to represent an aging-oriented change vector *d*, formulated as equation 2, where di,k−1mk−1,mk means the direction from mk-1th story in the (*k*-1)th visit to the mkth story in the *k*th visit. mk=1,2,…,Mi,k, where Mi,k is the total number of stories for subject *i* in the *k*th visit. Similarly, mk-1=1,2,…,Mi,k-1, where Mi,k-1 is the total number of stories for subject *i* in the (*k*-1)th visit.

(2)di,k−1mk−1,mk= fD(ei,kmk−ei,k−1mk−1)



In addition, during the training process, motivated by the research [11,23,24], we introduce 2 types of losses: subject alignment loss and group alignment loss. These alignment losses are designed to align both individual and group targets, helping the direction encoder learn more accurate aging-oriented changes. We expect that by applying these losses, the resulting direction *d* will carry more representative meaning, aiding the longitudinal model in accurately assessing the subject's cognitive condition.

Subject Alignment Loss

In the subject alignment loss L_S, the concept is to ensure that the same subject's internal directions are similar. In our problem setting, the stories of the input triplet are randomly paired in different visits. Therefore, it is expected that the directions from the same subject may vary in the latent space. However, the cognitive decline of a subject should be consistent. Figure 7 shows an illustration of the concept.

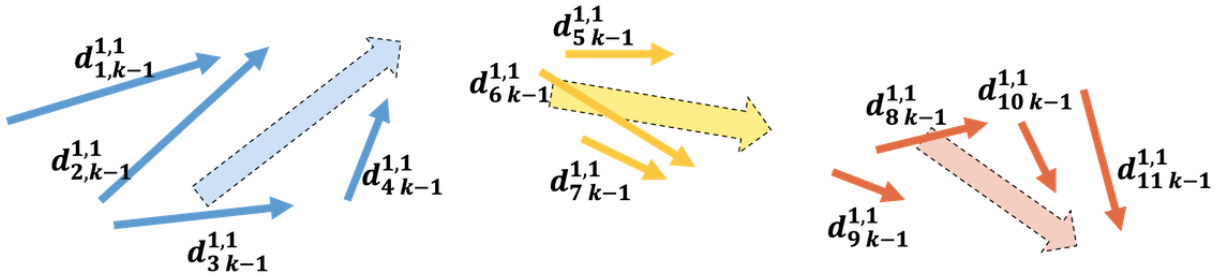
XSL•FO
RenderX

Figure 7. Illustration of the concept for subject alignment loss. It visualizes how the subject alignment loss ensures that the overall trajectory directions of the subject remain consistent, although the internal trajectory of story-level embeddings for the same subject may show slight variations across different visits.

Therefore, subject alignment loss aims to reduce the differences in direction within the same subject. The loss used here is cosine similarity loss. The process of calculating the subject alignment loss is to first calculate the average subject direction for each visit as shown in equation 2. We then compute the subject alignment loss by summing the alignment loss of all subjects as defined in equation 3. The generalized subject alignment loss is defined as equation 3, where di,k−1− represents the average direction of every audio file in the (*k*-1)th visit to *k*th visit from the subject *i* in the latent space, and *N* represents the total number of subjects. $L_{S,i}$ represents the subject alignment loss for subject *i*, and cos θA,B=A.BAB is the cosine similarity function. In our case, since the dataset contains 3 visits, our *V* is 3, and the loss is applied to the pairs (first visit and second visit) and (second visit and third visit).

(3)di,k−1−=1Mi,k−1×Mi,k∑mk=1Mi,k∑mk−1=1Mi,k−1di,k−1mk−1,mk

LS=∑i=1NLS,i



(4) =∑i=1N∑k=2V∑mk=1Mi,k∑mk−1=1Mi,k−11−cosθ(di,k−1−,di,k−1mk−1,mk)

Group Alignment Loss

In the group alignment loss L_G, the concept is to ensure that subjects with the same cognitive label have similar cognitive progression changes as illustrated in Figure 8. Unlike the subject alignment loss, which focuses on the internal alignment of directions within a subject, the group alignment loss emphasizes the external alignment of directions between different subjects. Specifically, we compare the cognitive change directions of subjects with the same label transitions. Here, we use the Supervised Contrastive Loss (SupConLoss) [25] to encourage the directions of subjects with the same label changes to be closer to one another. The label transitions considered are HC to HC, HC to MCI, and MCI to MCI. The process of calculating the group alignment loss is using equations 5 and 6, where *N* represents the total number of subjects, and $L_{G,i}$ represents each group alignment loss for subject *i*. SupConLoss(·, ·) is the SupConLoss function. lk-1,ki is the label transition type of subject *i* from (k − 1)th visit to *k*th visit.

XSL•FO
RenderX

Figure 8. Illustration of the concept for group alignment loss. It visualizes how the group alignment loss enforces consistency in progression directions among subjects sharing the same cognitive label. Blue represents the group from healthy control (HC) to HC, yellow represents the group from HC to mild cognitive impairment (MCI), whereas orange represents the group from MCI to MCI.

(6)LG=∑i=1NLG,i=∑i=1N∑k=2V∑mk=1Mk1Mk−1SupConLoss(ei,mk−1,mk,ik)

(6)LG=∑i=1NLG,i=∑i=1N∑k=2V∑mk=1Mk1Mk−1SupConLoss(ei,mk−1,mk,ik)

To summarize, group alignment loss L_G aims to minimize the distance between the cognitive progression directions of different subjects with the same cognitive label transitions types. This helps ensure that subjects exhibiting similar cognitive changes have consistent representations, thereby improving the model's ability to generalize across different subjects. By leveraging SupConLoss, we can effectively capture and align these progression patterns, leading to more accurate and robust cognitive state predictions.

Classifier and Overall Loss

After the ATM, we obtain the final outputs {e−i,1m1,e−i,2m2,e−i,3m3,di,1m1,m2, di,2m2,m3}, where e−i,kmk represents the enhanced latent representation after the cross-attention layer. These representations are then concatenated and fed into a classifier. The classifier comprises a batch normalization layer and a fully connected layer to produce the final prediction. Finally, the overall loss function can be formulated by equation 7, where Lclass is the binary classification loss, and α, δ, and γ are the hyperparameters of loss weight for L_E, L_G, and L_S, respectively. The hyperparameters are fine-tuned, and the optimal values are 0.01, 0.001, and 0.001.

(7)L= Lclass+αLE+δLG+γLS

The encoder loss L_E is a contrastive loss designed to enhance the representativeness of the embeddings generated by the encoder and is defined by equation 8, where N is the total number of the subjects, V is the total number of visits, and M_k is the total number of stories in the kth visit. This loss ensures that embeddings with the same cognitive status are closer to one another while pushing apart embeddings with different labels.

(8)LE=∑i=1NLE,i=∑i=1N∑k=2V∑mk=1MkSupConLoss(ei,mk,ik)

Dataset

Dataset Collection

Our experiments primarily focus on comparisons using our self-collected National Taiwan University Autobiographical Memory Test (NTU-AM) dataset. Previous studies [6,11,26,27] have confirmed that the AM test effectively tracks changes in cognitive function by evaluating subjects' memory functions. It can be used as a tool for MCI testing. During the test, subjects are asked to recall important life stories from different periods in their past. Compared with formal memory testing methods, this process resembles a general conversation, which helps reduce the stress experienced by subjects.

For the collected data used in this study, professional psychologists conducted one-on-one interviews. During these interviews, a microphone is used to record the conversation between the subject and the interviewer. Furthermore, subjects are asked first to talk about the titles of the important events they want to share (eg, "I want to share the story about when I was admitted to college at the age of 18 and my test result were announced"). The process of describing the events can be divided into two stages, namely, recall and probing.

1. Recall: The subject is first asked to roughly describe the events leisurely and then is encouraged to share as many details of the event as possible.
2. Probing: The interviewer then asks even more detailed questions based on what the subject mentioned in the recall stage. These questions cover various categories, such as "what," "when," "where," emotion or thought, and time integration.

During a single interview, the same subject can share multiple stories as a matter of fact. To sum up, the overall process of the AM interview test can be described as follows: (1) the subject decides the number and content of stories to be shared, (2) shares the recall content of each story, and then (3) the interviewer probes each story with a series of detailed questions.

Moreover, to track the cognitive changes of subjects over a long term, they are invited to take the AM test again after at least 6 months. In our current research, our longitudinal data include up to 3 rounds of AM interview test data, that is, each subject has 1 test data and 2 follow-up data. All data were collected by professional psychologists with institutional review board approval, ensuring high-quality data.

The National Taiwan University Autobiographical Memory Test Cross-Sectional (NTU-AM-CS) dataset was collected under a cross-sectional scenario, with the demographic distribution of participants shown in Table 1. This dataset includes 111 subjects, consisting of 56 HC and 55 MCI participants. Each participant could provide multiple important life stories during a single visit.

XSL•FO
RenderX

Table . The demographic distribution of participants in the National Taiwan University Autobiographical Memory Test Cross-Sectional dataset.

Group	N	Male	Female	Age (years), mean (SD)	Years of education, mean (SD)	MMSE[a], mean (SD)
HC[b] (n=56)	56	18	38	71.3 (5.4)	16.2 (9.8)	28.7 (1.6)
MCI[c] (n=55)	55	17	38	70.7 (6.9)	13.1 (7.1)	27.1 (2.0)
Total (N=111)	111	35	76	71.0 (6.2)	14.6 (8.7)	27.9 (2.0)

[a]MMSE: Mini-Mental State Examination.

[b]HC: healthy control.

[c]MCI: mild cognitive impairment.

The longitudinal scenario dataset, National Taiwan University Autobiography Memory Test Longitudinal (NTU-AM-LG), involves 54 of the original 111 subjects who participated in follow-up studies, including 28 HC and 26 MCI participants. The types of data collected are the same as in the cross-sectional scenario, encompassing both recall and probing audio files. The key difference is that NTU-AM-LG includes story audio files from 3 visits. The demographic distribution for this dataset is also shown in Table 2.

Table . The demographic information of the National Taiwan University Autobiography Memory Test Longitudinal dataset.

Group (N=54)	Male	Female	Age (years), mean (SD)	Years of education, mean (SD)	MMSE[a], mean (SD)
HC[b] (n=28)	12	16	74.0 (5.9)	14.3 (2.7)	28.4 (1.5)
MCI[c] (n=26)	7	19	72.5 (6.4)	14.0 (9.6)	27.5 (1.9)

Ethical Considerations

The collection of experimental data from human participants was reviewed and approved by the National Taiwan University Hospital Research Ethics Committee B (protocol no. 202105013RINB, approved on June 18, 2021). All participants provided written informed consent prior to data collection. The original consent and institutional review board approval explicitly permitted the secondary analysis of deidentified recordings and transcripts for research purposes, without requiring additional consent. All data were fully deidentified before analysis, and no personal or identifiable information was retained in the research dataset. Participant privacy was protected by storing all files on secure, access-restricted servers, and only aggregated results are reported. Participants received NTD 160 (equivalent to US $5.09) per hour as compensation for their time and contribution. No identifiable participant images are included in this manuscript.

Experiment Dataset

The summary of the collected dataset can be provided. The total number of datasets is shown in Table 3, where the unit of measurement is the number of stories. Since each story includes both recall and probing phases, the quantities are identical for recall and probing data.

Table . Primary dataset statistics.

Dataset	Visit 1		Visit 2		Visit 3		Total	
	HC[a]	MCI[b]	HC	MCI	HC	MCI	HC	MCI
NTU-AM-CS[c]	134	122	N/A[d]	N/A	N/A	N/A	134	122
NTU-AM-LG[e]	44	30	50	40	76	54	170	124

[a]HC: healthy control.

[b]MCI: mild cognitive impairment.

[c]NTU-AM-CS: National Taiwan University Autobiography Memory Test Cross-Sectional.

[d]N/A: not applicable.

[e]NTU-AM-LG: National Taiwan University Autobiography Memory Test Longitudinal.

XSL•FO
RenderX

NTU-AM-CS is a cross-sectional dataset that includes a total of 111 subjects (56 HCs and 55 with MCI). Each subject participated in a single AM interview, during which they could share multiple stories. Therefore, NTU-AM-CS does not include repeated follow-up visits.

NTU-AM-LG is the longitudinal subset derived from NTU-AM-CS. A portion of participants agreed to return for additional follow-up interviews, resulting in up to 3 visits per subject. As shown in Table 3, the number of stories per visit varies because the volume of data depends on how many stories participants chose to share during each session. In some cases, more stories were collected in visit 3 than in earlier visits, which explains the higher data volume observed.

To further clarify disease progression patterns, the number of subjects transitioning across cognitive status categories between visits, including stable (HC→HC, MCI→MCI) and progressive or recovered (HC→MCI, MCI→HC) cases, is shown in Table 4.

Table . Cognitive status transitions between consecutive visits in the National Taiwan University Autobiography Memory Test Longitudinal dataset across visits 1 and 2 and visits 2 and 3.

Transition	Number of cases (subject based), n =108
HC[a] to HC	50
HC to MCI[b]	10
MCI to HC	8
MCI to MCI	40

[a]HC: healthy control.

[b]MCI: mild cognitive impairment.

For additional experiments, we primarily used a semistructured speech dataset. The National Taiwan University Hospital Picture Description Test (NTUH-PIC) and National Taiwan University Hospital Memory Test (NTUH-MEM) datasets, which we collected ourselves, include speech data from picture description and logical memory tests, respectively. Both datasets feature 2 cognitive labels: HC and MCI. In the picture description task, participants are required to describe the scenario depicted in a specific picture as accurately and detailed as possible. In the NTUH-PIC dataset, the well-known "cookie theft" picture [28] is used. For the logical memory test, participants first listen to a story and then must repeat it from memory. The third dataset, ADReSSo [29], was introduced as part of the cognitive challenge at INTERSPEECH 2020. This dataset also involves a picture description test, which also used "cookie theft" [28] but differs from the other datasets in that it includes only 2 cognitive labels: HC and AD. Due to data access limitations, we used only the training set for evaluation in this case. By incorporating these additional datasets, we aim to comprehensively evaluate the robustness and generalizability of our model across various types of speech data and cognitive assessments. The statistics of the additional dataset are shown in Table 5.

Table . Additional dataset statistics.

Dataset	Total	HC[a]	MCI[b]	Language	Test
NTUH-PIC[c]	80	40	40	Chinese	Picture Description Test
NTUH-MEM[d]	104	52	52	Chinese	Logical Memory Test

[a]HC: healthy control.

[b]MCI: mild cognitive impairment.

[c]NTUH-PIC: National Taiwan University Hospital Picture Description Test.

[d]NTUH-MEM: National Taiwan University Hospital Memory Test.

Experiments

We conducted a series of experiments to evaluate our proposed longitudinal multimodal model under different data conditions and to verify the contribution of each model component.

Experiments on NTU-AM-LG

We evaluated the model on the longitudinal NTU-AM-LG dataset using 2 speaking tasks: recall and probing. For each task, we compared four variants of our model:

1. Ours (audio): acoustic branch only, wav2vec 2.0 to acoustic encoder to classifier.
2. Ours (text): linguistic branch only, BERT to linguistic encoder to classifier.
3. Ours (CS): cross-sectional problem setting
4. Ours (LG): full proposed longitudinal multimodal model with direction encoding and alignment losses.

XSL•FO
RenderX

These models were compared against standard baselines (BERT, wav2vec 2.0, and the prior AM-based work [11]), and the corresponding results are reported in the "Results" section.

An ablation study on NTU-AM-LG is made to examine the contribution of the ATM, direction embedding, and the 2 alignment losses, and we performed ablation experiments by removing (1) the direction, (2) the subject alignment loss, (3) the group alignment loss, and (4) both alignment losses.

Experiments on NTU-AM-CS

To demonstrate that the proposed encoders and fusion strategy also work without longitudinal information, we trained the same acoustic and linguistic encoders in the cross-sectional problem setting (Our [CS]) and compared them with BERT, wav2vec 2.0, and the prior AM method [11]. An ablation study is also conducted to highlight the importance of linguistic features and context embeddings.

Experiments on Additional Datasets

We further tested whether our proposed model transfers to other cognitive-speech datasets (NTUH-PIC and NTUH-MEM). We compared our method with that of Lin et al [18].

Finally, to enable comparison with existing AD or MCI speech work on a public dataset, we evaluated our model on the ADReSSo corpus.

Experimental Setup

In the subsequent experiments, due to the limitations of the dataset size, we will present the averaged performance of 10-fold cross-validation. To avoid data leakage, we will split the training set and validation set by subject for the NTU-AM-CS and NTU-AM-LG datasets. It ensures that audio files from different visits of the same subject will not appear in the training set and validation set simultaneously.

For the NTUH-PIC, NTUH-MEM, and ADReSSo datasets, since each subject provides only 1 audio file, there is no need to split the data by subject. We will perform down-sampling on the majority class in the training set during the experimental process to stabilize the model's learning capability. All experiments are conducted on an NVIDIA RTX 4090 GPU.

Evaluation Metrics

In the experimental section, we will use 6 different evaluation metrics to measure the performance of the model: accuracy, F_1-score, precision, sensitivity (recall), specificity, and AUROC. These are common indicators used to assess the predictive ability of a model. Each metric provides a different perspective on the effectiveness of the model.

In the NTU-AM dataset, since the dataset is split by subject, each evaluation set from every fold may have a similar number of subjects, but the number of audio files provided by each subject can vary. This can result in label imbalance in the final soft-voting results. Therefore, the most critical metrics in the subsequent experiments will be F_1-score and AUROC. These 2 metrics provide a fairer assessment in situations with label imbalance. As for other experiments, the primary metrics of interest will be accuracy and F_1-score.

Baseline

In the subsequent experiments in the NTU-AM dataset, we will use a fine-tuned BERT model and the wav2vec 2.0 model as baselines. Since these 2 models are the backbones of our proposed model, in the NTU-AM-LG dataset, the baseline model will be composed of these 2 main models as encoders. The embeddings generated from the 3 visits will be concatenated and passed through the same classifier. For the NTU-AM-CS dataset, the backbone model will serve as the encoder, followed by a classifier. However, these models will not have additional loss functions to assist training during the training process, relying only on the basic binary cross-entropy loss.

Implementation Details

The probing data are interview data, which include both the interviewer's and the subject's voices. Since our study aims to determine whether the subject has a tendency for MCI based on their audio data, the interviewer's speech is considered noise during training. To remove the interviewer's portion, we use the tool kit "pyannote" to split the audio into different speaker segments. This process results in audio files without the interviewer's voice. These cleaned files are then used to generate the linguistic features during the data preprocessing stage.

We used the "openai/whisper-large-v2" version from Hugging Face for the ASR tool. For data preprocessing, the pretrained Wav2vec 2.0 model used for the English dataset is "facebook/wav2vec2-base-960h," while for the Chinese dataset, we used "jonatasgrosman/wav2vec2-large-xlsr-53-chinese-zh-cn," which are also from HuggingFace. We used a 15-second clip segmentation with a 5-second overlap. Considering the limitations of the Wav2vec model, we resampled the audio files to 16,000 Hz and standardized them to mono-channel.

For the linguistic model, the BERT model used for the English dataset is "google-bert/bert-base-uncased," and for the Chinese dataset, it is "hfl/chinese-bert-wwm-ext," which is also the version used for the BERT baseline. In the Wav2vec baseline model, we used "jonatasgrosman/wav2vec2-large-xlsr-53-chinese-zh-cn." The hyperparameters used for implementing the proposed model are shown in Table 6.

Batch size for training	8
Batch size for evaluation	8
Maximum epoch number	150
Early stop	10
α for encoder loss	0.01
δ for group alignment loss	0.001
γ for subject alignment loss	0.001

[a]BERT: bidirectional encoder representation for transformer.

Results

Results of NTU-AM-LG

We experiment with the model's effectiveness on both recall and probing data. Given the limited research on longitudinal speech, we primarily compare our model against baselines such as BERT, Wav2vec 2.0, and the unimodal model within our longitudinal framework. In addition, we present an ablation study to demonstrate the necessity of each component in our model. We discuss the results for recall data and probing data separately. It is important to note that both the cross-sectional (CS) and longitudinal (LG) models are trained on the same NTU-AM-LG dataset, sharing identical subjects and feature representations. The difference lies only in the problem formulation: the CS model performs single-visit classification, while the LG model performs a prognostic task that leverages prior visit embeddings to predict the final cognitive state. Thus, the performance difference reflects the use of incorporating longitudinal context rather than architectural or data disparities.

Table 7 shows the performance of our proposed model and the baselines for the recall data. First, when the input consists only of audio data, our proposed model "Ours (audio)" outperforms the previous work [11] on most metrics. Notably, there are improvements of 5% and 6% in F_1-score and AUROC, respectively.

[a]AUROC: area under the receiver operating characteristic curve.

[b]Highest value for each metric.

[c]BERT: bidirectional encoder representation for transformer.

[d]CS: cross-sectional.

[e]LG: longitudinal.

As for the model using only linguistic data as input, our proposed linguistic longitudinal model, denoted as "Ours (text)," outperforms BERT, demonstrating that including extra-linguistic features and context embedding helps improve the model's performance with 7% increase in the F_1-score.

Finally, our model, which is denoted as "Ours (LG)" in Table 7, significantly outperforms other models across most metrics for the dual-modal longitudinal model that combines both data types. Specifically, there is up to a 16% improvement in accuracy, a 14% improvement in F_1-score, and a 22% improvement in AUROC. Since the previous work used only unimodal data, examining AM data from different perspectives benefits MCI detection. We also compare the cross-sectional setting results of NTU-AM-LG, denoted as "Ours (CS)" in Table 7, with the longitudinal settings, confirming that long-term tracking of subjects' cognitive trajectories in NTU-AM-LG helps improve the model's prediction accuracy. Specifically, there are improvements of 10% in accuracy, 6% in F_1-score, and 19% in AUROC.

Table 8 shows the results of the probing data. For the audio data, our proposed model outperforms wav2vec 2.0 in most metrics, with improvements of 9%, 18%, and 10% in accuracy, F_1-score, and AUROC, respectively. This indicates that instead of directly using wav2vec 2.0's output representation for classification, extracting features using wav2vec 2.0 followed by a convolutional neural network–based acoustic encoder structure can better capture the hidden cognitive patterns in audio data.

Ours (CS[c])	0.71	0.67	0.61	0.75	0.63	0.68
Ours (LG[d])	0.89[e]	0.83[e]	0.90[e]	0.82[e]	0.95[e]	0.89[e]

[a]AUROC: area under the receiver operating characteristic curve.

[b]BERT: bidirectional encoder representation for transformer.

[c]CS: cross-sectional.

[d]LG: longitudinal.

[e]Values in boldface are the highest values for each metric.

For the linguistic data results, our model performs comparably with BERT, with improvements of 8%, 3%, and 10% in F_1-score, precision, and sensitivity, respectively. This suggests that the inclusion of linguistic features and the context embedding layer can also aid in MCI detection on probing data.

Finally, in the dual-modal data tests, the proposed longitudinal model achieved the best performance, excelling in every metric. Specifically, it showed improvements of up to 13%, 30%, and 19% in accuracy, F_1-score, and AUROC, respectively. Comparing the longitudinal model with the cross-sectional model, it is evident that the longitudinal model continues to perform better. This indicates that incorporating input from multiple time points and considering the concept of aging direction can enhance the model's predictions, resulting in performance increases of 12%, 16%, and 21% in accuracy, F_1-score, and AUROC, respectively.

Ablation Study

In the longitudinal setting, the most crucial idea is the alignment loss we proposed. Therefore, this section examines the contribution of alignment loss by removing each loss individually. The results are shown in Table 9. In the table, "Without direction" refers to not including direction embedding as the classifier input; namely, the input would be ei,1m1, ei,2m2, ei,3m3 treating each time point's data as independent.

XSL•FO
RenderX

Table . Result of the ablation study for our proposed model on National Taiwan University Autobiography Memory Test Longitudinal dataset.

Method	Accuracy	F_1-score	Precision	Sensitivity	Specificity	AUROC[a]
Recall data						
Without direction	0.79	0.74	0.71	0.83	0.67	0.75
Ours (LG[b])	0.82[c]	0.78[c]	0.95[c]	0.72	0.97[c]	0.85[c]
Subject alignment loss	0.71	0.67	0.68	0.77	0.63	0.70

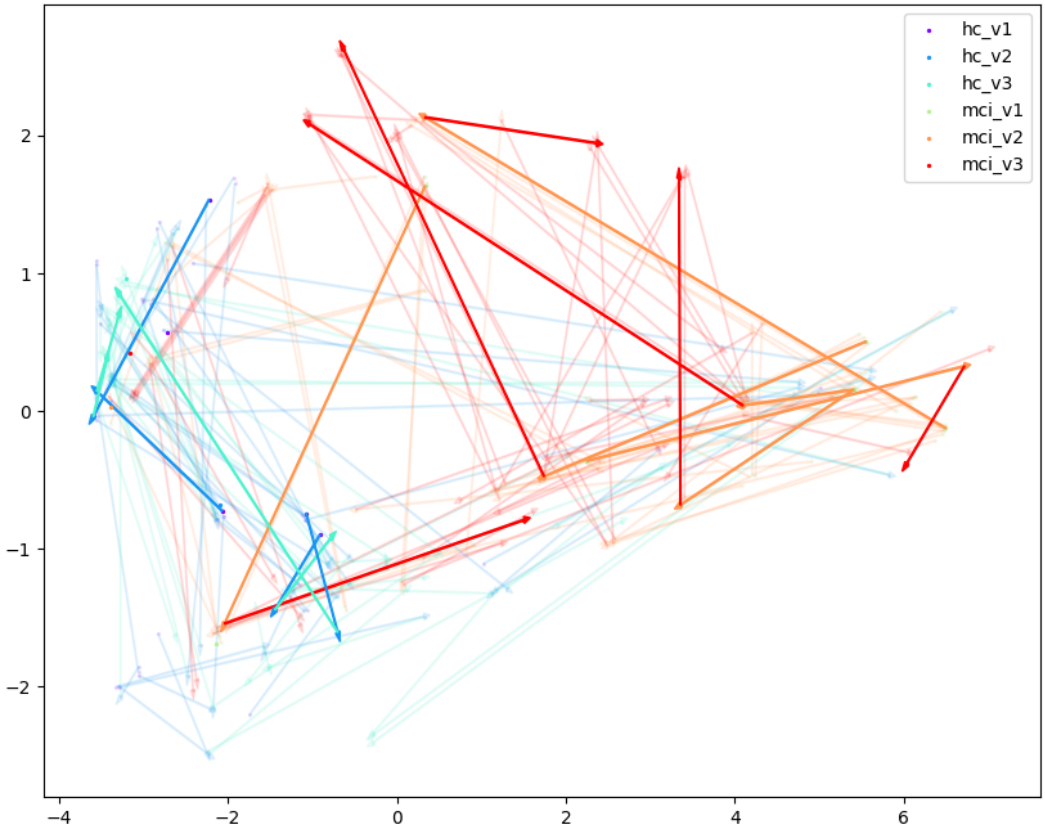
Both alignment loss	0.65	0.53	0.60	0.53	0.87	0.70

[a]AUROC: area under the receiver operating characteristic curve.

[b]LG: longitudinal.

[c]Highest value for each metric in recall data and probing data, respectively.

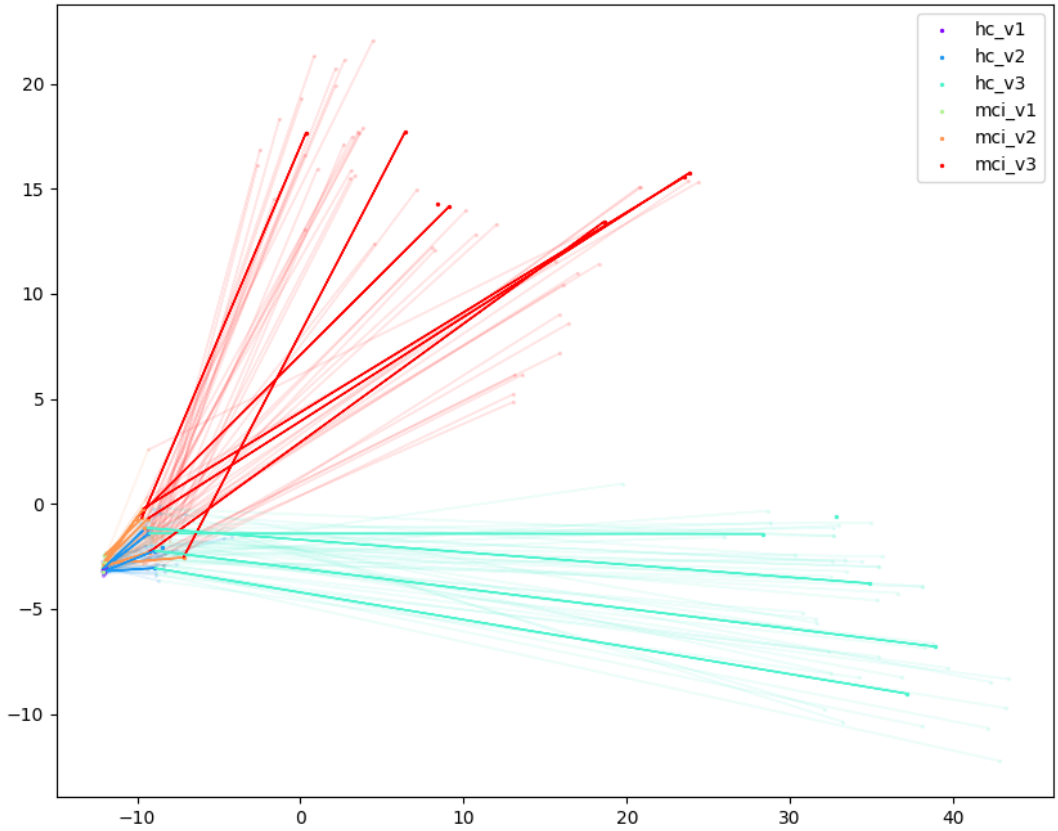
The results show that incorporating alignment losses with direction embedding improves performance across both recall and probing data. For instance, on recall data, our full model improves AUROC by 10% (0.85 vs 0.75) and F_1-score by 4% compared with "Without direction." On probing data, the gains are even larger, with AUROC improved by 12% (0.89 vs 0.77) and F_1-score improved by 13% (0.83 vs 0.70). Importantly, removing the group alignment loss results in the sharpest performance drop, with AUROC decreasing by 17% (0.68 vs 0.85) and 21% (0.68 vs 0.89) for recall and probing data, respectively. Similarly, removing both alignment losses further reduces AUROC to 0.63 (recall) and 0.70 (probing), confirming their necessity.



Overall, these results highlight the complementary importance of both alignment losses that rely on the strong supervisory signal of ground-truth label transitions to capture temporal progression patterns in longitudinal settings. Removing either the subject alignment loss or the group alignment loss results in significant performance degradation, and removing both leads to the sharpest decline. This indicates that while the subject alignment loss stabilizes intrasubject trajectory consistency, the group alignment loss aligns intersubject cognitive progression trends across similar diagnostic groups.

Visualization

We visualize the latent space distribution of subjects across different visits to better interpret the role of the alignment loss. After passing through all modules, we extracted the final embeddings, applied principal component analysis for dimensionality reduction, and projected the results into a 2D space. The arrows in Figures 9 and 10 represent the trajectory of each subject's embeddings across consecutive visits, thereby illustrating how cognitive states evolve over time.



XSL•FO
RenderX

Figure 9. Principal component analysis projection of subject embeddings without alignment loss. The x- and y-axes represent the first 2 principal components. Colors denote diagnostic group and visit (blue tones = healthy control visits 1 - 3; red tones = mild cognitive impairment visits 1 - 3). Arrows illustrate the trajectory of each subject's embeddings. The scattered trajectories reflect high variability and weak temporal consistency without alignment loss.

XSL•FO
RenderX

Figure 10. Principal component analysis projection of subject embeddings with alignment loss. The x- and y-axes show the first 2 principal components. Colors indicate diagnostic group and visit (blue tones = healthy control visits 1 - 3; red tones = mild cognitive impairment visits 1 - 3). Arrows illustrate the trajectory of each subject's embeddings. With alignment loss, trajectories become far more coherent and directionally consistent, indicating improved temporal stability and clearer separation between healthy control and mild cognitive impairment progression patterns.

As shown in Figure 9 (without alignment loss), the trajectories are scattered and inconsistent, with large variability both within and across groups. This makes it difficult to distinguish between HC and MCI or to capture stable temporal patterns. In contrast, Figure 10 (with alignment loss) reveals more coherent trajectories: subjects within the same group (HC or MCI) show consistent progression directions across visits, while the separation between HC and MCI becomes clearer. Importantly, this indicates that the alignment loss encourages the model to capture cognitive progression trends rather than random variability in story content, reflecting interpretable patterns of decline (for MCI) and stability (for HC).

These results demonstrate that the alignment loss not only improves metrics but also enhances interpretability by aligning temporal trajectories in a way that reflects clinically meaningful differences in cognitive change. Feature-level analyses could provide even more intuitive examples of how the ATM aligns specific cognitive markers in speech. Future feature-level analyses could further enhance this by providing more intuitive illustrations of how the ATM captures and aligns specific cognitive markers in speech.

Results of NTU-AM-CS

In addition to the main longitudinal experiment, we conducted further evaluations in a cross-sectional setting to assess the performance of our proposed model. Here, the primary comparison is with our previous work [11], which also used audio and text data. However, a key difference is that the prior work relied on manual transcripts, which are less scalable and require special preprocessing for the transcripts. The results are shown in Tables 10 and 11.

[a]AUROC: area under the receiver operating characteristic curve.

[b]BERT: bidirectional encoder representation for transformer.

[c]Highest value of each evaluation metric.

[d]CS: cross-sectional.

Our proposed method performs better or comparably on critical metrics such as F_1-score and AUROC in the results of recall data. Specifically, there is an 11% improvement in F_1-score. However, the precision is not as good as in the study by Chang et al [11]; our sensitivity metric performs better. For probing data, our method also yields better results in F_1-score and AUROC. However, the overall performance of the NTU-AM-CS dataset is not as promising as that of the NTU-AM-LG dataset. Detecting MCI features in AM data is challenging and reinforces the idea that long-term data relationships aid in model prediction.

Ablation Study

We investigated the contributions of linguistic features and context embedding in the encoder module for the prediction ability. The results are shown in Table 12. It demonstrates the impact of removing individual components on the model's predictions. For example, when linguistic features are removed, there is a noticeable decrease in specificity and a 6% drop in F_1-score. The most significant impact is seen when context embedding is removed, resulting in a 9% decrease in F_1-score and substantial declines in most other metrics. Only the sensitivity metric performs better, but overall, the original configuration still performs best in terms of F_1-score, which balances sensitivity and precision.

[b]CS: cross-sectional.

[c]Highest values of each evaluation metric.

These results indicated that linguistic features provide auxiliary information that aids the model's decision-making, particularly in identifying negative samples. Context embedding supports the model's understanding of the story by distinguishing between the story topic and content through embeddings.

Result of Additional Dataset

In the experiment with an additional dataset, our main goal was to confirm whether the method our model uses to encode data is also applicable to other datasets related to cognitive tests. This means whether the way we encoded each data contributes to MCI detection. In Table 13, we present several results related to the detection of MCI. Our primary comparison targets in the NTUH-PIC and NTUH-MEM datasets are as per the study by Lin et al [18], which use textual information, including pauses, for MCI prediction. From the NTUH-PIC experimental results, there was an improvement of 11% in accuracy and 18% in F_1-score.

Table . Results of the National Taiwan University Hospital dataset.

Dataset	Method	Accuracy	F_1-score	Precision	Sensitivity	Specificity	AUROC[a]
NTUH-PIC[b]	Lin et al [18]	0.68	0.63	0.81[c]	0.58	0.78[c]	N/A[e]

[f]NTUH-MEM: National Taiwan University Hospital Memory Test.

Similarly, in the NTUH-MEM dataset, a 10% improvement was observed in both accuracy and F_1-score compared with the study by Lin et al [18], indicating overall better performance. This experiment demonstrates that our data-encoding method effectively extracts latent representations suitable for MCI detection. Viewing data from multiple modalities provides consistent benefits for MCI detection. In addition, the performance differences observed in the NTU-AM-CS experiment indicate that using AM data for MCI detection is relatively challenging.

Due to the nature of the self-collected dataset, making comparisons with other works is challenging. Therefore, we present results on an open dataset in the final experiment. However, the ADReSSo dataset provides only HC and AD data. Table 14 shows our results alongside those of other state-of-the-art methods. Overall, our approach yields the best results, with a 4% improvement in both accuracy and F_1-score. In addition, our precision achieves the best performance. Once again, it confirms that our data-encoding method contributes to predictive outcomes in AD and MCI detection.

Discussion

Principal Results

In this study, we proposed a longitudinal framework for MCI detection using AM test speech data. The key innovation is the ATM, which leverages direction embeddings with subject and group alignment losses to model cognitive changes across multiple visits.

Our experiments demonstrate that the longitudinal framework substantially outperforms cross-sectional approaches. Compared with single-visit models, the longitudinal model achieved notable improvements, with AUROC gains of up to 21%, F_1-score increases of 16%, and accuracy improvements of 12%. These results confirm that incorporating multi–time point information provides a clearer picture of subtle cognitive trajectories that cannot be fully captured using only cross-sectional data.

The ablation studies further highlight the effectiveness of the alignment mechanisms. Removing the alignment losses led to considerable performance degradation, particularly a 17% - 21% drop in AUROC when the group alignment loss was excluded. This underscores the critical role of alignment in ensuring temporal consistency and improving the robustness of the framework.

In addition to evaluations on our self-collected dataset, we validated the framework on the publicly available ADReSSo dataset, which uses English picture description speech. Despite differences in language and task, our model achieved more than 88% accuracy, suggesting that the approach generalizes well across languages and cognitive assessment protocols.

In our analysis, the distribution of false positives and false negatives provides additional context for interpreting the model's sensitivity and specificity. False positives, which reduce specificity, were often linked to healthy subjects who displayed atypical speech characteristics such as disfluencies, pauses, or reduced lexical richness that mimicked early cognitive decline. On the other hand, false negatives, which lower sensitivity, were frequently observed in MCI subjects who retained strong narrative skills or enriched their responses with contextual details, thereby masking subtle impairments. These observations illustrate how individual variability in speech patterns can differentially impact sensitivity and specificity, underscoring both the strengths and the boundary conditions of the framework. While the alignment-based approach improves overall robustness, further refinement of feature representations and the inclusion of personalized modeling strategies may help balance sensitivity and specificity more effectively.

Taken together, these results highlight both the methodological and clinical significance of the proposed approach. Improvements in AUROC of 10% - 15% can translate into earlier identification of at-risk individuals and a reduction in false negatives in real-world screening. This demonstrates the potential of longitudinal, dual-modal speech analysis as a noninvasive, scalable tool for long-term cognitive monitoring, with the flexibility to be integrated into routine memory clinic assessments or used as a low-cost prescreening solution to complement standardized neuropsychological testing.

Limitations

Although the proposed framework shows promising performance for early MCI detection, several limitations remain. One major limitation of this study lies in the relatively small sample size of the NTU-AM-LG dataset, which includes only 54 subjects. Although each subject contributes multiple audio recordings across different visits, the limited number of unique participants poses inherent challenges for deep learning models, including a higher risk of overfitting, model instability, and low statistical power. As a result, while the proposed model demonstrates promising performance trends, its robustness and generalizability should be interpreted with caution. To mitigate these risks, we adopted strict subject-independent data splits and cross-validation to avoid data leakage and improve reliability. Nevertheless, future studies with larger and more diverse longitudinal datasets are essential to confirm the model's generalization capability and to further validate its clinical applicability. Furthermore, we also validate our approach on the publicly available ADReSSo dataset, although it is limited to a cross-sectional study. Cross-lingual robustness also presents a challenge, as our dataset is in Chinese while ADReSSo is in English. Linguistic and cultural factors such as narrative structure, emotional expression, and lexical choices may influence AM speech patterns and, in turn, affect model generalizability. Nevertheless, our results demonstrate encouraging cross-lingual generalizability. We highlight this as an open challenge and a direction for future work, where

XSL•FO
RenderX

cross-lingual adaptation and multilingual modeling will be crucial to improving robustness across diverse populations.

Moreover, the current longitudinal dataset includes 3 visits per participant, which restricts the ability to capture long-term trajectories of cognitive change. Collecting data across additional time points would allow the development of models better suited to characterizing the progression of cognitive decline.

This study also acknowledges potential confounding factors arising from the use of automatic speech processing tools. The *whisper-timestamped* model and *pyannote* diarization tool kit were used for transcription and speaker segmentation, respectively; however, the resulting ASR and diarization errors were not formally measured. Such errors, especially the higher ASR error rates likely to occur in participants with MCI due to disfluency or reduced articulation, and diarization inaccuracies that may introduce noise, could impact the extracted linguistic and acoustic features. These unaddressed confounders represent an inherent limitation of this study.

Further Studies

Based on the current findings, several directions can be explored in future work. First, extending the framework to multilingual settings will be essential for improving cross-lingual generalizability, as language and cultural factors strongly influence AM narratives. Second, adapting the model for low-resource scenarios will enhance its applicability in real-world clinical practice, where large-scale longitudinal datasets are often unavailable. Techniques such as transfer learning, data augmentation, and self-supervised pretraining could make the system more robust under such constraints.

Third, integrating AM speech analysis with other noninvasive modalities, such as wearable sensor data, offers the potential to capture complementary behavioral and physiological signals (eg, activity levels, sleep patterns, and heart rate variability). Such multimodal fusion could provide a more holistic view of cognitive health and improve early detection of decline. Finally, future studies should focus on personalized modeling of cognitive trajectories, acknowledging that the pace and pattern of decline vary across individuals. Personalized approaches may increase the clinical relevance of the framework and support tailored interventions.

Conclusions

We developed a dual-modal longitudinal analysis system to enhance the accuracy of diagnosing MCI. The system consists of an encoder and an ATM. We used a pretrained Wav2vec 2.0 model for speech data and BERT for text data to generate latent representations. Our proposed ATM generates significantly improved performance for MCI prediction, with F_1-scores of 0.78 and 0.83 on the recall and probing datasets, respectively. Combining data from both modalities improved understanding of the AM test data, with up to 19% and 12% improvements in F_1-score compared with unimodal models. In addition, ablation experiments verified the necessity of context embedding and linguistic features in the linguistic encoder. Our model's effectiveness was consistently superior across different datasets.

Abstract

Background: General anesthesia comprises 3 essential components—hypnosis, analgesia, and immobility. Among these, maintaining an appropriate hypnotic state, or anesthetic depth, is crucial for patient safety. Excessively deep anesthesia may lead to hemodynamic instability and postoperative cognitive dysfunction, whereas inadequate anesthesia increases the risk of intraoperative awareness. Electroencephalography (EEG)-based monitoring has therefore become a cornerstone for evaluating anesthetic depth. However, processed electroencephalography (pEEG) indices remain vulnerable to various sources of interference, including electromyographic activity, interindividual variability, and anesthetic drug effects, which can yield inaccurate numerical outputs.

Objective: With recent advances in machine learning, particularly unsupervised learning, data-driven methods that classify signals according to inherent patterns offer new possibilities for anesthetic depth analysis. This study aimed to establish a methodology for automatically identifying anesthesia depth using an unsupervised, machine learning–based clustering approach applied to pEEG data.

Methods: Standard frontal EEG data from participants undergoing elective lumbar spine surgery were retrospectively analyzed, yielding more than 16,000 data points. The signals were filtered with a fourth-order Butterworth bandpass filter and transformed using the fast Fourier transform to estimate power spectral density. Normalized band power ratios for delta, high-theta, alpha, and beta frequencies were extracted as input features. Fuzzy C-Means (FCM) clustering (c=3, m=2) was applied to categorize anesthetic depth into slight, proper, and deep clusters.

Results: FCM clustering successfully identified 3 physiologically interpretable clusters consistent with EEG dynamics during progressive anesthesia. As anesthesia deepened, frontal alpha oscillations became more prominent within a delta-dominant background, while beta activity decreased with loss of consciousness. The fuzzy membership values quantified transitional states and captured the continuum of anesthetic depth. Visualization confirmed strong correspondence among cluster transitions, Patient State Index trends, and spectral density patterns.

Conclusions: This study demonstrates the feasibility of using unsupervised machine learning to enhance anesthetic depth assessment. By applying FCM clustering to pEEG data, this approach improves the understanding of anesthesia depth and integrates effectively with existing monitoring modalities. The proposed FCM-based method complements current EEG indices and may assist anesthesia practitioners and even nonanesthesia professionals in assessing anesthetic depth to enhance patient safety.

Introduction

General anesthesia induces temporary loss of consciousness characterized by unconsciousness, immobility, and autonomic regulation of pain [1,2]. Maintaining an appropriate depth of anesthesia is essential for patient safety. Insufficient anesthesia may lead to intraoperative awareness, autonomic hyperactivity, and significant psychological distress [3]. Conversely, excessive anesthesia has been associated with neuroinflammation [4], neuronal injury, and postoperative cognitive dysfunction or delirium [5,6]. Therefore, continuous monitoring of anesthetic depth during surgery is of critical importance. Electroencephalography (EEG)-based monitoring serves as a valuable tool for this purpose. Real-time EEG analysis provides insight into anesthetic states, as oscillatory patterns vary with the anesthetic dose, type, and patient characteristics [7,8]. The Perioperative Quality Initiative 6 Workgroup, led by Chan, details the available EEG monitors [9]. Understanding perioperative neural activity enables anesthesiologists to optimize anesthesia delivery and enhance patient outcomes.

Artificial intelligence is revolutionizing anesthesiology, with techniques such as anesthesia depth monitoring [10]. Unsupervised machine learning operates without predefined hypotheses and identifies patterns and structures within datasets to classify patients, medications, and groups [11]. Unlike supervised machine learning, which correlates the input data with known outcomes, unsupervised machine learning categorizes instances based on inherent patterns. In EEG analyses, unsupervised machine learning methods such as fuzzy clustering have been used to analyze sleep stages [12], detect epileptic spikes [13], and identify significant elements in multichannel recordings [14].

Anesthesia management fundamentally involves 3 key components: hypnosis, analgesia, and muscle relaxation. During induction and maintenance, a reproducible spectral shift occurs in the EEG, wherein frontal alpha oscillations become prominent within a delta-dominant background, delta power progressively increases with deepening anesthesia, and beta activity decreases as consciousness is lost [8,15-17]. Power spectral metrics—including relative alpha, beta, and delta power, power ratios, and spectral entropy—have been shown to reliably distinguish between conscious and anesthetized states [18-20]. Inhalational agents such as sevoflurane and desflurane consistently produce dose-dependent increases in frontal alpha and delta power [17,21-23], providing a physiologic basis for categorizing anesthesia into light, proper, and deep stages. However, current perioperative EEG-based indices, such as the Bispectral Index (BIS) [24,25] and Patient State Index (PSi) [26,27], primarily reflect the hypnotic component but can be influenced by various factors, potentially leading to misleading processed numerical outputs. Therefore, this study aimed to enhance anesthetic depth assessment by focusing on the hypnosis dimension and applying unsupervised machine learning methods, specifically Fuzzy C-Means (FCM) clustering, to processed electroencephalography (pEEG) data.

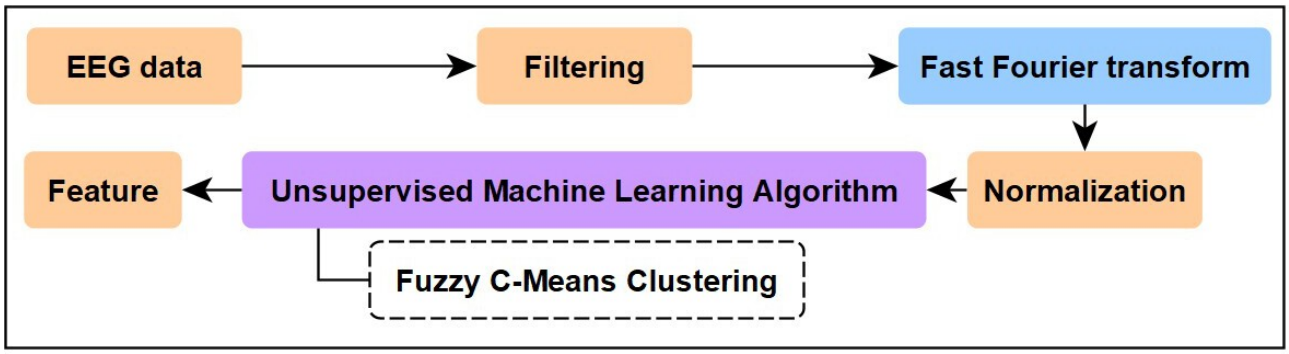
The primary objective of this study was to establish a methodology for automatically identifying anesthesia depth through a visualized presentation, leveraging machine learning–based clustering techniques. By applying unsupervised learning to pEEG data, this approach aims to enhance the classification and understanding of anesthesia depth and facilitate patient-specific anesthesia management.

Methods

Recruitment

Data were collected at the Veterans General Hospital, Taipei, with the approval of the Institutional Review Board (number 2021-09-008BC). More than 16,000 data points were collected from 10 participants (Participants 1 - 10) who underwent elective lumbar spinal surgery in the prone position. The ages of the participants ranged from 44 to 78 years, with the American Society of Anesthesiologists' physical status classifications ranging from class I to class III. Participants with conditions such as pregnancy, neurological disorders, ongoing infections, a history of central nervous system medication use, respiratory failure, heart failure, or renal failure were excluded.

Masimo SedLine [28] brain function monitoring was performed with the participant in the supine position. Induction included fentanyl at 1 - 3 mcg/kg as an adjunct for intubation, followed by propofol at 1 - 3 mg/kg as an induction bolus. Rocuronium was administered at an intubation dose of 0.6 - 1 mg/kg for muscle relaxation. The participant was then intubated.



During maintenance, the inhalational agent sevoflurane was administered, with dosage adjustments titrated based on the PSi levels and pEEG density spectral array (DSA) patterns. The participant was then placed in a prone position for lumbar spinal surgery. After the completion of the surgery, the participant was returned to the supine position, and the inhalation agent was gradually titrated off. Rocuronium administration was reversed using sugammadex. Subsequently, the participants were extubated and transferred to the postanesthetic care unit for further monitoring and recovery.

Data Collection and Processing

Figure 1 outlines the preprocessing steps for the EEG data in our study.

XSL•FO
RenderX

Figure 1. Signal processing flow diagram. Flow diagram illustrating preprocessing and feature-extraction steps applied to processed electroencephalography data obtained from participants who underwent elective lumbar spine surgery at Taipei Veterans General Hospital. Raw frontal electroencephalography signals were filtered with a fourth-order Butterworth bandpass filter, and power spectral density was estimated using the Welch method with a 30-second window and 2-second overlap. Normalized delta, high-theta, alpha, and beta band power ratios were extracted as input features for unsupervised clustering using the Fuzzy C-Means (FCM) algorithm (*c=3*, *m=2*). EEG: electroencephalography.

Signal Processing and Feature Extraction

EEG tracings from the 4 Masimo SedLine channels were averaged into 1-dimensional signals and synchronized for consistency. Each participant's EEG data were recorded at a sampling frequency of 178 Hz, with a data collection period ranging from 3 to 5 hours, depending on the duration of anesthesia. A fourth-order Butterworth bandpass filter (0.5 - 30 Hz) was applied to minimize the ripple and achieve a maximally flat response. Power spectral density was estimated using the Welch method implemented in Python (SciPy library), using a 30-second window with a 2-second sliding overlap to ensure both temporal continuity and frequency resolution. Additional preprocessing specifications are available in Multimedia Appendix 1. The Welch method and the fast Fourier transform were used to estimate the power spectral density, facilitating the extraction of alpha (8 - 12 Hz), beta (13 - 30 Hz), delta (0.5 - 4 Hz), and high-theta (6 - 8 Hz) band powers. Normalization was performed by calculating the ratio of each band's power to the sum of the power of these 4 specific bands (delta+high-theta+alpha+beta), ensuring that the sum of the feature vector elements equals 1. The 4 - 6 Hz and 12 - 13 Hz bands were excluded based on their limited variation across states. Removing these transitional zones established a "spectral buffer" to reduce noise, allowing the algorithm to prioritize the more discriminative delta and alpha and high-theta features. Manual artifact rejection was conducted by board-certified anesthesiologists and engineers to identify and exclude segments exhibiting abnormal, noisy epochs indicative of artifacts.

FCM Clustering Algorithm

FCM clustering categorizes data points into clusters with membership values between 0 and 1, accommodating the uncertainty in the cluster assignment. It was performed with 3 clusters (c=3), a fuzziness parameter (m) of 2, random initialization of cluster centers, and a convergence threshold of 0.005. The model iteratively updates the centroids and membership values until convergence, guided by a fuzziness parameter (m) that regulates cluster ambiguity. A global FCM model was established to generate fixed global cluster centroids. These fixed centroids were then applied to all participants to calculate membership values. Further implementation details are provided in Multimedia Appendix 1. This method extracts delta, alpha, high-theta, and beta band power ratios from pEEG signals to partition the data into 3 statistically distinct clusters. These clusters were subsequently labeled as "slight," "proper," and "deep" based on their physiological spectral characteristics. The capability of FCM to manage data ambiguity makes it suitable for nuanced depth assessments under general anesthesia.

Ethical Considerations

This study was conducted in accordance with the ethical principles outlined in the Declaration of Helsinki and was approved by the Institutional Review Board of Taipei Veterans General Hospital, Taiwan (number: 2021-09-008BC). Written informed consent was obtained from all participants prior to enrollment. The data used in this study were deidentified before analysis to ensure participant confidentiality and privacy. No identifiable personal information or images were included in the manuscript or supplementary materials. Participants did not receive any financial compensation for their participation in the study.

Results

Overview

In this study, an unsupervised learning method, FCM, was used to analyze the pEEG data from participants with complete datasets. Table 1 summarizes the demographic information and baseline characteristics of the participants. The analysis focused on a feature set comprising the delta-band power ratio and the sum of the alpha and high-theta band power ratios. The results revealed 3 distinct clusters. Based on the centroids' spectral features, we assigned post hoc clinical labels to these clusters representing different anesthesia depths: slight (green), proper (blue), and deep (red). This clustering approach was validated using visual representation to confirm the effectiveness of the feature set in differentiating anesthesia depths. Subsequently, the same method was applied to individual participant data, categorizing each participant's pEEG into 1 of the 3 clusters, thus providing a detailed estimation of the anesthesia depth for each individual.

FCM Clustering Analysis of pEEG Features

FCM clustering was applied to all participants, using alpha, beta, delta, and high-theta band power as the selected features for clustering. Figure 2 illustrates the FCM clustering results for all participants, with the delta band power ratio plotted on the *x*-axis and the sum of the alpha and high-theta band power ratios on the *y*-axis. Each data point represents a single time point of a participant's pEEG signal and is clustered into 3 distinct groups: slight anesthesia depth (green), proper anesthesia depth (blue), and deep anesthesia depth (red). The contribution of the beta band power ratio can be inferred as the sum of the delta, alpha, high-theta, and beta band power ratios equals 1, although not explicitly displayed. This visual depiction offers insights into the distribution of a participant's single time points within each anesthesia depth cluster.

After establishing the efficacy of the selected features and parameters through a collective analysis of the participants, our investigation shifted focus to the individual application of this methodology. The fixed global cluster centroids were then applied to the data of Participants 1 - 10 to calculate membership values and simplified estimation results. Following the methodology outlined, where all time indices share a common time scale, the pEEG data were combined with PSi data retrieved from the Masimo SedLine brain function monitoring system, and the time-frequency images were compared within the same figure, with each participant outputting a distinct figure. Within these figures, Participants 4 and 6 are described in the article. By incorporating this comprehensive approach, our study verified the applicability of the selected features and enhanced confidence in the adaptability of our methodology to diverse clinical scenarios and datasets, strengthening the reliability of our conclusions and paving the way for further exploration and validation within the anesthesia depth assessment domain.

RenderX

Figure 2. Fuzzy C-Means clustering results for all participants. Two-dimensional clustering distribution of processed electroencephalography features from participants undergoing elective lumbar spine surgery. The *x*-axis represents the delta-power ratio and the *y*-axis the combined alpha and high-theta power ratios. Fuzzy C-Means clustering (*c=3*, *m=2*) identified 3 physiologically interpretable clusters corresponding to anesthesia-depth levels: slight (green), proper (blue), and deep (red). Each point denotes a 30-second windowed segment of electroencephalography data, demonstrating the continuum of anesthetic states observed across the study population.

Participant 4 and Participant 6: FCM Clustering Analysis

Participant 4 underwent the same data retrieval and processing procedures as the other participants, with raw EEG data obtained from the Masimo SedLine brain function monitoring system. These data were subjected to filtering, fast Fourier transformation, normalization, and subsequent FCM clustering. The culmination of these processes is depicted in Figure 3, which comprises multiple panels, sharing a synchronized timescale on the *x*-axis.

Figure 3A shows the PSi of Participant 4 obtained from the Masimo SedLine brain function monitoring system. The *x*-axis represents the time scale, whereas the *y*-axis displays the PSi values, reflecting the PSi over time.

Figure 3B shows the results of FCM clustering for Participant 4. The *y*-axis illustrates the estimated membership values and denotes the degree of belongingness of each cluster. This belongingness quantifies the "fuzziness" of the FCM clustering, indicating the confidence level of each assignment of the data point to a particular cluster. It effectively quantifies the "color shading" shown in Figure 2, where darker shades represent higher confidence levels in cluster assignments. For example, a membership value of 1 signifies full belongingness to the cluster, and a value of 0.8 indicates 80% confidence in the assignment. This "soft" labeling approach allows for a more nuanced understanding of the clustering results, providing insights into the uncertainty associated with each classification of the data point.

Figure 3C represents a modified rendition of Figure 3B, specifically tailored to illustrate the anesthesia depth classification for Participant 4. Along the *y*-axis, this plot delineates the categorization into slight, proper, or deep anesthesia groups at individual time points. Figure 3B provides a detailed depiction of the continuous membership values, reflecting the degree of belonging to each cluster: slight, proper, and deep. However, this comprehensive display introduces the challenge of intuitively discerning the predominant cluster at a single point. While this approach offers a more complete dataset, it complicates the task of determining the cluster affiliations for each data point. Hence, the modified version in Figure 3C simplifies this interpretation by highlighting the cluster with the "higher value." This adaptation facilitates a more straightforward assessment of the anesthesia depth classification by presenting a clearer distinction. This clarity enhances the utility of visualization in aiding clinician decision-making during patient monitoring and management.

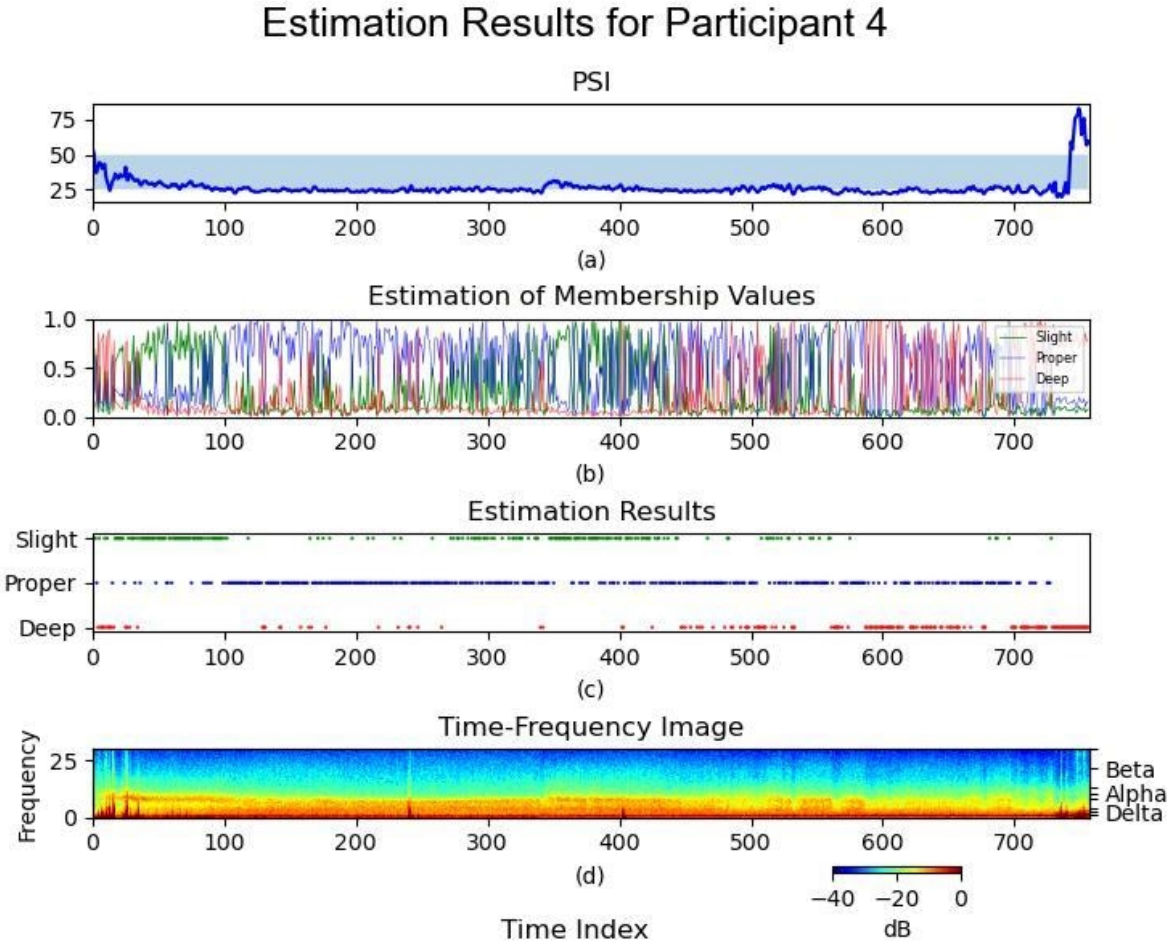

Figure 3D presents a time-frequency image derived from the raw EEG signal without processing, providing insights into the frequency components of the EEG signal over time. Overall, Figure 3 provides a comprehensive analysis of the EEG signals and anesthesia depth classification for Participant 4, contributing

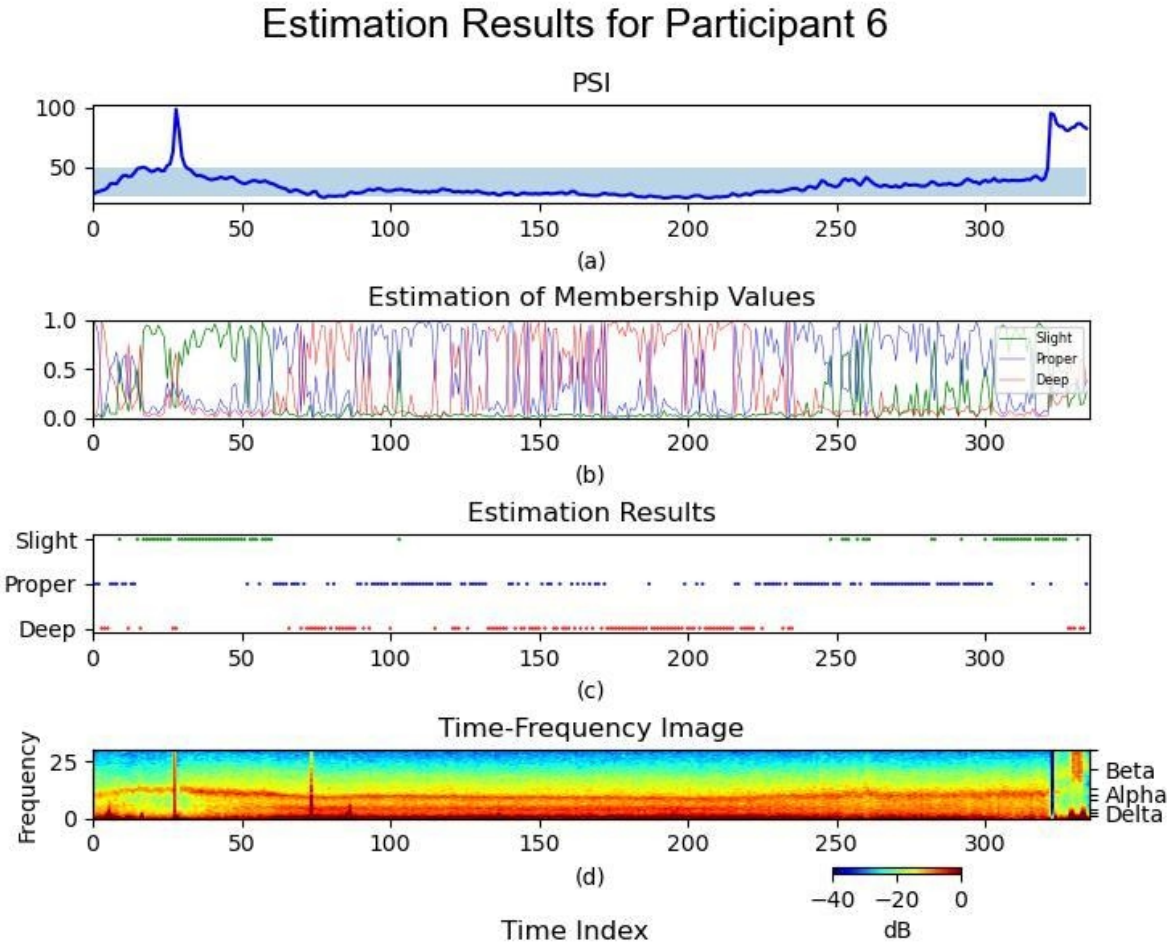
XSL•FO
RenderX

to the understanding of brain function monitoring and anesthesia management.



Participant 6 then underwent identical signal processing and analysis procedures, resulting in Figure 4. This comprehensive Figures 4A-D underwent the same rigorous process as shown in Figures 3A-D.

Figure 3. Fuzzy C-Means clustering analysis of Participant 4. Representative analysis of Participant 4 (male, 75 years, American Society of Anesthesiologists class II) who underwent lumbar spine surgery at Taipei Veterans General Hospital. (**A**) shows the Patient State Index trend over time; (**B**) displays Fuzzy C-Means membership values representing the degree of belongingness to each cluster; (**C**) illustrates the simplified classification into slight, proper, and deep anesthesia levels; (**D**) presents the corresponding electroencephalography time-frequency spectrogram. These plots depict temporal transitions in anesthetic depth.

Figure 4. Fuzzy C-Means clustering analysis of Participant 6. Representative analysis of Participant 6 (male, 45 years, American Society of Anesthesiologists class I) who underwent elective lumbar spine surgery at Taipei Veterans General Hospital. (**A**) shows the Patient State Index trend over time. (**B**) displays Fuzzy C-Means membership values representing the degree of belongingness to each cluster. (**C**) illustrates the simplified classification into slight, proper, and deep anesthesia levels. (**D**) presents the corresponding electroencephalography time-frequency spectrogram. These plots depict temporal transitions in anesthetic depth. PSi: Patient State Index.

Discussion

Principal Findings

This study explored the feasibility of improving anesthetic depth assessment by applying unsupervised machine learning to pEEG data. EEG patterns vary with the depth of anesthesia [10]. PEEG-derived indices, such as the BIS and PSi, are susceptible to various influences, presenting limitations in their interpretation [24]. Purdon et al [8] characterized the EEG signatures of intravenous and inhaled anesthetics, providing additional insights into the depth of anesthesia. In Figure 2, the delta ratio quantifies cortical suppression, as delta oscillations reflect deep anesthesia and thalamocortical inhibition. The theta and alpha ratios were selected for their modulation by anesthetics in the frontal cortex. Alpha oscillations indicate stable unconsciousness under propofol and sevoflurane, correlating with GABAergic inhibition, while theta oscillations become prominent at higher anesthetic concentrations, particularly with sevoflurane, signaling transitions between moderate and deep anesthesia. Figures 3 and 4 depict Participants 4 and 6, respectively, demonstrating the combination of PSi values, anesthesia depth clustering values, simplified clustering results, and processed time-frequency images. These visual presentations illustrate patient-specific anesthesia depth, facilitating the automatic identification of anesthesia depth.

Postoperative delirium and neurocognitive complications after spinal surgery remain significant concerns [29], and perioperative EEG monitoring may contribute to their management [30]. In this study, one participant (Participant 4) had a history of cognitive dysfunction due to dementia. All participants underwent lumbar spinal surgery in the prone position with sevoflurane as the maintenance agent. The operation time ranged from 170 to 405 minutes. Most participants were discharged within 1 week, and no other cognitive impairments were documented.

Limitations

This study was constrained by a small sample size. While the extensive dataset of over 16,000 EEG epochs ensures high within-subject data density and supports the internal stability of the model for the analyzed participants, we acknowledge that the limited number of independent participants restricts the external generalizability of the findings. Previous studies have indicated that a sampling frequency of 100 Hz is sufficient for EEG-based analysis [31]. While a larger sample size could

XSL•FO
RenderX

further refine the FCM clustering results presented in Figure 1, the primary determinants of clustering effectiveness in single-subject EEG analysis are the duration and density of the data. With 3 to 5 hours of continuous EEG recordings per participant, our study provided sufficient granularity for meaningful intrasubject clustering, as demonstrated in Figures 3 and 4. Our primary objective was to explore the feasibility and establish the methodological framework for applying unsupervised machine learning to processed EEG data.

García et al [32] explored EEG activity and delineated an analgesia-related axis alongside hypnosis during general anesthesia, revealing distinct changes in EEG patterns. We acknowledge the limitation of a single-dimensional index in capturing the full spectrum of neural activity during anesthesia. However, our primary goal is to demonstrate the feasibility of unsupervised clustering within a clinical framework, focusing on the hypnosis axis—one of anesthesia's 3 key components. This study used frontal EEG signals, as used in processed systems such as BIS and SedLine. Frontal EEG monitoring inherently limits spatial coverage but remains the clinical standard due to its accessibility and reliability. The frontal cortex exhibits predictable EEG dynamics—α-spindle emergence and δ-wave dominance—with increasing anesthetic depth, correlating with loss of consciousness and hypnotic adequacy [33-35].

While this study does not include external validation or direct quantitative comparisons, this reflects the broader challenge in anesthetic depth classification, which lacks a universal standard. Although no intraoperative recall was observed, determining the optimal depth of anesthesia remains complex. Conventional monitors, such as BIS and SedLine, along with DSA visualization, aid clinical judgment but do not serve as definitive references. The study introduces a complementary tool to enhance anesthetic depth assessment. This is reflected in Figures 3 and 4, where multiple monitoring modalities are integrated to provide additional insights.

Finally, the frame-by-frame analysis maximizes temporal sensitivity but may result in rapid state transitions, or "flickering," as observed in Figure 3C. For clinical application, future iterations would likely require temporal smoothing algorithms to stabilize the output and minimize alarm fatigue. Despite strong visual correspondence with PSi trends, standardized quantitative metrics were not calculated due to methodological constraints. Specifically, the significant time delay inherent in the PSi algorithm [36] limits direct linear correlation with the frame-by-frame FCM method, and imposing rigid thresholds for concordance rates contradicts the continuous, fuzzy nature of anesthetic depth.

Comparison With Prior Work

Unsupervised learning involves algorithms that identify patterns or structures within a dataset, facilitating the discovery of novel classification methods [10]. Systematic reviews have highlighted the effectiveness of unsupervised clustering methods in various medical applications. Clustering analysis has revealed pivotal features underlying the progression from early stage to advanced Alzheimer disease [37]. Unsupervised learning models applied in cardiac resynchronization therapy can accurately discern patient clusters and are valuable for phenotyping and predicting treatment responses [38]. In amyotrophic lateral sclerosis research, the k-means score, a hierarchical clustering method, has emerged as the most widely used method for stratification and progression prediction [39]. We predefined 3 practical categories—slight, proper, and deep anesthesia—to emulate the structured reasoning process that governs intraoperative anesthetic management. Clinicians continuously evaluate anesthetic depth and determine whether to increase, maintain, or decrease anesthetic delivery. Each titration is typically incremental and followed by a brief observation period to allow pharmacokinetic redistribution and physiological stabilization before reevaluation. Although the equilibration interval varies among individuals, such judgments integrate both the instantaneous anesthetic state and its temporal evolution [36]. FCM clustering offers distinct advantages for modeling this continuum. It enables classification into clinically interpretable states while concurrently generating fuzzy membership values that quantify the degree to which a given epoch inclines toward a "lighter" or "deeper" level of anesthesia. This property captures the continuous and overlapping nature of anesthetic depth and mirrors the gradual, feedback-driven adjustments that characterize intraoperative anesthesia management.

In our continuous monitoring data, transitions between anesthetic states occurred gradually, consistent with the physiological continuum of anesthesia depth. Abrupt shifts from "light" directly to "deep" anesthesia were uncommon and, when observed, were generally attributable to identifiable physiological perturbations—such as bolus drug administration, intense noxious stimulation, or sudden hemodynamic changes—rather than modeling artifacts. Processed EEG indices may also be transiently affected by electromyographic [40], electrocardiographic [41], or mechanical vibration artifacts, particularly during spine surgery. These interferences are usually recognizable in the raw EEG tracing and can be excluded from analysis.

Near-equal memberships across clusters (≈33% each) are uncommon and typically occur when a feature vector lies between centroids or during transient noise, reflecting a transitional or indeterminate phase rather than a distinct anesthetic state. Interpretation of anesthetic depth is inherently pattern-based, as clinicians assess temporal trends and spectral features in the DSA—for instance, alpha dominance suggests adequate hypnosis, whereas delta and theta predominance or burst suppression indicate a deeper anesthetic level [42]. Therefore, a single epoch with near-equal memberships would not influence clinical judgment, which relies on the overall evolution of EEG patterns rather than isolated points.

Prior research has focused on developing and enhancing automated system controls, including closed-loop anesthesia. Components such as measurement devices, controllers, and actuators are central to these advancements [43]. pEEG-derived indices, such as the BIS [43,44] and PSi [45], frequently serve as key targets. This study introduced unsupervised learning clustering as a potential new approach for assessing anesthesia depth, offering additional avenues for improving automated anesthesia control systems.

XSL•FO
RenderX

The novel clustering approach provides an alternative method for assessing anesthesia depth, particularly focusing on the "hypnosis" axis, as depicted in Figure 3B and C. These figures illustrate the EEG density spectral array data from Participant 4, suggesting segmentation into slight, proper, and excessively deep anesthesia depths. Unlike traditional PSi values, which provide singular metrics, the representation of Figure 3B with fuzziness on the *y*-axis shows nuanced membership toward anesthesia depth clusters. The graphical depiction in Figure 3C highlights the peak values, indicating the period of deep anesthesia. This approach offers a novel tool for assisting clinical judgment in anesthesia depth assessment.

Among conventional unsupervised clustering paradigms, FCM, Gaussian Mixture Models (GMMs), and density-based algorithms such as Density-Based Spatial Clustering of Applications with Noise (DBSCAN) exhibit fundamentally distinct analytical mechanisms. FCM minimizes a distance-weighted objective function while permitting graded memberships across clusters—an essential property for anesthesia-related data in which EEG and physiological variables vary continuously and overlap across anesthetic states. In contrast, GMM represents data as a superposition of Gaussian components and assumes that each cluster conforms to an elliptical, symmetric distribution. However, anesthetic EEG features often display non-Gaussian characteristics, including skewness and heavy tails arising from nonlinear pharmacodynamic effects and interindividual variability, rendering GMM less robust and prone to boundary instability. Density-based algorithms such as DBSCAN, although effective in identifying discrete or spatially separated clusters, depend on fixed density thresholds and therefore perform poorly with continuous-depth data, where transitions between anesthetic states are gradual and density gradients evolve smoothly. Considering these properties, FCM provides a mathematically rigorous and physiologically consistent framework for delineating the smooth, overlapping transitions that define anesthetic depth.

Building upon these theoretical considerations, we initially explored k-means clustering but found it less flexible in classifying anesthetic depth. When visualizing frequency band proportions, k-means struggled to capture transition zones effectively, reinforcing our decision to use FCM for a more adaptable classification. The FCM algorithm stands out in unsupervised machine learning because of its adaptability and effectiveness in increasing data volumes. It iteratively adjusts centroids and clusters, creating personalized representations tailored to individuals, analogous to bespoke garments [46]. This adaptability ensures an accurate assessment of anesthesia depth dynamics, which is crucial for personalized healthcare.

Conclusions

In conclusion, this study established a machine learning–based methodology for anesthesia depth assessment, demonstrating its feasibility and providing preliminary insights into classification, visualization, and patient-specific management. By applying FCM clustering to processed EEG data, this novel approach enhances the understanding of anesthesia depth patterns and integrates with existing monitoring modalities, including PSi values and time-frequency image visualization for a more comprehensive assessment. Although preliminary, these findings lay the foundation for future research and refinement.

Detailed data preprocessing workflow and Fuzzy C-Means (FCM) parameter settings. Electromyography signals were processed via the Welch method (*30-s windows, 2-s overlap*). Normalized delta, high-theta, alpha, and beta band-power ratios were extracted as input features. The FCM algorithm ($c = 3$, $m = 2$) was applied with random initialization of cluster centers to identify three anesthesia depth clusters. Measures of dispersion for the delta band within each cluster are summarized in Table S1. Figures S1 and S2 show additional two-dimensional clustering distributions, demonstrating consistent three-cluster separation across different frequency-band pairings.

Abstract

Background: Autosomal dominant polycystic kidney disease (ADPKD), characterized by progressive cyst growth and renal decline, is the leading genetic cause of end‐stage renal disease.

Objective: This study aims to develop and validate machine learning (ML) models for predicting the risk of progression to dialysis in patients with ADPKD using a nationwide administrative database. Early identification of high-risk patients is critical for timely monitoring.

Methods: This retrospective cohort study used data from Taiwan's National Health Insurance Research Database (2007‐2018) to identify newly diagnosed patients with ADPKD. Six ML algorithms, including logistic regression, random forest, and extreme gradient boosting (XGBoost), were employed to predict progression to dialysis. Models were developed using 10-fold cross-validation, with the Synthetic Minority Oversampling Technique applied within training folds to address class imbalance. An ensemble-based feature selection strategy was implemented to identify the most robust predictors and optimize final model performance. Model evaluation was conducted using a strict temporal split.

Results: The study included 1856 patients with ADPKD, of whom 302 (16.27%) progressed to dialysis. Multivariable Cox regression identified several significant risk factors, including age 66 years and older (hazard ratio [HR] 4.63, 95% CI 2.71‐7.92; P<.001), anemia (HR 4.33, 95% CI 3.25‐5.78; P<.001), congestive heart failure (HR 1.81, 95% CI 1.29‐2.54; P<.001), and acute kidney injury (HR 1.69, 95% CI 1.19‐2.41; P=.003). Among the ML models, the XGBoost model, using an optimized set of 27 features, demonstrated the highest predictive performance on the held-out temporal test set (accuracy 98.3%; area under the curve 0.955; F_1-score 0.800; Brier score 0.022). The top predictors in the XGBoost model largely aligned with age, comorbidity burden, anemia, and cardiovascular disease markers. Medication use (eg, anticoagulants, loop diuretics, febuxostat) was also among the most influential predictors; however, medication-related predictors should be interpreted as proxies for disease complexity rather than direct risk modulators.

Conclusions: ML models can predict dialysis risk in patients with ADPKD using administrative data with temporal validation. This approach may support risk stratification by helping identify individuals at higher predicted risk who may warrant closer monitoring and further specialist evaluation.

Introduction

Background

Polycystic kidney disease (PKD) is the leading genetic cause of end-stage renal disease (ESRD). The most common mutations in PKD occur in the *PKD1* or *PKD2* gene, which encode the proteins polycystin-1 and polycystin-2, respectively. These mutations result in abnormal cell proliferation, fluid secretion, and differentiation, leading to the formation and growth of cysts [1]. The progressive nature of renal cysts may cause structural and functional changes in the kidney. According to the latest guidelines, the estimated prevalence of PKD varies widely, ranging from approximately 2 to 14 per 10,000 individuals, depending on the study methodology and population characteristics [2].

Contemporary management of autosomal dominant polycystic kidney disease (ADPKD) has evolved to include both the management of associated complications and direct interventions aimed at the disease mechanism. A cornerstone of care remains the control of hypertension, a common and impactful complication. Angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin II receptor blockers (ARBs) are widely recommended for their established efficacy in blood pressure control and proteinuria mitigation [3,4]. In addition, lifestyle interventions, such as dietary sodium restriction and weight management, play a crucial role in preserving renal function [5,6]. In parallel, disease-modifying therapies, such as the vasopressin V2 receptor antagonist tolvaptan, have been developed to slow cyst growth in select patients with rapidly progressing disease, who are often identified using prognostic markers such as genetic status or total kidney volume (TKV) [7]. Furthermore, other medications, such as statins and metformin, are frequently prescribed to manage concurrent conditions in this population, though their role as primary treatment options for ADPKD itself remains under investigation [8,9].

Study Objective

While risk stratification using advanced tools is crucial for guiding specialized treatments, a significant need remains for risk assessment methods based on accessible, routinely collected data. Currently, the gold-standard models for prognostication in ADPKD include the Mayo Imaging Classification, which utilizes height-adjusted TKV and patient age to predict the rate of estimated glomerular filtration rate (eGFR) decline, and the PROPKD score, which integrates genetic information (*PKD1* vs *PKD2* mutation type) with early clinical manifestations [2,10,11]. Although these models are invaluable, their broad implementation is often hindered by their dependence on specialized and resource-intensive evaluations. For instance, the Mayo Classification requires magnetic resonance imaging (MRI) or computed tomography to measure TKV, while the PROPKD score necessitates comprehensive genetic sequencing. These resources can be costly and are not universally available in all clinical settings, creating a gap for more scalable screening tools.

In parallel with these clinical tools, artificial intelligence (AI) has been increasingly used in ADPKD management. AI models have been developed to predict glomerular filtration rate decline, aiding in the early identification of high-risk patients and facilitating proactive management [12]. In imaging-based classifications, deep learning algorithms have been applied to automate ADPKD severity assessment, enhancing objectivity and reducing interobserver variability [13]. AI has also been instrumental in TKV quantification, a crucial prognostic marker in ADPKD. Deep learning-based segmentation models have demonstrated high accuracy in automated kidney segmentation from MRI and computed tomography images, significantly reducing manual workload [14,15]. While these advancements improve disease monitoring, they often still rely on the availability of imaging or detailed clinical data, leaving a gap for predictive models that can leverage more widely accessible administrative data to forecast hard clinical end points.

Therefore, this study aimed to develop and validate an AI-assisted model to identify significant predictors of progression to dialysis in patients with ADPKD using a nationwide administrative database. We evaluated multiple machine learning (ML) algorithms using a prespecified temporal split for model development and evaluation and summarized predictors to enhance interpretability and clinical usability. Our goal was to create a complementary tool for risk stratification, potentially aiding clinicians in monitoring patients and identifying those who may warrant more specialized evaluation.

Methods

Data Sources

This retrospective cohort study was based on the National Health Insurance Research Database (NHIRD), which is derived from Taiwan's universal compulsory health insurance system covering nearly 99% of the 23 million individuals in Taiwan since 1998 [16]. The database includes patients' hospitalization and outpatient visit records, and each individual was continuously followed. Disease diagnoses were coded according to the International Classification of Diseases, Ninth Revision, Clinical Modification (*ICD-9*-CM). The NHI Administration fully adopted *ICD-10*-CM for clinical records in 2016.

Ethical Considerations

This study was conducted in accordance with the principles of the Declaration of Helsinki and was reviewed and approved by the Ethics Review Board of Shin-Kong Wu Ho-Su Memorial Hospital (approval number 20211008R). The requirement for informed consent was waived by the review board because this study involved a secondary analysis of routinely collected administrative data, and no direct contact with individual participants occurred. The original data collection procedures and this secondary analysis were approved without the need for additional consent.

All data obtained from the NHIRD were fully deidentified prior to analysis. Personal identifiers were removed by the data holder, and the authors had no access to information that could be used to identify individual patients. Data access and analysis were conducted in compliance with relevant data protection regulations.

XSL•FO
RenderX

No financial or other compensation was provided to participants, as this study did not involve direct recruitment or interaction with human subjects.

The manuscript and all supplementary materials did not include any images or information that could lead to the identification of individual participants.

Study Design and Population

We identified new-onset ADPKD cases from the Catastrophic Illness Patient Registry between 2007 and 2018. To minimize potential misclassification bias from ICD coding, we implemented stringent validation criteria for both the primary diagnosis and comorbidities. The identification of patients with ADPKD followed a 2-step process: subjects were first identified using ICD diagnostic codes, and their diagnosis was then validated against Taiwan's Catastrophic Illness Patient Registry. A catastrophic illness certificate requires formal review and approval by physicians, ensuring a high degree of diagnostic accuracy for our study cohort [17-19].

The index date was defined as the first date on which a patient met the ADPKD case definition and had validation in the Catastrophic Illness Patient Registry. Baseline predictors were ascertained during the 365-day lookback period preceding the index date.

To construct a clean incident cohort and reduce reverse causation, we excluded individuals aged below 19 years or above 85 years, those with missing core administrative information (eg, sex, age, or index date), and those with evidence of ADPKD during the 2005 to 2006 washout period. We also excluded patients with any evidence of dialysis (hemodialysis or peritoneal dialysis) before the index date and those with kidney transplantation before the index date. Patients were followed from the index date until initiation of dialysis, death, or December 31, 2019, whichever occurred first.

Baseline Variables

The dataset includes a variety of demographic, clinical, and medication-related variables for individuals with ADPKD. The key demographic variables include sex and age. Clinical variables encompass a variety of diseases grouped as cerebrovascular (intracranial aneurysms, ischemic stroke, and hemorrhagic stroke), cardiovascular (hypertension, atrial fibrillation, congestive heart failure [CHF], peripheral vascular disease, arrhythmia, and ischemic heart disease), gastrointestinal (liver cirrhosis, peptic ulcer, diverticulosis, cholangitis, and acute pancreatitis), renal and urological (urinary tract infection [UTI] and acute kidney injury [AKI]), pulmonary (chronic obstructive pulmonary disease [COPD], pneumonia, and asthma), metabolic (dyslipidemia, diabetes mellitus, and gout), mental (dementia, anxiety, and depression), and other (glaucoma and anemia). Each comorbidity was confirmed if the corresponding diagnosis code appeared in at least 1 hospitalization record or at least 3 outpatient visit records within the 365-day lookback period preceding the index date.

Medication variables cover a broad spectrum, including antihypertensives (beta-blockers, alpha-blockers, ACEIs/ARBs, calcium channel blockers [CCBs], methyldopa, hydralazine, minoxidil, clonidine, potassium-sparing diuretics, thiazide diuretics, and loop diuretics), antidiabetic drugs (metformin, sulfonylureas, dipeptidyl peptidase-4 inhibitors, thiazolidinediones, other oral hypoglycemic agents, rapid-acting insulins, and long-acting insulins), antimetabolic agents (statins, fenofibrate, and other lipid-lowering agents), urate-lowering agents (benzbromarone, allopurinol, febuxostat), and other medications (nonsteroidal anti-inflammatory drugs [NSAIDs], sedative hypnotics, tranexamic acid, mammalian target of rapamycin inhibitors, sodium bicarbonate, anticoagulants, antiplatelet agents, and vitamin K). As with the definition of comorbidities, we adopted a widely used and validated approach to enhance specificity. Medication variables were quantified as the cumulative number of prescription days during the 365-day lookback period preceding the index date. This approach was used to capture exposure intensity beyond a binary indicator. The specific codes used to define all comorbidities and medications are detailed in Tables S1 and S2 in Multimedia Appendix 1, respectively.

Outcome Definition and Follow-Up

The primary end point was ESRD, defined as initiation of dialysis or receipt of kidney transplantation without prior dialysis. Patients were followed from the index date until ESRD, death, or December 31, 2019, whichever occurred first. For the ML classification models, the binary outcome was ESRD by the end of follow-up (event=1). In the ML analysis, the label reflects whether ESRD was observed by December 31, 2019, and does not represent a fixed-horizon risk. Patients without ESRD were labeled as nonevents (event=0), including those who died before reaching ESRD.

Data Preprocessing and Handling of Missing Data

Our strategy for handling missing data involved 2 stages. First, case-wise deletion was performed to exclude any patient records with missing core administrative data (eg, sex, age, or date of diagnosis), as indicated in the study flowchart. For the final cohort, predictor variables were constructed such that no missing values remained. The absence of a record for a specific variable was treated as meaningful data rather than as a missing value. For instance, if a patient had no prescriptions for a given medication, the cumulative exposure days were coded as 0. Similarly, if a patient did not meet the predefined criteria for a comorbidity, the variable was coded as 0, indicating absence.

Statistical Analysis

Categorical variables were presented as frequencies with percentages and compared using the chi-square test. Continuous variables were expressed as means with SDs and compared using the *t* test. Multivariable Cox proportional hazards regression models were used to estimate adjusted hazard ratios (HRs) and 95% CIs for the risk of dialysis initiation. A 2-tailed *P* value of <.05 was considered statistically significant. All statistical analyses were performed using SAS version 9.4 (SAS Institute Inc).

ML Model Development and Feature Selection

Given the extended accrual period, we used a temporal split to preserve chronological separation between model development and evaluation. Records from 2007 to 2016 (80%) were used

XSL•FO
RenderX

for model training, and records from 2017 to 2018 (20%) were reserved as an independent held-out test set for performance assessment.

Within the training set, we performed 10-fold cross-validation to improve robustness and reduce overfitting. To address class imbalance, Synthetic Minority Over-sampling Technique (SMOTE) was applied only within the training folds of each cross-validation iteration to avoid information leakage into the validation folds. Model performance was evaluated on the held-out test set using accuracy, Cohen κ, sensitivity, specificity, area under the curve (AUC), F_1 score, and Brier score, recognizing that multiple complementary metrics are needed under imbalanced outcome distributions.

The 6 ML algorithms were chosen to encompass a broad spectrum of modeling techniques, ranging from interpretable linear models to complex, high-performance ensembles. Logistic regression was selected as a conventional statistical method widely used in clinical research, serving as a robust and interpretable baseline for comparison. To capture complex nonlinear relationships, we included 2 distinct models: classification and regression trees, a foundational decision tree algorithm, and multivariate adaptive regression splines, a flexible model adept at identifying interactions between predictors. Finally, to leverage the superior predictive power of ensemble learning, 3 state-of-the-art algorithms were selected [20]. Random forest represents the bagging method, which builds independent trees to reduce variance, whereas CatBoost and eXtreme Gradient Boosting (XGBoost) are representatives of boosting methods that construct models sequentially to correct the errors of their predecessors and often yield high accuracy. This comprehensive selection allowed for a thorough evaluation of predictive performance across different algorithmic families, and these methods have been successfully applied in similar medical informatics contexts [21-23] (see Supplementary Methods in Multimedia Appendix 1 for detailed model descriptions). Hyperparameters for each model were optimized using random search within the training set under 10-fold cross-validation. The held-out temporal test set was used only for final performance evaluation. The specific hyperparameters for all models are detailed in Table S3 in Multimedia Appendix 1. All model construction was conducted using Python (version 3.9; Python Software Foundation).

We employed a 2-pronged feature selection approach to identify the most significant predictors. In the first approach, each model performed feature selection based on its own internal mechanism, and its performance was evaluated using this algorithm-specific feature set. In the second approach, we constructed an overall consensus ranking of predictors using rank aggregation across the 6 algorithms. We prespecified that the best-performing algorithm would be selected based on performance on the held-out temporal test set, considering discrimination, class-imbalance–sensitive metrics, and calibration. For the selected best-performing model, we additionally evaluated parsimony by sequentially adding predictors according to the consensus ordering and selecting the feature count that maximized test-set performance.

Results

Characteristics of the Study Population

From the NHIRD, 2677 incident ADPKD cases were identified between 2007 and 2018. After applying exclusion criteria (n=821), 1856 patients were included in the final cohort (Figure 1).

XSL•FO
RenderX

Figure 1. Study flowchart of patient selection and machine learning model development. The diagram shows the patient selection process from the NHIRD for the period 2007 - 2018 and the subsequent workflow for model development. Patients were split temporally into a training set (2007 - 2016) and a held-out test set (2017 - 2018). ESRD was ascertained through December 31, 2019. ADPKD: autosomal dominant polycystic kidney disease; CART: classification and regression trees; ESRD: end-stage renal disease; eXGB: extreme gradient boosting; LGR: logistic regression; MARS: multivariate adaptive regression splines; ML: machine learning; RF: random forest.

XSL•FO
RenderX

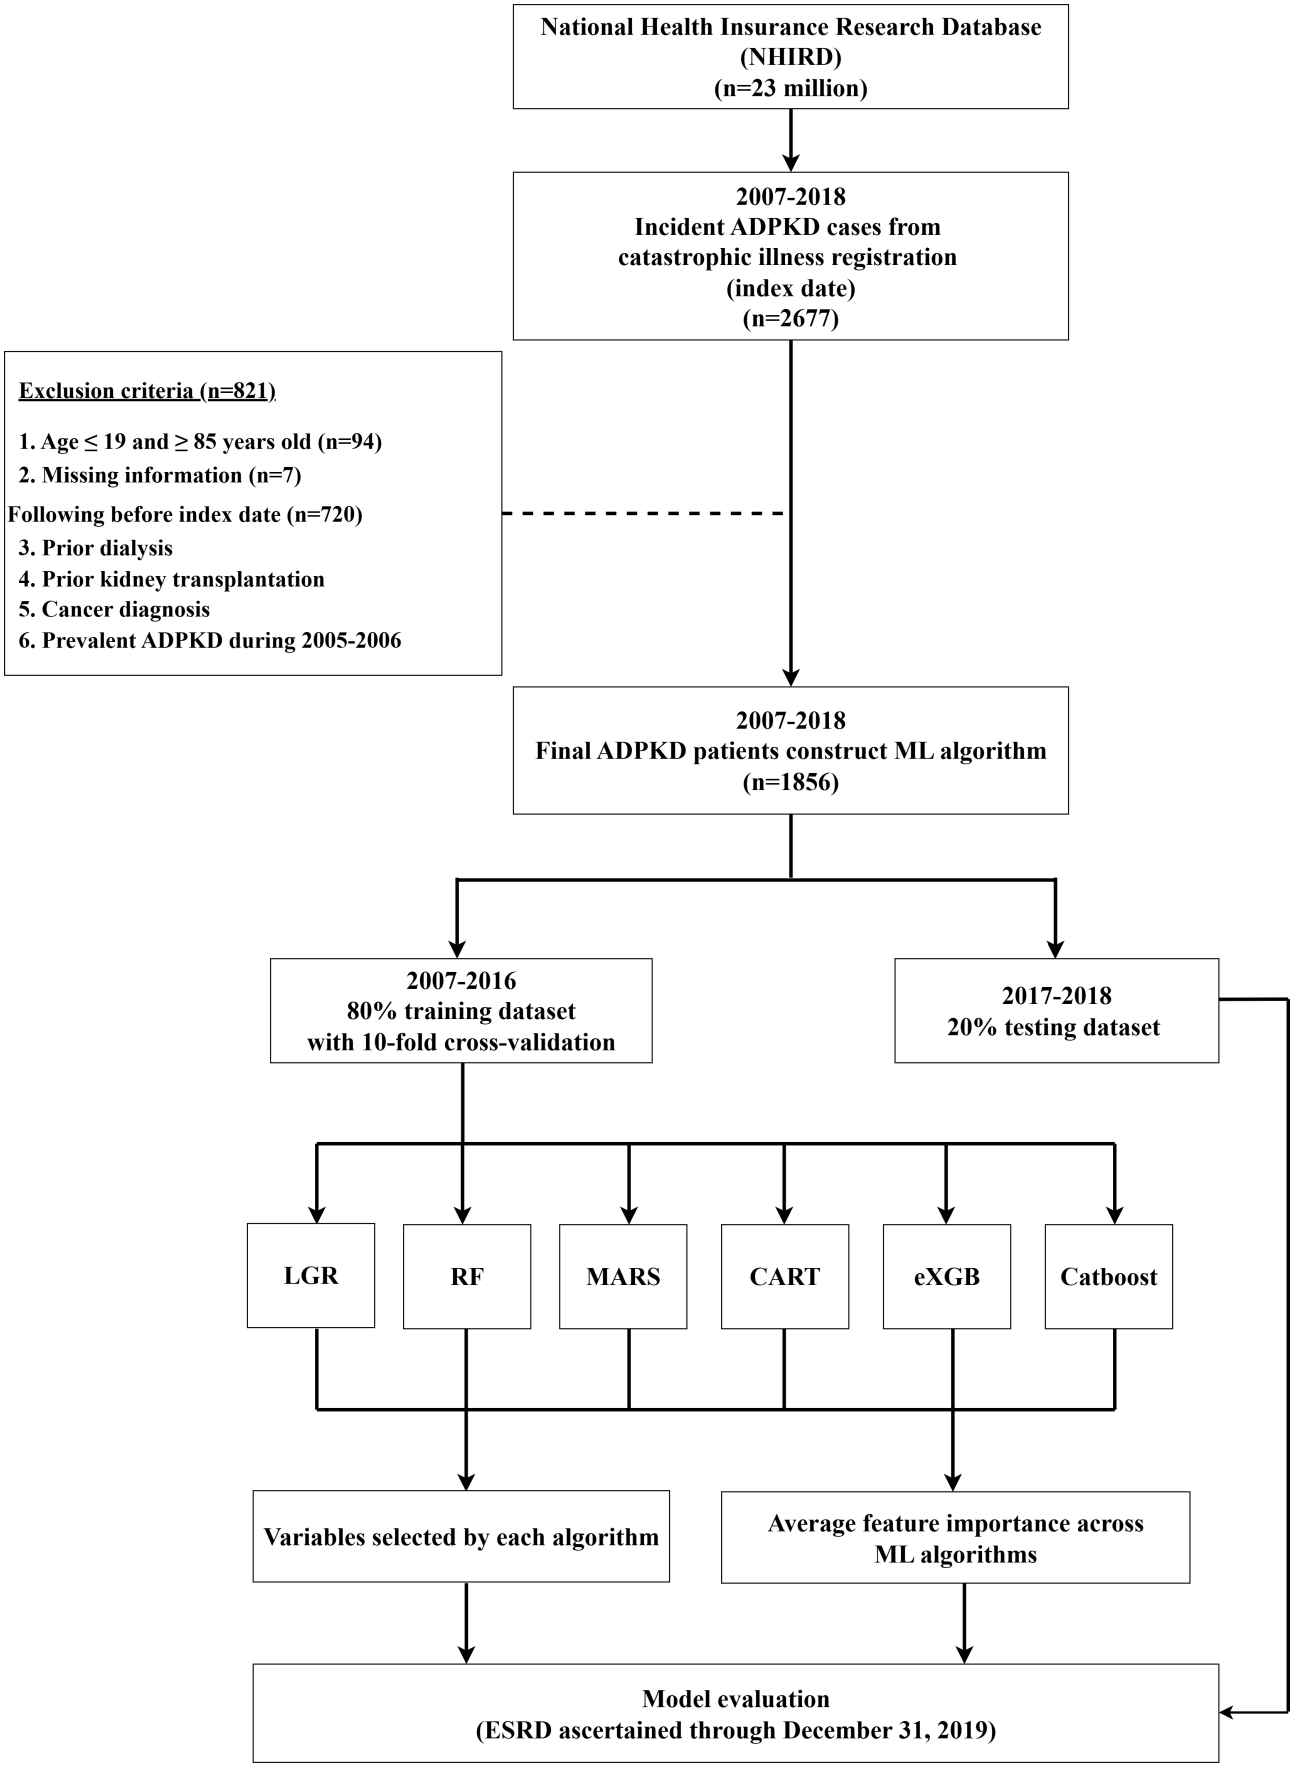

Table 1 summarizes baseline characteristics assessed during the 365-day lookback period preceding the index date. During follow-up through December 31, 2019, 302 patients (302/1856, 16.27%) initiated dialysis. Kidney transplantation without prior dialysis was observed in only 2 patients. Due to small cell size restrictions intended to protect patient privacy in the NHIRD

XSL•FO
RenderX

data release process, transplantation events could not be analyzed separately; therefore, ESRD outcomes are presented primarily in terms of dialysis initiation. The remaining 1554 patients (1554/1856, 83.73%) did not initiate dialysis and were censored at death or end of follow-up.

[a]PKD: polycystic kidney disease.
[b]CCI: Charlson Comorbidity Index.
[c]AF: atrial fibrillation.
[d]CHF: congestive heart failure.
[e]PVD: peripheral vascular disease.
[f]UTI: urinary tract infection.
[g]AKI: acute kidney injury.
[h]COPD: chronic obstructive pulmonary disease.
[i]DM: diabetes mellitus.
[j]ACEI: angiotensin-converting enzyme inhibitor.
[k]ARB: angiotensin II receptor blocker.
[l]CCB: calcium channel blocker.
[m]DPP4i: dipeptidyl peptidase-4 inhibitor.
[n]NSAID: nonsteroidal anti-inflammatory drug.
[o]mTOR: mechanistic target of rapamycin.

At baseline, the cohort had substantial cardiorenal comorbidity and medication use. The most prevalent comorbidities were hypertension (86.58%, 1606/1856) and UTI (50.38%, 935/1856), with pneumonia (29.26%, 543/1856), anemia (24.83%, 461/1856), and gout (23.01%, 427/1856) also common. Antihypertensive exposure was widespread (ACEI/ARB 161.30, SD 127.50 d; CCB 160.90, SD 133.70 d), and metabolic therapy was frequent (metformin 116.20, SD 137.10 d; long-acting insulin 91.71, SD 139.10 d).

Stratification by subsequent dialysis initiation highlighted clinically meaningful differences in baseline disease severity and management. Patients who later initiated dialysis were older (50.94, SD 11.94 vs 44.86, SD 13.39 y) and had higher comorbidity burden (Charlson Comorbidity Index [CCI] 4.18, SD 2.27 vs 2.27, SD 2.22; CCI≥6: 20.53% vs 7.72%), with the largest separations for anemia (65.89% vs 16.86%) and AKI (23.51% vs 6.56%). Baseline medication patterns were consistent with greater clinical complexity in the dialysis group, including lower metformin exposure (44.17, SD 95.41 vs 130.20, SD 148 d) and higher sodium bicarbonate exposure (20.52, SD 68.46 vs 7.25, SD 44.30 d).

Risk Analysis for Progression to Dialysis

Table 2 presents the multivariable Cox regression results. After adjustment for sex, age category, CCI category, and comorbidities, male sex was associated with a higher risk of dialysis initiation (aHR 1.55, 95% CI 1.13 - 2.11; *P*=.006). Age remained a strong predictor: compared with age younger than 55 years, the risk increased across categories. Among comorbidities, anemia showed the strongest association with dialysis initiation (aHR 4.33, 95% CI 3.25 - 5.78; *P*<.001). Congestive heart failure, AKI, and gout were also associated with a higher risk. Hypertension, COPD, and anxiety were associated with lower hazard in the adjusted model.

Feature Importance Across ML Models

Figure 2 presents the relative importance of variables in predicting dialysis risk, as determined by the 6 ML models. A consensus emerged across the different algorithms, highlighting several key predictors. The top-ranked predictors spanned comorbidity burden and medication patterns, including anticoagulant use, hypertension, CCB use, higher CCI category, loop diuretics, sodium bicarbonate, anemia, and ACEI or ARB use, together with age and sex. Additional contributors included cardiorespiratory comorbidities, UTI, gout, and neuropsychiatric conditions and related medications.

Performance Comparison of ML Models

Table 3 summarizes performance for 6 ML algorithms under 2 feature selection strategies: model-specific feature selection and a consensus feature set derived from rank aggregation. Using model-specific feature selection, XGBoost achieved the highest accuracy (0.9748) with specificity of 1, with an AUC of 0.9436 and a Brier score of 0.0254. Using the consensus feature set, performance improved across models. XGBoost achieved the highest accuracy (0.9832) and F_1-score (0.8), whereas MARS achieved the highest AUC (0.9762) and CatBoost achieved the lowest Brier score (0.0217), indicating strong discrimination with favorable calibration across top-performing models.

Optimization of the XGBoost Model via Feature Selection

Figure 3 shows the change in test set accuracy as top-ranked predictors from the consensus ranking were sequentially added to the XGBoost model. Accuracy increased rapidly as the highest-ranked predictors were included and reached its maximum with 27 predictors. This feature count was selected as the optimal balance between parsimony and predictive performance, and the 27-feature set was used for the final XGBoost model.

XSL•FO

Figure 3. Optimization of extreme gradient boosting model performance by sequential feature addition. The plot shows the change in model accuracy (y-axis) as the number of top-ranked predictor variables (x-axis). The dashed vertical line indicates the point at which maximum accuracy was achieved with 27 variables.

Key Predictors in the Final XGBoost Model

The final XGBoost model used 27 baseline predictors selected during feature optimization (Table 4). This set included demographic and comorbidity burden measures (age, sex, and CCI category), major clinical conditions linked to renal risk or frailty (anemia, hypertension, ischemic heart disease, gout, pneumonia, COPD, UTI, anxiety, and depression), and multiple medication exposures. Key medication predictors included antihypertensive classes (ACEI or ARB, CCB, beta-blockers, and alpha-blockers), agents reflecting advanced renal management or metabolic status (loop diuretics, sodium bicarbonate, potassium-sparing diuretics, and rapid-acting insulin), and medications that may relate to underlying diseases (anticoagulants, antiplatelet agents, NSAIDs, sedative hypnotics, tranexamic acid, febuxostat, and statins). It is crucial to note that these medication-related predictors should be interpreted as proxies for underlying disease severity and complexity (ie, confounding by indication), rather than as direct causal risk factors.

Discussion

Principal Findings

This retrospective cohort study used data from the NHIRD to predict ESRD progression in ADPKD using 6 ML algorithms, with ESRD operationalized as initiation of maintenance dialysis. On the held-out temporal test set, XGBoost demonstrated the best overall performance after feature optimization (accuracy 0.9832; F_1 score 0.8). The final optimized XGBoost model was derived by sequentially adding top-ranked predictors and achieved peak accuracy with 27 variables. The most informative predictors reflected underlying disease severity and care intensity, including age, CCI, anemia, hypertension, ischemic heart disease, gout, pneumonia, COPD, UTI, anxiety, and depression, as well as medication exposures such as anticoagulants, loop diuretics, ACEI/ARB, CCB, and febuxostat.

Interpretation of Major Clinical Risk Factors

Hypertension is a common early manifestation of ADPKD, often developing before renal function declines. It affects up to 86.6% of patients with ADPKD, frequently appearing around 30 years of age, with up to 20% of them diagnosed before the age of 20 [24,25]. The underlying mechanisms involve intrarenal ischemia, renin-angiotensin-aldosterone system (RAAS) activation, and endothelial dysfunction. Progressive cyst expansion leads to renal hypoperfusion and sustained RAAS stimulation, further exacerbating hypertension and accelerating kidney damage [26,27]. This mechanistic framework is consistent with our results, where hypertension and cardiovascular comorbidity markers, including ischemic heart disease and related medication patterns, contributed meaningfully to dialysis risk prediction.

Age and overall comorbidity burden were among the highest-ranked predictors in both the consensus feature ranking and the final XGBoost feature set. This pattern suggests that administrative claims-based models capture the cumulative burden of systemic illness, frailty, and health care utilization that often accompanies advanced kidney disease trajectories [28,29]. In our cohort, ischemic heart disease and cardiovascular medication proxies (eg, anticoagulants, antiplatelet agents, beta-blockers, and loop diuretics) were repeatedly selected, indicating that cardiovascular disease severity and its treatment intensity provide informative signals of near-term dialysis risk [30,31].

In our cohort, anemia showed the strongest association with dialysis initiation in the adjusted Cox model and was consistently selected by the ML algorithms. A study conducted in Japan found that, despite higher hemoglobin levels in ADPKD than in other CKD types, anemia remains a key predictor of renal disease progression. In nondialysis patients with ADPKD, lower hemoglobin levels were associated with faster kidney function decline, with men with hemoglobin levels less than 12 g/dL and women with hemoglobin levels less than 11 g/dL at higher risk [32]. Together, these findings support anemia as a clinically accessible marker of advanced disease and progression risk in ADPKD.

AKI and infection-related diagnoses such as pneumonia and UTI also contributed to the prediction. These events may accelerate loss of residual kidney function through hemodynamic instability, inflammatory injury, or nephrotoxic exposures, and they may also serve as markers of vulnerability and more frequent clinical encounters. In parallel, medication predictors such as sodium bicarbonate and NSAIDs plausibly reflect clinically recognized metabolic acidosis and nephrotoxic exposure that often accompany advanced CKD and precede dialysis initiation [33].

Medication Predictors as Markers of Disease Severity

As highlighted earlier, a critical aspect of interpreting our findings is the potential for confounding by indication, particularly for medication-related predictors. In a retrospective cohort study, the use of a specific medication is often a marker of underlying disease severity rather than a cause of the outcome itself. Therefore, while these medications emerged as strong predictors in our model, they should be viewed primarily as indicators of a higher underlying risk profile, and our findings do not imply a causal relationship or recommend changes in prescribing practices. Consistent with prior work using administrative claims for kidney failure prediction, these medication patterns should be interpreted primarily as proxies for clinical complexity rather than as causal determinants of dialysis initiation [31].

Renin-angiotensin system inhibitors have been established as the first-line treatment due to their benefits in hypertension control [34]. In our model, the selection of additional antihypertensive classes (eg, alpha-blockers and CCB) and loop diuretics likely reflects difficult-to-control blood pressure, volume management needs, or concomitant cardiovascular disease rather than direct causal effects on renal decline. Similarly, anticoagulant and antiplatelet use may act as proxies for atrial fibrillation, vascular disease, or prior cardiovascular events, conditions that commonly cluster with advanced CKD and a higher risk of dialysis initiation.

Tranexamic acid was also selected among the final XGBoost predictors. In ADPKD, clinically significant gross hematuria is a common and clinically relevant event, and tranexamic acid has been used in small series for severe hematuria, although evidence remains limited [2,35]. Therefore, in claims-based modeling, tranexamic acid likely functions as a proxy for clinically significant hematuria or bleeding-related care that clusters with more advanced disease trajectories, rather than as a causal determinant of dialysis initiation.

Hyperuricemia is increasingly implicated in CKD progression, and our model identified gout and febuxostat as informative predictors of dialysis. This finding does not suggest a causal link but rather reflects prescribing patterns that align with both international guidelines and local reimbursement policies. Major clinical practice guidelines for ADPKD recommend allopurinol as the first-line urate-lowering therapy [2]. This standard is strictly reflected in Taiwan's National Health Insurance system, where reimbursement for the second-line agent, febuxostat, was restricted during our study period. These restrictions likely limited its use primarily to patients with substantial preexisting conditions, most notably advanced chronic kidney disease

XSL•FO
RenderX

(defined as eGFR <45 mL/min/1.73 m^2) or other complications such as urate nephrolithiasis or severe tophaceous gout. Consequently, the predictive signal from febuxostat in our model arises because it serves as a powerful proxy, identifying a patient subgroup with higher baseline renal risk and greater disease complexity. Further prospective studies are needed to determine if urate-lowering therapy itself modifies the disease course in ADPKD.

Statins, primarily known for their cholesterol-lowering effects, also possess anti-inflammatory and antioxidant properties that could be beneficial in PKD. Chronic inflammation and oxidative stress play roles in the pathophysiology of PKD, contributing to cyst growth and renal function decline. Evidence regarding the efficacy of statins in PKD is equivocal. Some cohort studies and animal research suggest that statins may slow the decline in renal function in patients with PKD by reducing inflammation and oxidative stress [9]. However, findings from definitive clinical trials in PKD populations, which are scarce, remain inconclusive.

Comparison With Existing Risk Stratification Tools

Our ML approach should be compared with existing clinical risk tools for ADPKD, such as the Mayo Imaging Classification and the PROPKD score. The primary advantage of our model lies in its broad accessibility. By leveraging nationwide administrative data, it bypasses the need for resource-intensive assessments, such as MRI for TKV measurement or genetic sequencing, making it a scalable and cost-effective tool for initial risk stratification across a large population. The main disadvantage, however, is the lack of direct pathophysiological data. Without TKV or genetic data, our model relies on surrogate markers of disease severity and cannot offer the same level of mechanistic insight or precision as the gold-standard tools. Therefore, our model should not be viewed as a replacement for these established methods but rather as a complementary instrument. Its optimal clinical role would be to serve as a first-line screening tool to efficiently identify high-risk patients who could then be prioritized for more definitive prognostic evaluations like imaging or genetic testing.

Strengths and Limitations

To our knowledge, this study represents the first nationwide ML-based analysis of dialysis risk in ADPKD using administrative data. It provides a scalable framework for population-level risk stratification. The use of the NHIRD, a large population-based dataset with long-term follow-up, ensures high generalizability to the nationwide population of Taiwan.

Several limitations of this study should be acknowledged. First, its retrospective design precludes the establishment of causality. Second, and most importantly, our study is constrained by the nature of the NHIRD, which lacks the gold-standard prognostic markers for ADPKD including genetic data (PKD1/PKD2 status) and imaging biomarkers like TKV, and key laboratory values such as eGFR or proteinuria. Without direct access to TKV or genetic data, our model inherently relies on surrogate markers such as comorbidity burden and medication patterns to infer underlying risk. Despite the use of a washout period and validation via the Catastrophic Illness Patient Registry, truly incident ADPKD cases cannot be fully guaranteed in claims-based data. We therefore wish to emphasize that our model is proposed as a complementary tool for broad-based risk stratification, not as a replacement for comprehensive clinical evaluation. Third, because observation windows vary by index year, the binary labeling framework may under-ascertain events among patients with shorter follow-up and can bias absolute risk interpretation. In addition, calibration curves were not presented, limiting assessment of absolute risk calibration. Fourth, because deaths occurring before ESRD were labeled as nonevents in the binary ML framework, patients with high competing mortality may be misclassified as having low renal risk. Fifth, the measurement of medication exposure, quantified by prescription days, is a proxy that does not capture actual patient adherence, dosage, or treatment adjustments. This limits our ability to make definitive conclusions about the role of specific pharmacological agents. Finally, our model was developed using a Taiwanese population, and its performance and the relative importance of predictors may vary across different ethnic and geographic groups, which may limit generalizability.

Future Work

Future studies should prioritize prospective validation in diverse external cohorts. Methodologically, fixed-horizon prediction and time-to-event approaches, including survival ML and competing-risk or multistate frameworks, should be evaluated to better align modeling with clinical trajectories. External validation datasets that include laboratory, genetic, and imaging biomarkers (eg, eGFR, proteinuria, PKD1/PKD2 status, and TKV) will enable integrated, multitiered risk stratification and more complete assessment of calibration and clinical utility. Moreover, instance-level explainability methods (eg, SHAP) can be explored to support clinical interpretability.

Conclusions

This study developed and evaluated 6 ML models to classify dialysis initiation risk in a nationwide ADPKD cohort using administrative claims data and a prespecified temporal validation design. On the held-out temporal test set, XGBoost showed the best overall performance. The most informative predictors primarily reflected disease severity and care intensity captured in claims data, including age, comorbidity burden, anemia, and hypertension, whereas medication variables should be interpreted as noncausal proxies of clinical complexity.

Acknowledgments

No generative artificial intelligence tools were used to generate the manuscript text, analyses, figures, tables, or multimedia appendix. All study design decisions, analyses, interpretations, and final wording were produced and verified by the authors.

Abstract

Background: Upper and lower extremity lymphedema is a chronic, progressive condition that significantly impairs the quality of life of affected patients. Despite the recently established effectiveness of physical therapy and supermicrosurgical interventions, current guidelines frequently lag behind emerging evidence and commonly do not offer stage-specific treatment algorithms. This gap in evidence-based guidance may prompt clinicians with limited experience to seek support from large language models such as ChatGPT.

Objective: Given the potential of artificial intelligence to rapidly integrate emerging research, this study evaluated how clinicians from different professional backgrounds rate the quality and reliability of personalized lymphedema management recommendations generated by ChatGPT.

Methods: In this exploratory cross-sectional study, ChatGPT generated treatment recommendations for 6 standardized lymphedema case scenarios. An international panel of 67 participants (resident doctors, board-certified specialists, physiotherapists, and advanced practice nurses) from 34 institutions across 11 countries assessed the recommendations using a modified DISCERN questionnaire with a 9-point agreement scale ranging from 1 (completely disagree) to 9 (completely agree). Ratings were summarized as pooled means with variability measures and compared across clinician groups (residents vs board-certified physicians vs physiotherapists or advanced practice nurses) using group comparison testing.

Results: ChatGPT was rated most favorably for diagnostic accuracy and treatment relevance, with higher ratings among residents than board-certified physicians. Residents assigned significantly lower scores for source indication, source currency, and communication of uncertainty. Between-group differences were observed across multiple DISCERN items, consistent with systematically more critical appraisal by experienced specialists. Participants reported moderate to high trust and willingness to consider ChatGPT as a supplementary resource, with more favorable perceptions among younger respondents.

Conclusions: Clinicians perceived ChatGPT as potentially useful for preliminary orientation and educational support in lymphedema management, especially for less experienced users. Despite not being blinded, lower ratings in evidence transparency and uncertainty communication, particularly among experienced specialists, suggest that current artificial intelligence outputs should not be used as stand-alone guidance. Future work should test clinically integrated, citation-grounded workflows in prospective settings and evaluate whether they improve decision quality and efficiency.

KEYWORDS

artificial intelligence; AI; ChatGPT; decision-making; digital health; large language models; lymphedema; personalized medicine

Introduction

Lymphedema is a chronic condition characterized by the accumulation of interstitial fluid, typically resulting from damage or disruption of lymphatic pathways [1]. In the Western world, lymphedema is commonly caused by oncologic surgery or radiotherapy and significantly reduces quality of life due to extremity swelling, limited mobility, and psychosocial distress [1-5].

Lymphedema treatment is highly individualized, influenced by age, preexisting comorbidities, and prior interventions [1]. Conservative treatment includes complex decongestive therapy; however, recent literature has demonstrated promising long-term outcomes after supermicrosurgical interventions, such as lymphovenous anastomosis (LVA) and vascularized lymph node transfer (VLNT) [6-9]. Due to the personalized nature of lymphedema treatment, following the current guidelines of the AWMF (Arbeitsgemeinschaft der Wissenschaftlichen Medizinischen Fachgesellschaften, S2k) or the International Society of Lymphology (ISL) may result in difficulties providing universally applicable, stage-specific recommendations [10,11]. Furthermore, the guidelines may include outdated information, primarily due to the time-intensive nature of expert consensus and validation processes [10,11]. Given the rapid advancements in lymphatic surgery, the incorporation of novel treatment approaches into official guidelines may take years, as this process requires a predefined and structured consensus. Consequently, there is a possibility that patients may receive care that is no longer up to date in a clinical context.

Large language models (LLMs) such as ChatGPT (OpenAI) represent a new approach to the processing of knowledge, which also applies to medical information [12,13]. These technologies have the potential to reshape medical decision-making by accelerating the integration of novel research into clinical routines [14-17]. Thus, unlike traditional guidelines, artificial intelligence (AI) is hypothesized to accelerate the transition of new findings into personalized treatment recommendations. However, whether this potential is truly realized in practice strongly depends on data implementation and prompting [18].

Therefore, the goal of this study was to assess ChatGPT's ability to define and generate treatment recommendations for lymphedema by evaluating the quality, accuracy, and perceived utility of its recommendations across an interdisciplinary panel of relevant medical specialties. Additionally, the differences in acceptance were compared between resident doctors in training and board-certified plastic surgeons with experience in either lymphatic surgery or lymphedema management.

Methods

Study Design

The study was designed as a multidisciplinary assessment of ChatGPT-generated treatment recommendations of 6 cases of chronic lymphedema, ranging from ISL stage I to ISL stage 3 of the upper and lower limb (Multimedia Appendix 1). To ensure consistency, all cases were submitted to GPT-4o (GPT-4 Omni) on December 18, 2024, at noon Central European Time by the first authors (AF and CEE). Each case was entered into a distinct, separate chat session to limit session history bias. Only the initial response was considered, and the option to regenerate the response was not used. The responses obtained from GPT-4o were compiled into a PDF and were subsequently evaluated by a panel of resident doctors (considered inexperienced), board-certified doctors (considered experienced), and physiotherapists or advanced practice nurses (APNs) using a 9-point agreement scale [19].

Clinical Vignettes and Treatment Recommendations

The clinical vignettes were designed with the intention of incorporating the underlying etiology of lymphedema through past medical history, current patient symptoms, and findings from clinical examination. Cases were prepared to be as realistic as possible and to reflect real clinical scenarios. Patients were clearly categorized into the 3 ISL stages, with corresponding indocyanine green studies illustrating the lymphatic patterns consistent with the stage described in each clinical vignette [10]. Furthermore, the cases were illustrated with images adapted from Principles and Practice of Lymphedema Surgery by Cheng et al [20]. A standardized prompt was used for each case and is provided in Multimedia Appendix 1.

Evaluation

The evaluators had access to the original prompts, all 6 clinical cases, and the corresponding treatment recommendations generated by ChatGPT (Multimedia Appendix 1). The web-based questionnaire for subsequent evaluation was developed and distributed using the Research Electronic Data Capture (REDCap; Vanderbilt University) platform [21]. The DISCERN tool, a validated questionnaire for assessing the quality of written treatment information, was adapted to a 9-point agreement scale and then used for the quantitative evaluation of each generated response [19].

In accordance with the instructions provided in the DISCERN handbook [19], questions 1 and 2 ("Are the aims clear?" and "Does it achieve its aims?") were excluded from the evaluation as they were found to be irrelevant to the defined research question of this study. Two additional questions were included in the evaluation of each case: one concerning correct staging (question 1) and the other regarding overall final agreement with the treatment option recommended by ChatGPT (question 16). In summary, each response was evaluated using 16 questions rated on a 9-point agreement scale, where 1 represents complete disagreement and 9 represents complete agreement. Finally, 3 concluding questions were added to evaluate the overall agreement regarding the treatment recommendation by ChatGPT and the attitude regarding AI use as a clinical decision tool (Multimedia Appendix 2). In addition, each participant was given the option to offer feedback. These open-text comments were reviewed descriptively by the first authors to provide contextual insight alongside the quantitative results. No formal

XSL•FO
RenderX

qualitative analysis or coding approach was applied. All available comments were read in full, and relevant observations are summarized in Multimedia Appendix 3.

Survey Distribution

The survey was conducted from January 7 to March 18, 2025. Resident doctors without prior experience in lymphedema management were recruited internationally through the same broader professional networks as the expert panel, primarily via participating centers in the LYMPH trial, as well as international resident and student networks. Experienced, board-certified doctors specializing in lymphedema treatment were identified and contacted, most of whom had previously participated in the international lymphedema consortium through existing collaborations [22]. A total of 64 board-certified doctors were invited via email to take part in the study, receiving a survey link along with a comprehensive explanation of its objectives and requirements (response rate 24/64, 37.5%). Additionally, 30 physiotherapists and lymphedema APNs specializing in lymphedema treatment were invited (response rate 10/30, 33.3%) through the same consortium and a contact list provided by the Lymphödem Vereinigung Schweiz (a Swiss patient organization) [22,23]. As resident recruitment was conducted via mass email and a preexisting student group, the response rate of invited resident doctors could not be calculated.

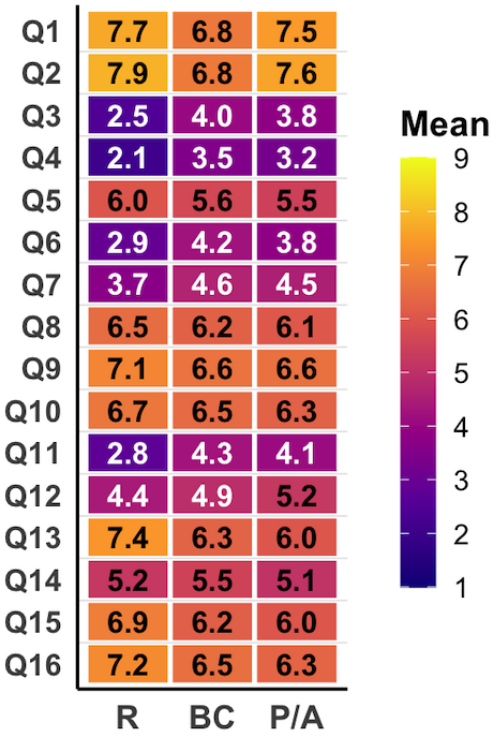
Statistical Analysis

Statistical analysis was conducted using R software (version 4.4.3; R Foundation for Statistical Computing) [24]. The primary end point was the scoring of agreement and reliability of ChatGPT-generated treatment recommendations stratified by experience groups. Consequently, participants were categorized into 3 groups: resident doctors, board-certified doctors, and physiotherapists or APNs. For each question, group-wise means and SDs were calculated. The Levene test was used to confirm homogeneity of variances prior to conducting 1-way ANOVA. Depending on the result of the Levene test, either standard ANOVA (for equal variances) or Welch ANOVA (for unequal variances) was used to test for differences between groups. Where applicable, an “overall” group comprising all participants was included for descriptive purposes only and was excluded from inferential statistical testing. A 2-sided P value of ≤.05 was considered statistically significant.

Ethical Considerations

This study was conducted in accordance with the Declaration of Helsinki. On the basis of the fictional nature of the cases and the absence of human subject data, the local ethics committee (Ethikkommission Nordwest- und Zentralschweiz) deemed that no formal ethics approval was required. Participation in the web-based survey was voluntary. All participants were informed about the purpose of the study, and informed consent was implied through completion of the survey. Participants had the option to discontinue the survey at any time without any consequences. All data were collected anonymously. Data protection and confidentiality were ensured in accordance with applicable regulations. No compensation was provided. No identifiable individuals are shown in any figures or supplementary materials.

Results



A total of 67 participants from 34 different institutions across 11 countries completed the survey, including 33 (49.3%) resident doctors, 24 (35.8%) board-certified doctors, and 10 (14.9%) lymphedema physiotherapists or APNs. The mean age was 35.6 (SD 14.1) years, with resident doctors averaging 28.0 (SD 6.0) years, board-certified doctors 45.0 (SD 14.0) years, and physiotherapists or APNs 42.0 (SD 19.9) years.

Diagnostic Accuracy and Relevance (Q1 and Q2)

Staging and diagnostic accuracy (question 1; Q1) were generally rated high (mean 7.3, SD 1.5), with board-certified doctors assigning significantly lower scores than resident doctors (P<.001; Table 1). Similarly, the relevance of the recommendations (Q2) was rated highly (mean 7.5, SD 1.4), with board-certified doctors rating significantly lower compared to resident doctors or physiotherapists or APNs (P<.001; Figure 1; Table 1). A detailed overview of scoring per case is provided in Multimedia Appendix 4.

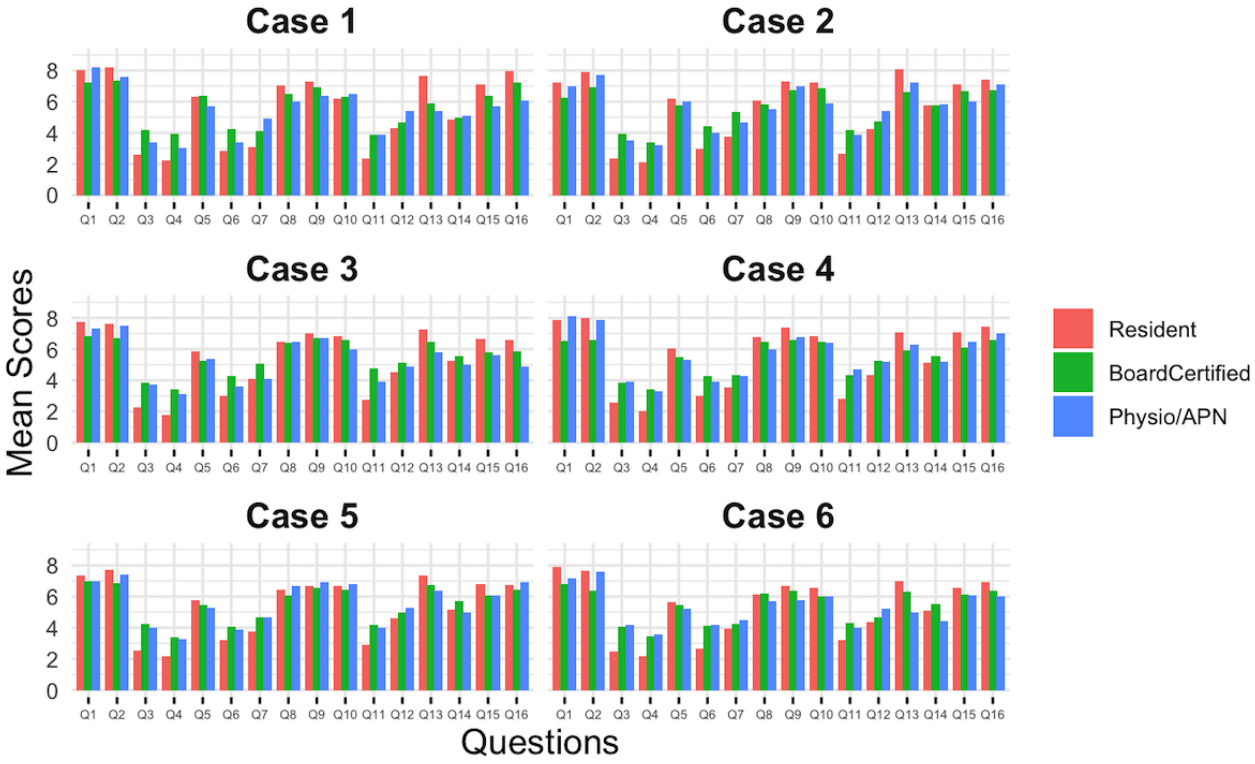
Question[b]	Overall (n=67), mean (SD)	Resident doctors (n=33), mean (SD)	Board-certified physicians (n=24), mean (SD)	Physiotherapist or APN[c] (n=10), mean (SD)	*P* value
Q1—diagnostic accuracy	7.3 (1.5)	7.7 (1.2)	6.8 (1.6)	7.5 (1.9)	*<.001*[d]
Q2—relevance	7.5 (1.4)	7.9 (1.0)	6.8 (1.6)	7.6 (1.1)	*<.001*
Q3—indication of sources used	3.2 (2.5)	2.5 (2.1)	4.0 (2.4)	3.8 (2.9)	*<.001*
Q4—currency of sources used	2.7 (2.1)	2.1 (1.6)	3.5 (2.1)	3.2 (2.9)	*<.001*
Q5—balanced and unbiased information	5.8 (1.8)	6.0 (1.7)	5.6 (1.6)	5.5 (2.2)	.07
Q6—additional supporting information	3.5 (2.3)	2.9 (2.1)	4.2 (2.0)	3.8 (2.7)	*<.001*
Q7—communication of areas of uncertainty	4.1 (2.1)	3.7 (2.0)	4.6 (1.8)	4.5 (2.5)	*<.001*
Q8—explanation of how the treatment works	6.3 (1.8)	6.5 (2.0)	6.2 (1.5)	6.1 (2.0)	.23
Q9—benefits of treatment	6.8 (1.6)	7.1 (1.8)	6.6 (1.3)	6.6 (1.7)	*.04*
Q10—risks of treatment	6.6 (1.9)	6.7 (2.0)	6.5 (1.5)	6.3 (2.0)	.22
Q11—consequences of treatment refusal	3.5 (2.2)	2.8 (2.0)	4.3 (1.9)	4.1 (2.7)	*<.001*
Q12—impact on quality of life	4.7 (2.4)	4.4 (2.3)	4.9 (2.1)	5.2 (2.8)	*.03*
Q13—availability of multiple treatment options	6.8 (1.9)	7.4 (1.7)	6.3 (1.8)	6.0 (2.2)	*<.001*
Q14—support for shared decision-making	5.3 (2.3)	5.2 (2.4)	5.5 (2.1)	5.1 (2.3)	.37
Q15—overall quality of the recommendation	6.5 (1.6)	6.9 (1.4)	6.2 (1.8)	6.0 (1.8)	*<.001*
Q16—overall agreement	6.8 (1.8)	7.2 (1.6)	6.5 (1.9)	6.3 (2.3)	*<.001*

[a]Values represent the pooled mean (SD) across the 6 standardized lymphedema case scenarios from an exploratory cross-sectional survey of 67 clinicians (resident doctors, board-certified physicians, and physiotherapists or advanced practice nurses) from 34 institutions in 11 countries (January-March 2025).

[b]Q: question.

[c]APN: advanced practice nurse.



[d]Values in italic demonstrate statistical significance ($P<.05$).

Source Transparency and Objectivity (Q3-Q5)

The clarity of source citation (Q3) and the dating of sources (Q4) were rated very low across all groups, with mean scores of 3.2 (SD 2.5) and 2.7 (SD 2.1), respectively (Figure 2). Interestingly, resident doctors gave both questions significantly lower ratings than the other groups ($P<.001$). Interestingly, Q5 (objectivity or neutrality of ChatGPT) received an average score of 5.8 (SD 1.8), with no significant differences between groups.

XSL•FO
RenderX

Figure 2. Mean scores by professional group for all cases. Overview of mean scores across 6 lymphedema case scenarios by professional group. Bars represent mean scores. APN: advanced practice nurse; Q: question. Exact values can be found in Multimedia Appendix 4.

Supportive Information and Areas of Uncertainty (Q6 and Q7)

The quality of additional resources (Q6) was rated badly, with a mean score of 3.5 (SD 2.3) across all cohorts. Similarly, the communication of uncertainty (Q7) received moderate scores of 4.1 (SD 2.1), with residents giving the lowest scores across both questions (P<.001).

Treatment Explanation and Options, Risk Communication, and Quality of Life Considerations (Q8-Q13)

ChatGPT's performance in communicating treatment options and possible risks was generally rated positively, with Q8 (how the treatment would work), Q9 (benefits of treatment), and Q10 (potential risks) all receiving favorable scores (mean 6.3, SD 1.8; mean 6.8, SD 1.6; and mean 6.6, SD 1.9, respectively). In contrast, Q11 (consequence of no treatment) consistently scored low (mean 3.5, SD 2.2). Q12 assessed whether the provided information addressed the impact of the treatment on patients' quality of life. Ratings were moderate (mean 4.7, SD 2.4), with residents rating the responses significantly lower than other groups. Q13 (ChatGPT mentioning that there may be more than one treatment choice) was generally rated positively (mean 6.8, SD 1.9).

Shared Decision-Making and Overall Quality (Q14-Q16)

Support for shared decision-making (Q14) was rated moderately (mean 5.3, SD 2.3). The overall impression of the quality of responses (Q15) and overall agreement with treatment recommendations (Q16) both received high ratings (mean 6.5, SD 1.6 and mean 6.8, SD 1.8, respectively), with physiotherapists or APNs rating the answers the lowest (P<.001).

Concluding Questions—Trust and Future Use

Concluding question (CQ) 1 assessed trust in ChatGPT's responses, CQ2 assessed willingness to use ChatGPT in future clinical work, and CQ3 assessed whether participants would recommend it for clinical decision-making. Resident doctors rated all 3 concluding questions (CQ1-CQ3) significantly higher than board-certified doctors and physiotherapists or APNs. CQ2 showed a similar pattern, with resident doctors at a mean of 6.5 (SD 1.4), board-certified doctors at 5.3 (SD 2.2), and physiotherapists or APNs at 5.3 (SD 2.3). Finally, for CQ3, which assessed whether participants would recommend AI as a clinical decision-making tool, residents again scored highest, followed by board-certified doctors and physiotherapists or APNs (Figure 3; Table 2). All survey comments are listed in Multimedia Appendix 3.

Discussion

In this exploratory, cross-sectional study, a total of 67 participants, comprising 33 resident doctors still in training, 24 board-certified doctors, and 10 lymphedema physiotherapists or APNs, from 34 different institutions across 11 countries evaluated ChatGPT-generated treatment recommendations for 6 fictional lymphedema cases. This is the first study to evaluate ChatGPT-generated treatment recommendations for lymphedema.

Notably Higher Acceptance of ChatGPT Among Younger Doctors

The overall high level of agreement with the ChatGPT-generated treatment recommendations (Q16) indicates broad acceptance across all cases and groups (Table 1). Resident doctors expressed a more positive opinion toward ChatGPT, a tendency that is presumably attributable to their lesser clinical experience and greater openness to digital technologies in medical practice, indicating that the evaluation of ChatGPT may also be influenced by generational factors (Figure 3) [25,26]. Importantly, however, this favorable perception was not uncritical. Residents assigned significantly lower scores than board-certified physicians for source transparency (Q3-Q4;

XSL•FO
RenderX

Figure 1). The lower ratings may reflect stricter expectations regarding explicit source citation, differences in grading thresholds, or a reduced ability to recognize implicit sources that experienced clinicians may infer based on prior knowledge [27]. As the study design does not allow discrimination between these explanations, no conclusions can be drawn regarding the underlying cause of this difference. Nevertheless, several resident doctors reported that ChatGPT already serves them as a useful orientation tool, particularly in situations with limited prior familiarity with a condition or treatment options. This underscores the tool's potential as a rapid decision support or educational aid, as it only uses a few seconds to generate an extensive response [18]. It also highlights the need to integrate the critical use of AI tools into medical education. As residents showed greater willingness to use ChatGPT, targeted training could help prevent misconceptions and ensure these tools complement, rather than replace, clinical reasoning.

However, board-certified doctors demonstrated a lower level of agreement with treatment recommendations provided by ChatGPT, possibly due to their greater clinical experience and higher expectations regarding therapeutic nuances. This may, in part, stem from the perception that AI systems are not yet capable of providing fully personalized treatment algorithms. This viewpoint was supported in the open comments section (Multimedia Appendix 3), where experienced clinicians repeatedly pointed out that well-established surgical interventions, such as LVA and VLNT, were insufficiently addressed. In this study, LVA and VLNT were only briefly mentioned in cases 2, 3, 4, and 6 and only as potential options if compression therapy and liposuction were deemed insufficient. Reconstructive procedures such as LVA and VLNT are mentioned in both the German AWMF (S2k) guidelines and the ISL consensus document [10,11]. While the AWMF (S2k) guidelines suggest considering surgical options only after 6 months of conservative treatment without any lasting beneficial effect, the ISL guidelines refer to microsurgical interventions without specifying any time frame regarding previous complex decongestive therapy [10,11]. However, recent literature suggests that these procedures may also be used earlier or even as a preventative measure, thus challenging the traditional time threshold [28,29]. Given that key papers and guideline discussions on LVA and VLNT were already available well before October 2023, their limited presence in the responses is unlikely to be explained by the model's knowledge cutoff alone [30]. A more plausible explanation is that ChatGPT defaults to what it has seen most often: conservative management pathways that are widely taught and described, and a generally "play it safe" tendency when asked broad clinical questions [31]. In other words, the model may not be unaware of surgery; rather, it may just not surface it unless the prompt explicitly asks for surgical options or provides more detail about operative candidacy [12]. Nevertheless, newer ideas such as prophylactic LVA may still be underrepresented due to the recency of the evidence. Future work should test whether prompting specifically for surgical options changes the balance and completeness of the recommendations. These findings also emphasize the necessity of incorporating temporal limitations when using AI tools in clinical decision-making processes [7,8,20,28-30,32,33]. Furthermore, the strong emphasis on lymphedema management using conservative treatment options may result from the broader and more established evidence base in this area, which has developed over decades and is therefore more prominently represented in ChatGPT's training data.

Physiotherapists or APNs expressed greater skepticism regarding ChatGPT's treatment recommendations, as highlighted in the open comments section. The recommendations were regarded as being too generalized and lacking personalization. It was emphasized that effective lymphedema care necessitates ongoing, individualized assessment, a component that the AI recommendations did not adequately address.

Prompt Quality and Lack of Sources Limit ChatGPT's Clinical Reliability

One of the key characteristics of ChatGPT is its reliance on user input—responses are generated solely based on the prompt it receives [12]. As a result, the specificity and clarity of the input significantly affect the quality, depth, and relevance of the output [12]. Shorter prompts tend to produce shorter, less detailed responses. Citations were completely absent in ChatGPT's responses and consistently rated poorly by participants (Q3; Table 1), demonstrating that the absence of sources significantly limited the reliability of AI-generated treatment recommendation and, consequently, did not earn the physicians' trust. Furthermore, the absence of information regarding additional sources (Q6), the lack of mention of areas of uncertainty (Q7), and the omission of potential consequences of forgoing treatment (Q11) were also rated negatively (Table 1).

As an LLM, ChatGPT does not inherently verify the information it provides, but instead generates content based on linguistic patterns, which may influence the accuracy of treatment recommendations [12]. Notably, previous studies emphasized the need to explicitly ask for citations, as the model may otherwise omit references or produce so-called "hallucinations," meaning fabricated or incorrect references [34,35]. As our prompt did not explicitly request sources, thus reflecting the expected real-world use of ChatGPT, the absence of citations was expected. However, this highlights 2 key limitations. First, when users lack the background knowledge to formulate precise prompts, the model's effectiveness is significantly reduced. Second, users currently have no possibilities to verify the origin or quality of the information provided. Previous studies have shown that such uncritical reliance on unverifiable information has the potential to result in inefficient or inappropriate treatment decisions and, consequently, potentially harm the patient [36]. It is also important to emphasize that ChatGPT does not *collect* information but rather generates responses based on statistical patterns in its training data, which further limit its interpretive reliability.

ChatGPT may also pose security risks [12]. Of particular concern is the use of false or deliberately misleading prompts, the aim of which is to manipulate the model into generating inaccurate responses [12]. To ensure patient safety, any clinical implementation would require strict regulatory oversight. A more realistic, and potentially safer, alternative could involve embedding ChatGPT within a clinical decision support system using prevalidated clinical data [37]. In this scenario, ChatGPT would function as a predictive model, assisting in

XSL•FO
RenderX

decision-making within a strictly regulated and supervised data environment.

Study Strengths and Limitations

This is the first exploratory, cross-sectional study evaluating the agreement, reliability, and decision-making value of AI using LLMs in generating treatment recommendations for lymphedema management in a global, multidisciplinary, and interprofessional panel. Strengths of this study include the sizeable expert panel of 67 doctors and lymphedema therapists from 34 different institutions across 11 countries. A potential limitation of this study is that evaluators were aware that responses were generated by ChatGPT, which may have introduced either positive bias (novelty or expectation effect) or negative bias (preexisting skepticism toward AI). The results should therefore be interpreted as clinicians' perceptions of AI-generated recommendations rather than a purely objective measure of model performance. The lack of human-generated reference standard represents an important limitation, as it prevents the interpretation of absolute DISCERN scores; these should instead be understood in a relative context across professional groups. Although the 6 vignettes were deliberately designed to reflect common clinical presentations across the ISL stage spectrum across both extremities, they cannot capture the full heterogeneity of lymphedema. Consequently, generalizability to all clinical contexts is limited, and future studies should evaluate a larger and more diverse set of cases. Another limitation of this study is the use of an adapted assessment tool based on the DISCERN criteria. Although the underlying framework is validated, modifications to the item set and scoring scale may have altered the original psychometric properties of the instrument. As resident recruitment was conducted via large email and international student group, the response rate of invited resident doctors could not be calculated. Moreover, all analyses were based on a single, time-stamped response per case and were not controlled for random seed values or multirun variability, as this would have substantially increased survey burden. Furthermore, because the study was conducted using the standard ChatGPT web interface rather than the application programming interface, we were unable to access or control key inference parameters such as temperature, top-p, or system prompts. As a result, these factors were not reported. Finally, the study did not assess how variations in prompt design might affect the consistency or accuracy of the generated recommendations. Additionally, participants did not generate the prompts themselves, which may limit user satisfaction to the generated responses.

Conclusions

ChatGPT has the capacity to provide relevant basic knowledge for lymphedema management and may be particularly useful for less experienced clinicians. However, it has not yet succeeded in replacing expert consultation and offers only limited personalization. Additionally, its constraints regarding source transparency and prompt dependency highlight the need for cautious and context-aware integration into clinical practice.

Acknowledgments

During the revision of this manuscript, the authors used GPT-5.2 to improve readability. The authors subsequently reviewed and edited the content as needed and take full responsibility for the final version of the publication.

Funding

This study was funded by the Freiwillige Akademische Gesellschaft Basel, the Swiss Cancer Research Foundation, Rising Tide Foundation, the Swiss National Science Foundation, and the Theodor und Ida Herzog-Egli Stiftung.

Data Availability

The datasets generated and analyzed during this study are stored on the secure Research Electronic Data Capture platform hosted by the Department of Clinical Research at the University of Basel and can be provided by the corresponding author upon reasonable request.

Authors' Contributions

All authors contributed to the study conception and design. Clinical vignettes were prepared by AF, CEE, and EAK. Data collection was conducted by AF, CEE, and EAK. Statistical analysis and figure preparation were performed by AF and SRW. Data interpretation and drafting of the manuscript were carried out by AF and CEE. The study was supervised by EAK. All authors reviewed and approved the final manuscript.

Abstract

Background: Digital twins (DTs) offer a paradigm for health care by enabling data-driven, simulation-capable representations of individual health trajectories. However, DT development remains limited by the scarcity of standardized, temporally structured, and multidomain data suitable for modeling chronic disease progression. Most existing DT studies rely on narrowly scoped or proprietary datasets, restricting generalizability. Public health datasets, such as the Midlife in the United States study, provide rich biopsychosocial information but are underused due to structural complexity and lack of semantic integration frameworks.

Objective: This study aimed to develop and evaluate an ontology-guided, agent-orchestrated framework for constructing offline, simulation-capable, and progression-aware DTs from public health datasets. Using diabetes as a case study, the framework integrates agent-based orchestration, medical ontologies, and large language model (LLM)–assisted semantic reasoning with machine learning to support explainable feature structuring, risk prediction, and predictive "what-if" progression analysis.

Methods: A 6-stage DT framework was developed and applied to Midlife in the United States wave 2 (baseline) and wave 3 (follow-up) data. Ontology- and LLM-assisted feature selection identified predictors across biological, behavioral, psychosocial, and socioeconomic domains. Cleaned and harmonized data were used to train predictive models (random forest, eXtreme gradient boosting, and logistic regression) to estimate diabetes onset at follow-up. A state-transition simulator was implemented to model between-wave progression dynamics, quantify transitions across low-, medium-, and high-risk states, and evaluate predictive "what-if" scenarios such as weight reduction and lifestyle improvement. Model performance was assessed using accuracy, F_1 score, area under the receiver operating characteristic curve (AUC), and calibration metrics.

Results: From 9976 candidate variables, ontology- and LLM-guided selection retained the top 200 relevant predictors spanning biological, behavioral, psychosocial, and socioeconomic domains. Predictive modeling achieved strong discrimination, with random forest (AUC=0.82, accuracy=0.76) and eXtreme gradient boosting (AUC=0.81, accuracy=0.75) outperforming logistic regression (AUC=0.78). The state-transition simulator reproduced realistic progression patterns: 33.9% (1414/4174) of participants changed risk states between waves, and the high-risk group increased from 10.8% (451/4174) to 32.2% (1344/4174). Next-state prediction accuracy reached 92.5%. Predictive "what-if" analyses showed that with a simulated 10% weight reduction, model-estimated diabetes cases decreased by 98 (from 576 to 478). A placebo test (0% weight change) produced less than 0.3% difference in risk distribution, confirming model stability.

Conclusions: This study presents a foundational, ontology-guided, and agent-orchestrated framework for constructing offline, simulation-capable, and progression-aware DTs from public datasets. By combining semantic reasoning, multidomain predictors, and predictive "what-if" progression simulation, the framework transforms static population data into longitudinal, interpretable representations of individual health trajectories. The proof-of-concept application to diabetes demonstrates that public health data can support robust and explainable DT models for exploratory risk analysis and hypothesis generation, without implying causal intervention effects or direct clinical decision support.

Introduction

Background

Digital twins (DTs) are virtual representations of physical entities that are designed to represent and simulate real-world systems to predict and optimize outcomes [1]. In health care, DTs can serve as individualized, data-driven models of patients, enabling proactive monitoring, personalized intervention, and scenario-based simulation [2]. By integrating longitudinal biomedical, behavioral, psychosocial, and environmental data, DTs offer the potential to transform chronic disease management from reactive treatment to anticipatory care.

Challenges in Health Care DTs

Despite this promise, the development of health care DTs is constrained by several challenges. First, there is a scarcity of high-quality, structured datasets that support temporal modeling and personalization, especially in chronic disease contexts [3]. Second, there is a lack of standardized frameworks for organizing heterogeneous health variables across domains and time points [4,5]. Finally, feature selection and semantic integration remain complex tasks, requiring both domain expertise and explainability [6]. These limitations are particularly acute for type 2 diabetes, where long-term behavioral, physiological, and psychosocial factors interact in complex, nonlinear ways. Current prototypes typically rely on narrowly scoped, proprietary datasets collected in controlled clinical settings, which limits generalizability and reuse and constrains their applicability beyond specific populations or case settings.

Opportunity in Public Health Datasets

In contrast, large-scale public health datasets, such as the MIDUS (Midlife in the United States) study [7], the National Health and Nutrition Examination Survey [8], and the UK Biobank [9], contain rich biopsychosocial profiles of individuals over time. These resources offer an underused opportunity for constructing inclusive and population-grounded DT representations.

However, they present structural and semantic challenges, including inconsistent variable definitions, fragmented modules, missing values, and a lack of standardized feature hierarchies. To date, most uses of these datasets have focused on regression or correlation analyses rather than longitudinal, simulation-capable modeling of individual risk trajectories.

Objective

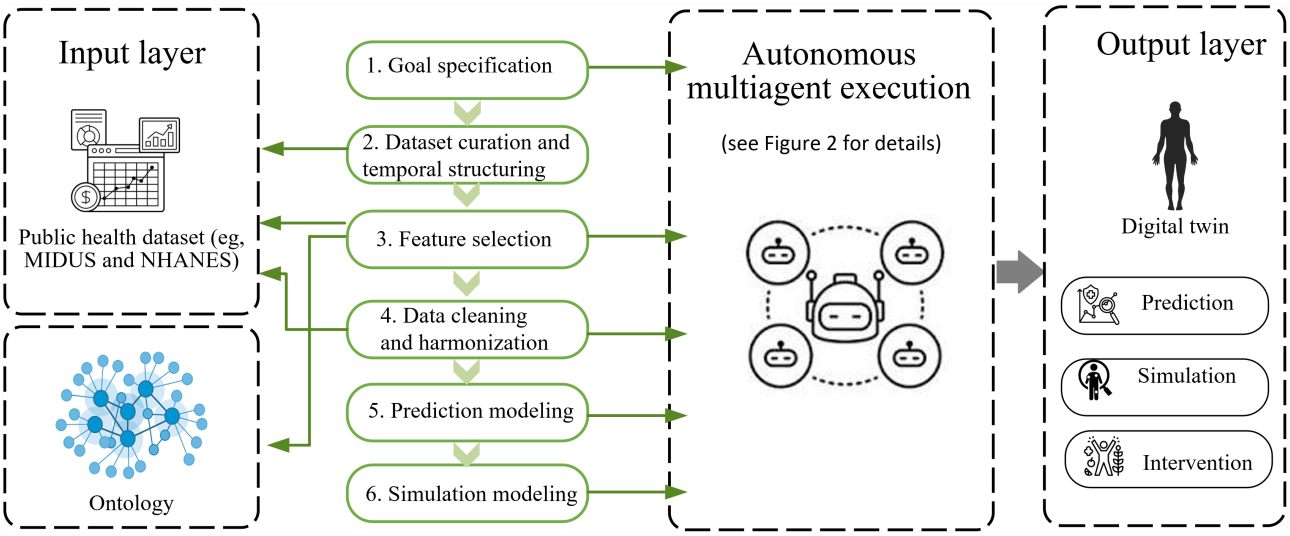
This study aimed to develop a foundational, ontology-guided, and agent-orchestrated framework for constructing offline, simulation-capable DTs from public health datasets. In this work, we adopt a restricted and pragmatic definition of a health care DT, referring to an offline, simulation-capable virtual representation derived from population-level data, rather than a continuously synchronized or clinically validated dynamic twin.

Using diabetes risk prediction as a demonstrative case study, we sought to do the following:

1. Transform longitudinal public health data into temporally structured, semantically enriched feature sets suitable for DT modeling;
2. Integrate medical ontologies and large language model (LLM)–assisted semantic reasoning to support intelligent and explainable feature selection; and
3. Develop prediction and simulation models that support risk estimation and predictive "what-if" scenario analysis rather than causal intervention inference.

By addressing data reuse, semantic organization, and interpretable predictive simulation, this work establishes a new methodological pathway for constructing progression-aware and explainable DTs from population-level data, with a focus on predictive modeling and exploratory analysis rather than real-time operation, causal inference, or direct clinical decision-making.

Methods



Framework Design

Overview

We developed a foundational, modular framework for constructing offline, simulation-capable DTs from public health data, illustrated using diabetes risk prediction in the MIDUS cohort. As illustrated in Figure 1, the framework is organized into six stages: (1) goal specification, (2) dataset curation and temporal structuring, (3) ontology- and LLM-assisted feature selection, (4) data cleaning and harmonization, (5) prediction modeling, and (6) simulation modeling.

XSL•FO
RenderX

Figure 1. Multiagent, ontology-guided framework for constructing digital twins from public health data. MIDUS: Midlife in the United States; NHANES: National Health and Nutrition Examination Survey.

These stages are coordinated through an agent-orchestrated architecture, in which specialized agents are assigned distinct roles, such as ontology mapping, LLM-based reasoning, data harmonization, prediction, and simulation. Agents operate as LLM-driven reasoning components with bounded autonomy, enabling semantic interpretation, ambiguity resolution, and iterative refinement rather than rigid rule-based execution.

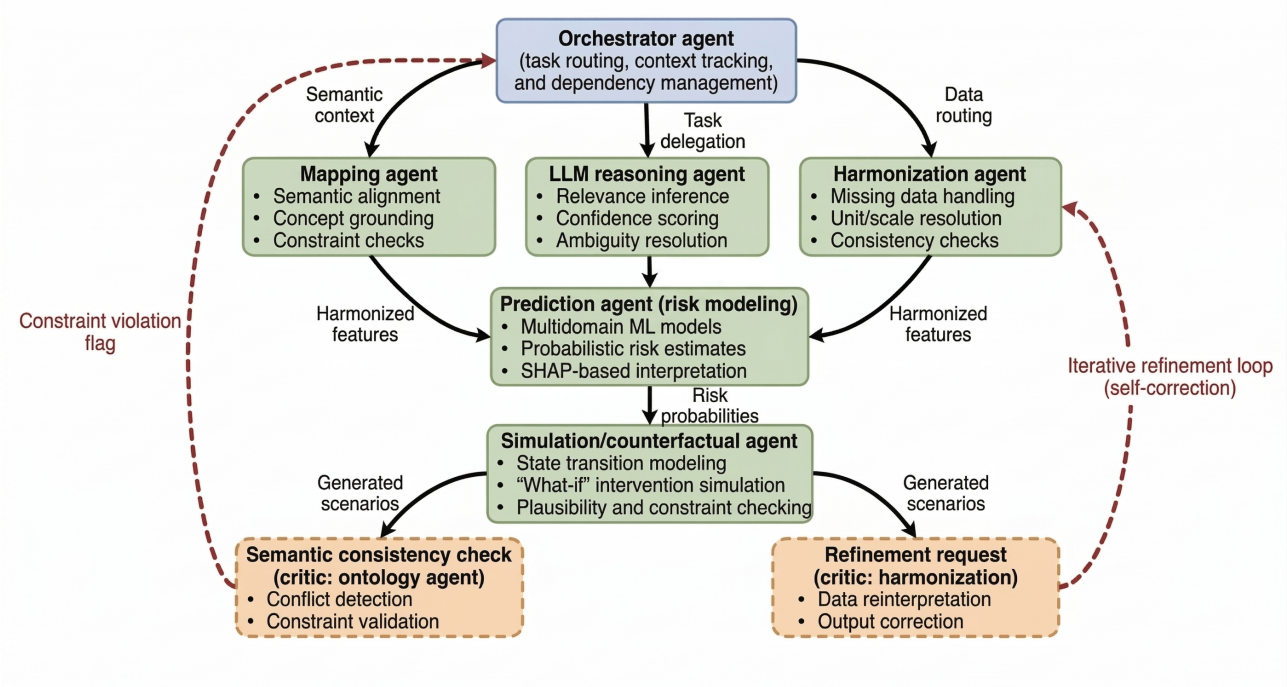
This design supports scalability, transparency, and modularity, enabling each component to function independently while contributing to the overall DT framework without implying real-time synchronization, causal inference, or clinical decision-making capability.

Scope of the DT Implementation

The DT instantiated in this study is offline and population-trained, using paired observations from MIDUS waves 2 and 3. Models are trained once and applied deterministically during simulation. The system is intended for progression-aware research and hypothesis exploration, rather than real-time operation, causal inference, or clinical decision support.

Agent Autonomy and Interagent Reasoning

While the overall workflow of the framework follows a logical progression from data curation to prediction and simulation, the internal execution relies on agentic reasoning rather than rigid pipeline heuristics. Unlike traditional software modules that execute predefined rules (eg, “if X then Y”), the agents in this framework leverage LLMs to perform probabilistic reasoning, semantic interpretation, and adaptive decision-making.



As illustrated in Figure 2, the framework departs from a static pipeline by employing a “Hub-and-Spoke” agentic topology centered on a dynamic orchestrator agent. This architecture enables 3 distinct forms of autonomy not present in the standard modular software:

1. Semantic adaptability: Agents resolve ambiguity in MIDUS variable definitions by inferring meaning from metadata, ontology context, and prior knowledge rather than requiring explicit hard-coded mappings.
2. Contextual interaction: Outputs produced by one agent condition the reasoning of downstream agents, and simulation outputs are checked against ontology constraints, enabling iterative refinement rather than one-pass execution.
3. Reflective evaluation: The simulation agent evaluates generated counterfactual scenarios for plausibility and internal consistency and regenerates outputs when conflicts are detected.

These behaviors distinguish the framework from a static processing pipeline and motivate the use of an agentic abstraction, while remaining intentionally lightweight and constrained compared to fully autonomous multiagent systems.

XSL•FO
RenderX

Figure 2. The multiagent collaboration architecture. Unlike a linear software pipeline, the orchestrator agent dynamically manages task execution based on semantic context. The architecture features explicit iterative refinement loops (red-dashed lines), where "Critic" functions (eg, semantic consistency check) autonomously flag errors or implausible simulations, triggering replanning and data reinterpretation by the functional agents. LLM: large language model; ML: machine learning; SHAP: Shapley Additive Explanations.

To complement the conceptual overview in Figure 2 and Table 1, we provide 2 brief execution traces (Textboxes 1 and 2) illustrating (1) semantic ambiguity resolution during feature selection and (2) critic-triggered refinement during counterfactual simulation.

Table . Comparison between a traditional pipeline and the proposed agentic framework.

Aspect	Traditional pipeline	Proposed agentic framework
Logic	Deterministic rules	LLM[a]-based probabilistic reasoning
Ambiguity handling	Manual preprocessing	Semantic inference and confidence scoring
Interaction	Unidirectional	Iterative, context-conditioned refinement
Adaptation	None	Output regeneration under constraints
Failure mode	Error or crash	Reasoned approximation

[a]LLM: large language model.

Textbox 1. Example trace: resolving semantic ambiguity in a MIDUS variable.

Input (ambiguous item). The orchestrator agent receives the MIDUS item "Falling or staying sleep frequency - 30 days", which conflates sleep-onset and sleep-maintenance difficulty and thus lacks a single unambiguous semantic label.

Ontology-grounded context. The orchestrator agent delegates grounding to the ontology mapping agent, which retrieves compact ontology evidence (top-matched concepts and a few relations) consistent with a broader sleep disturbance symptom frequency construct and packages it as a structured context for downstream inference.

Structured decision (LLM reasoning). Conditioned on the MIDUS metadata and retrieved ontology context, the LLM reasoning agent outputs a constrained JSON decision, eg,

{"classification":"Indirect","relevance_score":0.6,"reasoning":"Sleep disturbance is associated with metabolic dysregulation and increased diabetes risk."}

The orchestrator agent records a canonical label (eg, sleep_disturbance_symptom_frequency_30d) for harmonization and retains the feature in the ranked set used for modeling.

Reflective check (bounded loop). A Critic function validates schema/score range and checks semantic consistency with the retrieved evidence; if the score is below a predefined threshold, the orchestrator triggers a single re-query, otherwise the decision is accepted and logged.

XSL•FO
RenderX

Textbox 2. Example trace: critic-flagged implausible counterfactual and orchestrated refinement.

Input (candidate scenario). The simulation agent proposes a candidate "what-if" perturbation that attempts to vary a prescription-medicine checklist variable to reduce predicted diabetes risk; this proposal is subsequently screened by the Critic before any simulation is accepted.

Critic flag (implausible/nonactionable). A Critic function flags the scenario as nonactionable and semantically inconsistent with the DT's intervention scope: prescription history is a downstream proxy/outcome, not an upstream modifiable determinant for counterfactual exploration.

Orchestrator replanning (context-conditioned refinement). The orchestrator agent removes the nonmodifiable proxy variable and replans the scenario using upstream, modifiable factors already supported by the simulator (eg, body weight and physical activity). The simulator is rerun under these perturbations.

Refined output (accepted). The refined scenarios yield stable, monotonic risk changes consistent with the simulator's sensitivity design (eg, 5% and 15% weight reductions decrease average predicted risk), and the accepted trace is logged.

Goal Specification Using the Population, Intervention, Comparison, and Outcome Approach

Defining a clear objective is essential for aligning data engineering, modeling, and evaluation with actionable health care needs. In this framework, the objective is formalized through the Population, Intervention, Comparison, and Outcome (PICO) approach [10], which provides a structured foundation for prediction and simulation.

For this study, the following points should be noted:

- Population (P): adults aged ≥40 years in MIDUS wave 2, a group at elevated risk of type 2 diabetes due to age-related metabolic changes and cumulative lifestyle factors
- Intervention (I): a data-driven DT integrating multidomain predictors (eg, BMI, physical activity, sleep quality, psychosocial stress, and family history) derived from surveys and biomarkers to simulate diabetes risk
- Comparison (C): benchmark models using only biomedical or clinical variables, assessing the added value of including psychosocial and behavioral factors
- Outcome (O): diabetes onset at wave 3, defined through self-reported diagnosis, medication use, or biomarkers (fasting glucose and HbA_{1c})

This specification clarifies the DT's purpose, guides variable selection, and defines evaluation benchmarks. The PICO structure also generalizes easily to other chronic diseases or datasets.

Dataset Curation and Temporal Structuring

High-quality DTs require longitudinal data that capture changes in individual health states. Although MIDUS contains only 2 major waves, it provides sufficient longitudinal contrast for modeling transitions between baseline (wave 2) and follow-up (Wave 3).

The following procedures were applied:

1. Wave alignment and participant tracking: wave 2 served as baseline and wave 3 as follow-up. Participants with complete paired data were retained, yielding 4173 individuals with consistent identifiers and matched features.
2. Outcome labeling: diabetes onset was defined using wave 3 data (self-report, medication use, and biomarkers such as fasting glucose and HbA_{1c}) to provide ground truth for supervised learning.
3. Feature harmonization: variables across biological, behavioral, psychosocial, and socioeconomic domains were standardized and harmonized. Comparable constructs (eg, BMI, activity, stress, and income) were aligned for consistency across waves.
4. Temporal pairing for transition modeling: instead of computing explicit Δ features, health progression was represented implicitly through paired records (wave 2 → wave 3). Each baseline profile served as model input and its follow-up state as the target.

This process transformed MIDUS from a general-purpose survey into a longitudinal, simulation-ready dataset consistent with DT principles. Although limited to 2 waves, the paired design enabled population-level transition modeling and individualized progression analysis over nearly a decade.

Ontology-Assisted and LLM-Driven Feature Selection

Feature-Selection Overview

Public health datasets, such as MIDUS, include thousands of variables spanning biomedical, psychological, behavioral, and social domains. Selecting the most relevant features for DT construction requires scalable, explainable reasoning beyond traditional statistical filters. Conventional feature selection techniques, such as association tests [11], correlation thresholds [12], or heuristics [13], often overlook semantically subtle but influential variables (eg, stress or coping behavior).

To overcome this limitation, we developed a hybrid feature selection pipeline that integrates domain ontologies with LLM reasoning in a retrieval-augmented setting [14]. Feature selection is treated as a structured semantic reasoning task rather than a purely statistical filter [14].

Semantic Enrichment With Ontologies

Each MIDUS variable was mapped to a curated set of diabetes-related and study-design ontologies, enabling the LLM to reason across biomedical and psychosocial dimensions. The following ontologies were integrated:

- The Diabetes Mellitus Treatment Ontology (DMTO) [15] capturing treatment strategies, complications, and management protocols
- The Common Diabetes Medications Ontology [16] linking medication variables to pharmacological mechanisms (of action)
- The FHIR (Fast Healthcare Interoperability Resources) And SSN (Semantic Sensor Network)-based Type 1 diabetes Ontology (FASTO) [17] providing real-time monitoring and device-related concepts

XSL•FO
RenderX

- The BioMedBridges Diabetes Ontology [18] defining diagnostic and phenotypic concepts for translational research

Crucially, to contextualize the role of each variable within the MIDUS longitudinal design, we incorporated the Study Cohort Ontology [19,20]. This allowed the agent to understand the structural purpose of a variable (eg, as a baseline demographic, psychosocial instrument, or clinical outcome), which is essential for distinguishing direct from indirect relevance.

Variable metadata (labels, descriptions, and coding) were mapped using keyword matching, semantic similarity, and vector embeddings. The result was a structured, ontology-aligned representation that enabled the retrieval-augmented generation (RAG) agent to reason over deep conceptual relationships rather than surface-level text similarity.

In this framework, the ontology layer serves primarily as a semantic and organizational scaffold rather than as a direct performance-optimizing component. Its role is to (1) impose a consistent hierarchical structure over heterogeneous public health variables, (2) guide LLM-assisted feature selection toward domain-relevant predictors, and (3) enable interpretable grouping and reuse of features across modeling stages. Accordingly, ontology integration is intended to improve transparency, explainability, and reproducibility, rather than to guarantee higher predictive accuracy.

Relevance Classification With LLMs

After enrichment, the RAG agent evaluated each variable's relevance to diabetes risk prediction using structured prompts containing ontology context and metadata. Variables were classified as directly relevant, indirectly relevant, or not relevant, each with a confidence score and explanatory note. The agent operated in an iterative loop: (1) extract variable metadata and ontology matches; (2) construct prompts integrating semantic context; (3) generate classification, justification, and confidence; (4) requery or reformulate if confidence is low; and (5) log outputs for transparency and reproducibility.

This process yielded a feature set annotated with ontology links, metadata, and reasoning traces, ensuring transparency, auditability, and explainability for downstream modeling.

The confidence scores generated by the LLM represent the internal consistency of the relevance classification given the ontology-grounded prompt context and were used to control iterative requerying rather than to impose a hard inclusion threshold. To assess face validity, we manually audited the resulting feature set with respect to established diabetes risk factors. Core predictors, such as age, BMI, blood pressure, family history, physical activity, smoking, mental health indicators, and medication use, were consistently retained, and we did not observe systematic exclusion of known clinical predictors. Disagreements primarily occurred for borderline psychosocial or survey-specific variables rather than for established biomedical risk factors.

The LLM-assisted feature selection is not intended to replace statistical feature selection or expert curation, nor is it strictly required to achieve high discrimination with flexible tree-based models. Its primary contribution lies in semantic coverage, explainability, and scalability when working with large, heterogeneous public health datasets, where manual curation is impractical and purely statistical filters risk omitting contextually relevant variables.

Data Cleaning and Harmonization

Following feature selection, a standardized cleaning pipeline ensured data quality and consistency:

- Variable-type normalization: unified categorical, ordinal, and Boolean variables
- Missing-data handling: mean/mode imputation for low-missing features; k-nearest neighbor (kNN) imputation for complex patterns
- Scale and unit standardization: normalized continuous features and harmonized measurement units
- Semantic harmonization: merged equivalent constructs across waves via ontology tags
- Outlier detection: applied statistical thresholds and domain-specific plausibility rules

MIDUS contains both item-level missingness and wave-level attrition, which may correlate with health status and socioeconomic factors. We therefore do not assume that data are missing completely at random. We selected kNN imputation because it preserves multivariate relationships among mixed-type variables and avoids distributional assumptions required by parametric multiple imputation models, which are difficult to validate in high-dimensional survey data with thousands of heterogeneous variables. kNN uses observed similarity across individuals to infer plausible values and is widely used in biomedical machine-learning pipelines where predictive performance and internal consistency are the primary goals. Nevertheless, kNN does not correct for missing-not-at-random mechanisms, and any bias arising from differential dropout or nonresponse may propagate into downstream prediction and simulation.

Prediction and Simulation Modeling

The final stage of the framework focuses on developing models that support both risk prediction and scenario-based simulation, which are 2 core capabilities of a DT.

Prediction Modeling

Prediction models estimate the likelihood of diabetes onset at follow-up using multidomain features. This component extends beyond traditional biomedical risk scores by incorporating behavioral, psychosocial, and socioeconomic predictors.

Model objectives emphasize personalization, interpretability, and temporal continuity, ensuring that predictions remain clinically meaningful and adaptable as health states evolve.

Simulation Modeling

Given the availability of only 2 MIDUS waves, the simulator implements a single-step, between-wave state-transition model (wave 2 → wave 3). Therefore, it supports coarse-grained progression modeling and scenario-based sensitivity analysis but not continuous, multistep temporal dynamics or online updating. The counterfactual simulations are predictive rather

XSL•FO
RenderX

than causal: they quantify how model-estimated diabetes risk changes when selected inputs are perturbed, holding the learned model structure fixed. They do not represent real-world intervention effects. The simulation module operationalizes the DT's capacity to model how an individual's predicted diabetes risk evolves under changing behavioral and psychosocial conditions. Conceptually, the simulator is designed as a coarse-grained state-transition system, where each participant's health state at a future timepoint is estimated as a function of their baseline characteristics and current states. These states summarize multidomain attributes, including biological (eg, BMI and hypertension), behavioral (eg, physical activity, smoking, and alcohol use), and psychosocial (eg, anxiety and depression), into interpretable clusters that represent distinct risk levels.

To model transitions, a supervised learning function approximates P(St+1 ∣ St,Xt), where St and St+1 denote latent health states at consecutive waves and Xt represents observed features. Given the availability of only 2 MIDUS waves, this formulation supports single-step, between-wave transition modeling rather than fine-grained or continuous temporal dynamics. This enables the simulator to reproduce observed between-wave progression patterns progression patterns and estimate next-state probabilities under hypothetical scenarios.

Counterfactual reasoning is implemented through predictive scenario simulation, in which modifiable factors (eg, body weight, physical activity, smoking, alcohol use, stress, and depression scores) are systematically perturbed to assess their influence on predicted transition probabilities and future diabetes risk. The simulator then recomputes the resulting state distributions and outcome probabilities using the trained transition and outcome models.

By comparing such simulated trajectories, the DT supports multifactor "what-if" analysis at both individual and population levels, enabling exploration of model sensitivity to changes in key risk factors. Methodologically, this simulation framework complements the predictive component: while prediction estimates a static risk at a given timepoint, the simulator enables exploratory analysis of coarse-grained health evolution across survey waves.

The counterfactual simulations implemented in this framework are predictive rather than causal. They quantify how model-estimated risk changes when selected input variables are perturbed and do not represent real-world intervention effects. Accordingly, these simulations should be interpreted as model-based sensitivity analyses and hypothesis-generation tools, rather than estimates of causal impact or decision-grade clinical recommendations.

Integration

Together, prediction and simulation form the methodological foundation of the DT. Prediction provides individualized risk estimates, whereas simulation allows for the exploration of dynamic scenarios and potential interventions. This dual design ensures that the DT framework not only forecasts outcomes but also offers actionable insights for prevention and management in diabetes and other chronic diseases.

Agentic LLM Workflow and Reproducibility

The feature selection component is implemented as a retrieval-augmented, LLM-driven agent. We used OpenAI GPT-3.5 turbo (OpenAI Python SDK, openai>=1.0.0) with a temperature of 0.3 to reduce stochasticity. For each MIDUS variable, the agent receives the variable's name and metadata together with ontology-grounded context retrieved from 6 diabetes-related ontologies: Diabetes Mellitus Diagnosis and Support Ontology, DMTO, BioMedBridges Diabetes Ontology, Common Diabetes Medications Ontology, FASTO, and the Study Cohort Ontology.

Additional details are provided here:

- Ontology RAG. Feature names and ontology concept labels are embedded using sentence transformers (allMiniLML6v2). For each feature, the topk =5 ontology concepts above a similarity threshold of 0.3 are retrieved. For each retrieved concept, ontology relationships are extracted as triples (eg, Type2Diabetes → hasRiskFactor → Obesity), and short concept explanations are generated and filtered. These labels, Internationalized Resource Identifiers, triples, and explanations form a structured context block injected into the LLM prompt.
- Prompt and output schema. The LLM is prompted with a fixed system instruction and a user template containing (1) MIDUS variable metadata, (2) retrieved ontology context, and (3) an explicit scoring rubric. The model must return valid JSON with fields {relevance_score ∈ [0,1], classification (Direct/Indirect/Unrelated), reasoning}.
- Iteration and thresholds. Features are processed in batches of 40. If a feature's relevance score is below 0.3, it is requeried once with expanded ontology context; if it is still below the threshold, it is excluded. This bounded control flow ensures deterministic termination. Final selection is performed by ranking features by relevance_score and retaining the top 200.
- Reproducibility. We fix the feature-processing order, ontology-retrieval parameters, and LLM temperature and record all configuration parameters, data and ontology versions, and LLM outputs in run logs. Baseline selectors (L1-regularized logistic regression [LASSO] and MI) use random_state =42 to ensure deterministic comparisons.
- Agent orchestration layer. The orchestration layer acts as a central controller that sequentially invokes specialized agents, including ontology mapping, feature selection, data harmonization, prediction, and simulation. Agents do not communicate peer-to-peer; all interactions are mediated by the orchestrator. Feedback loops are implemented, wherein simulation outputs are checked for semantic consistency against ontology constraints and refined when inconsistencies are detected.

Ethical Considerations

This study used publicly available, deidentified data and did not involve interaction with individuals or the use of identifiable private information; therefore, it did not involve a human subject as defined under 45 CFR 46.102 [21], and institutional review board review was not sought. Informed consent for this secondary analysis was not required. Data were accessed and

XSL•FO
RenderX

analyzed in accordance with the applicable MIDUS and Inter-university Consortium for Political and Social Research data use terms [22]. To ensure compliance with these terms, the LLM was strictly provided with variable names, feature descriptions, and other documentation-level metadata; no participant-level or individual MIDUS data was entered into the LLM.

Results

Cohort Characteristics

After applying inclusion criteria, the analytic cohort consisted of 4174 participants with complete records in both MIDUS wave 2 (baseline) and wave 3 (follow-up), allowing individual trajectories to be tracked longitudinally. The sample size, therefore, remained constant across waves (n=4174), although the number of participants with diabetes increased over time. The mean age at baseline was 56.0 (SD 12.4) years; 54.8% (n=2288) were female. By wave 3615 (14.7%), participants met the diabetes definition, indicating a moderate class imbalance.

As shown in Table 2, across both waves, participants who had or developed diabetes were older, more often male, had lower education and household income, and showed higher cardiometabolic burden (eg, BMI and hypertension) than those without diabetes. Behavioral differences were smaller, but people with diabetes reported slightly higher levels of light physical activity at follow-up, possibly reflecting postdiagnosis behavior changes. By wave 3, depressive symptoms were also higher in the diabetes group.

Table . Descriptive statistics of the study cohort (MIDUS waves 2 and 3), stratified by diabetes status.

Feature-Selection Outcomes

Ontology- and LLM-assisted feature selection yielded a curated set of predictors spanning biological, behavioral, psychosocial, and socioeconomic domains. A representative subset is shown in Table 3. As expected, classic biomedical risk factors—BMI, hypertension, waist-to-hip ratio, and current weight—were classified as directly relevant. The pipeline also surfaced function- and lifestyle-related variables (eg, basic activities of daily living, shortness of breath while walking, and health limits walking >1 mile), which capture mobility and cardiopulmonary reserve and are not always selected by purely statistical filters. In addition, socioeconomic (household income) and psychosocial (anxiety symptoms) variables were retained as

XSL•FO
RenderX

indirectly relevant, extending the model beyond a biomedical-only view of diabetes risk.

Table . Representative variables selected by ontology- and LLM[a]-assisted feature selection for diabetes risk prediction.

Variable	Domain	Relevance classification	Ontology alignment (examples)	Notes/explanation
Body Mass Index - Metric	Biological	0.8 (direct)	DMTO[b]: 0000362 (overweight/obesity)	BMI is a well-established indicator of obesity and a major risk factor for diabetes.
Age	Biological	0.8 (direct)	DMDSONT[c]: Patient_hasAge; SNOMED CT[d]: chronological age	Age is a strong predictor due to accumulated lifestyle exposures and metabolic changes.
Hypertension (ever diagnosed, 12 mo)	Biological	0.8 (direct)	DMDSONT: Hypertension_b	Hypertension is a known comorbidity and a direct risk factor for type 2 diabetes.
Any chronic conditions (12 mo)	Biological	0.8 (indirect)	DMTO: DDO_0000201 (chronic disease)	Multimorbidity contributes to systemic inflammation and increases diabetes risk.
Weight compared to 5 years ago	Biological	0.8 (indirect)	DMTO: DDO_0000130 (weight trajectory)	Weight gain over time is closely associated with higher diabetes risk.
Current weight (pounds)	Biological	0.8 (direct)	DMTO: DDO_0000130 (weight)	Absolute weight is a central predictor of diabetes risk.
Waist-to-hip ratio	Biological	0.8 (direct)	DMTO: DDO_0000320 (waist circumference)	Central obesity predicts diabetes more strongly than BMI alone.
Basic activities of daily living (3-item)	Behavioral	0.7 (indirect)	DMTO: DDO_0000127 (activity level)	Functional limitations are correlated with higher chronic disease risk.
Shortness of breath while walking	Behavioral	0.7 (indirect)	DMTO: DDO_0009259 (respiratory function)	Reduced capacity reflects poorer cardiometabolic health.
Health limits walking >1 mile	Behavioral	0.7 (indirect)	DMTO: DMTO_0001830 (walk)	Mobility restrictions often signal underlying cardiometabolic burden.
Household income	Socioeconomic	0.6 (indirect)	FASTO[e]: socioeconomic factor	Lower income is associated with limited health care access and higher diabetes risk.
Anxiety symptoms	Psychosocial	0.6 (indirect)	DMTO: DDO_0000483 (anxiety)	Anxiety can indirectly influence diabetes risk via stress responses and lifestyle.

[e]FASTO: FHIR (Fast Healthcare Interoperability Resources) And SSN (Semantic Sensor Network)-based Type 1 diabetes Ontology.

To support transparency, the full ranked list of the top 200 features, including ontology alignment, relevance level, and notes, is provided in Multimedia Appendix 1. These results confirm that the ontology-guided, multiagent pipeline can identify multidomain predictors consistent with a biopsychosocial model of diabetes.

To evaluate the specific contribution of the ontology-guided RAG agent, we conducted a comparative ablation study against 2 established statistical baselines:

1. Lasso: a standard method for sparse feature selection that penalizes nonzero coefficients.
2. Mutual information (MI): a univariate filter that selects features based on their statistical dependency with the target.

All methods were restricted to a top-K setting (K=200) to ensure a fair comparison of information density. The complete list of 200 features can be found in Multimedia Appendices 1-3. Selection quality was evaluated based on downstream predictive

XSL•FO
RenderX

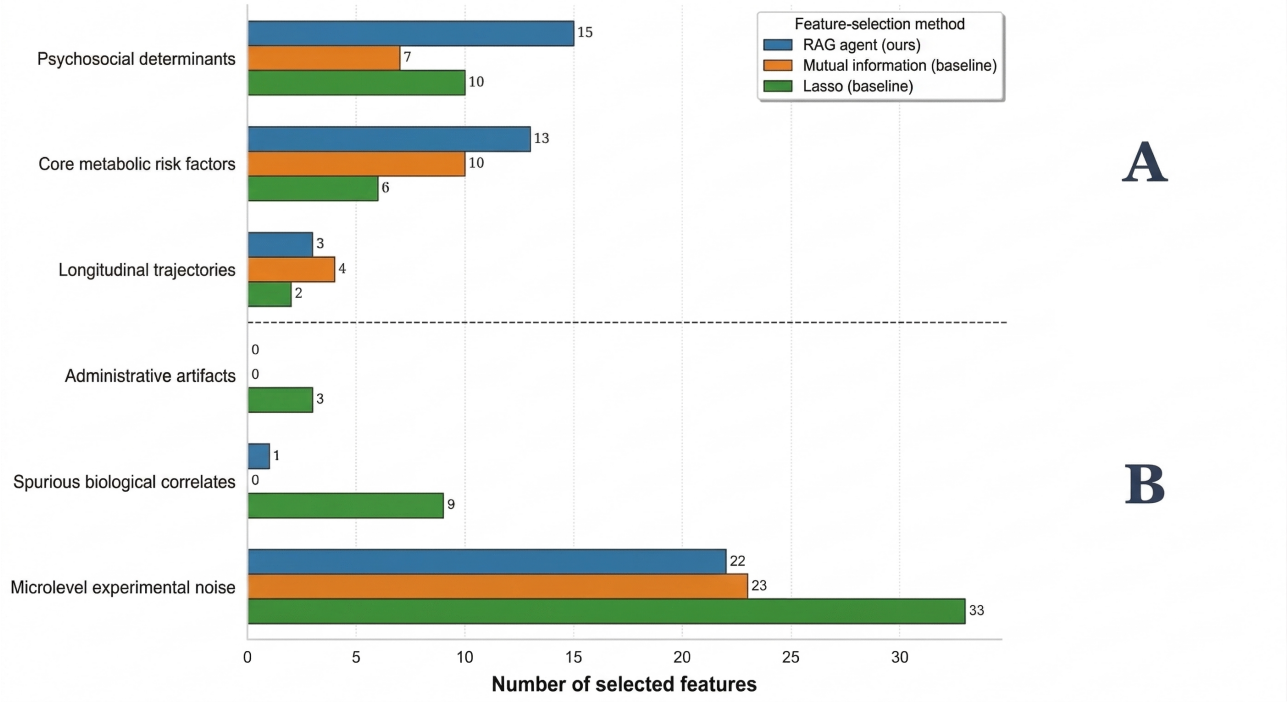
performance (area under the receiver operating characteristic curve [AUC]) and a manual semantic audit of feature relevance.

As shown in Table 4, the ontology-guided RAG agent achieved an AUC of 0.82, outperforming Lasso (AUC=0.73) and MI (AUC=0.78). This indicates that the agent identifies predictive signals that purely statistical filters overlook.

Table . Ablation study—feature-selection method comparison.

Feature-selection method	Number of features selected	AUC[a] (prediction)	"Noise" features included[b]	Clinical relevance score[c]
Baseline 1: mutual information	200	0.78	Medium (110)	Low
Baseline 2: Lasso[d] (L1)	200	0.73	High (135)	Medium
Ours (ontology+LLM[e] agent)	200	0.82	Low (70)	High

[a]AUC: area under the receiver operating characteristic curve.



[b]"Noise" features refer to variables classified through manual semantic audit as artifacts or administratively correlated variables without clear causal or actionable relevance to diabetes risk.

[c]Clinical relevance score indicates the overall qualitative relevance of the selected feature set to established diabetes risk factors, based on manual semantic audit.

[d]Lasso: L1-regularized logistic regression.

[e]LLM: large language model.

Figure 3. Comparative semantic audit of feature selection. (A) Target-relevant features (higher count is better) and (B) artifactual and noisy features (lower count is better). The RAG agent (blue) selects significantly more target-relevant features (eg, psychosocial determinants and metabolic risk factors) while suppressing artifactual noise compared to L1-regularized logistic regression (Lasso, green) and mutual information (orange). RAG: retrieval-augmented generation.

Beyond raw accuracy, the agentic approach demonstrated superior semantic precision. Statistical methods frequently selected "noisy" artifacts: variables that correlate with the target but lack causal validity.

- Reduction of artifacts: Lasso selected 135 features classified as noise or administrative artifacts (eg, "Interviewer ID" and "Data Collection Site"), whereas the RAG agent reduced this to 70, effectively filtering out spurious correlations.
- Actionable versus proxy features: as detailed in Figure 3, the RAG agent prioritized modifiable lifestyle constructs essential for DT simulation, selecting 21 physical activity items compared to only 4 for Lasso. Conversely, Lasso heavily relied on "Prescription Medicine" checklists (31 items vs 7 for RAG). While prescription history is a strong statistical proxy for disease, it represents a downstream outcome rather than an upstream, modifiable risk factor. By favoring upstream determinants (eg, "Lose 10 pounds by diet"), the agentic framework ensures the resulting DT is actionable.

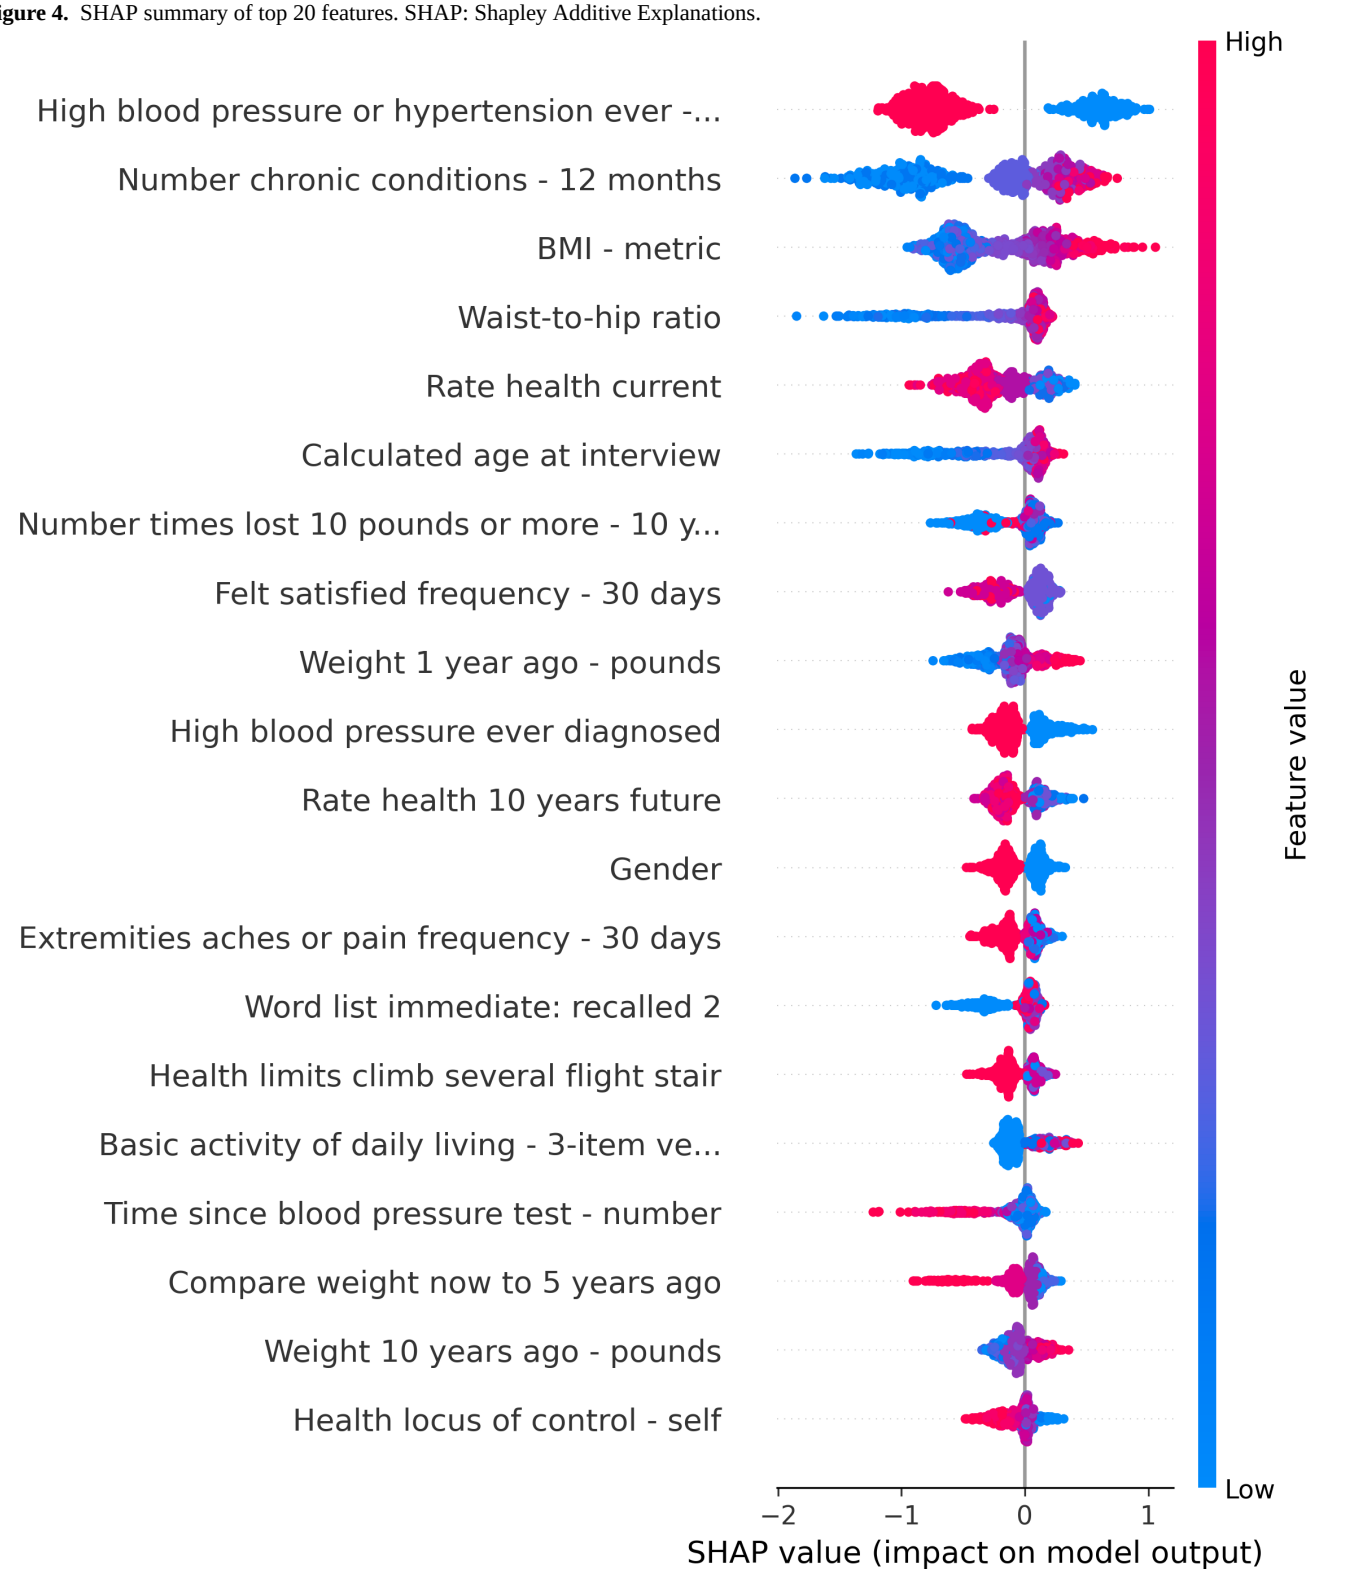
XSL•FO
RenderX

Figure S1 and Tables S1–S5 (Multimedia Appendix 4) provide a detailed ablation and semantic analysis of feature-selection methods. These results show that ontology-guided RAG selects a substantially different and nonredundant feature set relative to Lasso and MI, with greater emphasis on modifiable lifestyle and psychosocial constructs and fewer spurious or administrative artifacts, thereby supporting its suitability for interpretable, intervention-oriented DT modeling.

Prediction Performance

Prediction models were trained on wave 2 features to predict diabetes onset in wave 3. Of the 4174 participants, 615 (14.7%) developed diabetes, so the synthetic minority oversampling technique was applied during training to mitigate class imbalance. Three models were evaluated: random forest, eXtreme gradient boosting, and logistic regression. A 5-fold cross-validation with stratified splits was used.

All models showed good discrimination, with tree-based models performing the best:



- Random forest: accuracy 0.856, AUC 0.826
- eXtreme gradient boosting: accuracy 0.868, AUC 0.829
- Logistic regression: accuracy 0.807, AUC 0.81

Performance improved steadily as additional domains were added. Models restricted to biological variables reached only about AUC ≈ 0.75; adding behavioral variables increased performance to about AUC ≈ 0.79; and using the full multidomain set (biological + behavioral + psychosocial + socioeconomic) yielded the best performance (AUC up to 0.82). This pattern underscores that psychosocial and functional factors in MIDUS carry incremental signals for diabetes onset.

Model interpretability was examined with the SHAP (Shapley Additive Explanations) analysis [23]. As shown in Figure 4, the highest impact features included hypertension status, number of chronic conditions, BMI, waist-to-hip ratio, several functional-limitation items, and indicators of health monitoring (eg, time since the last blood pressure test). Together, these suggest that the learned model is capturing not only metabolic risk but also the accumulation of chronic disease burden and health care–engagement patterns.

Simulation Findings

State Construction and Risk Stratification

Discrete risk states were introduced to support interpretable, coarse-grained transition modeling, given the sparse temporal structure of the data. Clustering is used here only as a discretization of a continuous predicted-risk score into interpretable strata. We selected K=3 to align with standard clinical stratification into low-, medium-, and high-risk categories. When K>3, the clustering yields finer-grained strata of the same risk distribution rather than a different disease model. To preserve semantic comparability across K, we define the high-risk population as the union of the highest-risk clusters whose combined size matches the K=3 high-risk group.

Alternative state definitions could be used, including quantile-based binning of predicted risk, latent class or hidden Markov models, or continuous-state formulations that avoid discretization altogether. We selected k-means for this study

XSL•FO
RenderX

because it provides a transparent and data-driven partition of the risk distribution that is compatible with sparse 2-wave data. Exploring continuous-time and latent-state models is an important direction for future work as higher-frequency data become available.

We fixed the centroids learned at wave 2 and applied them to wave 3, so that states were compared between waves.

- Wave 2: low 79.1% with mean risk 3.03% (SD 3.35%), medium 10.1% with mean risk 27.8% (SD 10.77%), and high 10.8% with mean risk 93.5% (SD 10.84%)
- Wave 3: low 62.4% with mean risk 1.20% (SD 5.84%), medium 5.4% with mean risk 49.7% (SD 7.75%), and high 32.2% with mean risk 90.8% (SD 9.77%)
- Participants changing states: 1414/4174 (33.9%)

The substantial increase in the high-risk group (10.8% → 32.2%) and one-third of participants who changed states indicate meaningful between-wave shifts in modeled diabetes risk, supporting the use of a transition-based, coarse-grained simulator.

Transition Model (Wave 2 → Wave 3)

We trained a state-transition model to estimate

P(SW3 | SW2,xW2) where SW2 and SW3 represent cluster-based risk states and xW2 is the participant's wave 2 feature vector. Given the availability of only 2 time points, this model captures single-step, between-wave transitions rather than continuous temporal dynamics. Five-fold cross-validation with stratified splits was used. Inputs included demographics, biological, behavioral, psychosocial, and socioeconomic features. State-transition model performance is summarized in Table 5.

Table . State-transition model performance.

Model	Accuracy (SD), %	Macro F_1, %	Average log-likelihood
XGBoost[a]	92.54 (1.39)	91.64	–0.2572
Random forest	88.57 (1.31)	79.42	–0.4089
Logistic regression	60.42 (2.31)	50.22	–0.9475

[a]XGBoost: eXtreme gradient boosting.

Tree-based models substantially outperformed the linear baseline, capturing nonlinear interactions among M2 features and baseline states. Model calibration was further assessed with Brier scores (≈0.07) and expected calibration error (≈0.04), indicating well-calibrated predictive transition probabilities.

Outcome Model (Diabetes at Wave 3)

To link state evolution to clinical outcomes, we trained a second model to estimate

P(YW3=1 | SW2,SW3,xW2), where YW3 denotes diabetes onset at follow-up. Inputs included baseline features, wave 2 state probabilities, and predicted wave 3 state probabilities (soft outputs) from the transition model.

All 3 models achieved strong discrimination; tree-based models again delivered slightly better calibration, as shown in Table 6. This 2-stage design (state transition → outcome) supports progression-aware predictive modeling, consistent with the framework's DT abstraction.

Table . Diabetes outcome model performance.

Model	AUC[a] (SD), %	PR-AUC[b], %	Brier score
Random forest	90.89 (2.90)	75.60	0.0640
XGBoost[c]	90.34 (2.80)	75.10	0.0638
Logistic regression	88.69 (1.91)	67.45	0.1089

[a]AUC: area under the receiver operating characteristic curve.

[b]PR-AUC: precision-recall area under the curve.

[c]XGBoost: eXtreme gradient boosting.

Predictive "What-If" Simulator

We then used the trained transition and outcome models as a predictive scenario-analysis engine. Modifiable wave 2 covariates (weight/BMI, physical activity, smoking, alcohol consumption, anxiety, and depression) were perturbed, and the models were rerun to obtain new wave 3 state distributions and predicted diabetes risk predictions. All simulation runs were deterministic and logged for reproducibility.

Scenario 1: 10% Weight Reduction (Predictive Sensitivity Analysis)

A uniform 10% decrease in weight (and hence BMI, assuming a fixed height) was applied to all 4174 participants (Table 7).

- Participants with any state change: 280/4174 (6.7%)
- Largest single improvement: 53 transitions from high → low risk
- The model-estimated number of diabetes cases decreased from 576 to 478 (−98) under this perturbation
- Individuals with reduced predicted risk: 2417/4174 (57.9%)

XSL•FO
RenderX

These changes reflect the model's sensitivity to weight-related inputs rather than the projected real-world intervention effects.

Table . Effect of 10% weight/BMI reduction (predictive simulation).

Outcome	Preintervention	Postintervention	Change
Predicted diabetic (count)	576	478	–98
Any state change, n (%)	—[a]	280 (6.7)	—
High → low-risk transitions	—	53	—
Individuals with reduced risk, n (%)	—	2417 (57.9)	—

[a]Not applicable.

Scenario 2: Composite Lifestyle Scenario (Predictive Sensitivity Analysis)

A composite lifestyle scenario was simulated by increasing physical activity by 1 ordinal category (≈20% of the MIDUS 1 - 6 scale), switching current smokers to nonsmokers, reducing alcohol consumption by 2 units, and reducing anxiety and depression scores by 20%.

Model-estimated response includes the following:

- Participants with state change: 300/4174 (7.2%)
- High → low improvement: 49 participants
- The model-estimated number of diabetes cases decreased from 576 to 506 (−70)
- Individuals with lower diabetes risk: 1417/4174 (33.9%)

Because MIDUS stores activity on an ordinal scale rather than as minutes per week, the "20% increase" was operationalized as a +1 shift in the activity category, which preserves the semantic meaning of the item.

Illustrative Case Studies

To demonstrate individual-level exploratory use, we simulated 2 patients:

- Case 1 (10% weight loss): 50-year-old male, BMI 29.6 kg/m², baseline predicted diabetes risk 35.4%. After perturbing weight-related inputs to reflect a 10% reduction (BMI 26.6 kg/m²), the model-estimated risk decreased to 22.1% (−13.3% points).
- Case 2 (composite lifestyle scenario): A 57-year-old male with a baseline risk of 57.6%. After increased activity, smoking cessation, reduced alcohol intake, and a 20% reduction in lower anxiety/depression scores, the predicted risk dropped to 36.0% (−21.4% points).

These vignettes show that the same population-trained simulator can support individualized, predictive "what-if" reasoning, rather than personalized intervention recommendations.

Sensitivity and Robustness Checks

To evaluate the stability of the proposed framework and the robustness of the latent state definitions, we conducted a series of sensitivity analyses examining alternative perturbation magnitudes, state-definition choices, placebo perturbation, and subgroup calibration:

- Alternative perturbation magnitudes: Weight reductions of 5% and 15% yielded monotonic decreases in average predicted diabetes risk (−6% and −14%, respectively).
- State-definition robustness: For K>3, the high-risk state was defined as the union of the highest risk clusters whose combined size matched the K=3 high-risk group. Under this definition, the composition and clinical profile of the high-risk population remained stable for K=3 - 5 (>88% Jaccard overlap; Table S7 in Multimedia Appendix 4), and transition accuracy varied by <2%.
- Placebo test: A 0% weight change produced <0.3% difference in risk distribution, confirming model stability.
- Subgroup calibration: AUCs were consistent across age, sex, and income tertiles (variation <3%), indicating no major bias within the modeled population.

To assess the robustness of the latent state definitions, we performed a sensitivity analysis by varying K from 3 to 5. The "High Risk" state demonstrated high stability, maintaining a Jaccard membership overlap of >0.90 across configurations (see Table S7 in Multimedia Appendix 4). Increasing K primarily resulted in the granular subdivision of the "Healthy" state (eg, distinguishing normative vs optimal profiles) rather than altering the boundaries of the pathological state, confirming that the diabetic phenotype represents a distinct manifold in the data.

Discussion

Principal Results

This study demonstrates the feasibility of constructing a simulation-capable DT from a public, survey-based dataset using MIDUS waves 2 and 3. By integrating multidomain predictors, ontology-guided semantic structuring, and a 2-stage prediction–simulation design, the framework achieved strong diabetes risk prediction and reproduced meaningful between-wave risk transitions.

Our results highlight a critical limitation of traditional statistical feature selection in health informatics: the inability to distinguish causality from correlation. Although statistically rigorous, Lasso identified "Prescription Medicine" checklists as top predictors. In a static risk model, these are useful proxies; however, for a DT simulation, they are dead ends: one cannot "simulate" removing a history of hernia repair to cure diabetes. In contrast, the agentic framework successfully retrieved upstream determinants, such as dietary behavior and physical activity frequency. This shift from proxy-based prediction toward

XSL•FO
RenderX

modifiable-input simulation justifies the computational complexity of the LLM layer, as it enables structured predictive sensitivity analysis (eg, "What if the patient increases vigorous activity?") that statistical baselines cannot support. Across scenarios, observed changes should be interpreted as responses of the trained model to input perturbations rather than estimates of real-world intervention effects.

Generalizability and Portability to Other Diseases and Datasets

Although diabetes is used as a case study, the proposed framework is modular and largely reusable across chronic conditions and public-health datasets. Disease-agnostic components include (1) the data harmonization and temporal alignment pipeline, (2) the agent-orchestration and logging layer (bounded autonomy, traceable message passing), (3) the general ontology-RAG retrieval mechanism (embedding-based concept retrieval + structured context injection), (4) the downstream prediction stack (tree-based and linear models with calibration/SHAP), and (5) the sensitivity-analysis interface that perturbs modifiable inputs and re-evaluates model outputs. Disease-specific components primarily include (1) the ontology set used for grounding retrieval, (2) the prompt rubric and relevance criteria used by the feature-selection agent (what constitutes "direct/indirect relevance" for a target disease), (3) the outcome definition (case ascertainment and temporal window), and (4) the selection of modifiable factors emphasized in the scenario analysis.

Porting the framework to a different chronic disease (eg, cardiovascular disease [CVD] or chronic obstructive pulmonary disease [COPD]) would involve four practical steps: (1) define the target end point and prediction horizon consistent with the dataset (eg, incident CVD event, COPD exacerbation, and hospitalization), (2) swap or extend the ontology layer using disease-appropriate ontologies/terminologies (eg, condition-specific risk-factor and phenotype ontologies, and mappings to the Systematized Nomenclature of Medicine [SNOMED] and International Classification of Diseases [ICD], where applicable), (3) update the agent prompt templates and scoring rubric so that relevance classification and confidence scoring reflect domain-specific pathways (eg, lipids/blood pressure for CVD; smoking history, spirometry proxies, and symptom burden for COPD), and (4) retune the state definition and progression model to match disease dynamics and data cadence. In datasets with sparse waves (as in MIDUS), coarse-grained discretization and single-step transitions can provide an interpretable progression abstraction; however, for conditions with faster dynamics or richer longitudinal sampling, the same pipeline could replace k-means discretization with quantile bins or latent-state models (eg, hidden Markov models) and replace between-wave transitions with continuous-time or event-based progression models.

Finally, we note that portability also depends on dataset structure. Survey-based cohorts provide multidomain exposures but limited clinical end points, whereas electronic health record (EHR)–based cohorts provide richer outcomes but noisier measurement and coding artifacts. The framework's ontology-grounded RAG and semantic auditing steps are intended to mitigate such heterogeneity by making feature selection and simulation inputs more interpretable and traceable, while still requiring disease- and dataset-specific end point definitions and validation protocols.

Limitations

Data Quality, Missingness, and Measurement Error

This study relies on the MIDUS dataset, which consists largely of self-reported behavioral, psychosocial, and health measures. Such data are subject to recall bias, social desirability bias, and reporting inaccuracies, particularly for diet, physical activity, mental health, and substance use. These errors may attenuate or distort learned associations and propagate uncertainty into both risk predictions and counterfactual simulations. Although large sample sizes and robust machine-learning models can mitigate random noise, systematic reporting bias remains an inherent limitation of survey-based DT construction.

MIDUS also exhibits item nonresponse and wave-level attrition that are likely to be partially missing not at random. For example, participants with poorer health may be less likely to complete follow-up surveys, and sensitive behaviors may be systematically underreported. While kNN preserves multivariate structure and reduces information loss, it cannot recover information that is systematically missing. Consequently, both predicted risks and simulated outcomes may be biased if missingness is correlated with unobserved health status. Future work should explore explicit missingness indicators, sensitivity analyses, or joint models of outcome and dropout when higher frequency or linked EHR data become available.

Limited Temporal Resolution

The framework is trained on only 2 observation points (MIDUS waves 2 and 3), separated by approximately a decade. This supports single-step, between-wave transition modeling but does not capture short- or medium-term disease dynamics, nor does it allow continuous updating or multistep forward simulation. As a result, the proposed DT should be viewed as a coarse-grained, long horizon progression model rather than a high-resolution temporal simulator. Additional waves or higher-frequency data (eg, EHRs or wearables) would be required to support continuous or multistep DT updating.

Predictive (Not Causal) Nature of Counterfactuals

The counterfactual "what-if" simulations implemented in this framework are predictive rather than causal. They assume that the statistical associations learned by the transition and outcome models remain stable under hypothetical interventions (eg, weight loss, increased physical activity, and smoking cessation). Accordingly, quantities such as "98 fewer diabetes cases" represent model-estimated or projected changes in risk under perturbed inputs, not real-world treatment effects.

While placebo and monotonicity tests demonstrate internal numerical stability of the simulator, they do not establish causal efficacy. Therefore, the simulations reflect model sensitivity rather than physiologically or clinically validated intervention outcomes and should be interpreted as sensitivity analyses and hypothesis generation tools rather than the estimates of clinical impact. Although the magnitude and direction of predicted

XSL•FO
RenderX

effects are broadly consistent with major lifestyle intervention trials (eg, the Diabetes Prevention Program), such comparisons are illustrative only and do not constitute external validation or causal inference.

Clinical Applicability

The current framework is not intended for direct clinical deployment. Outputs such as transitions between cluster-based risk states or changes in population-level predicted incidence are not directly actionable at the individual patient level. Instead, the system is designed to support exploratory analysis, hypothesis generation, and population-level planning rather than point-of-care decision-making. Substantial additional work would be required for clinical translation, including calibration to clinical end points, alignment with guideline-based thresholds, and integration with EHR workflows.

Model-based simulations of hypothetical lifestyle changes also raise ethical and communication concerns. Without causal validation, simulated risk reductions could be misinterpreted as guaranteed outcomes, potentially leading to false reassurance or undue anxiety. Any future clinical deployment would require careful attention to explainability, uncertainty communication, and clinician oversight.

State Definition and Discretization

Health states were defined using k-means clustering for its simplicity, transparency, and compatibility with sparse 2-wave data. However, alternative discretization strategies—such as quantile-based risk bins, latent class models, hidden Markov models, or continuous-state formulations—could be used to define health states without hard clustering. Exploring such alternatives, particularly in datasets with higher temporal resolution, represents an important direction for future work.

Scope of the DT

The proposed framework does not implement several features of mature health care DTs, including continuous synchronization with real-world data, online learning, bidirectional patient feedback, or causal intervention modeling. It should therefore be interpreted as a foundational, offline, simulation-capable DT suitable for population-level exploration and hypothesis generation rather than a clinically deployed or continuously updating patient-specific twin.

Comparison With Prior Work

Most existing health care DT prototypes have relied on narrowly scoped, proprietary datasets, often collected in clinical settings with limited generalizability. Prior studies in diabetes modeling [24-26] have focused primarily on short-term glucose forecasting or clinical risk scoring, with relatively little emphasis on integrating psychosocial and behavioral variables. Our approach advances this field in two ways: (1) by leveraging publicly available, longitudinal health datasets to promote inclusivity and scalability, and (2) by combining multiagent orchestration, ontologies, and LLM reasoning to enable principled, explainable feature selection. These contributions distinguish our framework from traditional statistical or machine-learning models and align with emerging calls for DTs that are both interpretable and adaptable to real-world complexity.

It is important to note the distinction between the "simulation-centric" twin presented here and "operational" twins used in acute care. Our system lacks the continuous, real-time data synchronization typical of industrial DTs [1]. Instead, it functions as a progression-aware simulator, a foundational prototype that establishes the semantic and computational architecture (agents, ontologies, and state transitions) required for a DT. While currently powered by static survey waves, this same architecture is designed to ingest real-time streams (eg, wearables) in future iterations.

Conclusions

This study presents a foundational, progression-aware DT framework for predictive risk projection using public health data, rather than a validated dynamic or clinical DT. We show how large, heterogeneous cohort datasets can be transformed into simulation-capable, longitudinal digital patient representations using ontology-guided feature selection, agent-orchestrated LLM reasoning, and machine learning–based prediction and transition modeling. While the current implementation is offline and limited to 2 survey waves, it establishes a methodological foundation for DT construction as richer and higher-frequency data become available.

A key contribution of this work is demonstrating that public health data, when semantically aligned and processed through an LLM-assisted, agent-orchestrated pipeline, can support not only risk prediction but also predictive simulation. The resulting DT enables the exploration of how model-estimated risk trajectories change under hypothetical modifications to modifiable factors, such as body weight, physical activity, smoking, or psychosocial stress. These simulations reflect model sensitivity rather than real-world intervention effects, but they provide a practical and interpretable way to explore risk dynamics and generate hypotheses in chronic disease research.

For public health planners and clinical researchers, this framework enables population-level "what-if" analyses and supports exploratory individualized risk profiling and scenario analysis grounded in real cohort data. For medical informatics researchers, the proposed architecture, which combines ontologies, LLM-based agents, and transition-aware prediction models, provides a reusable blueprint for other slowly progressing, multidomain conditions, such as CVD, frailty, and COPD.

Future work will focus on the following 4 directions:

1. Extending single-step progression to multistep and higher-frequency updating through integration with EHR, wearable, and mobile-health data;
2. Incorporating decision-analytic and reinforcement-learning components to identify which modifiable factors are most influential for reducing individual risk;
3. Performing external and prospective validation to move from predictive projections toward decision-grade DTs; and
4. Integrating causal-inference and trial-linked data to transition from predictive counterfactuals to causally grounded DT simulation.

Abstract

Background: Antibiotic therapies are the main treatment for bacterial infections, but growing antibiotic resistance is a major global health threat, severely impacting patients with sepsis. Rapid selection of the most effective antibiotic therapy is critical for survival and for preventing further resistance. Physicians must consider numerous factors for proper empiric treatment selection. A clinical decision support system (CDSS) aims to support physicians in this process, facilitating rapid and targeted therapy.

Objective: The purpose of this work is to explore the extent to which the realization of a CDSS is possible based on the data available to us and to document insights gained during the development of a foundational model designed to assist physicians in determining empiric treatment options for patients with sepsis. In this regard, rather than aiming to develop a CDSS for clinical application, we highlight the importance of close interprofessional collaboration between scientists from various disciplines and analyze the effects of data quality and quantity on the performance of our statistical models.

Methods: Empirical scientists conducted interviews with medical practitioners to acquire the medical knowledge required to develop sound statistical models. We developed and applied 2-step cross-sectional, as well as time-series classification models, to carefully preprocessed data of patients with sepsis admitted to the intensive care unit of a German hospital.

Results: We identified several factors as crucial information for valid decisions on empiric therapy for treating patients with sepsis. These include the patients' core data, especially the infection focus. To prevent further resistance, individual risk factors such as travel history and professional background should be considered. The evaluation of a therapy's effectiveness is mainly based on the patient's general condition and blood values such as procalcitonin and interleukin 6. One key factor in the acceptance of a CDSS is the explainability of the results produced by the applied methods. Our models demonstrated mainly weak predictive ability for all considered empiric antibiotic therapies. However, they are not yet suitable for use in clinical practice, especially as they are based on prescribing habits rather than on optimal treatment decisions.

Conclusions: This work highlights the importance of interprofessional collaboration between medical experts and model developers, ensuring that data quality and clinical relevance are central to the process. It emphasizes the urgent need for high-quality, comprehensive data to overcome challenges such as data discontinuity and improve model performance, particularly through enhanced digitization in health care. This feasibility study will facilitate future efforts to develop a CDSS for treating patients with sepsis and to translate it into clinical use.

Introduction

Motivation

Antibiotic therapies represent a milestone within pharmacological and clinical research and are commonly used in the treatment of bacterial infections ranging from mild cystitis to life-threatening sepsis. Sepsis is a severe and rapidly progressing course of a bacterial infection that needs to be treated within the first 3 hours after diagnosis to increase the chances of patient survival [1]. The chance of treatment success rises with increased coverage of pathogens; thus, the Surviving Sepsis Campaign Guidelines for Management of Sepsis and Septic Shock 2021 [1] recommend a broad-spectrum antibiotic as empiric (ie, the initial) therapy. Accordingly, German hospital guidelines recommend the use of a broad-spectrum antibiotic, in particular if the focus of infection is unknown. While broad-spectrum antibiotics are likely to be effective, they come with a variety of side effects, such as gastrointestinal complaints and drug fever [2], and harbor the risk of developing antibiotic resistance [3,4]. Such resistance poses a global threat to health care systems [5,6]. Thus, an important goal is to minimize the use of broad-spectrum antibiotics. A direct point of action for this is inappropriate prescriptions, for example, in the case of viral infections [7], and still common self-prescriptions due to low-threshold access to antibiotics [8]. Overall, preventing the development of further resistance requires consistent antibiotic stewardship and support in selecting targeted antibiotic therapies. The latter is particularly difficult in the case of severe disorders such as sepsis, which are the focus of this work. Even for experienced physicians, the diagnosis and treatment of sepsis are challenging tasks [9].

Background

Project Background

This work has emerged from and shows an excerpt of the research in the interprofessional project “KINBIOTICS” [10], funded by the German Federal Ministry of Health from 2020 to 2024. An overarching objective of the “KINBIOTICS” consortium project was to develop an artificial intelligence (AI)–based clinical decision support system (CDSS) for the individualized prediction of targeted, effective antibiotic therapies with low side effects for patients with sepsis. Such a CDSS would help clinicians make rapid and targeted treatment decisions and thus save lives and reduce the progressive occurrence of antimicrobial resistance. Additionally, the process of developing a data-driven CDSS has the potential to reveal previously unconsidered patterns in the data, thereby providing substantial benefits to the current prescription process.

Research in the “KINBIOTICS” project was conducted by medical practitioners and empirical scientists from various disciplines, including information technology, data science, biotechnology, health sciences, and medicine. The scientists were affiliated with 5 institutions, namely Bielefeld University, University of Siegen, Evangelisches Klinikum Bethel, Klinikum Bielefeld, and Klinikum Lippe. The project was organized in work packages addressing a range of topics, including the prediction of the pathogen and resistance spectrum by nanopore sequencing [11], the setup of a data warehouse including the creation of preconditions for federated learning [12], the development of a resistance observatory [13], evaluation of a pilot CDSS [14], statistical model building as a basis for the CDSS, and the support system’s integration into clinical routine [15].

To achieve the project goals, model constructors and medical professionals were in close dialogue with each other, and this turned out to be particularly helpful for the process of data selection, data preprocessing, and statistical model fitting. In the following, we focus on this process and the steps we found essential to be taken before the development of an AI-based CDSS.

Sepsis

Sepsis is one of the main causes of illness and death all over the world. In 2017, an estimated 48.9 million incident cases of sepsis were recorded worldwide, and 11.0 million sepsis-related deaths were reported, representing 19.7% of all global deaths [16]. Therefore, the World Health Organization (WHO) urged its members through a resolution to include prevention, diagnosis, and treatment of sepsis in national health care systems and to develop and implement standard and optimal care for diagnosing and managing sepsis in health emergencies [17].

Sepsis has been defined as a life-threatening organ dysfunction caused by a dysregulated host response to infection (Sepsis-3 definition) [18]. The infection can be caused by most types of microorganisms, including bacteria, fungi, viruses, and parasites [19]. Organ dysfunction is characterized using the sequential organ failure assessment (SOFA) score [20], including 6 organ systems (respiratory, coagulation, liver, cardiovascular, central nervous system, and renal) with a rise of at least 2 points following the infection. The most severe state of sepsis is defined as septic shock with persistent hypotension requiring vasopressor therapy and a serum lactate level of more than 2 mmol/L despite adequate volume resuscitation. This status is characterized by circulatory, cellular, and metabolic abnormalities leading to an increased mortality of up to 40% [18].

According to the resolution of the WHO, international scientific organizations started the Surviving Sepsis Campaign in 2002, developing guidelines for the treatment of sepsis and septic shock [1]. According to these guidelines, sepsis and septic shock are medical emergencies requiring rapid diagnosis and immediate treatment. Consequently, the following measures should be carried out as quickly as possible: measurement of the lactate level, antibiotic susceptibility testing, administration

XSL•FO
RenderX

of broad-spectrum antibiotics, initiation of appropriate fluid administration and vasopressors if necessary, and remeasurement of the lactate level. In particular, the administration of antibiotics should not be delayed or fail to target the pathogen. The rationale behind these measures is that the time until effective antimicrobial therapy is a crucial determinant of survival in septic shock [21]: a delay in the initiation of effective antimicrobial therapy is associated with a mean decrease in survival of 7.6% per hour.

In clinical practice, the microbiological proof of the pathogen causing sepsis or septic shock is most often missing at the time of diagnosis. Therefore, the initial administration of antibiotics is empiric and generally follows the Tarragona strategy first described by Sandiumenge et al [22]. The principles of this therapy involve assessing patients and their risk factors to "hit hard and early", aiming at an immediate administration of an effective dose of antibiotics while considering the local antimicrobial situation. It also includes accurately identifying the site of infection and understanding the pharmacodynamics and pharmacokinetics of the antibiotics. Furthermore, it is essential to remain focused by continually reevaluating the effectiveness of administered antibiotics. Finally, the treatment should be de-escalated accordingly after identifying the pathogen.

Focus of This Work

Many disciplines aim to improve antibiotic therapies, including microbiology, pharmacology, chemistry, and clinical research. Research and knowledge transfer can be significantly more effective when they operate across disciplinary boundaries and connect fundamental research with clinical practice. In our work, we specifically focus on the interprofessional work between scientists from various disciplines with empirical and clinical backgrounds on the way to a CDSS for antibiotic treatment, which is an information system designed to assist (but not replace) physicians in making empiric treatment decisions for patients with sepsis. The particular value of our contribution arises from the close collaboration between disciplines and the integration of guidelines, constraints, and clinical experience into data analysis. We refrain from pursuing the development of a CDSS for widespread use in clinical practice. Instead, the paper constitutes a feasibility study and consolidates insights obtained during the development process to provide guidance for projects with comparable objectives. We describe preparatory steps required before the construction of statistical models used for a CDSS and model physicians' decisions regarding empiric antibiotic therapy. In this regard, we highlight the relevance of high data quality and close exchange between medical experts and model constructors.

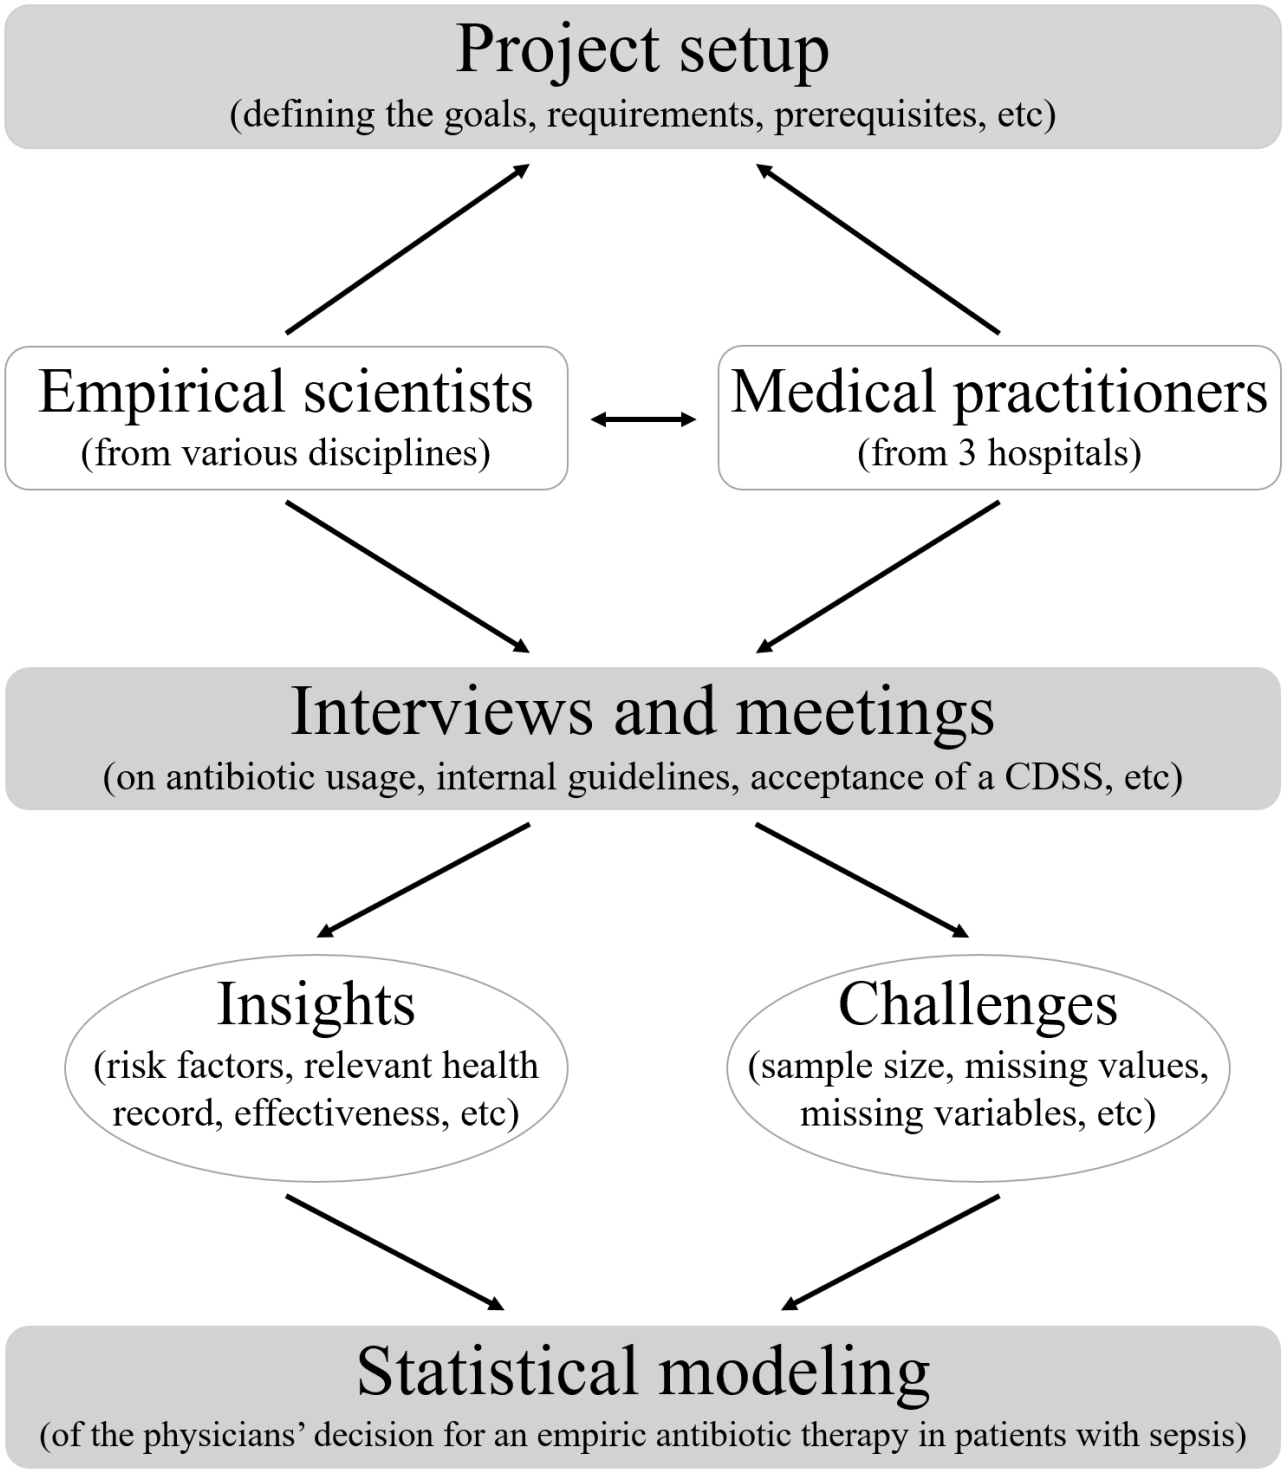
State of Research

The causes, diagnosis, treatment, and consequences of sepsis are highly relevant in various fields of research. In line with the focus of our work, machine learning and deep learning have commonly been applied to analyze data of patients with sepsis. In particular, numerous studies cover the early and accurate prediction of the onset of sepsis, for example [23-27], and Moor et al [28] provide a systematic literature review for early prediction of sepsis in intensive care units (ICUs). Further, many studies pursue the goal of predicting antimicrobial resistance. The literature review by [29] identified 12 studies that use machine learning in the context of antibiotic susceptibility pattern prediction (eg, [30-32]). Additionally, Sakagianni et al [29] selected 8 studies on machine learning–assisted antibiotic resistance prediction (eg, [33-35]). Paul et al [36] developed a computerized decision support system to predict appropriate antibiotic therapies to avoid the use of broad-spectrum antibiotics for treatment of infectious diseases. This study also considered the benefits of antibiotics (eg, reduction in the length of hospital stay) as well as costs (eg, adverse events). Such CDSS may also be beneficial for patients with sepsis, in particular in assisting physicians in selecting a proper empiric antibiotic therapy.

Methods

Data Acquisition and Preprocessing

Medical Knowledge Compilation



As described in the Focus of This Work subheading, we attributed great importance to interprofessional collaboration to appropriately meet the challenges of adequate treatment of sepsis, a multifaceted complication of an infection. Consequently, medical practitioners and empirical scientists maintained continuous dialogue to ensure a deep and comprehensive understanding of both the medical processes and the methodological requirements. This knowledge exchange aimed to guarantee that decisions made during data preprocessing and statistical model construction were congruent with the clinical procedure.

On the operational level, the empirical scientists conducted a series of interviews with predefined questions with representatives of the 3 participating hospitals, including physicians working at the bedside of patients with sepsis. In this way, nonclinicians were given a comprehensive overview of treatment options and guidelines, and relevant stakeholders were engaged at all stages of the CDSS development process.

In an initial interview series, 2 aspects were of primary interest: first, the nature and use of broad-spectrum antibiotics, along with aspects of combination therapies; second, the evaluation process for the effectiveness of administered therapies and the critical factors that influenced this evaluation. In 2 further series of interviews, we focused on relevant determinants of successful implementation of a CDSS in clinical routine settings by assessing the clinicians' general acceptance of such a system and identifying necessary information to be provided to make it as trustworthy as possible. In addition to the interviews, we conducted biweekly meetings between representatives from the hospitals and data scientists. Further, all 3 hospitals provided their internal guidelines for antibiotic administration and dosage depending on diagnosis and identified pathogens. This facilitated the data scientists' understanding of the specific procedures and decision-making processes. Figure 1 illustrates the overall project process, with a focus on statistical model development.

XSL•FO
RenderX

Figure 1. Schematic representation of the process within the "KINBIOTICS" project aimed at modeling physicians' decision-making for empiric antibiotic therapy in patients with sepsis. CDSS: clinical decision support system.

Data

We use retrospective health records from patients admitted to the ICU of the German hospital Evangelisches Klinikum Bethel between 2012 and 2023. All patients in this dataset were admitted to an intensive or intermediate care unit and diagnosed with sepsis or septic shock (in particular, they were diagnosed with one of the *ICD-10* (*International Statistical Classification of Diseases, Tenth Revision*) [37] codes: A40.0, A40.1, A40.2, A40.3, A40.8, A40.9, A41.0, A41.1, A41.2, A41.3, A41.4, A41.51, A41.52, A41.58, A41.8, A41.9, R57.2, or R65.1. The data were derived from 3 sources: first, the clinical information system included time-constant core data and diagnoses, as well as blood values and vital signs measured over the period of hospitalization. Second, the patient data management system contained the administration of catecholamines and antibiotics over time. Third, information about microbiology analyses was available from the hospital's laboratory, representing results of antibiotic susceptibility testing based on patient samples such as blood, urine, or smear. However, data on administered

XSL•FO
RenderX

catecholamines and microbiological analyses were not included in the analyses, as microbiology data, in particular, were not available at the time of diagnosis.

Before data analysis, we carefully preprocessed the data. As a first step, we excluded patients who did not receive any antibiotic therapy or who had not yet reached the age of 18 years at the time of admission. In collaboration with medical experts, erroneous values in variables such as age, height, and weight were either adjusted or removed, and thresholds for blood values and vital signs were included in accordance with medical recommendations. The suspected focus of infection was not documented in the available data. However, given its potential importance for addressing the research question, we derived the suspected infection focus from patients' *ICD-10* codes. To this end, a medical expert categorized all sepsis-related *ICD-10* codes from the clinical information system database according to their infection focus. This procedure resulted in many patients having more than one suspected infection focus. Consequently, we split the foci per patient into several variables, taking into account the order of occurrence. For further analysis, however, we exclusively used the first focus and refer to it as the suspected infection focus on the remainder of this text.

A complication occurred because the time point of diagnosis was only insufficiently documented in the patients' records. Consequently, we assumed that the time of sepsis diagnosis corresponded to the time of the initial antibiotic administration; this serves as an approximation that appears to be adequate to fulfill the objective of this work. Additionally, some patients were represented several times in the dataset. They were either repeatedly admitted to the hospital or had multiple infections during one hospital stay. In particular, there were 2482 individual patients with a total of 2986 infections, resulting from up to 6 infections per patient. We divided one hospital stay into 2 separate stays when no antibiotic was administered for at least 5 days, and there was a change in the infection focus during that time. Henceforth, for simplicity, we use the term "patients" in place of "infections", even in cases where a single patient is represented by multiple infections in the dataset.

The obtained dataset is presented as follows: core data were available for 2986 patients and contained 26 variables. The age of the patients ranged from 18 to 99 years, with an average age of 67.56 years; approximately 36% (n=1067) of patients were female. A total of 1257 (42%) of all patients died during the hospital stay. The aforementioned categorization to derive the suspected infection focus ultimately yielded the following 16 categories (with the number of occurrences in brackets): lungs (n=1074); urogenital tract (n=498); gastrointestinal tract (n=353); prosthesis inflammation (n=175); skin or muscle (n=118); bile (n=101); brain (n=82); bones, joints, tendons, or intervertebral discs (n=60); heart (n=34); vessels (n=14); liver (n=11); ear, nose, or throat (n=10); esophagus (n=8); oral cavity (n=3); spleen (n=1); and eye (n=1). For all patients, time series of vital signs and blood values (31 variables) were available from a maximum of 88 days before and up to 1610 days after the date of diagnosis. However, the measurement and documentation of time series variables were carried out with varying quantities and frequencies. Table 1 lists all available variables. Diagnoses were documented for 2945 patients with 3319 unique *ICD-10* codes in total; 24 of these were connected to sepsis or septic shock. In addition to these *ICD-10* codes, we had information about whether a patient had diabetes or required dialysis; further information about possible comorbidities was not available. Further, the data included information about administered antibiotics, including drug names as well as therapy start and end dates, for all patients. A total of 35 distinct antibiotics were administered at least once. We define the first antibiotic administered to a patient (during diagnosis or afterwards) as empiric. An overview of all antibiotics and their frequencies is provided in Figure 2.

Table . Description of the variables contained in the preprocessed dataset.

Source and variable	Unit	Description
Core data		
Infection ID	—[a]	Unique identifier per infection and patient
Admission date	Date	—
Discharge date	Date	—
Suspected time of diagnosis	Date	Documented date or time point of first administration of antibiotic treatment
Age	Years	—
Sex	—	Male or female
Diabetes	—	Patient has diabetes (“yes” or “no”)
Death	—	Patient died during hospital stay (“yes” or “no”)
Weight	kg	—
Height	cm	—
BMI	kg/m^2	—
Suspected infection focus	—	Suspected source of the infection (16 different categories)
Time series data		
Infection ID	—	Unique identifier per infection and patient
Date of record	Date	—
Minutes after diagnosis	Minutes	Difference between the time of diagnosis and the time of record
SOFA[b] score	—	SOFA score (containing FiO_2[c]/pO_2[d], thrombocytes, bilirubin, mean arterial pressure, GCS[e] score, and creatinine), ranging from 0 to 24
GCS	—	GCS score ranging from 3 to 15
RASS[f]	—	RASS score ranging from –5 to 4
Dialysis	—	Patient on dialysis (“yes” or “no”)
Ventilation	—	Patient is ventilated (“yes” or “no”)
Heart rate	bpm	—
Body temperature	°C	—
Respiratory rate	breaths/min	—
Urine	mL/h	—
Diastolic Ibp	mm Hg	Invasive diastolic blood pressure
mIbp	mm Hg	Invasive mean blood pressure
Systolic Ibp	mm Hg	Invasive systolic blood pressure
Diastolic NIbp	mm Hg	Noninvasive diastolic blood pressure
mNIbp	mm Hg	Noninvasive mean blood pressure
Systolic NIbp	mm Hg	Noninvasive systolic blood pressure
CAM-ICU	—	Confusion Assessment Method for the Intensive Care Unit (delirium “yes” or “no”)
Bilirubin	mg/dL	—
FiO_2	%	Fraction of inspired oxygen
pO_2	mm Hg	Partial pressure of oxygen

XSL•FO

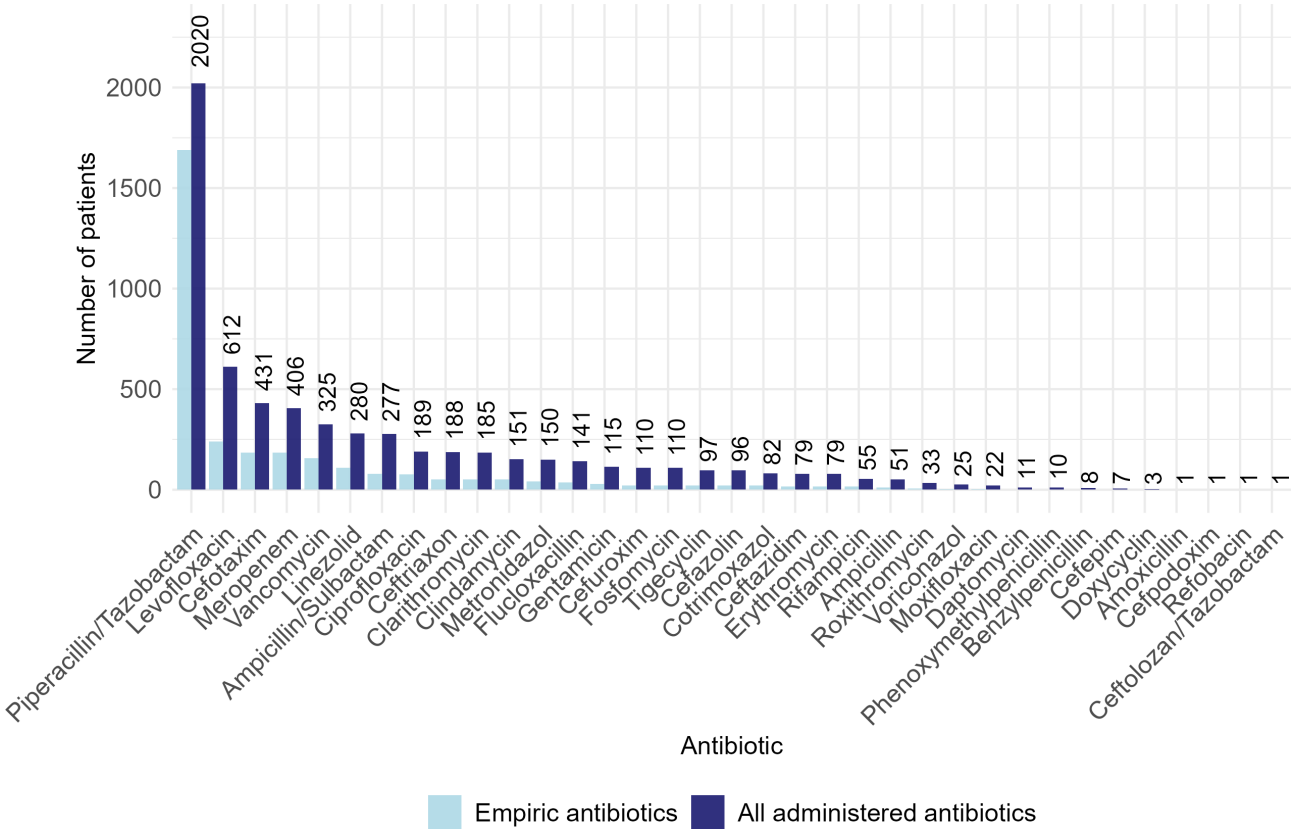
Source and variable	Unit	Description
Leukocytes	/nL	Number of white blood cells in the blood
Leukocytes in the liquor	/µL	Number of white blood cells in the cerebrospinal fluid
Thrombocytes	$10^3/mm^3$	Number of thrombocytes in the blood
CRP	mg/L	C-reactive protein
PCT	ng/mL	Procalcitonin
GFR	mL/min	Glomerular filtration rate
Creatinine	mg/dL	—
IL-6	pg/mL	Interleukin 6
Lactate	mmol/L	—
Blood sugar	mg/dL	—
Oxygenation index	mm Hg	—
Antibiotic	—	Name of administered antibiotic therapy
Diagnosis	—	*ICD-10*[g] codes of diagnosis

[a]Not available.

[b]SOFA: Sequential Organ Failure Assessment.

[c]FiO_2: fraction of inspired oxygen.



[d]pO_2: partial pressure of oxygen.

[e]GCS: Glasgow Coma Scale.

[f]RASS: Richmond Agitation-Sedation Scale.

[g]*ICD-10*: *International Statistical Classification of Diseases, Tenth Revision*.

Figure 2. Number of patients who received the respective antibiotics between 2012 and 2023. The light blue bars represent all empiric antibiotic prescriptions (simultaneously administered therapies, ie, combined therapies, are shown separately), while the dark blue bars additionally include all subsequent administered antibiotics. If antibiotics were administered more than once to one patient, they are counted only once. Printed numbers refer to the dark blue bars.

XSL•FO
RenderX

A review of the core data reveals that the variables weight, height, and BMI each contain 57% missing values. In addition, 15% (n=443) of patients have no suspected infection focus. However, all other information from the core data are completely available for all patients.

For a more effective comparison between patients, we extend the time series data containing laboratory values and vital signs to include the variable "minutes after diagnosis." This is calculated as the difference between the suspected time of diagnosis and the time of record. Importantly, not all variables are measured constantly or at equidistant intervals; certain values, such as heart rate, however, are frequently measured. Conversely, blood values, including lactate and C-reactive protein (CRP), are typically assessed no more than once per day.

In summary, when considering the average availability of measurements per patient (excluding those with no recorded measurements for a specific value), the values with the lowest frequency of measurement are leukocytes in the liquor, with an average of 0.87 measurements per patient, and procalcitonin, with an average of 4.10 measurements per patient. In contrast, along with dialysis and ventilation, heart rate (mean of 177.31 measurements per patient) and invasive blood pressure (mean of 160.87 systolic measurements per patient) are the values with the highest availability. An overview of the frequency and availability of all time series values is shown in Multimedia Appendix 1.

Statistical Analysis

Overview

On our way to a CDSS applicable in situations where patients have just been diagnosed with sepsis, we aimed, as an intermediate step, at statistical models that are able to predict an empiric antibiotic therapy. Consequently, we intend to predict the prescribed empiric antibiotic therapy based on patients' core data and health records. We address this goal through statistical classification, where each distinct therapy defines one class, and we train a classifier that assigns class memberships to patients. This is possible since the dataset used for training contains the relevant information about the administered initial antibiotic therapy, that is, the true class membership.

To start with, we assume a maximum of one measurement per variable for newly diagnosed patients. This mimics the constraints for a rapid decision after sepsis onset. Accordingly, in the Cross-Sectional Classification subheading, we reduce our dataset to cross-sectional data and apply a cross-sectional classification model (CCM).

In addition, we ask the question of how recommendations could have been improved when based on time series data. To that end, we consider time series classification models (TSCMs) in the Time Series Classification subheading.

Cross-Sectional Classification

Classification is a statistical method for supervised learning, where the true class memberships of training samples are known and can be used during model training to learn a mapping of covariates to classes. After model training, this learned mapping is applied to new data to make predictions for each sample. In our work, we rely on the following classifiers, which are robust to multicollinearity: random forests (RFs), gradient boosting classifiers (GBCs), support vector classifiers (SVCs), and multilayer perceptrons (MLPs).

To train the CCMs, we further prepare the data additionally to the general preprocessing. In particular, we generate covariates that contain cross-sectional instead of time series information as required: for each time-resolved variable, we obtain the relevant values for all patients by selecting the first value measured within the first hour after diagnosis, motivated by the clinical practice to obtain key measurements immediately after diagnosis to capture the current status of a patient. We assume this information to be available at the time of treatment decision. If no measurement is available within this time interval, we use the most recent value within 24 hours before the sepsis diagnosis. Further, we summarize categories of the suspected infection focus occurring less than 50 times as "others."

Many variables in the data have a high proportion of missing values. We refrain from data imputation, for example, multiple imputation [38] or filling missing values by the mean across all samples, as we want to avoid introducing additional uncertainty into the data. Instead, we discard those variables that have 30% or more missing values. Accordingly, we keep the following variables: age, sex, heart rate, average arterial blood pressure, body temperature, fraction of inspired oxygen, pressure of oxygen, leukocytes, thrombocytes, CRP, creatinine, lactate, blood sugar, bilirubin, requiring dialysis, requiring ventilation, and suspected infection focus. These serve as covariates for the CCMs. We do not include systolic and diastolic blood pressure, SOFA, oxygenation index, or glomerular filtration rate as this information is already contained in other variables. After variable selection, we filter for complete cases (ie, patients without any missing values) and end up with 1194 patients for model estimation.

As the target variable (ie, the variable that determines a patient's class membership), we consider the first administered antibiotic therapy (or a combination of several simultaneously administered therapies) for a patient, that is, the antibiotic treatment within the first hour after the diagnosis.

In the resulting dataset, we are faced with highly imbalanced class sizes. We mitigate this imbalance by merging antibiotic therapies with fewer than 20 occurrences as "others." This avoids the CCMs being trained on too few samples for some antibiotics, but even subsequent to this step, imbalanced classes in the target variable remain evident (Table 2): while the largest class, "Piperacillin/tazobactam," contains 550 patients, the smallest class, namely a combined therapy of "Piperacillin/tazobactam" and "Levofloxacin," consists of only 21 patients.

XSL•FO
RenderX

Table . Numbers of antibiotic therapies in the German hospital cohort used for the 2-step models.

Antibiotic therapy	Count
Piperacillin/Tazobactam	550
Other therapies	174
Cefotaxime	104
Meropenem	77
Ampicillin/sulbactam	75
Levofloxacin	54
Ceftriaxone	44
Cefuroxime	33
Vancomycin	33
Ciprofloxacin	29
Piperacillin/tazobactam–levofloxacin	21

Common rebalancing techniques, such as downsampling, would lead to a substantial decrease in the sample size. Thus, instead, we divide the original classification task into 2 consecutive tasks: in a first step, we perform binary classification to predict the majority class "Piperacillin/tazobactam" vs all others; in a second step, we perform multiclass classification to further distinguish between the remaining antibiotic therapies. As described in this section, we apply RF, GBC, SVC, and MLP as classifiers at both steps.

To account for the fairly small amount of data and to avoid model overfitting, we use nested cross-validation (CV) with an inner and an outer loop [39]. The outer loop consists of 10 folds and splits the whole dataset into 10 disjunct sets. The inner loop consists of 5 folds, allowing for a grid search to optimize the models' hyperparameters. For RF, we tune the splitting criterion, the total number of fitted trees, the maximum depth of the trees, and the minimum number of samples to perform a subsequent split. For GBC, in addition to the latter 2 parameters, we optimize the learning rate as well as the number of boosting stages. For SVC, the regularization parameter *C*, the kernel type, and the degree in case of a polynomial kernel are tuned during the grid search. For MLP, we optimize the number of hidden layers assuming each layer consists of 100 neurons, the activation function, the solver, the *L2* regularization term, and the initial learning rate. To measure the models' performance, we use the F_1-score, which is the harmonic mean of precision and sensitivity.

Estimating the binary model does not require any rebalancing. The dataset (before applying CV) contains 550 patients receiving "Piperacillin/tazobactam" (Table 2) and 644 patients receiving a different therapy. This is, however, different for the multiclass classification in the second step. The model is trained on those patients from the training set who received an antibiotic therapy other than "Piperacillin/tazobactam." As shown in Table 2, there are still large differences between the remaining 10 class sizes. At this point, after excluding the most dominant class "Piperacillin/tazobactam," we opt for rebalancing to prevent the model from ignoring the minority classes. As the difference between the largest and smallest class sizes is substantial, we downsample the classes whose sizes exceed the average frequency in the training data for the second step and upsample the other classes accordingly. This procedure prevents the dataset from becoming too small, which at the same time avoids excessive duplication of samples.

Time Series Classification

We apply a TSCM to investigate whether more information is beneficial to correctly predict an empiric antibiotic therapy for patients with sepsis. In contrast to the models described in the Cross-Sectional Classification subheading, TSCMs consider a time series of a sample instead of using just one measurement per variable. In the medical context, this poses a particular challenge, given that patients' health records are typically measured at different time points rather than at uniform intervals. Consequently, the individual time series often vary in length. This requires techniques that can deal with unequal sequences, such as the *k*-nearest neighbor (*k*-NN) algorithm using dynamic time warping (DTW) to measure distances.

To apply *k*-NN with DTW to our data, we consider the patients' time series starting at 24 hours before sepsis diagnosis and up to 1 hour afterwards. Our approach is based on the fact that no later measurements are available for new patients due to the need for fast antibiotic treatment. We use the same covariates and target variable as for the CCMs described in the Cross-Sectional Classification subheading. In contrast to these models, we cannot exclusively use complete cases for the TSCM, as the data basis would become far too small. Therefore, we use forward or, if no previous value is available, backward propagation to fill the missing values in the time series. This procedure is consistent with clinical practice: measurements are considered valid for 24 hours as long as the treating physicians have not seen a need for new values, for example, in case of a deterioration in a patient's health condition. The procedure to estimate the models is the same as for the CCMs: in a first step, we perform binary classification to derive a probability for "Piperacillin/tazobactam," and in a second step, we aim at classifying those antibiotic therapies that are different from "Piperacillin/tazobactam." Again, we use a nested CV and a combined procedure of upsampling and downsampling for class rebalancing in the second step.

Ethical Considerations

Ethical approval was obtained from the Ethics Committee of the Westphalia-Lippe Medical Association and the University of Münster (Ethik-Kommission der Ärztekammer Westfalen-Lippe und der Westfälischen Wilhelms-Universität Münster; case no 2021 - 699-f-S).

Results

Requirements and Insights From Clinical Knowledge

Overview

To enhance the reliability of the CDSS and to acknowledge its limitations, we investigated before the data analysis which kinds of information were regarded as relevant from a clinical perspective. A purely data-driven approach, in contrast, would have searched the wide variety of variables for patterns in an unrestricted manner. However, this approach carries the risk of inducing spurious correlations or therapies that may turn out impractical. Through the interviews and discussions described in the Medical Knowledge Compilation subheading, the following facts and requirements were compiled and subsequently served as a knowledge base for the nonclinical scientists in this project. The Challenges From Data Availability subheading describes to what extent the requirements were met by our data, including which variables were unavailable.

Including Relevant Factors for Treatment Decision

Following a diagnosis of sepsis, there are multiple factors that the treating physician takes into consideration when selecting an appropriate antibiotic. These include, among others, core data, measured vital signs and blood values, patient allergies, known comorbidities, adverse effects, and image data (eg, x-ray images or computer tomography scans). Further, the identification of the infection focus is of utmost importance as it allows for the identification of potential pathogens once the affected organ is confirmed. However, in some cases, the focus is not provided as it is not directly recognizable.

Considering Risk Factors for Antibiotic Resistances

To take potential resistances into account, whether on a global or patient-specific basis, it is necessary to consider additional kinds of information: the patient's origin and professional background, as well as their travel history, previous hospitalization or stay in nursing homes, and antibiotic intake within the last 3 to 6 months. This information may offer insights into the present pathogens and suspected resistances for specific patients.

Evaluation of Antibiotic Effectiveness

With regard to the evaluation of antibiotic effectiveness (ie, the assessment of whether the administration of a specific antibiotic was successful in treating a particular case of sepsis), the most important information is the SOFA score, oxygenation index, procalcitonin, CRP, interleukin 6 (IL-6), body temperature, and circulatory parameters such as blood pressure, heart rate, and respiratory rate. From these, especially procalcitonin and IL-6 are also identified in the literature [40]. Furthermore, leukocytes, thrombocytes, bilirubin, creatinine, lactate, the Confusion Assessment Method for the Intensive Care Unit, and urine output are considered as potential covariates. Generally, for an effective therapy, laboratory values should show a clear improvement. However, the clinical experts emphasized that the identification of relevant factors depends on the infected organ. Furthermore, they highlighted that the general health condition of a patient is more important than laboratory values. If a patient's well-being improves, irrespective of laboratory values, and they demonstrate, for example, increased responsiveness and alertness, it can be assumed that the administered therapy was effective.

Expectations and Acceptance of CDSS

One of the conducted interview series addressed the physicians' opinion on the practical implementation of a CDSS and revealed high interest in and need for support from such a system. This is because clinicians must process the available information within a short time frame, often facing incomplete data when the critical health status of a patient necessitates a rapid therapeutic decision. Furthermore, increasing antimicrobial resistance demands careful consideration of the numerous alternative therapies available. The establishment of a support system, therefore, is of great added value for physicians with limited practical experience, thereby helping them to make well-informed treatment decisions. However, it was also noted that there are still many operational hurdles to overcome, such as the lack of digitization in clinics or the availability of reliable and reasonable retrospective data, which hinder its use in practical hospital settings. A detailed analysis of the interviews is provided by Düvel et al [14]. Another important requirement for a CDSS, highlighted by the medical professionals, concerned the interpretability of the underlying statistical models. Since we use interpretable classification methods rather than AI tools here, this constraint is met, but must be given careful consideration in general.

Challenges From Data Availability

A goal of this study was to determine the extent to which the ideal and theoretically formulated requirements for a CDSS align with the reality of clinical practice. The result of the investigation was that we encountered a number of challenges regarding data quality and availability, which partially led to questions not being answered to the extent we had originally envisioned. These challenges do not solely exist at our site but arise generally from the common level of data documentation in everyday clinical practice and the prospective collection of data for research purposes, influenced by the degree of digitization of clinical data in German hospitals. We provide a detailed account of the 8 most impactful difficulties here to highlight the necessities, and we describe how we overcame some of them by identifying alternative solutions.

The first major limitation was the amount of data. While we had originally planned to export data from all 3 consortium hospitals, this was made impossible due to technical limitations as well as differing processes across the hospitals. As a consequence, this study is constrained to data from a single hospital. This resulted in a rather small sample size of 2986 patients, and this in turn excluded AI-based models that require much larger amounts of data [41]. Using data from several

XSL•FO
RenderX

clinics would have increased the size of the dataset and provided a more representative sample of patients. It would also have enabled us to investigate how much the results differ between clinics. However, obtaining data from multiple clinics would have posed additional challenges due to expected heterogeneity in terms of patient population, prescribing practices, data quality, and other factors. An approach to jointly train generative models on data from multiple hospitals by using federated learning is described by Düsing et al [12].

A second substantial restriction resulted from the fact that several variables, which had been identified as highly important, were not present in the dataset. These included patient history information from which one could have derived the risk of individual resistance against certain antibiotics, such as origin, profession, travel history, and previous antibiotic prescriptions. Moreover, we lacked information on the occurrence of adverse effects, which was not even provided for severe cases. Consequently, our investigation could not address the identification of antibiotic therapies with minimal adverse effects.

Third, the suspected infection focus, which was highlighted by the doctors as one of the most relevant factors in the decision-making process for an antibiotic therapy, was not routinely documented. To still obtain a realistic prediction, patient diagnoses associated with the infection foci were used to infer the suspected infection focus for individual patients (refer to the preprocessing steps outlined in the Data subheading).

Fourth, the exact time of diagnosis was unknown in the sense that its temporal alignment was partially shifted when the documentation started after the first treatment. Hence, there is uncertainty regarding the patient's condition at the time of diagnosis.

Fifth, regarding the effectiveness of an antibiotic therapy, the medical experts asserted that the clinical impression of a patient was given primacy over laboratory values. Still, no such data were documented. Thus, no direct quantitative measure was available to validate the effectiveness of the given therapies.

Sixth, even for those variables that were theoretically included in the dataset, there were many missing values. Thus, despite the ongoing digitization in hospitals and the consideration of retrospective data from more than 10 years, the final sample size of complete patient data was relatively small. Our decision not to impute missing values and to consider only complete cases further contributed to the small sample size and thus limited the feasibility assessment.

Seventh, particularly in the context of time series analyses, the longitudinal measurements are obtained at varying time intervals per patient and with differing frequencies among the measured values. The generation of the variable "minutes after diagnosis" (refer to the Data subheading) resulted in a data matrix for longitudinal values that was extremely sparse. This issue was addressed as described in the Statistical Analysis subheading.

Eighth, concerning the primary target variable, the empiric antibiotic therapy, we encountered high class imbalance (Figure 2). The 10 most frequently prescribed antibiotics accounted for more than 89% of all empiric antibiotics, with "Piperacillin/tazobactam" being the most frequently administered therapy, accounting for 54% (n=1765) of all prescriptions. This imbalance in prescriptions posed a major challenge in predicting outcomes for underrepresented classes and may have led to biased classification results [42]. We addressed this issue with a 2-step modeling approach as outlined in the Statistical Analysis subheading.

To evaluate our classification approach beyond the previously described dataset and to gain insights into the generalizability of our method, we sought to incorporate an additional dataset. The most suitable source for this purpose was the Medical Information Mart for Intensive Care, Fourth Version database [43], which contained health-related data from patients admitted to the ICU of the Beth Israel Deaconess Medical Center between 2008 and 2019. However, important information, such as the infection focus or procalcitonin measurements, were missing in the database. Further, we detected notable discrepancies between Germany and the United States of America with regard to the fundamental hospital procedures and guidelines for the management of sepsis, as well as the related data basis (eg, [44]), which disqualified the Medical Information Mart for Intensive Care, Fourth Version database as a solid basis for comparison within the presented feasibility study. Thus, to develop a targeted approach for common practice in Germany, we exclusively relied on the data described and emphasized the need for more and better data about the diagnosis and treatment of patients with sepsis.

Learnings From Statistical Modeling

Cross-Sectional Classification

Despite the aforementioned challenges, we used various approaches to statistically model the physicians' decisions for empiric antibiotic therapy. Table 3 shows the results of the CCMs (RF, GBC, SVC, and MLP) for the 3 exemplary antibiotics "Piperacillin/tazobactam," "Ciprofloxacin," and "Vancomycin." The results of the remaining antibiotics are provided in Multimedia Appendices 2 and 3. Due to the outer loop of the nested CV, we obtain 10 predictions for different test sets; the tables present their averages.

XSL•FO
RenderX

Table . Average performance of the cross-sectional classification models (CCMs) across 10 folds of nested cross-validation (CV) for 3 selected antibiotics. Measures are calculated across both classification steps and thus represent cumulative performance.

Model and metric	Piperacillin/tazobactam	Ciprofloxacin	Vancomycin
RF[a]			
Sensitivity	0.506	0.117	0.125
Specificity	0.728	0.955	0.962
Precision	0.613	0.108	0.051
F_1-score	0.552	0.110	0.069
GBC[b]			
Sensitivity	0.508	0.092	0.050
Specificity	0.642	0.985	0.969
Precision	0.546	0.117	0.050
F_1-score	0.524	0.102	0.050
SVC[c]			
Sensitivity	0.524	0.095	0.120
Specificity	0.721	0.973	0.964
Precision	0.621	0.095	0.064
F_1-score	0.564	0.095	0.072
MLP[d]			
Sensitivity	0.533	0.078	0.145
Specificity	0.677	0.973	0.949
Precision	0.594	0.108	0.052
F_1-score	0.556	0.090	0.069

[a]RF: random forest.

[b]GBC: gradient boosting classifier.

[c]SVC: support vector classifier.

[d]MLP: multilayer perceptron.

It becomes immediately apparent that none of the models achieved high sensitivity, precision, or F_1-score; consequently, the models are not reliable enough for use in clinical practice. For most antibiotics, the sensitivity is lower than 22%, and in many cases it is even lower than 10%. This low sensitivity comes along with a high specificity. The only exception is “Piperacillin/tazobactam,” for which all 4 classification models result in a sensitivity above 50% and a specificity above 60%. MLP achieved the highest sensitivity of 53.3%; this is accompanied by a medium-high specificity of 67.7%. Compared to all other antibiotic therapies, the performance of the 4 models for predicting “Piperacillin/tazobactam” is satisfactory: both sensitivity and specificity, and thus precision and F_1-score, are moderately high. However, this performance is still insufficient for clinical implementation. Even worse results are obtained for “Ciprofloxacin” and “Vancomycin”: the highest sensitivity of 11.7% and 14.5% is achieved by RF and MLP, respectively.

Time Series Classification

The averaged results from time series classification across the 10 folds of the CV for the 3 antibiotics “Piperacillin/tazobactam,“ “Ciprofloxacin,” and “Vancomycin” are shown in Table 4. The results for the remaining antibiotics are provided in Multimedia Appendix 4. No improvement over CCM results could be achieved using time series data. *k*-NN with DTW performed worse than the CCMs as measured by F_1-score. Even for “Piperacillin/tazobactam,” the F_1-score was on average 12.3% points lower when using the TSCM instead of CCMs. The poor performance for “Ciprofloxacin” and “Vancomycin” is conspicuous. In the case of “Ciprofloxacin,” the sensitivity is low (2%), and the same holds for “Vancomycin”: not a single sample belonging to this class was correctly classified.

XSL•FO
RenderX

Table . Average performance of time series classification models (TSCMs).

Metric	Piperacillin/tazobactam	Ciprofloxacin	Vancomycin
Sensitivity	0.416	0.020	0.000
Specificity	0.572	0.991	0.952
Precision	0.457	0.125	0.000
F_1-score	0.426	0.029	0.000

Baseline Model

To compare the results of the described CCM and TSCM against a simple baseline model, we predict the antibiotic therapy for all patients to be "Piperacillin/tazobactam" without further training of a statistical model. Naturally, for all antibiotics other than "Piperacillin/tazobactam," the sensitivity, precision, and F_1-score are zero, while the specificity is equal to one. The performance results for "Piperacillin/tazobactam" are shown in Table 5. As expected, the sensitivity equals one, while the specificity is zero. The F_1-score for "Piperacillin/tazobactam" equals $2m / n + m$, where n is the total number of patients and m is the number of those belonging to this majority class. The value of 0.629 directly results from the imbalance of class sizes and is higher for the baseline model than when applying the CCM and TSCM. However, the F_1-score for "no Piperacillin/tazobactam" equals zero. Precision is lower for the baseline model than for the CCM and similar to the TSCM. Consequently, when considering only the majority therapy, the complex modeling approaches are outperformed by a simple heuristic in terms of the F_1-score. This is hardly surprising since the CCM and TSCM are trained to differentiate between a number of therapies rather than putting all emphasis on the majority class. The (moderate) success is reflected in the performance metrics of the other therapies.

Table . Performance of the baseline model for all antibiotics.

Metric	Piperacillin/tazobactam	Any other antibiotics
Sensitivity	1.000	0.000
Specificity	0.000	1.000
Precision	0.461	0.000
F_1-score	0.629	0.000

Discussion

Summary

We embarked on an ambitious project to develop a CDSS aimed at recommending an appropriate initial antibiotic therapy for patients with sepsis. This CDSS was intended to be applicable immediately upon diagnosis and to provide recommendations regarding potential resistance and side effects. The system was to be developed using data science methods, drawing from data collected at 3 local hospitals.

However, the situation within the clinics revealed that various factors contributed to a relatively small dataset, comprising only 1194 complete cases, along with a substantial amount of unavailable information. Contemporary AI approaches typically require large datasets; therefore, a swift implementation using large language models, which may seem straightforward to an outsider, was not feasible in this context. Instead, we took on the challenge by combining meticulous information and data preparation with the adaptation of statistical learning methods. In fact, we achieved a satisfactory classification for one of the subquestions. Nonetheless, our project uncovered several limitations, and in this paper, we outline the key insights regarding the process.

To summarize, the process included the initial stages of knowledge acquisition, data preprocessing, overcoming data-related challenges, and constructing predictive models to classify the physician's choice of empiric therapies. We have described each relevant step, examined the challenges involved, and presented potential models together with the results derived from the available data.

Principal Findings: Exploration of Model Performance

Despite careful data preparation, modeling, and incorporation of clinical knowledge, the statistical models achieved only poor to moderate performance in predicting the physicians' decision for empiric antibiotic therapy. Only the first step of the 2-step approach (ie, the classification of "Piperacillin/tazobactam" against all other therapies) succeeded to some extent. We identify several reasons that we suspect are contributing to this issue.

Sample Size

Good predictions require sufficient sample sizes. Our final dataset contained only 1194 samples in total. Of those, 550 belonged to the class "Piperacillin/tazobactam," while all other class sizes ranged from 21 to 174. The comparably good performance in the first step of the classification procedure indicates that, all in all, our statistical models are appropriate as long as enough data are available. To put it another way, we suspect that the main reason for the poor overall predictive ability is the small sample and class sizes. Sepsis manifests in very different ways; to find similarities in patients' health records, many more samples may be needed for analysis. To develop a reliable CDSS for clinical usage, future projects

XSL•FO
RenderX

should be based on a large dataset containing several thousand patients, with particular consideration of class balance and complete data collection.

Broad-Spectrum Antibiotics

Notably, the most commonly prescribed therapy, "Piperacillin/tazobactam" (roughly 50%), along with several other documented treatments, are broad-spectrum antibiotics. This reflects how often this type of antibiotic is prescribed in clinical practice. In some cases, this antibiotic therapy is recommended by the guidelines; however, the high frequency of prescriptions also suggests a paucity of relevant information for a more targeted treatment decision. A retrospective evaluation of administered antibiotics by medical experts, under consideration of a patient's disease course, could be valuable to identify a targeted and effective antibiotic therapy. In doing so, a CDSS could learn to predict the best antibiotic therapy, and its predictive performance would not be affected by erroneous data.

Class Imbalance

Not only was the sample size small, but the classes were also substantially different in size. The overrepresentation of "Piperacillin/tazobactam" led to a notable class imbalance. To deal with this, we decided to split the classification task into 2 steps. For the first step, the prediction of "Piperacillin/tazobactam," no class rebalancing was needed, and we achieved comparably good results using CCMs. Still, these results are not yet suitable for clinical practice, highlighting the need for large, high-quality datasets, in particular for AI-based classifiers. In the second step, in contrast, we had to rebalance the classes as these were still unequally represented. Depending on the method used for rebalancing, useful information was removed (eg, when using random undersampling of the majority class [45]), samples were duplicated (eg, when using random oversampling of the minority class [45]), or synthetic data were added, potentially containing unrealistic or even wrong information (eg, when using the synthetic minority oversampling technique [46]). Consequently, the application of methods for class rebalancing comes with uncertainty. In particular, random oversampling of small classes might lead to model overfitting, resulting in a model's inability to learn generalizable patterns in the data. This, in conjunction with the small sample size, is a possible explanation for the poor predictive ability of the models. As already mentioned, future projects should therefore attach great importance to reliable and balanced data collection. This is one of the most relevant conditions for success in achieving good model performance.

Observed Initial Treatments

To model a physician's decision for an empiric antibiotic therapy, we used the first administered antibiotic contained in the dataset, regardless of whether the therapy was effective, because the dataset does not contain quantified information about the effectiveness (refer to Challenges from Data Availability subheading). However, there are indications that the first antibiotic was not necessarily the most effective one and could thus lead to inappropriate predictions: the data show that, due to constant reevaluation, the administered therapy was modified several times during one infection for many patients. As a consequence, our models describe prescribing habits rather than optimal treatment decisions. If appropriate information on effectiveness becomes available, the target variable could, however, be easily adapted.

Missing Information

As outlined in the Challenges from Data Availability subheading, relevant variables for an informed decision in favor of an antibiotic therapy were not included in the data. In particular, there were no variables that provided information needed to assess a patient's risk of infection with resistant bacteria, such as origin, travel history, profession, and previous antibiotic prescriptions. In addition, a predictive model could benefit from information about hospital-specific antibiotic resistance patterns, especially if patient-specific risk factors are not available, to limit the eligible antibiotic therapies. This information is not included in our data; however, the development of a resistance observatory was a concurrent task of the "KINBIOTICS" consortium [13]. Without any of this information, the model may not be able to predict an antibiotic therapy that is consistent with the empiric therapy chosen by the physician. A detailed discussion with medical experts about risk factors, necessary information, and the medical process for deciding on an antibiotic therapy before data collection is crucial. Ideally, a CDSS is based on prospective data so that all necessary information can be documented and subsequently extracted. According to literature, the infection focus, information about previous hospitalizations or stays in nursing homes, travel history, and origin of a patient, comorbidities, and hospital-specific antibiotic resistance patterns are of utmost importance for choosing an adequate antibiotic therapy for ICU patients [47].

Uncertain Infection Focus and Time of Diagnosis

Medical experts regarded the infection focus as of high importance within the decision-making process for antibiotic therapy (refer to Requirements and Insights From Clinical Knowledge subheading). In the Data subheading, we explained how we derived the suspected focus. The alignment of confirmed and suspected focus, however, comes with uncertainty, and we consider possible errors to further affect the models' performance. The use of retrospective discharge data to predict a hospitalization decision poses a limitation of our study, as it artificially inflates the feasibility of such a CDSS. A similar statement holds for the time point of sepsis diagnosis as derived by us. Our assumption that the time of sepsis diagnosis corresponds to the time of first administered antibiotic therapy will affect our models' performance, as we use data for prediction that likely do not match the prescription. More precisely, our models might include values that were measured close to the time of administration of empiric antibiotics or even afterwards. This renders the models unsuitable for clinical application. This issue should be addressed in future studies by using prospective data that contains the exact time of diagnosis, as well as information on crucial variables between this time and the time of antibiotic administration.

XSL•FO
RenderX

Missing Data

Many classifiers are unable to deal with missing values. Thus, we reduced the dataset to complete cases by removing certain covariates and patients. This further limits the classification models' interpretability and increases prediction uncertainty. Further, by removing laboratory values of high clinical importance, in particular procalcitonin, our models lack inflammatory markers.

In light of all the aforementioned limitations, the poor classification performance, especially in the second step of our approach, becomes comprehensible. The shortcomings highlight the need for large, high-quality data as a basis for a reliable CDSS for the individualized prediction of a targeted, effective antibiotic therapy for patients with sepsis. Future initiatives should place the highest priority on ensuring thorough and accurate data collection.

Conclusions

Overview

Our work yields 2 principal take-home messages: first, the importance of interprofessional collaboration, and second, the need for high-quality data and improvements in data acquisition processes.

Regarding the first, interprofessional collaboration and the continuous exchange between medical experts and model constructors turned out to be crucial both in the preliminary stages of the project and during its entire progress. Such collaboration increases the chance of obtaining meaningful results as all stakeholders are aware of the requirements for data availability and quality. Many medical relationships require detailed discussion before they can be integrated into the data and modeling processes. Simultaneously, critical questions—often stemming from one party's lack of expertise—can lead to new insights and perspectives.

Regarding the second, the results of the models highlight the critical need for comprehensive and large, high-quality data. In accordance with literature (eg, [47]), we particularly recommend the complete and correct collection of the following variables: time of diagnosis, administered antibiotics and their effectiveness, suspected infection focus at the time of antibiotic prescription, retrospectively confirmed infection focus, risk factors (eg, origin, profession, and travel history), and laboratory values (eg, procalcitonin, lactate, leukocytes, CRP, and IL-6). The performance of the model could be further enhanced by the incorporation of comorbidities, antibiotic allergies, and image data. At best, these values are available in electronic form, and a plausibility check is performed during data entry with the option for immediate clarification. The data should contain information on several thousand patients. We assume that an appropriate number of samples depends on the data quality.

Limitations and Recommendations: Data Documentation

Our dataset contains information on patients admitted to the ICU, where they are constantly monitored. Here, certain parameters are measured in an automated way, while the measurement of many other values has to be actively initiated and is carried out manually. The latter may lead to a lack of continuity in health records, and it is expected that data from less controlled units (such as non-ICU) are of even lower quality. This is a nationwide issue, beyond the study location of Bielefeld, partially caused by strict data protection regulations, including a rigorous interpretation of the European Union's General Data Protection Regulation. While these rules ensure a high standard of privacy, they also contribute to comparatively slow progress in digital transformation, as reflected in the European Union's Digital Economy and Society Index, where Germany is positioned in the middle range in digital public services and e-government readiness [48].

To improve the general documentation of health data, the optimization and expansion of digitization in German hospitals are of the highest importance. The implementation of the electronic patient record system (elektronische Patientenakte [ePA] [49]), which is currently being introduced in Germany, has the potential to offer great benefits for scientific analyses. Specifically, information regarding patients' origin, travel history, professional background, and time of diagnosis could be made more readily accessible. Even information from previous inpatient or outpatient stays can potentially provide relevant information that would be available through the ePA. The benefit of the ePA for research purposes is only provided if access to the data is granted. The draft of the German "Forschungsdatengesetz" [50] aims at improving access to and use of data for research purposes, consequently contributing to an improvement in data availability. Moreover, a health data usage act ("Gesundheitsdatennutzungsgesetz" [51]) was passed in March 2024 in Germany, with the objective of regulating the use of health data for research purposes in the public interest and for the data-based further development of the health care system. A further desirable future development would be the continued growth of extensive, high-quality datasets, such as those from the NFDI4Health initiative (Nationale Forschungsdateninfrastruktur für personenbezogene Gesundheitsdaten [52]), making small-scale, project-specific data collections unnecessary and/or serving as external data validation resources.

Limitations and Recommendations: Model Architecture

The context considered in the study led to the definition of 2 architectural elements that should be evaluated with caution and adapted to the specific context of application. These concern the 2-step approach and the choice of the performance measure for parameter optimization.

Regarding the presented 2-step approach, we observe that errors arising from misclassifications of samples in the first step are propagated to the second step. The low sensitivity and moderate specificity for "Piperacillin/tazobactam" indicate that a substantial number of patients are irretrievably misclassified in the first step: samples truly belonging to the class "Piperacillin/tazobactam" but classified as "no Piperacillin/tazobactam" can no longer be correctly identified in the second step, and vice versa for samples belonging to "no Piperacillin/tazobactam" that are predicted as "Piperacillin/tazobactam." In this case, the 2-step procedure was motivated by the severe imbalance between class sizes,

XSL•FO
RenderX

where upsampling or downsampling of all classes, including "Piperacillin/tazobactam," would have been the less favorable option. In this sense, the model choice was meaningful. Nevertheless, the architecture should be tested for robustness when the approach is transferred to another dataset with different class distributions or potentially clearer class boundaries.

Regarding the performance measure, we aimed to simultaneously account for both false-positive and false-negative predictions, in line with our study consortium's objective of predicting a targeted antibiotic with minimal side effects. Therefore, we placed particular emphasis on the F_1-score. For the translation of this approach to other projects, we recommend close coordination with the practicing physicians and clinics and, if necessary, adaptation of the statistical optimization objective.

Future Directions

The logical next steps that arise from our project are to move beyond mere classification of therapies that were prescribed in practice to providing recommendations for therapies that are expected to have high effectiveness. To overcome the lack of a quantitative measure for administered antibiotic therapies, this may involve a data-driven assessment of the health status of patients with sepsis from time series of laboratory values and vital signs. This may provide a basis for the development of methods that can learn from retrospective data to predict the best possible therapy outcome for an individual patient with sepsis. The steps achieved and presented here will contribute to the development of an effective CDSS for antibiotic prescription in sepsis, ultimately improving the survival of patients with sepsis and helping to reduce antibiotic resistance.

Acknowledgments

We thank all members of the "KINBIOTICS" project, especially the medical experts who took part in the interviews and meetings and thus made an important contribution to the model development. During the writing of this manuscript, the authors used ChatGPT (version 4.0; OpenAI) to improve language and readability. After using ChatGPT, the authors reviewed and edited the content as needed and take full responsibility for the content of the published paper. The data preprocessing was performed using R (version 4.4.2; R Core Team) [53], and the models were fitted using Python (version 3.11.9; Python Software Foundation) [54]. The code used for model fitting is available on GitHub [55].

Funding

This study was supported by a grant from the German Federal Ministry of Health (Bundesministerium für Gesundheit; grant no ZMVI1-2520DAT930; "KINBIOTICS").

Data Availability

Due to data protection and privacy regulations, we are not allowed to share the data from the German hospital used in this work.

Authors' Contributions

Conceptualization was conducted by CF, HM, and SS. Data curation was performed by CF, PH, HM, and SS. Formal analysis was carried out by PH, HM, and SS. Funding acquisition was secured by PC, CF, WG, OK, SR, JT, and MW. Methodology was developed by PH, HM, and SS. Project administration was managed by PC. Resources were provided by RB, PC, CD, OK, SR, SSS, JJT, MW, and DW. Supervision was conducted by PC, CF, and SR. Validation was performed by JD and SE. Visualization was performed by HM and SS. The original draft was prepared by RB, CF, HM, and SS.

Abstract

Background: The successful implementation of decision support systems promises to enhance high-quality care. However, the successful implementation of a clinical decision support system (CDSS) depends on user acceptance and adoption. A machine learning (ML)–based CDSS to assist primary care professionals treating urinary tract infections (UTIs) was implemented, and usability and usefulness were assessed through a questionnaire.

Objective: This study aimed to assess the system's usability by examining users' experiences with the software. A secondary goal was to assess users' attitudes toward evidence-based practice and innovation in health care.

Methods: In collaboration with the Netherlands Institute for Health Services Research (NIVEL) and Leiden University Medical Center (LUMC), Pacmed Ltd developed the CDSS. The cohort was mostly recruited at the care group level; practices within participating care groups were required to participate. Health insurers partly funded the research. Practitioners participated in the implementation study for 4 months. A survey based on the Unified Theory of Acceptance and Use of Technology (UTAUT) was sent to 263 general practitioners and assistants shortly after the implementation period. Furthermore, usage data were analyzed.

Results: Of the 34 participating practices that used the software, 30 (88%) submitted at least one survey response, with a mean of 2.23 responses per practice (SD 1.43). The CDSS was used throughout the pilot period, and 31 practices continued using the tool, with 9% dropping out during the first 8 weeks. Sixty-seven percent of respondents trusted the tool's output, and 73% found it understandable how the algorithm came to predictions. Sixty-five percent of respondents indicated that the information provided was useful in addition to the available guidelines, and 52% agreed that it supported their decision-making. However, many respondents were uncertain whether the tool improved patient care (46%) or patient outcomes (66%). Forty-eight percent of respondents found the software easy to integrate into their clinical workflow.

Conclusions: The CDSS was perceived as trustworthy and easy to use. However, users were unable to determine whether the CDSS improved patient outcomes. In addition, the CDSS development could have benefited from including assistants as well as general practitioners more in the design phase of the software. Because assistants play an important role in UTI care, designing the software to better fit existing workflows may reduce the perceived time investment associated with using the tool. Finally, respondents reported strong motivation to contribute to further research in this field and indicated willingness to embrace change in health care delivery, which may also reflect selection bias in our sample.

Introduction

Background

Machine learning (ML)–based applications are increasingly being developed for use in health care, and a growing body of this work is published in peer-reviewed journals [1]. However, only a small fraction of these applications are ultimately implemented in clinical practice, and their efficacy and usability in real-world settings are rarely evaluated [2].

The implementation of ML and data analytics in health care faces many challenges. One key barrier is health care professionals' willingness to adopt clinical decision support systems (CDSS) and to engage with insights derived from electronic health record (EHR) data. To explore these implementation challenges, we studied the introduction of a CDSS designed to support general practitioners (GPs) in selecting appropriate treatments for patients with urinary tract infections (UTIs).

With approximately 70 per 1000 female patients and almost 10 per 1000 male patients, UTI is one of the most common diagnoses in primary care. Effective UTI treatment has a high impact on quality of care and cost-effectiveness [3,4]. At the time of this study, the Dutch Association of General Practitioners (NHG) guideline in the Netherlands was based on 21 randomized controlled trials (RCTs) and underrepresented patients belonging to guideline-defined risk groups. As a result, evidence supporting recommendations for several risk groups was limited. Given the complexity and heterogeneity of UTI presentations in practice, treating all patients efficiently remains challenging. GPs therefore reported lack of agreement as a problem for all key recommendations while using that UTI guideline at the time of our intervention [5].

GPs have a gatekeeping role in the Dutch health care system, controlling patients' access to specialized care. GPs are usually the first health professionals to consult, and there is no copayment. Virtually all Dutch residents are registered in a GP practice, and nearly all GP practices use EHRs. This creates opportunities to identify determinants of treatment success and failure using routinely collected clinical data. Prior work has shown that reusing this data by mining it can help us learn about treatment effectiveness and outcomes on a real patient population, revealing unknown disease correlations in the process, resulting in increasing quality of care [6-8]. In a collaboration of Netherlands Institute for Health Services Research (NIVEL), Leiden University Medical Center (LUMC), and Pacmed (Ltd), a data-driven CDSS to aid the efficient treatment of UTIs was built. The aim was to support GPs and patients with UTI treatment decisions. The CDSS was implemented in 36 general practices and was associated with a statistically significant improvement in treatment success [9].

Goal of This Study

CDSSs have the potential to improve the quality of care and patient outcomes by helping health care professionals process large amounts of information. Despite the promise, studies consistently show that the mere provision of CDSSs does not guarantee their uptake [9-11]. Even where CDSSs are available and have demonstrated improved outcomes, they may fall short of their full potential because of limited adoption [4,11-13]. In the Netherlands, approximately 21% of GPs reported having access to a CDSS, and only about one-fifth reported using these during consultations [14,15]. Low adoption rates of decision support systems remain a major obstacle to realizing the full potential of CDSS.

Multiple factors contributing to limited CDSS adoption have been identified. Adoption in health care is often driven by users' perceptions of usefulness, including the relevance and applicability of information to individual patients, trust in the system, and fit with clinical workflows [16-22]. In addition, the user's attitudes toward changes in health care and evidence-based practice influence CDSS adoption [21,23]. These factors do not fully explain the limited adoption of CDSS, underscoring the need to better understand barriers to technology adoption among health care professionals. Furthermore, more elaborate research on possible risks and pitfalls of implementing decision support warrants further study. For example, decision support may contribute to overreliance on automated recommendations, potentially reducing care quality if clinicians do not critically appraise the presented information [24,25].

Several of these issues were addressed during the CDSS design phase, with the aim of maximizing applicability, interpretability, usability, and trust. To evaluate the usability and perceived usefulness of the CDSS, an implementation study was conducted in 36 primary care practices for a period of 4 months. The goal of this paper is to evaluate the usability and perceived usefulness by examining the user's use and experience with the software.

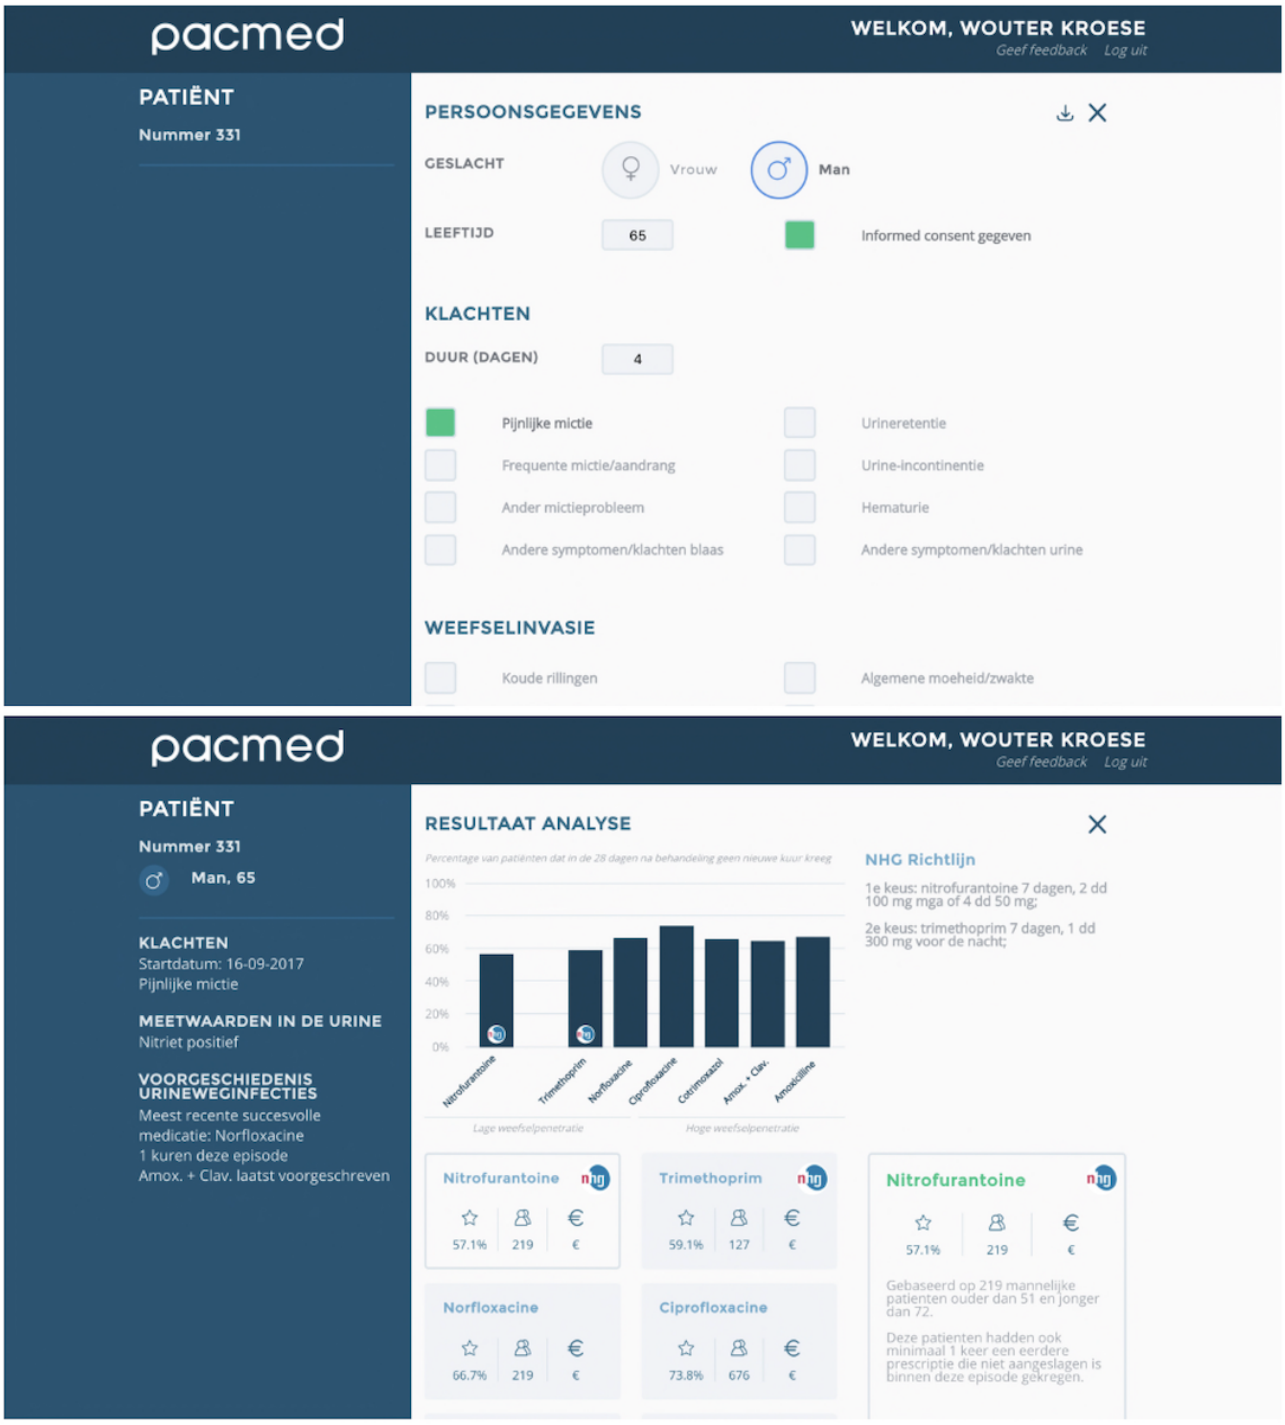
Methods

Recruitment

This was a quantitative interventional design. The cohort included 36 practices and 263 users in total (116 GPs and 147 assistants). The cohort was mostly recruited on the care group level, and all the practices within a care group were required to participate. In the Netherlands, care groups are collaborative organizations of health care providers that jointly coordinate specific elements of care delivery, such as chronic care management or participation in innovation and quality improvement programs. Practices participated in the implementation study for a period of 4 months. A 4-month implementation period was chosen based on a power analysis for the primary clinical outcome (change in treatment success for patients with UTI), as reported in our companion paper [9]. Clinicians at participating practices were trained in responsible use of the software and were instructed to use it to support decision-making for patients presenting with a UTI (ClinicalTrials.gov NCT04408976). As part of the study, a survey was conducted among all users to evaluate the usability and perceived usefulness of the software. Use of the software was nonmandatory, and no financial or other incentives were associated with its use.

This usability and perceived usefulness study was cross-sectional and used an online survey sent to all 263 users after the intervention period in 2018.

XSL•FO
RenderX



Use of the CDSS was recorded within the tool. Clinical outcomes and changes in prescribing behavior during the implementation period are reported in a separate paper [9]. This study evaluates usability, perceived usefulness, and acceptance of the CDSS after real-world use. Accordingly, we did not include a parallel control group because respondents needed to have interacted with the CDSS to meaningfully assess usability and perceived value.

Pacmed's CDSS

The decision support software was developed as a collaborative effort between NIVEL, LUMC, and Pacmed. The software uses algorithms based on the analysis of data from the NIVEL Primary Care Database, which included a total of 122,203 UTIs [26]. The software interface was developed in close collaboration with several primary care physicians through user tests and expert groups. Users were requested to enter patients' characteristics, and the CDSS then provided the users with a bar chart of the expected outcomes for the relevant treatment options based on similar patients in the database. In addition, the relevant part of the NHG guideline was displayed. Additional information supporting the expected outcomes could be retrieved by clicking on a treatment option. This information included the number of patients the analysis was based on, in addition to an age band of these patients and other clinically relevant features (Figure 1). Further details on the ML methods and datasets used for model training and validation are reported in our companion paper [9]. Before implementation, software use was explained in training sessions. During the implementation period, the interactions with the users were minimal and occurred primarily in response to feedback or support requests.

XSL•FO
RenderX

Figure 1. Decision support software: interface to enter patient characteristics (top); presentation of expected outcomes and NHG (Dutch College of General Practitioners) guidelines (bottom).

Usage Data

To investigate usage behavior with Pacmed's clinical decision support software, data of the user's interaction with the software was analyzed. Usage behavior was continuously recorded as users interacted with the software, which includes the time of service and the number of logins, as well as the activities mentioned above (creating new patient files, editing patient files, accessing patient files, medications suggested before and after results presentation, and provision of feedback to the developers).

Questionnaire

The questionnaire was developed using the unified theory of technology acceptance model as a structural model that was designed to measure users' experiences with the software and several of the health care professionals' attitudes and characteristics [27]. Of the 41 questions, 28 were Likert scale-based questions, where respondents were requested to indicate their level of agreement on a 5-point Likert scale (1: strongly disagree-5: strongly agree), with an additional "not applicable" response option.

XSL•FO
RenderX

Twenty of the 28 questions represented key operationalizations from the unified theory of acceptance and use of technology (UTAUT; concepts included ease of use, usefulness, trust in the system, and facilitating conditions [20,28,29]). An additional 4 questions were added to explore the system quality and satisfaction, and 4 more questions were added to explore users' intention to increase evidence-based practices in their daily activities, their opinion about the Dutch College of General Practitioners (DCGP or NHG), and their opinion toward the use of observational data for medical research [29]. Four open-ended questions were asked to allow more elaborate responses. These questions requested responses regarding how the software fit into their workflow, their personal most important reason to use the software, suggestions to improve information quality, and suggestions for improvement to the software. Finally, demographic and professional information were also requested (age, gender, years of experience, and previous use of CDSS).

To ensure the content validity of the questions, the draft questionnaire was reviewed by 4 GPs that did not participate in the implementation study but are familiar with the type of decision support that was being evaluated. The quality and reliability of the individual items were evaluated and improved using the Survey Quality Predictor (SQP). SQP is an online tool with an open-source database of questionnaire items and quality estimates that allows evaluation and improvement of survey questions during instrument development [30,31]. The question characteristics were coded by 2 authors (WEH and JK). The questions were improved on the basis of the quality prediction of SQP, as well as information about the effects of individual characteristics of the questions on the quality and validity. The reliability, validity, and quality coefficient estimates can be found in Table 1, and the accompanying statements in Table 2.

Table . Predicted survey quality predictor (SQP) reliability, validity, and quality coefficients (0 - 1), including SEs and method effect for each question.

Question	Reliability coefficients	SE (reliability)	Validity coefficients	SE (validity)	Quality coefficients	SE (quality)	Method effect
Q1	0.85	0.15	0.97	0.13	0.82	0.11	0.24

Q36	0.84	0.15	0.94	0.16	0.79	0.12	0.33

Users were invited to complete the questionnaire via email, which directed them to a 9-page web-based survey. They were able to review and change their responses. Each submission was linked to the same username used to access the CDSS.

XSL•FO
RenderX

Participation was voluntary, with no incentives provided. Three reminder emails were sent over a 2-month period after software usage.

XSL•FO
RenderX

Table . Items used within the questionnaire to measure agreement to each statement on a Likert scale are categorized with effort expectancy (EE), perceived usefulness (PU), trust (T), information quality (IQ), evidence-based practices attitude (EB-A), clinical decision support system attitude (CDSS-A), system quality (SQ), facilitating conditions (FC), and intended use in the future (ITU).

Question	Category	Survey item
Q1	EE[a]	"It was easy to integrate the system into my workflow."
Q2	EE	"I used the system while interacting with my patients."
Q6	PU[b]	"The information was effective in helping me making decisions."
Q7	PU	"The systems' output is a useful source of information in addition to the NHG[c] guidelines."
Q8	PU	"Using the system improved the quality of patient care."
Q9	PU	"Using the system improved patient outcomes."
Q10	PU	"I believe that the tool was particularly useful for certain patient groups."
Q13	PU	"I believe that using the tool, empowered my decision-making."
Q14	T[d]	"I trusted the outputs provided by the system."
Q15	IQ[e]/T	"The information accompanying the system's output enabled me to understand how the predictions were made by the algorithm."
Q16	IQ/T	"I used the knowledge acquired from the system in situations outside of the software."
Q18	EB-A[f]	"I consider myself as a person that embraces change in health care."
Q19	EB-A	"I would like to increase the use of evidence in my daily practice."
Q20	EB-A	"I believe that analyzing observational data is a strong method to learn about patients underrepresented in classical medical research."
Q21	EB-A	"I believe that the NHG guidelines are based on sufficient evidence."
Q22	CDSS-A[g]	"I believe that working according to the NHG guidelines will lead to improved patient care."
Q23	CDSS-A	"Overall, I believe that the advantages of clinical decision support systems outweigh the disadvantages."
Q28	SQ[h]/FC[i]	"The system was sufficiently fast."
Q29	SQ/FC	"I found the system interface too complex."
Q30	SQ/FC	"The content of the software was readable and clearly organized."
Q31	SQ/FC	"It was easy to enter the patient characteristics."
Q32	SQ/FC	"It was easy to quickly extract the relevant information to support my decision-making."
Q33	SQ/FC	"It was easy to access the analysis of previously entered patient data."
Q34	FC	"Technical support was available when I needed it."
Q36	ITU[j]	"Given that the most common diagnoses are incorporated in the decision support, I intend to use the system in the future."

XSL•FO
RenderX

Question	Category	Survey item
Q37	Satisfaction	"Overall, I am satisfied with the system."

[a]EE: effort expectancy.

[b]PU: perceived usefulness.

[c]NHG: Dutch Association of General Practitioners guideline.

[d]T: trust.

[e]IQ: information quality.

[f]EB-A: evidence-based practices attitude.

[g]CDSS-A: clinical decision support system attitude.

[h]SQ: system quality.

[i]FC: facilitating condition.

[j]ITU: intended use in the future.

Statistical Analysis

Usage Data

The present usage analysis extracted the extent of usage based on the number of entered patients, the total number of interactions with the software (General use), and the number of completed analyses with the software. The total number of interactions included the user's performed actions, such as accessing patient data or logging in. The number of completed analyses refers to the number of patient files that were completed and filled out with the final response regarding the chosen medication. Descriptive statistics were used to estimate the overall usage over the trial period on the individual and practice levels.

Questionnaire

Quantitative questionnaire results are reported, and summary descriptives are provided. The free-text comments were independently reviewed, and themes were extracted by 2 researchers (WEH and JK) to limit any potential sources of error. Given the descriptive and exploratory nature of this usability study, analyses are limited to descriptive statistics; no hypothesis testing or inferential statistics were performed.

The datasets generated or analyzed during this study are available from the corresponding author on reasonable request.

Ethical Considerations

The study protocol was reviewed and determined to meet the requirements for exemption from Ethics Committee (METC) review under the Dutch Medical Research Involving Human Subjects Act and to be in accordance with the Dutch Medical Treatment Act and the Dutch Data Protection Act. Patient privacy was protected throughout the study by design. All data were handled in accordance with applicable data protection regulations. No directly identifying information was accessed or included in the dataset used for this study, and no identifiable information is reported in this manuscript. Patients were informed about the use of their data for research purposes via the participating practices and were given the opportunity to opt out anonymously.

Results

Usage Data

Of the original 36 practices, 34 started with the implementation study (95%). Thirty-one practices continued using the tool throughout the pilot period, with a 9% dropout in the first 8 weeks.

Practices used the tool for an average of 40.14 consultations during the intervention period (SD 33.40; Table 3). Most of the activity was recorded within the first few weeks and slightly declined over time. A total of 153 (58%) users used the tool at least once, 98 (64%) of whom were assistants. On average, each user had 46 (SD 52.45) total system interactions and completed 8.42 (SD 10.64) analyses.

Table . Total number of clinical decision support system (CDSS) activities.

Usage type	In total	Per practice (n=36), mean (SD)	Range (minimum-maximum)
Patients with UTI[a] entered	1365	40.14 (33.40)	1-123
Completed analyses	1150	33.82 (29.41)	1-108
General use	4085	120.15 (102.54)	3-414

[a]UTI: urinary tract infection.

Questionnaire Statistics

Thirty out of 34 participating practices submitted at least one response, with practices submitting, on average, 2.23 responses (SD 1.43). In total, 67 health care professionals responded to the questionnaire, including 31 assistants and 36 GPs (Table 4) [32]. All pages of the questionnaire were completed by everyone.

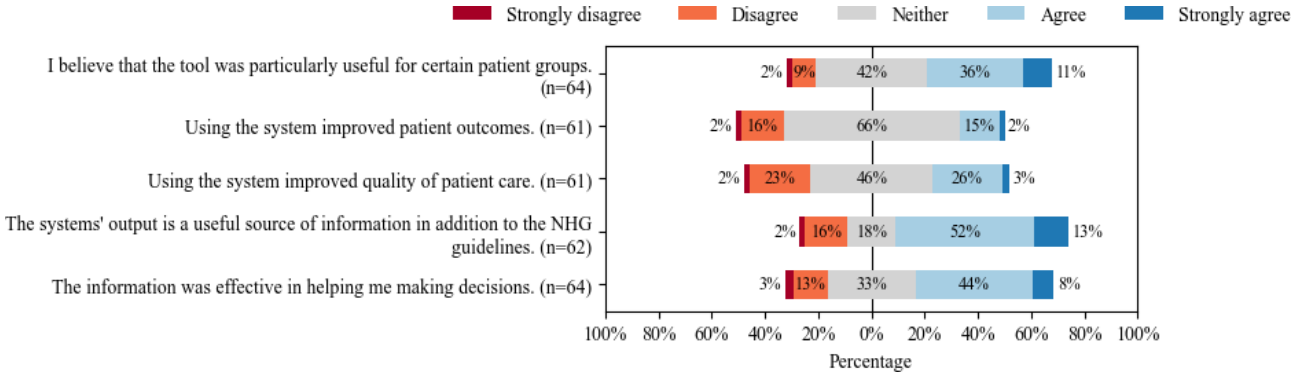
[d]CDSS: clinical decision support system.

Evaluation Outcomes

Clinical Process and Usefulness

Thirty-one out of the total 65 (48%) respondents indicated that it was easy to integrate the tool into their clinical workflow, and 8 out of 59 (14%) respondents indicated that the tool was used during patient interaction (Figure 2).

Figure 2. Respondents' opinion on the effort expectancy of the software.



Overall, 40 out of 62 (65%) respondents evaluated the tool as useful in addition to the NHG guideline, and 33 out of 64 (52%) respondents agreed to the tool supporting them in their decision-making process. While the software's usefulness is appreciated, the majority of respondents were not sure whether the tool improved patient care; 28 out of 61 (46%) respondents.

XSL•FO
RenderX

Furthermore, the majority of respondents were not sure whether the tool improved patient outcomes; 40 out of 61 (66%) respondents (Figure 3).

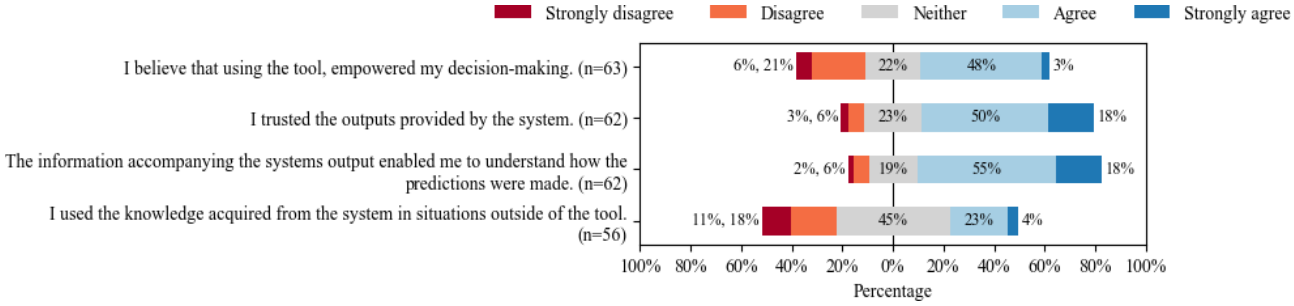


Figure 3. Respondents' opinion on the usefulness and relevance of the software in clinical practice.

Trust and Information Quality

Sixty-eight percent of respondents indicated that they trusted the system's output (Figure 4), namely 42 out of 62 respondents, which depicted the expected outcomes for each medication given specific patient characteristics. Additionally, 45 out of 62 (73%) respondents agreed that the output made it understandable how the algorithm came to its results.

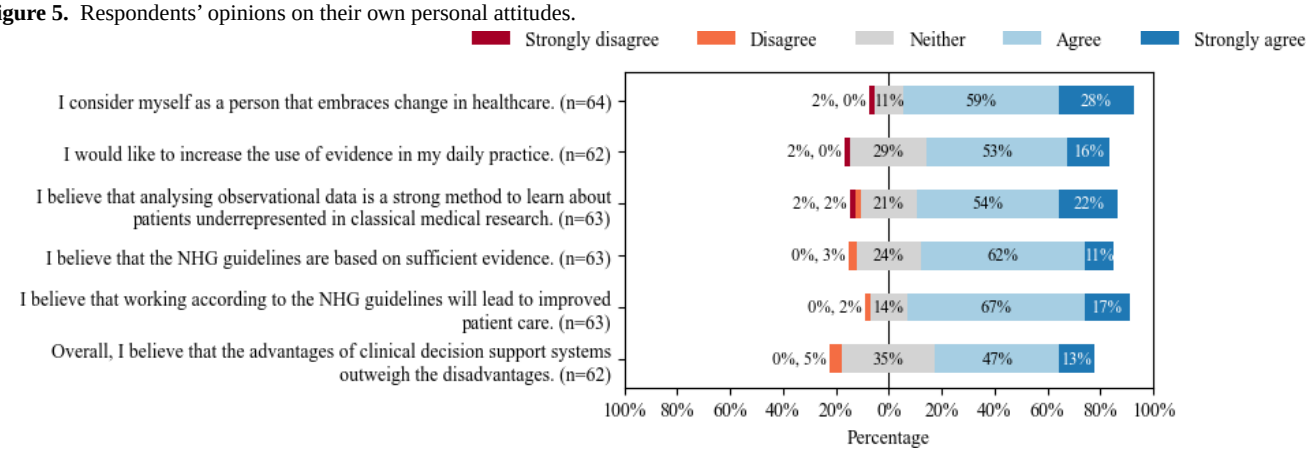

Figure 4. Respondents' opinion on the user's trust and the information quality of the software.

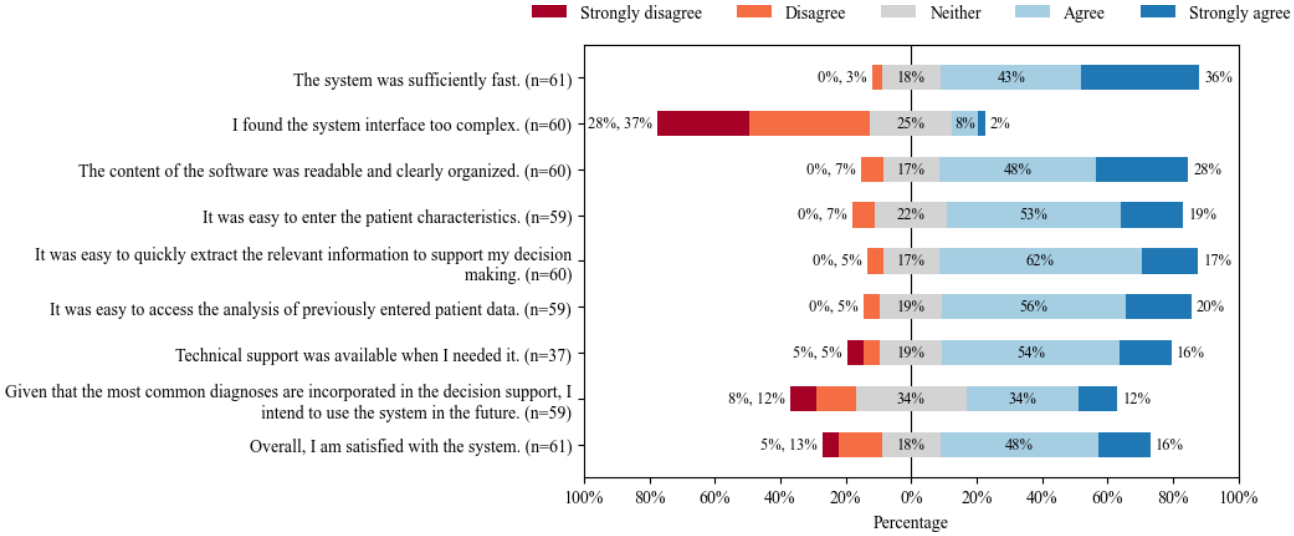
General Attitudes

Forty-three out of 62 (69%) respondents indicated that they would like to increase the use of evidence in their daily practice, with 48 out of 63 (76%) respondents indicating that the use of observational data can be a strong method to learn about patients underrepresented in medical research (Figure 5). Fifty-three out of 63 (84%) respondents agreed to the statement that working according to the official professional guidelines leads to improved patient care. In addition, 46 out of 63 (73%) respondents believe that these guidelines are based on sufficient evidence. Fifty-six out of 64 (88%) respondents indicated that they embrace changes in health care. Finally, 37 out of 62 (60%) respondents agreed with the statement that clinical decision support tools have more advantages than disadvantages, while 22 out of these 62 (35%) respondents neither agreed nor disagreed with this statement.

Figure 5. Respondents' opinions on their own personal attitudes.



System Evaluation

The overall system evaluation was positive, with 48 out of 61 (79%) respondents agreeing to the system being sufficiently fast and 46 out of 60 (77%) respondents agreeing to the system being clearly organized with an easy-to-understand interface (Figure 6). Furthermore, 47 out of 60 (78%) respondents indicated that it was easy to extract the relevant information.

XSL•FO
RenderX

Forty-two out of 59 (71%) respondents agreed that it was easy to enter the patient characteristics. Thirty-nine of 61 (64%) respondents indicated to be satisfied with the decision support software, and 27 of 59 (46%) respondents stated that they would use the software in the future if major diseases were incorporated (Figure 6).

Figure 6. Respondents' opinions on the system's quality, their intention to use it, and their satisfaction with the software.

Free Text Comments

There were 4 free-text fields in the questionnaire that allowed users to further elaborate on some of their responses. The first question requested users to further elaborate on how the software was integrated into their daily activities. The main theme that emerged was that the use of the software required too much additional work and was too time-consuming. A second theme that emerged was regarding how the tool was used. It was stated that it was mostly assistants who interacted with the software by entering the patients. The presented information was then used by the GP. This also resulted in redistribution of work and extra discussion between doctor and assistant.

The second question, concerning the users' main intentions to use the system, was answered by 47 out of 67 respondents (70%). The most frequently stated theme was the opportunity of added informative value that the users saw in decision support systems. The second theme that emerged was the potential of improved care through the delivery of more personalized treatments.

The final question requested further suggestions to improve the software, with the most common suggestions related to a request to integrate the tool into the EHR systems. Finally, respondents suggested the added value of additional training on how the software should be used well.

Discussion

Principal Results

The main results were that the CDSS was used frequently throughout the implementation period and that users perceived the information as effective in supporting decision-making and as a useful addition to existing professional guidelines. Participants also reported trusting the information, and the additional contextual information about the patient groups underlying predictions helped them understand how expected treatment outcomes were generated. This transparency may facilitate effective collaboration between clinicians and decision support. Participants stressed that the added informative value and potential improvement of patient outcomes are reasons to use a similar CDSS, which is in line with the relatively low dropout rate of 9%. Participants were, however, undecided about whether the CDSS indeed improved quality of care and patient outcomes during the implementation study. This could indicate either a discrepancy in the results of our study or imply the complexity of assessing the impact of a decision support tool on the quality of care for a physician. The fact that the CDSS was associated with a statistically significant improvement in patient outcomes during the intervention period suggests that the uncertainty may stem from the inherent complexity of evaluating the impact of such tools on quality of care [9].

Furthermore, participants clearly stressed the tool was easy to use and to retrieve and understand the information from the tool. Nevertheless, participants indicate that the use of the software required too much additional work and was too time-consuming. It was repeatedly mentioned that IT integration would facilitate a better match with this workflow. The fact that the use of the tool felt like a lot of extra work in practice seems to be the main reason for lack of use and adoption. This may partly explain why some participants were not inclined to use this type of CDSS in the future. The perceived time investment has been shown to influence the adoption of CDSS in previous research [15,20]. Even minimal additional steps can be perceived as too much if the tool does not align closely with existing routines. This highlights the importance of designing CDSS tools that align closely with existing clinical workflows, thereby minimizing perceived time investment and supporting sustained adoption.

Limitations

In general, participants stated they have a positive attitude toward change in health care. Most of the participants also stated that they would like to increase the amount of evidence in their

XSL•FO
RenderX

daily practice and that they see an opportunity in the use of observational data for doing so. In addition, the participants indicated that the NHG guideline leads to better patient care, and the participants mostly stated that the NHG guideline is based on sufficient evidence. This gives us reason to conclude that the participant sample was relatively positive toward change and several ways of increasing evidence in their daily practice. This could indicate a selection bias in our sample. The fact that part of the practice recruitment took place via care groups and thus not through the initiative of some of the practices themselves, this bias is possibly mitigated partly. Furthermore, although the response rate at practice level was very high (30 out of 34 practices), the response rate of the survey was substantially lower as compared to the total number of participants of the implementation study (67 out of 265 users). This means that the results of the survey could endure a response bias as well.

The use of the survey enables us to obtain relatively unbiased results from a large number of users. In the construction of the questionnaire, the UTAUT model was used, allowing the structure of the results and additional topics of specific interest were added. However, our particular survey was not fully validated before conduction. Doing an extensive pilot with a group of GPs that were not part of the study but were familiar with the software helped in assuring that the questions were interpreted and understood well. To further guarantee the reliability, validity, and quality of the survey items, SQP was used.

Another point of attention of the research is that the assistants had not been involved in the design phase of the CDSS, whereas they played an important role in the treatment of the UTIs in practice. In many participating practices, much of the work was done by assistants. As such, their role in the care path should not have been underestimated and future design should ensure that all potential user groups are included from the beginning. The different uses of the tool for assistants and GPs led to a redistribution of work, which resulted in less work. Nevertheless, evaluating and comparing the results between GP and assistant did not yield significant differences.

Conclusions

In general, the users were very open to research and wanted to be involved in the development and evaluation of intelligent clinical decision support. Thorough research on the desires and concerns of the end user is needed to develop clinically relevant, usable, and safe decision support systems. An important aspect of such research is the impact on the trust of the information by the user. Trust in the CDSS is a key factor in ensuring effective collaboration between physicians and ML and ultimately in achieving optimal clinical outcomes. However, trust should not be maximized uncritically, as excessive trust can also become a significant pitfall [33]. It is important that, as for all medical knowledge a doctor has access to, the information is approached critically and is continuously being evaluated and monitored on quality. Large trust in the system could be at the cost of this critical view, and a noteworthy risk is that doctors are less well equipped to evaluate this new source of information as opposed to other sources of clinical information and as such might fall for the “automation bias” [24]. Automation bias happens when users become less vigilant in processing the information and trust it uncritically. For example, it has been shown that with the introduction of a computer algorithm that supported computer-aided detection in mammography, the performance of radiologists decreased, as the algorithm provided incorrect classifications [24,25]. During this study, for example, the users have indicated that they trust the system well but did not ask questions about the underlying mathematics or technology of the system, while we would have liked to see that users would have required more information before accepting and trusting the recommendation. However, the trust in the system could have also been a result of the conscious design choice to use relatively simple ML methods, allowing for extensive explainability, such as showing the explicit group of patients in the training dataset on which the predictions were based [9]. Such transparency has been shown to strongly support a positive relationship between ML and physicians [33].

Next to trust in the methodology, there were also almost no questions asked about potential conflicts of interests by the manufacturer of the CDSS. It might well be that manufacturers have specific interests in selling algorithms that enhance other products that they sell, like algorithms that support in- and detubation timing, that enhance the value of respirators. Or manufacturers that have clear interests in reducing costs more than in improving the quality of care. For safe adoption on a large scale, these critical and sometimes ethical questions are important not to neglect.

Abstract

Background: Alzheimer disease (AD) is a progressive neurodegenerative disorder with rapidly growing global prevalence. Early detection is critical for timely intervention; yet, conventional diagnostic methods remain costly and invasive. Speech-based assessment has emerged as a noninvasive alternative, as AD characteristically impairs linguistic abilities including fluency, coherence, and informational content. Recent advances in large language models (LLMs) offer new opportunities to extract structured linguistic features from transcribed speech for automated AD classification. However, existing LLM-based approaches often lack transparency and clinical interpretability, limiting their adoption in clinical workflows.

Objective: This study aims to investigate the influence of linguistic features extracted from transcribed speech, as analyzed by LLMs, on the accuracy and interpretability of AD prediction.

Methods: We propose a framework that leverages LLMs to analyze linguistic features extracted from transcribed speech for AD classification. Our approach focuses on 4 key aspects, including readability, fluency, richness of detail, and keyword relevance. To enhance classification accuracy, the framework integrates transcript embeddings with feature explanation embeddings, forming a comprehensive linguistic representation. We conducted extensive ablation studies to evaluate the contributions of individual features and benchmarked our framework against existing LLM-driven methodologies through pairwise explainability evaluations. Output stability was assessed across 3 independent pipeline runs. A fully local configuration (Llama 3 8B + nomic-embed-text) was tested to evaluate privacy-preserving deployment feasibility. Explainability was assessed via LLM-based pairwise comparison (Gemini-3.1-flash-lite) against the method of Bang et al across 54 correctly classified cases and by blinded evaluation from 2 neurologists.

Results: The proposed framework achieved a mean precision of 91.52%, a sensitivity of 91.08%, a specificity of 96.29%, and F_1-score of 91.05% across 3 independent runs on the ADReSSo 2021 dataset, outperforming existing LLM-based approaches. A fully-local configuration (Llama 3 8B+nomic-embed-text, requiring no cloud application programming interface access) achieved an F_1-score of 81.58%, demonstrating framework transferability to privacy-preserving deployment environments. Keyword relevance was the most influential feature (F_1-score drop of 13.22 pp when removed). Explainability evaluations showed our method was preferred in 49 out of 54 cases via Gemini-3.1-flash-lite, with human experts preferring our method in 89 of 108 blinded assessments.

Conclusions: These findings highlight that a structured linguistic feature analysis using LLMs provides a robust and interpretable framework for preliminary AD detection. Our approach offers a scalable and accessible solution that bridges artificial intelligence–driven text analysis with clinical applications, supporting early detection of cognitive decline through noninvasive assessment methods.

Introduction

Background

Alzheimer disease (AD) is a progressive neurodegenerative disorder that primarily affects older adults. The global prevalence of AD is significant, as the number of people living with dementia is projected to increase from 55 million in 2019 to 139 million by 2050, according to the 2023 World Health Organization (WHO) report [1]. In the United States alone, as of 2024, approximately 6.9 million individuals aged 65 years and older are affected by Alzheimer dementia [2,3]. These alarming figures highlight the critical need for early detection and intervention strategies to improve patient outcomes, optimize treatment strategies, and reduce the burden on health care systems [4].

Early diagnosis of dementia offers substantial benefits, enabling individuals to make informed decisions, access essential services and treatments, and implement preventive measures to maintain safety and quality of life [5,6]. Patients, caregivers, and researchers highly value early detection due to its role in supporting life planning, improving end-of-life care, and facilitating research on disease pathology before advanced neuronal damage occurs [5,7]. Furthermore, early diagnosis may promote lifestyle modifications that could potentially delay or prevent the onset of AD, offering a proactive approach to health management [7].

Although neuroimaging and cerebrospinal fluid biomarkers are considered the gold standard for early detection, their limitations—including high costs, limited availability, and invasive procedures—create accessibility challenges, particularly in resource-limited settings [8,9]. Plasma biomarkers are emerging as promising, noninvasive alternatives that could improve accessibility and reduce wait times for specialized care [8,9]. However, they also face limitations, including variability in results, lower specificity compared to traditional biomarkers, and standardization challenges [10,11]. Additionally, dementia risk scores, such as Cardiovascular Risk Factors, Aging, and Dementia (CAIDE) and the Australian National University Alzheimer Disease Risk Index (ANU-ADRI), provide valuable support for early identification, though ongoing refinement is required for broader clinical application [12].

Integrating routine cognitive assessments in primary care can further enhance early detection rates, promoting proactive dementia management and improved patient outcomes [13-15]. Recent technological developments, including computerized adaptive testing (CAT), enhance the flexibility of digital assessments by tailoring testing experiences based on individual cognitive capabilities [16,17]. Additionally, digital cognitive assessments enable the discovery and longitudinal monitoring of novel digital biomarkers outside traditional clinical settings [18,19]. These tools offer significant advantages over traditional paper-based methods in both clinical practice and research, demonstrating increased sensitivity in detecting subtle cognitive changes that conventional assessments might overlook [18-20]. Digital assessments also provide greater reliability and validity through repeated measurements across multiple days, yielding more consistent intra- and interparticipant data compared to single-time-point traditional assessments [20,21].

The accessibility of digital cognitive assessments is another key advantage, as they allow remote self-administration, reducing the need for in-person clinic visits and improving access for underserved populations [18,22]. Additionally, these digital methods offer high ecological validity by enabling frequent, brief assessments in real-world settings, supporting a patient-centered approach, and generating data that better reflects daily cognitive functioning [20]. Their cost-effectiveness and efficiency make them particularly suitable for large-scale studies and clinical trials requiring scalable solutions [18,22].

AD is increasingly recognized for its impact on cognitive function, particularly memory impairment as an early hallmark. However, language impairment is also a notable early symptom that significantly hinders communication [23]. Studies indicate that integrating language assessments into conventional cognitive evaluations enhances the precision of AD progression prediction [24]. As cognitive decline advances, linguistic tasks become more challenging, highlighting the importance of understanding language dynamics in this patient population. Moreover, the distinct relationship between language deficits and cognitive deterioration underscores the potential of linguistic measures as critical markers for assessing the progression from mild cognitive impairment (MCI) to AD [25]. Recent findings suggest that language assessments can not only identify individuals at greater risk for developing AD but also aid in monitoring the severity of language impairments as the disease progresses [26]. Incorporating language assessment into routine cognitive evaluations could improve early detection strategies, enabling targeted interventions designed to help maintain communication abilities. Thus, recognizing and addressing language impairments in early AD stages could play a pivotal role in patient care and management.

In recent years, deep learning-based approaches have gained traction for automating feature extraction by learning complex representations from speech data. Various speech embeddings, such as VGGish, X-vectors, and Wav2Vec [27], along with language embeddings like Bidirectional Encoder Representations from Transformers (BERT), Robustly Optimized BERT Pretraining Approach (RoBERTa), and GPT, have been used to capture rich acoustic and linguistic information for AD detection [28-31]. Moreover, studies demonstrate that combining acoustic and linguistic features enhances AD detection performance by integrating multiple aspects of speech and language affected by cognitive decline [32-34].

Despite the strong performance of deep learning-based approaches, they face significant challenges regarding explainability and interpretability. A systematic review conducted by Shi et al [31] analyzed 72 studies and found that most only provided selective examples for their deep learning models, with very few explicitly addressing explainability. However, in clinical settings, there is a growing need for simpler yet interpretable methods for preliminary AD screening. Recent developments in large language models (LLMs) have demonstrated promise in analyzing speech transcripts from the Cookie Theft picture description task, with studies reporting

XSL•FO
RenderX

accuracies of 80.3% using GPT-3 [35] (OpenAI). Notably, Bang et al [36] developed a method incorporating LLM-driven explainability, achieving 85.92% accuracy using GPT-4 (OpenAI).

In this research, we expand on the explainability capabilities of LLMs and systematically refine their prompt design. We guide the LLM to evaluate 4 key linguistic dimensions—readability, fluency, richness of detail, and keyword relevance—before making a diagnosis. This approach enhances both accuracy and interpretability. Our proposed framework also introduces a structured prompt template that directs LLMs in systematic linguistic analysis. Our design includes (1) expert role definition as a speech therapist, (2) specific task instructions for feature analysis, (3) standardized feature definitions, and (4) exemplar demonstrations.

Using Whisper (OpenAI) for speech-to-text conversion and GPT-4 with our specialized prompt template, our framework addresses a binary classification task—distinguishing individuals with AD from cognitively control normal (CN)—and achieved around 91% precision and recall, with 96% specificity on the ADReSSo 2021 dataset, demonstrating that structured linguistic analysis alone can support reliable preliminary AD screening. Key contributions of this work include:

1. Proposing a novel framework integrating LLM-based linguistic analysis with structured feature evaluation and prompt engineering for generating explainable AD diagnosis.
2. Developing an AD classifier that incorporates both transcript content and LLM-explained features to enhance prediction accuracy.
3. Providing empirical evidence of stable and competitive diagnostic accuracy (F_1-score=91.05%; sensitivity=91.08%; specificity=96.29%) on the ADReSSo 2021 Challenge dataset using speech transcripts from the Cookie Theft picture description task [36].
4. Demonstrating superior explainability through a structured multifeature framework, significantly outperforming an existing approach in diagnostic reasoning, evidence support, and clinical insight, winning 49 out of 54 pairwise evaluations via Gemini-3.1-flash-lite.

Related Work

Before the advent of ChatGPT (OpenAI) in late 2022, most deep learning-based research for AD detection predominantly used BERT as the underlying machine learning framework. In these studies, linguistic features and language embeddings served as inputs to BERT. Subsequent studies adopted more advanced artificial intelligence (AI) models, such as GPT-3 and GPT-4, for AD detection. Below, we review these studies and highlight their strengths and weaknesses.

AD Detection With BERT

BERT is a transformer-based pretrained language model introduced by Google researchers in 2018 [37]. It represents text as a sequence of vectors, which can then be used to train a classification model. The application of BERT for direct transcript embedding has shown promising results in several studies. For instance, Padhee et al [38] applied BERT to raw transcriptions, achieving an F_1-score of 80% for classifying patients with AD, MCI, and, while Rohanian et al [39] highlighted BERT's adaptability to variations in transcription quality.

For feature-enriched embedding approaches, researchers have enhanced BERT's capabilities by incorporating additional linguistic features. Mahajan and Baths [40] improved multimodal classification by integrating lexical diversity and syntactic complexity features with BERT embeddings. Qiao et al [41] focused on model explainability by combining fluency and disfluency features, while Yuan et al [42] examined semantic similarity and information density as complementary inputs to increase diagnostic accuracy.

Despite these successes, BERT-based methods face key challenges; direct embedding approaches lack direct clinical explainability, while feature-enriched methods introduce additional complexity and require domain expertise.

AD Detection With Advanced LLM

The emergence of more advanced AI models, such as GPT-3 and GPT-4, has transformed AD detection through innovative approaches to linguistic feature extraction and analysis. Compared to earlier models like BERT, these LLMs excel at classification tasks, even with minimal or no additional training data, while also providing textual explanations.

Agbavor and Liang [35] pioneered the use of GPT-3 for dementia prediction from spontaneous speech, leveraging text embeddings to capture semantic meaning and achieving 80.3% accuracy in distinguishing between patients with AD and CNs. Wang et al [43] expanded this research by exploring GPT-4's capabilities for MCI screening, analyzing linguistic indicators via standardized prompts, and achieving 77.3% sensitivity and 83.3% specificity.

Bang et al [36] introduced a novel methodology by using GPT-4 for speech fluency evaluation, integrating AI-generated opinions with original text, and achieving 85.92% accuracy and 94.44% specificity. Additionally, Balamurali and Chen [44] conducted a comparative analysis of multiple LLMs in a zero-shot learning context, highlighting both the potential and the limitations of LLM technology in clinical settings at the time of this writing.

These developments illustrate the progression from basic text analysis to sophisticated diagnostic tools, while also emphasizing the need for standardized prompt engineering and clinical validation. This growing body of research suggests that well-structured LLM approaches could provide valuable support for preliminary AD screening while maintaining interpretability for health care professionals.

However, these LLM-based approaches face two major limitations:

1. Lack of transparency and interpretability: many LLM-driven approaches do not clearly specify the evaluation process. For instance, while Bang et al [36] used GPT-4 to assess speech fluency, they did not define which fluency aspects were being measured. Similarly, Agbavor and Liang's [35] approach using GPT-3 embeddings lacked clarity regarding the specific semantic features captured.

XSL•FO
RenderX

2. Absence of a structured analysis framework: previous studies varied significantly in their methodological approaches, lacking a standardized framework for LLM-based analysis. Although Balamurali and Chen [44] specified multiple linguistic aspects for evaluation, their LLM-based approach remained exploratory, without establishing scoring criteria or standardization. This lack of methodological structure limits the clinical applicability of these models.

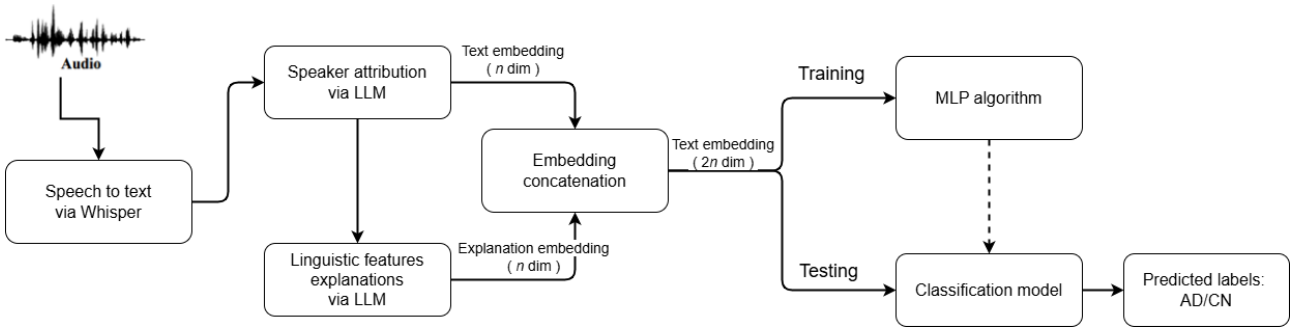
These limitations underscore the need for a systematic and interpretable approach to LLM-based AD detection, one that integrates structured feature evaluation with explainability. In this work, we address these challenges by developing a framework that enhances transparency, interpretability, and clinical relevance.

Methods

Overview

Before introducing our methodology, we first describe the dataset used in this research. Our approach begins with extracting AD-relevant linguistic features using an LLM. We meticulously design prompts to guide the LLM in analyzing linguistic patterns associated with AD. The resulting feature explanations, along with their corresponding transcripts, are then used to construct an AD classifier. Detailed descriptions are provided in the following subsections.

Dataset



The primary dataset used in this study is the ADReSSo 2021 Challenge corpus [45], derived from DementiaBank [46]. This dataset contains audio recordings of participants describing the Cookie Theft picture from the Boston Diagnostic Aphasia Examination (BDAE) [47], a standardized task widely used in cognitive assessments. The dataset has been carefully balanced to address common demographic biases in medical datasets, ensuring matched distributions of age and gender between groups.

The dataset comprises 166 training samples, including 87 AD cases and 79 CNs, and 71 test samples, including 35 AD cases. All audio recordings underwent preprocessing to ensure consistency. The dataset's balanced structure mitigates the common issue of group imbalance in clinical datasets, making it particularly suitable for developing and evaluating AD classification models.

The Framework

The overall framework of our AD prediction method is illustrated in Figure 1.

Figure 1. The framework of the proposed method that incorporates both transcript and its feature explanations for Alzheimer disease (AD) prediction. AD: Alzheimer disease; CN: control normal; LLM: large language model; MLP: multilayer perceptron.

The process consists of the following steps.

1. Speech-to-text conversion performed by Whisper.
2. Speaker attribution to extract the participant's description from the transcript using an LLM-based approach.

The first 2 preprocessing steps are described in the Preprocessing subsection. The examiner-free transcript is then analyzed by an LLM, which generates feature-based explanations across 4 linguistic categories. These features are detailed in the AD Related Linguistic Feature section. Both the transcript and its corresponding explanations are converted into n-dimensional vector representations. These embeddings are then concatenated into a $2n$-dimensional vector, integrating both semantic content and feature-based assessment. A multilayer perceptron (MLP) classifier processes the final representation to classify participants into AD or CN groups.

Preprocessing

Our preprocessing pipeline consists of 2 essential steps to derive transcripts from the dataset.

1. Speech-to-text conversion: all audio recordings were transcribed using the Whisper automatic speech recognition (ASR) system [48].
2. Speaker attribution: since the raw transcripts contain dialogues between examiners and participants, this step aims to isolate the participant's descriptions by removing examiner interventions (eg, "What's happening in that picture?"). We compared 2 methods: an LLM-based speaker attribution method and a conventional speaker diarization method using PyAnnote (pyannoteAI). Experimental results on the ADReSSo 2021 dataset show that the LLM-based speaker attribution method yields better performance (F_1-score=0.82) compared to the conventional speaker diarization method (F_1-score=0.92). We observe that the speaker diarization method using PyAnnote [49] was prone to failure or speaker misidentification in low-volume recordings and cases where examiner and participant voices were acoustically similar, resulting in incomplete or contaminated transcripts. The LLM-based method, by contrast, leverages semantic content to reliably identify and

XSL•FO
RenderX

remove examiner turns regardless of audio quality, preserving richer participant descriptions. Based on these results, the LLM-based approach was adopted for subsequent analyses. Readers are referred to Multimedia Appendix 1 for the detailed prompt design.

AD-Related Linguistic Feature Analysis With LLM

This study identifies 4 key linguistic features—readability, fluency, richness of detail, and keyword relevance—as critical for detecting AD from speech. These features were derived from a comprehensive review of linguistic studies and correspond to established categories in speech and language processing, including syntactic, semantic, lexical, disfluency, and pragmatic features. Each feature captures a distinct aspect of language impairment observed in AD, offering a structured framework for assessing cognitive decline. Table 1 summarizes these features, their relevant linguistic categories, primary focus, quantification metrics, and key references.

Table . Linguistic features for Alzheimer disease (AD) detection.

Feature	Relevant linguistic category	Core focus	Metrics	Key references
Readability	Syntactic and lexical	Evaluating syntactic complexity, lexical diversity, and discourse coherence to reflect the organization of speech.	• Lexical diversity (Type-Token Ratio; TTR) • Syntactic complexity (dependency parsing) • Discourse coherence (Coh-Metrix indices)	[38,40-42,50,51]
Fluency	Disfluencies	Measuring smoothness and flow of language, including hesitations, filled pauses, and repetitions.	• Pause frequency and duration • Speech rate • Self-repair rates	[39,40,52-54]
Richness of detail	Semantic and pragmatic	Assessing the density and specificity of meaningful content in descriptions.	• Proportion of information-bearing nouns and verbs • Content density (Latent Semantic Analysis) • Ratio of semantically empty words	[42,55,56]
Keyword relevance	Semantic	Evaluating alignment of spoken content with predefined key elements in a given context (eg, the Cookie Theft image).	• Frequency of target keywords • Semantic similarity (cosine similarity and topic modeling) • Neural attention weights for key terms.	[54,57,58]

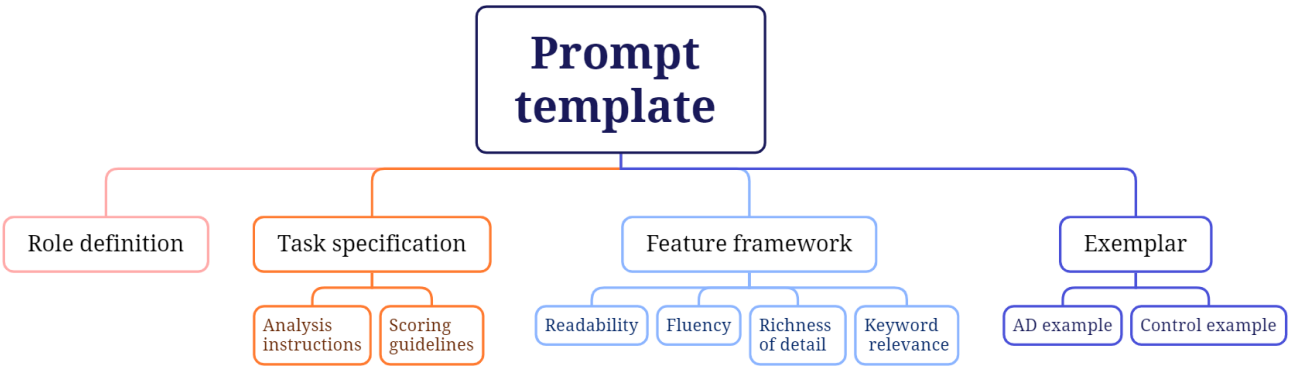
Readability encompasses syntactic complexity, lexical diversity, and discourse coherence, all of which are essential for evaluating the organization and comprehensibility of speech. Studies indicate that patients with AD often produce grammatically simplified sentences, shorter sentence segments, and less coherent discourse, reflecting a decline in their ability to construct complex and information-dense narratives [40,41,50]. Traditional readability assessments rely on dependency parsers and Coh-Metrix indices, but LLMs provide a holistic alternative by integrating syntactic and lexical patterns into a unified framework [42,51].

Fluency captures the smoothness and temporal flow of speech, focusing on pauses, hesitations, and repetitions. Patients with AD frequently exhibit disfluencies due to word retrieval challenges and sentence formulation difficulties, which signal cognitive decline [55,56]. Common metrics include speech rate, pause frequency, and self-repair rates. LLMs enhance fluency analysis by automatically detecting patterns within transcripts, offering a scalable and nuanced approach to fluency evaluation [40,52].

Richness of detail refers to the density of meaningful and specific information within a description. Studies indicate that patients with AD tend to provide fewer information-bearing propositions, relying on vague or semantically empty words [55,56]. This reflects impairments in semantic memory and access to stored knowledge. Metrics such as latent semantic analysis and content density analysis quantify these deficits. LLMs enable dynamic evaluations by assessing the use of descriptive language and narrative coherence, complementing traditional feature extraction methods [42].

Keyword relevance evaluates the degree to which spoken content aligns with predefined key elements of a context or scenario, such as the Cookie Theft picture used in our study. The patients with AD often omit critical objects or actions, reflecting impairments in lexical retrieval and semantic memory [55,56]. Neural attention models have shown that diagnostically relevant keywords (eg, “sink,” “water,” and “cookie”) appear significantly less frequently in the descriptions of patients with AD[57]. LLMs improve keyword analysis by leveraging

XSL•FO
RenderX



attention mechanisms to quantify the inclusion and contextual relevance of key terms [58].

These 4 linguistic features collectively address syntactic, lexical, semantic, and pragmatic aspects of AD-related language impairments. Traditional methods rely heavily on manual feature engineering and domain-specific tools, whereas LLMs provide an automated and holistic approach by integrating structured, semantic, and pragmatic analyses via carefully designed prompts. This LLM-driven approach provides a scalable and interpretable method for analyzing speech, aligning with recent advancements in biomedical informatics for dementia diagnosis [55,56,59].

Prompt-Template Design

We developed a structured prompt template to facilitate consistent and comprehensive LLM-based analysis of Cookie Theft picture descriptions. The complete template is provided in Multimedia Appendix 1. The template is designed hierarchically, consisting of 4 key components (illustrated in Figure 2).

Figure 2. The hierarchical structure of the prompt template, illustrating the relationships between components and their respective subelements. AD: Alzheimer disease.

The 4 key components are:

1. Role definition: establishes the expert context to ensure that the LLM provides clinically relevant responses [60]. This component positions the LLM as a speech and language therapist with expertise in identifying language dysfunctions in individuals with cognitive impairment.
2. Task specification: provides analysis instructions and scoring guidelines to ensure structured evaluations. The analysis instructions explain that language dysfunctions in AD often arise from compromised semantic and pragmatic processing abilities and that the Cookie Theft picture description task is specifically designed to assess cognitive function and memory. The scoring guidelines direct the LLM to evaluate each feature on a standardized 1 - 7 scale, where higher scores indicate better cognitive function. These guidelines emphasize the importance of providing detailed explanations and specific evidence from the transcript to support each feature assessment.
3. Feature definition: features to be evaluated include readability (syntactic complexity and comprehensibility), fluency (speech smoothness and coherence), richness of detail (information density and specificity), and keyword relevance (inclusion of essential elements from the Cookie Theft picture). Each feature definition includes brief descriptions of how these linguistic elements typically manifest in patients with AD compared to healthy individuals.
4. Exemplar demonstrations: the template includes 2 contrastive examples to calibrate the analysis, including a control example, generated from a participant with high cognitive function, and an AD example, produced by a participant with AD. The control example consists of a detailed, well-structured description demonstrating high scores across all features, whereas the AD example involves a description showing typical patterns of cognitive decline, characterized by fragmented expression and limited detail. Refer to Multimedia Appendix 1 for the full prompt and an example of AD-related linguistic feature analysis generated by the LLM.

Ethical Considerations

This study uses the publicly available ADReSSo 2021 dataset from the DementiaBank corpus, which does not involve direct patient contact or new clinical data collection. Institutional Review Board (IRB) approval (25-CT1-02[241015-2]) was obtained through an expedited review at Kaohsiung Veterans General Hospital, covering the methodological framework development and serving as a prerequisite for the associated clinical pilot study. No additional ethics approval was required for use of the publicly available dataset.

Results

Configuration

We developed a multicomponent framework for AD detection, with each component specifically configured. We adopted GPT-4 [61] as the large language model in our experiments. For the embedding process, we used OpenAI's text-embedding-ada-002 [61] model to generate embeddings from both transcript content and feature explanations. Each component produced a 1536-dimensional vector, resulting in a concatenated 3072-dimensional vector for the subsequent classification task. For the classification model, we implemented a 2-layer MLP architecture. The first layer transformed the 3072-dimensional input into 512 hidden units with rectified linear unit activation and dropout (rate=0.1), followed by a second layer outputting binary classification probabilities. The model was trained using the Adam optimizer [62], a batch size

XSL•FO
RenderX

of 8, a learning rate of 0.01, and ran for 50 epochs. We used 5-fold cross-validation for model evaluation, with each fold maintaining balanced AD/Control ratios, using the 176 training samples of the ADReSSo 2021 dataset. Cross-entropy loss was used as the optimization criterion.

Performance Results

The proposed framework was benchmarked against 3 comparative approaches that used LLMs for AD detection from speech transcripts using the ADReSSo 2021 dataset.

We compared against 2 published methods, including Agbavor and Liang [35], who derived semantic representations using GPT-3 embeddings, and Bang et al [36], who combined GPT-4-based fluency assessments with transcript embeddings.

To assess output stability under the inherent stochasticity of LLM-based feature generation, we conducted 3 independent runs of the full pipeline using identical configurations and report the mean results, which are shown in Table 2. The mean F_1-score of 91.05% and mean specificity of 96.29% demonstrate consistent performance across runs. Importantly, the mean F_1-score exceeds that reported in Bang et al [36] (85.80%) by 5.25 percentage points, confirming that the framework maintains its advantage over existing methods even under stochastic variation.

Table . Performance comparison of different LLM[a]-based approaches for AD[b] detection.

Research	LLM	Approach	F_1-score%	Accuracy%	Precision%	Sensitivity%	Specificity%
Agbavor.and Liang (2022) [35]	GPT3	Semantic embeddings	—[c]	80.3	80.6	80.6	—
Bang et al (2024) [36]	GPT4	Fluency assessment + embeddings	85.80	85.92	86.94	85.92	94.44
Our proposed framework	GPT4	Multifeature embeddings + MLP[d]	91.05	91.08	91.52	91.08	96.29
Our proposed framework Llama 3 8B+nomic-embed (fully local)	Llama 3	Multifeature embeddings + MLP (fully local, no cloud API[e])	81.58	81.69	82.30	81.69	88.89

[a]LLM: large language model.

[b]AD: Alzheimer disease.

[c]Not applicable.

[d]MLP: multilayer perceptron.

[e]API: application programming interface.

To evaluate feasibility for privacy-sensitive clinical environments where cloud-based application programming interfaces may not be permissible, we tested a fully local configuration using Llama 3 (8B) [63] for feature extraction and nomic-embed-text [64] for embedding generation, requiring no cloud application programming interface access. This configuration achieved an F_1-score of 81.58% and a specificity of 88.89%, as shown in the last row in Table 2. The performance gap relative to the proposed framework's mean (9.47 pp=91.05% mean F_1-score) highlights the capability limitations of the fully local configuration, specifically the LLM and embedding model used, namely, Llama 3 (8B) and nomic-embed-text. Note that in the future, as more capable open-source LLMs and embedding models mature, the performance of fully local deployments is expected to improve substantially.

Compared to previous LLM-based methods, our framework demonstrates substantial improvements. The enhancement over Bang et al [36], which also uses GPT-4, is particularly notable, with improvements of approximately 5 percentage points in accuracy and F_1-score and 1.9 percentage points in specificity. This improvement can be attributed to our systematic integration of 4 distinct linguistic features (readability, fluency, richness of detail, and keyword relevance) and the combination of transcript and feature explanation embeddings.

The mean specificity (96.29%) achieved by our framework is particularly significant in clinical contexts, as it indicates strong capability to correctly identify non-AD cases, thereby reducing false positives in preliminary screening scenarios. This specificity exceeds Bang et al [36] (94.44%), highlighting the clinical utility of our structured multifeature approach for reducing unnecessary follow-up.

Ablation Study

To assess the contribution of individual components in our framework, we conducted comprehensive ablation experiments across 3 key aspects, namely the impact of individual features, the effect of embedding combinations, and the consequence of prompt design. All ablation experiments were conducted using a single fixed pipeline run to ensure that observed performance differences reflect the contribution of each component rather than run-to-run stochastic variation. The results are shown in Table 3.

XSL•FO
RenderX

Table . Ablation study results: Impact of individual linguistic features on model performance.

Configuration	F_1-score	Accuracy	Precision	Sensitivity	Specificity
Full model	91.52	91.55	92.07	91.55	97.22
Without readability	85.90	85.92	86.02	85.92	88.89
Without fluency	88.73	88.73	88.73	88.73	88.89
Without richness of detail	84.50	84.51	84.53	84.51	86.11
Without keyword relevance	78.3	78.87	81.87	78.87	94.44

Individual Feature Impact

The full model (F_1-score=91.52%) in Table 3 represents the result of the same fixed run used across all ablation conditions, providing a controlled baseline for comparing the effect of each component removal. We evaluated the importance of each linguistic feature by removing them one at a time, with the results shown in Table 3. Our findings show that all features contributed greatly to the model's performance, with keyword relevance being particularly crucial (dropping from 91.52% to 78.30% F_1-score when removed). The other features showed smaller yet still notable impacts: readability (F_1-score=85.90%), fluency (F_1-score=88.73%), and richness of detail (F_1-score=84.50%).

Embedding Combination Effect

Our approach uses both transcript and feature embeddings. We intend to investigate the impact of each embedding type separately. Our findings, shown in Table 4, reveal that the use of both text and feature embeddings significantly outperformed those using either type of embeddings alone. The full model achieved a 91.52% F_1-score, while using only text embeddings or feature embeddings yielded 77.44% and 57.70%, respectively. This demonstrates the complementary nature of these representations.

Table . Impact of different embedding configurations and prompt structures on model performance.

Configuration	F_1-score	Accuracy	Precision	Sensitivity	Specificity
Full model	91.52	91.55	92.07	91.55	97.22
Embedding configuration					
Text embedding only (1536 dim)	77.44	77.46	77.53	77.46	80.56
Feature embedding only (1536 dim)	57.70	57.75	57.74	57.75	61.11
Prompt structure					
Without few-shot examples	85.86	85.92	86.36	85.92	91.67
Without feature definitions	85.80	85.92	86.94	85.92	94.44
Without AD[a] relation descriptions	85.90	85.92	86.02	85.92	88.89

[a]AD: Alzheimer disease.

Prompt Design Impact

Our approach involves a structured prompt with several key elements. In this experiment, we analyzed performance changes after removing specific prompt components. The results, as detailed in Table 4, show that the full structured prompt template significantly enhanced performance (F_1-score 91.52%), while removing few-shot examples (85.86%), feature definitions (85.80%), or AD relation descriptions (85.90%) led to performance declines.

Discussion

Principal Findings

To assess the explainability of our structured prompt design, we conducted a pairwise comparison with Bang et al [36], which also provides diagnostic explanations for each transcript. Pairwise comparison is a well-established evaluation method in which 2 alternatives are directly compared based on specific criteria. The comparison focused on 54 cases where both methods correctly classified the samples, ensuring a fair assessment that isolates the evaluation of explanation quality. The feature explanations used in this comparison were drawn from a single randomly selected pipeline run, ensuring that the

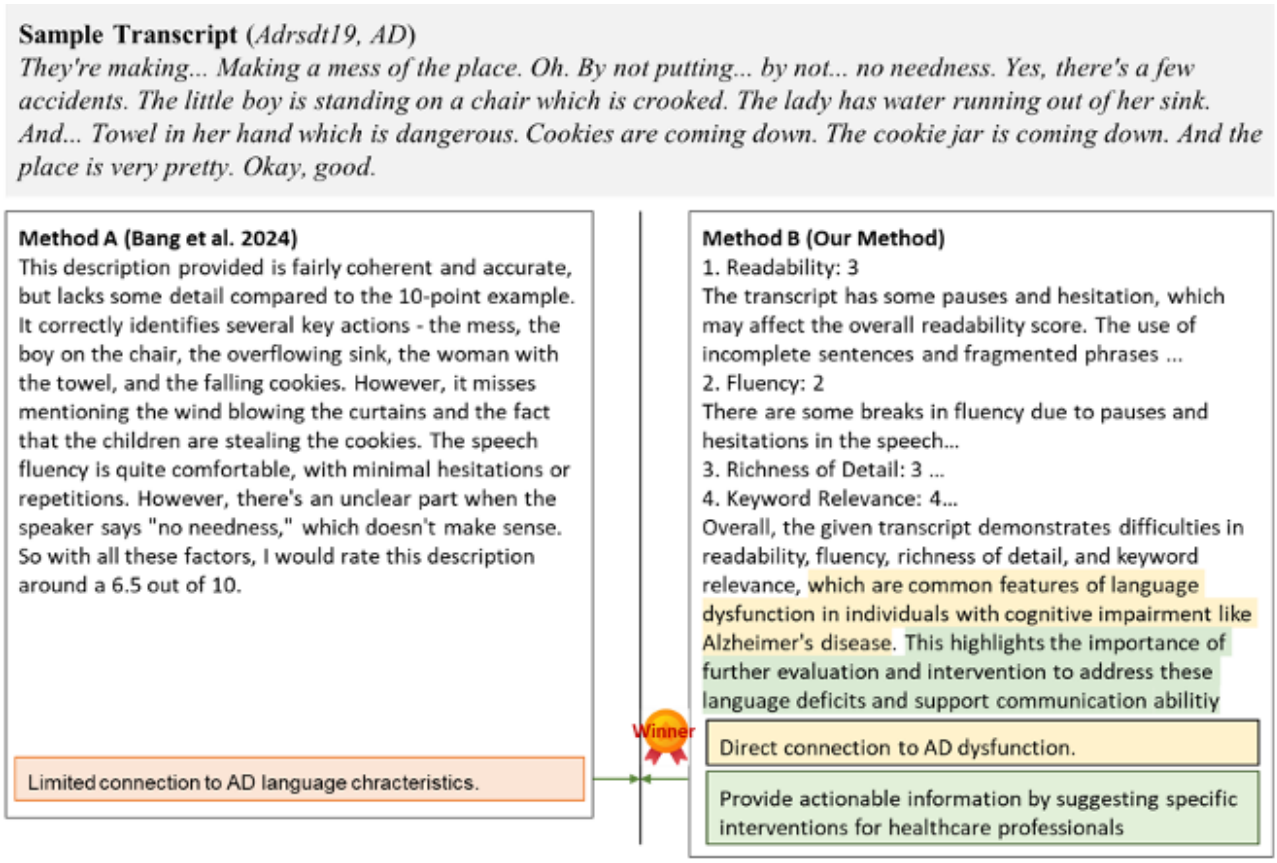
XSL•FO
RenderX

evaluation reflects a representative output rather than a curated best-case result.

We used Gemini-3.1-flash-lite [65] as an independent judge, instead of GPT-4 used in our method, to avoid self-preference, following recent natural language processing practices. This approach enables a cost-efficient, systematic, and consistent evaluation across multiple samples, making it particularly well-suited for comparing natural language explanations [66]. We evaluated the explanations using 5 key criteria derived from explainable AI literature [67-71], namely diagnostic connection, which assesses how well linguistic features are linked to AD diagnosis [67]; evidence support, which examines the concrete evidence provided from the transcript [68]; clinical insight, which evaluates the value of insights for clinical assessment [69]; feature coverage, which measures the comprehensiveness of linguistic feature analysis [70]; and actionable information, which assesses the usefulness for health care professionals [71].

Table 5 reports the numbers of wins for the method of Bang et al [36], wins for our method, and ties, as evaluated by Gemini-3.1-flash-lite. It shows that our method significantly outperformed the approach of Bang et al [36] across all criteria, with our method preferred in 49 out of 54 cases. The most notable difference appeared in feature coverage, where our approach received 52 out of 54 preferences. These results highlight the strength of our structured prompt design, which systematically addresses multiple linguistic dimensions (readability, fluency, richness of detail, and keyword relevance), providing a more comprehensive and clinically relevant explanation compared to fluency-focused approaches.

Table . Pairwise comparison results via Gemini-3.1-flash-lite.



Criteria	Wins for the method by Bang et al [36][a]	Wins for our method[a]	Ties
Diagnostic connection	3	31	20
Evidence supports	16	38	0
Clinical insight	9	45	0
Feature coverage	2	52	0
Actionable information	5	49	0
Overall winner	5	49	0
Confidence level			
High	9.26	90.74	0.00
Medium	0.00	0.00	0.00
Low	0.00	0.00	0.00

[a]Values represent counts out of 54 pairwise comparisons.

Figure 3 illustrates a representative case comparison between the 2 explanation methods. In this example, the method of Bang et al [36] provides a general assessment of fluency, lacking structured analysis or explicit links to AD symptomatology. By contrast, our method offers a systematic evaluation across multiple linguistic features, with numerical scoring and specific observations linked to language dysfunction in AD.

XSL•FO
RenderX

Figure 3. Comparison of explanation methods. AD: Alzheimer disease.

Human Expert Evaluation

To address potential concerns regarding LLM-based evaluation bias, we conducted an independent human evaluation involving 2 neurologists from Taiwan medical centers. The experts were presented with randomized explanations from both methods for the same 54 cases in a blinded fashion, without knowledge of which method generated each explanation.

Evaluator A assigned preference to our method in 53 (98.1%) cases and to the method of Bang et al [36] in 1 case, with no tied evaluations. Evaluator B assigned preference to our method in 36 (66.7%) cases and to the method of Bang et al [36] in 9 cases, with 9 tied evaluations. Combined results showed 89 total preferences for our method (53+36) versus 10 for the method of Bang et al [36] (1+9), with 9 ties. Such a difference between human annotators is not a surprise, as several research studies have demonstrated that human judgments are more diverse and variable [72-74]. Nevertheless, these results demonstrate strong interevaluator agreement favoring our structured multifeature approach, with Evaluator A showing near-unanimous preference and Evaluator B displaying greater variability while maintaining overall preference for our method.

The convergence between automated and human expert evaluations strengthens the validity of our explainability assessment and demonstrates that our structured multifeature approach provides substantially more interpretable and clinically relevant explanations for AD detection from speech.

Figure 3 illustrates a representative case comparison between the 2 explanation methods. In this example, the method of Bang et al [36] provides a general assessment of fluency, lacking structured analysis or explicit links to AD symptomatology. By contrast, our method offers a systematic evaluation across multiple linguistic features, with numerical scoring and specific observations linked to language dysfunction in AD.

Analysis of representative cases reveals that our structured approach explicitly connects linguistic observations to cognitive impairment patterns typical of AD. For example, in case “Adrsdt19,” our method identified specific language disruptions such as hesitations, repetitions, and fragmented expressions, directly linking these to potential cognitive decline. In contrast, the approach of Bang et al [36] often described language performance without establishing clear connections to AD-related impairments.

Note that LLM-based evaluation metrics should be interpreted with appropriate care; the convergence between Gemini-3.1-flash-lite and human expert assessments collectively strengthens the validity of our explainability findings.

To provide empirical support for feature selection, we conducted 2-tailed independent-samples *t* tests comparing LLM-derived feature scores between AD (n=122) and CN (n=115) groups (RStudio; Posit Software and R v4.5.0; R Foundation for Statistical Computing [75]). The feature scores were obtained from a single randomly selected pipeline run, consistent with the approach used for the pairwise explainability evaluation. As shown in Table 6, all 4 features showed highly significant group differences (all $P<.001$; df=235) with large effect sizes (Cohen *d* range: 1.11 - 1.19). The largest mean difference was observed for richness of detail (AD: 3.42 vs CN: 5.04; $\Delta=1.62$),

XSL•FO
RenderX

consistent with reduced informational specificity in AD speech. These findings independently validate the selection of the 4 features for the classification framework.

Table . *T*-test results comparing linguistic feature scores between Alzheimer disease (AD) and control normal (CN) groups.

Linguistic feature	AD[a] group, mean (SD)	AD, median (IQR)	CN[b] group, mean (SD)	CN, median (IQR)	*P* value
Readability	4.00 (1.47)	4 (3-5)	5.49 (1.12)	6 (5-6)	<.001[c]
Fluency	3.68 (1.37)	4 (2-5)	5.23 (1.24)	6 (5-6)	<.001[c]
Richness of detail	3.42 (1.48)	3 (2-4)	5.04 (1.44)	5 (4-6)	<.001[c]
Keyword relevance	3.84 (1.61)	4 (3-5)	5.54 (1.43)	6 (5-7)	<.001[c]

[a]AD: Alzheimer disease.

[b]CN: control normal.

[c]Degrees of freedom (df)=235.

We acknowledge that certain non-LLM state-of-the-art methods have reported higher diagnostic precision. For instance, Liu et al [76] achieved an accuracy of 97.18% and an F_1-score of 97.09% on the same dataset by using a Mozilla Deep Speech ASR and BERT-based pipeline. While such deep-learning models excel in raw performance, they often function as 'black boxes' with limited clinical interpretability. In contrast, our framework prioritizes explainable AI (XAI) by generating structured linguistic evidence across 4 dimensions. Our results demonstrate that while achieving an accuracy of 91.08%, the primary value of this work lies in providing transparent, actionable insights that are essential for clinical trust and diagnostic reasoning.

These findings suggest that our structured multifeature prompt design provides substantially more interpretable explanations for AD detection from speech. Enhanced explainability can improve clinical trust in AI-assisted diagnosis, potentially facilitating adoption in health care settings where transparency is essential. Furthermore, the detailed linguistic breakdowns generated by our method could support more targeted intervention strategies, enabling clinicians to focus on specific linguistic deficits observed in patients.

Conclusion

Our structured LLM-based framework, which leverages 4 key linguistic features (readability, fluency, richness of detail, and keyword relevance), achieved 92% precision and 97% specificity in detecting AD from speech transcripts. While further clinical validation is needed, this work demonstrates that well-structured linguistic analysis using LLMs can provide a reliable and explainable method for preliminary AD screening. Our framework offers an accessible tool for early detection of cognitive decline, potentially reducing barriers to timely diagnosis. The high performance and interpretable outputs of our model suggest promising directions for integrating AI-assisted cognitive assessment into clinical practice. Particularly in early screening stages, where accessible, noninvasive assessment tools are most valuable, our method could serve as an effective complement to traditional diagnostic approaches.

Despite presenting key innovations in AD detection through structured linguistic analysis, our study has several limitations. The ADReSSo 2021 dataset, while balanced, may not fully capture the linguistic variability found across the patient with AD population. Additionally, our method is currently designed for English-specific transcripts, requiring multilingual adaptation for broader clinical applicability. Although the ADReSSo 2021 dataset is demographically balanced with age and gender matched between groups, broader clinical deployment may require demographic-adjusted scoring baselines to account for variables such as education level, native language, and cultural background; this remains a direction for future work. Further studies are needed to assess how AI-based assessments align with real-world medical diagnoses and clinical outcomes. Furthermore, our reliance on transcript-based analysis introduces potential ASR errors, suggesting future work should incorporate direct audio processing techniques.

Despite these challenges, our findings demonstrate that structured LLM-based linguistic assessment provides a scalable, interpretable tool for early AD detection. This approach effectively bridges the gap between AI-based text analysis and real-world clinical applications, offering a step forward in leveraging AI for cognitive health monitoring.

Acknowledgments

During the preparation of this work, the authors used Claude AI and ChatGPT in order to improve the language and flow of the manuscript. After using this tool/service, the authors reviewed and edited the content as needed and take full responsibility for the content of the publication.

Abstract

Background: Timely hospital admission is a prerequisite for effective acute stroke management, yet a substantial proportion of patients fail to reach medical facilities within the optimal therapeutic window. Existing prediction models often lack temporal robustness and clinical interpretability, limiting their utility in real-world, evolving health care systems.

Objective: This study aimed to develop and temporally validate machine learning and deep learning models using multicenter clinical data to predict early hospital admission (≤24 h) after acute stroke.

Methods: In this multicenter retrospective study, we analyzed routinely collected electronic medical record data from 1327 patients across 6 hospitals in China. We developed and compared 6 predictive models: logistic regression, support vector machine, random forest, multilayer perceptron (MLP), convolutional neural network, and long short-term memory, for early admission (≤24 h from symptom onset). Model training was performed on a train set (2019-2022), followed by independent temporal validation on a testing set (2023-2025). Model prediction performance was evaluated using discrimination metrics, sensitivity, and robustness under temporal distribution shift. Model interpretability was assessed using Shapley additive explanations.

Results: A total of 1327 patients were included, of whom 821 were assigned to the train set and 506 to the independent temporal testing set. Among the 6 candidate models, the MLP showed the best overall performance in the independent temporal testing set, achieving an area under the receiver operating characteristic curve of 0.9020 (95% CI 0.8718-0.9283), sensitivity of 91.5%, specificity of 75.6%, and F_1-score of 0.9033. Formal statistical comparisons showed that the MLP achieved significantly higher area under the receiver operating characteristic curve values than logistic regression, support vector machine, random forest, and one-dimensional convolutional neural network after false discovery rate correction, with a smaller but still statistically significant

XSL•FO
RenderX

improvement over the long short-term memory. Calibration analysis further showed that the MLP had the most favorable overall calibration profile among the candidate models.

Conclusions: In this multicenter Chinese cohort, the MLP showed favorable temporal performance for predicting early hospital admission after stroke. The model may support future risk stratification and targeted public health interventions, although further external validation and calibration refinement are needed before deployment-oriented use.

KEYWORDS

stroke; early hospital admission; multilayer perceptron; temporal validation; prehospital delay; multicenter study

Introduction

Stroke remains a catastrophic global health emergency and a leading cause of mortality and long-term disability. In 2021, the global burden of stroke reached approximately 11.9 million incident cases and 7.3 million deaths, with China accounting for roughly one-third of this burden [1,2]. The management of acute stroke is highly time-dependent, as reflected in the well-established concept that “time is brain.” Timely hospital presentation is therefore essential for effective stroke care, particularly because the benefit of reperfusion therapy is greatest when treatment is initiated as early as possible, especially within the first 3 hours after symptom onset [3-5]. However, in this study, we used a 24-hour threshold as a pragmatic classification boundary to distinguish relatively early versus delayed hospital admission in this retrospective multicenter dataset, rather than to define the optimal therapeutic window. Delayed presentation may place patients beyond the period of greatest treatment benefit and is associated with worse neurological outcomes, higher mortality, and greater health care burden [6]. Therefore, identifying the determinants of earlier hospital admission remains important for improving emergency response systems and patient prognosis.

Despite the implementation of stroke code systems and improvements in emergency medical services (EMS), a substantial proportion of patients with stroke still do not reach the hospital within 24 hours of symptom onset. Traditional epidemiological studies have identified multiple barriers to early hospital admission, including older age, rural residence, lower socioeconomic status, and limited awareness of stroke symptoms [7-9]. In addition, organizational and health-system factors, such as EMS activation, prenotification routines, ambulance use, and regional stroke-care strategies, may also influence timely access to hospital-based stroke care [10]. However, these studies have primarily approached delay from a social and behavioral perspective, with less attention to the complex clinical and biological profiles of patients at presentation. Emerging evidence suggests that factors such as functional impairment, cognitive status, and comorbidity burden may themselves shape help-seeking behavior and transport urgency [11,12]. Yet conventional statistical approaches often have limited ability to integrate these high-dimensional and potentially interacting variables into a unified predictive framework. This gap raises an important question: can routinely collected electronic medical record data be leveraged not only for retrospective description, but also for prediction of early versus delayed hospital admission after stroke using data-driven modeling approaches?

To decode the complex interactions between patient demographics and physiological parameters, medical research is increasingly turning to artificial intelligence [13-15]. Machine learning (ML) algorithms, such as random forest (RF), have demonstrated superior performance over conventional regression methods in triage decision-making by handling nonlinear data more effectively [16,17]. However, as clinical data becomes more complex, traditional ML may reach a performance plateau. Deep learning (DL), particularly the multilayer Perceptron (MLP), offers a further leap in analytical capability by capturing intricate, high-level abstractions that traditional algorithms miss [18-20]. Although DL has shown strong performance in several medical prediction tasks, its use for classifying early versus delayed hospital admission after stroke remains less well studied. In addition, the interpretability of DL models remains a practical concern in clinical settings, which motivated our use of Shapley additive explanations (SHAP) to examine how individual predictors contributed to model output.

Given the importance of timely hospital presentation after stroke, this study aimed to develop and temporally validate predictive models for early hospital admission using multicenter clinical data from 6 hospitals in China. We systematically compared 6 algorithms, including conventional ML models (logistic regression [LR], support vector machine [SVM], and RF) and DL models (MLP, convolutional neural network [CNN], and long short-term memory [LSTM] network). We hypothesized that DL models, particularly the MLP, would achieve stronger discrimination than conventional ML baselines under temporal validation in the independent temporal testing set. To enhance the clinical relevance of model evaluation, we adopted a chronological validation strategy in which models were developed using data from 2019-2022 and then evaluated in an independent temporal testing set from 2023-2025. By identifying the most suitable modeling approach, this study sought to provide an interpretable, data-driven tool for identifying patients at risk of delayed hospital presentation after stroke.

Methods

Study Population and Design

This multicenter retrospective study was conducted using data from 1327 patients with stroke across 6 hospitals in China, spanning from January 2019 to March 2025. The inclusion criteria were: (1) clinically confirmed ischemic stroke or intracerebral hemorrhage based on computed tomography or

XSL•FO
RenderX

magnetic resonance imaging; (2) age ≥18 years; (3) admission to neurology or rehabilitation departments with stable medical status; and (4) documented time interval from symptom onset to hospital admission. Patients with subarachnoid hemorrhage were excluded because, although it is a hemorrhagic cerebrovascular event, it differs substantially from intracerebral hemorrhage in anatomical location, clinical presentation, pathophysiology, and acute management pathway. Patients were also excluded if stroke was not the primary reason for admission. The study protocol was approved by the Ethics Committee of the China Rehabilitation Research Center (approval number 2024-025-2). All records were de-identified before analysis, with direct personal identifiers removed prior to data integration and model development. Data transfer and use across participating centers were conducted in accordance with institutional approvals and applicable multicenter data-governance requirements.

To evaluate the temporal stability and model performance of the models against potential data drift, patients were partitioned chronologically:

1. Train set (n=821): Patients admitted between January 2019 and December 2022, used for feature selection, hyperparameter setting, and internal stratified 5-fold cross-validation. The train set was used exclusively for model development, and all candidate models were evaluated using the same cross-validation splits to ensure comparability across algorithms.
2. Independent temporal testing set (n=506): patients admitted between January 2023 and March 2025, reserved exclusively for final independent temporal validation and not used for feature selection, preprocessing parameter estimation, or model tuning.

Because this was a retrospective multicenter study based on consecutively collected real-world clinical records, no formal a priori sample size calculation was performed at the study design stage. In the train set, 821 patients were available for model development, and the final analytical pipeline retained 57 predictors. Based on the smaller outcome class in the train set (n=352), the corresponding events-per-variable ratio was approximately 6.18. We therefore interpret the present sample size as moderate rather than large for predictive modeling, particularly for flexible DL architectures, and we relied on independent temporal validation to provide an additional assessment of temporal performance under distribution shift.

Outcome Measures and Candidate Predictors

The primary outcome was early hospital admission, defined as presentation to the hospital within 24 hours of symptom onset. Symptom-onset time was extracted from the retrospective electronic medical record as the first symptom-onset time documented at admission. In routine clinical practice, this time was generally recorded based on patient or family report. Admission time was defined as the first documented hospital arrival time in the electronic medical record. The 24-hour threshold was selected as a pragmatic classification boundary to distinguish relatively early versus delayed hospital admission within this retrospective multicenter dataset. The interval between symptom onset and hospital arrival was then used to classify early hospital admission (≤24 h) versus delayed admission (>24 h).

A total of 120 candidate predictors were extracted from the electronic medical record system and organized into five clinical domains: (1) demographics, including age, sex, residence (urban or rural), marital status, number of children, stroke subtype, occupation, and lifestyle factors such as smoking and alcohol use; (2) medical history, including preexisting diseases and family history of stroke or vascular disease in first-degree relatives; (3) admission comorbidities, classified according to *ICD-11* (*International Classification of Diseases, 11th Revision*) and International Classification of Functioning, Disability and Health (ICF) frameworks, including cardiovascular and metabolic disorders (eg, hypertension and diabetes), neurological impairments (eg, dysphagia and cognitive impairment), and acute complications (eg, pulmonary infection); (4) admission functional scores, including the Holden Functional Ambulation Classification and modified Barthel index; and (5) laboratory data, including more than 30 continuous markers covering glycemic status, electrolytes, renal and liver function, inflammatory markers, and cardiac enzymes. Laboratory variables were standardized before model input to improve comparability across predictors.

Data Preprocessing and Feature Selection

An initial set of 120 candidate variables was extracted from the electronic medical record system. Variables with a missing rate >70% were excluded before model development; in total, 39 variables were removed on this basis. Among the retained variables, the overall proportion of missing data was 12.7%, and 43.5% of retained variables contained at least some missing values. For the primary analysis, missing values were imputed using *k*-nearest neighbors (KNN) imputation with k=5. The remaining variables were then preprocessed through encoding of categorical predictors and *z*-score standardization of continuous variables before model input. To avoid data leakage, within each fold of the stratified 5-fold cross-validation in the train set, missing-value imputation, normalization, and feature selection were fitted only within the fold-specific training subset and then applied to the corresponding validation subset.

To address high dimensionality and multicollinearity, feature selection was performed using least absolute shrinkage and selection operator (LASSO) regression with an L1 penalty. The optimal penalty parameter (λ) was determined by stratified 5-fold cross-validation within the development framework [21]. The final model retained 57 predictors with non-zero coefficients for subsequent model construction. To examine the robustness of feature selection, we additionally assessed selection stability across the cross-validation folds. The number of selected features showed moderate consistency across folds (mean 47.2, SD 9.4), and the mean pairwise Jaccard similarity of the fold-specific selected feature sets was 0.581 (SD 0.092), indicating moderate stability rather than arbitrary split-dependent selection. Several clinically relevant predictors, including cognitive impairment, diabetes, hypertension, and intracranial aneurysm, were selected consistently across folds.

After internal cross-validation, the final preprocessing pipeline, LASSO feature-selection procedure, and predictive models were

XSL•FO
RenderX

refitted using the entire train set only. The fitted pipeline was then applied once to the independent temporal testing set for final temporal validation.

Model Development and Internal Validation

To compare the predictive performance of conventional ML and DL approaches, we developed six candidate models: LR, SVM, RF, MLP, a 1D convolutional neural network (1D-CNN), and an LSTM network. All models were developed in the train set and evaluated using the same stratified 5-fold cross-validation splits. For the DL models, learning rate, batch size, and number of epochs were selected through pilot experiments within the train set, whereas conventional ML models were primarily implemented using prespecified or standard settings to provide strong and interpretable baselines. No formal early stopping procedure was used; instead, a fixed training schedule of 25 epochs was adopted for comparability across DL architectures.

LR: to establish a linear baseline, we implemented LR with L2 regularization using the liblinear solver. The model was fitted with class-weight adjustment to reduce the influence of class imbalance and a fixed random seed (random_state=42). Unless otherwise specified, the regularization strength was kept at the default setting (C=1.0), and the maximum number of iterations was 100 [22,23].

SVM: we implemented an SVM with a linear kernel to maintain a balance between model complexity and interpretability. Probability estimation was enabled through Platt scaling to support ROC-based evaluation. Class-weight adjustment and a fixed random seed (random_state=42) were applied, while the regularization parameter was kept at the default setting (C=1.0) [24-26].

RF: as an ensemble learning method based on bootstrap aggregation, RF was configured with 100 decision trees (n_estimators=100) and the Gini impurity criterion for node splitting. Other parameters were left at their library defaults, including max_depth=None, min_samples_split=2, and min_samples_leaf=1, with a fixed random seed (random_state=42) [27].

MLP: we designed a fully connected feed-forward neural network to capture nonlinear interactions among predictors. The final architecture consisted of an input layer followed by 2 hidden layers with 256 and 128 units, respectively, batch normalization, rectified linear unit activation, dropout, and a linear output layer. The model was trained using the Adam optimizer with a learning rate of 1×10^{-3}, batch size of 32, and 25 epochs. These settings were selected through pilot experiments within the train set based on convergence behavior, training stability, and predictive performance [28,29].

1D-CNN: we adapted a 1D-CNN for tabular input by treating the predictor vector as a one-dimensional sequence. The final architecture comprised 2 convolutional layers (Conv1d(1,32), kernel size=3, padding=1; and Conv1d(32,64), kernel size=3, padding=1), followed by adaptive global average pooling and dropout. The network was trained using the Adam optimizer with a learning rate of 1×10^{-3}, batch size of 32, and 25 epochs [30,31].

LSTM network: we included an LSTM model as an exploratory deep-learning comparator adapted to reshaped tabular input rather than as a genuine longitudinal sequence model. Input features were reshaped into a single-step format only to enable empirical comparison with an LSTM-based neural architecture; this design was not intended to model true temporal sequences. The architecture used a hidden dimension of 64 and 2 recurrent layers, followed by a fully connected layer with 128 units and dropout before the output layer. The model was trained using the Adam optimizer with a learning rate of 1×10^{-3}, batch size of 32, and 25 epochs [32].

Sensitivity Analyses

To assess the robustness of the preprocessing strategy, we conducted supplementary sensitivity analyses using alternative imputation methods, including KNN with k=3 and k=7, multiple imputation by chained equations (MICE), and mean imputation. Because the MLP showed the best overall predictive performance in the primary analysis, these additional imputation analyses were conducted using the MLP as the reference model. The results supported the use of KNN with k=5 as the primary strategy, as it provided the most favorable overall balance of discrimination and classification performance in the independent temporal testing cohort (Table S1 in Multimedia Appendix 1).

Model Evaluation and Validation

Model performance was comprehensively assessed using discrimination, calibration, and decision-analytic measures. Discrimination was evaluated by accuracy, precision, sensitivity (recall), specificity, F_1-score, and the area under the receiver operating characteristic curve (AUC-ROC). Calibration was assessed in the independent temporal testing set using the Brier score, calibration intercept, calibration slope, and calibration curves. To evaluate potential clinical utility beyond discrimination alone, decision curve analysis was performed by comparing each model with the treat-all and treat-none strategies across a range of threshold probabilities. In the primary analysis, binary classification metrics were calculated using the default probability threshold of 0.5 for all models. We additionally performed a threshold sensitivity analysis for the MLP model at representative probability cutoffs of 0.3, 0.4, 0.5, and 0.6.

To formally compare model performance, we conducted additional statistical analyses in the independent temporal testing set. The AUC of the MLP model was compared with that of each alternative model using the DeLong test. Paired classification errors at the primary operating threshold of 0.5 were compared using the McNemar test. For key performance metrics, including AUC, sensitivity, specificity, and F_1-score, 95% CIs were calculated. To account for multiple pairwise comparisons, P values were adjusted using the false discovery rate (FDR) procedure.

To enhance the interpretability of the optimal model, SHAP analysis was performed for the positive class, defined as early hospital admission (≤24 h). We used GradientExplainer for the

XSL•FO
RenderX

final MLP model, with the first 200 samples from the train set serving as the background dataset. SHAP values were computed on the final preprocessed model inputs; accordingly, feature values displayed in the SHAP beeswarm and dependence plots reflect the values used by the model after preprocessing rather than the raw variables recorded in the electronic medical records. For binary indicators such as dysphagia, the plotted values therefore represent the encoded model inputs used in the SHAP analysis, whereas continuous variables are shown on their standardized scale after *z*-score normalization. Global interpretation was summarized using SHAP beeswarm plots, and additional feature-specific dependence plots and representative local waterfall plots were used to examine the directional contribution of selected predictors at both the cohort and individual levels. To assess the robustness of the SHAP findings, we further repeated the analysis using alternative background samples, and the corresponding supplementary results are provided in Multimedia Appendix 1. All experiments were conducted with a fixed random seed of 42. The analyses were performed in Python 3.10 using PyTorch 1.13.1, scikit-learn 1.5.2, and SHAP 0.46.0. Model training was conducted on an NVIDIA GeForce RTX 4060 GPU. R software (R Foundation for Statistical Computing) was used for selected supplementary statistical analyses and figure preparation.

Ethical Considerations

This study was performed in accordance with the principles of the Declaration of Helsinki. The study protocol received ethical approval from the Ethics Committee of the China Rehabilitation Research Center (approval number 2024-025-2). Given the retrospective design of the study and the use of de-identified medical records, the requirement for informed consent was waived by the ethics committee. All records were anonymized before analysis, and data handling and transfer were conducted in accordance with institutional approvals and applicable multicenter data-governance requirements. No financial or material compensation was provided to participants for their involvement in this study. Participation was entirely voluntary, and all procedures were conducted following relevant ethical guidelines.

Results

Baseline Characteristics

Of the included patients, 52.4% (n=696) arrived at the hospital within 24 hours of symptom onset, whereas 47.6% (n=631) presented later than 24 hours. The comprehensive baseline characteristics, stratified by admission timing, are detailed in Table 1. Additional baseline variables and extended laboratory results are provided in Table S2 in Multimedia Appendix 1.

[a]Data are mean (SD), median (IQR), or n (%).

[b]*P* values are from chi-square test, Fisher exact test, Student *t* test, or Mann–Whitney *U* test, as appropriate.

Significant demographic differences were observed between the 2 cohorts. Patients in the early-arrival group (≤24 h) were significantly older (mean age: 66.03, SD 12.20 vs 59.66, SD 12.38 years; *P*<.001) and were more likely to be married (677/696, 97.27% vs 580/630, 92.06%; *P*<.001) and urban residents (569/686, 82.94% vs 303/412, 73.54%; *P*<.001). Social factors also played a role, as early arrivals had a higher proportion of used individuals and more children. Lifestyle factors showed a significant association with admission timing (*P*<.001). A substantial majority of early arrivals were either

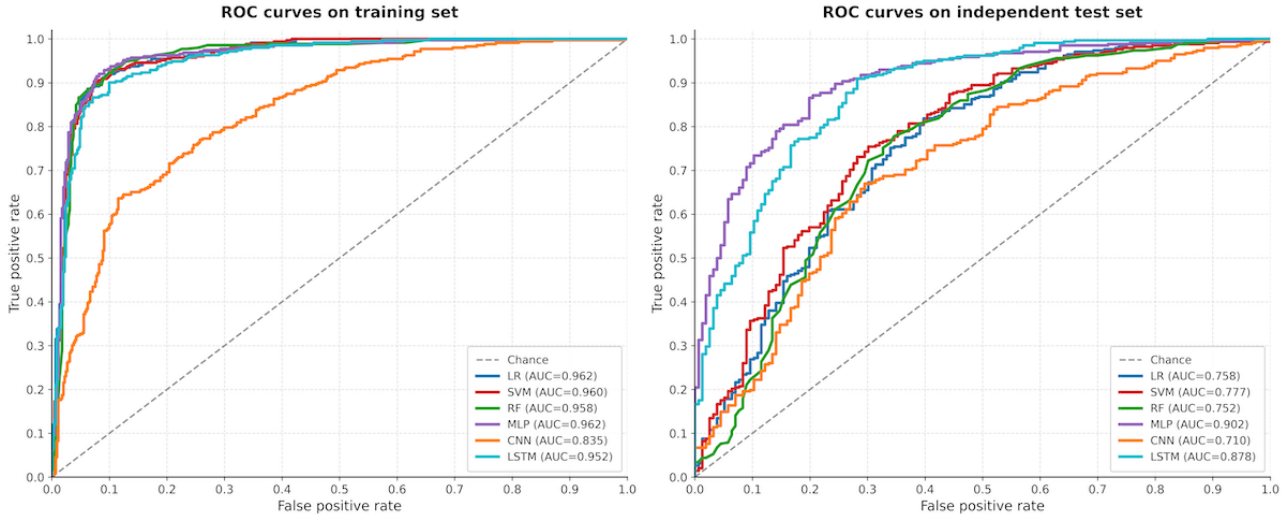
RenderX

current or former smokers (226/246, 91.87%) and drinkers (201/251, 80.08%), whereas over half of the late-arrival group reported never smoking (277/500, 55.40%) or never drinking (285/542, 52.58%).



Clinical presentations at onset significantly influenced the speed of hospital presentation. Ischemic stroke was almost universal in the early-arrival group (693/696, 99.57%) compared to the late group (468/631, 74.17%; *P*<.001). Patients with a personal medical history of atrial fibrillation, carotid stenosis, and cancer were significantly more likely to arrive within 24 hours. Patients with a family history of ischemic stroke, hypertension, or diabetes were more prevalent in the delayed-admission group (*P*<.001). Upon admission, the early-arrival group presented with higher rates of hypertension (494/696, 70.98%) and diabetes (295/696, 42.39%). In contrast, the late-arrival group exhibited significantly higher frequencies of cognitive impairment (228/631, 36.13% vs 113/696, 16.24%), sensory loss (141/631, 22.35% vs 91/696, 13.07%), and dysphagia (237/631, 37.56% vs 211/696, 30.32%), suggesting that functional and cognitive barriers may contribute to prehospital delays.

Physiological parameters at admission further differentiated the groups. The early-arrival group presented with significantly higher blood pressure (Systolic: 141.94 vs 136.16 mm Hg; Diastolic: 84.17 vs 82.04 mm Hg; *P*<.001) and elevated lactate dehydrogenase (LD) levels (224.02 vs 191.56 U/L; *P*<.001). Laboratory tests revealed that late arrivals had significantly higher levels of uric acid (UA: 309.22 vs 276.72 umol/L; *P*<.001) and lower albumin (ALB: 38.62 vs 40.35 g/L; *P*=.01). Furthermore, the respiratory rate was higher in the late-arrival group (18.64 vs 18.09 bpm; *P*<.001).

Model Performance and Comparative Analysis

Across the 6 candidate models, DL approaches generally showed better performance than the conventional ML models in the independent temporal testing set (Table 2; Figure 1). Among all models, the MLP achieved the highest overall performance, with an AUC of 0.9020 (95% CI 0.8718-0.9283), sensitivity of 0.9152, specificity of 0.7564, and F_1-score of 0.9033 in the independent temporal testing set. The LSTM network also showed relatively strong discrimination (AUC 0.8778), whereas the 1D-CNN showed lower overall performance (AUC 0.7105). LR, SVM, and RF demonstrated lower performance in the independent temporal testing set, with AUC values of 0.7576, 0.7769, and 0.7523, respectively.

Figure 1. Receiver operating characteristic (ROC) curves of the six predictive models for early hospital admission. [a]AUC: area under the receiver operating characteristic curve.

[b]MLP: multilayer perceptron.

[c]Italicized values indicate the best performance among the compared models for each metric.

[d]LSTM: long short-term memory.

[e]CNN: convolutional neural network.

[f]RF: random forest.

[g]SVM: support vector machine.

[h]LR: logistic regression.

Formal statistical comparisons supported the superior discrimination of the MLP model. Compared with the alternative models, the MLP achieved significantly higher AUC values than LR (ΔAUC=0.1444; FDR-adjusted P<.001), SVM (ΔAUC=0.1251; FDR-adjusted P<.001), RF (ΔAUC=0.1497; FDR-adjusted P<.001), and 1D-CNN (ΔAUC=0.1916; FDR-adjusted P<.001). The improvement over the LSTM was smaller but remained statistically significant (ΔAUC=0.0243; FDR-adjusted P=.03). At the primary operating threshold of 0.5, McNemar tests showed that the MLP made significantly fewer classification errors than LR, SVM, RF, and 1D-CNN after multiple-comparison correction, whereas the difference between the MLP and LSTM was not statistically significant (FDR-adjusted P=.65).

From a clinical perspective, sensitivity is particularly important for identifying patients at risk of delayed hospital presentation. In this regard, the MLP maintained a sensitivity of 91.52% in the independent temporal testing set, markedly higher than that of LR and SVM. In a supplementary comparison, the LASSO-selected model achieved slightly higher discrimination and markedly better sensitivity than the full-feature model in the independent temporal testing set (AUC 0.9020 vs 0.8894; sensitivity 0.9152 vs 0.8452), while using fewer predictors, supporting the parsimony of the final modeling strategy (Table S3 in Multimedia Appendix 1). Detailed CIs and pairwise DeLong and McNemar comparisons are provided in Tables S4-S6 in Multimedia Appendix 1.

Calibration and Clinical Utility Analysis

We further evaluated model calibration and clinical utility in the independent temporal testing set. Among the 6 candidate models, the MLP showed the most favorable calibration profile, with the lowest Brier score (0.1153) and a calibration curve closest to the ideal reference line (Table 3; Figure 2). However, calibration showed some room for improvement: the calibration intercept was 0.279, and the calibration slope was 0.600, suggesting mild overall risk underestimation and some deviation from ideal probability calibration.

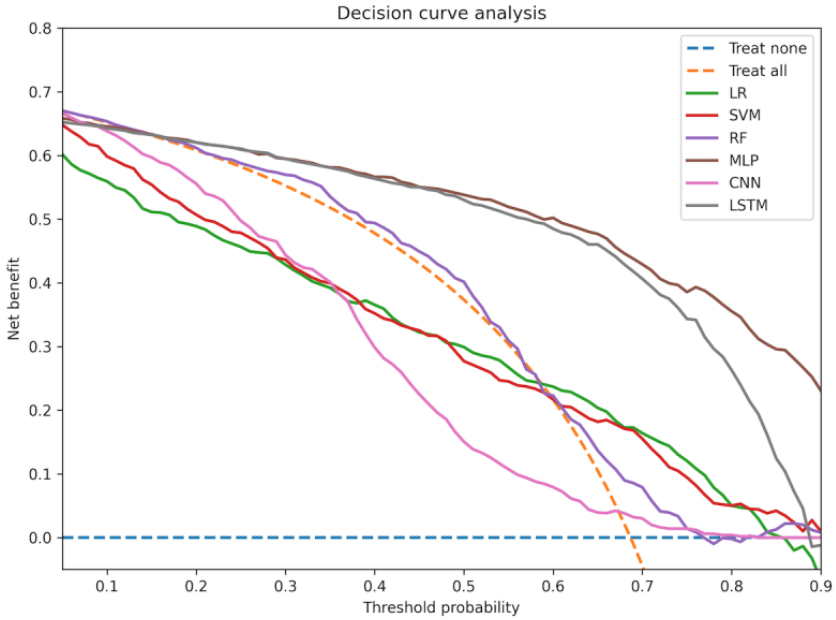

Figure 2. Calibration curves of the six predictive models in the independent temporal testing set CNN: convolutional neural network; LR: logistic regression; LSTM: long short-term memory; MLP: multilayer perceptron; RF: random forest; SVM: support vector machine.

Decision curve analysis showed that the MLP generally provided greater net benefit than the alternative models across a range of clinically relevant threshold probabilities, supporting its potential clinical utility beyond conventional discrimination metrics (Figure 3). In the primary analysis, a default threshold of 0.5 was used for binary classification. Additional threshold sensitivity analyses showed that the MLP maintained a favorable balance between sensitivity and specificity across representative cutoffs of 0.3, 0.4, 0.5, and 0.6, with the threshold of 0.5 providing the most balanced overall operating point in the independent Temporal Testing Set (Figure S1 and Table S7 in Multimedia Appendix 1).

Interpretability and Temporal Stability of Feature Contributions

To improve the interpretability of the MLP model and assess the temporal stability of feature contributions, we performed SHAP analysis in both the train set and the independent temporal testing set (Figure 4). In the train set, the model was influenced by a combination of demographic, clinical, and complication-related features. Smoking, stroke type, age, liver dysfunction, and admission hypertension ranked among the most important contributors, whereas family history of hypertension, speech disorder, sex, occupation category, and number of children also contributed to the model output. These findings indicate that, during model development, prediction reflected not only acute clinical status but also broader demographic and contextual characteristics. Because SHAP analysis was based on the final preprocessed model inputs, the feature values shown in the SHAP plots should be interpreted on the model-input scale rather than as raw variable values recorded in the medical records.

Figure 4. Shapley additive explanations beeswarm plots for the multilayer perceptron model in the train set and the independent temporal testing set. (A) Train set (2019-2022); (B) independent temporal testing set (2023-2025). Each point represents an individual patient, with color indicating the feature value (red for high, blue for low) and position on the x-axis representing the contribution of that feature to the predicted probability of early hospital admission (≤24 h). Feature values shown in the beeswarm plots represent preprocessed model inputs rather than raw variable coding; continuous variables are displayed on their standardized scale after z-score normalization, and binary variables such as dysphagia are shown according to the encoded values used in the final model input. MLP: multilayer perceptron; SHAP: Shapley additive explanations.

In the independent temporal testing set, the SHAP pattern shifted toward more overt acute clinical features. Admission hypertension and diabetes emerged as the leading predictors, followed by history of hypertension, stroke type, cognitive impairment, smoking, dysphagia, history of diabetes, occupation category, and respiratory rate. Dysphagia remained among the top predictors, and the feature-specific SHAP dependence plot showed that higher dysphagia values, corresponding to the presence of dysphagia after preprocessing, were predominantly associated with negative SHAP values for the positive class, indicating a lower predicted probability of early hospital admission. This pattern was consistent with the baseline

XSL•FO
RenderX

descriptive analysis, in which dysphagia was more frequent among patients with delayed admission. At the same time, local SHAP values showed that the contribution of dysphagia was not uniform across all individuals, indicating that its effect should be interpreted within the broader nonlinear multivariable structure of the model rather than as an isolated deterministic signal. Overall, although the relative ranking of predictors changed from the train set to the independent temporal testing set, the model retained clinically coherent feature contributions over time. The dysphagia dependence plot, representative local waterfall plots, and background-sensitivity analyses are presented in Figure S2, Figure S3, and Table S8 in Multimedia Appendix 1.

Subgroup Performance, Feature Drift, and Error Analysis Under Temporal Validation

Additional analyses were conducted in the independent temporal testing set to further characterize temporal performance patterns of the MLP, including subgroup performance analysis, feature-drift assessment, and prediction-error analysis. Subgroup analysis showed that the MLP maintained generally strong discrimination across major demographic and clinical strata. The AUC was 0.903 in patients aged ≤65 years and 0.883 in those aged >65 years, and was 0.905 in male patients and 0.895 in female patients. Performance was also favorable in clinically relevant subgroups, including patients with dysphagia (AUC 0.944; sensitivity 0.955), admission hypertension (AUC 0.919; sensitivity 0.942), and admission diabetes (AUC 0.902; sensitivity 0.972), although these subgroup results should be interpreted cautiously because some strata were relatively small.

Feature-drift analysis showed that the temporal shift between the train set and the independent Temporal Testing Set was selective rather than global. After false discovery rate correction, the most notable changes involved several physiological and complication-related variables, including CKMB (standardized mean difference [SMD] = −0.463), admission hypertension (prevalence difference = +0.124), respiratory rate (SMD = +0.110), liver dysfunction (prevalence difference = −0.053), and family history of hypertension (prevalence difference = −0.034). These findings indicate that temporal change was concentrated in specific clinical domains rather than reflecting a complete restructuring of the predictor space.

Prediction-error analysis further showed that residual misclassification was clinically patterned. Among patients with true early admission, false-negative cases were less likely than true-positive cases to present with admission hypertension (45.5% vs 79%) or diabetes (12.1% vs 45%), and they had higher uric acid levels (median 312, IQR 271-389 vs 255, IQR 198-313). Among delayed-admission cases, false-positive predictions differed most clearly from true-negative cases in stroke type, whereas other differences were smaller and less consistent after multiple-comparison correction. Detailed subgroup, drift, and error-analysis results are provided in Tables S9-S11 in Multimedia Appendix 1.

Discussion

Principal Findings

This multicenter retrospective study developed and temporally validated a prediction framework for early hospital admission after acute stroke using routinely collected clinical data from 6 hospitals in China. Within this multicenter Chinese cohort, the MLP showed the most favorable overall performance in the independent temporal testing set. Additional analyses of calibration, SHAP-based interpretation, and temporal degradation patterns provided further insight into the strengths and remaining limitations of the model.

Our findings delineate distinct phenotypic profiles between early presenters and patients with delayed admission. Individuals arriving within the therapeutic window were generally older and more likely to reside in urban areas. This observation is consistent with national registry evidence indicating that older adults often benefit from established health care networks and heightened vigilance related to multimorbidity, whereas younger populations and rural residents encounter structural barriers and lower stroke literacy, resulting in prolonged onset-to-door times [33,34]. The pronounced urban-rural disparity underscores persistent inequities in EMS accessibility and the uneven coverage of “Stroke Map” networks, with transport logistics remaining a critical bottleneck in rural regions [35,36]. Clinically, the higher prevalence of cognitive impairment and sensory deficits among delayed presenters supports the “symptom imperceptibility” hypothesis, whereby anosognosia or nonmotor manifestations attenuate symptom recognition and postpone EMS activation [37].

This study showed the most favorable overall performance of the MLP in predicting early hospitalization risk. Its optimal performance on the independent temporal testing set was consistent with our study hypothesis that DL excels at capturing complex nonlinear interactions among clinical variables. In sharp contrast to traditional linear models, which exhibited a marked decline in temporal validation performance and a substantial decline in sensitivity during temporal extrapolation, the MLP demonstrated robust generalization capabilities [38,39]. Furthermore, due to its global feature processing mechanism, the MLP outperformed the CNN in handling nonspatial tabular data. Critically, the MLP maintained a high sensitivity of 91% in the testing cohort, establishing its suitability as a prehospital screening tool where the prioritization of low false-negative rates is essential to ensure high-risk patients are not overlooked. Combined with the interpretability support provided by SHAP analysis, these findings indicate that the proposed architecture possesses potential clinical utility. Additional temporal analyses suggested that the relative robustness of the MLP was associated with selective rather than global temporal drift. The model maintained strong performance in clinically relevant subgroups, particularly among patients with dysphagia, admission hypertension, and admission diabetes. This pattern is broadly consistent with previous evidence showing that more severe or more readily recognizable stroke presentations are associated with earlier hospital arrival, whereas atypical presentations may be more vulnerable to delayed recognition [40,41]. Residual

XSL•FO
RenderX

errors were also clinically patterned rather than random: false-negative early-admission cases were less likely to exhibit overt physiological warning signs, whereas some false-positive delayed-admission cases shared characteristics with early presenters.

SHAP analysis further contextualized these findings by revealing temporally evolving yet clinically coherent feature contributions. In the train set, model predictions were influenced not only by clinical impairments but also by system-level and social-contextual factors. Hospital-level and family-related variables, for example, underscored the potential roles of health care accessibility and social support in shaping early help-seeking behavior [42]. Dysphagia also remained an important predictor across analyses. In the independent temporal testing set, higher dysphagia values were generally associated with a lower predicted probability of early hospital admission. However, this effect was not strictly uniform at the individual level, indicating that the contribution of dysphagia should be interpreted within the broader nonlinear multivariable structure of the model rather than as an isolated deterministic signal. This finding may reflect delayed recognition of atypical or posterior-circulation-related stroke presentations in some patients, because posterior circulation strokes may present with less typical prehospital symptom patterns and may therefore be more vulnerable to delayed identification and hospital presentation [43,44]. However, this interpretation should be considered cautiously and warrants further confirmation with richer clinical and imaging data. Meanwhile, the model's reliance on the independent temporal testing set shifted toward more overt physiological abnormalities, with admission hypertension and diabetes emerging as dominant predictors of early presentation. This pattern suggests that acute, measurable physiological derangements may function as immediate triggers for EMS activation [45]. The persistence of dysphagia and stroke type across both periods further supports the clinical stability of these predictors and reinforces the temporal robustness of the model.

The integration of an MLP-based framework into prehospital stroke systems may support more targeted risk stratification for patients at risk of delayed presentation. Because all predictors were derived from routinely available electronic medical record data, the model may be scalable in digitally enabled clinical settings. Beyond binary classification, the framework also provides a more granular risk profile of patients vulnerable to prehospital delay. Through SHAP-based interpretation, predictors such as dysphagia and other clinical or contextual factors may help identify patient groups who are less likely to present promptly after stroke onset. These insights could inform more targeted public health strategies, rather than relying solely on broad, non-specific stroke awareness campaigns, and may be relevant for improving resource allocation in high-risk populations. At the same time, although the MLP demonstrated the best overall calibration profile among the candidate models, calibration was not fully optimal, and recalibration may be necessary before implementation in deployment-oriented settings. In addition, although the MLP showed favorable performance under temporal validation, this study does not constitute true geographic external validation because all participating hospitals were located within the same national health care system. Further validation across independent institutions, regions, and health care settings will therefore be necessary before broader implementation can be considered.

Several limitations should be acknowledged. First, the retrospective design of this study precludes the complete elimination of information bias. In addition, we did not formally evaluate the underlying missing-data mechanism (eg, missing completely at random, missing at random, or missing not at random), and some residual bias related to missingness cannot be excluded. The accuracy of symptom-onset time also depended on retrospectively documented medical records and was typically based on patient or caregiver recall at admission, which may have introduced imprecision in the onset-to-admission interval, particularly in wake-up strokes or in individuals with cognitive impairment. Second, the current model was developed exclusively using structured electronic medical record data. Although this enhances feasibility for routine clinical implementation, the absence of imaging-derived variables limits the model's ability to directly capture lesion location and radiological severity, including clinically important patterns such as posterior circulation involvement. This limitation may partly explain why some clinical proxies, such as dysphagia, emerged as influential predictors. Third, despite the use of SHAP to improve interpretability, neural networks still retain residual "black-box" characteristics, and the high-dimensional feature interactions learned by the MLP may not be fully transparent to clinicians. Although the use of an independent temporal testing cohort helped mitigate concerns regarding optimistic bias, we did not implement a formal nested cross-validation framework. In addition, while the present sample size was sufficient to support model development and independent temporal validation, larger prospective multicenter datasets are still needed for further refinement and validation of DL models. Future research should therefore prioritize prospective external validation, multimodal data integration, including imaging and prehospital process metrics, and the development of clinician-centered explanation interfaces to improve interpretability and clinical acceptability.

Conclusions

In this multicenter retrospective study, the MLP showed favorable temporal performance for predicting early hospital admission (≤24 h) after acute stroke within a multicenter Chinese cohort. SHAP-based interpretation suggested that dysphagia, admission hypertension, diabetes, and stroke type were important contributors to model predictions. These findings may support future risk stratification and more targeted public health interventions, although external validation, recalibration, and further prospective evaluation remain necessary before deployment-oriented application.

Acknowledgments

We gratefully acknowledge the contributions of the 6 collaborating hospitals in this multicenter study: China Rehabilitation Research Center (Beijing Bo'ai Hospital); Affiliated Rehabilitation Hospital of the National Research Center for Rehabilitation Technical Aids; Qilu Hospital of Shandong University; Shengli Oilfield Central Hospital; Qilu Hospital of Shandong University Dezhou Hospital; and People's Hospital of Rehabilitation Weifang City. We sincerely thank the clinicians, rehabilitation therapists, research staff, and all participants with stroke for their invaluable support, commitment to patient care, and assistance with data collection and management. Their contributions made this study possible.

Data Availability

The datasets analyzed during this study are not publicly available due to patient privacy and hospital regulations, but are available from the corresponding author on reasonable request. The code used for data preprocessing, model development, validation, and Shapley additive explanations (SHAP) analysis is publicly available in the GitHub repository [46].

Funding

This work was supported by the National Natural Science Foundation of China (NSFC, General Program, number 82371348) and the Chinese Academy of Medical Sciences Initiative for Innovative Medicine (CIFMS, Grant number 2022-I2M-1-019). The funding agencies had no role in study design, data collection, data management, statistical analysis, data interpretation, or in the writing, revision, or approval of the manuscript.

Abstract

Background: Primary care is becoming increasingly complex, with primary care physicians (PCPs) facing rising workloads driven by workforce shortages, growing administrative demands, and expanding clinical responsibilities. Recent advances in large language models (LLMs) offer new opportunities to support PCPs across clinical, administrative, and communication-related tasks within their workflows. Understanding how these technologies are perceived and used in primary care practice is, therefore, critical to inform their safe, effective, and human-centered implementation.

Objective: This study aimed to explore Dutch and US PCPs' perceptions and experiences regarding the use of LLMs in clinical practice, with particular attention to clinical usability, communication and teamwork, and implications for everyday workflows.

Methods: We conducted a qualitative study using semistructured interviews with 15 PCPs from the United States and the Netherlands. Data were collected between February and June 2025 and analyzed using reflexive inductive thematic analysis.

Results: Ten themes emerged related to the use of LLMs in primary care clinical practice, each theme consisting of a set of subthemes. We found that LLMs are being integrated into primary care as both clinical and communication support tools, assisting with diagnostic reasoning, administrative tasks, workload management, and interprofessional and patient communication. While PCPs reported perceived benefits, they also expressed concerns related to safety, efficiency, authenticity, and the preservation of the therapeutic relationship, highlighting the need for careful and context-sensitive use.

Conclusions: Our findings suggest that LLMs are already being integrated into primary care in diverse ways, with their value shaped by both contextual factors and clinician judgment. Understanding how clinicians navigate LLM use in everyday practice is essential to ensuring that LLMs support high-quality, patient-centered primary care and inform organizational policy and LLM design.

(JMIR Med Inform 2026;14:e91652) doi:10.2196/91652

KEYWORDS

LLM; large language model; primary care; communication; teamwork; diagnostic assistance

Introduction

Primary care physicians (PCPs), also referred to as family doctors or general practitioners (GPs), are the cornerstone of the health care system, serving as the initial point of access for patients and facilitating comprehensive care throughout the care process. They manage a broad spectrum of health needs and focus on prevention, diagnosis, and treatment of common conditions, while also dealing with a wide range of other responsibilities, including administrative documentation, quality reporting, and diagnostic research [1]. PCPs also play a central role in coordinating care across disciplines. Effective teamwork with nurses, specialists, and other professionals is crucial in the

XSL•FO
RenderX

diagnostic process and ensures smooth care transitions, shared decision-making, and safe information flow [2]. Simultaneously, strong communication and shared decision-making with patients are at the core of primary care, depending on trust, empathy, and mutual understanding.

Primary care systems across the United States and Europe are facing a common challenge of increasing care complexity, administrative burden, and workforce shortages, placing a growing strain on frontline physicians [3,4]. Within Europe, the Netherlands is frequently considered a leading example of a strong, gatekeeping primary care system with high levels of digital maturity, making it a relevant comparator to the United States despite differences in health care organization [5,6]. While the United States operates within a more fragmented, performance-based system and European systems tend to be more coordinated and welfare-based, physicians in both contexts encounter similar pressures related to workload, time constraints, and managing complex patient needs [7]. Increased workload is associated with job stress, burnout, and early retirement among physicians, patterns that are increasingly documented in global primary care research [3,8].

In 2022, OpenAI introduced ChatGPT, a publicly available and scientifically informed tool that demonstrated remarkable capabilities in areas such as decision-making, diagnosis, symptom assessment, and triage [9]. Despite its strong performance, ChatGPT is trained on broad, general data and lacks the domain-specific knowledge required for medical accuracy [10]. Since then, numerous large language model (LLM)–based tools have emerged for primary care. While these models can generate coherent text, pass professional examinations, and sometimes outperform humans, they also raise concerns about hallucination, privacy, security, and bias [10,11]. Many LLMs are publicly available, including ChatGPT (OpenAI), Gemini (Google), Phi-3 (Microsoft), OpenEvidence, and Perplexity, which have not been officially authorized for clinical use in practice. Despite that, a study among GPs in the United Kingdom found that a significant proportion (20%) use these tools in their practice [12].

For the successful and effective implementation of innovative technologies, it is essential to establish user trust and usability by engaging and understanding end users during human-computer interactions [13]. The use of LLMs could potentially be beneficial for primary care doctors by supporting process efficiency, quality of care, and clinical decision-making, but if not carefully managed, it may be a significant burden to the already overdemanded physicians and could lead to unsafe practice [14,15]. It is essential to address the challenges and limitations of LLMs and create awareness among doctors to prevent overreliance and medical errors [10].

In digitally advanced health care environments, both the United States and countries such as the Netherlands are increasingly exposed to emerging technologies, including LLMs. While there has been research on the potential applications and limitations that may affect usability in primary care and clinical practice [11,16], limited attention has been given to how PCPs perceive and experience their use in everyday practice, particularly across different health care contexts. To address this gap, this study explores PCPs' perceptions and experiences with LLMs in the United States and the Netherlands, focusing on clinical usability, communication and teamwork, and integration into routine workflows. By examining these perspectives across 2 distinct yet comparable Western health care systems, this study aims to generate insights that can inform the responsible and effective integration of LLMs in primary care and support shared learning across settings facing similar challenges.

Methods

Ethical Considerations

This study was reviewed and approved by the institutional review board (IRB) of Stevens Institute of Technology (IRB ID 2024-070 (N)). Participants were informed of their right to withdraw at any time without consequence, and oral informed consent was obtained prior to the commencement of each interview. They received a modest incentive for their time, which was not contingent on completion of the interview. All data were anonymized and stored securely to protect participants' confidentiality.

Research Design and Participants

This study used a qualitative research design using interviews to explore participants' experiences, perspectives, and practices related to the use of LLM tools in primary care, and followed the COREQ (Consolidated Criteria for Reporting Qualitative Research) guidelines for qualitative research (Multimedia Appendix 1) [17]. A qualitative approach was chosen to allow for in-depth exploration of complex and context-dependent phenomena and to capture the nuanced views of participants in their own words [18]. Participants were recruited through purposive sampling to ensure that they had relevant experience and insight into the topic under investigation and were informed by maximum variation principles to capture perspectives across 2 comparable yet structurally distinct primary care systems and practices [19]. We also used snowball sampling, which occurred when participating PCPs shared the study invitation with colleagues within their professional networks. Inclusion criteria required participants to be a PCP (MD), either in the United States or the Netherlands, be fluent in English, and have experience with an LLM tool in their practice. Most PCPs from the United States were recruited through the research team's personal network and subsequent referrals. One PCP from the United States was approached independently through LinkedIn. All Dutch PCPs were recruited through national GP associations ("Arts en Zorg" and "Landelijke Huisartsen Vereniging") and subsequently through referrals. Every PCP was approached and given information about the interview through email. During the interviews, participants described working in a variety of practice contexts and settings (urban or rural and individual practice or large organization). However, organizational size and rural or urban classifications were not systematically collected or formally assessed as part of the study. Informed consent was obtained prior to data collection. An incentive of a US $30 gift card (€30 [US $34.80] gift card for Dutch participants) was provided for each participant after interview completion.

XSL•FO
RenderX

Data Collection

Semistructured interviews were conducted by the lead author (IS). No prior relationship was established with participants, although the research advisor was acquainted with some. Participants were informed about the researcher's role, research aims, and broader PhD topic. The interviewer has an interest in LLMs, holding a generally positive view while acknowledging associated risks, and a broader research focus on teamwork and communication in primary care. Data were collected via Zoom (Zoom Communications, Inc), a widely used videoconferencing platform that supports audio communication and automated transcription. The data collection took place from February to June 2025. An interview guide (Multimedia Appendix 2) was used to ensure consistency across interviews while allowing flexibility to follow up on relevant themes that emerged during the conversation and was pilot-tested with 1 physician. The questions covered demographic information and questions regarding the research aim. Demographics, such as years of experience as a PCP, were self-reported by participants during the interviews and therefore reflect perceived professional experience rather than verified employment records. Similarly, other demographic and background characteristics, including gender, nationality, affinity with IT, and tools used in practice, were collected through self-report during the interviews rather than through a separate structured survey instrument. Participants were given the opportunity to provide additional input at the end of the interviews. All interviews were audio-recorded via Zoom with participants' consent. Video was not recorded, as IRB approval permitted the collection of audio data only and did not allow for analysis of nonverbal communication. Interview sessions lasted approximately 30-45 minutes. The audio recordings were automatically transcribed using Zoom's built-in transcription feature. Subsequently, all interview transcripts were manually reviewed for accuracy by listening to the audio recordings and verifying the corresponding textual data. Transcripts were anonymized and were not returned to participants for review.

Thematical Analysis

Interview transcripts were analyzed using reflexive thematic analysis, following an inductive, data-driven approach described by Virginia Braun and Victoria Clarke [18,20], covering the 6 steps of data familiarization, generation of initial codes, searching for themes, reviewing themes, defining and naming themes, and producing the final report. The analysis aimed to provide a rich thematic description of the dataset, appropriate for an underexplored area, capturing patterns of meanings across participants' experiences with LLM use in clinical practice. The study was conducted within a realist (essentialist) epistemological framework, assuming that participants' accounts reflect their experiences and perspectives in a direct and meaningful way. Coding was conducted manually in a Microsoft Excel spreadsheet, and themes were identified and defined as patterns of shared meaning across codes relevant to the research questions and were reviewed to ensure that they accurately represented the dataset. Themes were identified at a semantic level, focusing on the explicit content of participants' accounts, without extending into deeper latent interpretation. We coded as many interviews as were needed to reach data saturation [20]. Data saturation was assessed iteratively during data collection and analysis and was considered achieved when no new codes or themes emerged from successive interviews and when additional data did not contribute further to the development or refinement of existing thematic structure (N=15) [21]. All initial analyses were conducted by the lead author (IS). To enhance the rigor of the analysis, the lead author developed an initial codebook using affinity diagramming, engaged in regular reflexive discussions with an experienced advisor (OA) and practicing PCP (HB), and code checking with 2 assisting bachelor students (BG and AK), who are acknowledged for their contributions. Themes were presented with supporting participant quotations to ensure consistency between data and findings, with both major and minor themes clearly reported.

Results

Participant Characteristics

On average, the interviews lasted 32 minutes and 9 seconds, with the shortest interview lasting approximately 18 minutes and the longest interview approximately 47 minutes. Our sample comprised 15 PCPs, including 8 (53.3%) from the Netherlands and 7 (46.7%) from the United States. PCPs used a mix of publicly accessible LLMs (eg, ChatGPT, Perplexity, and OpenEvidence) and integrated LLMs, mostly artificial intelligence (AI) scribes (eg, Juvoly and Abridge). About 33% (5/15) of the PCPs reported to have a significant role in IT within their practice (eg, chief medical information officer) or possessed specialized knowledge on IT. Table 1 presents additional demographic data collected during the interviews, covering gender, PCP type, experience in the profession, LLM tools mentioned during the interview, and their affinity expressed with IT.

Through inductive thematic analysis, we revealed 10 primary themes related to the use of LLMs in PCP clinical practice. Each theme covers a set of subthemes. Multimedia Appendix 3 presents an overview of all themes and subthemes, including their definitions. Multimedia Appendix 4 provides additional representative quotes for each subtheme.

[a]PCP: primary care physician.

[b]Not available.

[c]AI: artificial intelligence.

Theme 1: Diagnostic Assistance

Our interview data showed that a frequently used case of LLMs in primary care practice was assistance with differential diagnosis. It was helpful for PCPs for complex, difficult, or rare cases, or when they felt that something was missing in their assessment. The LLM tool helped them figure out what was going on with the patient, while still maintaining their own interpretation of the patient's symptoms. A PCP stated an illustrative example:

> *I had a person in front of me a few months ago, a lady, 60 years old, really, really sick. I was sure, I'm going to send her to the hospital, but I was not having a single clue what was going on. So with her consent, I was able to prompt an LLM [...]. What is your diagnosis? And bizarrely it ended up with a really rare systemic disease which I afterwards looked up in my guidebook, and it was right.* [PCP 9, NL]

LLMs also showed to be a good alternative or a useful addition to specialist assistance. LLMs provided the PCPs with specialist knowledge on a wide range of diagnoses that they do not possess themselves or cannot easily access. PCPs describe the LLMs as quicker and more easily accessible, such as this PCP:

> *...otherwise I would have called my specialist colleague from the hospital nearby, or I would have needed another, [...] sending a request or a question to the medical specialist from the nearby hospital, and then, with a delay of a couple of days I will get my answer back. And now I can get to my suggestions straight away.* [PCP 14, NL]

To draw medical conclusions, PCPs often did individual research to build up a rapport for patient cases. LLMs were described as functioning as an assistive search engine for tasks ranging from looking up simple definitions to gathering complex scientific research. PCPs appreciate the broad range of knowledge that LLMs can quickly access and provide to them in the right context. A PCP said:

XSL•FO
RenderX

> *And I really like that, of course, because we as family medicine doctors, there are so many topics we need to know a lot about, of course, but we don't. That's just not feasible. So it's also really nice to kind of stay up to date but also frame that in a way that is primary care based.* [PCP 13, US]

Another use case described by PCPs was interpreting medical test results, which can sometimes be difficult for PCPs because they may contain unexpected findings (eg, blood work and magnetic resonance imaging reports). Using LLMs to provide additional information on results was described by a PCP:

> *So if I'm having some lab results, and I cannot quite figure out why the blood is different than what I would think, in combination with the symptoms, and sometimes I type in the symptoms with the physical examination and the lab results, and then I also ask them to give some interpretation, just to see if I'm also missing out on something.* [PCP 12, NL]

When using LLMs for diagnostic assistance and decision-making, PCPs pointed out the ability of LLMs to prevent bias, such as availability bias and anchoring bias, by providing evidence-based reasoning behind their suggestions and providing a second opinion. LLMs supported their thought process and reminded them of potential missed information, as described by this PCP:

> *The benefit for me is, I might undercover uncover a different diagnosis or a consideration. The other thing that I'm interested in through these models is a little bit of the reasoning. Why might one thing be more likely than another? And I might be seeing what I could learn from thinking through that. I'm just kind of interested in the clinical reasoning, because I know that there are certain cognitive biases that clinicians have in terms of information availability.* [PCP 7, US]

Theme 2: Streamlining Routine Tasks

PCPs described using LLMs for streamlining routine tasks, such as using them for simple calculations, such as blood pressure or medication dosage.

> *For instance, when a patient has a note with all his blood pressures written on it, then it's kind of chaotic. Then I send the note anonymous to perplexity and say, can you calculate the mean blood pressure.* [PCP 3, NL]

PCPs also expressed their liking for LLMs for summarization of a consultation after using an AI scribe to document the conversation, translating audio transcripts into usable language for documentation.

> *But now the AI scribe, that is just quite revolutionary. So, it is basically listening to the whole conversation, so, all you may be doing is just putting the orders in, but it's basically listening to your conversation between you and the patient, and it summarizes and transcribes the entire note.* [PCP 2, US]

Additionally, it is also reported to be used for professional writing and administrative tasks, for example, writing appeal letters and doctors' notes for patients, and creating vacancies and policies for the practice.

> *I find it most useful in terms of, drafting an appeal letter to an insurance company for an imaging study that was denied. And I basically inputted, give me a draft email of how to write the appeal letter, and for these reasons, without putting in specific patient information, and it gave me a 3-paragraph letter that was nicely worded.* [PCP 1, US]

One PCP also described how LLMs can be specifically used for writing narrative history of present illness data.

> *I guess even narrative HPI data and then having the large language model prioritize or identify some key issues or things that really need to be addressed or worked on.* [PCP 5, US]

Theme 3: Workload Support

Another emerging theme that PCPs were experiencing was the use of LLMs for workload support. Many PCPs experienced time savings when having LLMs assist with documentation and research. They described having to search for information scattered over the internet in different databases and protocols as a time-consuming and sometimes difficult task that can be quickly done by an LLM tool, which does a thorough job and provides evidence safely.

> *It's saves me a lot of time in administration, because I don't have to Google and search and find the right kind of articles. I don't have to go on PubMed. It basically presents all the suitable research already for me. So, it saves me time.* [PCP 4, NL]

Another way in which PCPs described being supported in their workload is that it helped them with efficiency. PCPs emphasized how they did more work within a consultation or treated more patients with LLM assistance in the same amount of time: "Well, by saving time I can take more patients in my practice" [PCP 6, NL]. In addition, some also described that the tool can reduce cognitive load and burden, describing how LLM assistance (eg, AI scribes) made them feel more relaxed when the LLM made notes during consultation or when it took over tedious tasks: "I still think the number of tasks doesn't change. It takes some burden of the task of writing down the consult, and that's a very good one" [PCP 3, NL]. Although some PCPs thought that the number of tasks did not change, some thought that it could take over some of the workload of PCPs. They expected LLMs to take over tasks such as writing letters and answering patient questions, which could free up time for physicians:

> *I think that when I think there are ways that I do see it adding value to the patients in the future, though, for example, if we're using more and more tools to take some of this growing in-basket workload off the physicians, it could start and advance practitioners.* [PCP 5, US]

XSL•FO
RenderX

Theme 4: Interprofessional Communication and Teamwork

Some PCPs mentioned that they used LLMs to help them communicate with other health care professionals. They used the tool to improve their team messaging by having an LLM draft an initial message or improve the quality and tone of their message:

> *I think it's improved the quality of my communications to the team dramatically. It's able to help me find a style and tone that's hopefully going to land. Well, especially in these non-face-to-face communications like, email, where it's really easy to misconstrue tone if you're not really careful, so I think it's led to a lot of improvement.* [PCP 5, US]

Another way in which LLMs improved communication between health care professionals was by bridging the gap in expertise between disciplines, supporting collaboration and shared decision-making:

> *I think it kind of bridges our disciplines. Because it can help us, like, with cardiology and the AI ECG tool. [...] because of this transdisciplinary and a collaborative tool, when you come to your colleague in cardiovascular, you say, well, the tool told me this, and these are the symptoms. Can you please help me and advise how to proceed? It's a simple example, of course, but I feel when it's supported by both departments, it can really help also in communicating the results.* [PCP 13, US]

Another more administrative way LLMs also supported communication between health care professionals was by taking automated discussion notes from recorded professional meetings:

> *Communication with fellow health professionals, I would say, maybe by having some intervention or meetings with colleagues where minutes were taken by the system. So again, the recording part.* [PCP 14, NL]

Theme 5: Patient-Centered Communication

PCPs highlighted the use of LLMs to improve patient-centered communication. Similar to professional use for team communication, they described using LLMs to provide patient-friendly messages and answer questions:

> *Yeah, I've been indeed, but this I think the first and single time I've been using it, ask Aletta, when I really was wondering how to reply to a patient with an e-consultation and a digital request in my inbox. So, I asked Aletta, I got a response, I shaped the response or made it a bit more patient friendly language, and then I replied back. So yeah, the doctor with actually the system replied. But I edited a bit.* [PCP 14, NL]

PCPs also used LLMs for simplifying clinical information for patients. Medical jargon is not always easy for patients to comprehend, especially when receiving test results. LLMs can be helpful in translating medical texts into plain language that is easy to understand. This also made health care more accessible for patients with low literacy:

> *...sometimes it gets difficult to be able to communicate some of that with patients who don't have the medical knowledge, or medical literacy, that we do, so in some ways I could see it being helpful in kind of, taking all that medical jargon and making it a lot more colloquial or understandable to someone who didn't go through all the training that we did.* [PCP 11, US]

Some PCPs also talked about how AI scribes specifically helped by restoring contact between patient and provider. They emphasized how it took focus away from taking notes and looking at a screen to paying more attention to the patient, allowing for more patient-centered care:

> *...with the AI listening with you, if you don't have to type anything in, your concentration on the patient is better. You make more eye contact, you can see more of the verbal and nonverbal communication which the patient sends, you can be more polite by your posture towards the patient.* [PCP 6, NL]

Considering the use of LLMs in communication toward the patients, PCPs also mentioned that the output of LLMs was often more empathic and patient-friendly:

> *...the answer that is formulated by the AI is a little bit more. How should I say? User friendly? It has a much friendlier tone, it can be like a little bit more empathetic sounding, whereas a nurse may just say, okay, I'm sorry to hear that, can you tell me these questions, but the AI may go into more details, so it kind of helps them, but not always.* [PCP 2, US]

Another way in which PCPs have seen useful integration of LLMs in patient-centered care was using it for shared decision-making between the doctor and the patient, as the LLM presented useful information and specialist knowledge during discussions:

> *I mean definitely, I can see a lot of opportunity for it in shared decision making so as a tool to augment the discussion between a physician and a patient by presenting timely and appropriate information and data.* [PCP 5, US]

PCPs also mentioned using it for after-visit summaries to provide information to the patient after consultation. AI scribes and other LLM tools can create summaries based on the consultation, helping the doctor and the patient by not missing out any important information:

> *Then if you end up at the doctor, you might use those LLMs to make summaries and to make summaries that are good for doctors and good for the patients themselves, since we all know people tend to forget stuff when they leave the consultation. So, there are so many benefits there to improve the full experience for a doctor and for a patient perspective.* [PCP 9, NL]

XSL•FO
RenderX

Theme 6: Caution With LLM for Communication

Although PCPs mentioned many positive aspects of using LLMs in their communication, they also talked about caution being taken when doing so. One of the things PCPs said was that they were cautious about losing personal touch, as the vocabulary used was different from their personal language, which could alter the tone of the message. They also described that messages become less unique and less personal:

> *Honestly, the way that it writes sometimes is a little...it's not as conversational as I would like it to be, and I think it adds a lot of words that aren't normally used in everyday language. So I think that it just wouldn't give me the tone that I'm looking for a lot of the time.* [PCP 11, US]

Other reasons for PCPs not to use it for communication efforts were wanting to keep short ties with their colleagues and patients. They mentioned that it did not improve their efficiency when communicating online and a lot of communication could be done in real time or in person: "If I communicate with another provider, my communication is usually like 15 to 30 second email or chat message. And the reply probably is just as efficient" (PCP 15, US). PCPs who do use LLMs for communication often validate their output before sending it off, as LLM-created drafts could introduce errors or misconstrued meaning. They also described validating and editing to make sure that the right tone was used or to give it more of a personal touch before sending:

> *I never share a broad communication that comes out of ChatGPT, without having reread it to make sure that I'm comfortable with the way that it's being presented. So, I always read it back over, because sometimes it will change in the attempt to kind of improve that style, it'll change a meaning accidentally by how the words are arranged, and so I'll have to do some subtle editing.* [PCP 5, US]

Theme 7: Patient Looking up Symptoms

PCPs are not the only people in the consultation room who use LLM tools; patients also use some publicly available LLMs. Some PCPs reported that they knew or heard patients using LLMs to look up their symptoms, and some viewed it as an alternative to Google, which has been widely used by patients in the past to look up symptoms:

> *I'm not afraid of it. As I am not afraid of Google. People look up a lot by Google, but I know well, I should know my stuff and my profession, so I'm still able to say to patients, well, that's good information, I think you're right, or it's wrong information, maybe, better do this or that, because I think it's better for you, and it's more to the guidelines.* [PCP 6, NL]

Not every PCP was enthusiastic for patients to use LLMs in their care process, but some did express their enthusiasm and thought that LLMs will be a useful addition for patients to use. They thought that patients could use it to better understand clinical information, to create an understanding of their symptoms and diagnosis, and provide reasoning and urgency in their communication toward physicians:

> *And I think what you're going to see is that people will start with LLMs as part of their care journeys. And you know, do I need to go to the doctor or not will be something that will be increasingly available, I think, being able to translate the complex jargon and words of research papers, and CT Scans and doctor's notes into something that is easier to understand and grasp, I think, will be really revolutionary. So, I think a lot of it's going to be on the patient, direct end of it.* [PCP 7, US]

While it could be a useful addition, some other PCPs talked about careful considerations when patients use the LLMs, as it could introduce anxiety when they misinterpret medical information or could oversimplify based on the information provided to the LLM. With this, it becomes apparent that the level of knowledge and information provided by the patient determines the quality and trustworthiness of the model output:

> *...you have to be very careful how you ask how you denounce your symptoms, and how you write it down, and you have to be very careful what model you use and how trustworthy it is so, yes, there are risks, but I think the benefits will be more.* [PCP 3, NL]

Theme 8: Model Limitations and Concerns

PCPs also talked about the limitations and concerns regarding the models themselves. Generally, PCPs were aware of hallucinations and took caution when using LLMs and validating the output. Catching hallucinations can be tricky for PCPs, and missing incorrect output can cause safety issues, which in this case gave one PCP a paranoid feeling:

> *No, I'm still a little bit cautious about it, because I know there are hallucinations. I know it can sometimes give an answer that looks correct, but isn't correct, so I'm still a little bit paranoid.* [PCP 3, NL]

PCPs also said to be aware of the fact that LLMs are built on data-bound intelligence, meaning the model is trained on broad data and a mathematical model: "The model is only as good as the information data that it's trained on. So, I think there's a risk" (PCP 7, US). Another limitation mentioned by PCPs of the LLM models is the lack of traceability and reproducibility, as it can be difficult to retrace old interactions and provide inconsistent answers over multiple uses:

> *It does, but there's going to be no way for me to like...I'm not going to record those references for future purposes, whereas, like a textbook or up to date, I can always go back to go back there and find those references if I wanted.* [PCP 15, US]

Theme 9: Ensuring Validity

One way to overcome some of the limitations and concerns with LLMs was to ensure the validity of the output before using it. One way PCPs shared how they did this was by manually double-checking based on personal knowledge, gut feeling, rereading, or challenging the model by asking additional questions. Although output is perceived to be mostly accurate, double-checking by challenging the model and critically thinking

XSL•FO
RenderX

about the output provided helped the doctors to maintain the quality of their health care provision:

> *...that's also something that you have to validate as a doctor. And I think for that, you just need your own smart brain. Yeah, a little bit blunt. You have to be sharp about it and think, okay, this is like a very suitable answer. It looks right. I can use this one. Or this is a very weird answer. I can't use it. So you have to use your own gut to see that.* [PCP 4, NL]

PCPs also mentioned validating by source reliability as an additional way to validate the output. Often, LLMs provided references included in their output, which could be validated by looking at the reliability of the source and what methods were used. Checking the references provided by the LLMs assured doctors of the quality and accuracy of the LLM output and gave them a sense of security:

> *And that's why I use perplexity, perplexity gives the sources, and then I can check which sources it uses. Sometimes I see it uses a source like, for instance, MedNet, which is not a reliable source, and then I am a little bit suspicious about the answer.* [PCP 3, NL]

In addition to checking the model's output, some PCPs also highlight the importance of prompt writing and input. When looking for very specific content or questions, input provided to the model (eg, questions, documents, and information) was a big contributor to the output of the model. This was also specifically commonly mentioned among the Dutch PCPs, as a lot of information LLMs are trained on is based on American standards, and if they wanted to look up Dutch standards, they had to clearly specify this in their prompt to get the right information: "I've learned the hard way, providing more information gives me much better results than giving little information" (PCP 8, NL).

Theme 10: Patient Safety and Data Security

The final theme was patient safety and data security. Most of the PCPs mentioned concerns about data storage and breaches. They highlighted that many LLMs store information and that there are no laws or regulations specifically addressing data handling for LLMs, which is especially important in the health care context:

> *I think there needs to be some sort of rules or regulations from a safety perspective because, let's say I'm being very cautious about not putting in any information but if other folks are putting information, I'm not entirely sure if it's true, but like it probably gets built into some sort of large database that I imagine is probably hard to retrieve back from, or take it down from.* [PCP 1, US]

This is also related to some PCPs who talked about trust in technology providers. A lot of trust is put into the hands of large companies and their integrity, which some PCPs perceived as a risk. Especially, as LLMs are widely adopted in the health care industry, it is important to ensure quality, safety, and accessibility:

> *I think that that that it and the trustworthiness of an app needs to be really forward, that is one of the most and important aspects, and I do have these feelings about like Juvoly. But I have to admit that I didn't do really a background check or so to this app. But I think that the big app, that ChatGPT, it's more like who owns ChatGPT. What happens with the data? It's more dangerous, I think, it seems more dangerous for us.* [PCP 10, NL]

The way PCPs tried to prevent data breaches and ensure patient privacy was deidentification and anonymization of the patient data they provided to the LLM, which was especially important when using public LLMs that are not integrated into the electronic health record (EHR) to remain Health Insurance Portability and Accountability Act (HIPAA) compliant: "When it comes to privacy, you just have to be really careful about not filling out like a date of birth, or a name, or whatsoever. I don't think people do it, but you never know" (PCP 12, NL). Many PCPs mentioned the limited system integration as a security barrier. They struggled with transferring information safely from the EHR to separate systems. EHR integration could be a way to make LLM use more regulated and controlled, which is important to ensure privacy and patient safety:

> *So ChatGPT is not integrated in our EHR. It's a separate thing. So, I have to be careful when I put information, ChatGPT. I have not used it for my medical profession on a regular basis, but if I do, I have to be extra careful, like making sure that all the information is HIPAA compliant. And all the patient identifiers are removed and we're just asking for pure information...* [PCP 2, US]

One PCP brought up the issue of liability, describing how traditional methods such as textbooks seem more reliable than a new tool, as they remain accountable for their care delivery:

> *I mean, you can imagine like, if we were in like a courtroom or something, and you were on one side and I was on the other side as a physician, and you had gotten harmed by something that I did. And my answer to your lawyer was like, Why did you do this? And my answer was, you know, ChatGPT told me to do it versus my answer was, well, here's the textbook. You know the textbook says to do this thing that I did. and it didn't work out for you, but it's still standard practice, according to the textbook that pretty much the majority of like us physician's use. You'd have some sympathy for that answer right?* [PCP 15, US]

LLMs have the potential to help PCPs, but it was also essential for them to maintain patients' trust. PCPs talked about the perception of patients when using LLMs and making sure that they did not lose their trust, as they could be perceived as less professional or make the patient feel uncomfortable by using it. Patients losing trust due to reasons such as harmful recommendations and privacy concerns could eventually cause patients to distrust their provider, which could harm the relationship between the doctor and the patient:

> *So, safety in terms of protecting their health is one perspective, but also safety in in the perspective of*

XSL•FO
RenderX

> *safeguarding the biggest importance, most important value in healthcare. That's trust. If someone does not trust me anymore, because it seems like a recorder is on the background, pumping all my data to some other country where they have opinions about me. Then I might lose this trust. And then I can't do my work properly. So yeah, it is really really important to be aware of that to do an informed consent?* [PCP 9, NL]

PCPs also highlighted the risk of overreliance on LLM outputs, which could pose a safety issue for both the PCP and the patient. This could occur when taking over recommendations or statements that are incorrect due to overtrusting the LLM to be correct:

> *And one of the concerns that I have again, with the Large language model in that setting is that they could make recommendations or statements that aren't actually like medical best practice, and that it could easily be missed because people just get in the habit of, you know, hitting.* [PCP 5, US]

Discussion

Principal Findings

This study provides an in-depth qualitative examination of how 15 Dutch and American PCPs integrate LLMs into clinical practice. The findings demonstrate that LLMs are being used as clinical support tools, enhancing diagnostic reasoning, streamlining administrative tasks, and relieving (cognitive) workload for PCPs. Next to that, they are identified as multifaceted communication support tools that facilitate interactions and teamwork among PCPs, specialists, and patients, and, in some cases, informally supplement specialist consultation when access is limited. At the same time, PCPs articulated important concerns related to safety, data security, efficiency, authenticity, and the preservation of the therapeutic relationship, underscoring the need for careful, context-sensitive use. To our knowledge, this is the first paper to highlight key aspects of LLM use in primary care settings, directly from PCPs in the United States and the Netherlands. The qualitative design of this study allows for the firsthand perspectives of PCPs to be captured and shared, based on real experiences. It is interesting to note that PCPs in 2 different countries had similar thoughts and concerns regarding the use of LLMs in primary care, as both countries were represented along all identified themes.

Comparison With Prior Work

LLMs are rapidly emerging as powerful tools across many areas of medicine, including primary care [22]. As the foundation of preventive health and the first point of contact for most patients, PCPs often operate under significant time pressures and limited resources [23]. As a result, LLMs are being actively explored and increasingly implemented in primary care practices to help clinicians manage workload and improve the efficiency and quality of patient care [24].

Physicians undergo years of training in medical school and residency to build a strong medical knowledge base initially and then, with experience, refine this knowledge to learn illness scripts that guide their diagnostic reasoning. This is especially important when caring for patients with complex conditions or atypical presentations, where subtle cues and pattern recognition are essential for accurate diagnosis. Several PCPs discuss their methods of using LLMs in assisting their diagnostic reasoning. For example, some clinicians may use LLMs to develop a differential diagnosis and use them to double-check that no important possible diagnoses have been overlooked. PCPs offered an interesting perspective, noting that LLMs can be used as a safeguard against cognitive biases, such as anchoring and availability bias, by prompting clinicians to reconsider initial impressions and broaden their diagnostic thinking. Although many of these tools were not vetted for this use, other PCPs in the United Kingdom have also reported using them for this purpose [12].

Another key area in which LLMs can assist PCPs is in rapidly synthesizing information at the point of care. This spans the whole clinical workflow—before, during, and after a visit. Prior to the visit, physicians often prechart by reviewing prior notes, specialist consultations, hospital records, and relevant laboratory and imaging results. Several PCPs highlighted that LLMs can be used to summarize prior data and interpret complex results. For the complex patient, precharting also involves digging into literature to find treatment recommendations and weighing all the risks and benefits. One PCP highlights that LLMs can condense this work from hours to minutes while probably being more comprehensive in their review. During the visit, PCPs may need to quickly reference current guidelines or evidence-based recommendations to inform treatment plans. LLMs may be used to summarize data that patients bring in, such as blood pressure or blood glucose logs. Clear and concise patient instructions are also written for patients as a point of reference in most cases, and LLMs can do this quickly as well. After the visit, clinicians must integrate all this information into a clear, accurate, and concise note. Other administrative tasks include reviewing results and communicating them to the clinical team and patients, reviewing medication refill requests, and writing appeal letters for medications or imaging tests. LLMs can help streamline each of these steps, which are also reported as opportunities throughout the literature [12].

One major area of development worth mentioning is the use of LLMs to synthesize a comprehensive and accurate clinical note at the end of a patient visit [25]. AI scribes or ambient voice technology automatically captures clinical conversations and has been shown to decrease documentation time by 28.8%, alleviating physician burnout [26]. Physicians report feeling less distracted and more connected with the patient during the visit itself. Several of the interviewed PCPs highlight this aspect of LLM-listening technologies, which are already being implemented and have gotten support from GPs in European primary care [14,27]. Reducing technological workload by engaging with computers during consultations may also enhance patient satisfaction with the clinical encounter [28].

Communication and teamwork emerged as central aspects of LLM use in primary care. Participants described LLMs as facilitating bidirectional communication among PCPs, specialists, and patients, positioning these tools as

XSL•FO
RenderX

quasi-members of the health care team, a vision that previous research among PCPs found for the consultation of the future [29]. Within interprofessional collaboration, PCPs reported using LLMs to support team messaging and to bridge communication gaps across specialties and, in some cases, as an informal substitute for specialist consultation when questions were perceived as low risk. In patient-facing communication, LLMs were used to draft responses to patient messages, simplify clinical information, support shared decision-making, and enhance empathetic tone. Despite these perceived benefits, PCPs expressed concerns about potential loss of personal connection, efficiency trade-offs, and the risk of errors, emphasizing the need for careful validation before patient-facing use. Participants also reported mixed views on patients' use of LLMs for health-related communication: some welcomed increased patient autonomy, while others expressed caution regarding misinformation and its impact on the doctor-patient relationship. Previous studies found that most American patients look for health information on the internet, and 1 study even showed that for 81% of their respondents, the information provided by ChatGPT is at least as useful as the information provided by their doctor [30,31]. Patients communicating information they found online can have a serious effect on the doctor-patient relationship, especially if the information brought up is deemed inaccurate, and, therefore, it is important to understand how PCPs respond to patients communicating LLM-generated findings and how they can support patients in finding accurate information [32].

PCPs also highlight some of the risks in using LLMs for such tasks. First, patient privacy and data security are important factors and appear to be the primary concerns among PCPs. Concerns are raised regarding how information that is input into an LLM is used and stored. Second, LLMs have been noted to have hallucinations, or instances where the output has been fabricated by the LLM itself. This requires users to proofread each output and ensure its accuracy. Output depends on the resources that the LLM reviewed, and so results need to be validated to ensure that it is correct medical information. Third, some PCPs expressed concern about overreliance on automated documentation. If clinicians begin to depend too heavily on AI-generated notes, critical thinking and active information processing during the visit may decrease over time. The shortfalls of LLMs have been widely discussed in the literature, and the most important point for PCPs is to be conscious and aware of these shortfalls and use effective ways to overcome or prevent the negative aspects of the tools, for example, by not inputting HIPAA-protected information and validating outcomes to prevent patient harm [33-35]. Additionally, when PCPs notice potential risk of harm for the patient or low quality of output, they are likely to not use the AI service in the future [36].

Implications for Practice

The findings suggest several implications for practice across design, workflow, policy, and training. PCPs described concerns regarding hallucinations, overreliance, transparency, and data security when using LLMs and reported developing their own strategies, such as validating outputs, assessing source reliability, and using prompt engineering, to mitigate these risks. These clinician-driven practices highlight opportunities for tool developers to integrate safeguards directly into system design, reducing reliance on individual work-arounds and supporting safer, more trustworthy use of AI [37]. At the workflow level, LLMs were perceived as valuable for supporting workload by saving time, reducing cognitive burden, and assisting with administrative and routine tasks, suggesting that prioritizing tools that align with these needs may improve efficiency while allowing greater focus on direct patient care. At the organizational level, the reported use of publicly accessible LLMs for clinical purposes underscores the need for clear, context-specific policies that address appropriate use, data security, and accountability, particularly as technological advances outpace broader regulatory frameworks. In addition, the findings indicate a need for targeted training, as PCPs reported using LLMs beyond their originally intended purposes. One university is already offering a combined doctor of medicine and master of science in AI degree, which is one step on the way to PCPs prepared for a future involving regular LLM use [33]. Training efforts should address both the potential benefits and the risks of LLM use, including strategies for effective validation and communication, to support responsible integration while preserving clinician judgment and maintaining patient trust.

Limitations and Further Research

Some limitations of this study include the small sample of physicians from only 2 countries. Although the in-depth analysis of the interviews provided rich insights and perspectives, the limited sample size could restrict the generalizability of our findings to broader populations of PCPs. Future research could validate certain findings and insights with larger sample sizes and qualitative or mixed method designs for strengthened generalizability. This study captures early-stage perceptions of LLM use rather than outcomes from in-context clinical trials; however, such insights are critical for informing the design and evaluation of future rigorously trialed applications within real-world primary care settings [38]. Further studies may be conducted to see whether LLM use improves diagnostic accuracy and, therefore, overall mortality. Other studies may be conducted to look at efficiency in seeing patients and whether this improves health care access, changes in patient satisfaction, and improvements in physician well-being. Additionally, the expanding role of LLMs will likely reshape medical education, opening a large area of investigation into how trainees learn diagnostic reasoning, documentation, and communication skills from the beginning of their training. With thoughtful implementation and continued research, LLMs can become a powerful aid in the work of PCPs.

Conclusions

Our findings suggest that LLMs are already being integrated into primary care in diverse ways, with their value shaped by both contextual factors and clinician judgment. By highlighting both the advantages and disadvantages of LLM-supported clinical practice and communication, this study contributes to a more nuanced understanding of how these technologies are reshaping primary care in everyday clinical practice. As LLMs become increasingly embedded in primary care, understanding how clinicians navigate their use in real-world practice will be

XSL•FO
RenderX

essential to ensuring that these tools enhance, rather than undermine, high-quality, patient-centered care.

Acknowledgments

The authors would like to thank Ahmet Kaval and Benjamin Good for their valuable contributions to the coding process and their support of the thematic analysis as summer research interns. The generative artificial intelligence (AI) tool ChatGPT (OpenAI) was used to assist with language editing and improve the clarity and readability of the manuscript. All AI-generated suggestions were reviewed, revised, and approved by the authors, who take full responsibility for the final content.

Abstract

Background: The United States Army Institute for Surgical Research conducted an analysis of 3 prototype sensor suites; all candidates were designed to passively document care delivery in tactical combat casualty care environments.

Objective: This study aims to ensure sensor suites remain resilient and adaptive in complex battlefield environments. This research effort conducts a systematic comparative assessment of prototype solutions.

Methods: The assessment methodology prioritized functionality, usability, and performance. The assessment consisted of three phases: (1) tabletop evaluations, (2) simulated use testing, and (3) a sensor suite rodeo simulation event. The second and third phases included human participants leveraging the technology prototypes in hyperrealistic tactical combat casualty care simulation environments. Additionally, the third phase allowed the researchers to assess the performance of each prototype in a range of operational environmental lighting conditions.

Results: During the tabletop evaluation phase, all 3 prototype sensor suite solutions demonstrated acceptable results (≥1) in the technical specification assessment. The 2-part heuristic analysis revealed variability, where the least complex configurations received the highest assessment scores. To capture and record raw data, scores ranged from 44.6 to 87 on a 100-point scale. To offload and export the raw data, scores ranged from 22.9 to 87.5 on a 100-point scale. During simulated user testing, all 3 sensor suites achieved passing quantitative scores (≥60); the system usability scores (SUS) ranged from 60 to 85 on a 100-point scale. More complex technology configurations received higher usability scores. From a qualitative perspective, vital sign monitor latency display issues led to reliability concerns. All 3 prototypes successfully generated raw data; the individual outputs ranged from 0.06 to 0.13 GB/minute. During the sensor suite rodeo simulation event, all 3 sensor suites achieved passing quantitative scores (≥60); the SUS ranged from 66.7 to 86.7 on a 100-point scale; the most complex technology prototype configuration scored higher. Qualitative findings identified data transfer issues with large file sizes and pairing issues with vital sign monitors. All 3 prototypes successfully generated raw data; the individual outputs varied (ranging from 0.012 to 0.24 GB/min) based on the environmental lighting conditions (full sun, indoor lighting, and low light). However, from a data quality perspective, only 1 camera component produced viable video data in all 3 environments.

Conclusions: The comparative assessment revealed opportunities to combine the strengths of both approaches in a next-generation implementation. This preliminary assessment was constrained by several factors: (1) effective tracking of consumable medical supplies, (2) advancement of artificial intelligence algorithms to process the raw data, and (3) ability to manage multiple casualties or patients. Follow-on evaluations are needed to address these limitations. This systematic, 3-part methodology evaluates early-stage sensor suite prototypes and provides a reproducible framework for advancing battlefield medical technologies.

KEYWORDS

autonomous medical documentation; comparative technology performance assessment; military medical documentation; multi-phase assessment methodology; passive medical documentation; tactical combat casualty care; prototype sensor suites; simulation-based assessment

Introduction

The Military Health System faces a persistent challenge: while medical documentation is mandated at all echelons [1], providers in high-intensity combat situations must prioritize lifesaving measures over record-keeping, often leading to significant data gaps. Manual, paper-based documentation is not only

XSL•FO
RenderX

burdensome but also prone to result-interpretation errors due to varying environmental factors.

To address this challenge, the United States Army Institute of Surgical Research (USAISR), formerly known as the Telemedicine and Advanced Technology Research Center, commenced an effort to prototype systems specifically designed to passively document care delivery within the tactical combat casualty care (TCCC) environment. The sensor suite systems used individual commercial-off-the-shelf components integrated with an edge computing device and/or end user device as shown in Table 1. The 3 specific systems were selected by the government after their respective proposed approaches were determined to have merit.

Table . Sensor suite prototype configurations.

	Medical Wearable Audio Video Entry	Autonomous Communication Medical Ecosystem	Point of Treatment Aggregator
Audio or video component	• PatrolEyes visible or near infrared camera	• GoPro Hero 13 Black action camera	• MOHOC M2 Camera • Sennheiser Lapel microphone
Patient vital sign monitor component	• Vivalink electrocardiogram patch • Vivalink pulse oximeter	• Masimo MightySat pulse oximeter	—[a]
Provider activity tracking component	• Electromyography armband	• Movella DOTs	• Movella DOTs
Consumable medical supply use tracking component	—	• Near field communication tags	—
Edge computing device	• NVIDIA Jetson Orin Nano	—	—
End user device	• Samsung Galaxy S23 FE smartphone	• Samsung Galaxy S21 smartphone	• Dell Latitude 7230 Rugged Extreme tablet

[a]Not applicable.

Between September 2023 and July 2025, the USAISR conducted a formal analysis of the 3 early-stage prototype sensor suites: the Medical Wearable Audio Video Entry (M-WAVE), the Autonomous Communication Medical Ecosystem (ACME), and the Point of Treatment Aggregator (PoTAg). The results from this initial comparative assessment highlighted opportunities to integrate the unique strengths of each approach, paving the way for a next-generation solution. By identifying complementary features and capabilities among the various prototypes, the assessment established a foundation for designing systems that are resilient and adaptive to complex battlefield environments.

The systematic, 3-part methodology used to evaluate these early-stage sensor suite prototypes provides a robust and reproducible framework for guiding the future development of advanced medical technologies for the battlefield. This approach not only ensures objective comparison and evaluation of devices or systems but also facilitates iterative improvement based on empirical data. Ultimately, such a structured process accelerates the innovation cycle, enhances decision-making for future investments, and supports the creation of integrated solutions that can better address the dynamic and unpredictable needs of battlefield medicine.

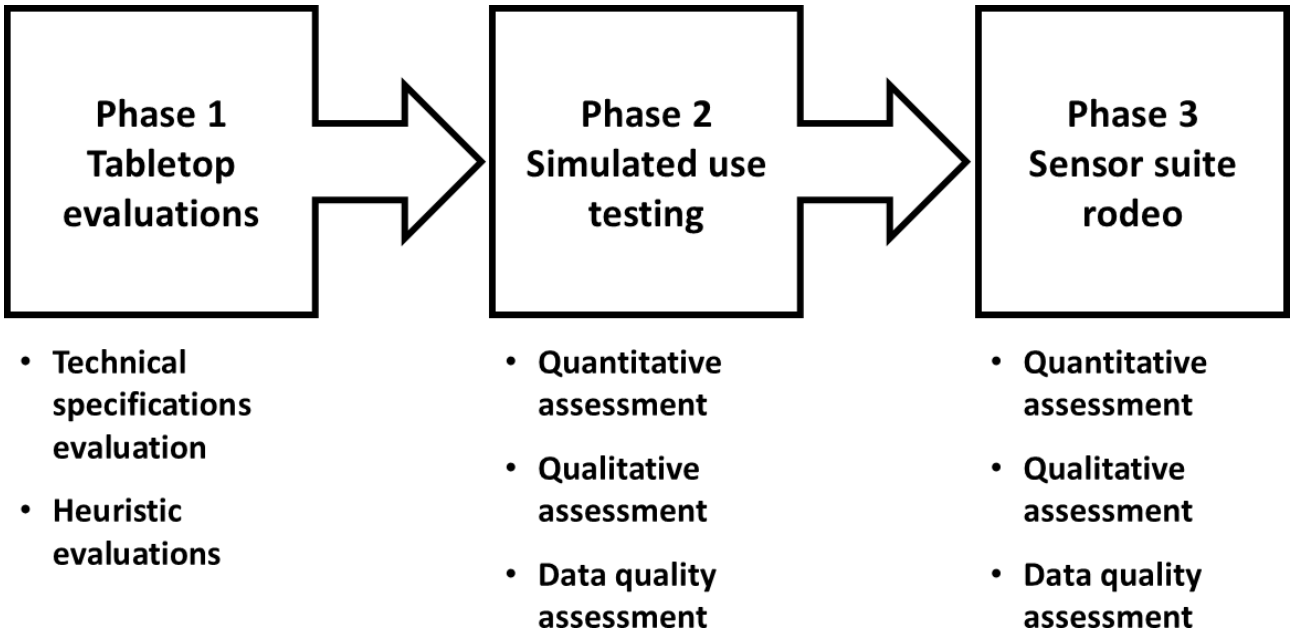
The premise behind this prototyping effort is that smart devices, defined as context-aware electronic devices capable of autonomous computation and data exchange [2], offer a unique solution to this TCCC medical documentation capability gap. By integrating these technologies into sensor suites, they serve as a force multiplier for the TCCC level provider, which includes the following:

1. Reduced cognitive load: By automating the capture of patient statuses and caregiver actions, the sensor suite system alleviates the medic's cognitive burden, allowing them to remain fully "hands-on" with the patient without the distraction of manual documentation [3,4].
2. Data integrity for handoffs: The sensor suite system facilitates the accurate generation of a digital TCCC care, ensuring that life-critical information (including medication dosages and tourniquet times) is seamlessly transferred to the next echelon of care without requiring the medic to pause treatment for manual logging [5].
3. Mass casualty and patient management: Mature sensor suite technologies will enable continuous, simultaneous, and passive monitoring of multiple vital signs across multiple patients through a centralized interface, significantly enhancing a care provider's situational awareness in complex environments [6].
4. Enhanced operational readiness: Near real-time monitoring of physiological parameters and environmental exposures (eg, noise, radiation, chemical agents) ensures that the health and safety of military members are maintained throughout the mission [7-9].

In the long term, the resulting sensor suite datasets will empower the development of artificial intelligence (AI) and clinical decision support systems to further aid care delivery in austere environments.

This comparative assessment evaluates the performance, usability, and refinement needs of these initial prototypes based on four main hypotheses:

XSL•FO
RenderX



1. Synchronized passive sensor modalities can establish large, reliable TCCC encounter datasets.
2. Passively collected data can effectively train future patient documentation algorithms.
3. Mature algorithms can reliably automate real-time data inputs for digital TCCC cards.
4. Passive, autonomous collection will eliminate the need for manual care provider input at the point of care (POC), improving both efficiency and accuracy.

Methods

Overview

There were three phases to the assessment: (1) tabletop evaluations, (2) simulated use testing, and (3) a sensor suite rodeo simulation event as shown in Figure 1. The assessment methodology prioritized 3 factors: functionality, usability, and performance. For each prototype, both the entirety of the sensor suite configuration and the individual components were included in the assessment process.

Figure 1. Sensor suite assessment phases.

Study Design or Recruitment

All nonpersonally identifiable information data collected for this assessment were conducted under an exempt research protocol (protocol ID# M-11061). A more expansive, human subject research protocol assessment methodology (protocol ID# M-11057) for the sensor suite prototype assessments has been previously described in the Journal of Medical Internet Research [10].

Analysis

The sensor suite analysis had 3 discrete phases (Figure 1). The first phase was a benchtop assessment of each component of the individual sensor suites, and the second and third phases required the use of hyper-realistic TCCC simulation scenarios with human subject participants engaging with the sensor suite technologies.

Phase 1: Tabletop Evaluations

The initial phase of the assessment process took place in a controlled laboratory environment and was conducted by independent evaluators systematically reviewing each component of the 3 sensor suite configurations (Figure 2). There were two parts to this tabletop evaluation: (1) a technical specification assessment and (2) a 2-part heuristic analysis.

XSL•FO
RenderX

Figure 2. Tabletop evaluations.

Phase 1A: Technical Specification Assessment

Evaluators considered the overarching sensor suite's technical specifications and documentation associated with the individual components (Textbox 1). The validity of the technical specifications and documentation was assessed for each defined top-level attribute (Table 2).

XSL•FO
RenderX

Textbox 1. Sensor suite specifications.

Technology

- Suite includes at least 2 commercial off-the-shelf sensors and a physical data hub
- Commercial off-the-shelf sensors include audio, video, physiological monitors, wearables, and radio frequency identification technologies
- Sensor components are established technologies, not prototypes
- The suite is reliable, effective, and easy to use
- Suite is size, weight, and power efficient, runs for at least 2 hours
- Suite enables passive monitoring of patients, caregivers, and/or resources
- Suite is suitable for collecting combat casualty care data
- Suite is fit for austere, tactical environments

Data outputs

- Meets industry standards, is not proprietary
- Data outputs include raw sensor data
- Data separate patient and caregiver data
- All data are downloadable, organized, time-stamped, and include descriptive tags
- Data processing is efficient and effective

Technical documentation

- Lists targeted tactical combat casualty care fields
- Details data standards used
- Estimates data output or bandwidth
- Estimates power or battery needs
- Describes software
- Provides user manuals
- Includes both a training and project plan

XSL•FO
RenderX

Table . Technical specification attributes.

Attribute	Sub attribute
Systemwide factors	• Automatic data aggregation • Data aggregation system • Synchronized data format • Time synchronization • Data processing steps • Key metadata or tags • Approximate cost
Form factor	• Size (width, length, height) • Weight
Device power requirements	• Power modality • Approximate battery life
Interface	• Attaches to (eg, caregiver or patient) • Attachment method • User interface modality • Passive or active collection • Required actions (if active)
Data capture and storage	• Data type • Data format • Data streams • Data intended use case • Key metadata • Software required to access data • Real-time data availability • Time recording modality • Sample or frame rate
Device flexibility	• Key settings
Data transfer	• Wireless transfer capabilities • Connection type

Each component of the sensor suite was independently evaluated by 2 separate raters using a 3-point scale (0=lowest, 2=highest). The scores were then consolidated; if the raters provided different scores for the same component, the lower score was recorded as the official score for that component. Next, the scores for all the individual components were averaged.

Phase 1B: Heuristic Analysis

A heuristic evaluation is a systematic inspection methodology to quantify the usability of the sensor suite prototype interface design. During this phase of the analysis, 2 subject matter expert evaluators examined the interface and determined compliance with recognized usability principles, specifically the Nielsen Norman Group 10 Usability Heuristics model [7], as outlined in Table 3.

XSL•FO
RenderX

Table . Nielsen Norman Group's 10 heuristics.

Heuristic	Example
Visibility of system status	Keeps users informed with timely feedback.
Match between system and real world	Leverages end user language and real-world conventions; avoids jargon and presents information logically.
User control and freedom	Provides clear exits so users can easily undo mistakes.
Consistency and standards	Ensures consistency by following platform and industry conventions.
Error prevention	Prevents problems before they occur; eliminates error-prone conditions or confirms risky actions.
Recognition rather than recall	Reduces memory load by making key elements and information visible or easily accessible.
Flexibility and efficiency of use	Provides shortcuts for experienced users and allows customization of frequent actions.
Esthetic and minimalist design	Removes irrelevant or rarely needed information from the interface.
Help users recognize, diagnose, and record from error	Writes error messages in plain language, clearly stating the problem and solution.
Help and documentation	Aims for a self-explanatory system but provides helpful documentation if needed.

There were 2 discrete parts to the heuristic assessment. Task 1 focused on the ability of the sensor suite components to capture and record data in a usable fashion (eg, openly accessible, and not using proprietary data formats). Task 2 focused on the ability to offload and leverage the data that were generated by the sensor suite components. To conduct the task 1 heuristic assessment, all the sensor suite components were powered up, connectivity was established in accordance with the performer's documentation, and data collection or recording was commenced. Once this process was completed, the data offloaded from the sensor suites were exported to a secure, cloud-based research data repository (eg, the task 2 heuristic assessment). In instances where the data were not generated by the individual sensor component in task 1, the task 2 heuristic assessment did not occur.

For each individual sensor suite component, it was assessed across 10 discrete heuristic factors, described in Table 3, with a maximum score of 2 per factor resulting in a maximum of 20 total points. Evaluator scores were averaged to determine a final score. Each sensor suite configuration score was then calculated using the sum of the individual components.

The resulting summary score was then divided by the total possible points a sensor suite could receive, which was based on the total number of component devices multiplied by 20 (eg, number of components × 20). After this division, the resulting number was multiplied by 100 to standardize the 100-point scale, as follows:

$$\text{Sensor suite configuration score} = (sn \times 20) \times 100$$

where s is the sum of all individual suite component heuristic scores and n is the total number of individual sensor suite component devices.

This scoring process was used for both the task 1 and task 2 heuristic assessments. For the purposes of this assessment, a total score of 60 or higher was considered a passing score, a standard used with other validated usability instruments. In addition to providing numerical scores, each evaluator added comments to their ratings. These qualitative comments were combined into a thematic analysis for each of the heuristics to add more information about the quantitative ratings.

Phase 2: Simulated Use Testing

Simulated use cases involving end user testing, and data quality assessments were conducted as a second phase of the sensor suite evaluation [11] (Figure 3). The simulated use cases were carried out in a controlled field setting, where the prototypes were deployed under carefully managed conditions and known reference points for comparison (Textbox 2).

XSL•FO
RenderX

Figure 3. Simulated use testing.

Textbox 2. Simulated use testing live actor scenarios.

Clinical presentations

- Open tibia or fibula fracture
- Minor head laceration
- Second degree burn to upper extremity

Expected treatments

- Splinting of leg
- Management of minor laceration
- Burn management
- Initiating intravenous
- Administering medications
- Hypothermia prevention

During the simulated use testing phase of the assessment, each sensor suite prototype was used within a high-fidelity simulation where the care provider or medic participant was a TCCC provider (eg, tier 1, 2, and/or 3). The care provider or medic participant performed casualty care on live actors. The simulation team used testing scenarios that were run twice to ensure that a complete dataset was collected during the assessment. Once each simulation was complete, the participant was given two surveys to fill out: a quantitative instrument and a qualitative tool.

Phase 2A: Quantitative Assessment

The objective, quantitative instrument selected for this assessment was the System Usability Scale (SUS) [12] questionnaire. The SUS instrument is a validated, standardized survey that has been used across all types of systems and technologies to evaluate usability. Once the final SUS scores are calculated, they are stratified against published norms based on the technology types. In general, a total SUS score of 60 or higher is considered passing from a usability perspective, and this widely accepted criterion was used for the sensor suite evaluation.

XSL•FO
RenderX

Phase 2B: Qualitative Assessment

The qualitative assessment consisted of specific short answer questions that more specifically targeted the sensor suites that are being assessed in a subjective manner. This assessment was limited in scope to the sensor suite components that were worn by the care provider or medic (eg, audio or video and activity tracking sensor components) during the simulated use case assessment.

Phase 2C: Data Quality Assessment

The data quality assessment was conducted by 2 evaluators after the sensor suite data were extracted from simulated use testing events. The primary focus of this assessment was to ascertain the usefulness of the data outputs for algorithms to achieve passive, autonomous documentation based on the defined data output specifications (Textbox 1). While the preponderance of this assessment was qualitative and presented in a narrative format, the overall data output quality from each sensor suite configuration was also quantitatively rated. This rating used a 3-point scale, where a "2" indicated that the data quality satisfied the requirements, a "1" meant the data quality required additional clarification to determine minimal viability, and a "0" signified that the data quality did not meet the minimum viability required.

The scoring process was designed to minimize the risk of overestimating performance or outcomes. By employing stringent criteria and favoring lower or more cautious scores when uncertainty existed, the process ensured that only clear evidence of achievement or competency was rewarded with higher marks. Ambiguous, incomplete, or borderline cases were typically scored on the lower end of the scale, reducing the likelihood of inflating results. Additionally, the use of standardized rubrics and, where applicable, multiple reviewers further contributed to the conservative nature by encouraging consistency and discouraging leniency. This approach ultimately provided a more reliable and defensible assessment, emphasizing accuracy and restraint over optimism or assumption.

Phase 3: Sensor Suite Rodeo Simulation Event

To directly compare each sensor suite configuration, the team conducted a "sensor suite rodeo" simulation event in March 2025 (Figure 4). The rodeo event was conducted using 3 different environmental venues (outdoor or full sun, indoor or full lighting, and low-light conditions). The assessment team collected data within each setting, which had 9 discrete clinical TCCC skills [13] using both live actions and manikins (Table 4). End user feedback was collected after each simulation through the same quantitative and qualitative survey instruments used in the simulated use assessment (eg, phase 2).

Figure 4. Sensor suite rodeo simulation event.

XSL•FO
RenderX

Table . Sensor suite rodeo simulation event summary.

Lighting conditions	Clinical TCCC[a] skills performed	Casualty type
Outdoor or full sun	• Chest needle decompression • Apply pressure dressing to open extremity fracture • Apply chest seal	• Manikin • Live actor with moulage • Live actor with moulage
Indoor full lighting	• Nasopharyngeal airway placement • Start intravenous line • Medication administration	• Manikin • Live actor (no moulage) • Live actor with moulage
Low-light conditions	• Cricothyrotomy • Tourniquet placement • Pelvic binder placement	• Manikin • Live actor with moulage • Live actor without moulage

[a]TCCC: tactical combat casualty care.

Ethical Considerations

Institutional Review Board or Ethics Board Approval

This protocol was reviewed and approved by the United States Army Medical Research and Development Command Institutional Review Board Office, which included human participants' ethics review. The approved protocol (#M-11057) was classified as minimal risk to human participants and undergoes annual continuing reviews by the Institutional Review Board Office to ensure the safety and ethical considerations of research on all human participants in our research.

Informed Consent

Prior to conducting simulation scenarios, individual participants were provided with a consent form. This form explained the activities, potential risks, and data collection that the principal investigator would like to conduct. If the participant agrees to participate, they are asked to sign the consent form, either in hard copy or electronically.

Privacy and Confidentiality

All simulation participants (eg, care providers and simulated patients) are assigned a participant ID to be associated with collected demographics, video, and physiological signal recordings. All data are stored in Department of War (DoW)–compliant and Health Insurance Portability and Accountability Act–compliant safety and security compliant e-storage facilities. All hard copy documents, including completed consent forms, are stored in locked filing cabinets at the USAISR. Following data collection sessions, all recordings are checked to ensure that any nonconsented individual's identifiable information was not recorded. If any inadvertent recordings were made, the principal investigator or a study team member deleted these segments of recordings. All recordings are stored securely in DoW-approved, USAISR-maintained server or repository, including a network attached storage at Fort Detrick, Maryland. Additionally, photo release waivers for image use in nonresearch activities also accompany the consent forms at the start of participation but are entirely optional for participation in the study.

Compensation Details

Military volunteers who meet the eligibility requirements and consent to participate in the study had the opportunity to participate in volunteer hours as a participation incentive. After completion of their participation in the study, the participant may request a letter of participation from the research team. The eligibility for volunteer hours toward service recognition will be determined by the units or offices who grant the volunteer hours. The research team will provide the letter of participation in an electronic format to the participant's email address. This process will be mirrored at all data collection locations. There are no monetary incentives or compensation for this research effort for volunteers.

Results

During the first phase of the assessment (eg, the tabletop evaluations), all 3 prototype sensor suite solutions demonstrated acceptable results (scores >1) during the technical specification assessment. The ACME and PoTAg sensor suites received the maximum possible scores for specific technical specifications. The ACME configuration stood out for its intuitive form factor, and the PoTAg prototype received distinction for its power requirements, data capture and storage, and device flexibility, as noted in Table 5.

XSL•FO
RenderX

Table . Results of sensor suite system wide technical specifications assessment[a].

Technical specification	M-WAVE[b]	ACME[c]	PoTAg[d]
	Average score	Average score	Average score
Form factor	1.7	2.0	1.8
Power requirements	1.7	1.8	2
Interface	1.50	1.6	1.3
Data capture and storage	1.8	1.6	2
Device flexibility	1.8	1.8	2
Data transfer	1.8	1.8	1.8

[a]The evaluation used a 3-point scale (0=lowest and 2=highest) for scoring each attribute where a score of >1 is considered acceptable or passing. Two research team evaluators conducted this tabletop assessment separately; their individual scores were averaged.

[b]M-WAVE: Medical Wearable Audio Video Entry.

[c]ACME: Autonomous Communication Medical Ecosystem.

[d]PoTAg: Point of Treatment Aggregator.

The results of the 2-part, tabletop-based heuristics analysis revealed variability, where the least complex configuration (ACME) received the highest assessment scores from the research team (Table 6). To capture and record raw data, the quantitative assessment results ranged from 44.6 (M-WAVE) to 87 (ACME) on a 100-point scale. To offload and export the raw data, the scoring ranged from 22.9 (M-WAVE) to 87.5 (ACME) on a 100-point scale.

Table . Results of heuristic analysis[a].

Heuristic analysis criteria	M-WAVE[b]	ACME[c]	PoTAg[d]
Task 1: Capture or record data score	44.9	87	67.5
Task 2: Offload or export data score	22.9	87.5	75

[a]Due to the varied number of sensor suite components, scores were adjusted to a 100-point scale (0=lowest and 100=highest). Two research team evaluators conducted this tabletop assessment separately; their individual scores were averaged.

[b]M-WAVE: Medical Wearable Audio Video Entry.

[c]ACME: Autonomous Communication Medical Ecosystem.

[d]PoTAg: Point of Treatment Aggregator.

During the second phase of the assessment (eg, simulated use testing), the quantitative assessment portion resulted in SUS scores for each sensor suite prototype. The M-WAVE configuration total score was 85, the ACME SUS score was 60, and the PoTAg total score was 80. While all 3 suites received passing scores (>60), it is noteworthy that the M-WAVE prototype, which had the lowest phase 1 assessment scores, received the highest usability scores from the TCCC provider end users.

During simulated user testing, all 3 sensor suites achieved passing quantitative scores (>60); the system usability scores (SUS) ranged from 60 to 85 on a 100-point scale. The more complex technology configurations (M-WAVE and PoTAg) received higher usability scores from the TCCC provider end users.

The qualitative assessment inputs from the simulated use testing were organized thematically by sensor suite prototype, as shown in Textbox 3. M-WAVE vital sign monitor latency display issues led to reliability concerns. Additionally, the NFC tags associated with the ACME prototype required active engagement by the TCCC provider, which did not align with the overarching passive data collection objective.

XSL•FO
RenderX

Textbox 3. Simulated use testing: qualitative thematic analysis. Thematic qualitative input was provided by 2 tactical combat casualty care (TCCC) providers.

Medical Wearable Audio Video Entry

- Participants found that the use of the Medical Wearable Audio Video Entry sensor suite did not encumber the care delivery process.
- One participant noted the bulkiness of the MindRove electromyography armband component, specifically that it would make it hard to roll up their operational camouflage pattern sleeves when required.
- With respect to the Vivalink Pulse Oximeter, it was noted that there was a delay in displaying the patient vital signs and pairing with the rest of the sensor suite system.

Autonomous Communication Medical Ecosystem

- Participants found the use of the Autonomous Communication Medical Ecosystem sensor suite was easy to use.
- Participants specifically noted that the near-field communication tags interfered with the care delivery workflow and were cumbersome to use.
- One participant stated they failed to scan the near-field communication tags in more than one instance during the simulation events.

Point of Treatment Aggregator

- The MOHOC M2 camera and Sennheiser Lapel microphone were unobtrusive, and the hard-wired connections from these components did not get in the way of the care provider or medic actions.
- Participants found that the sensor suite did not interfere with care delivery progress.

The data quality assessment portion revealed that all 3 prototypes successfully generated raw data outputs in file formats that were compliant with the sensor suite specifications (Textbox 1). However, the raw data generated by the 3 sensor suite configurations varied significantly in terms of gigabytes/minute (Table 7). The M-WAVE configuration generated 0.06 GB/minute of raw data outputs, the PoTAg prototype generated 0.1 GB/minute, and the ACME sensor suite generated 0.13 GB/minute. In disconnected, denied, intermittent, and limited operational environments, where synchronous cloud-based connectivity is not an option, the ability to locally process the raw sensor data efficiently is a priority, so maximum data efficiencies are desired (eg, lower amounts of data per minute). The M-WAVE sensor suite prototype demonstrated the most promise, but all 3 prototypes will require additional refinement to streamline the raw data outputs to rates that are more suitable for processing by local edge compute devices in TCCC environments in the future.

Table . Simulated use testing: data file sizes.

Sensor suite	GB/min
M-WAVE[a]	0.06
ACME[b]	0.13
PoTAg[c]	0.10

[a]M-WAVE: medical wearable audio video entry.

[b]ACME: autonomous communication medical ecosystem.

[c]PoTAg: point of treatment aggregator.

Additionally, the evaluation team noted specific quality constraints about the data generated by all 3 initial prototypes (Textbox 4). The M-WAVE camera had the most flexibility in terms of lighting conditions, but the mounting on the TCCC provider had to be refined to a helmet-mounted position from the chest to ensure appropriate field of view. The Movella Dot IMU sensors leveraged by both the ACME and PoTAg prototypes generated concerns about data file sizes and reliability. Finally, the cabling associated with the PoTAg microphone was prone to disconnection, making data outputs unreliable.

XSL•FO
RenderX

Textbox 4. Simulated use testing—data quality assessment: qualitative thematic analysis. Thematic qualitative input was provided by 2 members of the research team.

Medical Wearable Audio Video Entry

- The PatrolEyes visible or near-infrared camera automatically transitions between the modes based on lighting conditions (visible vs near-infrared).
- When the camera was affixed to the chest (as intended by the performer), it provided a narrow field of view that did not align with the care provider or medic's line of sight, which impacts the quality of the video data generated, which in turn could impact future algorithm detection performance.

Autonomous Communication Medical Ecosystem

- The right and left Movella Dot inertial measurement unit (IMU) sensor data are not collected simultaneously into a single data output file as expected; instead, the system generates 2 separate data (.csv format) files. As a result, it is possible to have a slight data differential (milliseconds) between the right and left IMU data files during data collection. The origins of this potential data discrepancy would need to be further explored in future assessments to fully appreciate the impact.

Point of Treatment Aggregator

- During the tactical combat casualty care simulations, one of the Movella Dot sensor components consistently disconnected, and as a result, no IMU activity data for that sensor were generated during that data collection event.
- In one collection event, the hard-wired audio connection from the microphone to the end user device disconnected, resulting in a loss of data.

The third phase of the assessment (eg, sensor suite rodeo simulation assessment) resulted in quantitative, qualitative, and data quality assessments. The sensor suite rodeo was the first opportunity to assess the performance of each prototype sensor suite in a range of operational environmental conditions, rather than a fixed laboratory environment.

The quantitative assessment portion resulted in separate SUS calculated scores for each sensor suite prototype, with all receiving passing scores (>60). M-WAVE had a total SUS score of 86.67. ACME's SUS score was 66.67, and the PoTAg received a score of 76.67.

The SUS scores ranged from 66.7 to 86.7 on a 100-point scale. The M-WAVE sensor suite prototype received the highest usability scores from the TCCC provider end users, mirroring the results from the phase 2 simulated use testing.

The qualitative assessment inputs of the sensor suite rodeo simulated use testing were organized thematically by sensor suite prototype and further stratified based on simulation participant (TCCC provider) and researcher inputs as shown in (Textboxes 5 and 6), respectively. From the simulation participant perspective, the M-WAVE prototype was noted to have latency issues with its vital sign monitor component, and the electromyography armband required acclimation by the simulation end users.

Textbox 5. Sensor suite rodeo simulation qualitative assessment: simulation participant thematic analysis. Thematic qualitative input was provided by 3 simulation participant evaluators or tactical combat casualty care (TCCC) providers.

Medical Wearable Audio Video Entry

- Medical Wearable Audio Video Entry sensor suite was easy to use and did not hinder care
- Vivalink SpO2 data latency on reduced confidence in accuracy
- MindRove electromyography armband and NVIDIA edge computing device felt bulky at first but were not distracting during use

Autonomous Communication Medical Ecosystem

- Autonomous Communication Medical Ecosystem sensor suite was easy to use and did not hinder care
- GoPro and Masimo interfaces were familiar to users

Point of Treatment Aggregator

- Point of Treatment Aggregator sensor suite was easy to use and did not hinder care
- Audio or video components and wired connections did not interfere with care

XSL•FO
RenderX

Textbox 6. Sensor suite rodeo simulation qualitative assessment: researcher thematic analysis. Thematic qualitative input was provided by 4 research team members.

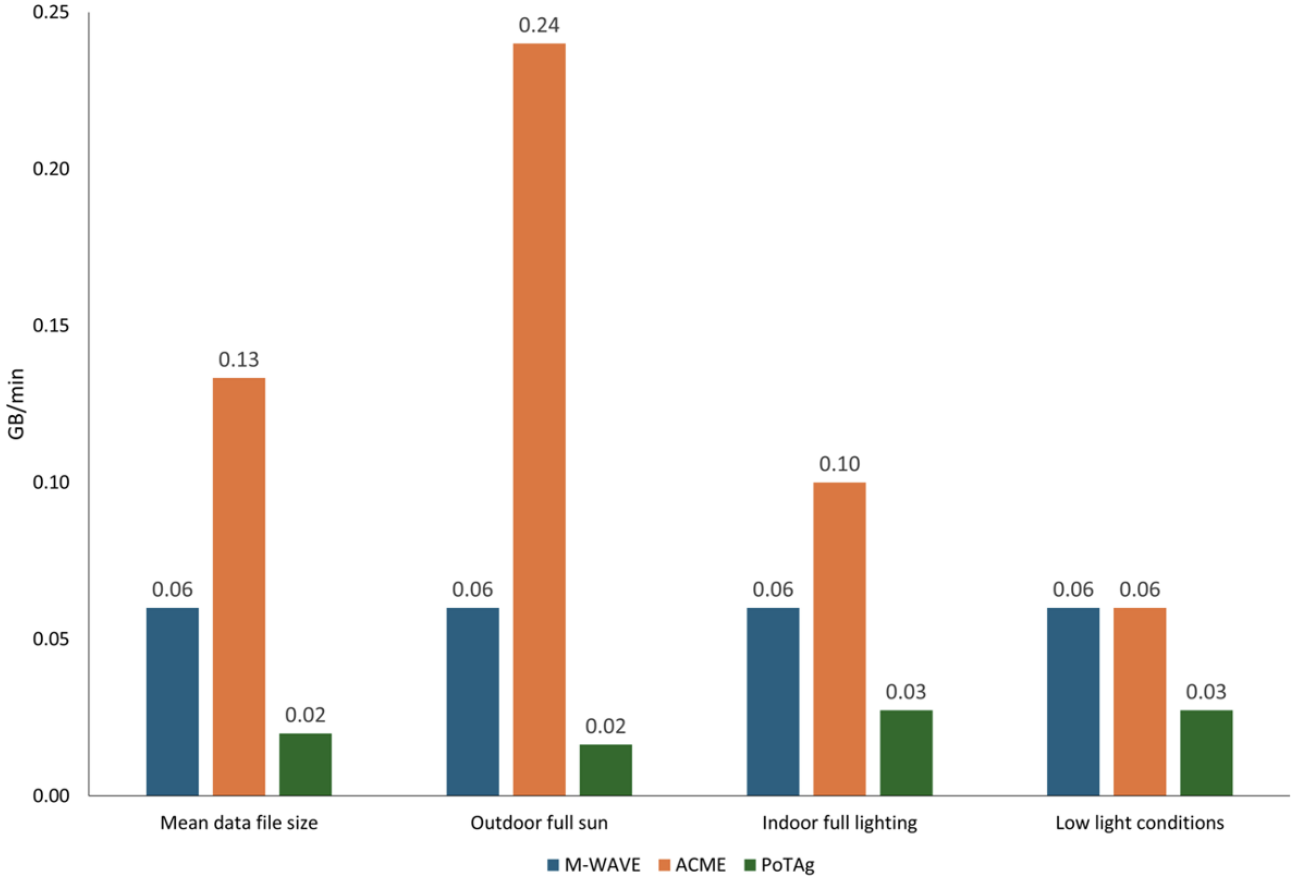
Medical Wearable Audio Video Entry

- Medical Wearable Audio Video Entry (M-WAVE) setup is cumbersome and requires components to sync in a specific order
- The M-WAVE app has limited functions, lacks troubleshooting options, and does not clearly show setup status
- Large video files do not auto-transfer, and M-WAVE does not notify users of failed transfers
- M-WAVE file naming makes offloading multiple events tedious and risks data errors
- Offloading less than 5 GB of data from the edge computing device requires third-party software

Autonomous Communication Medical Ecosystem

- Autonomous Communication Medical Ecosystem app was simple and showed clear component statuses
- Movella Dot inertial measurement unit setup with end user device was streamlined
- Pairing Masimo sensor required toggling Bluetooth, or vital sign monitor data were lost

Point of Treatment Aggregator



- No setup issues with the Point of Treatment Aggregator were noted by the research team
- Sennheiser microphone mini-jack connection to the tablet was unreliable due to its proprietary plug

The researchers conducting assessments of the prototypes noted concerns with the complexity and reliability of the raw data transfers with the M-WAVE prototype, pairing issues with the ACME components, and the vulnerability of hardwired connections on the PoTAg configurations (Textbox 6).

With respect to the data quality assessment, all 3 sensor suite prototypes were able to generate raw data outputs successfully during the sensor suite rodeo simulation event. The sensor suite data outputs varied (ranging from 0.012 to 0.24 GB/min) based on the environmental lighting conditions (full sun, indoor lighting, and low light), as shown in Figure 5. The M-WAVE prototype generated data at consistent rates regardless of lighting conditions. The PoTAg configuration provided the lowest (most desirable) raw data outputs, even with variability in different lighting conditions. However, from a data quality perspective, only 1 camera component, the visible or near infrared (NIR) camera leveraged by the M-WAVE configuration produced viable video data in all 3 environments.

XSL•FO
RenderX

Figure 5. Sensor suite rodeo simulation: data file sizes (GB/min). ACME: Autonomous Communication Medical Ecosystem; M-WAVE: Medical Wearable Audio Video Entry; PoTAg: Point of Treatment Aggregator.

The evaluation team noted specific data quality constraints, which are highlighted in Textbox 7. The camera components leveraged by the ACME and PoTAg prototypes were not optimized for all lighting conditions, whereas the NIR or visible camera leveraged by the M-WAVE solution was ideally suited for all conditions that were assessed in this phase.

Textbox 7. Sensor suite rodeo: data quality assessment: qualitative thematic analysis. Thematic qualitative input was provided by 2 research team members.

Medical Wearable Audio Video Entry

- Helmet mounting improved video field of view and made camera adjustment easier. A preview feature before recording is recommended
- Medical Wearable Audio Video Entry video was consistently clear in all lighting conditions

Autonomous Communication Medical Ecosystem

- GoPro Hero 13 had poor video quality in low light due to reduced visibility

Point of Treatment Aggregator

- MOHOC M2 video was washed out in bright sunlight outdoors
- Sennheiser microphones' wired connection caused unreliable and incomplete audio data

Each of the 3 sensor suite systems assessed during these 3 phased evaluation processes had unique solutions with varying levels of complexity and performance, which directly impacted the results (Table 8). None of the sensor suites were fully optimized at this early stage of prototype development, and the systematic assessment of each configuration identified opportunities for improvement in future phases.

XSL•FO
RenderX

Table . Summary of sensor suite prototype strengths and weaknesses.

	M-WAVE[a]	ACME[b]	PoTAg[c]
Strengths	• PatrolEyes visible or NIR camera auto-switched modes • MindRove electromyography[d] armband outperformed other IMUs[f] • ECD[g] and EUD[h] worked well with files less than 1 GB • Sensor suite data were consistent in all conditions	• Simple setup • VSM[e] component was optimized • Only prototype tracking resource use	• Reliable prototype • Data were efficient but varied slightly by environment
Weaknesses	• No resource usage component • Vivalink ECG[i] Patch and Pulse Oximeter were hard to configure and had latency issues • ECD and EUD could not manage files less than 1 GB	• NFC[j] resource tracking was poorly received by users and was not passive • Camera struggled in low light conditions • Raw data generation was inefficient and inconsistent across environments	• Limited scope; lacked both VSM and resource usage component • The camera did not perform optimally in bright sunlight, impacting data quality • The directional nature of the Sennheiser Lapel microphone limited audio capture • Specific components required hard-wired connections to the EUD, making it vulnerable to disruptions during use

[i]ECG: electrocardiogram.

[j]NFC: near field communication.

Discussion

Principal Findings

This 3-part methodology (Figure 1) demonstrated the value of employing a systematic methodology for technology assessments, including, but not limited to, future advanced development of sensor suite prototypes. This discovery-based research approach, including tabletop exercises and systematic technological evaluations, serves as a critical precursor to more formal, controlled studies; it narrows down the vast field of possibilities to a manageable number of promising avenues for further investigation.

While the resulting data from this initial assessment do not yield large enough sample sizes to be assessed for statistical significance, the mixed methods approach is repeatable from both a quantitative and qualitative perspective and can be implemented at a larger scale for more mature technology prototypes.

There are several limitations to the findings of this initial, early-stage prototype assessment. These constraints are expected at this early stage of the prototype development process, as the continuum of technology refinements is intended to be a multiphase, Agile development process [14].

The first limitation was the lack of a prototype solution that was effective in providing passive tracking of the use of consumable medical supplies at the POC. This is an unmet need based on the results of this initial assessment. Future solutions may be dependent upon computer vision algorithms, where tactical cameras can detect consumable medical supplies (eg, tourniquets, blood products) using AI resources, but this assumption will need to be tested and proven in the future phases.

A second confounder is that the data quality assessments performed during this initial assessment were constrained to raw data outputs from the individual components. The initial raw data outputs will require efficiencies to be of future value. Furthermore, providing a complete data assessment requires a systematic evaluation of the edge computing component's ability to process AI algorithms in disconnected, denied, intermittent, and limited environments and generate orchestrated and consolidated data outputs. This could not be addressed in this evaluation because the AI algorithms were under development. Future, final data outputs will also need to be assessed for their

XSL•FO
RenderX

potential to be exported to patient record systems (eg, Battlefield Assisted Trauma Distributed Observation Kit, Operational Medicine Information Systems–Army) and Command and Control systems (eg, MAVIN smart system et al.) in an interoperable fashion to achieve the overarching, autonomous documentation objectives.

Additionally, the results of this assessment are limited with respect to the sensor suite prototypes' abilities to manage multiple patients or casualties at the POC in mass casualty environments.

Finally, mature sensor suite systems will need to be hardened for the operational environment (eg, ruggedized) and will consider the constraints of cyber and electronic warfare risks. Cyber and electronic warfare protections ensure that future sensor suite technologies for use in TCCC environments do not place service members on the battlefield at risk by generating electronic signatures that can be detected by adversaries. Follow-on development and cyber-specific assessments will be required to address these issues.

Conclusions

The systematic, 3-part methodology leveraged to evaluate the initial, early-stage sensor suite prototypes is a reproducible process to determine the direction of advanced battlefield medical technology capabilities. The outcomes of this initial comparative assessment revealed opportunities to blend the strengths of each sensor suite prototype approach into a next-generation implementation.

Based on the quantitative results of the tabletop assessment, the form factor of the ACME prototype and the size, weight, and power and data management approaches leveraged by the PoTAg solution should be modeled in future research. The quantitative data from the phase 2 and 3 assessments demonstrate that the M-WAVE configuration was favored by the end users with respect to overall system usability. The raw data output measurements revealed that the M-WAVE provided the most consistent data in all environments, but the PoTAg provided the greatest data efficiencies. All thematic, quantitative data will be leveraged to drive the next generation of sensor suite prototypes.

Further refinement of the prototype sensor suites will adopt a best-of-breed collaborative approach, leveraging the superior components identified in this assessment from both a quantitative and qualitative perspective into a next-generation unified system. There are several notable commercial-off-the-shelf components recommended to be advanced as best-of-breed candidates: the PatrolEyes visible or NIR camera, the Masimo Pulse Oximeter, and the MindRove EMG armband.

This systematic evaluation process is a critical step in determining the shape and direction of future medical capabilities on the battlefield. Technologies inserted into military medicine must improve battlefield health care, making it more effective without compromising the quality of care. To that end, the Institute of Surgical Research is committed to providing fair and unbiased assessments of prototype capabilities, which align with key Defense Health Agency and DoW tenets.

Acknowledgments

This sensor suite evaluation was a collaborative, United States Army Institute of Surgical Research–wide effort led by members of the Medical Robotics and Autonomous Systems, Science and Technology Innovation Management and Synchronization, and Medical Modeling, Simulation, Information, and Visualization functional teams.

The following individuals are acknowledged for their direct and indirect support to this effort: Dr Omar Badawi, Ms LeNiqua Ballou, Mr Joe Barrick, SSG Lam Bui, Dr Jonathan Chambers, Mr Valmik Desai, Ms Alix Donnelly, MAJ Clarence Ducummon, Dr Dion Edwards, Ms Stephanie Edwards, Mr Evan Feuer, Mr Nate Fisher, Dr Stephanie Fonda, Ms Bethzaida Gonzalez-Lanham, Ms Ollie Gray, Mr Todd Hall, Ms Tina Hamrick, Ms Airi JungRhee, Mr Daniel Kalala, Ms Courtney Kentrus, Dr Ben Knisley, Ms Buffy Krall, Mr Zach Lattimore, Dr Jaeyeon Lee, Mr Carl Manemeit, Mr Larry Markins, LTC Rachel Morgans, Ms Moriah Newman, COL Jeremy Pamplin, Ms Yema Pizzuto, Ms Tiffany Quach, Mr Matt Quinn, Mr Ethan Quist, CPT Tamara Richardson, Mr Tyler Ring, Ms Triana Rivera-Nichols, Mr Jeff Robbins, Ms Kerri Root, COL Sharon Rosser, Taylor Somers, Mr Mark Spears, Mr Jesse Steffens, SPC Dustin Turner, Ms Ann Trout, Mr Nick Williams, and Mr Chevas Yeoman.

The authors did not use generative artificial intelligence tools to develop this manuscript. However, during the preparation of this work, the authors used the Grammarly tool to improve language and readability. Abstract

Background: Recent crises involving zoonotic diseases (Ebola, COVID-19, and Mpox) have highlighted the limitations of fragmented public health systems for the prevention and response to health emergencies at the international and continental level, and particularly in Africa, more specifically in the Democratic Republic of the Congo (DRC). In this context, the One Health (OH) approach and its extension, One Digital Health (ODH), articulated with the findable, accessible, interoperable, reusable (FAIR) principles, offer a framework for rethinking the digital transition in health in the DRC. This study analyzes the reality of this transition in Kinshasa, DRC, and questions the feasibility of ODH in this context.

Objective: This study aimed to (1) explore how stakeholders across human, animal, and environmental health sectors perceive and experience digital tool integration and data interoperability in Kinshasa; (2) identify structural, institutional, and technical constraints affecting cross-sectoral data sharing; and (3) analyze the sociotechnical conditions required for the operationalization of ODH in a fragmented digital health (DH) context.

Methods: A qualitative study was conducted in Kinshasa, DRC, between November 10, 2025, and November 25, 2025, combining semistructured interviews with key actors (health professionals, administrative officials, digital experts, and engaged citizens) and a document review of strategic and regulatory texts related to DH in the DRC. The data were analyzed using a thematic approach to identify the representations, uses, and constraints related to DH and the operationalization of ODH.

Results: Overall, 22 stakeholders participated (n=9, 40.9% human health; n=8, 36.4% animal health; n=4, 18.2% environmental health; n=1, 4.50% digital sector), predominantly male (n=15, 68.2%) and mainly in operational roles (n=12, 54.5%). Three interrelated topics emerged. First, a dual-track digital ecosystem characterized by the coexistence of formal platforms (eg, District Health Information Software 2 and electronic records) and informal tools (eg, WhatsApp [Meta]), with persistent paper-digital double-entry generating inefficiencies. Second, structural and governance bottlenecks, including electricity instability, limited connectivity, software incompatibility, external data-hosting concerns that affect sovereignty, and institutional silos that privilege human health over animal and environmental sectors. Third, prerequisites for operationalizing ODH emphasize foundational infrastructure (energy and internet), sustainable capacity building beyond one-off training, interoperable “bridges” between fragmented systems, and high-level political leadership. These elements were synthesized into an ODH-FAIR DRC conceptual model structured around three enabling pillars linking sectors for integrated zoonotic surveillance.

XSL•FO
RenderX

Conclusions: Operationalizing ODH in DRC requires addressing foundational enablers beyond tools: synchronized energy-digital policies, decompartmentalized governance, and context-adapted capacity building. These insights inform low- and middle-income countries' DH strategies, urging donors and ministries to prioritize interoperability over isolated pilots to achieve sustainable zoonotic surveillance.

(JMIR Med Inform 2026;14:e93321) doi:10.2196/93321

KEYWORDS

One Digital Health; One Health; FAIR principles; digital health; data interoperability; data governance; zoonotic disease surveillance; qualitative research; Democratic Republic of Congo; lower-middle-income country

Introduction

Background

In recent decades, we have seen a notable increase in emerging and reemerging diseases, such as the West and Central Africa Ebola outbreak (2014-2016) [1], the COVID-19 pandemic (2019-2023) [2], and Mpox epidemics (2022-2026) [3]. Emerging and reemerging infectious diseases, largely of zoonotic origin, are now a growing threat to health systems, particularly in low- and middle-income countries (LMICs) [1-3]. These dynamics are reinforced by environmental, climatic, and urban transformations, which complicate interactions between ecosystems and human and animal populations [4,5]. In this context, the One Health (OH) approach has emerged as a strategic framework to promote integrated cross-sectoral and multisectoral action to optimize human, animal, and environmental health [6,7].

At the same time, digital health (DH) strengthens health systems, improves surveillance, supports decision-making, and contributes to universal health coverage goals [8,9]. However, in sub-Saharan Africa, DH remains fragmented, with isolated and unsustainable initiatives [10-12]. Several studies have shown that the introduction of digital tools, when not accompanied by solid governance and a systemic vision, can lead to "e-chaos" rather than to a real strengthening of health systems [11]. Nevertheless, despite these developments, the interactions between fragmented DH systems and the multidimensional and multisectoral ambitions of OH remain insufficiently explored.

In this context, One Digital Health (ODH) extends OH by linking digital technologies, data governance, and cross-sector collaboration to support integrated health action [13-15]. ODH is based on three interconnected digital spheres (health at the individual level, population-based, and environmental issues), as well as on five cross-cutting areas focused on uses: (1) education, (2) civic engagement, (3) environmental monitoring, (4) health of humans and animals as a whole, and (5) standardization, interoperability, and digitalization. On the other hand, ODH advocates for and encourages the development and implementation of data governance based on the findable, accessible, interoperable, reusable (FAIR) principles [16,17]. This approach aims to go beyond simple sectoral digitalization to build digital ecosystems that support interdisciplinary collaboration and the production of transversal knowledge.

In the Democratic Republic of the Congo (DRC), issues related to DH and the OH approach are explicitly recognized in several national strategic frameworks, including the National Health Information Systems Development Plan (PNDIS II) [18], DHIS2 (District Health Information Software 2) initiatives [19], as well as the overall orientations of the National Strategic Development Plan [20]. However, existing studies highlight that health information systems remain poorly interoperable, insufficiently integrated across sectors, and highly dependent on external technical solutions [21,22].

Recent years have also been marked by growing digitalization efforts across multiple sectors in the DRC. Particularly, in the human health sector, the Integrated Disease Surveillance and Response 3rd edition (IDSR; in French, "Surveillance Intégrée de la Maladie et Riposte") [23] explicitly promotes the use of digital tools for surveillance and reporting. In the environmental sector, initiatives led by the Ministry of Environment and the Congolese Institute for Nature Conservation (ICCN; in French, "Institut Congolais pour la Conservation de la Nature"), often implemented with international technical and financial support, aim to strengthen environmental monitoring and data management. In animal health, the Integrated Animal Disease Surveillance and Response (IADSR; in French, "Surveillance Intégrée des Maladies Animales et Riposte") framework similarly supports digital approaches for disease surveillance [24]. However, important challenges persist in translating these initiatives into routine operational practice to mitigate the remaining visible fragmentation within sectors (intrasectoral interoperability) and across sectors (intersectoral interoperability), limiting integrated digital governance.

In addition, the local context of a low-income country with a gross domestic product (GDP) per capita of US $649.40 [25] is characterized by significant structural constraints, including an unstable electricity supply, poor internet connectivity, and uneven penetration of digital technologies, especially outside major urban centers [26]. Human and organizational challenges, such as low digital literacy, reinforce these infrastructural limitations [27], resistance to technological change [28], and concerns about data security and sovereignty [15,17].

Although the DRC has significant experience implementing the OH approach, particularly in managing zoonoses and health emergencies [29], few studies have empirically explored the relationship between OH and DH from an integrated perspective. In particular, there is a lack of qualitative data on how actors perceive digital tools, their daily use, the institutional conditions for their adoption, and the obstacles to operationalizing an ODH approach in the DRC context.

While DH in the human health sector has been relatively well documented in DRC, much less is known about digital practices,

XSL•FO
RenderX

constraints, and expectations that align or diverge across the animal and environmental health sectors. In this regard, ODH should not be understood as a simple extension of existing human DH systems, but rather as a multisectoral framework that highlights systemic fragmentation and coordination challenges across sectors. However, empirical evidence on how such integration is perceived and operationalized in real-world low-resource settings remains limited.

Aims, Objectives, and Goals

The primary aim of this study was to explore how stakeholders across human, animal, and environmental sectors perceive and experience the integration of digital tools in the DRC context.

Specifically, the study objectives were to (1) examine how digital practices and constraints differ or align across sectors; (2) identify structural, institutional, and technical barriers to cross-sectoral interoperability; and (3) analyze the sociotechnical conditions required for the operationalization of ODH in a fragmented DH environment.

By using a qualitative methodology comprising semistructured interviews and a targeted literature review anchored in the ODH conceptual framework, our main goal was to develop a contextualized understanding of the challenges inherent in integrated DH [13,15].

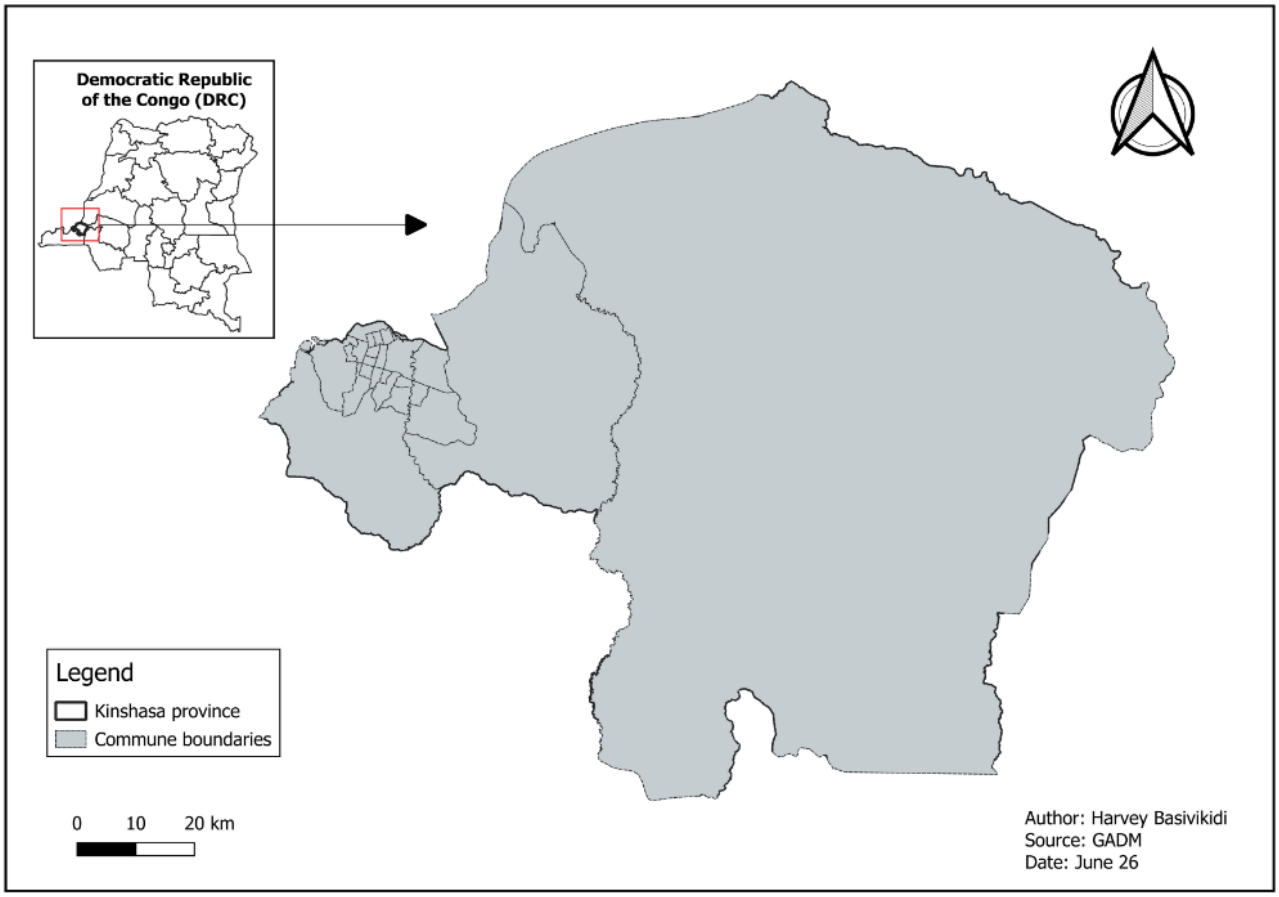
This study does not presuppose ODH's success; rather, it seeks to identify the enabling conditions and barriers that will determine whether such a framework can be meaningfully operationalized in a low-resource, multisectoral context. Ultimately, the overarching goal of this work was to provide a robust empirical evidence base to inform public policies and enhance data governance, thereby promoting the development of more coherent, sustainable, and equitable DH ecosystems in LMICs, with a specific focus on the needs of sub-Saharan Africa. The main research question was: "How do key stakeholders across human, animal, environmental, and digital sectors in Kinshasa perceive and use DH tools, and what conditions do they identify as necessary to operationalize ODH and FAIR data principles?"

Methods

Study Type

We used an exploratory qualitative design to examine stakeholder perceptions of digital tools, cross-sector collaboration, and data governance [30].

Scope of the Study



The study took place in Kinshasa, the capital of the DRC, which serves as the country's primary digital hub. The city accounts for approximately 40% of the national telecommunications market and has an estimated mobile penetration rate of 126% and a mobile internet access rate of 63.9% [26]. However, this apparent hyper-connectivity hides a more fragile reality, marked by network instability, reliance on multiple network operators to ensure adequate coverage for effective communication, and persistent energy limitations.

Figure 1 provides a general overview of the study setting in Kinshasa.

At the institutional level, the DH ecosystem is characterized by a coexistence of sector initiatives that lack interoperability, limiting the seamless circulation of data and the development of an integrated vision of health [21,22].

XSL•FO
RenderX

Figure 1. Geographic location of the study setting in Kinshasa, Democratic Republic of Congo. The map shows Kinshasa Province and its commune boundaries, with the inset map indicating its location within the Democratic Republic of Congo.

Study Population and Sampling

Target Population

The target population consisted of professionals in Kinshasa working in the human, animal, environmental, and DH sectors who were involved in the use, management, production, or circulation of digital data and tools. Inclusion and exclusion criteria are given in Textbox 1.

Textbox 1. Inclusion and exclusion criteria.

Participants included in the study were those who:

- Worked in one of the health sectors (human, animal, and environmental) or in the digital field.
- Had varying levels of experience in the use, management, or production of data or digital tools.
- They were primarily involved in operational, coordination, or mid-level management and planning functions within their respective areas.
- Provided free and informed consent for their participation in the study.

Excluded from the study were:

- Individuals who were no longer engaged in professional activity at the time of the study.
- Persons who refused to participate or consent to the interview.

Sampling

Purposive sampling was used for the relevance of the information [31]. The diversification of the sample was based on three dimensions:

1. The sector of activity (human, animal, environmental, or DH). The participant from the DH sector was included primarily to provide technical insights on digital infrastructure and interoperability. The other sectors were prioritized as they represent the main population responsible for implementing the ODH framework in the DRC.
2. The institutional level (central, operational, and community).
3. The type of role (coordination, management, and operational).

XSL•FO
RenderX

The sampling strategy intentionally prioritized stakeholders involved in operational and mid-level coordination roles. This choice was motivated by the study's objective to capture real-world practices, constraints, and day-to-day interactions with digital tools across sectors. Operational actors are directly exposed to interoperability challenges, infrastructural limitations, and practical implementation barriers, making them key informants for assessing the feasibility of ODH in context. While some participants held coordination or management roles, the study did not specifically aim to represent high-level strategic decision-makers.

The deliberate exclusion of high-level strategic actors from the inclusion criteria reflects the study's focus on operational implementation dynamics rather than policy design. This choice was motivated by the need to document a systematically underrepresented perspective in the ODH literature, while recognizing that governance-level voices are essential for a complete understanding of ODH feasibility and will be prioritized in future research.

Data Collection

Semistructured interviews were conducted between 10 and 25 November 2025. They were guided by five thematic axes aligned with the study objectives: participants' institutional role within the OH framework, perceptions of digital maturity and strategic vision of digital tools, current operational digital practices, perceived technical, human, and institutional barriers to interoperability, and perspectives on the feasibility of implementing ODH in the Congolese context.

Interviews lasted up to 45 minutes and were conducted in person or via Zoom [32] depending on participant availability [33].

Interviews were conducted in French, with clarifications in Lingala (a DRC *lingua franca*) when needed. Coding and interpretation were also conducted in French, and selected excerpts were translated into English for reporting. Key medical informatics and DH terminology were harmonized using the Medical Informatics and Digital Health Multilingual Ontology (MIMO) [34] to ensure consistency across interviews. MIMO was applied to map participant expressions to standardized DH and OH terms, improving the accuracy of thematic coding and enabling cross-sector comparability. Audio recordings were made and accurately transcribed. If recording was declined, detailed notes were taken with prior consent. All data were securely stored on a protected hard drive to ensure confidentiality and integrity.

The interview guide was adapted according to participants' institutional level (central, operational, and community) to ensure contextual relevance. Before data collection, the guides were pretested with a small group of professionals from similar backgrounds to refine clarity and flow. All interviews were conducted by only one interviewer, ensuring consistency in data collection. Regular debriefing and iterative adjustments of probing techniques were used to maintain coherence across interviews and reduce interviewer variability.

Targeted Document Review

A nonsystematic literature review complemented the interviews, contextualizing the policy and institutional frameworks. It focused on:

1. The National Plan for the Development of Health Information Systems (called PNDIS II) [18],
2. The National Digital Plan [35],
3. The National Strategic Development Plan 2024-2028 [20],
4. The One Health Strategic Plan 2022-2027 [36],
5. The IDSR 3 [23] and IADSR [24] guides.

The selected documents met all the following criteria:

1. Published by Congolese public institutions,
2. Published between 2018 and 2025,
3. Available in French and with official access.

Data Analysis

The data were analyzed by an inductive thematic analysis inspired by Braun and Clarke [37] and Miles and Huberman [38]. Braun and Clarke's framework guided the identification and interpretation of recurring topics across interviews through a six-step process, from familiarization to topic definition. Miles and Huberman's approach provided practical tools for coding, data reduction, and cross-case comparison, including matrices to visualize patterns and relationships. By combining these frameworks, we ensured both interpretative depth and structured organization of qualitative data. The transcripts were imported into NVivo 15 (Lumivero) for encoding [39].

The transcripts were analyzed in their original language (French), which was also the primary language of the interviews. English was used only at the manuscript writing stage, where selected excerpts were translated for reporting purposes.

Saturation was assessed iteratively throughout data collection. After each interview, the coding structure was reviewed for emergent themes. Saturation was considered achieved when no new codes emerged over three successive interviews and when existing thematic categories were sufficiently dense and consistent across sectors and institutional levels.

The analysis was processed following six steps:

1. An initial phase of in-depth familiarization with the interview transcripts.
2. Open coding to identify 46 initial codes.
3. Development of a preliminary codebook: classification of the 46 keywords (of step 2) into intermediate categories.
4. Axial coding: Initial categories from open coding were grouped and linked to form broader topics, enabling the identification of patterns and relationships among concepts for a structured understanding of the data.
5. Structuring the codes into seven families: perceptions, digital practices, obstacles, data governance and FAIR, OH collaboration, opportunities, and recommendations.
6. Synthesis of the findings into three major topics directly related to the research objectives.

The "Technology Acceptance Model" (TAM) [40] and the "Unified Theory of Acceptance and Use of Technology" (UTAUT) [28] frameworks were used to guide coding and

XSL•FO
RenderX

interpretation of participants' attitudes toward digital tools. TAM helped contextualize perceived usefulness and ease of use, while UTAUT constructs such as performance expectancy and social influence explained patterns like anxiety or reluctance. These frameworks informed coding without constraining the inductive approach, capturing both expected and emergent factors affecting technology adoption.

Quality Assurance and Validation

To ensure the integrity and rigor of the analytical process, we used several validation measures. Methodological triangulation was achieved by cross-referencing interview data with strategic documents, providing a multifaceted perspective on the research phenomenon. The analysis used a systematic, iterative coding approach across 3 distinct cycles to ensure thematic consistency.

To maintain transparency and accountability, a comprehensive audit trail was preserved through Excel matrices and NVivo exports. Furthermore, providing a thick description of the research context and participant profiles enhances the credibility, dependability, and transferability of the findings [41]. Finally, the study adheres to the COREQ (Consolidated Criteria for Reporting Qualitative Research) guidelines to ensure standardized and transparent reporting (Multimedia Appendix 1) [42].

Reflexivity was considered throughout the research process. The research team brings together complementary disciplinary backgrounds spanning global health, biomedical and health informatics, DH, epidemiology, OH, and ODH [13]. Team members have a local and international understanding of these research challenges. This interdisciplinary, international, and cross-institutional composition was treated as an analytical asset, enabling multiple interpretive lenses to be brought to bear on the data. At the same time, the team remained attentive to how prior expertise, particularly in OH frameworks, DH governance, and FAIR data principles, may have shaped the framing of research questions, the interpretation of findings, and the proposed conceptual model. To mitigate such risks, analytical decisions were documented systematically, coding processes were discussed iteratively across the team, and a deliberate effort was made to foreground participant voices in the presentation of results rather than prematurely mapping findings onto existing theoretical constructs.

Ethical Considerations

The protocol has been approved by the National Committee on Health Ethics (N°725/CNES/BN/PMMF/2025). Participation was voluntary. Oral or written informed consent was obtained before each interview. Anonymity and confidentiality are guaranteed through alphanumeric codes and secure data storage.

Results

Overview

Inductive thematic analysis identified three main topics:

1. Perceptions and representations of DH technology.
2. Conditions, constraints, and structural factors influencing digitalization and interoperability.
3. The necessary conditions for the operational implementation of an ODH approach integrating the FAIR principles.

Characteristics of the Participants

The study included 22 participants from the human, animal, environmental, and DH sectors in Kinshasa, DRC. Participants were recruited purposively; initial contacts were identified among key professionals, who then facilitated introductions to additional relevant stakeholders. Interviews were scheduled based on participants' availability and conducted directly by a qualified researcher (HB), enabling engagement across different roles while maintaining independence.

The majority of participants came from human health (n=9, 40.9%) and animal health (n=8, 36.4%), with fewer from environmental health (n=4, 18.2%) and a single DH expert (n=1, 4.50%). The inclusion of one digital expert was intended to provide specialized technical insights into digital systems and interoperability. In contrast, the remaining participants represented the primary users of DH tools. Participants were predominantly male (n=15, 68.2%) and mostly aged 35 to 49 (n=9, 40.9%), followed by those aged 34 and under (n=8, 36.4%) and those aged 50 and older (n=5, 22.7%).

From a role-type perspective, half of the participants were in operational positions (n=12, 54.5%), followed by 31.8% (n=7) at the central level and 13.7% (n=3) at the community level. All participants provided informed consent before the interviews (Table 1). The imbalance in sector representation, particularly the inclusion of only an ODH expert, is acknowledged as a limitation. This participant was not intended to represent the broader community's adoption of ODH, but rather to provide specialized technical insights into digital systems and interoperability challenges.

XSL•FO
RenderX

Table 1. Socio-professional characteristics of the interviewees.

Variables	Participants (N=22), n (%)
Sex	
Male	15 (68.2)
Female	7 (31.8)
Age (years)	
35-49	9 (40.9)
≤34	8 (36.4)
≥50	5 (22.7)
Industry	
Human health	9 (40.9)
Animal health	8 (36.4)
Environmental health	4 (18.2)
Digital	1 (4.50)
Hierarchical level and type of role	
Central and decision-making actor	7 (31.8)
Operational and technical professional	12 (54.5)
Community and field actor	3 (13.7)

To better assess the functional and institutional diversity of the sample, a matrix was developed that cross-referenced the activity sector, the institutional level, and the hierarchical level and role type (Table 2). This matrix shows the intentional structuring of the population studied across three complementary dimensions. It highlights the joint presence of decision-making actors, technical professionals, and field actors, enabling documentation of digitalization and the OH approach at different levels of the system.

Thus, this study, therefore, focused on understanding perceptions, practices, and adoption among nondigital professionals, while the digital expert served to contextualize the technological environment.

The average interview duration was 29 minutes (SD 11 minutes and 20 seconds).

Table 2. Diversification matrix of participant profiles.

Hierarchical level and type of role	Animal health (n=8, 36.4%)	Environmental health (n=4, 18.2%)	Human health (n=9, 40.9%)	Digital (n=1, 4.50%)
Central and decision-making actor (n=7, 31.8%)	Coordinator (n=1, 12.5%)	Director, program expert (n=2, 50%)	Coordination and management of health data (n=4, 44.5%)	—[a]
Operational and technical professional (n=12, 54.6%)	Management and operational implementation (n=6, 75%)	Professor (n=1, 25%)	Physician, laboratory technician (n=4, 44.5%)	Software engineer (n=1, 100%)
Community and field actor (n=3, 13.6%)	Farmer (n=1, 12.5%)	Farmer (n=1, 25%)	Community relay (n=1, 11%)	—

[a]Not applicable.

Topic 1: Perceptions and Representations of DH

This topic explores how actors envision, understand, and engage with DH in their daily professional practices. The results highlight both positive representations associated with modernizing work. However, there are mixed feelings about the challenges of understanding and appropriating this concept.

Individual Perceptions, Understanding, and Affective Relationship to Digital Technology

For most participants, digital technology is not perceived as a simple technical tool, but as a marker of modernity and a factor in the transformation of work. Stakeholders often associate digitalization with increased efficiency, better information organization, and the alleviation of constraints associated with manual file management.

XSL•FO
RenderX

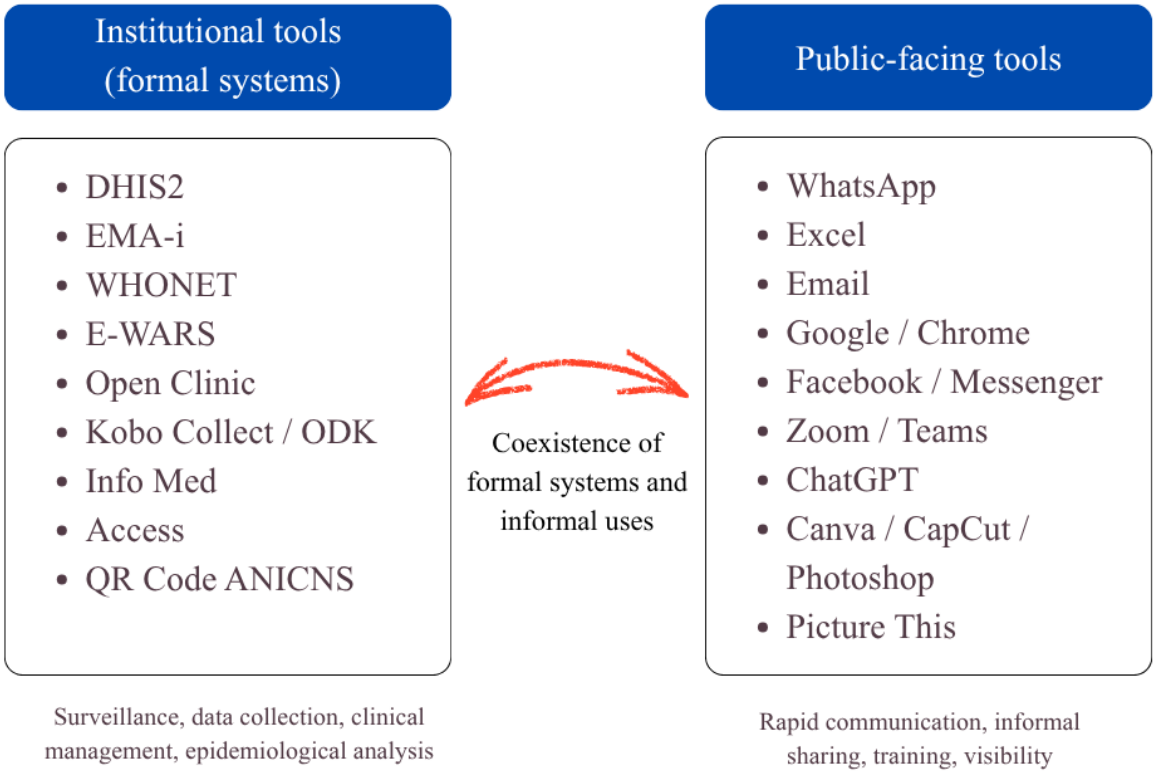
A physician in the human health sector describes the contribution of digital technology in patient management as follows:

> *All of our patients' files are encoded in the machine... it allows us to go a little faster than if we had to look, especially patients who have chronic problems; the sick who come back often.* [P04, Human Health, Physician]

Beyond functional use, some participants express a strong emotional attachment to digital technology, associating it with their professional and generational identities. Digital technology then becomes a symbol of belonging to technological modernity.

> *I'm a total fan of digital technology. I'm from the digital generation. I am from the generation of artificial intelligence. I can't be indifferent to digital technology.* [P09, Animal Health, Veterinarian]

However, this positive relationship is not homogeneous. Several participants highlighted difficulties with appropriation, particularly among older agents, for whom using digital tools can be a source of anxiety or exclusion.



> *...We still have staff who are sometimes quite old and who are not used to smartphones and tablets.* [P10, Human Health, Division Manager]

These results show heterogeneity in relationships with digital technology, ranging from enthusiastic adherence to a form of distance or reluctance linked to age and technological experience.

Digital Practices, Fragmentation, and Local Appropriations

The interviews highlight the coexistence of formal institutional digital systems and informal practices of appropriating digital tools (Figure 2). Participants described using official platforms such as DHIS2, electronic medical records, and specialized databases, while highlighting the persistence of paper in daily practice.

Figure 2. Typology of digital tools used by One Health actors in Kinshasa, Democratic Republic of Congo. DRC: Democratic Republic of Congo.

In many contexts, data is still collected manually before being entered into digital systems, which is perceived as an additional workload.

> *...It's really a notebook. There are notebooks from 1900... When a piece of data arrives, we write the date, record it, and it passes.* [P13, Animal Health, Veterinarian]

This double entry is often described as tedious.

> *...It's really a tedious exercise... Asking them to go back to the tools, correct, and recorrect in DHIS2 again isn't easy.* [P14, Human Health, Program Officer]

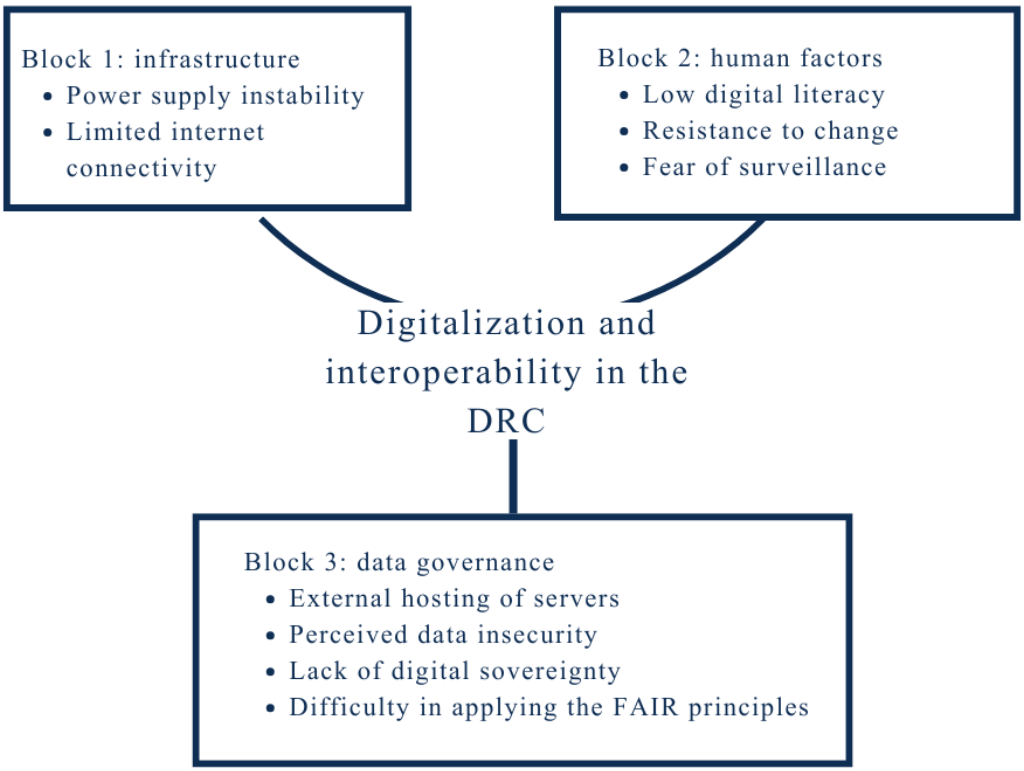
Digital practices are thus divided between mandatory institutional use for reporting and significant use of digital tools by the general public, particularly for communication and the exchange of information between peers.

> *So for us to use the data, we enter DHIS2 and then we extract, we do the analyses...* [P14, Human Health, Program Officer]
>
> *...Digital tools help us to get in touch with other colleagues. […] when we exchange on WhatsApp,*

XSL•FO
RenderX

they also give us their experiences... [P11, Animal Health, Veterinarian]

Overall, the participants described a pragmatic appropriation of digital technology: tools are used where they are perceived as useful, fast, and accessible, while institutional platforms are sometimes experienced as cumbersome, complex, or poorly adapted to realities on the ground.



These results show that, despite an overall positive perception of digital technology, its integration into professional practices remains marked by fragmented systems, paper-digital coexistence, and a strong dependence on informal communication tools.

Topic 2: Structural and Institutional Impediments to Interoperability

This topic brings together the material, human, and organizational elements that shape the effective use of digital technology and the potential for interoperability between sectors. Participants describe persistent structural constraints limiting the functionality of digital tools and their integration into OH logic.

Figure 3 summarizes these constraints by showing that the challenges of DH in the DRC stem from the interaction among three main blocks: hardware infrastructure, human factors, and data governance.

Figure 3. Architecture of the structural constraints of digitalization and interoperability in the DRC. DRC: Democratic Republic of Congo; FAIR: findable, accessible, interoperable, reusable.

Technical and Infrastructural Barriers

Electricity instability and poor internet coverage are major obstacles to digitalization, especially in rural areas. Several participants indicated that the absence of these prerequisites makes digital tools unusable in many contexts.

> *There are places where there is no electricity, and there is no connection, and all that…* [P11, Animal Health, Veterinarian]

> *But here, we don't even have electricity. How do you want us to be in the digital world?* [P16, Animal Health, Breeder]

These speeches show that the use of digital technology depends directly on basic material conditions that are not guaranteed uniformly across the territory.

Sociotechnical and Human Barriers

Participants report a lack of technical training and limited mastery of digital tools among some staff, which limits the adoption of these tools.

> *The obstacles can be first and foremost on the service provider's side, the use of phones and tablets, because not everyone is... well-versed in the use of digital equipment…* [P10, Human Health]

Some participants also report mistrust of digitalization, linked to fears of surveillance or data security.

> *...And a few more services... who refuse to digitize their file. They want to stay with the hard file because they don't trust our security system…* [P04, Human Health, Physician]

These elements show that the barriers to digitalization are not only technical, but also human and organizational.

XSL•FO
RenderX

Institutional and Governance Constraints

Several participants pointed out that external hosting of servers raises concerns about national sovereignty and data security.

> *...These are solutions that are foreign. These are mostly American solutions. The retrieval of information in these platforms is subject to American laws* [P18, Digital, IT]

The question of data security and durability is also recurrent in the speeches.

> *...It's not safe for data storage... Is there a bug? Is there a hack? Will our data survive?* [P04, Human Health, Physician]

Overall, participants agreed that electrical instability, limited connectivity, and reliance on external solutions are major structural constraints on digitalization and the effective application of FAIR principles.

Topic 3: Conditions Necessary for the Operational Implementation of ODH, Incorporating the FAIR Principles

This topic brings together the elements that participants consider essential for making an ODH approach functional in the Congolese context.

OH Collaboration and Relationship Challenges

Cross-sectoral collaboration is often constrained by power relations and symbolic hierarchies between sectors, particularly to the detriment of animal and environmental health.

> *...The human side takes over and takes the lion's share... they leave the least to the vets…* [P19, Animal Health, Accounting]
>
> *...There are human doctors who think they are superior to veterinarians…* [P11, Animal Health, Veterinarian]

Opportunities to Improve Public Health

Digital technology is seen as a way to strengthen cross-sector collaboration and better anticipate health risks.

> *Digitalization can facilitate collaboration [...] Animal health plays the role of sentinel in relation to human health…* [P20, Human Health, Coordinator]

Human Capabilities and Digital Literacy

Participants stressed the need to strengthen human skills to enable sustainable ownership of ODH.

> *The One Health concept still has a very long way to go: it is to train the epidemics, to train the different doctors, to train the different experts…* [P20, Human Health, Coordinator]

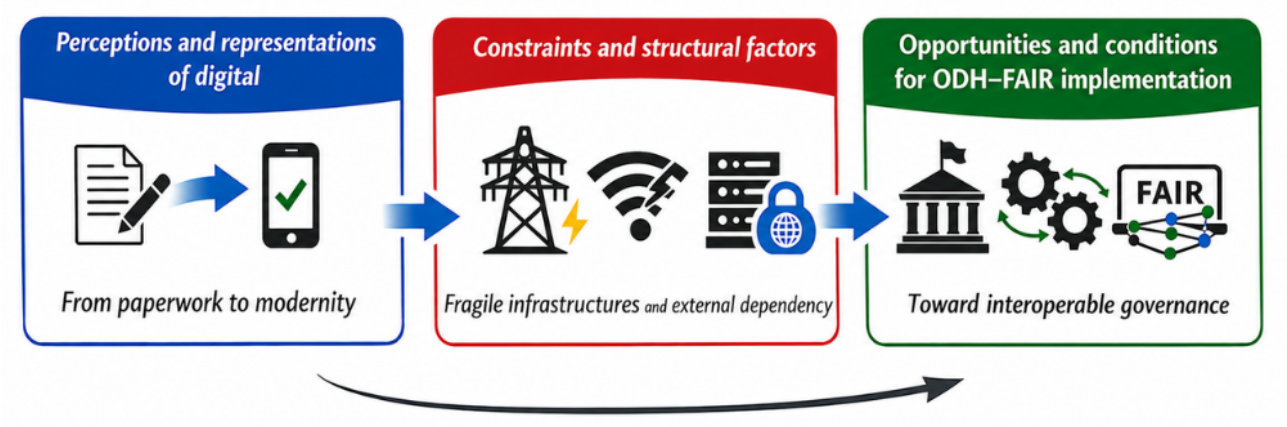
The training is described as going beyond the one-off seminar framework.

Interoperability and Infrastructure: The Material Foundation of the FAIR Approach

Interoperability depends on stable infrastructure and solutions adapted to the local context.

> *The main problem... is this concern for the lack of digital solutions compatible with the realities that we are experiencing here in the DRC.* [P18, digital, IT]
>
> *We should develop bridges between the tools…* [P01, Animal Health, Head of Department]

Strategic Recommendations and Institutional Levers



The need for strong leadership is widely shared.

> *...We have to create a framework... at the level of the Presidency or the Prime Minister…* [P20, Human Health, Coordinator]

Narrative Synthesis According to the Three Analytical Axes

Figure 4 illustrates the articulation among digital perceptions and practices, structural constraints, and the conditions necessary for implementing ODH.

Figure 4. Conceptual model of One Digital Health operationalization in the Democratic Republic of Congo, integrating (findable, accessible, interoperable, reusable) FAIR principles. The model illustrates the interplay between stakeholder perceptions and digital practices, structural and infrastructural constraints, and the essential conditions for One Digital Health implementation. Three pillars identified by participants: energy and connectivity, human capacity building, and system interoperability form a "digital bridge" connecting the human, animal, and environmental health sectors, facilitating coordinated surveillance and collaboration. FAIR: findable, accessible, interoperable, reusable. ODH: One Digital Health.

XSL•FO
RenderX

It represents the implementation of ODH in the DRC as a digital bridge connecting the human, animal, and environmental sectors, based on three pillars identified by the participants: energy and connectivity, human capacity building, and system interoperability.

In this context, the DH campus project is mentioned in the PNDIS II.[18] appears to be a relevant structural response to the institutionalization of intersectoral and continuing training. Without sustainable investment in training and collaborative governance, the ODH risks remaining an ambitious conceptual framework that is difficult to apply in the Congolese context.

Discussion

Main Findings

Our study identifies three critical dimensions affecting the implementation of ODH in the DRC.

The first dimension is a dual-track digital reality. While digital tools such as DHIS2 and sectoral platforms are acknowledged as catalysts for modernization, their formal use is often overshadowed by what is termed "informal adaptability." Practitioners frequently circumvent institutional gaps by using private message platforms (eg, WhatsApp), creating tension between immediate operational efficiency and long-term concerns about data security and confidentiality.

The second identified dimension concerns "infrastructures and data sovereignty bottlenecks." Indeed, digitalization is currently an "add-on" rather than a replacement for paper, leading to a double workload and "e-chaos." Success is fundamentally bottlenecked by unstable energy and connectivity, as well as significant concerns about digital sovereignty and the external hosting of national health data.

Finally, the third and most critical dimension concerns "siloed intersectionality." Although digital technology is perceived as a potential bridge between sectors, current efforts are hampered by "digital islands." Institutional hierarchies and power dynamics between disciplines prevent the FAIR principles from being operationalized.

Sociotechnical Synthesis and Theoretical Implications

Behavioral Appropriation and the Cognitive Divide

Digital technology is mainly perceived as an instrument of modernity and efficiency, improving access to information and reducing administrative burdens. This perceived utility confirms technology acceptance patterns, which identify utility as a central determinant of adoption [28].

The speeches also reveal a symbolic dimension of digital technology, associated with professional and generational identity. This reading aligns with the idea that, in Africa, digital technology is as much a "state of mind" as a technical tool [43]. However, this appropriation remains unevenly distributed. Older agents express more anxiety and reluctance, which corresponds to UTAUT models highlighting the role of perceived skills and trust in the tool [28].

Thus, the observed digital divide appears less a matter of material access than of a cognitive and professional divide, linked to skills, training, and perceived system security. This interpretation is consistent with the notion of "eHealth literacy" developed by Norman and Skinner [27].

Finally, the widespread use of consumer tools such as private messaging platforms like WhatsApp illustrates participants' strong ability to adapt to the limitations of institutional platforms. However, these informal practices raise significant ethical concerns regarding confidentiality and illustrate institutional fragility, in which the continuity of systems depends more on individual initiative than on solid organizational structures [12]. For the ODH, the acceptance of digital technology must therefore be accompanied by secure institutional frameworks and structured human capacity building.

Infrastructural Realities and the Sovereignty Challenge

The results confirm that energy and connectivity are the main bottlenecks to digitalization in the DRC. The absence or instability of electricity and the Internet makes digital tools ineffective, especially outside urban centers. This situation illustrates the gap between ambitious digital policies and material realities on the ground, described as the "rural myth versus urban reality" [10].

The national data also highlight that low energy coverage is a major structural constraint for any DH strategy [20]. The digital transformation thus appears inseparable from a robust energy policy, calling into question a strictly technological vision of digitalization.

The coexistence of paper and digital generates a double workload and confirms that digitalization tends to add to existing practices rather than replace them [12,44]. This overlap promotes the fragmentation of initiatives and feeds the risk of "e-chaos," characterized by the proliferation of noninteroperable tools [11].

In addition, concerns about external data hosting underscore the strategic issue of digital sovereignty. This dependency aligns with UNESCO's analyses of the fragility of data ecosystems in LMICs [45]. It is also consistent with the guidelines of the Plan national du numérique (PNN) and PNDIS II, which recommend establishing sovereign national data centers [18,35].

From the perspective of ODH and the FAIR principles, interoperability cannot be effective without a stable, secure, and sovereign national infrastructure that guarantees the accessibility, reusability, and governance of data [16].

Paths Toward Integrated Governance and ODH

The results show that relational and institutional barriers across sectors initially hamper the ODH. Symbolic tensions and the implicit hierarchization of disciplines confirm that intersectoral collaboration cannot be taken for granted. This observation is consistent with the analyses of Zinsstag et al [46], which identify power relations and institutional compartmentalization as major obstacles to the OH approach. It is also in line with the findings of the DRC's OH strategic plan 2022-2027, which highlights weaknesses in operational coordination mechanisms [36].

XSL•FO
RenderX

At the same time, participants perceive digital technology as a lever to overcome this compartmentalization by facilitating the circulation of information and the development of a shared vision of health risks. This reading is consistent with ODH's conceptual framework, which defines digitalization as a catalyst for OH integration [13]. However, this promise remains conditional on the effectiveness of interoperability. Without technical bridges between sectoral systems, data remains fragmented into "digital islands," rendering the FAIR principles, in particular interoperability and reusability, inoperative [16].

Finally, the emphasis on training confirms that the success of the ODH is largely based on the development of human capacities. Digital transformation cannot be reduced to a question of equipment; it requires an evolution in skills and professional cultures. This conclusion aligns with the recommendations of Bhutta et al [47] on health education reform and with Norman and Skinner's expanded definition of digital literacy [27].

Strengths and Limitations

This study is a pioneering multisectoral analysis in DRC, particularly for its empirical application of the ODH framework from a FAIR principles' perspective. This research moves beyond purely theoretical models to document real-world implementation challenges in an LMIC.

A primary strength lies in the methodological triangulation used. By combining a diversified qualitative sample with perspectives from human, animal, and environmental health sectors, the study captures the "symbolic dimension" of digital tools that quantitative surveys often miss. This approach enabled the identification of the "cognitive divide" and "institutional fragility," providing a nuanced understanding of how professional identity and generational shifts affect technology adoption. Furthermore, the inclusion of both formal systems (DHIS2) and informal communication practices (eg, WhatsApp) provides a highly realistic map of the digital ecosystem, offering a unique contribution to the PNN and PNDIS II evaluations.

Despite these contributions, several limitations must be acknowledged. First, the geographic scope was primarily concentrated in Kinshasa. While Kinshasa serves as the institutional hub, the findings may not fully capture the extreme infrastructural constraints found in deep rural provinces, where the "rural myth" of digitalization faces even harsher material realities. Consequently, the results offer a "centralized" view of the DRC's DH landscape that may not fully generalize to the entire national territory.

The study primarily included operational and mid-level stakeholders, which provided valuable insights into day-to-day implementation challenges but limited the analysis of higher-level governance, policy coordination, and strategic decision-making. Therefore, the operational focus was a deliberate design choice, rooted in the study's primary aim to capture ground-level, real-world experiences of digital tool integration across sectors that are often invisible in policy discourse yet determinative of implementation outcomes. As Braun and Clarke's framework and our purposive sampling rationale make clear, operational actors represent the primary interface between institutional aspirations and daily practice. In a context such as Kinshasa, where the distance between policy design and field implementation is well documented, this perspective carries significant empirical weight. Nevertheless, the strategic and governance frameworks were not absent from the study; they were addressed through a targeted document review that examined the PNDIS II, the PNN, the One Health Strategic Plan 2022-2027, and related regulatory texts. This layer of analysis provided the institutional and policy backdrop against which operational perceptions were interpreted. Future studies should adopt a multilevel sampling strategy that integrates high-level governance and strategic decision-makers alongside operational actors to assess the coherence or disconnect between institutional ambitions and ground-level realities in the operationalization of ODH.

While the sample was diverse, only a single DH expert was included. This participant provided technical insights on system architecture and interoperability, rather than representing broader adoption of the ODH framework, which remains primarily informed by human, animal, and environmental health professionals. The absence of direct field observations and in-depth technical system audits means that the specific performance of software platforms and the exact nature of data silos cannot be technically measured. Finally, the study focuses on a specific point in time; given the rapid evolution of DH policies in the DRC, the findings reflect a snapshot of a transition period that may shift as new sovereign data centers are established.

Conclusions

This study reveals a crucial insight: the success of the ODH approach in LMICs hinges not just on access to digital tools, but fundamentally on the robustness of their structural, institutional, and human foundations. In Kinshasa, while digital technology is viewed as a powerful catalyst for modernizing and enhancing professional practices, its true potential is severely constrained by energy instability, fragmented information systems, weak intersectoral governance, and stark disparities in digital skills. These challenges must be addressed to unlock the transformative power of technology. Thus, future DH strategies in the DRC should move toward implementing standardized reference architectures. Specifically, integrating the DH domains through a cloud-edge approach may support improved data interoperability while addressing the systemic connectivity constraints identified in this study [48].

Acknowledgments

We want to thank all the participants in the study for their time and for the richness and relevance of their contributions. Our gratitude also goes to the One Health Institute for Africa teaching team supervisors for the institutional support provided throughout this work and the academic exchanges. We also thank these people for their support in one way or another: M. Alphonse Basivikidi,

Abstract

Background: The medical burden caused by stroke is increasingly severe, and a small minority of high-cost patients consume the majority of medical expenditures. Therefore, revealing the formation mechanisms of this population and exploring a scientific cost-risk stratification system are crucial for improving the quality of care and achieving the optimal allocation of medical resources.

Objective: This study aimed to construct a comorbidity network for patients with stroke using standardized front-page medical record data, extract network features that reflect complex disease interactions, and develop identification models in combination with machine learning algorithms. The study focused on building a core model integrating variables from the near-discharge stage for stratifying the risk of high hospitalization costs in patients at the near-discharge stage. In addition, an early prediction model was developed using only data available at admission.

Methods: We conducted a retrospective study, collecting the hospital discharge data of inpatients with stroke from a tertiary hospital in Northeast China between 2021 and 2023. The data from 2021 to 2022 were used to construct a network and extract features to capture the potential relationship between diseases and high costs. Using the 2023 data partitioned into training and testing sets, we developed 5 models to identify inpatients with stroke who incurred high hospitalization costs and compared their performance when input with different features. In addition, the Shapley Additive Explanations interpretability method was adopted to explain the global and local contributions of the model features.

Results: The inclusion of network features significantly improved the model's performance, among which Extreme Gradient Boosting performed the best. The global feature importance showed that network features occupied a major proportion. The results of the Shapley Additive Explanations interaction analysis indicated potential phased changes in patient resource consumption. However, the overall performance of the early identification model constructed solely from admission data was subject to clear limitations.

Conclusions: This study developed an integrated framework combining comorbidity network analysis with machine learning, which significantly improved the accuracy of identifying inpatients with stroke at high risk of incurring excessive hospitalization costs. The core model demonstrated good performance in risk stratification during the near-discharge stage, showing potential for application in the formulation of risk management strategies and the optimization of health care resource allocation. It also laid the foundation for the subsequent development of more accurate early identification models.

Introduction

According to the 2021 Global Burden of Disease study, stroke remains the second leading cause of death worldwide [1]. It is estimated that the number of stroke-related deaths will increase by 50% between 2020 and 2050, with this health burden predominantly borne by low- and middle-income countries [2]. In China, the economic burden of stroke is particularly heavy; in 2018, its direct treatment costs reached $58.6 billion, of which

XSL•FO
RenderX

hospitalization expenses accounted for 79.03% [3]. Notably, the consumption of medical resources typically exhibits a significantly skewed distribution, with disproportionate medical expenditures often concentrated within a small group of high-cost patients [4]. This phenomenon of cost concentration is prevalent worldwide [5-7]. Although interventions, such as interdisciplinary transitional care and complex care management, aim to control costs by optimizing services [8-11] and have been proven to have certain short-term effects [12,13], many high-cost patients still face issues of overtreatment or inefficient care [14]. In this context, implementing rational risk stratification according to patients' overall disease conditions could potentially address existing shortcomings, ultimately leading to improved cost containment and the optimal allocation of health care resources.

Owing to its powerful data processing capacity, machine learning has been extensively used in research concerning health care expenditure prediction. For example, Ma et al [15] predicted the average daily costs of patients with psychiatric disorders, Hu et al [16] identified the determinants of high costs among patients with breast cancer, and Osawa et al [17] developed a predictive model for high-need, high-cost patients. Although previous studies have confirmed the utility of machine learning in predicting medical costs and identifying high-cost patients, it remains necessary to extract latent features closely related to medical expenditures from limited datasets to further enhance model performance. Stroke is typically characterized by a high incidence of multiple comorbidities [18], making the effective use of patients' rich comprehensive diagnostic information crucial. Complex comorbidities not only increase the difficulty of treatment and the risk of mortality but are also closely associated with significant escalations in hospitalization costs [19,20]. Although existing predictive models generally incorporate comorbidities as key features [21-23] regarding feature processing, most studies rely on rule-based scoring systems (eg, the Charlson comorbidity index [CCI] and the Elixhauser comorbidity index [ECI]) [24,25] or simple disease counts. These traditional methods focus solely on the linear accumulation of comorbidities, ignoring the intricate interactions among diseases, which leaves latent information in the data untapped and thereby limits the models' ability to identify high-cost patients.

To overcome the aforementioned methodological limitations, network analysis provides a systematic methodological framework. This network-based analytical paradigm goes beyond traditional simple disease counting; by integrating multiple quantitative indicators such as correlation coefficients, odds ratios (ORs), and the Salton cosine index [26], it can effectively evaluate the strength of associations between diseases and subsequently construct comorbidity networks [27,28]. This topological perspective not only helps identify frequently co-occurring disease clusters but also further reveals the potential interactions between diseases. With the widespread application and standardization of the *International Classification of Diseases, Tenth Revision* (*ICD-10*) codes, it has become possible to construct phenotypic comorbidity networks (PCNs) using hospital discharge data. For example, Xu et al [29] improved the prediction accuracy of self-harm behavior by incorporating comorbidity network features, while Hu et al [30] effectively predicted patients' length of stay (LOS) using a multiplex network and a patient similarity network. Notably, Yang et al [31] constructed a dual network using the diagnostic records of patients with ischemic heart disease, revealing that the extracted network features significantly outperformed traditional comorbidity indices, thereby effectively enhancing the model's ability to identify high-cost patients.

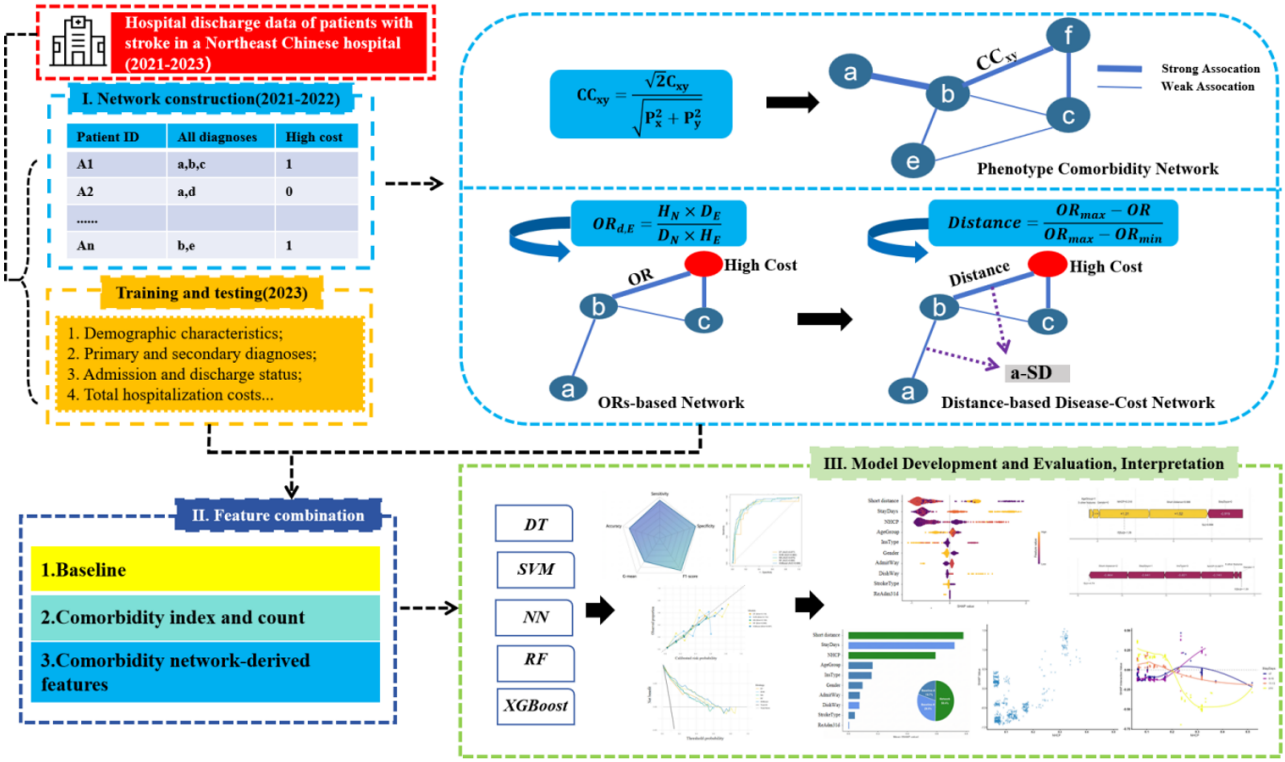
To the best of our knowledge, network analysis has not yet been applied to the identification and risk characterization of high-cost inpatients with stroke. Given that stroke, as the second leading cause of death globally, imposes a profound resource burden on health care systems, addressing this research gap holds significant practical relevance. Furthermore, previous studies have largely focused on improving overall model performance while often neglecting the interpretability of internal decision-making mechanisms, thereby failing to fully elucidate the specific contributions of individual features to medical costs and their association patterns. Therefore, this study aimed to construct a comorbidity network based on data from the medical record front pages of discharged patients, extract topological features that characterize the complex interactions among diseases, and subsequently build a near-discharge classifier to verify the applicability of network analysis in this research field. Simultaneously, by introducing the Shapley Additive Explanations (SHAP) analysis method, this study is dedicated to developing a robust and clinically interpretable evaluation framework, aiming to provide valuable references for the cost-risk stratification of patients with stroke, thereby offering a scientific basis for hospital administrators to formulate more refined and targeted cost control strategies.

Methods

Data Sources and Preprocessing

This retrospective study used discharge data from a tertiary hospital in Northeast China. The data collection period was from January 1, 2021, to December 31, 2023. The dataset contains comprehensive information on inpatients, including demographic characteristics (such as age and gender), diagnostic information at admission, including primary and secondary diagnoses, admission and discharge status, and total hospitalization costs. On the basis of the *ICD-10* coding system, this study screened for patients with stroke and ultimately included inpatient cases with a primary diagnosis code of I60, I61, or I63. To minimize information bias and ensure data quality, this study established a rigorous data screening and preprocessing workflow. During the data quality control phase, extreme cases with a LOS of less than 24 hours or more than 90 days were first excluded. Subsequently, a systematic evaluation of the missingness of key features was conducted. To balance data integrity and sample representativeness, as well as to prevent the introduction of potential systematic bias from overreliance on data imputation, variables demonstrating a missingness rate greater than 20% were eliminated [32]. Among the initially extracted raw features, a total of 2 variables were excluded for exceeding this threshold; the remaining variables exhibited good data completeness, with missing proportions

XSL•FO
RenderX



ranging from 0.13% to 1.95%. Statistical evaluation confirmed that the missing data in this study satisfied the assumption of missing at random, and no statistically significant differences in missingness rates were detected across the various cost groups. To impute the remaining missing values, this research used the K-Nearest Neighbors (KNN) imputation technique, a method that estimates missing data by leveraging local structural similarities across samples, thereby effectively retaining the original data's distributional properties and the underlying associations among variables. To avoid data leakage from distance-based imputation, we fitted the KNN imputer using only the 2021 to 2022 network construction cohort and the 2023 training set and then applied the trained fixed model to the 2023 test set for missing value imputation, which ensured complete isolation of data between the training and test sets.

As readmission within 30 days of discharge typically exhibits a strong clinical correlation with the initial hospitalization, it is considered to reflect continuous disease progression following the primary admission. Therefore, for patients with multiple hospitalization records, this study referred to the processing methods of previous health services research and merged the data using a 30-day time window rule based on unique inpatient numbers and admission and discharge dates [33,34]. The specific record integration rule was as follows: if the time interval between a patient's previous discharge and subsequent admission was ≤30 days, they were merged into a single hospitalization event; if the time interval was greater than 30 days, they were treated as independent inpatient cases. For cases with multiple consecutive hospitalizations where the intervals between all adjacent admissions met the ≤30-day condition, this study adopted a continuous sequential merging strategy, unifying them into one complete medical event. When merging specific variables, the following principles were adhered to: for features such as gender, age, insurance type, admission year, and primary diagnosis, data from the first record within the merged period were extracted; the admission route was determined using a priority rule (ie, prioritizing emergency admissions, followed by outpatient, and finally other routes); regarding the planned readmission within 31 days indicator, if any record within the merged group was marked as "yes," the entire merged event was classified as "yes"; and the discharge disposition was based on the status at the time of the final discharge. For secondary diagnostic codes, the system aggregated all records within the group and performed deduplication to construct a complete, comprehensive diagnostic set for the patient. Furthermore, the total hospitalization costs and LOS were calculated by summing all records within the merged group. In this merging process, a total of 396 patients accounted for 1096 repeat hospitalization records; through the aforementioned rules, 518 records were retained individually, and the remaining records were merged into 132, ultimately forming 650 hospitalization event records.

Following the aforementioned screening and processing, this study ultimately included 10,556 patients with stroke, of which 6618 were from 2021 to 2022 and 3938 were from 2023. To prevent data leakage, this study adopted a time span–based data partitioning strategy: data from 2021 to 2022 were used to construct the comorbidity network and extract topological features (the definition of high-cost nodes within the network was also determined entirely based on data from this period); meanwhile, data from 2023 were independently divided into training and testing sets. It should be specifically noted that the network features extracted on this basis are essentially supervised risk representations based on historical data, but no information related to the 2023 data was used during their derivation process. In addition, to eliminate measurement bias caused by macroeconomic fluctuations and inflation, this study uniformly adjusted the total hospitalization costs for 2021 and 2022 to the 2023 value level based on the Consumer Price Index. The complete research flowchart is shown in Figure 1.

XSL•FO
RenderX

Figure 1. Study design and workflow for identifying inpatients with stroke who had high hospitalization costs. This retrospective study used hospital discharge data of inpatients with stroke from a tertiary hospital in Northeast China (2021 - 2023). The workflow consists of three phases: (1) Network construction: data from 2021 to 2022 were used to construct comorbidity networks and extract network features. (2) Feature combination: clinical baselines, conventional comorbidity indices, and the derived network features were integrated for the 2023 cohort. (3) Model development and evaluation: The 2023 dataset was partitioned to train and test 5 machine learning models. Model performances were evaluated, and the Shapley Additive Explanations framework was applied for feature interpretability. Note: a, b, c... represent patient diseases. In the high cost column, "1" indicates a high-cost patient, and "0" indicates otherwise. DT: Decision Tree; NN: Neural Network; OR: odds ratio; RF: Random Forest; SVM: Support Vector Machine; XGBoost: Extreme Gradient Boosting.

Ethical Considerations

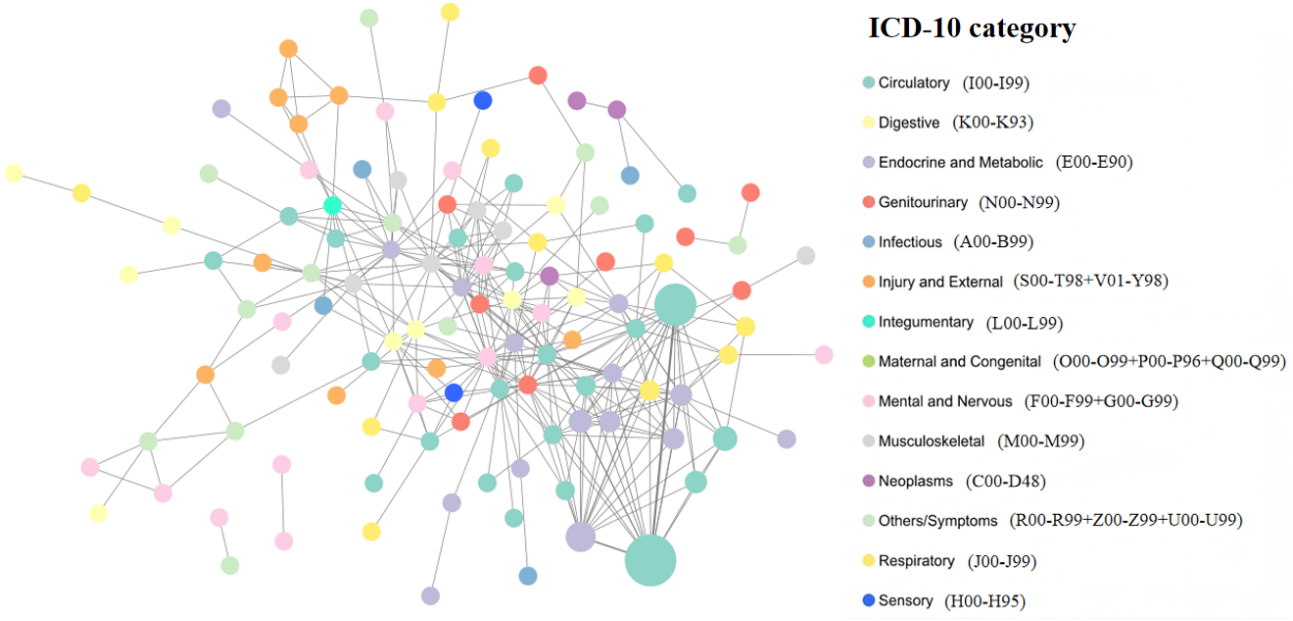
This study was approved by the Scientific Research Ethics Committee of Hangzhou Normal University (approval 2025 - 1026). All procedures strictly complied with the Declaration of Helsinki and relevant ethical guidelines. Data were collected retrospectively through medical record reviews. To ensure patient privacy, all data were deidentified prior to analysis.

Network Construction and Feature Extraction

Prior to network construction, this study established a minimum prevalence threshold, based exclusively on the 2021 to 2022 network construction cohort. Specifically, only diseases with ≥5 affected individuals within this cohort were included as network nodes, thereby ensuring the stability of the constructed network and the statistical representativeness of the extracted features. Additionally, this study incorporated the patients' primary and secondary diagnosis codes in the early stage after admission into the network construction process. Considering the extremely high prevalence of the primary diagnosis within the study cohort, to avoid its potential computational bias on the assessment of disease associations, this study performed corresponding statistical corrections in the subsequent calculation formulas for feature indicators.

Phenotypic Comorbidity Network

In this network, nodes represent the included disease categories, and edges represent the pairwise correlations between them. Previous studies have shown that the choice of association measure can significantly affect network topology and research findings [26]. Therefore, this study used a co-occurrence correlation as the indicator to quantify the strength of association between disease pairs [35]. Compared with traditional measurement methods, the core advantage of this calculation formula lies in its denominator, which uses the arithmetic square root of the sum of the squared occurrence frequencies of each disease. This characteristic makes the indicator more robust when dealing with extremely unbalanced occurrence frequencies of 2 diseases; even if a certain disease is relatively rare, as long as it has a very high co-occurrence ratio with another high-frequency disease, this formula can still objectively assign it a reasonable association weight. To filter out noisy edges caused by coincidental co-occurrences, this study set a minimum edge weight screening mechanism, retaining only associations with an edge weight >0.01. The final constructed PCN contained 139 valid nodes and 2404 valid edges, with a network density of 0.251. The specific calculation formula is defined as follows:



$$CCxy=2CxyPx2+Py2$$

Here, C_{xy} refers to the co-occurrence frequency of diseases x and y within each patient, while P_x and P_y represent the prevalence rates of diseases x and y, respectively. Figure 2

XSL•FO
RenderX

illustrates the generated PCN; to optimize visualization, the network displays only edges with weights ≥0.1.

Figure 2. Schematic representation of the phenotype comorbidity network. Node colors denote different *International Classification of Diseases, Tenth Revision* (*ICD-10*) categories. The thickness of the edges indicates the strength of the correlation, and node size represents disease prevalence.

Distance-Based Disease-Cost Network

Before constructing the distance-based disease-cost network (DDCN), this study first built an initial network, specifically using the OR to quantify the strength of association between nodes. Unlike the aforementioned network, this network introduced a specific "high-cost" node in addition to the conventional disease nodes, aiming to further explore the association patterns between specific diseases and high medical expenditures. The calculation formula is defined as follows:

$$\mathrm{ORd,E=HN\times DEDN\times HE}$$

In this framework, E represents the specific high-cost outcome. D_E and D_N represent the number of high-cost and non–high-cost patients, respectively, in the patient subgroup with the specific comorbidity d. Accordingly, H_E and H_N, respectively, represent the number of patients corresponding to high-cost and non–high-cost states in the control subgroup (ie, patients without the comorbidity d). As disease co-occurrence relationships are symmetric, the constructed DDCN is an undirected graph. To address the issue of undefined OR values caused by zero cells in the 2×2 contingency table, this study introduced the Haldane-Anscombe correction, which adds 0.5 to all 4 cells of the contingency table to avoid division-by-zero errors and smooth extreme values generated by small samples. To ensure the high specificity of the network edges, the network only retained significant association edges with an OR >1 and a lower bound of its 95% CI >1. Subsequently, this study used the min-max normalization formula to transform the ORs into distance metrics, thereby completing the construction of the DDCN. Through this formula, all association strengths were mapped into the standardized distance space of [0, 1], effectively smoothing the extreme numerical fluctuations associated with the extremely high prevalence of the primary diagnosis. The finally constructed DDCN contained 140 valid nodes and 1713 valid edges, with a network density of 0.176.

$$\mathrm{Distance=ORmax-ORORmax-ORmin}$$

Feature Engineering and Outcome Variables

Network Features

Normalized High-Cost Propensity

Derived from the PCN, this topological feature aims to quantify the cumulative risk associated with high medical expenditures for a specific disease and its adjacent network nodes [31,35]. Specifically, this indicator effectively captures direct and indirect risk association patterns: if a patient presents with a characteristic disease of the high-cost group, or if their disease exhibits significant topological connectivity with highly prevalent comorbidities in that population, the likelihood of the patient exhibiting a high-cost status increases significantly. The calculation formula for the normalized high-cost propensity (NHCP) of disease d is defined as follows:

$$\mathrm{NHCPd=\Omega d+\sum c\in C(CCdc\ \Omega c\sum c\in CCCdc)}$$

In this calculation formula, Ω_d represents the proportion of high-cost patients among cases with disease d, CC_{dc} represents the edge weight between disease d and its co-occurring disease c within the PCN, and C constitutes the set of all adjacent nodes directly connected to node d. Mechanistically, Ω_d quantifies the inherent and direct high-cost risk associated with disease d, while the second term of the formula evaluates the indirect risk brought about by the network spillover effect. By introducing a normalization mechanism through dividing by the denominator $\sum_{c\in C}CC_{dc}$ (ie, the sum of all edge weights connected to d), the risk metrics of different nodes are standardized to a uniform scale; this effectively offsets the influence spillover of the primary diagnosis caused by its massive number of connections, enabling the indicator to more objectively reflect the true intensity of comorbidity risks rather than being solely dictated by the absolute number of node connections. As minimum

XSL•FO
RenderX

disease prevalence thresholds and edge weight filters were established prior to network construction, certain ICD codes from 2023 might not be incorporated into the network; for such marginal conditions or specific rare diseases, we assumed no additional network connectivity risk and assigned them an NHCP of 0. Ultimately, the NHCP for a patient's diagnostic set D is determined as follows:

$$NHCP=\max_{d\in D}(NHCP_d)$$

Shortest Distance

Shortest distance is a global risk indicator extracted from the DDCN. Distinct from the isolated analysis of a single disease, this indicator uses Dijkstra's algorithm to calculate the weighted shortest path from a specific disease node to the "high-cost" node, thereby quantifying the topological reachability of a disease leading to a high-cost status via the comorbidity network. The edges fed into the algorithm incorporate both "disease-disease" and "disease-cost" associations, allowing diseases that lack direct links to the high-cost node to establish indirect connections via bridging nodes. As shown in Figure 1, although the direct association between specific disease node *a* and the high-cost node may not reach statistical significance, node *a* exhibits a strong association with node *b*, and node *b* itself is closely related to high medical expenditures. Therefore, node *a* can establish a potential indirect connection to the high-cost status through node *b* acting as a mediating bridge. For isolated nodes lacking an effective connectivity path to the specific "high-cost" node after screening, this study adopted an extreme-value penalty strategy for assignment: extracting the finite maximum shortest distance length in the current network and adding a constant penalty term (+1) to assign to such isolated nodes. Numerically, this operation maps them to the position furthest from the high-cost node, thereby objectively reflecting their relatively low association strength. Similarly, out-of-network nodes appearing in the 2023 data were also assigned this extreme distance. Ultimately, the shortest distance feature value for the patient's comprehensive diagnostic set D is determined as follows:

$$\text{Shortest distance}=\min_{d\in D}(\text{shortest distance}_d)$$

Comorbidity-Related Features

In addition to the topological features extracted from the comorbidity network, this study also extracted comorbidity-related features similarly derived from patients' diagnostic coding data to compare the impact of different feature subsets on the model's identification efficacy in subsequent analyses. Specifically, these features include the number of comorbidities, the CCI, and the ECI.

Baseline Features

This study extracted a total of 8 baseline features from the medical record front pages, specifically including gender, age, insurance type, stroke type, admission route, discharge disposition, LOS, and planned readmission within 31 days. Among these, the insurance type was divided into 4 categories based on the local medical insurance pooling management structure: municipal insurance (applicable to the insured population in the municipal pooling area where the medical institution is located), provincial insurance (corresponding to the insured population in the provincial pooling area), out-of-town insurance (referring to the situation where the insured location and the treatment location belong to different administrative regions), and others (covering various special forms of medical security). The stroke type was defined based on the primary diagnosis code: cases with codes I60 or I61 were classified as hemorrhagic stroke, and cases with code I63 were classified as ischemic stroke. The admission route was divided into emergency, outpatient, and others; the discharge disposition covered routine discharge upon medical advice, discharge against medical advice, and death. The planned readmission within 31 days was dichotomized as "yes" or "no" based on the discharge record in the hospital discharge data.

It is worth noting that among the 8 baseline features mentioned earlier, 5 features—gender, age, insurance type, stroke type, and admission way—can be obtained at the initial stage of patient admission, whereas discharge disposition, LOS, and planned readmission within 31 days can only be finally determined at the hospital discharge stage, exhibiting an obvious information lag. Accordingly, in the subsequent analysis, we excluded these 3 lagging features and additionally developed a prediction model specifically for patients in the early stage of hospitalization to investigate its performance in the early identification of high-cost patients.

Outcome Variables

Although previous literature has not reached a complete consensus on the definition of high-cost status, using the top 10th percentile as a classification benchmark has been widely recognized and adopted [36,37]. Consequently, this study defined cases ranking in the top 10% of total hospitalization costs within the study cohort as high-cost patients. Furthermore, the detailed components of inpatient costs were solely used to define the outcome variable and were strictly excluded from subsequent analyses. The selection of this threshold was mainly based on the following considerations: on the one hand, this criterion can effectively alleviate the extreme data imbalance problem associated with setting a threshold too strictly, thereby ensuring the efficacy of subsequent statistical tests and classification evaluations; on the other hand, this criterion can also prevent the dilution of the typical distribution characteristics of the high-cost group caused by a definition scope that is too broad. Furthermore, from the macro perspective of medical policy, the top 10% classification can accurately cover the high-multiplier case groups closely monitored under China's current medical insurance payment system, highly aligning with the practical governance needs of current hospital cost control and refined medical insurance management. To further verify the robustness of the research findings, we conducted expanded testing in the sensitivity analysis using other alternative thresholds.

Model Development and Comparison

This study used the 2023 data subset for the construction and validation of models. To ensure the consistency of the target variable distribution between the training and testing sets, this study adopted the hold-out method, performing a stratified random splitting based on the outcome variable at a ratio of 8:2. After splitting, a training set of 3151 cases (including 315

XSL•FO
RenderX

high-cost cases) and an independent testing set of 787 cases (including 78 high-cost cases) were ultimately generated. Aiming at the class imbalance problem existing between high-cost and non–high-cost cases, this study strictly applied the Synthetic Minority Over-sampling Technique (SMOTE) only within the training set before formally training the models. To rigorously prevent overestimation of model performance due to data leakage, no global oversampling was performed prior to cross-validation. Instead, the SMOTE algorithm was specifically embedded within the resampling pipeline. Specifically, during each iteration of the 5-fold cross-validation, SMOTE was dynamically applied only to the training folds, whereas the validation fold always retained the original real-world data distribution. This strategy effectively balanced the class distribution, mitigated the classification bias of machine learning algorithms toward the majority class, and ensured the objectivity of model evaluation. On the basis of the processed data, this study constructed 5 machine learning models to identify high-cost stroke inpatient cases, specifically covering Decision Tree (DT), Support Vector Machine (SVM), Neural Network (NN), Random Forest (RF), and Extreme Gradient Boosting (XGBoost). To guarantee the reproducibility of the experiment and effectively control the risk of overfitting, the model's hyperparameter optimization process used a grid search strategy combined with 5-fold cross-validation strictly executed within the training set. This was done to objectively screen and determine the optimal parameter combination for each model. During the hyperparameter tuning phase, specific search spaces were tailored to the architecture of each model. For DT, the cost-complexity parameter was primarily adjusted. For SVM, both the Radial Basis Function kernel parameter and the regularization penalty were optimized. For NN, the optimization focused on the number of hidden nodes and the weight decay. For RF, the number of candidate variables per split and the minimum node size were fine-tuned. Finally, for XGBoost, a simultaneous optimization was performed on core parameters, including the number of boosting iterations, maximum tree depth, learning rate, and minimum child weight. To balance computational efficiency and mitigate the risk of overfitting, the grid search was restricted to predefined boundaries. Consequently, the identified parameters represent local optima within these ranges rather than exhaustive global optima. The identification performance of all final models was objectively evaluated on the single-split independent hold-out testing set, combined with 1000 Bootstrap resampling to obtain the 95% CIs for various evaluation metrics. To comprehensively measure the overall identification ability of the models, this study adopted the following multidimensional evaluation metric matrix: the area under the curve (AUC), sensitivity, specificity, accuracy, G-mean index, and F_1-score [38]. Addressing the class imbalance characteristic commonly found in medical data, this study specifically introduced the G-mean and F_1-score to more accurately and robustly reflect the overall balanced performance of the model in simultaneously handling the identification of both minority and majority classes. Furthermore, to objectively evaluate the potential gain of network topological features on the model's identification performance, this study used the DeLong test to conduct a statistical examination of the AUC differences between models containing only baseline features and composite models integrating both baseline and network features.

In addition to the aforementioned evaluation metrics, this study further introduced calibration curves and the Brier score, aiming to evaluate the consistency between the high-cost identification probabilities output by the model and the actual observed true proportions. Finally, this study used decision curve analysis (DCA) to evaluate the net clinical benefit that the model can generate across a wide range of threshold probabilities, thereby verifying its practical application value in medical management and decision-making. Furthermore, to deeply explore the incremental value of the extracted network topological features, this study also implemented an ablation comparative analysis to systematically compare the objective differences in identification performance between "models containing only baseline clinical features" and "models further integrating traditional comorbidity features or network features."

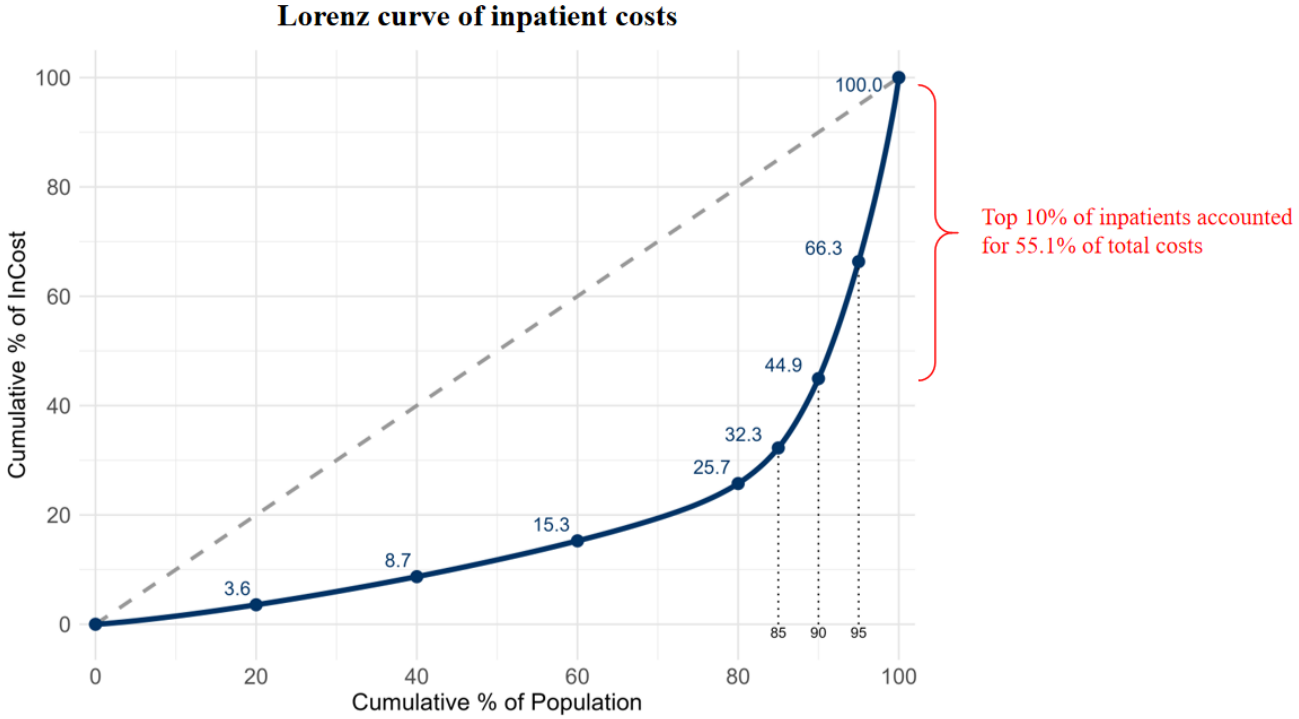
Model Interpretability

To deeply analyze the key associated features behind the high medical expenditures of inpatients with stroke, this study introduced the SHAP technique to provide post-hoc interpretability analysis for the optimal-performing machine learning model. Given that the XGBoost model ultimately used for feature attribution is a tree-based ensemble algorithm, this study specifically selected the TreeExplainer optimized for such algorithms in the analysis to accurately calculate the local and global explanations of features. On the basis of co-operative game theory, the SHAP method can theoretically and fairly distribute the model's identification results among all input variables. Under this framework, the global importance of a feature is quantified by the average level of its absolute SHAP values across the entire study cohort. Specifically, a positive SHAP value indicates that the feature is associated with an increased probability of a case being classified as "high cost," while a negative SHAP value denotes a decrease in this classification probability.

Statistical Analysis

This study used R (version 4.4.2; R Core Team) for related statistical analyses and plotting. In the comparative analysis of features between groups, the distribution characteristics of categorical variables were expressed as frequencies and percentages, and the differences between the high-cost and non–high-cost groups were compared using the chi-square test; continuous variables underwent a normality test prior to analysis, where data conforming to a normal distribution were presented as mean (SD), and intergroup comparisons were conducted using the independent samples *t* test; continuous variables not conforming to a normal distribution were represented by the median and IQR, and intergroup comparisons adopted the Mann-Whitney *U* test. The visualization of the PCN was completed in Cytoscape (Cytoscape Consortium).

Results



Patient Characteristics

According to the previously defined high-cost threshold criteria (the top 10%, equating to ≥94,696.79 RMB), of the 3938

XSL•FO
RenderX

inpatient with stroke incorporated into the 2023 analysis, 393 cases were assigned to the high-cost cohort, and the remaining 3545 cases comprised the non–high-cost cohort. Figure 3 displays the distribution of inpatient costs among patients with stroke, with the total health care expenditures of the high-cost group making up 55.1% of the overarching cohort's total costs.

Figure 3. Lorenz curve of inpatient costs in 2023 revealing that the top 10% of inpatients accounted for 55.1% of total costs.

The results of the intergroup analysis presented in Table 1 reveal that the high-cost and non–high-cost groups exhibit statistically significant differences across various features. Specifically, regarding demographics, the proportion of female patients in the high-cost group was significantly higher than that in the non–high-cost group; in terms of age distribution, the proportions of patients aged 51 to 60 years and 61 to 70 years in the high-cost group were slightly higher than those in the non–high-cost group, whereas the proportion of the population aged over 71 years in the high-cost group was distinctly lower than in the non–high-cost group. In terms of clinical features, stroke types exhibited substantial intergroup differences. Ischemic stroke predominated in the overall population, while hemorrhagic stroke accounted for 57% of the high-cost group, a proportion significantly higher than the 14.9% observed in the non–high-cost group. Furthermore, the LOS showed a strong positive correlation with high-cost status. The proportion of patients with provincial insurance among high-cost cases was markedly higher than in the non–high-cost group. Regarding network features, the intergroup comparison revealed that the NHCP value was significantly elevated in the high-cost group; conversely, the short distance value in this group was significantly reduced. As for comorbidity features, the results indicated that the high-cost patient group had a higher proportion of lower CCI scores and fewer comorbidities compared to the non–high-cost group.

Model Development and Performance Comparison

Table 2 presents the identification performance of the 5 machine learning models after incorporating the 2 network features. Overall, after incorporating the network-derived features, the identification performance of all models achieved a certain degree of improvement. Among them, XGBoost exhibited the largest AUC improvement, increasing from 0.814 to 0.899; moreover, the remaining evaluation metrics of this model also demonstrated the optimal performance among the 5 models.

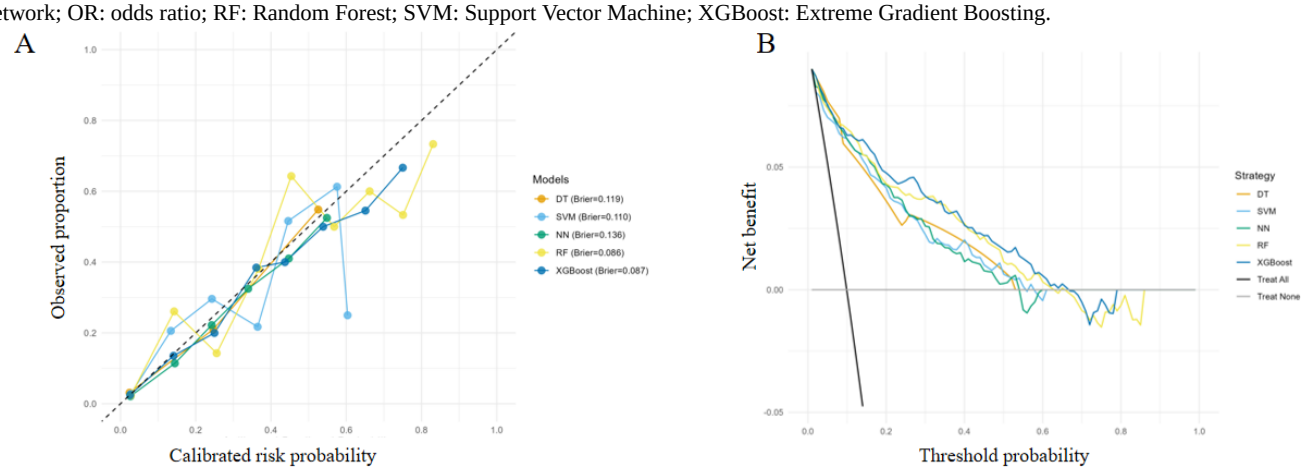

Figure 4 displays the receiver operating characteristic curves of the 5 machine learning models combined with network features; the DeLong test results in Figure 4B further confirmed that the difference in AUC gain between the "composite model fusing network features" and the "initial model containing only baseline features" is statistically significant. Specifically, the difference in AUC between the 2 models was 0.085 (95% CI 0.052 - 0.123), with an exact *P* value of 1.42×10 according to the DeLong test.

Figure 4. Receiver operating characteristic (ROC) curves of different machine learning models for identifying high-cost patients and comparison of feature gains. AUC: area under the curve; DT: Decision Tree; NN: Neural Network; OR: odds ratio; RF: Random Forest; SVM: Support Vector Machine; XGBoost: Extreme Gradient Boosting.

The calibration curve results in Figure 5A show that the curve trajectory of the XGBoost model is closest to the ideal reference line, indicating a high degree of consistency between the high-cost identification probabilities output by the model and the actual observed true proportions. Simultaneously, XGBoost achieved a Brier score of 0.087, belonging to the low-error tier alongside RF. Its overall calibration performance was significantly better than that of the SVM, DT, and NN, further confirming the robust reliability of its output identification probability estimates. In the DCA shown in Figure 5B, XGBoost similarly highlighted significant practical application advantages. Specifically, within the broad threshold probability interval of clinical and management significance, the net benefit curve of XGBoost consistently remained at the highest level; this means that compared to other machine learning models participating in the evaluation, using this model to guide medical resource allocation can yield a more substantial comprehensive net benefit. Given the outstanding comprehensive identification performance described earlier, this study ultimately selected XGBoost as the core model for subsequent feature attribution and mechanism analysis. The optimal hyperparameter combinations and their specific configurations for each model are detailed in Table A1 in the Multimedia Appendix 1.

Ablation Analysis

To objectively evaluate the specific contributions of traditional comorbidity features and single network topological features to the model's identification performance, this study further implemented an ablation analysis relying on the XGBoost model. The outcomes are presented in Table 3: in terms of traditional comorbidity features, regardless of the introduction of CCI, ECI, or a basic comorbidity count, the model's identification performance demonstrated a certain degree of enhancement; however, its overall performance still fell markedly short of the model integrating network features. In contrast, the incorporation of CCI led to a certain degree of performance degradation. Furthermore, the 2 network topological features also had different focuses regarding their gains in identification performance. Specifically, the "baseline+SD" model demonstrated better discrimination in the AUC metric; in contrast, although the "baseline+NHCP" model had a slightly lower AUC value, it performed better on the F_1-score. Finally, by rigorously excluding lagging variables that could only be determined after discharge and retaining only features available in the early stage of hospitalization, we independently developed a corresponding early identification model. The results showed that, although the model achieved an acceptable AUC, its F_1-score was markedly low, suggesting a potential imbalance in model performance when based solely on the currently available features.

Table . Performance evaluation of models based on single network features, traditional comorbidity features, and preadmission features. The data in parentheses are 95% CI.

[e]Baseline features available at admission.

Previous intergroup analysis of baseline features showed a statistically significant difference in stroke type between the 2 groups, indicating a high degree of clinical relevance between this feature and high-cost status. Given that all diagnostic codes, including the principal diagnosis, were incorporated in the construction of the comorbidity network, the resulting network topological features to some extent captured information inherent to stroke subtypes. To deeply explore the potential multicollinearity and information overlap effects among features, this study additionally constructed a model that excluded the stroke subtype and retained only the network features. The results showed that after excluding this subtype feature, the model's identification performance was basically unaffected (relevant evaluation data are detailed in Table A2 in the Multimedia Appendix 1). In other words, the value of network features lies more in complementing existing clinical information than in providing discriminative ability that is entirely independent of stroke subtypes. Therefore, the incremental value of network features should be interpreted as a marginal improvement beyond established clinical variables, rather than as a complete replacement for conventional features. Table A2 in Multimedia Appendix 1 also summarizes the performance comparison of models fusing all feature combinations. The comprehensive analytical results corroborated that the feature combination of "baseline characteristics+dual network features" delivered the most optimal overall identification capabilities across all evaluation metrics. Therefore, this study ultimately selected this feature subset as the standard input for the subsequent SHAP feature attribution analysis.

Meanwhile, to verify the applicability and robustness of the aforementioned identification framework in specific clinical subgroups, this study further evaluated the model's performance within the hemorrhagic and ischemic stroke subgroups in the independent testing set, based on this optimal feature combination. The stratified analysis results (Table 4) showed that although the AUC value of each model within a single subgroup slightly decreased by approximately 0.03 to 0.04 compared to the overall cohort, they still demonstrated stable identification performance across different clinical subgroups.

Model Interpretability

To enhance the transparency and interpretability of the model in the context of clinical decision-making, this study introduced the SHAP method to objectively quantify the marginal contribution of each input variable to the final identification result. This method covers 2 dimensions: global interpretability at the feature level and local interpretability at the individual level. In terms of global interpretability, the bar chart in Figure 6A is sorted in descending order based on the mean absolute SHAP values of the features, intuitively illustrating the relative importance of different variables in the identification of high-cost patients. The analysis results showed that the top 5 core associated features contributing to the model's performance were, in order, short distance, LOS, NHCP, age, and insurance type. As shown in the pie chart in Figure 6A, the cumulative contribution of network features accounts for 50.4% of the model's total output. Among the baseline features, baseline features available at admission account for 19.7%, while baseline features available at hospital discharge reach 29.9%. The SHAP beeswarm plot in Figure 6B intuitively presents the distribution trend of SHAP values across various features for the entire sample. Figure 6C displays the SHAP dependence plots for the top 3 features, showing how these variables regulate the model's output within different value ranges. Specifically, a lower value of shortest distance, along with higher values of LOS and NHCP, is significantly associated with a high probability of cases being identified as a high-cost status. The SHAP interaction analysis in Figure 6D reveals that the interaction effects between network features and LOS exhibit complex nonlinear synergistic associations. Specifically, patients with a LOS ≥14 days show a significant inverted U-shaped trend, with the interaction value reaching a positive peak when shortest distance is at a moderate level, significantly elevating the high-cost risk; the 11 - to 13-day group displays a U-shape with mostly negative interactions; whereas the ≤10-day group has a flat interaction effect, fluctuating around the baseline. On the other hand, when examining the interaction between NHCP and LOS: for patients with an LOS of 8 to 10 days, the interaction effect shows an upward trend, turning from a negative value to a positive value as NHCP increases. Conversely, for the subgroup with an LOS ≥14 days, the interaction effect presents a downward trend, turning negative with the increase of NHCP. In contrast, for the subgroups with an LOS ≤7 days and 11 to 13 days, the interaction values remain relatively stable across different levels of NHCP.

RenderX

Figure 6. Global interpretation of the Extreme Gradient Boosting model using Shapley Additive Explanations (SHAP) analysis. (A) SHAP feature importance bar chart, Baseline-A: Baseline features available at admission; Baseline-H: Baseline features available at hospital discharge. (B) SHAP summary plot (beeswarm) showing the distribution of feature impacts. Each dot represents a sample; color indicates feature value (yellow=high and purple=low). Taking StayDays as an example, yellow dots (longer stays) are predominantly distributed on the positive SHAP side, indicating that prolonged hospitalization increases the likelihood of high-cost classification, while purple dots (shorter stays) cluster on the negative side, suggesting an inhibitory effect on high-cost generation. (C) SHAP dependence plots for top features (SD, StayDays, and normalized high-cost propensity [NHCP]), illustrating the marginal relationship between the feature value and its impact on the model output. (D) SHAP interaction plots illustrating the interaction effects of SD and NHCP with length of stay. Variable name mapping: StayDays=Length of Stay; InsType=Insurance Type; AgeGroup=Age; AdmitWay=Admission Way; DischWay=Discharge Way; ReAdm31d=Planned 31-day Readmission.

At the local explanation level, we generated SHAP force plots to elucidate the contribution of each feature to the identification result for a specific individual. Figure 7A displays a patient who was identified by the model as highly likely to be in a high-cost status. The core features making the primary positive contribution to this identification probability were shortest distance and NHCP, while the LOS played a certain mitigating role. Conversely, the patient in Figure 7B was identified as having an extremely low probability of being in a high-cost status. The dominant associated features supporting the identification of this case into the non–high-cost group were, in order, a higher shortest distance, a shorter LOS, a lower NHCP, and a specific insurance type.

Figure 7. Local explanations for individual predictions using Shapley Additive Explanations force plots. The plots illustrate how specific feature values contribute to pushing the model's output from the base value (E[f(x)]) toward the final prediction (f(x)). Yellow bars indicate features that increase the likelihood of being a high-cost patient (positive contribution), while purple bars indicate features that decrease it (negative contribution). (A) A representative high-cost patient sample (f(x)=0.894). (B) A representative non–high-cost patient sample (f(x)=−4.740). Variable name mapping: StayDays=Length of Stay; InsType=Insurance Type; AgeGroup=Age. NHCP: normalized high-cost propensity.

Sensitivity Analysis

As presented in Table 5, at the extreme threshold of 5%, the model's AUC value reached its highest level; however, affected by the extremely imbalanced data, the model's F_1-score was below 0.4, meaning that the model performance was poor and the identification ability was relatively weak. As the threshold was relaxed, although the model's AUC value experienced a slight decline, it showed a relatively stable trend within the 10% to 20% range. In addition, due to the steady increase in the number of positive samples, the class imbalance phenomenon was effectively alleviated, prompting the F_1-scores of all models to show a gradually increasing trend. Among them, the threshold adjustment from 5% to 10% optimized the model performance most significantly, and the F_1-scores of all models achieved substantial improvements. This indicates that the 10% threshold effectively improved the problem of impaired model performance caused by extreme class imbalance under the low threshold.

Table . Sensitivity analysis of model performance under varying thresholds. The data in parentheses are 95% CI.

Thresholds	Performance					
	AUC[a]	Sensitivity	Specificity	Accuracy	G-mean	F_1-score
5%	0.939 (0.914 - 0.963)	0.951 (0.881 - 1.000)	0.847 (0.814 - 0.880)	0.852 (0.820 - 0.884)	0.897 (0.859 - 0.930)	0.389 (0.296 - 0.479)

Discussion

Principal Findings

Unlike most previous models, which incorporated clinical laboratory, imaging, or genomic data [39-41], this study used hospital discharge data to develop a high-performance model for identifying patients with stroke who have high hospitalization costs by combining diagnostic network analysis with machine learning algorithms. Compared with these data sources, hospital discharge data offer several important advantages, including greater standardization, lower cost, and broad availability across hospitals at all levels, making it a practical basis for implementation in diverse health care settings. Although this data source has inherent limitations in dimensionality, incorporating topological features derived from the comorbidity network substantially improved the performance of all models, consistent with previous studies [30,31]. Moreover, compared with other models for identifying high-need, high-cost patients that did not include network features, our model showed superior performance [17,42-44].

Our results indicate that, although both are derived from diagnostic data, network features from the comorbidity network contributed more to model performance than conventional comorbidity measures such as CCI, ECI, and comorbidity count. By quantifying the pathway from a specific disease node to high-cost outcomes and integrating the disease's intrinsic risk with the combined effects of its local neighborhood, these features captured latent information that is difficult to detect using traditional statistical methods, thereby substantially improving the model's ability to identify high-cost patients. Additionally, subgroup analyses across different stroke subtypes further verify the stability and reliability of the comorbidity network features extracted in this study. The model maintained satisfactory predictive performance under the macroscopic classification of hemorrhagic and ischemic stroke, demonstrating good applicability across major clinical subgroups. Nevertheless, this classification is relatively coarse and ignores substantial clinical heterogeneity among different subtypes within hemorrhagic stroke. We therefore conducted a further refined subgroup analysis focusing on subarachnoid hemorrhage (I60) and intracerebral hemorrhage (I61), as presented in Table A3 in Multimedia Appendix 1. The results showed that the model performed stably in the I61 subgroup but yielded unsatisfactory outcomes in the I60 subgroup. This discrepancy can be explained by the sample characteristics of the I60 population. This subgroup had a small sample size and a high degree of internal homogeneity. Among the total of 247 patients with I60, 170 were categorized as high-cost cases, indicating highly consistent hospitalization costs in this subtype. Limited information from routine hospital discharge data failed to capture subtle individual differences, which impaired the model's discriminative ability. In future research, we will expand the sample size and incorporate more clinical indicators, treatment-related information, and other variables to develop refined models for individual stroke subtypes.

In the global feature importance ranking, LOS was the second most important feature, after shortest distance. Previous studies have likewise highlighted the critical role of LOS in identifying high-cost pediatric inpatients [42]. SHAP interaction analysis further showed that the association between LOS and comorbidity network features was strongly time dependent, suggesting that the trajectory of medical resource use in stroke may evolve dynamically over the course of the disease. In the subgroup with an LOS of 8 to 10 days, higher NHCP showed a clear positive synergistic interaction, which may reflect the clinical profile of complex cases requiring highly

XSL•FO
RenderX

resource-intensive interventions during the acute phase. However, when LOS was ≥14 days, high NHCP instead showed a strong negative interaction; at the same time, this long-stay subgroup exhibited a positive interaction peak at moderate levels of shortest distance. This time-varying pattern may suggest a law of diminishing marginal costs: as hospitalization becomes substantially prolonged, the main drivers of high expenditure may shift from fluctuations in acute disease severity to the cumulative baseline costs of ongoing care. Meanwhile, the 11 to 13 days subgroup showed a U-shaped pattern, with negative interactions across most of the value range, which may indicate a transitional stage in cost generation as patients move from the acute phase to the longer-term recovery phase.

Age and insurance type were also important determinants of the model's identification performance. In particular, the effect of age on high hospitalization costs showed a nonlinear pattern, with older age exerting a negative effect on the identification of high-cost patients. One possible explanation is that because comorbid degenerative conditions increase surgical risk [45], older patients are more likely to receive conservative treatment and, compared with younger patients, are less likely to undergo high-cost interventional procedures, such as mechanical thrombectomy [46]. This pattern of clinical management is consistent with the baseline finding that patients in the high-cost group were, on average, younger. In addition, this study found a relatively high proportion of patients with a low comorbidity burden in the high-cost group. As patients in this group were generally younger, the prevalence of chronic underlying diseases would be expected to be lower, which may partly explain the clustering of relatively mild comorbidity in this group. However, given the inherent limitations of retrospective observational studies, future research should further examine the causal relationships among age, comorbidity, and high hospitalization costs in patients with stroke through prospective study designs. Notably, the performance of CCI, comorbidity count, and ECI in between-group comparisons was not entirely consistent, which may be attributable to differences in disease composition and weighting structure among these comorbidity measures. Comorbidity count reflects only the number of coexisting conditions and does not incorporate disease-specific weights. In contrast, the CCI applies weights based on a relatively limited set of comorbidity categories, whereas the ECI encompasses a broader range of comorbidity conditions and is based on a different scoring framework. Regarding insurance type, patients covered by provincial medical insurance generally benefit from higher reimbursement rates and broader formulary coverage. As a result, they may have greater financial access to high-cost diagnostic and therapeutic services and, when treated at tertiary grade A hospitals, may be more likely to accept more comprehensive or resource-intensive interventions. This may explain the significant positive association between provincial medical insurance and high-cost status. In contrast, patients with cross-provincial medical insurance or other payment methods may be constrained by reimbursement limits or out-of-pocket affordability. In clinical decision-making, these patients may therefore be more likely to adopt more economical or conservative treatment strategies, which is reflected in the model as a lower probability of high medical expenditure. Clinical management in these groups may prioritize cost-effective care, resulting in a negative association with high-cost status. This observed pattern is consistent with the findings of Yang et al in the Chinese ischemic stroke population [47].

Sensitivity analysis showed that when the outcome threshold was set at 5%, the constructed model performed poorly, with limited practical value for management purposes. As the threshold was relaxed from 10% to 20%, the model's AUC tended to stabilize, while the F_1-score increased. However, this improvement in F_1-score may mainly reflect the passive effect of a larger number of positive samples and a more balanced class distribution, rather than a true improvement in the model's discriminative ability. In addition, a broader threshold of 15% or 20% may dilute the core characteristics of the truly high-expenditure group, thereby creating potential challenges for the precise allocation of clinical resources and the refined management of medical insurance cost control. In contrast, a 10% threshold allows greater concentration on the core high-cost group and more accurately targets the disproportionately high-expenditure cases prioritized under the current medical insurance payment system. It should be noted, however, that at this 10% prevalence level, the optimal model yields a positive predictive value of approximately 0.41. While this implies a certain false-positive fraction, these misclassified cases typically represent moderately complex patients who may still benefit from subsequent care management. Ultimately, the practical implementation of this model relies on available administrative capacity. If hospital resources are relatively sufficient, health care managers can effectively absorb the interventions for these false positives and may even appropriately increase the threshold to expand coverage, thereby minimizing the risk of overlooking other potential high-cost cases.

Limitations and Future Directions

First, the training and test sets in this study were generated using a single stratified random split, and the model evaluation results may therefore be influenced by variability arising from random sample partitioning. Although bootstrap resampling was used to estimate CIs, it could not fully eliminate the bias inherent to a single split. Due to the constraints of the study design for temporal validation and to preserve the original temporal characteristics of the cohort, repeated data splitting was not performed. Future studies could further enhance the reliability of the results through repeated split-sample validation. Second, the data were primarily sourced from a single center, which may introduce biases related to region-specific medical practices or insurance policies. Future research should prioritize multicenter external validation to confirm the model's robustness; furthermore, the generalizability of this network feature-based framework to other disease spectra remains to be validated. Third, given the retrospective nature of this study and its reliance on hospital discharge data, some features exhibit information lag, which limits the utility of the model for preadmission screening. Although we used features available at admission to construct an early identification model, achieving more precise screening will require incorporating other features available at admission based on this study. However, SHAP-based interpretability analysis still holds significant value

XSL•FO
RenderX

in providing decision support for clinical process management and guiding personalized interventions. Additionally, a specific limitation exists regarding the "planned readmission within 31 days" indicator. Owing to our 30-day aggregation strategy, merged readmission episodes accrue higher total costs, introducing a potential circularity issue that could theoretically inflate this feature's apparent contribution. Although our SHAP analysis revealed it had the lowest importance contribution—indicating a minimal practical impact on the model's identification performance in this cohort—future studies should carefully account for this potential confounding effect when constructing cost-related variables. Fourth, although the combination of comorbidity network features enriches the feature space, the current absence of biomarkers may limit the granularity of disease severity representation. Future research should prioritize the development of multimodal fusion models to evaluate the incremental value of biomarkers relative to network topological features, thereby establishing a more comprehensive and multidimensional risk profile for patient expenditures. Fifth, the static network constructed in this study may not fully capture high-order dependencies or the dynamic trajectories of disease evolution. Therefore, future research should integrate advanced algorithms, such as Graph Neural Networks and temporal network analysis [48,49], to unlock new opportunities for mining deep comorbidity associations and optimizing identification performance. Sixth, certain limitations remain in our data processing. Continuous variables were neither standardized nor normalized prior to KNN imputation and model training. Although our optimal model, XGBoost, is invariant to feature scaling, the lack of normalization may have impaired the performance of distance-based algorithms, such as SVM and NN. Additionally, despite a low missing data rate (0.13% - 1.95%), applying KNN imputation without prior scaling is a methodological limitation that may introduce minor computational biases. Future studies using distance-sensitive algorithms should incorporate a comprehensive data scaling pipeline. Finally, total hospitalization costs were adjusted for economic fluctuations using the Consumer Price Index. As the general Consumer Price Index primarily tracks a standard basket of consumer goods and medical inflation often outpaces general inflation, this approach may slightly misestimate the true medical cost inflation.

Conclusions

By integrating comorbidity network analysis with machine learning, this research used hospital discharge data to develop a high-performance framework for the identification of high-cost stroke patients. Our results confirm that, compared to stroke type within baseline features and conventional comorbidity features, network topological features are able to capture deeper information regarding disease complexity. The inclusion of network features improved model performance, with the XGBoost model demonstrating the best identification performance. Furthermore, SHAP analysis identified strong associations between high costs and relevant features while also revealing complex nonlinear interactions among these variables. These findings indicate that this framework demonstrates promising application prospects for cost-risk stratification in patients with stroke. If validated externally and prospectively in the future, this model could provide valuable decision support for exploring early identification of medical costs and stratified intervention strategies, thereby assisting in the optimization of medical resource allocation.

Abstract

Background: Stress and inflammatory bowel disease (IBD) symptoms may vary over short time scales, but these dynamics are not well captured by intermittent clinical assessments.

Objective: The study aimed to characterize exploratory time-varying stress-symptom patterns using intensive longitudinal monitoring and to evaluate a transparent, patient-clustered analysis framework.

Methods: A prospective longitudinal design was used with 74 patients with IBD monitored for 90 days. Daily data comprised 12 core indicators and 2 auxiliary measures. The canonical analysis used patient-level partial-correlation PCMCI (Peter and Clark Momentary Conditional Independence) with a τ of 0 to 2, patient-specific network scaling, a fixed 30-day cycle-end stress contrast, exploratory module-control, and effective-information summaries, and a secondary exploratory time-varying effect model (TVEM).

Results: Mean stress was higher during cycle days 26 to 30 (mean 4.789, SD 1.079) than during nonwindow days (mean 4.160, SD 1.013), with a mean within-person difference of 0.629 (95% CI 0.550 - 0.708; P<.001); 71 of 74 (95.9%) participants showed a positive difference. Symptom scores had the highest mean of 9.88 (SD 0.09) and lowest dispersion, whereas stressors showed greater variability (mean 3.68, SD 0.49). The estimated network showed predominant forward connections from psychosocial factors through emotion regulation and psychophysiological amplification indicators to gut-specific symptoms. The psychophysiological amplification module had the highest micro-to-macro flow efficiency and macro-level control metric. In the TVEM analysis, the full module-control and causal-emergence models explained 64.4% and 45.6% of the deviance, respectively.

Conclusions: In this longitudinal IBD patient cohort, daily monitoring identified a reproducible end-of-cycle stress comparison and an exploratory multiscale organization that links psychosocial, emotional, psychophysiological, and gut-specific symptom domains. The psychophysiological amplification module provides the most informative, comprehensive representation, although its organization varies depending on follow-up and disease status. These findings support the use of digital phenotypes to generate clinical evidence for the coordination of stress symptoms, tailored to individual situations.

KEYWORDS

inflammatory bowel disease; longitudinal digital phenotype; causal emergence; time-varying causal network; module control; central sensitization

Introduction

Inflammatory bowel disease (IBD) is a chronic gastrointestinal (GI) disease characterized by a relapsing-remitting course, comprising Crohn disease and ulcerative colitis, and it imposes a substantial global health and socioeconomic burden [1,2]. In addition to the hallmark GI manifestations (eg, abdominal pain, diarrhea, and rectal bleeding), IBD is increasingly recognized as a systemic disease [3] characterized by heterogeneous GI and extraintestinal manifestations, with psychological stress increasingly recognized as a key moderator of symptom severity and risk of recurrence [4,5], which often exacerbates symptoms and induces disease recurrence. The complexity of these phenotypes is further compounded by the highly dynamic nature

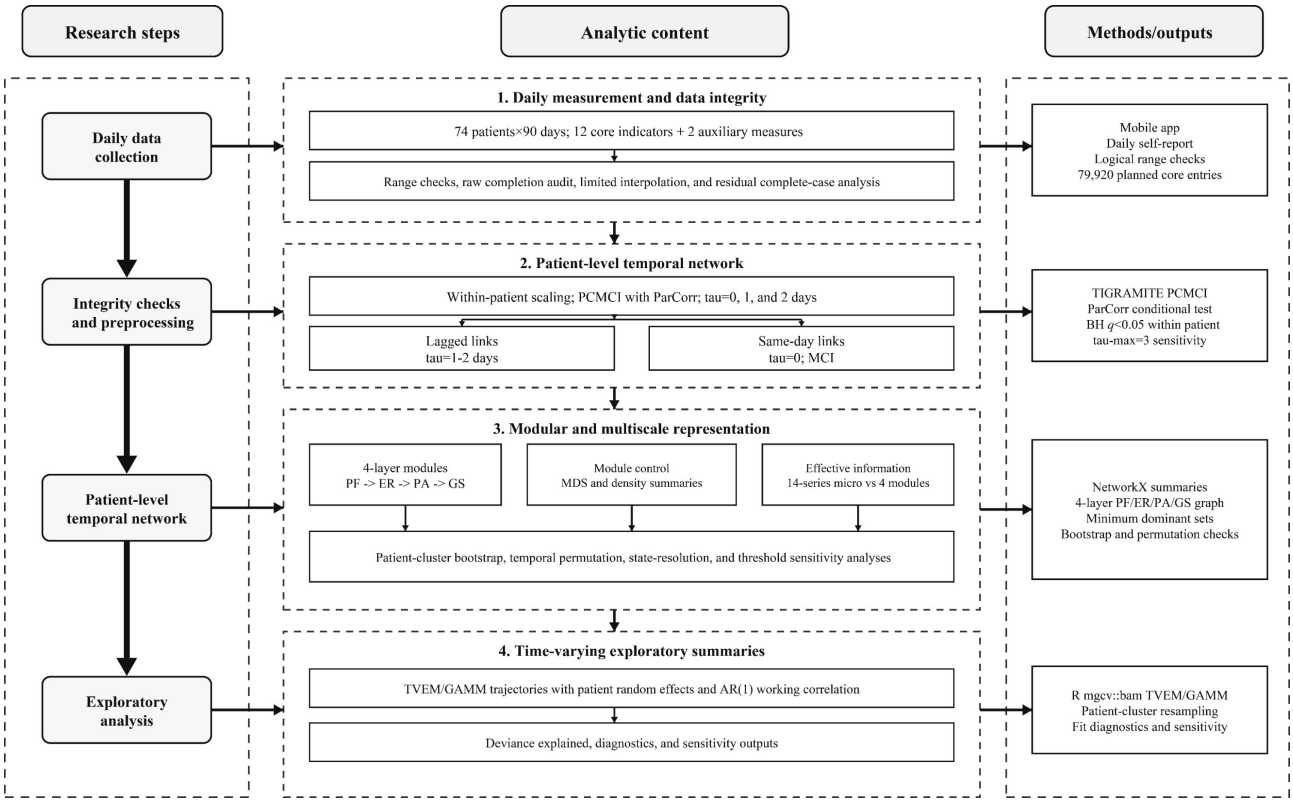
of the disease, and clinical management of IBD is currently hampered by 2 interrelated challenges: a lack of mechanistic understanding of disease dynamics and an inability to identify actionable, patient-specific targets for intervention [6,7]; despite advances in biologic agents and small-molecule therapies [8-10], the unpredictable switch between remission and relapse, combined with stress-related fluctuations in symptoms, remains a major clinical challenge. Network-based simulations and personalized time-series models have also been proposed as approaches for generating patient-specific hypotheses and identifying actionable intervention targets [11,12]. This limitation is exacerbated by reliance on cross-sectional or sparsely sampled longitudinal data, which masks the temporal dynamics of symptom evolution and causal relationships between disease-related variables [12,13].

Recent advances in digital health technologies, including wearable sensors, mobile health (mHealth) apps, and continuous physiological monitoring, have allowed us to collect dense longitudinal microdata (eg, daily symptom scores, physiological parameters, and behavioral metrics) with unprecedented temporal resolution [12,13], which offer a unique opportunity to characterize IBD and reveal the complex causal networks underlying disease activity. Translating this wealth of data into actionable clinical insights will require integrated analytic frameworks that can effectively decipher the complex interconnections among stress, symptoms, and disease dynamics to support precision decision-making. Current clinical practice and research increasingly need tools that can connect data collection and clinical applications to achieve a holistic understanding of disease progression. Comprehensive approaches that integrate causal inference [14,15], network science [16], and time-varying modeling [17] are essential to identify key regulatory modules, verify their clinical relevance, and track dynamic changes. This framework can not only unlock the potential of longitudinal microdata but also fit the core goal of precision medicine in IBD to provide targeted interventions for each patient at the right time.

This study aimed to develop and evaluate an integrative longitudinal analysis framework for characterizing the interaction between stress and IBD symptoms. The objectives were to describe time-lagged and instantaneous relationships among stress, cognitive behavioral, psychophysiological, and symptom variables; to identify functional network modules; and to evaluate dynamic changes in causal-emergence and module-control metrics.

Methods



Study Design and Participants

This study used a prospective longitudinal design to collect high-density time-series data from patients with IBD, with the aim of evaluating the proposed integrative analysis framework. The overall analytic workflow is summarized in Figure 1. Eligible participants had a diagnosis of IBD, were 18 to 65 years of age, had a disease duration of 6 months or more, and had disease activity within the prespecified baseline eligibility ranges (Mayo score of 2-4 for ulcerative colitis and Simplified Endoscopic Activity Score for Crohn Disease [SES-CD] score of 3-7 for Crohn disease). The Mayo score and SES-CD are disease-specific instruments; their raw scores were not treated as directly interchangeable measures across IBD subtypes. Exclusion criteria included serious mental disorders requiring systematic treatment (eg, schizophrenia, bipolar disorder); use of glucocorticoids, immunosuppressants, or biological agents within 1 month before enrollment; other serious GI diseases (such as gastric cancer and intestinal obstruction); or inability to complete daily data recording or use study equipment.

A total of 74 patients with IBD were recruited from the First Affiliated Hospital of Xinjiang Medical University from January 2024 to March 2025. The follow-up period was 90 days (days 0 - 89). Clinical visits were scheduled at baseline (day 0), day 45, and day 89 for standardized assessments and data verification. Disease activity was characterized using the disease-specific instrument for each subtype: the Mayo score for ulcerative colitis and the SES-CD for Crohn disease. These measures were used as subtype-specific clinical covariates and were not combined into a common raw disease activity score.

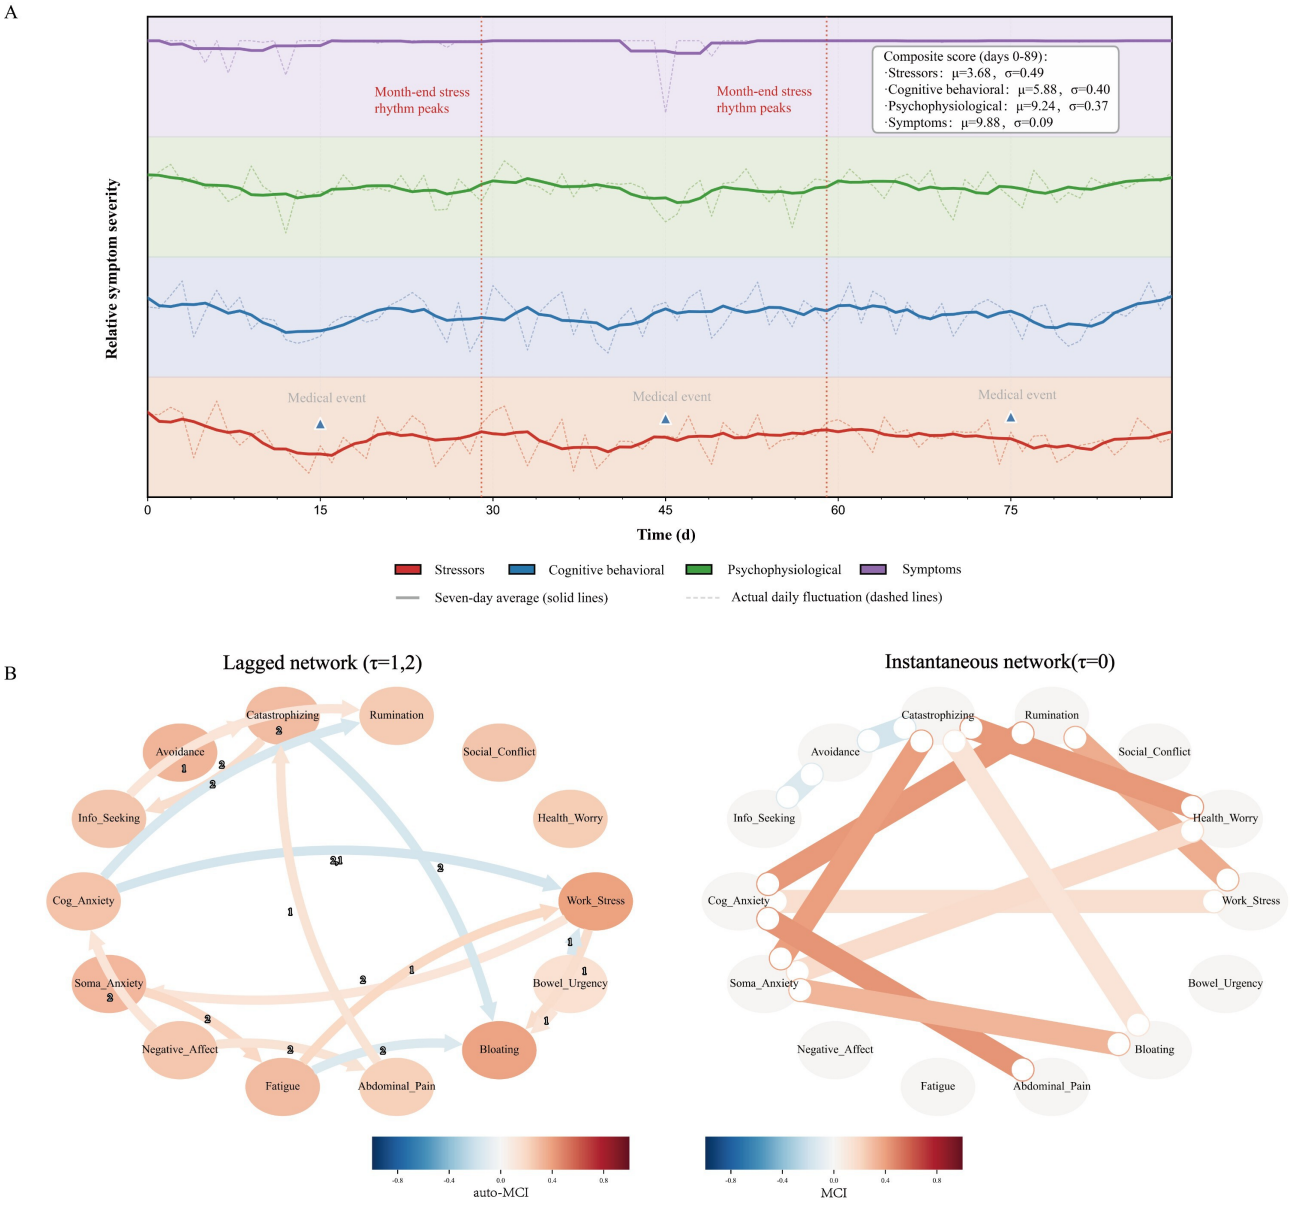
Figure 1. Methods workflow. The diagram summarizes the analytic sequence from daily data collection and integrity checks to patient-level temporal network estimation, modular and multiscale representation, and exploratory time-varying summaries. AR(1): first-order autoregressive; BH: Benjamini-Hochberg; ER: emotion regulation; GAMM: generalized additive mixed models; GS: gut-specific symptoms; MCI: momentary conditional independence; ParCorr: partial correlation; PA: psychophysiological amplification; PCMCI: Peter and Clark Momentary Conditional Independence; PF: psychosocial factors; TVEM: time-varying effect model.



Data Collection and Variable Definitions

High-density time-series data were collected daily for 90 consecutive days. To make the analysis set explicit, the daily measures were organized into 12 core indicators across 4 domains: psychosocial factors (PF: work stress, health worry, and social conflict), emotion regulation (ER: rumination, catastrophizing, and avoidance), psychophysiological amplification (PA: cognitive anxiety, somatic anxiety, and negative affect), and gut-specific symptoms (GS: abdominal pain, bloating, and bowel urgency). Information seeking and fatigue were collected as 2 auxiliary daily measures and mapped to ER and PA, respectively. These auxiliary measures were not counted in the 12-indicator denominator or the 94.3% (75,365/79,920) core completion calculation, but they were retained in explicitly exploratory network and module analyses. Accordingly, Figure 2 displays 14 nodes or dimensions (12 core indicators+2 auxiliary measures). The source instruments, score handling, and analysis roles of all core and auxiliary measures are specified in Table S2 in Multimedia Appendix 1. For stressor assessment, the brief Perceived Stress Scale, 10 item (PSS-10) [18,19] was used to assess daily stress levels, and the 90-day average daily score was calculated. The cycle-end window was prespecified as a window for exploratory dynamic analysis and was defined as cycle days 26 to 30 of each 30-day study cycle. We calculated each participant's mean stress score within and outside this window and estimated the participant-level difference with a 2-sided 1-sample *t* test and 95% CI. We also fitted a linear mixed effects model with daily stress score as the outcome, cycle-end window and study day as fixed effects, and a participant-specific random intercept. This analysis quantified a prespecified window contrast; it was not a test of full periodicity and did not establish that the window represented each participant's maximum stress. The 79,920 figure refers to the planned core variable-day matrix (74 participants×90 days×12 core indicators), whereas the 94.3% (75,365/79,920) completion rate refers to raw core entries before preprocessing. For each variable, interpolation was permitted only when raw missingness was at most 5% and only across internal gaps of at most 2 observations; variables with completion below 92% were flagged, and residual gaps were analyzed on a complete-case basis. Cognitive behavioral factors were assessed using the Cognitive Emotion Regulation Questionnaire (CERQ) [20] and the Health Information Seeking Behavior Scale (HISBS) [21]. The Hospital Anxiety and Depression Scale (HADS) [22], Positive and Negative Affect Schedule (PANAS) [23], and 20-item Multidimensional Fatigue Inventory (MFI-20) [24,25] were used to evaluate psychological and fatigue-related measures. IBD symptoms were evaluated using the study-labeled Inflammatory Bowel Disease Symptom Score Scale (IBD-SI) [26], including bowel urgency, bloating, and abdominal pain. Raw daily data were retained for the primary analyses; any 7-day smoothing used in descriptive figures was labeled as visualization-only and was not used in inferential models. Medical events reported during follow-up were recorded when available, but treatment changes, infections, and flare status were not systematically captured as daily time-varying covariates. Objective inflammatory measures, including

XSL•FO
RenderX

endoscopic activity, C-reactive protein, and fecal calprotectin, were not systematically available across the follow-up and were not included as fully time-varying covariates. Sleep, diet, menstrual-cycle effects, and medication adherence were also not systematically collected for model adjustment. Daily data were collected with a customized mHealth application with built-in logical checks to ensure data validity (eg, scoring-range limits). Missing data were handled by a prespecified variable-level policy: interpolation was permitted only when raw missingness was at most 5% and only for internal gaps of at most 2 observations; variables with completion below 92% were flagged; and residual gaps were analyzed on a complete-case basis. Baseline data were collected using a structured questionnaire, medical record review, and clinical assessment.

Figure 2. High-resolution longitudinal monitoring describes temporal coupling between stress patterns and symptom severity in a representative patient with inflammatory bowel disease. (A) Daily symptom severity trajectories (relative score) over 90 days, showing temporal coincidence in the displayed individual series with a prespecified cycle-end window (cycle days 26 - 30). Blue and green shaded areas demarcate periods of symptom exacerbation and attenuation, respectively, in the displayed time series. The table inset summarizes composite scores (mean, SD) across 4 key dimensions. The legend distinguishes the 7-day average random-volatility value from the actual daily data fluctuation; both labels were retained and strengthened for readability. (B) Model-derived conditional-association networks among the displayed variables. The lagged network (left) depicts estimated 1- to 2-day temporal associations, while the instantaneous network (right) captures same-day associations. Functional domains are identified by node labels and panel layout; node fill is not used as a domain key. Arrows indicate the direction and relative strength of estimated links. The lagged network uses the auto-MCI color scale, whereas the instantaneous network uses the MCI color scale. Cog_Anxiety: cognitive anxiety; Info_Seeking: information seeking; MCI: momentary conditional independence; Som_Anxiety: somatic anxiety.

PCMCI and Group-Level Temporal Network Summary

Time-lagged and contemporaneous conditional associations among the daily series were estimated using the exploratory PCMCI (Peter and Clark Momentary Conditional Independence) algorithm [27] and the Tigramite package (Causal Inference Lab). PCMCI is a 2-stage time-series procedure: the principal component 1 phase removes conditionally independent candidate links, and the momentary conditional independence phase tests the remaining lagged links while conditioning on relevant past variables. PCMCI was fitted separately for each eligible patient using the analytic partial-correlation (ParCorr) conditional independence test, with τ of 0, 1, and 2 days and Benjamini-Hochberg *q*-values controlled at 0.05 within each patient. The primary lag window was limited to 0 to 2 days to represent short-term carryover that can be resolved by daily assessments while also limiting parameter growth and the sparsity of effective transitions in the 90-day patient-level series. This restriction does not imply that longer delays are absent; a τ-max sensitivity analysis through 3 days is reported in Table S5 in Multimedia Appendix 1. The patient, rather than the person-day, was the independent unit. Network inputs were standardized within patients after the prespecified missing-data step. These outputs are directed, model-derived conditional associations under linear and stationarity assumptions; they do not establish experimental causality, biological mechanisms, mediation, or intervention responsiveness. Patient-cluster bootstrap intervals summarize support and signed direction across fitted patient-level links; the bootstrap resamples patients after PCMCI fitting and does not refit PCMCI. Lag-order and alpha-threshold sensitivity grids are reported in Multimedia Appendix 1. NetworkX was used for exploratory centrality summaries.

We integrated model-derived phase, entropy, and energy metrics to describe exploratory changes in directed temporal network structure. Based on disease trajectory patterns, participants were categorized into 3 subgroups. We compared network metrics across subgroups, identified candidate transition boundaries and symptom-feedback nodes, and tracked changes in model-derived phase trajectories during disease-state transitions. Positive Causal Entropy was interpreted as the uncertainty in forward temporal transmission, whereas Reverse Causal Energy was interpreted as symptom-related feedback intensity acting on upstream variables.

Network Structure and Module Control Analysis

Based on the directed temporal network estimated using exploratory PCMCI, a 4-layer modular network representation was constructed. The input layer (PF) contained the 3 core PF indicators; the processing layer (ER) contained the 3 core ER indicators plus auxiliary information seeking; the amplification layer (PA) contained the 3 core PA indicators plus auxiliary fatigue; and the output layer (GS) contained the 3 core GS indicators. The resulting module-control metrics are exploratory summaries of a thresholded, model-derived graph. Minimum dominant sets were defined as the smallest sets of driver nodes that collectively reached all module nodes in the thresholded graph. Driver nodes, controllability proxies, module flows, and threshold sensitivity were calculated with the patient as the resampling unit.

Effective-Information and Causal-Emergence Metrics

Exploratory multiscale information analysis compared a 14-series micro representation with 4 prespecified macro modules. Each micro variable was converted to 2 within-patient rank categories; each macro-state was the rounded mean category of its assigned variables. Observed adjacent transitions were counted without crossing patient boundaries. Transition probabilities were estimated with additive smoothing of 0.50 and a uniform intervention distribution across the represented current states. Effective information was reported in bits, and causal-emergence strength was defined as macro effective information minus micro effective information. A patient-cluster bootstrap, within-patient temporal permutation, and sensitivity to 2-category vs 3-category state resolution were prespecified.

Time-Varying Effect Model

A secondary exploratory time-varying effect analysis was specified only for daily model-derived outcomes supplied in the analysis input. In R, mgcv::bam used cubic regression splines with primary fixed day knots at 0, 10, 25, 50, 65, 75, and 89 (including cycle landmarks 25, 50, and 75), a patient-level random intercept, and a patient-level first-order autoregressive (AR(1)) working correlation. The AR(1) rho estimate, based on ordered within-patient outcome residual proxies, was recorded in the output manifest. Models were adjusted for IBD subtype, age, sex, disease duration, and within-patient *z*-scored disease activity and HADS. Sensitivity models varied the time-basis dimension and used a scaled-t outcome family. All time-varying effect model (TVEM) results were exploratory descriptions of model-derived outcomes and were not interpreted as treatment effects, biological mechanisms, or causal trends.

Because the independent sample consisted of 74 patients and the downstream models were exploratory, we did not treat the large collection of module, subtype, and time-varying terms as confirmatory hypothesis tests. The sensitivity output reports basis-dimension comparisons, scaled-t alternatives, effective degrees of freedom, residual diagnostics, and dependence parameters.

Covariate Adjustment

To assess potential confounding of the relationships between the core variables and the model-derived outcomes, study participants were stratified according to key categorical covariates, and differences in network structure and module metrics between subgroups were compared at each level. Generalized additive mixed models were used to quantify the contribution of the available covariates, with adjustment for individual random effects and time-series autocorrelation. This covariate strategy does not eliminate residual confounding by clinical, treatment-related, behavioral, or physiological factors that were not systematically measured.

Statistical Analysis

The reproducibility repository contains a pinned Python (version 3.11; Python Software Foundation) environment and an R (version 4.3.1; R Foundation for Statistical Computing)

XSL•FO
RenderX

environment description. The canonical Python analysis uses analytic Tigramite ParCorr with a τ of 0 to 2, patient-specific within-person *z*-scores, patient-level Benjamini-Hochberg control, and patient-cluster stability summaries. The primary cycle-end contrast uses raw stress scores and fixed 30-day study cycles. Network, module-control, causal-emergence, and TVEM analyses are exploratory; all resampling uses patients as the independent unit.

Ethical Considerations

This study was reviewed and approved by the Ethics Committee of the First Affiliated Hospital of Xinjiang Medical University (approval number K202412-86). All participants provided written informed consent before enrollment. No directly identifiable participant information is presented in this study.

Results

Study Cohort

The planned core microdynamic matrix comprised 79,920 variable-days (12 core indicators×90 days×74 participants). Before interpolation and exclusion, the raw core completion rate was 94.3% (n=75,365). Information seeking and fatigue were auxiliary measures and were excluded from both the denominator and the completion calculation; the exploratory network, module-control, and multiscale information analyses nevertheless retained these 2 measures, yielding 14 input series. The baseline demographic and clinical characteristics of the 74 participants are summarized in Table 1.

[e]Indicates that the instrument was not applicable to the opposite subtype rather than that data were missing.

[f]HADS: Hospital Anxiety and Depression Scale.

Individual Stress-Symptom Dynamics

Through in-depth analysis of 90 days of high-density monitoring data from 74 participants, we quantified stress differences between the prespecified cycle-end window and nonwindow days. A representative 90-day symptom trajectory and the corresponding model-derived lagged and instantaneous networks are shown in Figure 3. The analytic dataset contained 6660 participant-days, including 1110 cycle-end-window observations and 5550 nonwindow observations. Mean stress was 4.789 (SD 1.079) during cycle-end days 26 to 30 and 4.160 (SD 1.013) outside the window. The mean participant-specific difference was 0.629 (95% CI 0.550 - 0.708 points; *P*<.001), and 71 of 74 (95.9%) participants had a positive cycle-end minus noncycle-end difference. In a linear mixed effects model adjusted for study day and including a participant-level random intercept, the cycle-end-window coefficient was 0.608 (95% CI 0.553 - 0.663; *P*<.001). These results support higher average stress during the prespecified window but do not establish an individual-specific maximum or a recurring population-wide monthly rhythm. The corresponding individual-level distributions and daily trajectory are provided in Table S1 and Figure S1 in Multimedia Appendix 1. The remaining network findings are interpreted as model-derived temporal associations and do not establish mediation or biological causality. The symptom dimension exhibited the highest mean (μ=9.88) and extremely low dispersion (σ=0.09), indicating high homogeneity in symptom burden across the cohort. In contrast, stressors (μ=3.68, σ=0.49) and psychophysiological indicators (μ=9.24, σ=0.37) exhibited greater interindividual variability.

Figure 3. Exploratory patient-level network summaries and sensitivity results. (A) Peter and Clark Momentary Conditional Independence (PCMCI)–derived patient trajectories in forward causal entropy vs reverse causal energy space, with trajectory classes, the transition boundary, and the time course of reverse causal energy shown in the inset. (B) Adjusted stress-to-symptom module flow across the 90-day observation period for the group mean and 2 illustrative patients. (C) Adjusted symptom-to-stress feedback across the follow-up period for the group mean and 2 illustrative patients. Group-Level Temporal Network Summary

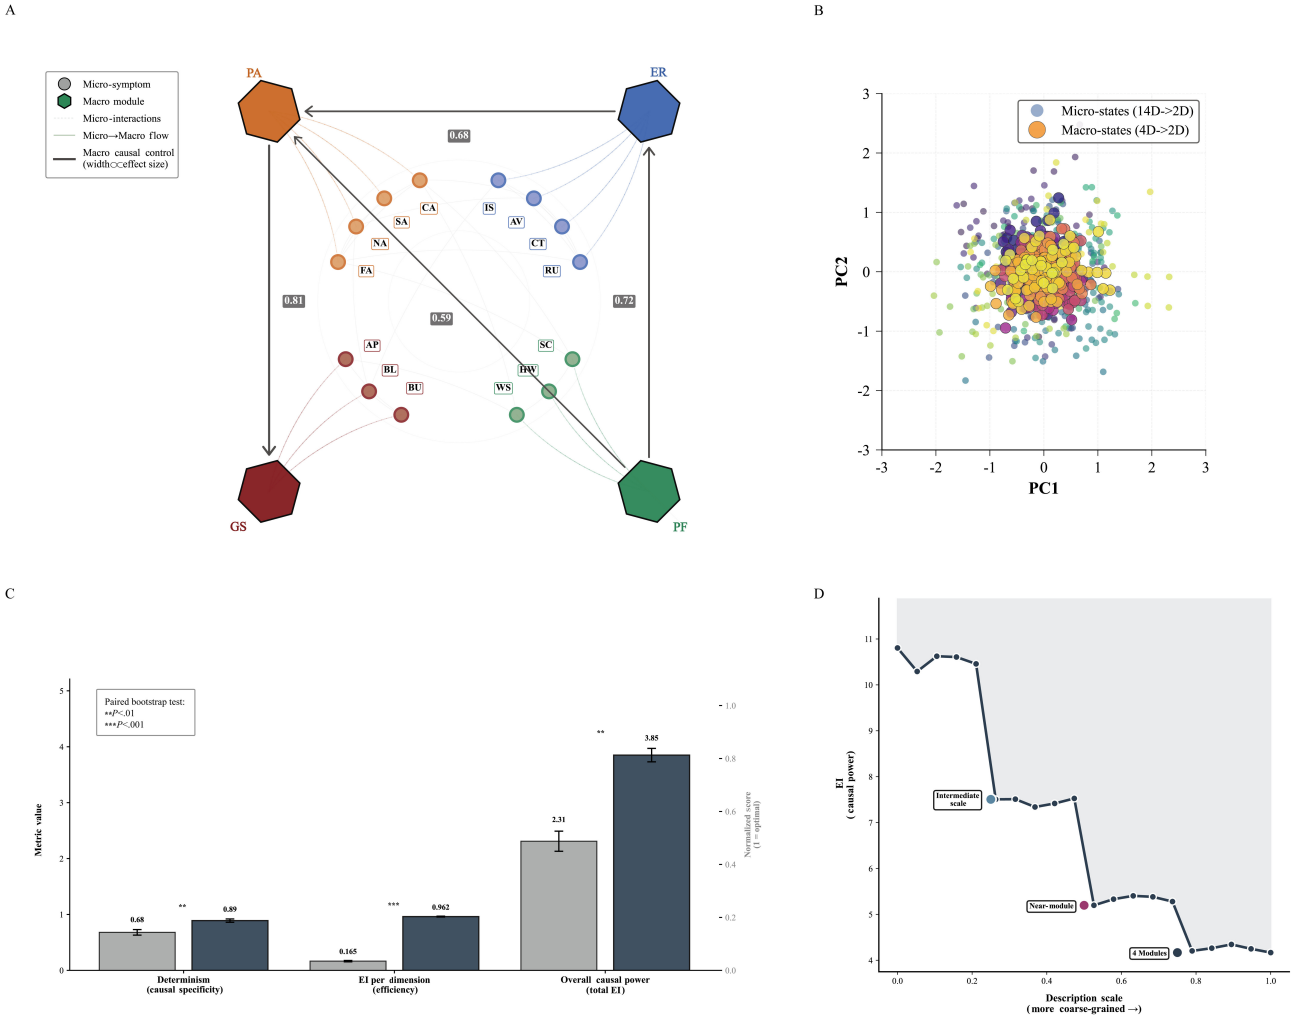
The exploratory network analysis was summarized at the patient level rather than being interpreted as a stable population mechanism. We report the number of eligible patients, patient support, signed direction agreement, and cluster bootstrap intervals for retained links and module summaries. Any time-varying pattern shown in Figure 4 is a model-dependent descriptive summary and may reflect inflammation, treatment, reporting behavior, or other unmeasured influences.

Figure 4. A hierarchical modular network representation summarizes the exploratory organization of inflammatory bowel disease symptom–related variables. (A) The 14 displayed nodes comprise 12 core indicators and 2 auxiliary measures: information seeking in emotion regulation (ER) and fatigue in psychophysiological amplification (PA). The 4-layer network extends from psychosocial factors through ER and PA to gut-specific symptoms (GS); edge colors distinguish forward control, feedback, and intramodule integration, and outlined nodes denote model-derived control nodes. (B) Intramodule connection density across treatment duration. (C) Module-level modularity (*Q*) with patient-level distributions and the group summary. (D) Intermodule connection density for psychosocial factors (PF)-to-ER, ER-to-PA, PA-to-GS, PF-to-GS, PF-to-PA, and ER-to-GS interfaces. MDS: minimum dominant set.

XSL•FO
RenderX

Module Control Network Analysis



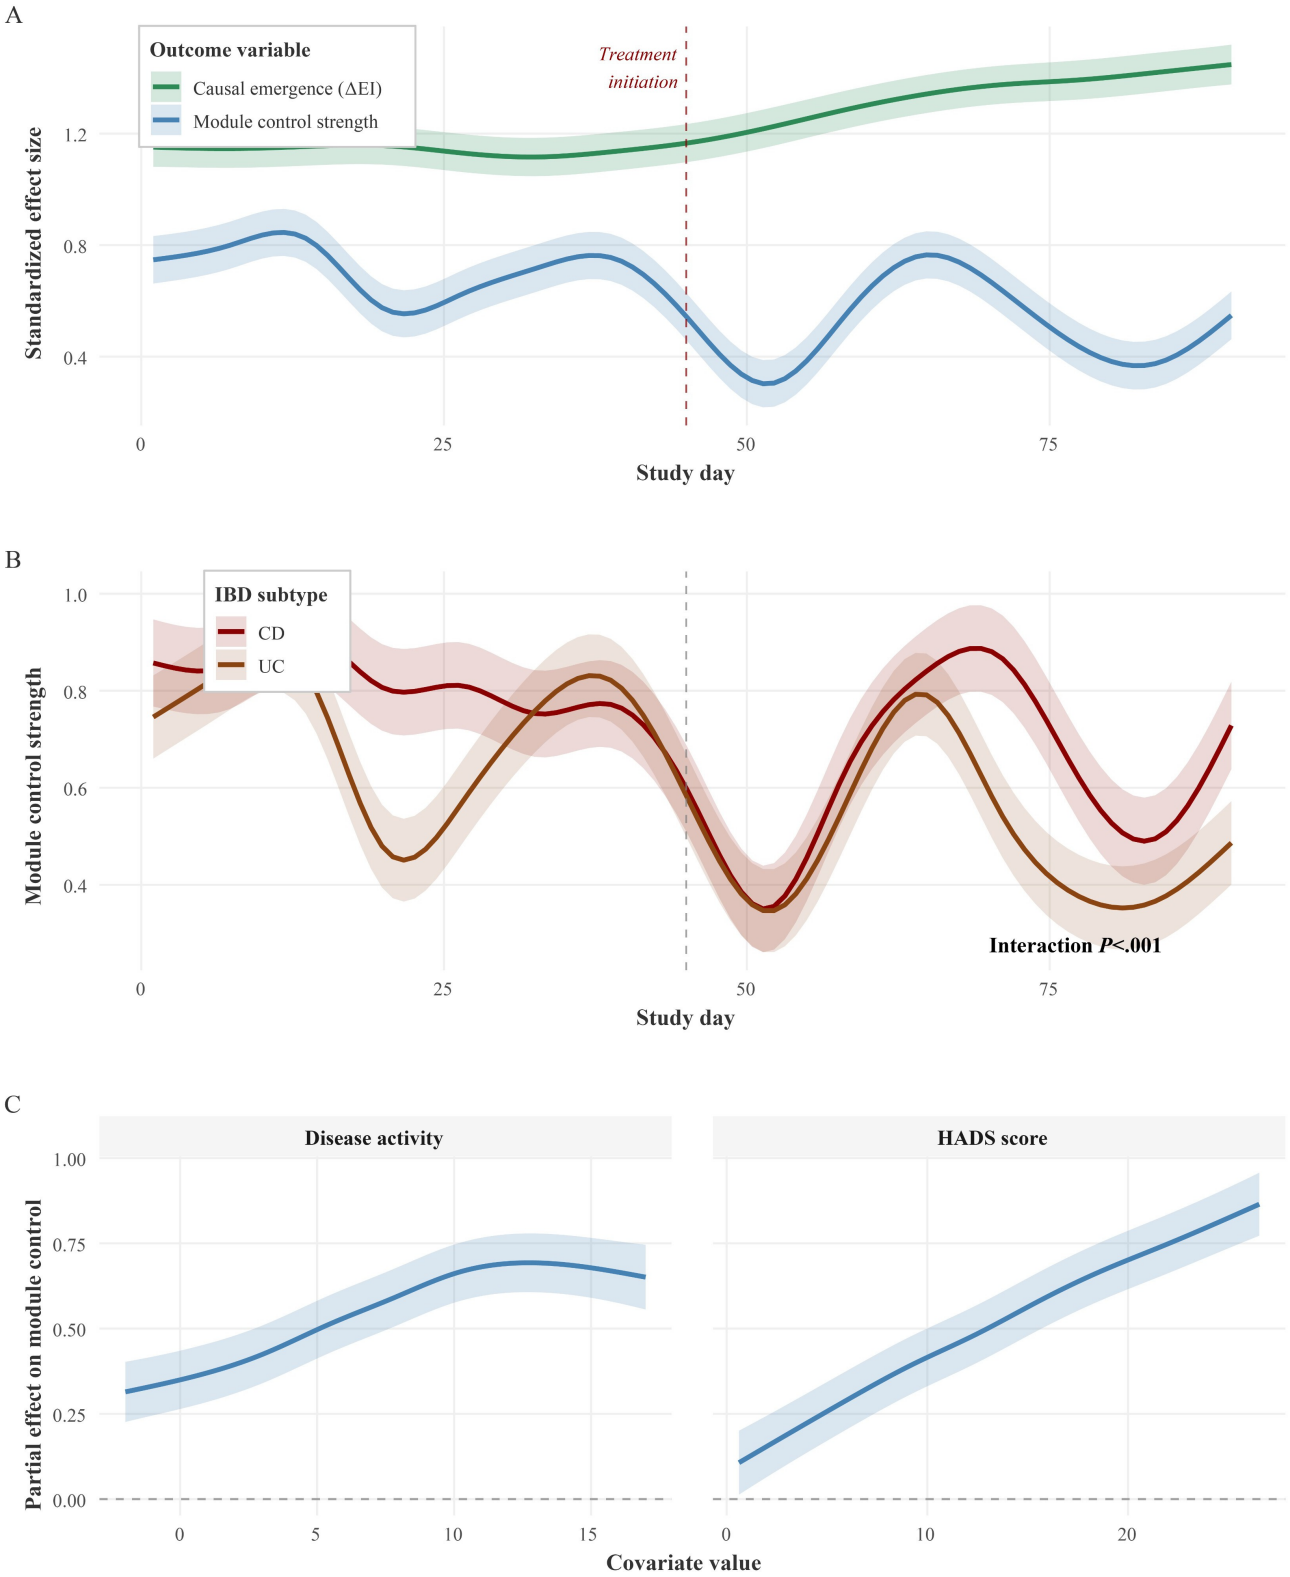
Network analysis identified 4 functionally defined modules organized sequentially for information processing (Figure 4A). The exploratory representation contained 14 nodes: 12 core indicators and 2 auxiliary measures. The input layer (PF module) contained work stress, health worry, and social conflict; the processing layer (ER module) contained rumination, catastrophizing, and avoidance plus auxiliary information seeking; the amplification layer (PA module) contained cognitive anxiety, somatic anxiety, and negative affect plus auxiliary fatigue; and the output layer (GS module) contained abdominal pain, bloating, and bowel urgency. Connections between modules predominantly showed a feedforward temporal pattern from stress-related cognition toward emotional and symptom variables. Feedback connections from the output layer to the amplification layer were also identified, consistent with a possible reciprocal association between somatic symptoms and emotional or psychophysiological states. Within modules, high-density integrative connections and core-dominant nodes represented model-derived information convergence. Intramodule connection density showed an overall upward trend during follow-up (Figure 4B). The ER and PA modules had the highest modularity *Q* values (Figure 4C), indicating greater relative separation within this exploratory network. Intermodule connection density was highest from PF to ER, followed by PA to GS (Figure 4D).

Causal-Emergence Summary

The exploratory module analysis summarized the psychophysiological amplification module as a model-derived integrative unit in the thresholded model-derived graph. The corresponding module-level control and effective-information metrics are shown in Figure 5. The label describes the functional grouping of measured affective, cognitive, and fatigue-related variables; it is not a validated central-sensitization or pain-amplification construct. Module metrics, effective-information contrasts, patient-cluster bootstrap intervals, temporal permutation results, and state-resolution sensitivity are reported without assigning biological or intervention meaning.

XSL•FO
RenderX

Figure 5. A model-derived multiscale information metrics identify the psychophysiological amplification (PA) module as a model-derived integrative unit. (A) Module-level causal-control and information-flow metrics for the 4 functional modules; the PA module shows the highest micro-to-macro flow efficiency and macro-level control metric. (B) Principal-component (PC) representation of the 14-dimensional exploratory micro-state and 4-dimensional macro-state representations. (C) Paired bootstrap comparisons of model-derived metrics between micro-symptom and macro-module descriptions; asterisks (** and ***) denote the displayed bootstrap significance convention. (D) Dependence of the model-derived effect size on description scale, with the largest value at the 4-module scale. The 14 micro nodes comprise 12 core indicators plus information seeking and fatigue. AP: abdominal pain; AV: avoidance; BL: bloating; BU: bowel urgency; CA: cognitive anxiety; CT: catastrophizing; ER: emotion regulation; FA: fatigue; GS: gut-specific symptoms; HW: health worry; IS: information seeking; NA: negative affect; PF: psychosocial factors; RU: rumination; SA: somatic anxiety; SC: social conflict; WS: work stress.



TVEM

The TVEM used 6660 daily observations from 74 patients. The archived fast restricted maximum likelihood evaluation output for the canonical TVEM input reported 64.4% deviance explained (adjusted R^2=0.642) for the full module-control model and 45.6% (adjusted R^2=0.453) for the full causal-emergence model. The subgroup fits were reported 64.7% and 45.7%, respectively; the basic module-control fit was 62.9%. TVEM fit metrics, residual diagnostics, dependence parameters, and basis/scaled t-sensitivity results are reported in Tables S2 and S8 in Multimedia Appendix 1. Figure 6 reproduces the original 3-part presentation: panel A displays the adjusted population trajectories for module-control strength and the causal-emergence summary; panel B displays subtype-specific module-control trajectories; and panel C displays the adjusted covariate-effect curves for disease activity and HADS. Lines are model-derived estimates with pointwise 95% intervals. The treatment-initiation marker is descriptive and is not an intervention contrast. The model fit and complexity metrics for the basic, full, and subgroup TVEM specifications are summarized in Table 2.

[e]EDF: effective degrees of freedom.

Discussion

Principal Findings

In this 90-day prospective cohort of 74 patients with IBD, intensive daily monitoring identified a reproducible temporal organization of stress and symptoms that is not visible in intermittent clinic assessments. The prespecified cycle-end contrast was the clearest empirical signal: mean stress was 0.629 points higher during study days 26 to 30 than during the remaining days (95% CI 0.550 - 0.708; P<.001), and 71 of 74 (95.9%) participants showed a positive participant-specific contrast. This finding is important because it establishes a temporal regularity without requiring the stronger claim that IBD has a universal monthly rhythm. Against this temporal background, the exploratory network analyses converged on a structured sequence linking PF, ER, PA, and GS. PF-to-ER and PA-to-GS interfaces were the densest cross-module connections, while symptom-to-PA feedback and increasing within-module density suggested that the observed system was both directional and reciprocal. Finally, the multiscale analysis showed its largest model-derived effect at the 4-module description and highest micro-to-macro flow efficiency and macro-level control for PA. The secondary time-varying models were consistent with changing organization over the follow-up period, but their fit statistics remain descriptive. Taken together, the study provides a compact, clinically interpretable map of temporal coordination.

Temporal Organization of Stress and Symptoms

The cycle-end result gives the framework a concrete behavioral anchor; it was based on a prespecified window and a participant-level mixed model, and the direction was concordant across nearly the entire cohort. The most defensible interpretation is therefore that perceived stress was temporally patterned in this sample, with a recurring increase near the end of each 30-day observation cycle. Such organization could arise from work schedules, social obligations, health-related planning, or other recurring contexts. The distinction matters clinically. A patient whose stress and abdominal symptoms repeatedly co-occur around a predictable period may benefit from anticipatory assessment and support, whereas a patient with no such pattern should not be assigned to the same schedule. Digital phenotyping makes this distinction empirically approachable by resolving within-person timing rather than treating stress as a single baseline covariate [28-31].

The individual and cohort summaries also show why temporal heterogeneity should be retained rather than averaged away. Symptom burden had a high mean and very low dispersion in the aggregate, whereas stressors and psychophysiological indicators varied more across patients. A high average symptom score can therefore coexist with different routes through which stress is experienced, regulated, and reported. The lagged network should be interpreted in that context: the PF-to-ER organization is compatible with stress being expressed through rumination, catastrophizing, avoidance, or information seeking before appearing alongside gut symptoms, but it does not prove that any one node transmits a biological signal. Likewise, the absence of a single population-level coefficient for every stress-cognition pair would not invalidate the cycle-end contrast; a common timing pattern can coexist with heterogeneous pairwise associations. This is precisely the value of reporting patient support, signed direction agreement, and cluster-bootstrap uncertainty rather than presenting one pooled edge as a universal mechanism.

Multiscale Architecture of Stress-Symptom Coupling

The 4-module representation organizes the results around interfaces that are recognizable to clinicians: PF contains work stress, health worry, and social conflict; ER contains rumination, catastrophizing, avoidance, and information seeking; PA contains cognitive anxiety, somatic anxiety, negative affect, and fatigue; and GS contains abdominal pain, bloating, and bowel urgency. The highest PF-to-ER density indicates that psychosocial exposures were most consistently connected to ER variables in the fitted network. The next most prominent

XSL•FO
RenderX

interface, PA-to-GS, places affective and somatic amplification close to the symptoms that patients bring to care. Feedback from GS to PA is equally informative: abdominal sensations may become inputs to the same affective-somatic configuration that accompanies symptom escalation. This topology is more consistent with reciprocal brain-gut coupling than with a one-way stress-to-symptom chain, while remaining agnostic about the underlying physiology [29-32].

The increase in within-module density during follow-up and the relatively high modularity of ER and PA add a second layer of interpretation. Variables within these modules increasingly covaried as a functional unit, yet the modules remained distinguishable from one another. In network terms, the data suggest coordinated clusters and bottlenecks rather than 12 independent symptom scores; in clinical terms, a change in one affective or fatigue-related measure may be accompanied by changes in several neighboring measures. The PA label is deliberately descriptive. It denotes the measured grouping of cognitive anxiety, somatic anxiety, negative affect, and fatigue and should not be equated with a validated neurobiological central-sensitization construct. Existing work on the brain-gut axis and central sensitization provides a biologically plausible context for this grouping [31,32], but this study did not measure nociceptive processing, neural activity, or peripheral mediators. Its contribution is to identify a candidate integrative representation that can be tested against those measures.

Why the Module Scale Matters

The effective-information analysis helps explain why the module-level description was useful: when 14 daily series were compressed into 4 prespecified modules, the model-derived representation showed greater micro-to-macro flow efficiency and macro-level control for PA, and the largest effect size occurred at the 4-module scale. It indicates that, within the chosen state encoding and transition model, correlated indicators could be summarized with less apparent noise and more coherent transition information at the module scale. In other words, the module may function as an information bottleneck: many small fluctuations are represented by a smaller number of clinically legible states. This is closely aligned with the motivation of network medicine, in which patterns of interaction can be more informative than isolated variables [27,33,34]. It also provides a principled reason to report both micro-level and module-level results rather than selecting the most striking metric post hoc.

The multiscale result should therefore be understood as a hypothesis about representation. If the PA module is a robust integrative unit, its summary state should replicate in independent cohorts, remain stable under alternative scaling and missing-data procedures, and correspond to external measures of symptom amplification or brain-gut function. Conversely, if the apparent gain disappears when the state definition, lag window, or cohort changes, the finding will have identified a property of this analytic representation rather than a general feature of IBD. This distinction turns the causal-emergence terminology into a testable methodological proposition and avoids treating a model-derived quantity as a treatment target.

Temporal Reorganization and Disease-State Context

The time-varying analyses extend the cross-sectional network picture by showing that the organization of these relationships was not constant over 90 days. Within the canonical input, the full module-control model explained 64.4% of deviance (adjusted R^2=0.642), and the corresponding causal-emergence model explained 45.6% (adjusted R^2=0.453); subgroup and lower-dimensional fits were similar. These values describe how well the specified smooth functions represented the supplied daily model-derived outcomes. They do not show that the network became more effective due to treatment, nor do they show that a higher curve predicts recovery. The descriptive treatment-initiation marker in Figure 6 should be read accordingly.

The upward trajectory in within-module coordination and the moderation by baseline disease activity are nevertheless clinically informative observations. They suggest that the same measured stress-symptom architecture may be expressed at different tempos in patients entering follow-up with different inflammatory burdens. Several processes could produce this pattern, including inflammation-driven peripheral input, treatment exposure, adaptation to monitoring, changes in symptom appraisal, or regression toward the mean. The important result is not that one of these explanations has been proven, but that disease state is a plausible context variable that should be carried into future longitudinal designs. This complements treat-to-target principles, which distinguish inflammatory control from patient-reported symptom control and require both to be monitored [35,36].

Clinical Meaning as a Testable Hypothesis

The immediate clinical value of this work is, therefore, phenotyping rather than prescribing. A gastroenterologist could use repeated measures to ask whether a patient's stress, affective, fatigue, and gut-symptom signals form a stable temporal pattern, whether the pattern changes with inflammatory activity, and which time windows merit closer review. Such information could complement, rather than replace, objective disease assessment and routine symptom measures. It may also help explain why patients with apparently controlled inflammation continue to report substantial symptoms, a recognized challenge in IBD care [35,36].

The framework also creates a disciplined path toward intervention research. Cognitive behavioral and mindfulness-based approaches are reasonable candidates because prior studies have examined psychological and functional GI outcomes [37,38], and individualized time-series models provide tools for studying person-specific change [39,40]. In this study, however, no psychological, behavioral, or pharmacologic intervention was assigned, and no analysis tested whether changing PF, ER, PA, or GS improved symptoms, quality of life, inflammation, or treatment response. Consequently, the network and module metrics should be used to generate prespecified hypotheses for pragmatic or micro-randomized trials, not to justify a module-specific therapy. Future studies can test whether an intervention changes the predicted edge, module state, or clinically meaningful end point, with

XSL•FO
RenderX

inflammatory and patient-reported outcomes assessed together. That progression preserves the potential clinical relevance of digital phenotyping while keeping exploratory association, mechanistic explanation, and therapeutic efficacy analytically distinct.

Limitations

This study has 4 principal boundaries. The 74 participants were recruited from a single region, so the patient-level support and module summaries require replication in larger, multicenter cohorts. Although the repeated daily records improve temporal resolution, they did not increase the independent sample size beyond 74 participants. Most inputs were self-reported, and the observational design leaves room for unmeasured influences such as treatment changes, sleep, diet, adherence, infection, and inflammatory biomarkers. The prespecified cycle-end contrast, PCMCI links, module-control metrics, effective-information summaries, and TVEM trajectories were analyzed as exploratory or descriptive results, with code and preprocessing details supplied for reproduction. Longer follow-up, multimodal measurement, external validation, and intervention-based causal tests are needed before any network feature is used for clinical decision-making.

Conclusions

Ninety days of daily monitoring among 74 patients with IBD revealed a reproducible cycle-end stress contrast and a model-derived multiscale organization linking PF, ER, PA indicators, and GS. The PA module was the most informative integrative representation in the selected effective-information analysis, while temporal and disease-state patterns indicated that this organization can change during follow-up. These findings support digital phenotyping as a way to formulate clinically grounded, person-specific hypotheses about stress-symptom coordination.

Acknowledgments

The authors are grateful for the technical support provided by Dr Shuangjie Chen, a research assistant, who was involved in the development and maintenance of mobile health apps for digital phenotyping.

Generative AI Use

During the preparation of the revised manuscript, the authors used ChatGPT (GPT-5; OpenAI) solely to assist with technical consistency in document formatting. It was not used to collect data, determine study outcomes, or replace the authors' scientific interpretation. All manuscript content and scientific decisions were reviewed and approved by the authors, who take full responsibility for the accuracy and integrity of the work.

Funding

Research support for this study was provided by the Key Special Project of "Research on Prevention and Treatment of Common Diseases" of the National Science and Technology Department (2022YFC2505100), the Wenzhou Basic Scientific Research Project (YC20250289), the Wenzhou Basic Public Scientific Research Project (Y20240439), the Open Project of the Xinjiang Key Laboratory of Oncology (XJKL0-2025U008), and the National Science and Technology Major Special Project (2025ZD0545303).

Data Availability

The data presented in this study have not been previously published, and no studies based on the same dataset are currently under review or in press elsewhere.

Authors' Contributions

ZL and YC conceptualized and designed the study and wrote the main text. YA and QD were responsible for patient recruitment, clinical data collection, and follow-up management. ZL and LH performed data preprocessing and statistical analysis. YW implemented the algorithm and conducted the analysis. YC, as the corresponding author, supervised the overall research, acquired funding, and finalized the manuscript. All authors participated in the interpretation of the results, critically revised the manuscript, and approved the final version for submission.

Conflicts of Interest

None declared.

Multimedia Appendix 1

Figure and tables describing participant-day stress distributions, the primary cycle-end stress contrast, variable definitions and scoring rules, data availability and missingness, preprocessing and model specifications, and sensitivity and diagnostic analyses.

Abstract

Background: Low peak oxygen consumption ($V\dot{}O_2$) is associated with higher cardiovascular and all-cause mortality, while improvements in peak $V\dot{}O_2$ reduce this risk. Although early detection allows timely intervention, practical screening tools remain lacking. As electrocardiograms (ECGs) reflect both cardiac and age-related changes, they may offer a viable screening approach.

Objective: This study aimed to detect low peak $V\dot{}O_2$ using resting 12-lead ECGs analyzed by a trained neural network.

Methods: The low peak $V\dot{}O_2$ estimation model was developed using data from 965 individuals (n=540, 56% with cardiac or pulmonary disorders) mainly at Chang Gung Memorial Hospital, Linkou, and validated in an independent cohort of 242 individuals (n=194, 80% with cardiac disorders) at the Keelung branch. Resting ECGs were recorded immediately before cardiopulmonary exercise testing. Low peak $V\dot{}O_2$ was defined as a peak $V\dot{}O_2$ of <14 mL/kg/min.

Results: The mean peak $V\dot{}O_2$ was 17.5 (SD 6.1) and 15.4 (SD 3.9) mL/kg/min in the training and validation datasets, with 27% (261/965) and 38% (92/242) classified as low peak $V\dot{}O_2$, respectively. Wavelet analysis improved model accuracy, underscoring its value for feature extraction. Three input models were compared: (1) individual characteristics (IC; age, sex, BMI, resting heart rate, and heart rate variability), (2) ECG alone, and (3) ECG plus IC. ECG alone outperformed IC, and combining both yielded the highest accuracy. For low peak $V\dot{}O_2$ prediction, ECG plus IC achieved mean area under the curve, precision, and recall values of 0.89, 0.72, and 0.72 in cross-validation, and 0.87, 0.67, and 0.61 in external validation.

Conclusions: An artificial intelligence–driven ECG-based algorithm showed strong potential for screening low peak $V\dot{}O_2$, enabling early identification of individuals with low peak $V\dot{}O_2$ and facilitating timely clinical intervention.

Introduction

Peak oxygen consumption (peak $V\dot{}O_2$) is a composite measure of oxygen transport chain efficiency and serves as an integrative marker of cardiorespiratory fitness. Substantial evidence has firmly established the association between low peak $V\dot{}O_2$ and high risk of cardiovascular disease and all-cause mortality [1-4]. Low peak $V\dot{}O_2$ is also linked to a decreased quality of life and a decline in functional abilities for activities of daily living. Importantly, improvement in peak $V\dot{}O_2$ is linked to lower mortality rates and enhanced quality of life [5-8]. The timely identification of high-risk patients enables the implementation

XSL•FO
RenderX

of various pharmaceutical, cardiac, exercise, and nutritional interventions. Additionally, peak $V\dot{O}_2$ has been demonstrated to be a key predictor of surgical complications in thoracic surgeries and is useful for preoperative risk stratification [9,10]. Although early identification of low peak $V\dot{O}_2$ is beneficial, peak $V\dot{O}_2$ assessment requires cardiopulmonary exercise testing (CPET), which is a time-consuming and resource-intensive procedure, making it uncommon in clinical practice. Therefore, a simple and cost-effective screening tool is warranted; however, such a tool remains lacking and represents an unmet need.

It is reasonable to speculate that electrocardiogram (ECG) data could potentially serve as a screening tool for low cardiorespiratory fitness. First, previous cross-sectional and longitudinal studies have reported that age-related changes in ECG patterns include a decrease in R and S wave amplitudes, a leftward shift in frontal plane axis measurements, an increase in P-R and Q-T interval durations, a shortening of QRS duration, and a decrease in T wave amplitude [11]. Moreover, the prevalence of ECG abnormalities increases with age [12]. Second, several studies have further reported that artificial intelligence (AI) algorithms based on 12-lead ECGs can detect a reduced left ventricular ejection fraction (LVEF) [13-15]. Third, ECG abnormalities can be observed in a wide range of noncardiac conditions, including electrolyte imbalances, central nervous system diseases, and others [16]. These conditions, which are associated with ECG characteristics, simultaneously affect cardiorespiratory fitness. To the best of our knowledge, only one published study has investigated this topic [17]. However, that study used a training dataset composed primarily of relatively healthy individuals, whereas our dataset included older adults and a substantially higher proportion of patients with cardiopulmonary diseases. Further details are provided in the Discussion section.

We hypothesized that resting 12-lead ECG signals can be used to estimate individuals with low peak $V\dot{O}_2$ through a properly trained neural network model. To test this hypothesis, we analyzed the databases of simultaneously conducted resting ECGs and CPET from 2 hospitals over a 13-year period. The aim of this study was to use resting ECGs for screening individuals with low peak $V\dot{O}_2$ in a clinical setting.

Methods

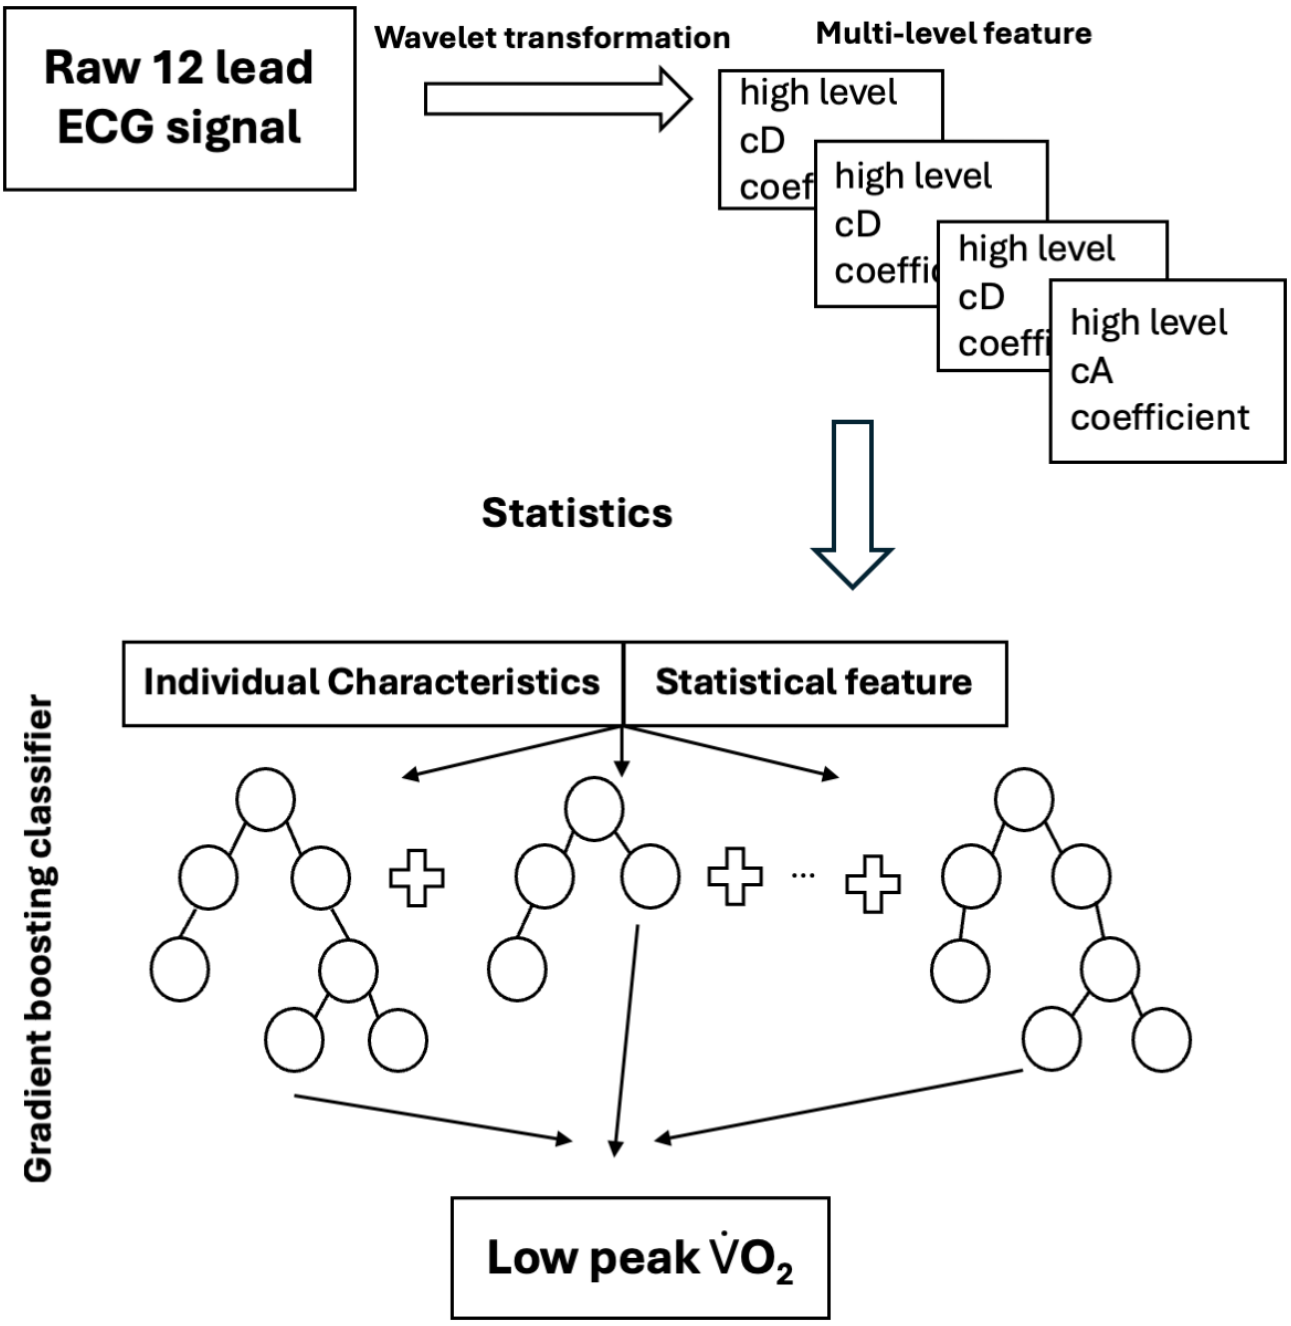
Ethical Considerations

This research was approved by the Research Ethics Committee of the Chang Gung Medical Foundation (202301068B0C501). A waiver of consent was granted by the institutional review board. To maintain confidentiality, participants were identified only by numbers, and all research data were securely stored.

Database

CPET data at the Chang Gung Memorial Hospital in Linkou and Keelung from 2010 to 2022 were retrieved. A 1-minute resting 12-lead ECG was performed immediately before CPET. Low peak $V\dot{O}_2$ was defined as a peak $V\dot{O}_2$ of <14 mL/kg/min, a clinical threshold indicating markedly impaired cardiorespiratory fitness and poor prognosis [11,18-20]. Data from Chang Gung Memorial Hospital, Linkou (2010 - 2022; n=832) and Keelung (2010 - 2013; n=133) were used as the training dataset. The data from Keelung (2014 - 2022; n=242) were used for the validation dataset.

Cardiopulmonary Exercise Testing



A symptom-limited incremental exercise test was conducted in an upright position on a calibrated cycle ergometer (Ergoselect 150P; ergoline GmbH) to evaluate cardiorespiratory fitness. The CPET was performed 2 to 4 hours after a light meal. The protocol began with a 1-minute rest period followed by a 1-minute warm-up at 10 W. The workload was then progressively increased at a rate of 10 W per minute until the participant reached exhaustion. $V\dot{O}_2$ was recorded on a breath-by-breath basis using a computerized system (MasterScreen CPX; Cardinal Health), with data averaged every 15 seconds. Resting and exercise 12-lead ECGs were monitored via a stress ECG recorder (CardioSoft; GE Healthcare), arterial blood pressure was measured using an automated device (Tango; SunTech Medical), and arterial oxygen saturation was tracked using a pulse oximeter (model 9500; Nonin Onyx). The exercise test was terminated if any of the following conditions occurred: (1) the participant was unable to maintain a pedaling frequency of 50 rpm or greater, (2) the participant reached volitional fatigue or requested to stop, (3) a plateau or decline in peak $V\dot{O}_2$ was observed despite continued effort, or (4) a cardiovascular event occurred [5,21].

ECG Data Processing

The ECG electronic signal is a 1D time-series data sampled at a rate of 200 Hz, consisting of continuous cardiac beats that form repetitive wave groups as the analyzed data. Standard preprocessing steps for ECG signal analysis were applied. A bandpass filter (0.5 - 40 Hz) was used to remove baseline drift and high-frequency noise while preserving the main frequency components of the ECG waveform. Baseline correction was then performed to eliminate low-frequency fluctuations and stabilize the signal for more reliable feature extraction [22-24]. To preserve the integrity of the original ECG data as much as possible, we applied a 3-level decomposition using the biorthogonal wavelet to process the signal [25,26] (Figure 1).

XSL•FO
RenderX

Figure 1. Mathematical data processing flowchart. This method analyzes 12-lead electrocardiogram (ECG) time-series data by first applying a 3-layer wavelet transform to decompose the signal into different frequency components, capturing both low-frequency rhythms and high-frequency variations. The extracted wavelet coefficients serve as features for further analysis. A gradient boosting classifier then learns from these features, using multiple decision trees to enhance prediction accuracy. This approach enables the classification of ECG signals and the prediction of low peak oxygen consumption ($V\dot{O}_2$), which is crucial for assessing cardiovascular risk and cardiorespiratory fitness. cA: high-frequency coefficient of wavelet; cD: low-frequency coefficient of wavelet.

Three Types of Training Sets

We trained the mathematical model for calculating low peak $V\dot{O}_2$ using (1) individual characteristics (IC; age, sex, BMI, resting heart rate, and heart rate variability), (2) the 60-second 12-lead resting ECG performed immediately before the CPET, and (3) IC plus 60-second 12-lead resting ECG data. Resting heart rate was defined as the average heart rate during the last 15 seconds of a 1-minute resting period. Heart rate variability was calculated from ECG signals recorded during a 1-minute resting period, based on the SD of the normal-to-normal intervals.

Wavelet Transform for Multiresolution Analysis of Physiological Signals

Wavelet transform is an effective frequency-domain analysis method widely used for nonstationary signals, as it is capable of capturing localized and transient features within specific time intervals [27,28]. Unlike conventional Fourier-based approaches, wavelet transform simultaneously provides time-domain and frequency-domain representations, making it suitable for analyzing physiological signals such as pulse waves and ECG signals.

XSL•FO
RenderX

In practical applications, the discrete wavelet transform (DWT) is commonly used due to its ability to retain abundant signal information while significantly reducing computational time [29]. The DWT decomposes a signal x[n] into approximation cA[s,t] and detail cD[s,t] coefficients by applying scaling functions (ϕ) and wavelet functions (ψ):

$$cA[s,t]=\sum x[n]\varphi(n-t2s2s)$$

$$cD[s,t]=\sum x[n]\psi(n-t2s2s)$$

At each hierarchical level, approximation coefficients are further decomposed into approximation and detail components, forming a multiresolution analysis structure analogous to a filter bank that separates signal frequency components for both coarse and fine feature analysis [30]. Compared with traditional time-frequency methods, wavelet transform provides adaptive time-frequency resolution, enabling accurate capture of rapid temporal variations while supporting noise reduction and feature compression, thereby preserving essential physiological signal morphology and improving downstream model performance [27,28]. Moreover, because many physiological signals are inherently nonstationary, the wavelet transform is particularly well suited to capturing dynamic and transient characteristics in signals such as ECG signals [31].

In this study, biorthogonal wavelets were selected for their favorable mathematical and signal-processing properties [32]. Their symmetry and linear-phase response help minimize edge distortion and preserve waveform morphology—critical for physiological signals. They also satisfy perfect reconstruction conditions, allowing signals to be decomposed and rebuilt without distortion [33]. In addition, compared with other wavelet families such as Daubechies, biorthogonal wavelets provide more flexibility in controlling smoothness and decomposition depth, enabling more stable multiscale feature extraction.

During multiresolution decomposition, each level generates a unique set of DWT coefficients representing the signal's characteristics at corresponding scales. To extract meaningful information, statistical measures (eg, mean, variance, energy, and entropy) are computed from these coefficients, providing a quantitative representation of the signal distribution and dynamics across resolutions [33]. These features support comprehensive and robust physiological signal characterization.

Gradient Boosting Classifier for Physiological Signal Classification

The gradient boosting classifier (GBC) is a stage-wise ensemble learning framework that constructs a strong predictive model by sequentially combining multiple weak learners, typically small regression or classification trees [34]. Formally, the predictive function can be expressed as:

$$F(x;an,bn)=\sum n=1Nbnh(x;an)$$

where h denotes a base learner and b_n is the weight assigned at each boosting stage. At each iteration, the model adds a new regression tree fitted to the negative gradient of the loss function, progressively correcting residual errors from previous stages. This iterative gradient-guided refinement enables the ensemble to capture complex patterns, nonlinear relationships, and subtle decision boundaries within physiological signal datasets [35].

GBC is well suited for physiological signal classification because it effectively captures nonlinear feature interactions and handles heterogeneous data. Compared with single decision trees, it offers improved accuracy and generalization through reduced bias and variance, with tunable hyperparameters and feature importance supporting model control and interpretability.

GBC can be computationally heavy, sensitive to hyperparameters and noise, and hard to interpret, yet it remains effective for classifying variable or noisy physiological signals in biomedical applications. In this study, the key hyperparameters of the GBC, such as tree depth, learning rate, and number of iterations, were optimized using systematic tuning combined with cross-validation. The model used shallow trees, a small learning rate, and cross-validated iterations to balance nonlinear modeling and prevent overfitting. Improper hyperparameters can cause overfitting or underfitting, so careful tuning is essential for stable performance. On the basis of this strategy, we believe that the selected hyperparameter combination enables the GBC to classify ECG signals effectively while maintaining stability and generalizability.

Resampling Strategy

The prevalence of low peak $V\dot{O}_2$ in this dataset is 29%. Training a model on such imbalanced data may introduce bias toward the majority class, potentially overlooking important information within the minority class and compromising the reliability of model predictions. To address this issue, we used a data resampling strategy. Specifically, we used oversampling of the minority class to balance the number of samples across different classes. The resampling ratio was determined according to the original class distribution (27%) in the training dataset, aiming to improve the model's ability to recognize the minority class while preserving the integrity of the original data. Oversampling substantially improved the model's classification performance for the minority class, leading to enhanced overall accuracy and greater performance stability. This methodological choice is supported by prior studies, which also suggest that oversampling is a simple yet effective strategy for addressing class imbalance in small-sample physiological signal classification tasks [36,37].

In our resampling approach, each class was represented by a comparable number of data points during training, balancing the influence of each class and allowing the model to learn effectively from both majority and minority classes. To ensure robustness, multiple experiments were conducted by repeating the process and meticulously recording statistical results. This iterative procedure demonstrates the consistency and reliability of our method across trials, highlighting its effectiveness in handling imbalanced datasets.

Additionally, the wavelet transform was compared with the outcomes obtained using a 1D convolutional neural network (1D CNN), based on prior research demonstrating its effectiveness in extracting key features from ECG data and achieving high classification accuracy [38]. This 1D CNN used a standard architecture and parameter settings that have been widely validated in ECG analysis. It comprised 2 convolutional layers, 2 downsampling layers, and a fully connected layer, with ECG data processed without applying a wavelet transform, allowing the model to automatically learn relevant features.

RenderX

Cross-Validation and External Validation

In the training dataset, a 4-fold cross-validation [39] was also applied to avoid overfitting and verify accuracy. It was performed by assessing model performance and comparing the numbers of true and AI-generated low peak $V\dot{O}_2$ and non–low peak $V\dot{O}_2$ cases. The original ECG data were randomly partitioned into 4 equal-sized subdatasets. Of the 4 subdatasets, a single subdataset was preserved as validation data to test the model, and the remaining 3 subdatasets were used as training data. The cross-validation process was repeated 4 times, with each of the 4 subdatasets used once as the validation data. The results were then averaged. To evaluate the model's ability to identify individuals with markedly impaired cardiorespiratory fitness, defined as a peak $V\dot{O}_2$ of <14 mL/kg/min—a clinical threshold for substantial impairment—external validation was also conducted [19,20].

Statistics

The validation of our model was assessed using precision, recall, and total accuracy. Precision, defined as the ratio of correctly predicted positive observations to the total number of predicted positives, measures the accuracy of positive predictions, while recall represents the ratio of correctly predicted positive observations to all observations in the actual class. Total accuracy reflects the proportion of correctly predicted observations, including both low peak $V\dot{O}_2$ and non–low peak $V\dot{O}_2$, among all observations. Additionally, a receiver operating characteristic curve analysis was conducted to determine the area under the curve (AUC) for predicting low peak $V\dot{O}_2$. All data are reported as means (SD), with statistical significance set at P<.05.

Results

The training dataset comprised 965 individuals, of whom 77% (n=743) were male. The mean age and BMI were 57 (SD 13) years and 24.4 (SD 4.6) kg/m^2, respectively. The average peak $V\dot{O}_2$ was 17.5 (SD 6.1) mL/kg/min. A total of 263 (27.2%) individuals had low peak $V\dot{O}_2$. Common morbidities potentially associated with reduced peak $V\dot{O}_2$ included heart failure (n=241, 25%), coronary artery disease (n=166, 17%), chronic obstructive pulmonary disease (n=57, 6%), esophageal cancer (n=237, 25%), and stroke (n=105, 11%; Table 1). The validation dataset included 242 individuals, with 174 (71.9%) being male participants. The mean age and BMI were 59 (SD 12) years and 25.8 (SD 4.4) kg/m^2, respectively. The mean peak $V\dot{O}_2$ was 15.4 (SD 3.9) mL/kg/min. Among these, 91 (37.6%) cases were classified as having low peak $V\dot{O}_2$. Cardiac disorders accounted for 80% (n=194) of the patients in the dataset (Table 1).

In Table 2, the accuracy of all the parameters, when compared with the null hypothesis of random guessing, has a P value of <.01. Moreover, the accuracy of the AI model was higher when using wavelet analysis than when not using wavelet analysis, suggesting that wavelet analysis assisted in feature detection. ECG alone demonstrated clearly higher accuracy than IC. Incorporating IC into ECG signals led to a modest improvement in estimation accuracy in both cross-validation (Figure 2) and external validation. In the external validation, the AUC increased from 0.84 with ECG alone to 0.87 when combined with IC (Table 3).

For low peak $V\dot{O}_2$ estimation, the combination of ECGs and IC achieved a mean AUC, precision, and recall of 0.89, 0.72, and 0.72 during cross-validation, and 0.87, 0.67, and 0.61 during external validation. In other words, during external validation, the model successfully identified 61% of low peak $V\dot{O}_2$ cases (Table 3).

Discussion

Principal Findings

This study demonstrated that a complete resting ECG signal can effectively screen individuals with low cardiorespiratory fitness using a well-trained neural network. Wavelet-based feature extraction contributed to greater accuracy in AI models. For low peak $V\dot{O}_2$ estimation, combining ECGs with IC, including age, sex, BMI, resting heart rate, and heart rate variability, yielded an AUC of 0.87, which is considered acceptable for clinical use. The AI model used wavelet transform for feature extraction, a GBC for prediction, and resampling techniques to address imbalanced data. Notably, ECG alone outperformed IC in estimation accuracy, while the addition of IC to ECGs resulted in a modest improvement. Overall, resting ECGs, either alone or combined with IC, serve as a valuable tool for identifying individuals with low cardiorespiratory fitness with satisfactory accuracy. Early identification of this at-risk population enables timely medical intervention and may improve prognosis.

To the best of our knowledge, our research is the second study that has investigated the use of ECGs to calculate peak $V\dot{O}_2$. The first study demonstrated the feasibility of estimating peak $V\dot{O}_2$ from ECGs using deep learning techniques trained on 1410 samples and validated on 3 different sets [28]. The present experimental findings largely reproduce the results of this previous study, confirming that resting ECG-based deep learning is a noteworthy new approach to screen for low peak $V\dot{O}_2$. The difference from previous research lies in the composition of the current database, which mostly includes patients with frailty and ailments. The peak $V\dot{O}_2$ in this dataset was 17.5 mL/kg/min, compared with 33.6 mL/kg/min in the Massachusetts General Hospital (MGH) training set [28]. We observed a higher prevalence of peak $V\dot{O}_2$ at <14 mL/kg/min in this study than in the MGH training set (27% vs 8.5%). The mean age of the patients in this dataset was 57 (SD 13) years, whereas that in the MGH training dataset was 45 years. In addition, differences in the distribution of clinical traits were observed between the patient populations in the 2 studies. For instance, the present database includes a higher proportion of patients with cardiac or pulmonary diseases (Table 1). Specifically, the prevalence of heart failure was 25% (245/965) in the training dataset and 68% (165/242) in the validation dataset, compared with only 4% in the MGH training dataset. It is also worth mentioning that this method still cannot accurately predict the absolute value of peak $V\dot{O}_2$. The true estimation error of peak $V\dot{O}_2$ by the ECG-deep learning method is quite wide. The lower and upper limits of agreement range from −14.95 to 15.08 and from −17.6 to 10.5 mL/kg/min in the 2 test sets [28]. This study also reported that individuals with higher peak $V\dot{O}_2$ seem to exhibit greater R and S wave amplitudes, as well as more pronounced ST segments and T waves [28]. In conclusion, our study further illustrates that resting ECGs by deep learning could still identify individuals with low peak $V\dot{O}_2$ in a vulnerable population. Accordingly, this approach may influence clinical decision making and warrants further investigation. The value of this method is particularly highlighted in patients who have conditions that preclude them from undergoing CPET, such as musculoskeletal disorders, frailty, and others.

Peak $V\dot{O}_2$ represents the integrative performance of the oxygen delivery and use system. Cardiac electrical signals may, to some extent, reflect certain aspects of this system. Therefore, from a physiological standpoint, resting ECGs may not precisely predict the exact value of peak $V\dot{O}_2$, although it remains effective in identifying individuals with low peak $V\dot{O}_2$.

Current studies demonstrate that incorporating IC leads to only modest enhancements in estimation accuracy. This can be explained by a previous study illustrating that applying AI to ECG data enables the prediction of sex and age [29]. In addition, ECGs provide various biological data. Several studies have reported that using an AI algorithm based on a 12-lead ECG can enable the early diagnosis of low LVEF defined by an LVEF of ≤35% in patients in the routine primary care setting [13-15]. ECGs also predict the onset of various cardiovascular diseases, including atrial fibrillation, myocardial infarction, heart failure, and death [15,28]. Moreover, ECGs show promise in detecting dysglycemia [28,31,32]. Furthermore, blood lactate concentration during exercise was accurately estimated from exercise ECG data using 2D convolution and artificial neural network–based methods [26]. Collectively, these studies underscore the wealth of biological information in ECG data that awaits further exploration.

A standard resting ECG is a simple and widely used clinical examination that is routinely performed in patients with cardiovascular disease or as part of routine preoperative assessment. The ECG-based algorithm developed in this study shows strong potential as a large-scale screening tool for identifying individuals at high risk of low peak $V\dot{O}_2$. For clinical implementation, the algorithm could be directly integrated into the GE ECG autointerpretation system or embedded within ECG recorders from partnering manufacturers. In the latter case, appropriate calibration—such as matching the sampling frequency—would be required to maintain accuracy and reliability, followed by further validation.

On the basis of this result, when the raw ECG signals were directly input into the 1D CNN, the classification performance decreased compared with using features extracted via wavelet transform. The main reasons are as follows: first, raw ECG signals exhibit high-dimensional and nonlinear characteristics, with transient waveform variations and multifrequency components, which can make it difficult for a 1D CNN to effectively capture all relevant features when the signals are used directly; and second, the wavelet transform provides joint time-frequency information by converting raw ECG signals into informative multiscale features that emphasize key transient waveforms and frequency components, which are more easily exploited by downstream classifiers (such as GBC or 1D CNN), thereby improving classification performance. In addition, previous studies have shown that time-frequency analysis methods, such as the wavelet transform, can significantly improve the classification accuracy of machine learning and deep learning models applied to ECG signals [22,40].

XSL•FO
RenderX

In summary, this study demonstrates that resting ECGs, either alone or combined with IC, can effectively identify individuals with low cardiorespiratory fitness using a deep learning framework. Wavelet-based feature extraction contributed to the model's accuracy, and the GBC provided robust prediction capabilities for low peak $V\dot{O}_2$ estimation. While ECGs combined with IC yielded an AUC of 0.87, ECG alone already performed strongly, indicating its potential as a practical screening tool. Compared with other classifiers such as support vector machines or random forests, GBC offers several advantages for ECG analysis: it can automatically model high-dimensional, nonlinear, and transient features; it demonstrates stability and generalization for heterogeneous, small, or noisy datasets; and it provides feature importance insights that help interpret which waveform patterns are most influential [41]. Prior studies have also reported that GBC or its variants (eg, Extreme Gradient Boosting) achieve high accuracy in ECG classification or arrhythmia detection, often outperforming support vector machines and random forests [42]. Accordingly, the combination of wavelet transform for feature extraction and GBC for classification represents a methodologically sound and effective approach.

Our findings further reproduce and extend previous studies on ECG-based estimation of peak $V\dot{O}_2$, highlighting its utility even in populations with a high burden of comorbidities. Although resting ECGs cannot precisely predict absolute peak $V\dot{O}_2$ values, it effectively identifies at-risk individuals who may benefit from timely intervention. This approach is particularly valuable for patients who cannot undergo CPET due to musculoskeletal disorders, frailty, or other limitations. Future work may focus on further refining model accuracy, expanding validation in diverse populations, and exploring integration into clinical ECG systems for real-world screening and decision support.

Regarding the slight decrease in accuracy observed in the external validation set, several factors may account for this phenomenon. First, the external validation data were collected using different devices and obtained from distinct subject populations, which may result in subtle differences in signal characteristics compared with the training dataset. Such cross-dataset performance fluctuations are commonly reported in ECG-based machine learning studies and do not necessarily indicate model instability. Second, the GBC model is inherently sensitive to high-dimensional and nonlinear features derived from multiscale wavelet transforms. Although these features substantially enhance overall classification performance, they may also amplify the impact of minor distributional differences between datasets. As a result, even small discrepancies in signal morphology or noise characteristics can lead to a modest reduction in accuracy when the model is applied to an external cohort. Overall, the slight decrease in accuracy in the external validation set is a common issue in physiological signal analysis and does not compromise the methodological validity or the main conclusions of our ECG pattern recognition model.

Limitation

First, incorporating other factors such as the severity of comorbidities could potentially enhance the model's accuracy. However, this study focuses on clinical application, where usability is just as crucial as accuracy. Therefore, we prioritize easily accessible input parameters, such as the IC defined in this study. With the current model, we achieve both acceptable accuracy and practical usability, with an AUC of 0.84 using ECG alone and 0.87 when combining ECGs with IC. Second, the dataset comprised mostly of East Asian individuals with a high prevalence of morbidities; therefore, caution is needed when applying the algorithm to other populations. Third, we did not specifically analyze the relationships between individual ECG features and low peak $V\dot{O}_2$, because the model is designed to automatically extract multiscale, high-dimensional features that capture global ECG waveform patterns, rather than one-to-one associations between single features and clinical traits.

Conclusions

This study demonstrated that a 12-lead resting ECG, a widely accessible test, can effectively identify individuals with a peak $V\dot{O}_2$ of less than 14 mL/kg/min when used in a well-trained neural network, with satisfactory accuracy. Wavelet feature extraction significantly enhanced the performance of AI models. This approach has the potential to improve patient care by facilitating earlier identification and intervention for individuals with markedly reduced cardiorespiratory fitness and an elevated risk of cardiovascular events.

Acknowledgments

The authors would like to express their sincere gratitude to all the patients whose data were essential for this study.

Funding

This work was supported by the Chang Gung Medical Foundation (CMRPVVL0123, CORPVV0071 and CMRPVVQ0021) and National Science Council of Taiwan (114-2314-B-182A-066-).

Abstract

Background: Laboratory testing is a cornerstone of diagnostic decision-making in emergency departments (EDs), yet its overuse contributes substantially to unnecessary health care costs and inefficiencies. Predictive approaches that leverage electronic health record data may help optimize and guide more appropriate test use.

Objective: This study aims to develop and evaluate machine learning models that predict laboratory test use during ED visits by integrating structured clinical data and unstructured text from electronic health records.

Methods: We analyzed 13,115 adult ED visits from the 2021 National Hospital Ambulatory Medical Care Survey–Emergency Department dataset. Structured predictors included demographics, vital signs, insurance status, and medical history, while unstructured data from chief complaints and injury descriptions were encoded using Bidirectional Encoder Representations from Transformers–based embeddings. Four model configurations were developed: structured-only, unstructured-only, combined structured and unstructured data, and an ensemble (mean probability) approach. Model performance was evaluated using the area under the receiver operating characteristic curve (AUC).

Results: The combined model achieved the highest predictive performance (AUC=0.83), outperforming both the structured-only model (AUC=0.78) and the unstructured-only model (AUC=0.74). The ensemble model also performed well but did not exceed the combined model. Key predictors of laboratory testing included older age, ambulance arrival, abnormal vital signs, and chronic comorbidities, whereas injury-related visits were associated with a lower likelihood of testing.

Conclusions: Integrating structured and unstructured electronic health record data improves the prediction of laboratory test use in ED settings. These findings support the development of data-driven clinical decision support tools aimed at enhancing diagnostic efficiency and reducing unnecessary testing.

Introduction

The ordering of laboratory tests is a cornerstone of diagnostic medicine, guiding providers' clinical decision-making across various healthcare settings, especially in emergency departments (EDs) [1]. In hospitals and EDs, laboratory tests inform the assessment of disease severity, therapeutic decisions, prognosis, and monitoring strategies. However, studies have found that the sheer volume of laboratory orders, including many that may be routine, defensive, or redundant, has raised concerns about overuse, patient burden, and resource inefficiency [2]. This is especially pertinent in EDs, with studies revealing that nearly 80% of patients who present to the ED receive laboratory testing, averaging 7.7 tests per patient [3,4]. Notably, unnecessary laboratory testing contributes to an estimated US $210 billion in additional health care costs annually, underscoring the importance of optimal test use that not only saves costs but also improves ED workflow.

XSL•FO
RenderX

Traditionally, decisions to order laboratory tests are based primarily on clinicians' judgment, informed by vital signs, presenting symptoms, medical history, and institutional protocols. Yet these decisions can vary significantly across providers and settings, often lacking standardization or transparency [5]. In this context, data-driven approaches—particularly those that leverage electronic health record (EHR) data—offer the potential to identify patterns that precede test ordering, thereby informing real-time decision support tools [6].

Recent developments in machine learning (ML) have enabled predictive modeling of clinical decision points and corresponding actions using *structured data*, such as demographics, vital signs, comorbidity indices, and other variables [7]. Numerous algorithms, such as gradient boosting classifiers, are well-suited for handling heterogeneous tabular data to model the complex interactions between predictors [8]. In addition, a significant portion of providers' clinical reasoning is captured in *unstructured data*, such as free-text notes, including primary complaints, triage narratives, and clinicians' nonverbal assessments. Importantly, these unstructured data sources often precede test orders and provide valuable context not captured in structured data fields, underscoring the need and potential to integrate unstructured data into model building [9]. One highly promising approach to achieving this is the use of transformer-based language models.

Although prior studies have explored ML approaches to predict laboratory test ordering, most have relied primarily on structured EHR variables or basic natural language processing (NLP) methods, focusing on single tests or narrow clinical contexts [10,11]. Consequently, the extent to which contextualized information embedded in free-text clinical documentation can meaningfully improve the prediction of general laboratory test use in the ED remains largely underexplored. Addressing this gap is critical to developing scalable, data-driven decision-making tools that better align with real-world clinical reasoning.

Transformer-based language models, such as GPT-2, provide a robust approach for extracting insights from unstructured text sources. By leveraging self-attention mechanisms and deep learning architectures, these models can capture complex linguistic patterns and semantic relationships across large text corpora [12]. Consequently, transformer-based language models can capture the clinical nuances that may influence decisions to order specific laboratory tests, such as concerns about sepsis, renal impairment, or metabolic derangements, among others. Most importantly, ML models that integrate both structured and unstructured data tend to produce the most robust predictive outcomes. With structured data offering a reliable foundation of quantifiable variables, unstructured data captures rich contextual nuances that are often absent in structured formats [13]. As a result, ML algorithms can uncover deeper patterns, improve generalizability, and enhance prediction.

In this study, we aim to develop and evaluate ML models for predicting the likelihood of general laboratory test orders during patients' ED visits, using both structured EHR data and unstructured clinical text. The models that use structured data alone, unstructured data alone, and a combined approach were evaluated. We hypothesize that integrating structured EHR data with unstructured clinical text will yield more accurate predictions than either source alone, thereby supporting the development of real-time decision tools that can inform laboratory test use in the ED and promote more efficient, patient-centered, and evidence-based care. For this work, the study defines general laboratory tests as a set of commonly ordered panels and individual assays across multiple organ systems and clinical indications, comprising 20 laboratory tests (defined later). By focusing on this representative set, the study aims to capture a wide range of clinical scenarios, including metabolic panels, coagulation profiles, and electrolyte monitoring. Ultimately, this work seeks to improve the prediction of laboratory test use, thereby providing a foundation for further developing and scaling up clinical decision algorithms to support patient care in the ED.

Methods

Ethical Considerations

Ethical approval and consent for participation are not applicable, as the research was conducted using publicly available, anonymized data from the NHAMCS-ED (National Hospital Ambulatory Medical Care Survey–Emergency Department) dataset.

Data Source

We used data from the 2021 NHAMCS-ED dataset [14], a nationally representative dataset that captures a wide range of information about visits to EDs across the United States. NHAMCS-ED is administered by the National Center for Health Statistics and uses a multistage probability sampling design to ensure generalizability to the national population [15]. The dataset includes visit-level records detailing patient demographics, clinical characteristics, reasons for visits, procedures, diagnostic tests, medications, and disposition. For this study, the sample was restricted to adult patients aged 18 years or older. The study excluded visits with missing data on our primary outcome of interest—laboratory test use—as well as records with critical missing values for key predictor variables. The final analytic cohort comprised all eligible adult ED visits for which complete information on laboratory testing and associated predictors was available.

Outcome Variable: Laboratory Test Use

Laboratory test use was operationalized as a binary outcome, indicating whether one or more laboratory tests from a predefined set of commonly ordered assays were prescribed during an ED visit. Using available NHAMCS-ED variables and informed by prior literature, we identified 20 laboratory tests and panels spanning multiple organ systems and clinical indications, such as metabolic, hematologic, renal, hepatic, and coagulation-related tests.

For each visit, test ordering was coded as "1" if at least one of these tests or panels was ordered and "0" otherwise. Visits involving multiple tests or panels were treated as positive events without additional weighting, as the objective was to capture the occurrence of laboratory evaluation rather than test volume,

XSL•FO
RenderX

sequencing, or clinical appropriateness. Because there is no widely accepted approach for encoding the complex combinations and ordering patterns of laboratory tests in large-scale ED datasets, this binary operationalization is a pragmatic, scalable strategy that avoids arbitrary weighting while supporting robust predictive modeling.

Structured Predictors

Structured predictors were drawn from multiple domains within the NHAMCS dataset. These included demographic variables (eg, age, sex, race, or ethnicity), visit characteristics (eg, day of the week, time of arrival, arrival by ambulance, and mode of arrival), and vital signs (eg, heart rate, blood pressure, respiratory rate, temperature, oxygen saturation, and pain level).

We also included a comprehensive set of medical history variables, coded as binary indicators for the presence of specific chronic or acute conditions. These included Alzheimer disease or dementia, asthma, cancer, cerebrovascular disease, chronic kidney disease, chronic obstructive pulmonary disease, congestive heart failure, coronary artery disease, diabetes mellitus (types I and II), end-stage renal disease, HIV/AIDS, hyperlipidemia, hypertension, obesity, obstructive sleep apnea, osteoporosis, depression, substance abuse or dependence, and thromboembolic conditions such as deep vein thrombosis or pulmonary embolism.

Additional structured features included insurance type (private, Medicare, Medicaid, Children's Health Insurance Program, uninsured, or other); residence type (private home, nursing home, homeless, or other); whether the visit was a follow-up or related to an earlier episode of care; and whether the visit involved injury or trauma, poisoning or overdose, or adverse effects of treatment. These structured features were selected based on prior literature, clinical rationale, and exploratory data analysis.

Prior to modeling, continuous variables were standardized using the StandardScaler method to facilitate model convergence and ensure comparable feature-importance estimates across models.

Missing data analysis revealed that, except for the pain score variable (with 38.3% missing), all structured features exhibited low to moderately low levels of missingness, that is, less than 10% (Multimedia Appendix 1). To assess the plausibility of the missing-at-random assumption, we examined patterns of missingness in relation to laboratory test use and observable visit characteristics for the pain score variable. Notably, the missingness of the pain score variable was not associated with laboratory testing rates (ie, 59.6% for observed vs 59% for missing), and was more frequent among ambulance arrivals, consistent with higher-acuity encounters in which clinical priorities may precede formal pain documentation.

For other administrative and visit-level variables, differences in laboratory testing rates between missing and observed groups were very low to modest. Larger differences were observed for vital signs, such as temperature, oxygen saturation, and pulse, reflecting ED workflows in which these parameters are preferentially measured in higher-acuity encounters, which are also more likely to undergo laboratory evaluation. Taken together, these patterns suggest that missingness in structured variables is largely driven by observable clinical context and documentation practices rather than outcome-dependent mechanisms, thereby supporting the use of median imputation under the missing-at-random assumption.

Unstructured Data and Bidirectional Encoder Representations from Transformers Model

The NHAMCS-ED dataset includes two primary unstructured text fields: (1) the chief complaint, which captures the patient's primary reason for visiting the ED, and (2) the reason-for-visit injury text, which describes any injury-related circumstances. These free-text fields provide rich clinical context often unavailable in structured variables and are frequently used by ED staff to understand the patient's presenting condition.

To process these fields, we applied a text-cleaning pipeline to enhance consistency and remove irrelevant noise [16]. This included converting all text to lowercase, removing punctuation and numerals, stripping whitespace, and filtering out common stopwords (eg, "and," "the," "of") using a predefined list from the Natural Language Toolkit [17]. The resulting cleaned text provided the input for our NLP pipeline.

We used a pretrained Bidirectional Encoder Representations from Transformers (BERT) model from the HuggingFace *Transformers* library to encode the cleaned text [18]. BERT is a state-of-the-art transformer-based language model that learns deep contextual relationships between words through bidirectional attention. The BERT-base-uncased model and its tokenizer were used to convert each text entry into input tokens compatible with the BERT model architecture [19].

These tokenized inputs were then passed through BERT to extract sentence-level embeddings—dense vector representations capturing the semantic content of the chief complaint and injury text. Performance was robust to alternative text-embedding pooling ([CLS], also known as classification, token vs mean pooling). These embeddings, typically 768-dimensional vectors, served as the unstructured input features for downstream modeling. They enabled us to leverage the rich semantic meaning encoded in patient narratives, augmenting the structured clinical features.

To assess whether our reliance on the [CLS] embedding affected model performance, we also evaluated an alternative, widely used aggregation strategy: mean pooling over token embeddings [20]. The 2 approaches yielded highly comparable results in the gradient boosting classifier (receiver operating characteristic curve, AUC=0.83 for [CLS] vs 0.84 for mean pooling), indicating that sentence-level performance was robust to the choice of pooling method. Given the comparison result, we retained the [CLS] representation as our primary specification, consistent with standard BERT practice for sequence-level encoding [21].

Association Analysis

To identify factors independently associated with laboratory test use, a logistic regression with Lasso regularization was performed for variable selection [22]. This approach penalizes less informative predictors and retains only those with the strongest associations, helping reduce overfitting and improving

XSL•FO
RenderX

model interpretability. After selecting variables with nonzero coefficients from the Lasso model, a standard multivariable logistic regression was fitted using the selected predictors to estimate adjusted odds ratios (ORs) and 95% CIs. A forest plot was generated to visualize the direction and strength of associations. Variables with ORs above 1 were associated with higher odds of laboratory testing, while ORs below 1 indicated a reduced likelihood. This analysis highlighted key clinical and demographic drivers of test-ordering decisions in the ED.

Predictive Model Development

To predict laboratory test use during ED visits, we developed 4 supervised ML models: logistic regression, random forest, gradient boosting, and extreme gradient boosting. These models were selected to capture both linear and complex nonlinear relationships among predictors. Logistic regression served as a benchmark model due to its interpretability, while the ensemble-based models (random forest, gradient boosting, and extreme gradient boosting) offered greater flexibility in capturing variable interactions and improving classification performance.

Each model was applied to four configurations of input data: (1) structured data only, including demographics, vitals, medical history, and visit details; (2) unstructured text data only, using BERT-generated embeddings from chief complaints and reasons for visit; (3) combined structured and unstructured data; and (4) a mean probability model, which averaged predicted probabilities from the structured-only and unstructured-only models.

Structured data were preprocessed using median imputation and standardized for modeling. Unstructured data were cleaned, tokenized, and processed through a pretrained BERT model to generate contextual embeddings. All models were trained and evaluated using 5-fold cross-validation to ensure robust performance estimates across data splits.

Evaluation Metrics

Model performance was evaluated using standard classification metrics: area under the receiver operating characteristic (ROC) curve (AUC) [23], accuracy, precision, recall (sensitivity), specificity, and F_1-score [24]. AUC was the primary measure of discrimination, reflecting the model's ability to distinguish between visits with and without laboratory testing. Precision and recall offered insights into the model's accuracy in predicting test use, with the F_1-score providing a balanced measure of both.

We also examined specificity to assess how well the models avoided false positives—cases where testing was not conducted but was predicted as such. Optimal classification thresholds were determined using the point on the ROC curve closest to the top-left corner.

To aid interpretation, we visualized logistic regression coefficients using forest plots and generated word clouds from unstructured data to highlight common terms associated with laboratory testing decisions.

Model Interpretability

As an important extension of our analysis, feature contributions were quantified using Shapley additive explanations (SHAP) [25]. For tree-based models, TreeExplainer was used and for logistic regression [26], the linear explainer was used with the model's logit link [27]. To synthesize the unstructured input (ie, BERT embeddings), we computed SHAP values and aggregated them into a single textual feature by summing the mean absolute SHAP values across all dimensions, reported as Combined_Chief_Complaint.

Results

Descriptive Statistics and Feature Selection

Among adult ED visits in the 2021 NHAMCS-ED dataset, 7784 (59.3%) visits included laboratory test orders. Significant differences were observed across nearly all demographic and clinical variables between patients who received laboratory tests and those who did not (Table 1). Patients who underwent laboratory testing were more likely to be female (4341/7784, 55.8% vs 2741/5331, 51.4%) and older, with 2298 out of 7784 (29.5%) aged 65 years or older compared to 834 out of 5331 (15.6%) in the no-test group. The proportion of White patients was slightly higher in the tested group (4779/7784, 61.4% vs 2958/5331, 55.5%), while Black and Hispanic patients were slightly underrepresented. Laboratory-tested patients were more likely to reside in nursing homes (208/7784, 2.7% vs 58/5331, 1.1%) and to be insured through Medicare (2296/7784, 29.5% vs 905/5331, 16.9%), while the no-test group had higher proportions of Medicaid (1766/5331, 33.1% vs 2033/7784, 26.1%) and uninsured individuals (480/5331, 9% vs 461/7784, 5.9%). Patients with laboratory testing were more frequently transported by ambulance (2012/7784, 25.8% vs 682/5331, 12.7%) and less likely to have injury-related visits (1015/7784, 13% vs 2137/5331, 40%). Clinical severity indicators also differed: higher proportions of laboratory-tested patients had abnormal vital signs, including heart rates of more than 90 bpm (3110/7784, 39.9% vs 1712/5331, 32.1%), diastolic blood pressure of less than 60 mm Hg (536/7784, 6.9% vs 218/5331, 4.1%), oxygen saturation of less than 95% (996/7784, 12.8% vs 297/5331, 5.6%), and respiratory rates of more than 20 breaths/minute (914/7784, 11.7% vs 210/5331, 3.9%). Patients who received laboratory tests had a higher prevalence of chronic conditions, including hypertension (3116/7784, 40% vs 1183/5331, 22.2%), diabetes (type II: 936/7784, 12% vs 301/5331, 5.6%), coronary artery disease (839/7784, 10.8% vs 192/5331, 3.6%), chronic kidney disease (537/7784, 6.9% vs 100/5331, 1.9%), congestive heart failure (569/7784, 7.3% vs 110/5331, 2.1%), and chronic obstructive pulmonary disease (684/7784, 8.8% vs 231/5331, 4.3%). Other conditions significantly more common in the laboratory-tested group included cancer, dementia, stroke, end-stage renal disease, and hyperlipidemia.

[a]The variables “Respiratory rate,” “Temperature,” “Pulse oximetry,” “Heart rate,” “Payment type,” “Seen within last 72 hours,” and “Episode of care” have missing data proportions ranging between 5% and 10%. The variables “Arrival time,” “Patient residence,” “Arrival by ambulance,” “Systolic blood pressure,” “Diastolic blood pressure,” and “Visit related to injury or trauma, overdose or poisoning, or adverse effect of medical or surgical treatment” have missing data proportions of less than 5%.

[b]CHIP: Children’s Health Insurance Program.

[c]DBP: diastolic blood pressure.

[d]SBP: systolic blood pressure.

[e]CVA: cerebrovascular accident.

[f]CKD: chronic kidney disease.

[g]COPD: chronic obstructive pulmonary disease.

[h]CHF: congestive heart failure.

[i]CAD: coronary artery disease.

[j]ESRD: end-stage renal disease.

[k]PE: pulmonary embolism.

[l]DVT: deep vein thrombosis.

[m]VTE: venous thromboembolism.

[n]OSA: obstructive sleep apnea.

Figure 1 displays adjusted odds ratios (ORs) and 95% CIs for predictors of laboratory test use during ED visits, derived from Lasso-selected logistic regression models. Older age, particularly aged 65 years and older (OR 2.30, 95% CI 2.01 - 2.62), and arrival by ambulance (OR 2.31, 95% CI 2.07 - 2.58) were among the strongest predictors of laboratory test use. Patients with chronic conditions such as hypertension (OR 1.87, 95% CI 1.68 - 2.08), type II diabetes (OR 1.69, 95% CI 1.47 - 1.93), chronic kidney disease (OR 2.12, 95% CI 1.75 - 2.56), and cancer (OR 1.85, 95% CI 1.48 - 2.30) had significantly higher odds of receiving laboratory tests. In contrast, visits related to injury or trauma were associated with substantially lower odds of testing (OR 0.39, 95% CI 0.35 - 0.43). Elevated heart rate (>90 bpm) (OR 1.32, 95% CI 1.20 - 1.45), low diastolic blood pressure (<60 mm Hg) (OR 1.36, 95% CI 1.15 - 1.60), respiratory rate of more than 20 breaths/minute (OR 1.66, 95% CI 1.37 - 2.02), temperature of more than 38°C (OR 1.87, 95% CI 1.32 - 2.65), and oxygen saturation of less than 95% (OR 2.38, 95% CI 2.03 - 2.78) were all significantly associated with increased odds of laboratory testing, reflecting the influence of clinical instability on diagnostic intensity.

Figure 2 illustrates the ROC curves for the 4 ML models developed to predict laboratory test use during ED visits. These models included (1) a structured-only model, which used demographic, clinical, and visit-level features; (2) an unstructured-only model, which used BERT-derived embeddings from free-text chief complaints and reason-for-visit narratives; (3) a combined model, which integrated both structured and unstructured inputs; and (4) a mean probability model, which averaged the predicted probabilities from the structured-only and unstructured-only models without retraining.

Figure 2. Receiver operating characteristic (ROC) curves for the 4 models evaluated in the study. Each model includes the structured data model, which uses only structured data such as patient demographics, visit characteristics, vital signs, and medical history; the unstructured data model, a Bidirectional Encoder Representations from Transformers (BERT)–based natural language processing (NLP) model that uses only unstructured data, including chief complaints and reasons for injury; the combined input model, a machine learning (ML) classification model that integrates both structured data and BERT-extracted features from the unstructured data; and the mean probability model, which averages the predicted probabilities from the structured data model and the unstructured data model. (A) Logistic regression, (B) random forest, (C) gradient boosting, and (D) extreme gradient boosting. AUC: area under the ROC curve.

Among the models, the combined model demonstrated the highest predictive performance, with an AUC of 0.83, indicating excellent discrimination between visits with and without laboratory test orders. This performance reflects the model's ability to capture both quantifiable patient characteristics and nuanced clinical context embedded in free-text narratives. The structured-only model achieved a slightly lower AUC of 0.78, suggesting that structured data alone provided a strong baseline for prediction but lacked the richness conveyed in narrative data. The unstructured-only model, based entirely on transformer-derived text embeddings, yielded an AUC of 0.74. While lower than the structured and combined models, it still demonstrated that free-text chief complaints and injury descriptions carry meaningful predictive signals for test use, especially in the absence of structured data. The mean probability model—a late-fusion ensemble averaging outputs from the structured-only and unstructured-only models—achieved an AUC of 0.81, performing better than either source alone but slightly below the fully integrated combined model. This result underscores the benefit of model ensembling, even without retraining or direct feature integration. All detailed performance metrics are presented in Table 2.

Global Feature Importance

SHAP analysis findings were consistent with logistic regression. The Combined_Chief_Complaint was the most influential feature across all models. Similar findings were observed across models; the most influential features included age, a visit related to injury, poisoning, or an adverse effect of medical or surgical treatment, ambulance arrival, and vital signs (hypertension, chronic kidney disease, and diabetes). Table 3 presents all SHAP values across models.

ML model and feature group	Mean |SHAP|
Coronary artery disease	0.0358

[a]SHAP values for textual input were aggregated by summing the mean absolute SHAP values across all BERT embedding dimensions, treating the text as a single composite feature, that is, CCC, VRIPA, ABA, and EOC.

[b]The reference group is "2016-only (no revisits in 2017–2019)".

[c]CCC: Combined_Chief_Complaint.

[d]ABA: arrival by ambulance.

[e]VRIPA: visit related to injury, poisoning.

[f]ED: emergency department.

[g]EOC: Episode of Care.

Discussion

Summary of Main Findings

This study developed and evaluated ML models to predict whether general laboratory tests are ordered during ED visits and found that combining structured EHR variables with unstructured clinical text yields the strongest predictive accuracy. Across model families, the combined approach consistently outperformed models built on structured-only or unstructured-only inputs, underscoring the complementary value of integrating quantifiable patient factors with the contextual nuance present in free-text narratives. Notably, such a finding builds on and further affirms the existing methodological literature suggesting the potential of combining structured and unstructured data [28,29].

Methodologically, our work extends prior studies that either relied exclusively on structured EHR data or incorporated unstructured text using basic NLP techniques. By leveraging contextualized language model embeddings (BERT) alongside structured features and comparing structured-only, unstructured-only, and combined inputs within a common framework, we demonstrate the added value of free-text clinical narratives for laboratory-order prediction at scale. In 5-fold cross-validation, the combined model achieved an AUC of 0.83, compared with 0.78 for structured-only, 0.74 for unstructured-only, and 0.81 for a simple late-fusion mean-probability ensemble, indicating that feature-level integration captures informative cross-modal interactions beyond the ensemble alone. Performance was robust to alternative text-embedding pooling strategies ([CLS] vs mean pooling), suggesting that gains are not an artifact of a particular representation choice. Model interpretability analyses were concordant across methods: the aggregated text-embedding feature and clinically intuitive predictors (eg, age, ambulance arrival, injury indicator, comorbidities, and vital signs) were among the most influential contributors, consistent with associations observed in Lasso-selected logistic regression.

Across all ML model families, SHAP analyses demonstrated a highly consistent set of influential predictors, including patient age, arrival by ambulance, abnormal vital signs (notably tachycardia, tachypnea, hypoxia, and fever), chronic comorbidity burden, and injury-related visit status. These findings align closely with established emergency medicine literature showing that older age, higher acuity of arrival, and physiologic instability are central drivers of diagnostic intensity and laboratory use in ED populations [30,31]. Large observational studies and multicenter cohort analyses have consistently demonstrated that derangements in initial vital signs are strongly associated with downstream diagnostic evaluation, admission, and short-term adverse outcomes, particularly among older and medically complex patients [32]. Similarly, chronic conditions such as diabetes, hypertension, and chronic kidney disease have been shown to increase clinicians' diagnostic vigilance due to higher baseline risk, atypical presentations, and concern for occult metabolic or infectious pathology, reinforcing their consistent importance across predictive models [33].

In contrast, injury-related or trauma-related visits were consistently associated with a lower predicted likelihood of laboratory testing, reflecting well-described trauma workflows that emphasize imaging, procedural assessment, and protocolized resuscitation over broad laboratory evaluation in the absence of physiologic instability [34,35]. Prior trauma-focused studies have shown that routine laboratory testing in low-to-moderate-severity trauma often yields limited actionable information, supporting more selective testing strategies [36]. Notably, the aggregated unstructured text feature (Combined Chief Complaint) emerged as the most influential predictor across all models, underscoring the critical role of free-text documentation in capturing early diagnostic reasoning. Recent explainable machine-learning studies in emergency care have demonstrated that clinical narratives encode nuanced contextual signals—such as concern for infection, metabolic disturbance, or cardiorespiratory compromise—that may precede or extend beyond structured data in shaping test-ordering behavior [28,33]. Together, these findings indicate that integrating unstructured clinical text not only improves predictive performance but also closely mirrors real-world clinical reasoning during early ED decision-making.

Clinical Implications

These findings have practical implications for diagnostic stewardship in ED settings. Because unnecessary or default laboratory testing contributes to avoidable costs, patient burden, and workflow inefficiency, predictive models that identify encounters with a lower likelihood of testing could serve as a lightweight prompt for clinicians to reassess routine or defensive ordering. In this way, model outputs can support more efficient, evidence-informed, and patient-centered care while preserving clinician judgment [37].

The results also highlight the use of transformer-based language models in clinical prediction tasks: contextual embeddings

XSL•FO
RenderX

capture linguistic complexity and semantic relationships in chief complaints and triage narratives, such as early concern for infection, hemodynamic instability, or metabolic disturbance, which may precede and inform ordering decisions in ways not fully represented by structured data [38]. As large language models trained on clinical corpora continue to evolve, there is potential to further improve performance, interpretability, and operational usability for diagnostic stewardship applications.

Beyond model performance, we observed differences in laboratory testing by race and insurance status that mirror longstanding variations in diagnostic intensity across US EDs. Prior work has documented that minoritized racial groups often receive fewer diagnostic tests and procedures, even after accounting for presenting features, while Medicare-insured patients–typically older with a higher comorbidity burden—more often undergo extensive evaluation, and uninsured or Medicaid-insured patients experience reduced diagnostic intensity. Our findings align with this broader literature and underscore the importance of examining how predictive systems may interact with existing disparities in care [30,39]. Future development should incorporate subgroup performance assessment and formal fairness analyses to mitigate the risk of reinforcing inequities [40,41].

Generalizability also warrants consideration. Although NHAMCS-ED provides a nationally representative picture of US emergency care, practice patterns, documentation structures, and diagnostic workflows can differ across individual hospitals, integrated health systems, and international ED settings. Variations in staffing models, triage protocols, and resource availability may influence both baseline testing rates and the predictors of ordering decisions. Accordingly, site-specific validation and prospective assessment are needed prior to operational deployment to ensure reliable performance across diverse clinical environments.

Finally, the clinical relevance of use prediction depends on its linkage to diagnostic quality and outcomes. While our models accurately predict the occurrence of laboratory testing, they do not evaluate appropriateness or downstream benefits (eg, diagnostic yield, treatment changes, ED length of stay, admission, and 72-h revisit). As such, this work should be viewed as a use-prediction study rather than an assessment of diagnostic quality. Prospective studies that pair deployment with adjudicated appropriateness criteria (eg, guideline-concordant ordering and choosing wisely targets) and patient-relevant outcomes are needed to establish clinical utility beyond use reduction.

Translating these models into decision support also requires attention to implementation details. Interpretability is essential for clinician trust; concise, case-level explanations (eg, SHAP-based summaries or simplified feature highlights) can clarify why a prediction was generated. User-interface design should minimize workflow disruption by surfacing predictions at natural decision points (eg, triage or during order entry) and offering actionable, context-aware cues rather than prescriptive directives. To avoid exacerbating alert fatigue, signals should be delivered judiciously, preferably through passive or noninterruptive displays with configurable thresholds and governance oversight. Addressing these considerations will be critical to realizing the potential of combined structured–unstructured models to support diagnostic stewardship in emergency care.

Limitations

Despite the promising results, several limitations must be acknowledged. First, though nationally representative, the NHAMCS-ED dataset is cross-sectional, thus limiting our ability to further evaluate the long-term pattern of laboratory testing in future ED admissions, if any. Second, while the models performed well in predicting laboratory orders, they do not assess clinical appropriateness. Future work should aim to distinguish between necessary and unnecessary testing to directly address overuse. Third, laboratory test use was operationalized as a binary outcome, which does not capture the complexity of test selection, test combinations, or sequencing during ED encounters. While this approach supports scalable modeling and avoids arbitrary weighting of heterogeneous tests, more granular representations of laboratory ordering behavior may yield additional insights in future studies. Fourth, integrating predictive tools into clinical workflows requires tailored and setting-specific design, critical provider engagement, and diligent ethical oversight to ensure that the integration of ML models supports rather than replaces clinician judgment. Fifth, this study did not formally assess algorithmic fairness or evaluate subgroup performance using established fairness metrics (eg, disparate impact, equal opportunity, or calibration across race or ethnicity or insurance groups). Given the observed variation in laboratory testing across demographic and insurance strata, future research should incorporate formal fairness analyses to ensure that predictive models do not inadvertently reproduce or amplify existing inequities in diagnostic care. Sixth, this study did not assess the clinical appropriateness or downstream benefit of laboratory testing; as such, results reflect the prediction of test occurrence rather than diagnostic quality or impact on outcomes. Finally, the study could enhance its applicability by outlining practical steps for real-world implementation and validation within hospital environments. Specifically, it should address strategies for effectively integrating predictive insights into existing clinical workflows in a manner that is nonintrusive yet informative for clinicians, ensuring these models enhance rather than hinder decision-making processes.

Conclusions

In summary, this study confirms the feasibility and added value of using combined structured and unstructured EHR data to predict laboratory test orders in ED settings. Such models can inform more intelligent diagnostic workflows by capturing quantifiable risk factors and nuanced clinical reasoning. Future work should focus on the real-time implementation and validation of diagnostic stewardship, aiming to reduce health care waste and improve patient outcomes in acute care environments.

No generative artificial intelligence tools were used at any stage in the preparation of this manuscript.

Funding

This research was supported by internal funding allocated to XZ from the Department of Communication Science and Disorders at the University of Pittsburgh.

Data Availability

The National Hospital Ambulatory Medical Care Survey–Emergency Department (NHAMCS-ED) dataset can be accessed through the website of the US Centers for Disease Control and Prevention. All the data are in a Statistical Analysis System (SAS) format. To get the unstructured data, one needs to run the SAS format files before importing the data into the analysis software.

Conflicts of Interest

None declared.

Abstract

Background: There are multiple sources that document the date of a person's death in the United States. Unfortunately, this seemingly simple information is either incomplete or costly to obtain. Nevertheless, information on such events is critical for both health systems and clinical studies to assess the outcomes of operational and therapeutic interventions.

Objective: As part of a larger assessment of the quality of multisource death information, we compared the death data from two health systems serving the same region and the Social Security Administration Death Master File (SSADMF).

Methods: This study linked death records for patients seen in either health system with the SSADMF from 2007 to 2020 to identify concordant and discordant death data among sources. Analyses included cross-system matching, classification of death records by overlap, and calculation of agreement using the Fleiss κ.

Results: Among 904,581 matched patients, only 209 (0.02%) deaths were confirmed by all 3 sources. Large proportions of deaths were uniquely recorded by a single source: 54.32% (10,697/19,691) by health system A, 5.16% (1017/19,691) by health system B, and 20.17% (3972/19,691) by the SSADMF. The Fleiss κ was negative (−0.312), reflecting less agreement than expected by chance.

Conclusions: While this study is not generalizable, it showed that, without processes in place to obtain external data regarding patient deaths, health care facility death information should not be relied upon as a complete list of those who have died. The discordances observed highlight the potential for significant gaps in death reporting within health care systems, which could impact the accuracy of mortality-based analyses and quality assessments.

Introduction

Mortality is the ultimate outcome of health care and wellness interventions. As such, mortality data are important to many clinical studies. In the era of learning health systems and real-world evidence, institutions increasingly rely on routinely collected electronic health record (EHR) data to evaluate care delivery, monitor outcomes, and iteratively improve practice [1,2]. However, the accuracy and completeness of mortality information within these data remain uncertain, particularly for deaths that occur outside individual health systems [3,4].

Our clinical data warehouse, serving a large academic health center in the southwestern United States, is used for approximately 100 clinical studies per year. Many of these studies focus on our local population and address whether they improve or worsen particular outcomes and include tracking or intervening in health disparities in our region, including observational comparative effectiveness studies, local quality

XSL•FO
RenderX

improvement initiatives, and program evaluations targeting population health and health disparities in the surrounding region. These data are used primarily for retrospective and hybrid retrospective-prospective designs, where mortality end points are often ascertained from EHRs and linked administrative sources rather than from dedicated, trial-specific follow-up. Because findings from such studies can inform guideline development, institutional policies, and clinical decision support within learning health systems, inaccurate or incomplete mortality data can directly affect patient care.

In clinical research evaluating treatments for diseases with low mortality rates (eg, due to short follow-up), errors in the few available death data points can introduce significant bias, potentially compromising the validity of the study [5]. Clinical studies are increasingly using EHR real-world data in the United States, where recent regulatory guidance requires assessment of accuracy and completeness [1]. Unfortunately, many institutions lack comprehensive information about death for patients who die outside of their facilities, making the use of EHR real-world data less reliable in these studies. The increasing trend of in-home end-of-life care further limits mortality data in EHRs [6].

Researchers and clinicians in the United States have used public data sources such as the National Death Index (NDI) or the Social Security Administration Death Master File (SSADMF) to obtain mortality data [7-10]. The reports of NDI sensitivity range from 87% to 97%, with SSADMF sensitivity ranging from 71% to 83%, although performance varies by cohort, identifiers available, and period [3,11-15]. Importantly, a Social Security Administration policy change in November 2011 removed protected state death records from the publicly disseminated Death Master File, eliminating approximately 4.2 million existing records and sharply reducing capture of more recent deaths, with continuing implications for the completeness of SSADMF-based mortality ascertainment [16]. These national resources; near ubiquitous EHR adoption; and significant strides in EHR interoperability, such as health information exchanges supporting the long-used Health Level Seven Admission, Discharge, and Transfer message that can indicate a death, imply good availability of reliable death information. However, obtaining high-quality data for mortality end points in clinical studies remains a significant challenge [17,18].

These national sources are also costly and logistically constrained. The costs of obtaining external death information range from 15 cents per patient per year (NDI) to an approximately US $3000 initial fee and US $7000 annual subscription fee per user for the Limited Access SSADMF [4]. The NDI data are only available for research, their use is time limited, and reuse is constrained through a data use agreement. These limitations lead some health systems to purchase and routinely integrate such data and others to rely solely on local or regional sources [3].

Even when national mortality data are purchased and linked, there is no single contemporary gold standard for deaths occurring outside a given health system, and both national and local sources show imperfect sensitivity and date accuracy [19]. Increasing trends toward in-home and hospice end-of-life care further reduce the proportion of deaths directly captured within hospital EHR systems [20]. Consequently, one can reasonably argue that all health systems lack fully comprehensive information about out-of-hospital deaths, and that practical strategies rely on combining multiple imperfect data sources to approximate a gold standard for mortality ascertainment.

Academic health centers need a sustainable way to maintain high-quality mortality data linked to health care data. For example, our cancer registry requires death information, as do many clinical trials. In this context, we posed two major questions. (1) What is the accuracy of death data, such as occurrence and date? (2) What is the quality and relative contribution from available death data sources? To begin, we compared patient deaths reported in our health system, a neighboring health system serving the same region, and the SSADMF.

Methods

Data Sources and Linkage

This study evaluated the concordance of death information between 2 health systems serving the same geographic region and the SSADMF over a 13-year period (January 1, 2007, to July 10, 2020), as determined by the availability of data from both health systems. Patient records from the 2 health systems were linked using three approaches: (1) an existing identifier crosswalk; (2) matching first name, last name, gender, and birth date; and (3) matching medical record number. To link SSADMF data with the health system records, five distinct hash-based tokens were used: (1) last name, first initial of first name, gender, and birth date; (2) Soundex last name, Soundex first name, gender, and birth date; (3) last name, first name, gender, and birth date; (4) Social Security number, gender, and birth date; and (5) Social Security number and first name. For linkage, a match on both token 1 and token 2 was required, whereas tokens 3, 4, and 5 were each sufficient for linkage when matched individually.

Death Record Categorization

Death records were classified into mutually exclusive groups to capture concordance and discordance across the 3 sources. For the matched patient cohort (patients identified in both health systems), deaths were categorized as follows: (1) concordant deaths were deaths recorded in all 3 sources (health system A, health system B, and the SSADMF), and (2) discordant deaths were deaths recorded in only 1 or 2 sources among the matched patients, further subdivided into those recorded only in health system A, recorded only in health system B, recorded only in the SSADMF, and recorded in combinations of 2 sources (eg, health systems A and B, health system A and the SSADMF, or health system B and the SSADMF). For patients present in a single health system, deaths recorded exclusively in that system or in the SSADMF were also identified. This approach allowed us to distinguish between deaths that were consistently captured across all sources and those that were discordant, reflecting differences in reporting or population coverage.

To further investigate discordant death records, we analyzed “lost contact” patients, defined as individuals who had at least

XSL•FO
RenderX

1 encounter at 1 facility during the observation period (January 1, 2007, to July 10, 2020) but no subsequent encounters at that facility for at least 12 consecutive months after their last visit there while maintaining contact with the other facility after those 12 months. This analysis helped identify potential gaps in follow-up or differences in patient retention between systems.

In addition, we performed 2 exploratory analyses: date discrepancies of more than 1 month for deaths recorded between sources and postdeath encounters occurring more than 1 year after the recorded death date. The first analysis indicated inconsistencies in death reporting between sources, which can affect the accuracy of mortality statistics and clinical research. For postdeath encounters, we compared the death dates from the 3 sources to the encounter dates from both health systems. The analysis revealed potential issues in death recording or patient management, suggesting inaccuracies in encounter or death records or possible misuse of deceased individuals' health care credentials.

κ Analysis for Intersource Agreement

To measure the consistency of death reporting across the 3 data sources, we calculated observed agreement; expected agreement; and the Fleiss κ, a statistic used to evaluate agreement among multiple raters with categorical data. Each patient in the matched cohort was classified as either "dead" or "not dead" by each source. We then grouped patients into 8 mutually exclusive categories based on the combination of sources that reported their death. These metrics allowed us to assess the level of concordance in death classification across health system A, health system B, and the SSADMF.

Visualization

A 3-set Venn diagram was constructed to illustrate the overlap and unique contributions of each data source in identifying deaths within the matched patient cohort. Each region of the diagram was annotated with the corresponding patient counts, providing a comprehensive view of concordance and discordance in death ascertainment across health system A, health system B, and the SSADMF. This visualization facilitated the identification of patterns and gaps in death reporting among the 3 sources.

Ethical Considerations

This study was reviewed by the Institutional Review Board of the University of Texas Health Science Center at San Antonio and determined to meet the criteria for exemption from institutional review board review in accordance with Title 45 of the Code of Federal Regulations §46.104 [21] on February 21, 2024 (STUDY00000154). As this research involved secondary analysis of existing death data and no direct interaction with human participants, informed consent was not required. All data were handled in accordance with institutional and national ethical standards to ensure the privacy and confidentiality of the individuals' information.

Results

Health system A reported 1,708,399 unique patients, including 21,623 (1.27%) reported deaths, while health system B reported 1,535,936 unique patients, including 8740 (0.57%) reported deaths (Figure 1). A total of 11,052 death records from the SSADMF were linked to the combined cohort, encompassing both matched and unmatched patient records from the 2 health systems.

Among the 904,581 matched patients, health system A reported 14,659 (1.62%) deaths, health system B reported 3951 (0.44%) deaths, and the SSADMF identified 5295 (0.59%) deaths (Figure 2). Collectively, the total number of unique death records across these sources was 19,691. Figure 2 shows that 1.06% (209/19,691) of deaths were recorded by all 3 sources, whereas 54.32% (10,697/19,691) of deaths were identified exclusively by health system A, 5.16% (1017/19,691) were identified exclusively by health system B, and 20.17% (3972/19,691) were identified exclusively by the SSADMF. The proportion of death overlap between health system A and the SSADMF, health system B and the SSADMF, and the 2 health systems was 5.44% (1071/19,691), 0.22% (43/19,691), and 13.62% (2682/19,691), respectively. Health system A contributed 74.45% (14,659/19,691) of the unique deaths observed in at least one source, health system B contributed 20.07% (3951/19,691), and the SSADMF contributed 26.89% (5295/19,691).

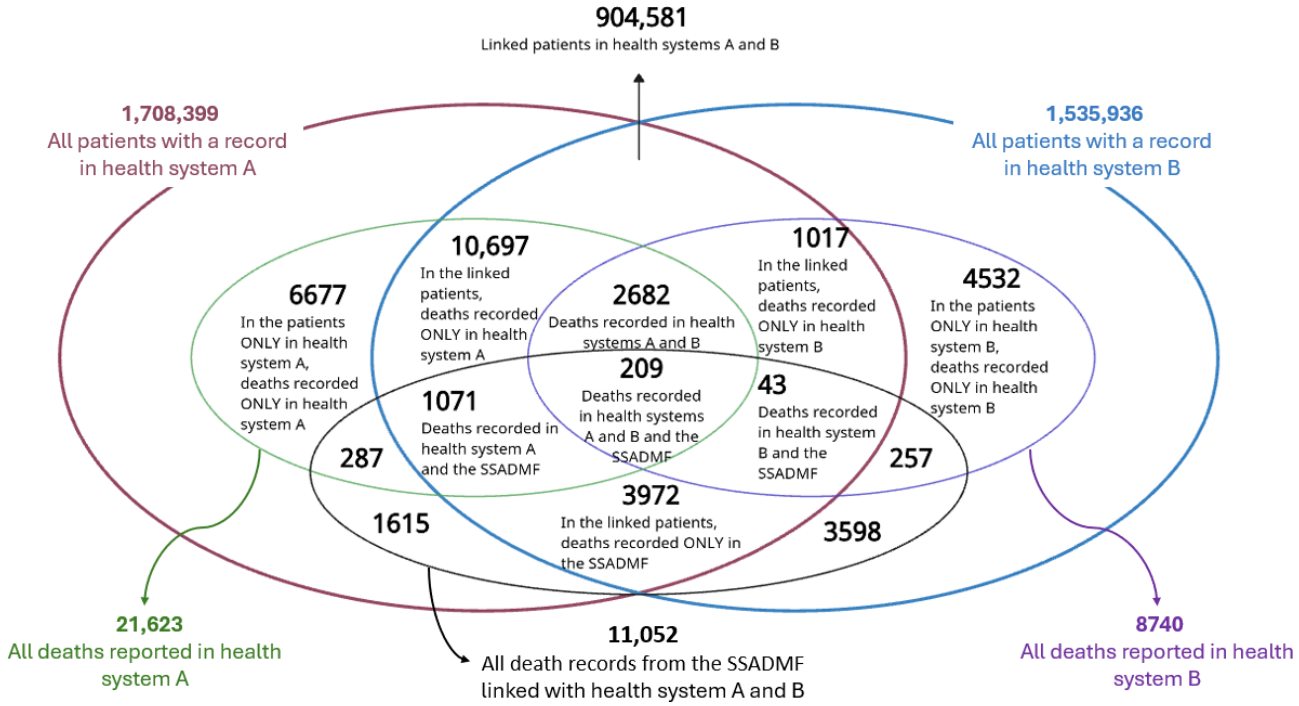
Figure 1. Patients and deaths reported among health systems A and B and the Social Security Administration Death Master File (SSADMF; encompassing matched and unmatched patient records).



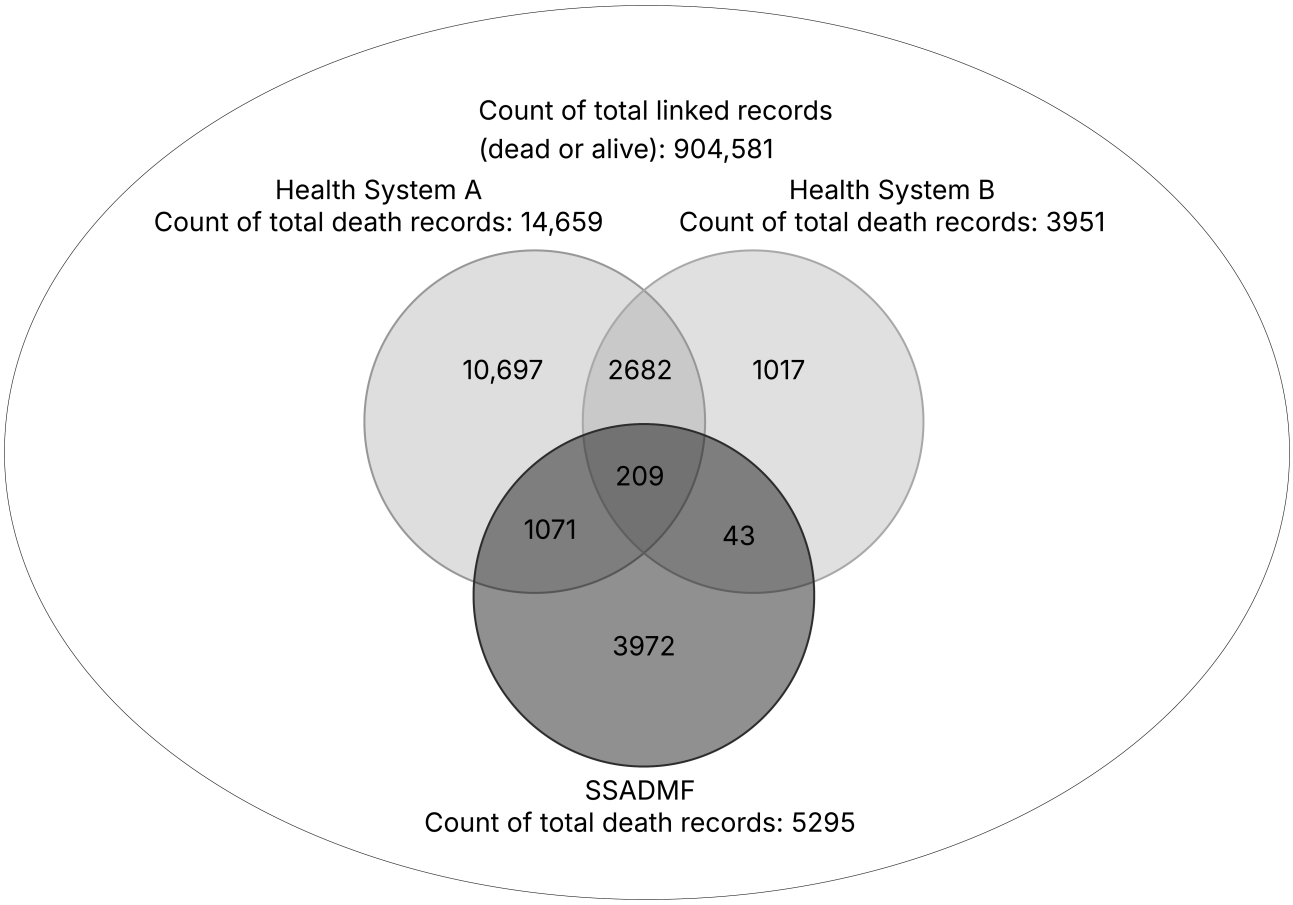


Figure 2. Three-set Venn diagram for the matched patient records. SSADMF: Social Security Administration Death Master File.

To quantify overall agreement in death classification among the 3 sources, the Fleiss κ was calculated using the distribution of death status assignments across all matched patients (Table 1). The observed agreement, defined as the proportion of patients for whom all 3 sources concurred on death status (either all "dead" or all "not dead"), was 0.9771. The expected agreement by chance based on the marginal probabilities of each source assigning "dead" or "not dead" was 0.9826. The Fleiss κ, summarizing agreement beyond chance, was −0.312, with a 95% CI from −0.330 to −0.294.

XSL•FO
RenderX

Table . Distribution of death status among the 3 sources in the matched cohort (N=904,581).

Overlap category	Patients, n (%)
Deaths in all 3 sources	209 (0.02)
Deaths in health systems A and B only	2682 (0.30)
Deaths in health system A and the SSADMF[a] only	1071 (0.12)
Deaths in health system B and the SSADMF only	43 (0.00)
Deaths in health system A only	10,697 (1.18)
Deaths in health system B only	1017 (0.11)
Deaths in the SSADMF only	3972 (0.44)
Not dead in any source	884,890 (97.82)

[a]SSADMF: Social Security Administration Death Master File.

Further investigation of discrepancies in matched patients revealed that, of the 11,768 patients recorded as deceased in health system A but not in health system B, 4796 (40.75%) lost-contact patients in health system B switched to health system A. Similarly, of the 1060 patients recorded as deceased in health system B but not in health system A, 44 (4.15%) lost-contact patients in health system A switched to health system B. These lost-contact patterns suggest that patient migration between facilities may contribute to the discordance in death reporting.

To explore the potential benefit of data quality checking rules, we identified 0.20% (39/19,691) of cases in which the date of death recorded in health system A differed by 1 month or more (median 2, range 1 to 20 months) from that recorded in health system B. Similarly, 0.23% (45/19,691) of the cases showed a discrepancy of at least 1 month (median 29; range 1-122 months) between the date of death recorded in health system A and the SSADMF, whereas 0.02% (3/19,691) of the cases showed a discrepancy of at least 1 month (median 52; range 49-122 months) between the date of death recorded in health system B and the SSADMF.

An analysis of postdeath encounters revealed that 1.22% (179/14,659) of the cases from health system A had visits recorded in either of the 2 health systems more than 1 year following their documented date of death. Similarly, 0.35% (14/3951) of such cases were identified in health system B, and 8.48% (449/5295) of cases were identified within the SSADMF.

Discussion

Principal Findings

Death records from 2 major health systems serving the same region and the SSADMF provide new insights into the complexities and limitations of mortality reporting in health care research. Ideally, each health system would maintain a complete and accurate record of all deaths, including precise date of death for every deceased patient. However, our study revealed substantial variability and discordance in mortality ascertainment across these 3 sources, underscoring the challenges inherent in relying solely on health care facility records for vital status determination.

Significant discrepancies were observed in both the identification of deaths and the recording of death dates among the 2 health systems and the SSADMF. The Venn diagram analysis demonstrated that a considerable number of deaths were uniquely captured by only 1 data source, with relatively few cases identified by all 3. This pattern highlights the risk of systematic bias and under-ascertainment when mortality surveillance depends on a single institutional record system. The presence of deaths recorded exclusively by the SSADMF (deaths not captured in either health system) emphasizes the value of integrating external sources to enhance completeness.

In Texas, hospitals are required to report deaths that occur within their facilities to the local registrar, who then forwards this information to the Texas Department of State Health Services Vital Statistics Section. This process ensures that deaths occurring in hospitals are captured in the official state vital records. However, a critical regulatory change further complicates the concordance between health system records and the SSADMF. Deaths reported solely to state vital record offices after November 1, 2011, may not appear in the publicly available SSADMF even if they are accurately captured in hospital or state databases. These reporting practices and regulatory constraints may explain the observed discrepancies between the health system data and the SSADMF. Deaths that occur in hospitals and are reported to the state may be present in the state's vital records but absent from the SSADMF if they are considered protected state records. Conversely, deaths reported directly to the Social Security Administration through other means (such as funeral directors or family members) may appear in the SSADMF but not in hospital records if the patient was not under active care at the time of death or if the hospital was not notified.

Analysis of lost-contact patients suggests that the discrepancies in death reporting may be partially explained by differences in patient engagement with each health system over time. Patients who continued to receive care primarily from one system or had no recorded visits in the other system were more likely to have their death recorded by the system with which they last interacted, potentially due to more up-to-date information or discovering deaths through postcare follow-up or billing interactions. The higher proportion of health system B–to–health system A switching compared to health system A–to–health

XSL•FO
RenderX

system B switching explains part of health system A's substantially greater volume of death records overall. These findings suggest that patient migration between systems contributes to death reporting discordance, although the reasons for migration require further investigation. While these findings offer insight into the discrepancies, they do not fully account for the substantial differences observed. This substantial difference suggests that additional factors such as institutional practices, death documentation processes, or data management systems may significantly influence death reporting.

The presence of postdeath encounters in both systems is particularly concerning. These instances could represent data entry errors, identity mix-ups, fraudulent use of a deceased patient's identity and health care coverage by another individual or entity, or other root causes. These should be investigated to identify opportunities for improvement. The results reported in this paper emphasize the importance of cross-referencing death information from multiple sources to identify discrepancies and incompleteness.

The integration of the SSADMF into our analysis allowed for a more robust assessment of concordance across sources. A high observed agreement was driven primarily by the predominance of patients classified as "not dead" by all sources. In the context of this highly imbalanced outcome, the negative κ should not be interpreted as strong paradoxical disagreement but rather as a statistical artifact of extreme class imbalance where chance agreement among "not dead" classifications is very high. Therefore, the Venn diagrams and Table 1 provide a more informative description of how often each source captured deaths and how frequently those deaths were uniquely identified by one source vs shared across sources. The finding is that the 3 sources showed limited concordance in identifying deaths themselves.

Limitations

A persistent limitation of our study is the absence of a definitive gold standard for mortality ascertainment. Without such a reference, we are unable to calculate accuracy statistics such as sensitivity and specificity and cannot definitively identify false positives or false negatives. While some potential false positives may be inferred from the presence of postdeath encounters, the true extent of missed deaths (false negatives) remains unknown and likely requires external validation. Errors in patient linkage, crosswalks, or record attribution may also contribute to misclassification. In addition, differences in linkage methodology may influence the observed discordance: the SSADMF linkage required agreement on 2 composite name–demographic tokens recommended by the data provider to balance tolerance for name variation, a design that may reduce missed matches but carries a higher risk of false linkages when names are similar yet pertain to different individuals. Future work should incorporate more reliable data sources, including the NDI, state death records, obituary data, and family-reported information. These additional sources would provide a more comprehensive and accurate picture of mortality, allowing for a better assessment of false positives and false negatives in health care facility death data.

We report this evaluation as a marker and example of significant discordance in death data among 2 health systems serving the same region and the SSADMF. While not an unexpected or groundbreaking result, such assessments serve as important reminders that, although we have come a long way toward EHR adoption and interoperability of health information, we have a long way to go before even the most basic health care data can be assumed to be accurate and complete.

Conclusions

This study demonstrates that death data from health care facilities, even when supplemented with data from the SSADMF, exhibit substantial discordance and should not be presumed to be accurate or complete without corroboration from additional sources. The persistent discrepancies among the 3 sources highlight the limitations and potential unreliability of depending solely on the EHR. Despite advances in EHR adoption and interoperability, obtaining high-quality, comprehensive mortality data for research remains challenging. Researchers and clinicians should not rely solely on facility death data for mortality end points in observational studies unless death information is systematically and prospectively collected as part of the study protocol; instead, they are strongly encouraged to incorporate external sources, such as the NDI or state vital records, to improve accuracy and completeness. Further research is needed to understand the causes of discordance and develop strategies for enhancing the quality of mortality information in clinical and epidemiological studies.

Abstract

Background: Repeated blood product ordering is associated with order entry errors and potential patient harm. Traditional electronic health record order sets require repeated re-entry for recurrent transfusions, creating inefficiencies and opportunities for error, and contributing to physician burnout. Historically, we have used order sets to order blood products, which must be re-entered each time a transfusion is needed. Reusable transfusion therapy plans may address these challenges by standardizing and streamlining transfusion workflows. We conducted a pre-post study at a single pediatric academic center, evaluating the implementation of reusable transfusion therapy plans for packed red blood cells and platelets in oncology patients and those undergoing hematopoietic stem cell transplantation.

Objective: The primary outcome was to evaluate the proportion of transfusions originating from the transfusion therapy plans during the postimplementation period. Secondary outcomes included evaluating (1) the proportion of eligible patients with applied transfusion therapy plans, (2) changes in transfusion efficiency (time from laboratory result to transfusion release and administration, premedication timing, and estimated overnight pages), and (3) the impact on safety (guideline-concordant dosing, irradiated product ordering, and transfusion thresholds). We also assessed health care practitioner experience using an adaptation of the technology acceptance model survey.

Methods: The prestudy period consisted of the 1-year preimplementation, and the postperiod consisted of the 1-year post implementation. We used our institution's enterprise data warehouse (SickKids Enterprise-Wide Data in Azure Repository) to obtain demographic and transfusion details for all eligible patients. The adapted technology acceptance model survey was administered to eligible oncology clinicians.

Results: The preimplementation cohort had 558 unique patients who received a total of 2678 transfusions. The postimplementation cohort had 521 unique patients who received 2777 transfusions. During the postimplementation period, 59% of transfusion orders originated from a therapy plan, increasing to 71% in the final month. Compared with order sets, therapy plan–derived transfusions were released and administered significantly faster following laboratory results (P<.001). Guideline-concordant transfusion volumes increased significantly postimplementation for both packed red blood cells and platelets (P<.001), as did the ordering of irradiated blood products (P<.001). No differences were observed in pretransfusion hemoglobin or platelet thresholds between study periods. Use of therapy plans was associated with an average avoidance of 4 overnight blood product entries per night. Survey responses from nurses and providers demonstrated high perceived usefulness and ease of use, with 95% endorsing continued use.

Conclusions: Reusable transfusion therapy plans improved efficiency, standardized safe ordering practices, and were highly acceptable to clinicians. This longitudinal, noninterruptive electronic health record intervention represents a scalable approach to supporting high-risk transfusion workflows in pediatric oncology.

Introduction

Blood products, such as platelets and packed red blood cells (pRBCs), are frequently required during pediatric cancer therapy. Ordering blood products is inherently complex, and incorrect orders can lead to severe adverse outcomes for patients [1]. A common cause of blood product safety events is the inappropriate ordering of blood products, including transfusion above recommended thresholds, omission of required premedications, and incorrect dosing [2-6].

Electronic health records (EHRs) can support safer transfusion practices by providing access to comprehensive medication, allergy, and laboratory information [7,8]. Standardized order sets, a grouping of related orders within EHRs, are increasingly used to strengthen workflow efficiency, improve the accuracy and timing of medication administration, and reduce medication errors [9,10]. Ensuring end user evaluation of digital tools to support complex ordering is important to ensure they are achieving the intended impact, are acceptable to end users, and have adequate usability [4,11-13].

A common approach for blood product ordering is the use of an order set, a collection of related orders that are grouped together to facilitate ordering. When patients require repeated transfusions, the order set must be manually re-entered by a health care provider with each transfusion. Given the need for frequent transfusions among patients with pediatric cancer and patients undergoing hematopoietic stem cell transplantation, we identified an opportunity to eliminate the repeated ordering of transfusions using a transfusion therapy plan. A therapy plan differs from an order set in that the orders can be reused longitudinally without a provider needing to manually re-enter them. Transfusion therapy plans allow clinicians to predefine recurring transfusion orders, including indication, volume, precautions, and premedications. We hypothesized that, compared to the traditional order set, a therapy plan would be better for blood product ordering as it might: (1) reduce order entry errors; (2) reduce the time to transfusion; (3) improve transfusion guideline–consistent care; and (4) improve practices consistent with patient-specific needs, such as precautions and premedications.

Therefore, our primary objective was to understand the usage patterns of transfusion therapy plans. Our secondary objectives were to understand how transfusion therapy plans impact: (1) efficiency, (2) safety, and (3) clinician experience.

Methods

Study Design and Setting

This study was conducted at The Hospital for Sick Children (SickKids), a large academic pediatric institution in Toronto, Canada. SickKids cares for approximately 350 new patients with cancer and performs 100 hematopoietic stem cell transplants (HSCTs) per year. SickKids has used Epic as its EHR since 2018 [14]. The project consisted of two 1-year periods: November 2023 to October 2024 (preimplementation) and November 2024 to October 2025 (postimplementation) of the transfusion therapy plans. All data were obtained from our institution's enterprise data warehouse, named SickKids Enterprise-Wide Data in Azure Repository [15].

Ethical Considerations

This project was approved by the Quality Improvement Review Board at SickKids (QIP-2024-01-26T13-52-53). Informed consent was not required, and participants were not compensated for participation. Patient privacy and confidentiality were maintained through anonymization of data.

Transfusion Workflows

The workflows for ordering, preparing, and administering blood using both EHR tools (order set and transfusion therapy plan) are detailed in Table S1 in Multimedia Appendix 1. In brief, using the order set for transfusion, orders are entered by a provider at the time a transfusion is needed and cannot be reused, whereas with the therapy plan, the orders can be entered in advance or at the time of transfusion and can be reused. Regardless of how the transfusion orders are entered, a nurse then reviews the orders and "releases" them, rendering them active in the system. One of these orders is a "prepare" order, which specifies the blood product requirements to the blood bank. The blood bank then prepares the requested product and delivers it to the patient's nurse. The nurse then administers any premedications, uses a "transfuse" order to administer the blood product, monitors for transfusion reactions, and administers the emergency medications if a reaction occurs.

Transfusion Therapy Plan Creation

Two transfusion therapy plans were created—one for pRBC orders and one for platelet orders. New sections in our "Treatment" activity, where cancer-specific orders are placed, were created for applying the transfusion therapy plans (Multimedia Appendix 2). Both therapy plans contain the prepare and transfuse orders for their respective blood components (Multimedia Appendices 3 and 4). The blood product orders were configured to maximize adherence to our transfusion volume guidelines. For pRBC orders, if the patient weighs less than 25 kg, providers are presented with order options in mL/kg/dose, and if they weigh 25 kg or more, they are presented with order options in units. For patients less than 25 kg, the maximum mL/kg/dose volume that can be ordered is 10 mL/kg, and for patients more than 25 kg, only 1 unit of pRBC can be ordered at a time. For the platelet orders, if the patient weighs less than 20 kg, providers are presented with order options in mL/kg/dose, and if they weigh 20 kg or more, they are presented with order options in units. For patients less than 20 kg, the maximum dose that can be entered is 10 mL/kg (200 mL), and for patients more than 20 kg, the only dose that can be entered is 1 unit. Hard stops were configured within the orders to prevent ordering transfusion volumes that exceed the recommended maximums. If additional units are required, direct communication with the blood bank is required.

XSL•FO
RenderX

Both plans contain optional premedications to prevent transfusion reactions and emergency medications that can be administered in the case of a transfusion reaction. The pRBC plan also contains a type and screen order. Both plans also include a communication order that indicates in what context the nurse can release the transfusion orders. For the pRBC therapy plan, the default options a provider can select are to transfuse for a hemoglobin level of less than 70, 80, or 90 g/L, and for the platelet therapy plan, the default options a provider can select are to transfuse for a platelet count of 10 or 20 (if febrile), 20, 30, or 50 kcells/μL. However, a provider can manually enter a patient-specific threshold. If a transfusion is needed and the threshold in the communication order is not met, but a transfusion is felt to be clinically indicated by the team (eg, threshold indicates transfuse for hemoglobin of 70 g/dL, and the patient's hemoglobin is 71 g/dL in a patient with tachycardia and fatigue), an ad hoc one-time nursing communication order can be entered approving the use of the transfusion therapy plan. Dosages of both blood products and supportive care medications automatically update using the patient's most recent weight. An automated in-basket message to the primary oncology provider is generated every 6 months, indicating that the plan must be reviewed and either renewed or discontinued.

Once the therapy plan is applied and signed, the orders within the therapy plan can be released by a nurse without the need for a provider to enter additional orders. The therapy plan orders can be reused each time a transfusion is required, eliminating the need to reorder blood products each time a transfusion is required.

Population

Patients with active cancer and those undergoing HSCT were included. Patients with active cancer were defined as those seen in an oncology clinic or admitted to an oncology service with an active chemotherapy treatment plan (defined as 1 chemotherapy day within the last 30 days). Patients with HSCT were defined as any patient within 100 days of the infusion of a cellular therapy product.

Transfusion Therapy Plan Use

We evaluated therapy plan usage in 3 ways. Our primary outcome was to evaluate the proportion of eligible blood product orders that came from a transfusion therapy plan on a monthly basis. Secondary outcomes included evaluating the proportion of eligible patients who had a transfusion therapy plan applied and the proportion of eligible patients who received a transfusion during the study period and had a transfusion therapy plan applied. Only transfusions given within an oncology or HSCT department were considered (ie, transfusions in the emergency department, operating room, or intensive care unit were not included). The use of the platelet and pRBC therapy plans was tracked separately.

Impact on Efficiency

We evaluated changes in hospital efficiency in 3 ways. First, for patients who received a blood product, we evaluated the time between the complete blood count (CBC) being reported in Epic and the blood being released and administered by the nurse caring for the patient. These metrics were calculated on a per-transfusion basis. If more than one unit of a blood product was included in a single release, these were counted as a single transfusion, and the release of the transfusion was counted as the time for the first unit. Second, we hypothesized that our transfusion therapy plan might decrease the number of times where a CBC and type and screen were drawn in separate blood draws. We evaluated the proportion of transfusions where the CBC and type and screen were drawn within 5 minutes of each other. Since many inpatients might already have one of these premedications ordered for an alternative indication, we only evaluated premedications for outpatient administrations of blood products. Finally, we evaluated the estimated change in overnight transfusion ordering related to eliminating the need for providers to order blood overnight. We calculated the number of blood product orders placed between 7 PM and 7 AM.

Impact on Safety

To evaluate changes in blood product ordering patterns, we evaluated the mean pretransfusion hemoglobin and platelet levels prior to the transfusion of blood or platelets, respectively. All oncology patients and patients with bone marrow transplants (BMTs) should have their blood ordered as irradiated. We evaluated the proportion of blood products ordered with this precaution during both periods as well. We also evaluated the proportion of patients receiving an appropriate transfusion volume. For blood, the maximum appropriate transfusion volume was defined as 10 mL/kg for patients weighing less than 25 kg and 1 unit for patients weighing more than 25 kg. For platelets, the maximum appropriate transfusion volume was defined as 10 mL/kg up to 200 mL for patients weighing less than 20 kg and 1 unit for patients weighing more than 20 kg. These volumes are in accordance with our internal blood transfusion policy. In the postimplementation period, we also compared the same safety metrics for transfusions that came from a therapy plan compared to those that came from an order set. In addition, we hypothesized that premedications would be less frequently missed with the use of the new therapy plan. We calculated the proportion of patients who had an allergy to blood or platelets listed in Epic and who had a premedication (hydrocortisone, diphenhydramine, cetirizine, or acetaminophen) ordered within 5 minutes of the blood product they were allergic to being ordered.

Health Care Practitioner Experiences

To assess health care practitioner experiences using the transfusion therapy plan, a survey was administered 6-months post go-live of the transfusion therapy plan to physicians and nurses who care for oncology patients and those with BMT via REDCap (Research Electronic Data Capture; Vanderbilt University). The survey consisted of three parts: (1) demographic information about the respondent, (2) an abbreviated version of the technology acceptance model (TAM) questionnaire, and (3) specific questions related to the impact on transfusion-related practices [16-18]. Demographic information included health care role (oncology attendings, oncology fellows, pediatric residents, clinic nurses, or ward nurses), primary area of practice (leukemia or lymphoma, solid

XSL•FO
RenderX

tumor, neuro-oncology, or BMT), and duration of employment at our institution. The TAM is a questionnaire that assesses technology acceptance across two main constructs: (1) perceived usefulness of the technology and (2) perceived ease of use of the technology. The TAM has been shown to be both reliable and valid. To assess the impact of the transfusion therapy plan on specific blood ordering practices, novel questions were developed by a subset of the study team with expertise in questionnaire development, clinical informatics, usability, and transfusion medicine.

Statistical Analysis

Descriptive statistics were used to summarize demographic data, transfusion history, and therapy plan usage. To determine factors associated with the use of a therapy plan and differences in outcomes between order set and therapy plan–derived transfusions, the chi-square test and Fisher exact test were used for categorical variables, and the Wilcoxon rank-sum test was used for continuous, nonnormally distributed variables (RStudio version 1.4.1717; Posit PBC).

Results

Demographics

The demographics of the preimplementation and postimplementation cohorts are shown in Table 1. The preimplementation cohort included 558 patients and the postimplementation cohort included 521 patients. No statistical differences in the baseline characteristics of the 2 cohorts were identified.

Table . Cohort characteristics of patients who received at least 1 transfusion.

Characteristic	Preimplementation cohort (n=558)	Postimplementation cohort (n=521)	*P* value
Sex, n (%)			.62
Male	319 (57)	290 (56)	
Female	239 (43)	231 (44)	
Age (y), median (range)	7.7 (0-24)	7.8 (0-20)	.80
Disease group, n (%)			.23
Bone marrow transplant	132 (24)	95 (18)	
Leukemia or lymphoma	338 (61)	307 (59)	
Neuro-oncology	70 (13)	75 (14)	
Solid tumor	109 (19.5)	107 (21)	
Inpatient admission during period, n (%)	374 (67)	351 (67)	.90
Outpatient clinic visit during period, n (%)	499 (89)	474 (91)	.39

Transfusion Therapy Plan Use

During the 1-year postimplementation period, 26% (n=138) and 24% (n=125) of eligible patients had a pRBC or platelet therapy plan applied, respectively. Of the 238 patients with either transfusion therapy plan applied, 59% (n=141) had both plans applied. The proportion of eligible patients who had either transfusion therapy plan applied ranged from 32% (97/307) for patients with leukemia or lymphoma to 100% for patients with neuro-oncology (75/75) and BMT (95/95; Table S2 in Multimedia Appendix 1). Of the 220 patients who received pRBCs, 58% (n=127) had a pRBC transfusion plan, and of the 158 patients who received platelets, 67% (n=106) had a platelet transfusion plan. Overall, during the postimplementation period, 59% (n=1634) of transfusion orders originated from a transfusion therapy plan. The proportion of eligible patients with either therapy plan, the proportion of patients who received a transfusion who had a therapy plan, and the proportion of transfusion orders coming from a therapy plan, stratified by month, are shown in Figures 1-3. In the last month of our evaluation period (October 2025), 39% (60/156) of eligible patients had at least 1 therapy plan, 60% (35/58) of patients who were transfused had the corresponding transfusion therapy plan, and 72% (88/122) of all transfusion orders came from a therapy plan.

RenderX

Figure 3. Proportion of blood product orders originating from a transfusion therapy plan.

Impact on Efficiency

Changes in efficiency metrics preimplementation and postimplementation of the transfusion therapy plans are shown in Table 2. There was a significant difference in the timing between the transfusion and premedication orders (median 14, IQR 0-159 vs 10, IQR 0-145 min; *P*=.04). In the postimplementation period, there was a significant difference in the median time between the CBC being reported and the transfusion being released (178, IQR 35-394 vs 129, IQR 15-315 min; *P*<.001) and between the CBC being reported and transfusion administration (227, IQR 92-443 vs 181, IQR 76-367 min; *P*<.001) when using the therapy plan compared to the order set (Table 3). In the postintervention period, 1453 transfusions from therapy plans were released between 7 PM and 7 AM, suggesting an estimated avoidance of 4 overnight orders per night by the overnight resident or fellow.

Table . Impact of transfusion therapy plan implementation on efficiency.

Efficiency metric	Preimplementation cohort (n=2678 transfusions)	Postimplementation cohort (n=2777 transfusions)	Difference (95% CI)	*P* value
Type and screen drawn more than 5 minutes after CBC[a,b], % (n/N)	26 (271/1041)	29 (277/941)	3.4 (0.5 to 7.4)	.10
Time between CBC result and nurse releasing the transfusion orders (min), median (IQR)	143 (25-345)	146 (21-352)	2.5 (−6.2 to 11.2)	.58
Time between CBC result and transfusion administration (min), median (IQR)	201 (88-388)	198 (83-402)	−3.2 (−11.9 to 5.6)	.47
Time between transfusion order and premedication order for all patients receiving premedications (min), median (IQR)[c]	14 (0 - 159)	10 (0 - 145)	−5.8 (−21.6 to −3.8)	.04

[e]pRBC: packed red blood cell.

Impact on Safety

The impact of the transfusion therapy plans on safety metrics is shown in Table 4. There was a significant difference in the proportion of patients with allergies who were ordered premedications (273/724, 38% vs 292/651, 45%; *P*=.008). No significant differences were identified in pretransfusion thresholds between the preimplementation and postimplementation cohorts. There was a significant increase in the proportion of patients receiving guideline-concordant transfusion volumes in the postimplementation period compared to the preimplementation period (58% vs 85%; *P*<.001). In the postimplementation period, there was a significant difference in the mean hemoglobin value prior to pRBC transfusion (73, SD 11 g/dL vs 70, SD 5 g/dL; *P*<.001), the mean platelet value prior to platelet transfusion (24, SD 17 kcells/μL vs 19, SD 13 kcells/μL; *P*<.001), the proportion of blood products where the volume ordered was guideline-concordant (87/1143, 76% vs 1484/1634, 91%; *P*<.001) and the proportion of blood products that were ordered as irradiated (814/1143, 71% vs 1595/1634, 98%; *P*<.001; Table 3).

[b]pRBC: packed red blood cell.

Health Care Practitioner Experiences

The health care practitioner experience survey was completed by 57 individuals (27 nurses and 30 providers). This represents a response rate of approximately 15% of our oncology workforce. Of the 27 nurses, 19 worked primarily in the inpatient setting, and 8 worked primarily in the outpatient setting. Of the 30 providers, 4 were attending physicians, 8 were nurse practitioners or physician assistants, 9 were hematology or oncology fellows, and 9 were general pediatrics residents. Results of the abbreviated TAM questionnaire are presented in Figure 4 and Table S3 in Multimedia Appendix 1. Self-reported preferences related to ordering tools for blood products are shown in Table 5. Overall, 95% (n=54) of respondents felt we should continue to use the transfusion therapy plans.

Table . Preferences of oncology clinicians regarding ordering tools for transfusions.

Questions	Transfusion order set preferred, n (%)	No difference, n (%)	Transfusion therapy plan preferred, n (%)
Oncology provider-specific questions (n=21)			
Which tool allows you to order blood more efficiently?	2 (9.5)	0 (0)	19 (90.5)
Which tool allows you to order blood in the safest way?	3 (14.3)	16 (76.2)	2 (9.5)
Which tool best ensures your patients' blood is ordered with the correct precautions (eg, irradiated)?	2 (9.5)	16 (76.2)	3 (14.3)
Which tool best identifies a patient's specific transfusion parameters?	2 (9.5)	15 (70.5)	4 (19)
Which tool best ensures that your patients have the correct blood product volume ordered?	1 (4.8)	16 (76.2)	4 (19)
Which tool best ensures that your patients have the correct pre-medications ordered?	2 (9.5)	18 (85.7)	1 (4.8)
Trainee-specific question (n=18)			
Which tool results in less unnecessary overnight pages?	0 (0)	12 (66.7)	6 (33.3)
Nursing-specific questions (n=27)			
Which tool allows you to access blood orders most easily?	0 (0)	22 (81.5)	5 (18.5)
Which tools allows you to administer blood in the safest way?	3 (11.1)	14 (51.9)	10 (37)
Which tool results in the fewest clicks or least amount of time in Epic?	8 (29.6)	16 (59.6)	3 (11.1)
Which tool resulted in the clearest communication with ordering providers?	8 (29.6)	17 (63.3)	2 (7.4)
Which tool results in fewer delays in care?	3 (11.1)	21 (77.8)	3 (11.1)

Discussion

In this study, we evaluated the implementation of transfusion therapy plans for pediatric oncology and HSCT patients and demonstrated meaningful improvements in efficiency, safety, and health care practitioner experience compared to traditional transfusion order sets. Collectively, these findings suggest that reusable transfusion therapy plans represent a valuable EHR-based intervention for supporting complex, high-risk ordering workflows in pediatric cancer care.

Although only one-quarter of eligible patients had a transfusion therapy plan applied during the evaluation period, over half of the patients who required a transfusion had a therapy plan, and nearly 60% of all transfusion orders originated from a therapy plan. Importantly, adoption increased over time. This is consistent with prior EHR-based workflow interventions, where uptake is often gradual and influenced by clinician familiarity, trust in the tool, and perceived value [19]. The higher adoption rate among patients who actually received transfusions suggests that clinicians may preferentially apply therapy plans to patients with anticipated or recurrent transfusion needs, aligning with the intended use case of the tool. Adoption rates also differed by section, with patients with leukemia or lymphoma having a much lower adoption rate. This is understandable, given that many patients with leukemia have 2 to 3 years of maintenance therapy where transfusions are infrequent and a transfusion therapy plan might not be useful.

Use of transfusion therapy plans was associated with improvements in several measures of operational efficiency. In the postimplementation cohort, we demonstrated an increase in premedication usage and improved timing of ordering for outpatients with documented allergies; however, given these were modest improvements, these changes may not have significant clinical impacts. Additionally, we saw no improvement in the time between the CBC being resulted and the transfusion being released or administered in the precohort versus postcohort. In contrast, we did see a difference in the

XSL•FO
RenderX

postcohort when comparing the order set to the therapy plan. This likely reflects that in the postcohort, given the significant usage of the order set, the impact of the improved timeliness of blood administration with the therapy plan was ameliorated when analyzing the entire cohort instead of conducting a subanalysis by ordering tool. The effect size of these changes in the postimplementation period between the 2 ordering tools was clinically meaningful, with blood being administered 37 minutes earlier with the use of the therapy plan.

We observed significant improvements in guideline-concordant transfusion volume ordering following the implementation of the therapy plans. This finding is particularly notable given our prior work demonstrating that adherence to care pathway recommendations for supportive care in pediatric cancer is often low [20]. Ensuring that transfusion volumes are guideline-consistent is important as inappropriate transfusion volumes are a common source of safety events [2,3,6]. By embedding hard stops and weight-based dosing logic directly into the order configuration, the therapy plans effectively operationalized institutional transfusion policies at the point of order entry. The higher rates of irradiated blood product ordering in the postimplementation period further support the role of structured, reusable orders in reducing reliance on clinician memory for critical safety requirements in immunocompromised populations. These changes are likely to have a meaningful clinical impact, given the magnitude of the improvements and the impact of guideline-concordant care on clinical outcomes.

Health care practitioner feedback strongly supported the continued use of transfusion therapy plans, with high ratings for perceived usefulness and ease of use across both nursing and provider roles. High acceptability across disciplines is especially important in transfusion workflows, which require close coordination between providers, nurses, and the blood bank. Ensuring usability is particularly important given the known impact of EHR usage on clinician burnout [21-23]. When clinicians were asked about their preferences between the order set and therapy plan, the majority found no difference between the tools but supported the continued use of the transfusion therapy plans.

This study has several limitations. First, as a single-center observational study, findings may not be generalizable to institutions with different EHR configurations, transfusion policies, or staffing models. However, the concept of using transfusion therapy plans instead of ad hoc orders would be easily transferable to other centers. Second, the response rate to our survey was low and may not represent the opinions of all staff. Third, adoption was incomplete during the study period, and outcomes may further improve with sustained use and targeted education. Future work should explore strategies to increase adoption, including clinical decision support to suggest therapy plan application, and expansion to other patient populations that receive high volumes of transfusions. Multicenter evaluations will be important to assess generalizability as well.

In summary, our findings suggest that transfusion therapy plans are a promising approach to improving the safety, efficiency, and user experience of blood product ordering in pediatric oncology and HSCT populations.

Abstract

Background: This exploratory study investigated the impact of computer use on physician performance during clinical simulations. Standardized patient (SP) scenarios used in family practice certification examinations were adapted to include the use of the electronic health record (EHR).

Objective: The goal was to compare the impact of EHR use during simulated virtual patient encounters on resident physicians' and staff physicians' patient-centeredness (PC) and overall clinical performance, as well as to measure the cognitive load (CL) imposed by EHR use.

Methods: Sixteen participants each completed 2 video telemedicine simulations with SPs. One simulation case included limited past medical history for the SP in the EHR, while the other did not. Participants were instructed to completely document the encounter using the EHR. Participants' self-perceived CL was measured using the raw National Aeronautics and Space Administration Task Load Index (NASA-TLX). Video recordings were analyzed for participant PC and overall clinical performance. In addition to interacting with the EHR, multiple participants also conducted internet searches. The proportion of time that participants spent interacting with the computer, either using the EHR or searching the internet, was calculated. Inductive qualitative coding of a subset of video recordings (18 of 32 encounters) was performed, with a focus on signs of stress/CL. All videos were assessed for usability problems.

Results: Staff physicians (n=6) scored higher on PC compared to resident physicians (n=10) for both cases, though differences were not statistically significant after correction for multiple comparisons (family-wise error rate). Physicians' overall CL, as measured by the raw NASA-TLX, was not significantly correlated with computer use. Exploratory qualitative data analysis found both verbal and nonverbal signs of stress/CL due to computer use while interacting with the SPs. The proportion of time displaying nonverbal signs of stress/CL was calculated for a subset of participants (6 resident physicians and 3 staff physicians). Participant interpretations of instructions to completely document the encounter using the EHR varied widely. It is likely that participants' usual style of documenting, either primarily during or after patient encounters, impacted their use of the EHR while SPs were present.

Conclusions: Use of the computer during video telemedicine appointments may negatively impact physician PC and overall clinical performance. Exploratory qualitative coding identified both verbal and nonverbal signs of stress/CL when participants interacted with the computer and the patient simultaneously. Increased clinical experience helped to mitigate the negative impact of computer use. If the use of the EHR is included in physician certification examinations, clear instructions regarding which tasks must be completed in the EHR during interactions with SPs should be provided.

Introduction

Background

Electronic health records (EHRs) have become ubiquitous in both hospital and office environments. Primary care physicians, on average, spend more time interacting with the EHR than on direct patient care [1-3]. In 2024, 95% of Canadian physicians used an EHR to document patient encounters [4]. In most countries, the term EHR is now used to refer to both office-based and hospital-based record systems, which create electronic versions of traditional paper charts.

Interaction with the EHR may impact physician-patient communication, physician clinical reasoning, and patient satisfaction [5-7]. Patient-centered communication may decrease, and pauses in conversation may increase when physicians spend more time looking at a computer screen [6]. Despite this well-known impact of the EHR on patient care, training on the effective use of the EHR has not been added to medical school curricula in Canada [8,9]. The 2025 Canadian Medical Student Digital Health Survey had an 8.3% (1103/13,217) response rate [10]. This survey found that 57% (630/1103) of responding medical students did not receive formal digital health training in medical schools [10]. Confidence in performing tasks related to the EHR ranged from 8% (92/1103) for using an eReferral system to a high of 31% (339/1103) for documenting an encounter [10]. The largest barrier to learning about digital health, cited by 65% (713/1103) of medical students, was a lack of formal instruction [10]. Most physicians in Canada learn to use EHRs while charting patient encounters during clinical placements in medical school and residency.

The documentation burden related to EHRs has added to physicians' workloads and is contributing to physicians' burnout in Canada [11,12]. The increase in telemedicine during the COVID-19 pandemic has resulted in an increase in the time spent by ambulatory care physicians working in the EHR [13]. Charting contemporaneously during patient visits can decrease the time physicians need to spend working in the EHR after clinic hours. Prompt documentation can also improve the accuracy of medical records. However, the negative impacts on patients due to physicians' distraction while interacting with the EHR during patient appointments must be avoided when possible.

Goals of This Study and Hypotheses

This study sought to examine patient-centeredness (PC) during 2 standardized clinical simulations typical of new patient family medicine visits. We hypothesized that experienced family physicians with more years spent refining communication skills would be more patient-centered compared to resident physicians. Another premise was that interaction with the EHR while the standardized patient (SP) was present would impact resident physicians more than staff physicians, who were assumed to be more confident in the use of the EHR and more aware of how to remain patient-centered during patient visits involving the use of the EHR. A simulation case containing historical medical information in the EHR and thus requiring participants to navigate the EHR to find this information was hypothesized to create a higher cognitive load (CL) for participants compared to a simulation case without any medical history.

This project was originally planned for in-person interactions between physicians and SPs to assess clinical reasoning and the impact of a newly implemented EHR. Due to the COVID-19 pandemic, the format was changed to a virtual environment, with physicians interviewing SPs over Zoom. The focus became restricted to PC, a component of clinical reasoning, and overall clinical performance scores as assessed by physicians trained in certification examination scoring.

Virtual encounters increased during the COVID-19 pandemic, and this shift in appointment format has persisted in Canada to a lesser extent in the following years [14]. Assessing the impacts of EHR use during virtual encounters is thus an important area of study. In a survey of patients' feelings about video telemedicine visits, some patients expressed concerns that their physicians paid less attention to them and that it was difficult to find opportunities to speak up during video telemedicine visits [15]. Therefore, this study's pivot to a video telemedicine format provided an opportunity to study the impact of a virtual format on physician-patient communication.

Prior Work

Patient-Centered Clinical Method

The patient-centered clinical method was developed in the 1980s as a conceptual framework and was subsequently revised several times [16]. It is based on a 4-component framework: (1) exploring the patient's illness experience, (2) trying to understand the whole person, (3) finding common ground, and (4) improving the patient-physician relationship [16,17]. The Patient Perception of Patient-Centeredness (PPPC) questionnaire was developed in the 1980s and has been used as a survey tool for patients in family practice populations and with SPs [16]. The PPPC was revised in 2019, with the new version termed the revised PPPC (PPPC-R). This version contains 18 items, with possible responses to each item ranging from 1 (*completely*) to 4 (*not at all*). Given this reverse anchoring in the PPPC-R, a lower score indicates a higher PC rating.

The College of Family Physicians of Canada (CFPC) developed an instrument to measure resident physicians' PC and overall clinical performance for their certification examination. This is termed the simulated office oral (SOO) examination and is scored by experienced family physicians using a standardized rubric [17]. A comparison between the PC score from the SOO and the PPPC-R measure of PC has not been explicitly described in past studies. We note that a higher score indicates better performance in terms of PC on the SOO, whereas a lower score indicates better performance on the PPPC-R. The National Library of Medicine Medical Subject Headings, a controlled vocabulary thesaurus for PubMed, uses the spelling *patient-centered* [18]. Therefore, the spelling *patient-centered* will be used throughout this paper.

Cognitive Load

In addition to investigating the impact of the EHR on physician communication, this study also sought to measure the cognitive impact of the EHR on physician participants. Psychometric

XSL•FO
RenderX

instruments measure self-perceived CL. The National Aeronautics and Space Administration Task Load Index (NASA-TLX) was the most frequently used psychometric measure of CL found in a literature review of CL measurement related to EHRs [19]. Therefore, this tool was chosen to measure the cognitive impact of the EHR on physicians.

The NASA-TLX contains 6 domains of task load: mental demand, temporal demand, physical demand, frustration, performance, and effort [20]. The traditional method of scoring the NASA-TLX asks participants to rate each domain on a scale from 0 to 100 and then compare pairs of domains to weight them in importance [21,22]. The weighting, combined with the Likert scale scoring of each domain, is used to obtain an overall score for each participant. The traditional method of scoring the NASA-TLX has fallen out of favor in recent years, as it can be time-consuming to collect the required data from participants, and the calculation of overall workload is more complicated [23,24].

The simplified raw NASA-TLX scoring method uses the unweighted mean of the subscale scores, which minimizes the time required for participants to complete the questionnaire [25,26]. Raw NASA-TLX scores have been used in studies of clinicians' workload [27,28]. Currently, there is no consistent method for scoring the NASA-TLX in studies of health care provider workload. Both the traditional and raw methods for calculating the overall workload from the 6 dimensions of the NASA-TLX can be problematic, and thus, the use of the 6 dimensions separately may be preferred [23].

Verbal and Nonverbal Signs of Stress/CL

Prior studies have found both verbal and nonverbal indicators of stress/CL during human-computer interaction. Multiple studies have noted spontaneous self-touch gestures to be signs of stress, anxiety, or CL, though the neurophysiological mechanism is still not well understood [29]. Other terms for these gestures include self-adaptors, body-focused movements, displacement behaviors, and self-directed behaviors. These behaviors may help regulate negative emotional states and increase focus during cognitively demanding tasks [29-32]. Spontaneous self-touch or self-directed behaviors have been defined as involuntary hand movements involving touching, rubbing, grooming, or scratching one's body, as well as fumbling with adornments, such as clothing or accessories [32,33].

Grunwald et al [30] discovered that spontaneous facial self-touch gestures increased dramatically during a delayed memory task designed to be emotionally and cognitively straining by playing unpleasant sounds. The facial self-touches were found to help with working memory maintenance and emotional regulation. Spille et al [34] found that spontaneous facial self-touches were associated with neurophysiological changes related to the regulation of attention and emotion. Spontaneous self-touch of the face increased in frequency when participants' attention was distracted by unpleasant sounds during a delayed memory task.

Previous linguistics research has reported that when a speaker is performing a task under stressful conditions, such as high cognitive workload or psychological tension, speech features may change. These changes include observable and measurable speech features, which as a group are termed disfluencies; they include stuttering, repeating words, pauses between utterances, fillers, and repairs [35,36]. Fillers, also known as filled pauses, include vocalizations such as *uh*, *uhm*, and *mh*, as well as words such as *well*, *you know*, and *yeah* [36-38]. Repairs occur when the person speaking stops what they were saying and restarts their sentence. Speech hesitations, which include silences and fillers, have been found to increase in frequency due to high CL and stress [38,39]. A recently published scoping review reported that an increase in speech disfluencies under dual-task conditions that imposed high CL was identified in 5 out of 6 studies that met inclusion criteria [40].

Objectives

This exploratory study aimed to determine if the use of the EHR during SP encounters had an impact on physicians' PC and clinical performance and whether the impact varied between residents and staff physicians. Physician examiner–assigned PC scores were compared to PPPC-R questionnaire scores to assess if there was a difference between physician and patient perceptions of participant PC. Physicians' CL was measured using the raw NASA-TLX to determine if use of the EHR and internet searches while interacting with SPs impacted physician self-perceived CL. Inductive qualitative analysis was also carried out to assess usability problems and signs of stress/CL. Possible correlations between computer use and physicians' CL, PC, and overall clinical performance scores were investigated.

Methods

Ethical Considerations

The ethical approval for this study was granted by the Ottawa Health Science Network Research Ethics Board (OHSN-REB number 20190160 - 01H), which complies with the requirements of the Tri-Council Policy Statement: Ethical Conduct for Research Involving Humans (TCPS2) [41]. All participants were given a participant informed consent form to review prior to deciding whether to participate. Identifying information of participants was kept confidential by the research team. Research data files were stored in a secure SharePoint (Microsoft) site managed by The Ottawa Hospital, which only members of the research team could access. Login required 2-factor authentication. Participants were assigned ID numbers. Participant scores on each simulated case were only recorded with participant ID numbers, not with participant names. SPs and simulated clinical scenarios were used to alleviate privacy concerns. Participants were compensated for their time with a CAD $100 gift card.

Recruitment

We aimed to recruit 15 first-year residents from the Family Medicine program at the University of Ottawa and 15 experienced academic family physicians with more than 5 years of practice, based at 2 campuses. This represented a convenience sample of first-year residents and staff physicians in the Family Medicine department using the same EHR, which was implemented in June 2019. The participants were invited by email to participate in this study. First-year residents were

XSL•FO
RenderX

selected as they would have the least experience with EHRs and PC. Due to an insufficient number of first-year resident volunteers, we also invited early second-year residents to enhance our participant pool. We believed that early second-year residents would also perform differently from the experienced physicians, as they have had fewer years of practice with patient-centered communication while using the EHR. Recruitment was a challenge, given the timing of the study soon after the onset of the COVID-19 pandemic. The stress of working in the pandemic environment, combined with the academic and teaching demands of the residents and staff physicians, limited the number of residents who agreed to participate to 10 and staff physicians to 6. Participants filled out a demographic questionnaire, which included information on age group, gender, decade of graduation from medical school, and number of years in practice.

Study Design

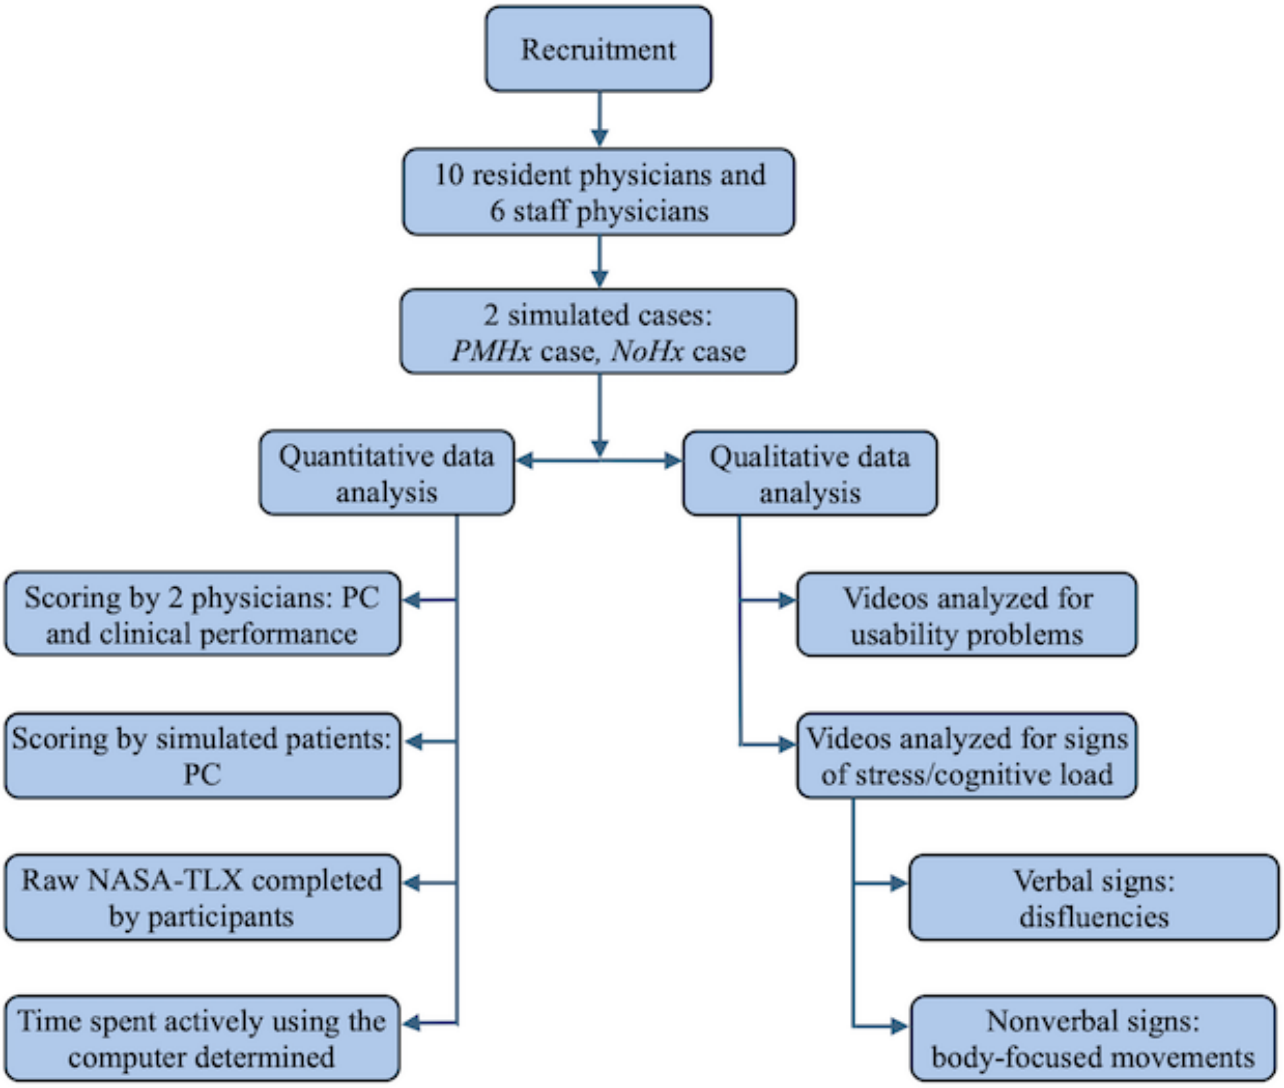
SPs, played by actors, were used in simulated clinical scenarios to negate the variability of actual patient encounters and alleviate privacy concerns. Two actors were trained by experienced physician examiners with support from the Ottawa Exam Center prior to the COVID-19 pandemic. There was no opportunity to retrain them or readily monitor their performance once this study had to pivot to a virtual format. Two clinical simulations drawn from the CFPC certification examination in family medicine were adapted for use in this study. The CFPC SOO exams do not include the use of the EHR. Therefore, the cases were slightly modified to include documentation in the EHR. Past medical history in the EHR was included for 1 SP case (abbreviated as *PMHx* case), including a consultation note from a visit to an emergency department, a computed tomography scan report, and an X-ray report. The other case, referred to as the *NoHx* case, did not include any past medical information in the EHR.

The encounters were designed to simulate routine new patient family medicine visits. Participants were provided with the following instructions on EHR use: "You will be expected to completely document the encounter, using our electronic health record. You will have about 20 minutes to interact with the patient and an additional 5 minutes to complete your documentation of the encounter." Participants were also advised that documentation would occur in the EHR training environment, where EHR customizations, templates, and smart phrases were not available. The full instructions given to participants are detailed in Multimedia Appendix 1. Time limits were extended by 5 minutes from the standard 15-minute SOO exam format to 20 minutes with the SP, plus an additional 5 minutes allotted for documentation after the encounter. Figure 1 summarizes the quantitative and qualitative assessment methods used in this study.

Encounters were completed virtually between 2021 and 2022 to accommodate physical distancing requirements and the continuing challenges of a post-COVID-19 clinical environment. The video telemedicine simulated encounters were recorded using Zoom. Ten resident physicians and 6 staff physicians from an academic, university-affiliated family practice clinic each completed 2 sequential SP scenarios (both the *PMHx* case and the *NoHx* case) during one session, with a research assistant monitoring the Zoom encounters remotely.

After each scenario, participants completed the raw NASA-TLX questionnaire. The raw NASA-TLX score was used during data analysis, as well as separate scores on single dimensions of the NASA-TLX that were determined by group consensus to be the most relevant (mental demand, time pressure, and frustration). The SPs answered a survey regarding their perception of the participants' PC, using the PPPC-R questionnaire.

Physicians' PC and overall clinical performance were rated based on the scoring standards of the CFPC SOO exam. Two family physicians experienced in scoring these exams evaluated each participant's PC and overall clinical performance.



Transcripts of the audio generated by Zoom were manually corrected when speaker identification or words spoken were captured incorrectly. Transcripts and timestamps from the Zoom video recordings were analyzed to calculate the time spent actively using the EHR, as well as the time spent conducting internet searches. Active EHR time was counted until there were no keystrokes or mouse activity for the following 5 seconds. This method was used by the EHR vendor to determine active EHR use time and was selected for this study to make the count as objective as possible [1].

Video recordings were analyzed to determine the number of EHR pages, also known as screens, that participants clicked on during their interactions with the SPs. The EHR navigation count was calculated as the number of times participants switched between different pages of the EHR during the time they were interacting with the SPs. Participants were given 5 minutes after the SPs logged off to complete tasks in the EHR. Any tasks completed using the EHR after the SPs logged off were not included in the analysis, as they were not relevant to interactions with the SPs.

Exploratory qualitative analysis by a single coder was based on a video-coding framework developed for investigating cognition and usability in health care informatics [42]. Coding was discussed during group meetings and refined based on an inductive approach. A codebook was developed, and transcripts were coded and analyzed using NVivo software version 14 (Lumivero). The initial focus was on usability codes. As the analysis of the video recordings continued, signs of stress/CL became evident through both verbal and nonverbal behaviors, and thus, new codes were developed. The analysis of video recordings included the calculation of the proportion of time displaying spontaneous self-touch/self-directed behavior for a subset of 6 resident physicians and 3 staff physicians, for a total of 18 encounters. This was a very time-consuming task, and thus, it was impractical to code all 32 encounters for nonverbal signs of stress/CL. Spontaneous self-touch/self-directed behavior frequency was calculated as a proportion of total time while the SPs were present [32].

Results

Principal Results

Sixteen participants each completed the 2 SP simulation cases and the raw NASA-TLX questionnaire after finishing each encounter. Table 1 details participant demographics.

Data were graphically summarized using box plots created in RStudio (version 2025.09.2+418; Posit Software, PBC), which display the 25th, 50th, and 75th percentiles and outliers. Medians and IQR values of variables by the physicians' experience level and simulation case are detailed in Table 2.

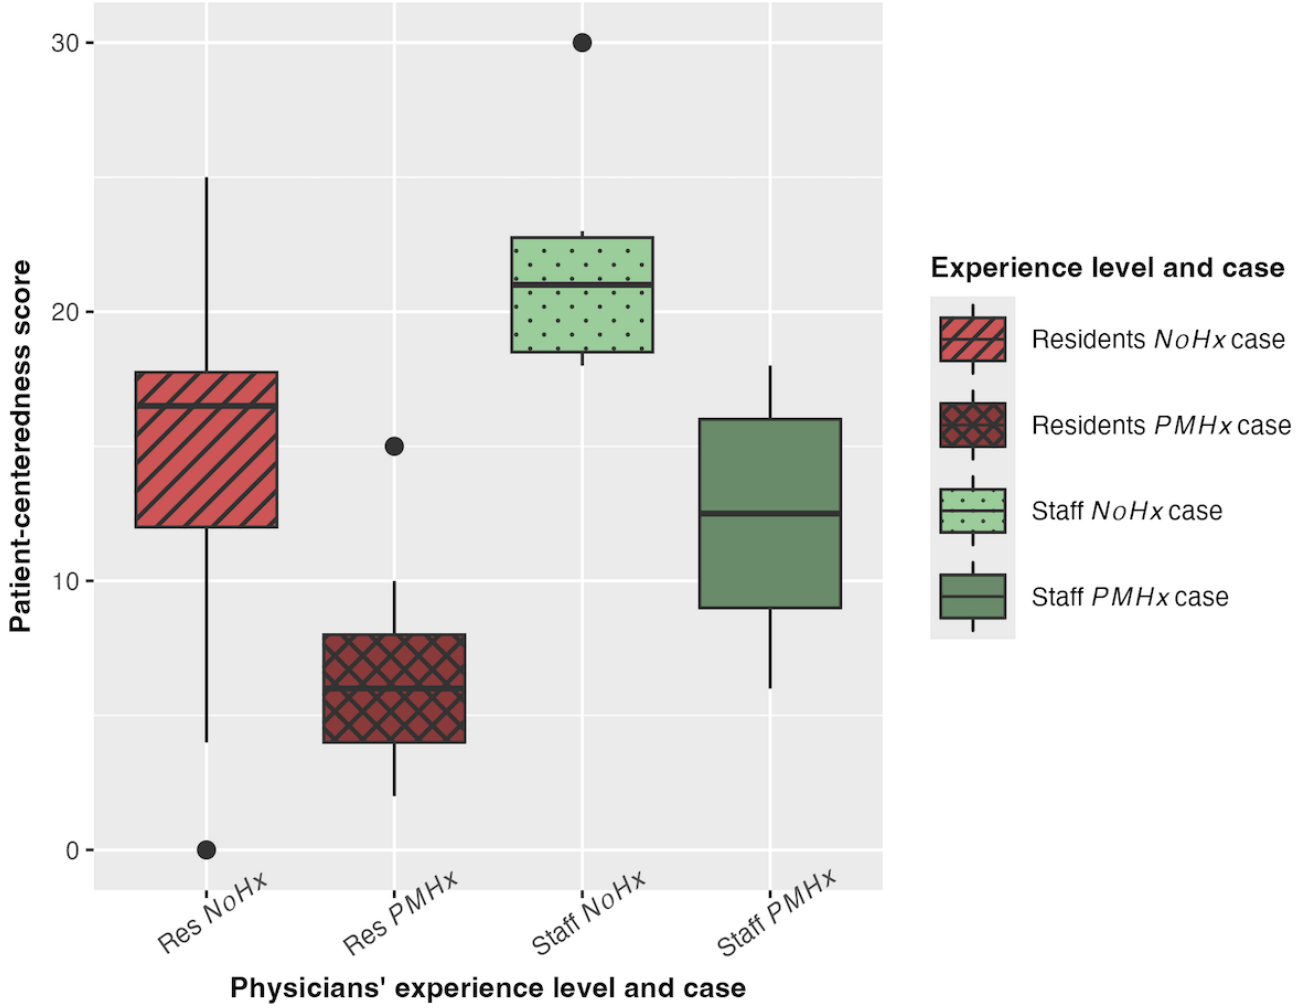
[d]PPPC-R: Revised Patient Perception of Patient-Centeredness (PPPC) questionnaire. On the PPPC-R scale, a lower score indicates better performance due to reverse anchoring.

[e]NASA-TLX: National Aeronautics and Space Administration Task Load Index.

Due to small and unequal group sizes and uncertainty regarding the normality of the data, nonparametric statistical tests conducted in RStudio were used for data analysis [43,44]. The predetermined α level was .05. Due to multiple comparisons between groups, the Holm-Bonferroni correction test was applied to reduce the likelihood of false-positive findings (ie, to control for the family-wise error rate). The Wilcoxon-Mann-Whitney rank sum test was used to compare resident physicians to staff physicians on the outcome variables of computer use, PC scores, SOO total scores, and NASA-TLX scores. Complete Wilcoxon Mann-Whitney rank sum test results and thresholds as per the Holm-Bonferroni correction test are provided in Tables S1 and S2 in Multimedia Appendix 2. Not surprisingly, given the small sample size, none of the observed trends achieved statistical significance.

As hypothesized, staff physicians received higher PC scores (as rated by physician examiners) compared to resident physicians, though differences between groups were not statistically significant after correction for the family-wise error rate. Figure 2 displays the median PC score for each group of physicians by the experience level and the simulation case, as well as the first quartile (25th percentile), third quartile (75th percentile), and outliers shown as points outside the box plots.



SP ratings of participants' PC using the PPPC-R questionnaire also found that staff physicians scored better than resident

XSL•FO
RenderX

physicians for both the *PMHx* case and the *NoHx* case. Due to reverse anchoring, lower scores on the PPPC-R scale indicate better performance, as detailed in Table 2.

The use of the EHR and internet searches during SP appointments varied widely. The majority of EHR usage time was spent in the "Progress Notes" section. During appointments with SPs, EHR page counts varied from 0 to 11, while EHR navigation counts varied from 0 to 123. Participants clicked on only the "Progress Notes" section of the EHR in 11 of 32 encounters. Ten out of 16 participants attempted to view past medical history reports for the *PMHx* case. Some resident physicians had difficulty finding imaging order forms, as well as locating past imaging reports scanned into the EHR, which led to an increase in navigation count for these residents. Staff physicians were familiar with the location of scanned documents in the EHR and did not encounter this difficulty. Resident physicians conducted more internet searches during appointments with SPs than staff physicians. Four residents searched the internet during 6 encounters (2 during both encounters they completed) versus 1 staff physician during 1 encounter.

Figure 2. Patient-centeredness score by the physicians' experience level and case. EHR: electronic health record; *NoHx* case: simulation case that did not include any past medical history in the EHR; *PMHx* case: simulation case that included some past medical history in the EHR; Res: resident physicians; Staff: staff physicians.

Most participants did not attempt to order investigations or complete referrals during SP appointments. Participants who completed more EHR tasks while the SPs were present had lower performance scores, though this finding was not statistically significant after correction for the family-wise error rate. Participants who attempted to input orders or complete EHR *Wrap Up* tasks (such as booking follow-up appointments), while the SPs were present, received the lowest PC scores in their experience-level groups (residents or staff physicians). Some participants did not hear time prompts over Zoom, resulting in appointment times ranging from 10.35 to 33.71 minutes. Due to this issue, active time spent using the computer was calculated as a proportion of overall appointment time.

The proportion of time spent interacting with the EHR varied by SP case, as was anticipated due to the inclusion of historical medical information in the EHR for only the *PMHx* case. Time spent using the computer was not significantly different between resident physicians and staff physicians for either SP case, though both groups spent more time interacting with the EHR during the *PMHx* case, which contained historical medical information in the EHR.

Correlations between computer use and other variables were assessed using the nonparametric test Kendall τ_b in RStudio [45,46]. With the Holm-Bonferroni correction method applied to control for the family-wise type 1 error rate, the results were

XSL•FO
RenderX

not statistically significant. The complete results of Kendall τ_b tests of correlation and thresholds, as per the Holm-Bonferroni method, are provided in Tables S3-S6 in Multimedia Appendix 2.

Qualitative Results

The exploratory qualitative analysis of video recordings found an increase in signs of stress/CL when participants were using the computer while the SPs were present. Verbal signs of stress/CL included the use of filler words, repetition of words, restarting sentences, stuttering, nonlexical conversational sounds, and pauses lasting longer than 5 seconds during conversations with SPs. Nonlexical conversational sounds include verbalizations, such as "mm-hm" and "uh-uh" [47]. Filler words include words such as "okay, sure, yeah, like, all right, so, and perfect," which were repeated by participants when they were multitasking by speaking to the SP and using the EHR concurrently. Due to the frequency of verbal signs of stress/CL, it was impractical to calculate counts to compare residents and staff physicians.

Participants sometimes missed information stated by the SPs when they were distracted by interactions with the computer. For example, several resident physicians asked the SP to repeat details regarding symptoms that the patient had already stated while the resident was interacting with the EHR. One resident physician also asked the SP if she was married, even though she had already mentioned her spouse multiple times. Verbal turn-taking was challenging in the video telemedicine setting. Accidental interruptions seemed to occur more often compared to in-person conversations. This problem has been noted in studies examining video telemedicine interactions, as there are short periods of latency in video-mediated interactions that can disrupt conversational turn-taking [48].

The proportion of time spent displaying nonverbal signs of stress/CL was calculated for a subset of participants (2 encounters each for 6 residents and 3 staff physicians, for a total of 18 encounters). The nonverbal signs of stress included self-directed touch of the face, head, neck, or hands, as well as adjustments to adornments, such as glasses. During the PMHx case, the median proportion of time spent displaying nonverbal signs of stress/CL while the SP was present was 0.16 (0.05-0.24) among resident physicians compared with 0.06 (0.04-0.10) among staff physicians. During the NoHx case, the median proportion of time spent displaying nonverbal signs of stress/CL was 0.10 (0.02-0.14) among resident physicians compared with 0.05 (0.04-0.06) among staff physicians.

Sample sizes included in the calculation of the proportion of time spent displaying nonverbal signs of stress/CL (n=6 for resident physicians and n=3 for staff physicians, for a total of 18 encounters) were too small to conduct statistical analysis for possible associations between variables.

Discussion

Principal Results

This study investigated the use of the EHR and internet searches by family practice resident physicians and staff physicians during simulated video telemedicine appointments with SPs. Staff physicians had higher PC and overall clinical performance scores compared to resident physicians, as was hypothesized due to their increased experience in remaining patient-centered while interacting with the EHR during patient appointments. Differences in performance scores based on the physicians' experience level were not statistically significant after correction for the family-wise error rate, possibly due to small sample sizes and resulting low power. The active use of the computer, including both interacting with the EHR and conducting internet searches, had a negative impact on physicians' PC. This finding was evident through the qualitative video analysis, though correlations between the proportion of time spent using the computer while interacting with SPs and physician performance scores did not achieve statistical significance after correction for the family-wise error rate.

There was a wide variation in the tasks participants chose to complete in the EHR while the SPs were present. While this partly reflects a major limitation of this study due to a lack of specificity in the instructions, it is also likely related to the personal documentation styles of the residents and staff physicians who participated in this study. Some physicians prefer to document in the EHR while speaking with patients, while others take notes on paper and complete documentation in the EHR after the encounter has ended. Many physicians adopt an approach somewhere between these 2 strategies, with documentation and ordering tasks in the EHR completed both during and after patient encounters. Therefore, the finding that some participants completed more documentation and other EHR tasks while the SPs were present is unlikely to be solely due to their interpretations of the instructions.

If a similar study is conducted in the future, clearer instructions for participants are recommended, including whether participants should order relevant investigations and referrals in the EHR. Participants who interpret the instructions as requiring them to order laboratory investigations, imaging, and referrals while the SP is present are disadvantaged in terms of their overall clinical performance and PC scores. Screen-recording software could be used to capture keyboard and mouse activity, thus simplifying the calculation of time spent actively using the EHR or searching the internet. Improved SP training and feedback are recommended to achieve consistency in acting and the provision of medical details when questioned by participants. The selection of case scenarios where interpretation of body language is key should be avoided, as this can be missed over Zoom.

Comparison With Prior Work

This study's findings align with those of Street et al [6], who concluded that medical school curricula should be modified to include EHR management skills. When physicians focus too much on the EHR, this can decrease patient-centered communication and cause long conversational pauses. Physicians in training should be taught to maintain conversational flow with patients while interacting with the EHR [7].

Currently, there is a lack of formal teaching for medical learners on effective communication during video telemedicine

XSL•FO
RenderX

consultations [10]. Given the increase in telemedicine that occurred during the COVID-19 pandemic and has persisted to some extent in Canada, consideration should be given to teaching medical students and resident physicians interpersonal skills specific to telemedicine. Important skills for video telemedicine visits include explaining the process to patients, using clear language, maintaining active listening, and directing eye contact toward the camera [49]. Tone of voice and nonverbal communication are also important; physicians should face the camera and minimize gaze directed at the keyboard. When entering notes into the EHR, narrating the purpose of doing so to the patient can be helpful [50]. Lighting and positioning of the video telemedicine platform within the computer screen should be considered to ensure that both the physician's and patient's faces are clearly visible [50]. Distracting background noise should be kept to a minimum, and patients should be made aware if anyone else is present in the room with the physician. Family practice SOO certification examinations in Canada do not currently require the use of the EHR. If the use of the EHR is incorporated into the CFPC SOO certification exams in the future, resident physicians may benefit from formal teaching on using the EHR effectively during patient appointments.

A recent study of EHR time allocation among primary care clinicians found that EHR time during patient visits varied widely between physicians, ranging from a low of 20% to over 50% [51]. For video visits, the average proportion of time spent on EHR work during the visit was 39% (95% CI 31-47%) [51]. This result is similar to the findings from this study. The median proportion of visit time spent interacting with the computer was 30% (IQR 14%-36%) for residents for the NoHx case, 30% (IQR 26%-34%) for staff physicians for the NoHx case, 38% (IQR 32%-50%) for staff physicians for the PMHx case, and 42% (IQR 32%-47%) for resident physicians for the PMHx case.

Limitations

A major limitation of this study was that participants interpreted the instructions differently in terms of which EHR tasks were required. Some participants attempted to order laboratory tests and imaging and to arrange for referrals and follow-up appointments, while others only clicked on the "Progress Notes" section of the EHR. Although this is in part due to the exact wording of the instructions, it also reflects variation in day-to-day practice patterns regarding whether to document in the EHR while the patient is present or after the medical encounter has concluded. All participants knew that they would have an additional 5 minutes after the patient left to document in the EHR; however, many chose to document while the SP was present. One staff physician took notes using pen and paper and did not use the computer at all until after the medical encounters with each SP had ended. It is likely that each participant followed their usual practice for how much to interact with the EHR during a telemedicine appointment, versus leaving documentation until after the encounter with the patient was over. Therefore, the variability in the EHR interaction during telemedicine encounters observed in this exploratory study is a valuable finding, despite the possible variation in interpretation of instructions.

Exploratory qualitative coding of the video recordings was conducted by only one person. While this is a major limitation in terms of the qualitative findings, the coding of participants' verbal and nonverbal behaviors was extremely time-consuming. It was not feasible to have 2 team members devote this much time to qualitative coding, given the other components of this study that required 2 scorers. While not all encounter videos were coded for verbal and nonverbal signs of stress/CL, the coding was informed by detailed viewing of all 32 videos. As discussed in the *Methods* section, the qualitative coder watched all 32 encounter videos multiple times to accurately calculate the time spent interacting with the computer, as well as EHR page/navigation counts. The signs of stress/CL were noted in all encounters to varying extents.

Technical challenges included errors in Zoom-generated transcripts due to nonlexical conversational sounds, filler words, and the inability of Zoom to determine the speaker when the physician and SP spoke at the same time. Transcripts had to be manually corrected to ensure that the correct speaker and dialogue were recorded. Some participants did not hear time prompts over Zoom, resulting in variable appointment lengths. To address this issue, active time spent using the EHR was calculated as a proportion of overall appointment time. One of the SPs displayed inconsistent acting, which affected the participants' ability to elicit the medical history and interpret nonverbal cues of the symptoms being portrayed.

Physician examiners who rated the participants for PC and overall clinical performance had prior interactions with some participants while working at the same clinic as them. This could potentially have influenced their ratings of the participants because they could not be blinded to the participants' identities. Participants volunteered to participate in the study; thus, selection bias could have influenced the results.

Conclusions

In this small exploratory mixed methods study, interaction with the EHR or internet searches conducted during video telemedicine appointments negatively impacted patient-centered communication and overall clinical performance. The exploratory inductive qualitative coding of the video recordings identified possible verbal and nonverbal markers of increased stress/CL due to multitasking by interacting with the computer and the SP simultaneously. Future research on the potential for automated analysis of these verbal and nonverbal markers as indicators of stress or increased CL may be useful.

A digital communication curriculum for telemedicine appointments may be beneficial to medical education. Physicians may benefit from training on remaining patient-centered and communicating effectively while using the EHR during virtual appointments. Video telemedicine communication best practices include directing eye gaze at the camera, being mindful of the length of pauses after physician statements, using clear language, and practicing active listening. Effective communication practices during telemedicine appointments can facilitate contemporaneous charting while minimizing the potential negative impacts on patients caused by physicians' distraction from the computer. When developing SP simulation scenarios for assessing medical students and resident physicians where

XSL•FO
RenderX

the use of the EHR is expected, clear instructions should be provided on which tasks involving the EHR are required.

Acknowledgments

The authors would like to thank Dr Laura Santos for her work integrating the standardized patient data into the electronic health record and for promoting participation in this study among her peers. The authors would also like to thank Dr Tim Ramsay from the University of Ottawa Methods Centre for reviewing the manuscript and providing advice on statistical test results.

Funding

This project was supported by a Program for Research and Innovation in Primary Care and Medical Education (PRIME) Grant from the University of Ottawa.

Abstract

Background: Data quality is the degree to which data are fit for their intended purpose and is described using quality dimensions. The increased use of medical data in clinical research and medical artificial intelligence development has rendered data quality assessment essential. Despite existing data quality definitions, frameworks, and tools, data quality assessment in real-world settings faces multiple challenges. This stems from a lack of understanding of how to assess real-world data quality and interpret the results. Therefore, practical approaches to data quality assessment are needed that are appropriate for diverse data environments, intended uses, quality dimensions, and requirements.

Objective: This study proposes a practical approach for assessing the completeness of electronic health records (EHRs) for medical research. This approach integrates structural completeness, rule-based assessment, and descriptive analyses of completeness and data diversity to clarify how data quality can be measured and meaningfully interpreted in practice.

Methods: The completeness of a large-scale EHR dataset from Gachon University Gil Medical Center was evaluated covering January 2005 to December 2023. Completeness was assessed using a three-part approach comprising (1) structural completeness assessment, (2) rule-based assessment, and (3) descriptive analyses of completeness and data diversity. Assessments were conducted using clinical data quality assessment tools. This practical approach was used to assess EHR completeness for medical research from 1,798,153 patient records.

Results: In the structural assessment, 12.8% (5/39) of the data tables were unavailable, indicating limited capturing of clinician free-text data. The rule-based assessment identified substantial missingness in vocabulary fields (38/124, 30.6%) and missing or special characteristic values in relation to observations (3,643,581/15,313,287, 23.8%), measurements (25,583,622/642,623,715, 4%), care sites (28/1715, 1.6%), and deaths (117/34,330, 0.3%). Descriptive analyses demonstrated a balanced gender distribution (886,489/1,798,153, 49.3% male and 911,664/1,798,153, 50.7% female) and a predominantly Korean racial distribution (1,739,628/1,798,153, 96.7%). Collectively, these findings illustrate the completeness quality of a multiperspective completeness assessment for medical research.

Conclusions: This study demonstrates how data quality dimensions can be measured in practice through a real-world completeness assessment. This practical approach enables evaluation of EHR completeness and provides insights into data quality. Its findings have implications for researchers conducting data quality assessments and applying quality dimensions in medical research.

KEYWORDS

data quality; quality assessment; completeness; diversity; electronic health record; artificial intelligence; AI

Introduction

In the era of big data and artificial intelligence (AI), data are widely recognized as a valuable asset that enables knowledge discovery and value creation [1]. Researchers are increasingly leveraging data-driven insights, the reliability of which depends on data quality, to support decision-making [2,3]. Therefore, high data quality is essential for generating valuable and trustworthy evidence.

Data quality is defined as the degree to which data meet the requirements of their intended use and purpose [4]. It is commonly assessed in terms of quality dimensions, which reflect data characteristics [5,6]. Data quality dimensions describe and quantify how well the data satisfy their set purpose [7].

XSL•FO
RenderX

For example, medical data include information generated throughout the process of medical services, such as diagnoses, examinations, treatments, and surgical procedures [8]. These data are used for health care claims and clinical decision-making to develop patients' diagnostic and treatment plans [9]. When such uses do not align with the original purpose of data collection, medical data are increasingly reused for broader purposes, including for medical research and AI development [10,11]. Thus, data quality assessment, which evaluates data structures and conditions, is a foundational step for determining whether data are appropriate for their intended use [12].

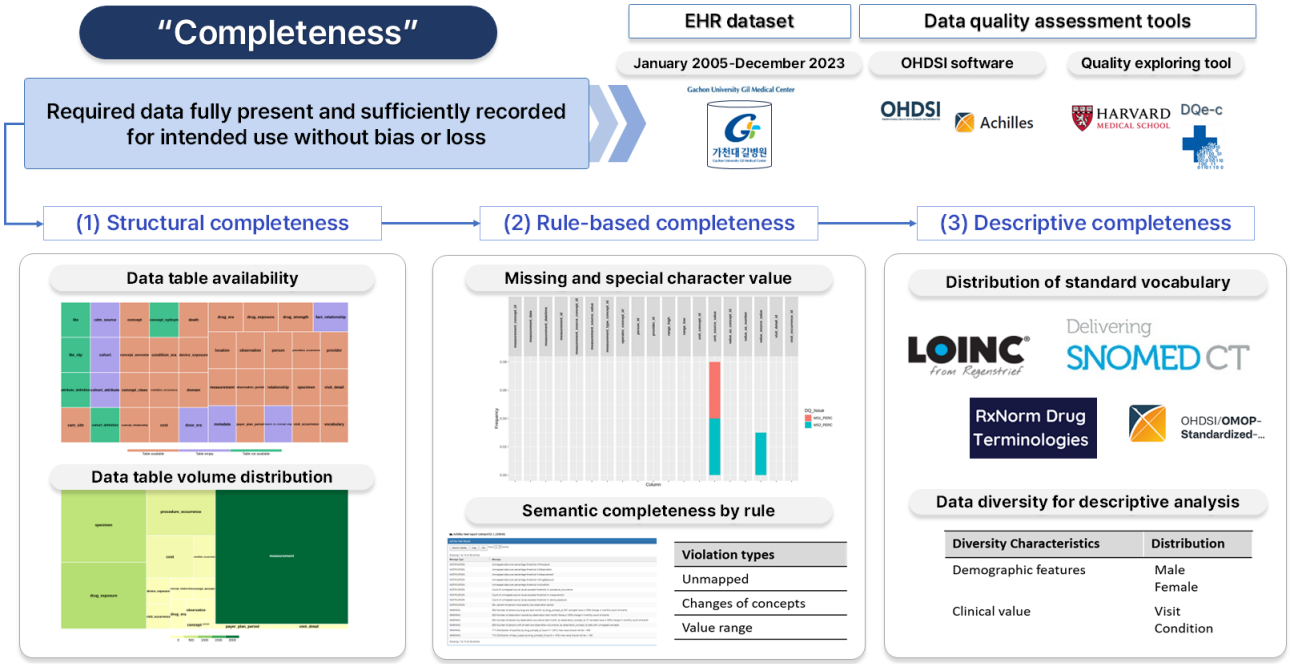
Various data quality dimensions and assessment frameworks have been proposed to support systematic quality evaluation [5]. In 2016, Kahn et al [13] proposed the harmonized data quality assessment framework to support the standardized use of medical data, which established a shared understanding of the data quality of electronic health records (EHRs) by introducing dimensions and terminology, including completeness (missingness and absence of data), conformance (whether data adhere to predefined formats), and plausibility (credibility or truthfulness of data values).

In 2017, Weiskopf et al [14] proposed a dynamic 3 × 3 framework that operationalizes quality dimensions (complete, correct, and current) across patient, variable, and time perspectives, highlighting the context-dependent nature of data quality and its variability depending on what is measured and when it is measured. Recently, Schwabe et al [15] introduced METRIC, a framework designed for medical AI development and model training, proposing quality characteristics such as measurement process, timeliness, consistency, informativeness, and representativeness.

Additionally, the International Organization for Standardization and International Electrotechnical Commission defined principles for managing data quality across the data life cycle [16,17]. Specifically, the ISO 8000 standard outlines the approach for measuring and managing data quality, and the ISO/IEC 5259 standard provides a data quality framework intended to support data analytics and machine learning [18-20]. Other proposed approaches such as ontology-based definitions of quality dimensions reflect the breadth and diversity of data quality frameworks in the field [21-23].

Despite the definition of quality dimensions and frameworks, standardized and practically implementable methods for evaluating data quality remain limited [24-26]. This indicates an insufficient understanding of how to assess data quality through dimensions and a lack of practical guidance on how to understand data quality in real-world datasets [27,28].

To fill this gap in the literature, this study focused on "completeness," a fundamental quality dimension that reflects whether required data are fully present and sufficiently captured for a use purpose without bias or loss. Additionally, we evaluated EHR data completeness in a real-world health care setting and derived results using a practical, multi-perspective approach. This study aimed to deepen understanding of how to measure and assess data quality dimensions in practice and provides evidence and guidance that can inform quality management strategies aligned with specific data environments and research objectives.



Methods

Overview

This study used a large-scale EHR from a tertiary university hospital to evaluate data completeness and demonstrate its practical measurement using data quality assessment tools [29]. Figure 1 summarizes the completeness assessment workflow, the study dataset, and the tools used.

XSL•FO
RenderX

Figure 1. Overview of the completeness assessment workflow applied to the Gachon University Gil Medical Center electronic health record (EHR) dataset from January 2005 to December 2023. Completeness was evaluated using clinical data quality assessment tools. The workflow comprises three complementary components: (1) structural completeness assessment based on table availability and volume, (2) rule-based completeness assessment using SQL validation rules, and (3) descriptive analyses of data distributions to assess both completeness and data diversity. OHDSI: Observational Health Data Sciences and Informatics.

Practical Completeness Assessment Approach

For the completeness assessment, this study applied a practical three-component approach integrating (1) structural assessment, (2) rule-based assessment, and (3) descriptive analyses of completeness and data diversity. First, it assessed structural completeness by verifying database availability and table characteristics, including whether each table was populated, the table status, row counts, and volume. This component provides an overview of database structure and condition before examining missing values and other data issues [30].

Second, the study conducted a rule-based completeness assessment by predefining quality rules according to the data context and characteristics. The rules were implemented as SQL queries executed directly against the database to identify records with missing, invalid, or incomplete values [31]. Table S1 in Multimedia Appendix 1 provides detailed descriptions of the quality rules.

Third, the study analyzed descriptive distributions to assess data diversity and completeness from a researcher perspective. Specifically, it examined baseline characteristics of key variables to understand the coverage of data classes and categories and identify potential imbalances in the study population and recorded events [32,33]. These component results support the interpretation of completeness assessment findings on intended medical research use.

Overall, this multiple practical assessment approach provides actionable guidance for measuring and assessing data completeness in real-world EHR databases.

Data Quality Assessment Tools

To assess completeness and implement its practical measurement, the study applied established data quality assessment tools to the EHR dataset [34]. It used the Observational Health Data Sciences and Informatics data quality software (ACHILLES) to generate automated database characterization and descriptive statistics for tables and data values [35]. The DQe-c tool was used to examine structural completeness for data availability and distribution for completeness pattern [36-38]. We selected these tools to complement the assessment by enabling evaluation of completeness. Table S2 in Multimedia Appendix 1 provides details regarding tool versions, system specifications, and execution environments.

EHR Dataset

This study used an EHR-derived dataset from Gachon University Gil Medical Center. The dataset spanned January 2005 to December 2023 and included records from 1,798,153 patients. Table S3 in Multimedia Appendix 1 provides detailed descriptions of the included data tables. This large-scale, real-world dataset provides a robust basis for evaluating completeness and related data quality characteristics in an applied medical research setting.

Ethical Considerations

This study used secondary, deidentified data from the Gachon University Gil Medical Center EHR, and thus, informed consent was waived. We also confirmed that all data were anonymized and that no individual could be identified. The study protocol was approved by the institutional review board of Gachon University Gil Medical Center (GFIRB2024-243).

XSL•FO
RenderX

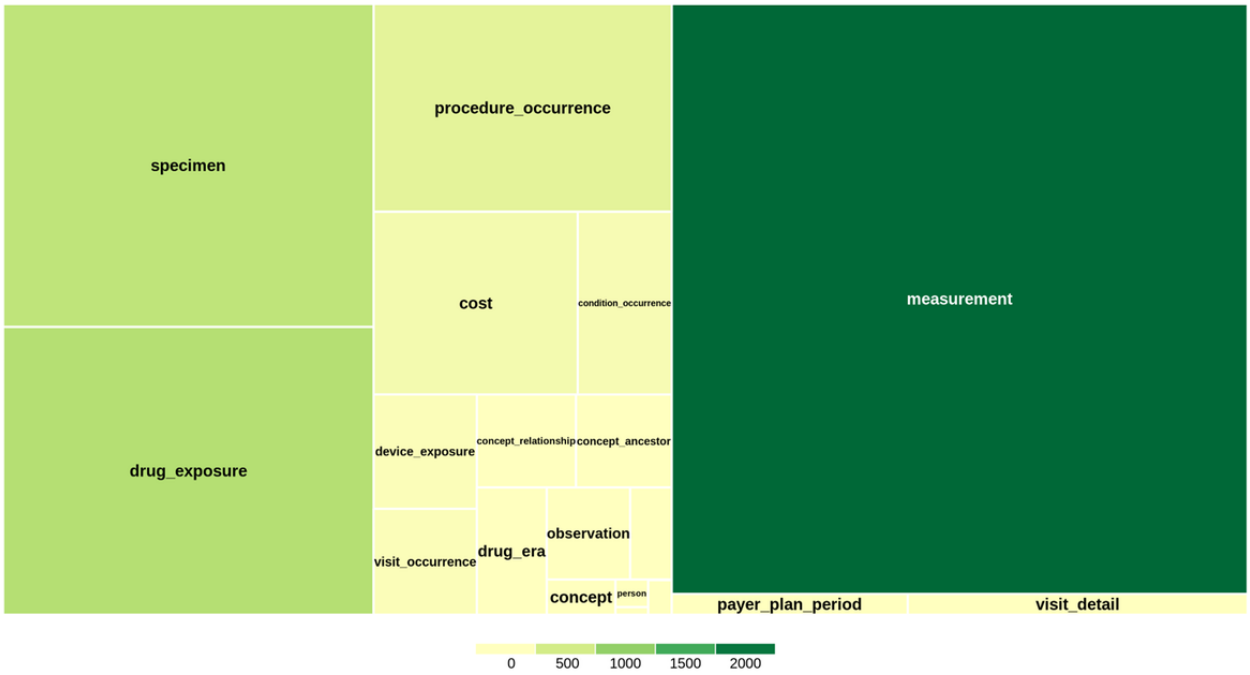
Results

We assessed completeness in the study dataset comprising 1,798,153 patients and approximately 1.67 billion rows of data. Following the practical assessment approach described in the Methods section, results are presented across three components: (1) structural completeness assessment, (2) rule-based completeness assessment, and (3) profiling of completeness and diversity for medical research use.

Structural Completeness Assessment

This section presents the structural availability and overall scale of the study dataset. As illustrated in Figure 2, the dataset contained 39 tables. Of these 39 tables, 7 (17.9%) were empty, and 5 (12.8%; "note," "note_nlp," "attribute_definition," "cohort_definition," and "concept_synonym") were not available. The unavailable "note" and "note_nlp" tables are designed to store unstructured clinical narratives documented by clinicians. The "cohort_definition" and "attribute_definition" tables support the creation and management of study-specific cohorts and their attributes, such as covariates defined through cohort construction algorithms. The "concept_synonym" table stores alternative names and descriptions for concepts. These results indicate the limited availability of free-text documentation and researcher-defined cohort management tables and the unavailability of concept synonym information. Additionally, empty tables such as "metadata" and "dose_era" suggest that certain metadata and derived medication era information were not recorded in the current database. The "metadata" table stores metadata information, and the "dose_era" table represents time spans during which a person is assumed to be exposed to a constant dose of a specific ingredient. The "dose_era" table is typically derived during extract, transform, and load (ETL) from the "drug_exposure" table together with dose information from the "drug_strength" table using standard derivation scripts.

Figure 2. Table availability results from the structural completeness assessment of the database. Table availability was categorized as "available" (orange), "empty" (purple), or "not available" (green). "Not available" indicates that the table was not present in the database and could not be queried. "Empty" indicates that the table existed but contained no records. In this database, 7 tables were empty, and 5 tables were not available, reflecting structural completeness characteristics of the electronic health record database.



In the structural completeness assessment, the "note" and "note_nlp" tables were unavailable because note data were not collected, and the tables were not implemented in the current database. The "metadata" table was present but contained no records, indicating that dataset metadata were not populated. In particular, the "dose_era" table is a derived table generated during ETL. Therefore, an empty "dose_era" table most likely indicates that the derivation scripts were not executed rather than missing source medication exposure data.

Figure 3 profiles the scale of the available tables in the study database by summarizing data table volume. Among the tables, "measurement"—containing laboratory results, pathological findings, and vital sign measurements—accounted for the largest share of the table volume. The dataset comprised 1,677,839,014 records in total, and a detailed table record count is provided in Table S4 in Multimedia Appendix 1. Notably, large volumes were also observed in the "drug_exposure" table, which captures medication exposure information, and the "specimen" table, which records biological sample information.

XSL•FO
RenderX

Figure 3. Data table volume (in GB) distribution across available tables in the database. Each rectangle represents a data table; rectangle area is proportional to the table size, and the color indicates the size volume (in GB). This visualization highlights where data volume was concentrated across tables, supporting structural completeness assessment and scoping of research-relevant data domains.

These distribution patterns indicate that the dataset was particularly rich in measurement-related data, medication exposure records, and specimen information. This scale profiling provides context for planning use by summarizing table coverage and volume.

Rule-Based Completeness Assessment

The rule-based completeness assessment applied predefined validation rules to the study database. Table 1 reports results focusing on value presence and rule-defined invalid entities in the data. Textbox 1 presents outputs for extended completeness, which evaluates whether recorded values are semantically sufficient.

Table . Rule-based completeness assessment results for missing and special character values. The table presents the number and proportion of records flagged based on predefined quality rules for each table-column pair.

Table name	Column name	Records flagged, n/N (%)[a]
Concept_relationship	invalid_reason[b]	55,082,424/55,082,424 (100)
Drug_strength	invalid_reason	2,932,914/2,935,461 (99.9)
Vocabulary	vocabulary_version	38/124 (30.6)
Observation	value_as_string	3,643,581/15,313,287 (23.8)
Measurement	unit_source_value	25,583,622/642,623,715 (4)
Measurement	value_source_value	1,910,233/642,623 (0.3)
Care_site	place_of_service_source_value	28/1715 (1.6)
Care_site	care_site_name	26/1715 (1.5)
Location	state	2/452 (0.4)
Death	cause_source_value	117/34,330 (0.3)
Drug_exposure	dose_unit_source_value	232/166,706,078 (0)

[a]Records in each table-column pair that were flagged based on the predefined rules as having missing (NULL) values or special character entries.

[b]The “invalid_reason” field indicates why a relationship or concept was invalidated and can take values of “D” (deleted), “U” (updated), or “NULL” (default). These high-count values represent valid data rather than incompleteness as this field is “NULL” by default.

XSL•FO
RenderX

Textbox 1. Results of additional rule-based completeness checks. The textbox lists rule outputs related to unmapped concepts, discontinuities in event counts over time, and value range violations in prescription-related rules.

Data with unmapped concepts

- Number of persons by race; data with unmapped concepts
- Number of persons by ethnicity; data with unmapped concepts
- Number of persons in the "death" table by cause_concept_id; data with unmapped concepts
- Number of persons with at least one drug exposure by drug_concept_id; data with unmapped concepts
- Number of persons with at least one procedure occurrence by procedure_concept_id; data with unmapped concepts
- Number of persons with at least one condition occurrence by condition_concept_id; data with unmapped concepts
- Number of persons with at least one condition era by condition_concept_id; data with unmapped concepts
- Number of persons with at least one observation occurrence by observation_concept_id; data with unmapped concepts

Changes in concepts

- Number of persons by drug exposure start month by drug_concept_id; 1059 concepts had a 100% change in monthly count of events
- Number of persons by drug era start month by drug_concept_id; 567 concepts had a 100% change in monthly count of events
- Number of persons by procedure occurrence start month by procedure_concept_id; 401 concepts had a 100% change in monthly count of events
- Number of persons by condition occurrence start month by condition_concept_id; 703 concepts had a 100% change in monthly count of events
- Number of persons by condition era start month by condition_concept_id; 875 concepts had a 100% change in monthly count of events
- Number of persons by observation occurrence start month by observation_concept_id; 27 concepts had a 100% change in monthly count of events

Value range

- Distribution of days_supply by drug_concept_id; maximum value should not be >180
- Distribution of quantity by drug_concept_id; maximum value should not be >600

As shown in Table 1, notable findings required interpretation based on dataset semantics. In the "concept_relationship" and "drug_strength" tables, the "invalid_reason" column is "NULL" by default and is populated only when a relationship or mapping has been invalidated. Therefore, the predominance of "NULL" values in this column data does not indicate incompleteness.

However, several columns showed missingness or special character values. In the "vocabulary" table, "vocabulary_version," which stores released vocabulary version information, was missing in 30.6% of records (38/124). In the "observation" table, "value_as_string" column, which stores observation values recorded as text, showed substantial missing data, with 23.8% (3,643,581/15,313,287) of records flagged as incomplete.

In the "measurement" table, "unit_source_value" and "value_source_value," which store measurement units and source result values, respectively, contained special character entries at relatively low rates, indicating that several source units or values were carried forward without sufficient normalization. Special characters were also detected at very low rates in several source value fields, including "place_of_service_source_value," "care_site_name," "state," "cause_source_value," and "dose_unit_source_value." These results indicate localized nonstandard formatting in several source value fields, including location, death, and drug exposure tables.

Textbox 1 highlights 3 types of rule findings. First, the study identified unmapped concept patterns in multiple domains, including demographic fields such as gender, race, and ethnicity, and event-based tables. These results indicate that values in the source data are not fully represented using standard concepts, limiting their interpretability and consistent use for research. Second, the rules flagged abrupt shifts in event count for condition occurrence, procedure occurrence, and drug exposure. These abrupt changes indicate breaks in the temporal continuity of data recording or loading. From a completeness perspective, events may have been incompletely captured during specific periods. Third, value range checks identified data such as "days_supply" and "quantity" exceeding predefined bounds. These out-of-range values suggest that a subset of records may not align with expected clinical patterns or may reflect data transformation issues, which can reduce the reliability of downstream analyses that depend on these fields.

These rule-based findings demonstrate that completeness assessment can address not only whether values are present but also whether data meet use conditions and semantic meaning, facilitating the detection and identification of major quality issues.

Completeness and Diversity for Medical Research

As part of descriptive profiling to support the research purpose, this study examined the distribution of mapped standard vocabularies across key clinical domains. EHR data are commonly standardized using terminologies such as Logical

XSL•FO
RenderX

Observation Identifiers Names and Codes and Systematized Nomenclature of Medicine–Clinical Terms (SNOMED CT); however, mapping coverage can vary according to clinical and institutional practice [39]. Understanding the mapped vocabulary landscape is important for planning data use and interpreting the data standard [40].

Table 2 summarizes the distribution of standard vocabularies used by data across clinical domains. In the "measurement" table, most records were mapped to Logical Observation Identifiers Names and Codes (468,274,853/642,638,656, 72.9%), followed by SNOMED CT (116,316,640/642,638,656, 18.1%). In the "drug_exposure" table, mappings were dominated by RxNorm Extension (143,512,501/166,702,480, 86.1%) with additional use of RxNorm (16,810,245/166,702,480, 10.1%). In the "observation" table, the mapped concepts were predominantly SNOMED CT (14,833,557/15,313,463, 96.9%). In the "procedure_occurrence" table, mappings were distributed across Observational Medical Outcomes Partnership standardized vocabularies (85,344,562/159,014,912, 54.0%) and SNOMED CT (69,604,840/159,014,912, 44.1%).

Table . Distribution of mapped standard vocabularies across major clinical domains. Counts and proportions are reported for the primary vocabularies used to represent concepts in the "measurement," "drug_exposure," "observation," and "procedure_occurrence" tables in the study dataset.

Table name and vocabulary	Rows, n (%)
Measurement (n=642,623,715)	
LOINC[a]	468,274,853 (72.9)
SNOMED CT[b]	116,316,640 (18.1)
OMOP[c] standardized vocabularies	52,320,453 (8.1)
Other	5,726,710 (0.9)
Drug_exposure (n=166,706,078)	
RxNorm Extension	143,512,501 (86.1)
RxNorm	16,810,245 (10.1)
OMOP standardized vocabularies	4,026,859 (2.4)
Other	2,352,875 (1.4)
Observation (n=15,313,287)	
SNOMED CT	14,833,557 (96.9)
LOINC	399,874 (2.6)
Other	80,032 (0.5)
Procedure_occurrence (n=159,007,634)	
OMOP standardized vocabularies	85,344,562 (53.7)
SNOMED CT	69,604,840 (43.8)
Other	4,065,510 (2.6)

[a]LOINC: Logical Observation Identifiers Names and Codes.

[b]SNOMED CT: Systematized Nomenclature of Medicine–Clinical Terms.

[c]OMOP: Observational Medical Outcomes Partnership.

Examining these vocabulary distributions provides a foundational understanding of the dataset structure for research use.

Descriptive diversity profiling characterized the study cohort by describing how records were distributed across demographic groups and clinical contexts, and it was used to summarize population characteristics and recording patterns. There is no gold-standard distribution for these profiles because the expected distribution depends on the intended use of the data. However, when a study requires specific subpopulations or clinical settings, evaluating whether the dataset provides sufficient representation of these target populations is an essential component of data quality assessment for medical research. Thus, limited diversity may indicate that the dataset does not meet the requirements for its intended use.

Table 3 presents descriptive diversity profiling results for the study dataset with gender, race, ethnicity, and clinical characteristics. The gender distribution was balanced, with male patients accounting for 49.3% (886,489/1,798,153) and female patients accounting for 50.7% (911,664/1,798,153) of the dataset. In contrast, race and ethnicity information showed substantial skewness and limited standardization. Race was predominantly mapped to Korean, which is expected given the national context of the data source. However, a small proportion of records were labeled as "No matching concept," suggesting either the presence of non-Korean race values or incomplete mapping to standard concepts. Ethnicity was not mapped to a standard concept for the entire dataset and was recorded as "No matching concept." This is because the ethnicity field is primarily intended to distinguish "Hispanic or Latino" from

XSL•FO
RenderX

"Not Hispanic or Latino." This field was designed for US-based datasets to support ethnicity classification and is typically not applicable or routinely collected in Asian settings, including South Korea. Therefore, the observed ethnicity results should be interpreted not as a data collection quality issue but as a reflection of the US-centric design and intended use of the data model.

Table . Descriptive profiling of data diversity for research use. The table summarizes the distribution of key demographic attributes in the study patients and the most frequently recorded categories for visit type, condition, drug exposure, and measurement concept by person (n=1,798,153).

Diversity characteristic	Patients, n (%)
Sex	
Male	886,489 (49.3)
Female	911,664 (50.7)
Race	
Korean	1,739,628 (96.7)
No matching concept	58,525 (3.3)
Ethnicity	
No matching concept	1,798,153 (100)
Visit type	
Outpatient visit	1,444,995 (80.4)
Emergency room visit	687,254 (38.2)
Inpatient visit	494,492 (27.5)
Health examination	272,061 (15.1)
Intensive care	46,651 (2.6)
Condition type	
Inflammatory disorder of the digestive tract	134,783 (7.5)
Essential hypertension	115,262 (6.4)
Gastritis	111,126 (6.2)
Drug exposure type	
100-mL sodium chloride 9–mg/mL injectable solution (JW NS)	360,530 (20.1)
10,000-mL oxygen gas for inhalation	358,831 (20.0)
Artemisia argyi leaf extract 60-mg oral tablet (Stillen)	282,130 (15.7)
Measurement type	
Hemoglobin (mass per volume) in blood by calculation	1,068,822 (59.4)
Alanine aminotransferase (enzymatic activity per volume) in serum or plasma	1,037,714 (57.7)
Aspartate aminotransferase (enzymatic activity per volume) in serum or plasma	1,037,534 (57.7)
Creatinine (mass per volume) in serum or plasma	1,005,168 (55.9)

Additionally, through determining the most frequently recorded categories across the dataset, it was possible to characterize where data capture was concentrated. Most visit-related records were generated from outpatient encounters, whereas records associated with intensive care were comparatively rare. This distribution indicates that the dataset primarily reflects limited representation of intensive care populations, which is important to consider when defining research aims and target studies [41]. For the condition, drug exposure, and measurement domains, the most frequently recorded categories were identified to provide practical context for understanding baseline data coverage and typical clinical content in the database. These distribution summaries support the interpretation of data class completeness and understanding of diversity by documenting demographic information and identifying domains where data are concentrated.

Discussion

Principal Findings

A key finding from the structural completeness assessment was that the database did not contain "note" and "note_nlp" tables, indicating that clinical free-text narratives were not available. Because clinical notes are increasingly used for studies based

XSL•FO
RenderX

on natural language processing (NLP) and large language models (LLMs), this limits the dataset's suitability for NLP and LLM study purposes [42]. Although some text information may exist in other tables, NLP research requires clinical narrative text [43]. Therefore, establishing a systematic framework for collecting and constructing incomplete data is necessary.

In the rule-based assessment, we applied detailed validation rules to examine completeness across multiple tables and columns. However, we also found that rule outputs cannot be interpreted without understanding the meaning of each field and the data context. For example, "invalid_reason" appeared to be missing in most records, but "NULL" was the default value. This highlights that completeness assessment is not only about running rules but also about interpreting results based on data characteristics and semantics. Additionally, the detection of unmapped concepts and abrupt changes in monthly events indicate crucial data quality issues. These findings illustrate that rule-based assessment must extend beyond value presence to evaluate the integrity of the data quality. Specifically, by identifying unmapped patterns, temporal shifts, and out-of-range values, we can pinpoint systematic data quality issues such as capture failures or transformation errors. This assessment approach serves as a diagnostic warning system to identify specific types of issues and helps examine data quality from missing values to semantic issues [31,44]. However, interpreting the outputs requires an understanding of data. As illustrated by the "invalid_reason" example in our results, rule outputs do not always reflect the same meaning. Therefore, rule-based assessment requires expertise to implement rules and interpret the outcomes. It also requires review of the rules to ensure validity and meaningfulness in the assessment [45].

Medical research should conduct descriptive diversity profiling to characterize the study cohort by quantifying how records are distributed across demographic groups and clinical contexts [32]. This approach does not rely on a single ideal distribution because a dataset can still be complete even when certain encounter types are absent if the data source is designed not to capture them. However, when the intended use requires specific subpopulations or care settings, limited representation can constrain research feasibility and may contribute to biased findings in medical research and model behavior in medical AI [46]. Therefore, diversity should be interpreted not only as a description of data distribution but also as an indicator of whether the dataset sufficiently covers the target populations and clinical contexts needed for the intended use. In other words, these data quality assessment results underscore that data quality should be assessed and interpreted according to the definition of data quality, dimensions, and criteria; measurement methods; and intended use of the dataset.

The principal findings have broader implications for medical informatics by illustrating how completeness challenges emerge in real-world EHR data. To contextualize our approach, we compared our completeness assessment with prior data quality studies in Asia and with international Observational Medical Outcomes Partnership–related work [47-49]. Previous studies have largely relied on Observational Health Data Sciences and Informatics tools to characterize datasets and flag rule-based issues. In contrast, this study focused on completeness for medical research and operationalized it using three complementary components: (1) structural completeness assessment, (2) rule-based validation, and (3) descriptive profiling. We further interpreted the assessment outputs in relation to data generation processes, ETL decisions, and analytic intent rather than treating the results as simple quality status indicators. This comparison suggests that completeness assessment for secondary use should extend beyond issue detection to include interpretation and cause-oriented reasoning because these issues directly affect data reusability and comparability.

Specifically, the unavailability of clinical note data in our dataset can be interpreted as an infrastructure and representation gap for clinical narratives rather than as a simple missing data issue [50]. This finding reflects real-world barriers to collecting and standardizing unstructured clinical text and transforming it into structured representations for secondary use. These barriers have motivated ongoing work on clinical text processing and NLP and LLM integration approaches for clinical note generation [51]. As the practical feasibility of these approaches increases, evaluating the reliability and usability of AI-generated narratives becomes an additional data quality requirement [52]. Additionally, mapping gaps and incomplete standardization issues highlight the need for continued ETL process improvement and tool development to support reliable transformation in real-world EHR databases [53,54].

Collectively, these findings indicate that data quality assessment is not an end point. It is part of an iterative process in which quality findings lead to remediation efforts such as refining ETL and mapping workflows or generating synthetic data. The outputs of these remediation steps should then be re-evaluated for reliability, usability, and fitness for the intended secondary use.

Together, these findings suggest that this case study can offer broad data quality insights for improving EHR reusability.

Data Quality

Data quality is a foundational prerequisite, and numerous frameworks have been proposed to define quality dimensions, terminology, and evaluation perspectives.

However, translating these concepts into practical assessment and interpretation in real-world settings remains challenging. Although many frameworks provide a shared language for describing data quality, it is difficult to connect framework concepts to practical data quality assessments [55]. For example, medical AI frameworks emphasize quality characteristics relevant to model development, yet these considerations are not incorporated into dataset curation and training pipelines [15].

Ultimately, achieving meaningful data quality requires a holistic approach that integrates quality definitions, dimensions, and frameworks with practical assessment methods and tools. Appropriate interpretation of results, together with continuous efforts and monitoring, is necessary for quality management.

Strengths and Limitations

A key strength of this study is its completeness evaluation of a large-scale EHR dataset in which completeness was assessed

XSL•FO
RenderX

using multiple complementary perspectives and the findings were interpreted in context. By providing an empirical example of how completeness can be measured in practice, this study offers a practical reference for researchers planning completeness assessments and supports efforts to improve data quality.

This study also has limitations. Because data quality is context dependent and may be defined and operationalized differently depending on purpose and perspective, our assessment focused primarily on completeness and did not evaluate other quality dimensions or frameworks. Completeness cannot be fully captured by a single set of rules or metrics across all research contexts. Thus, the specificity and depth of data quality findings can vary substantially by assessment method and tool. This reflects the wide variation in underlying frameworks, dimensions, criteria, and tool capabilities in real-world data quality evaluation, making assessment outputs inherently heterogeneous.

Conclusions

This study operationalized and assessed data completeness in a large-scale EHR dataset. A practical approach was applied consisting of structural completeness assessment, rule-based validation, and descriptive statistical profiling, and completeness findings were derived from each component. This completeness assessment workflow demonstrates how data quality can be measured and interpreted in real-world clinical settings.

In conclusion, this study emphasizes that data quality work requires not only quality definitions but also practical assessment methods and interpretable outputs. By presenting a methodology-based assessment workflow and results from a real clinical dataset, it provides a concrete reference for applying data quality dimensions in medical research settings. These results and insights provide a representative case for data quality research.

Acknowledgments

The authors would like to express their sincere gratitude to the Health IT Research Center at Gachon University Gil Medical Center for providing the data environment and supporting technical infrastructure for this study. The authors also gratefully acknowledge the Korea Institute of Drug Safety and Risk Management for their support and collaboration in this research. During the preparation of this manuscript, the authors used GPT-4 (OpenAI) to assist with translation and drafting responses to reviewers, with the aim of improving the clarity and expression of the original content. After this, the manuscript underwent multiple rounds of professional English-language editing, and the authors reviewed and finalized the content, taking full responsibility for the publication.

Funding

This research was supported by a grant from the Korea Health Technology R&D Project through the Korea Health Industry Development Institute funded by the Ministry of Health and Welfare, Republic of Korea (grant RS-2022-KH125153), and the Gachon University Research Fund of 2023 (GCU-202400550001).

Data Availability

The datasets are not publicly available due to data protection agreements but are available from the corresponding author and Gachon University Gil Medical Center on reasonable request.

Authors' Contributions

SL and ML conceptualized the study. ML developed the methodology, conducted the research, drafted and edited the manuscript, and prepared the tables and figures. NS supported the provision of study computing resources and programming, software development; designing computer programs; implementation of computer code and supporting algorithms; testing of existing code components. WS reviewed the study ideas from a clinical perspective. DA curated the literature.

Conflicts of Interest

None declared.

Abstract

Background: Electronic health records (EHRs) have the potential to improve service delivery through record keeping and monitoring health outcomes. As countries move toward universal health coverage, digital health tools such as EHRs are essential for achieving this goal. However, EHR implementation in middle-income countries like South Africa faces obstacles.

Objective: This study explores the reasons behind a stalled implementation of the electronic tick register (E-tick) system (an electronic version of a paper primary health care register to record services provided), using the Consolidated Framework for Implementation Research.

Methods: Using a qualitative design, in-depth interviews were conducted with 38 participants to explore their perceptions and experiences, and the factors surrounding the success and stalling of E-ticks. Participants included managers, stakeholders, implementers, and end users from the 3 implementation clinics. Data was collected using semistructured interview guides. The Thematic and Consolidated Framework for Implementation Research framework analysis (innovation, inner setting, individual characteristics, implementation process, and outer setting) was applied.

Results: The E-tick system was designed to improve data quality in paper health registers, addressing inaccuracies in reporting to district and provincial health departments (Innovation domain). Implementers iteratively developed the system through user input from managers and clinicians, and stakeholder engagement of software developers, funders, health managers, and decision-makers from the provincial health department (individual characteristics). Although the system was initially well adopted by end users, it stalled primarily due to outer setting factors, which included a change of developers, funding cuts, and limited support at the provincial health department level due to capacity gaps, political appointments, and mistrust stemming from corruption and abuse of the tender system. Moreover, resistance to leveraging lessons from locally developed small-scale systems further constrained institutional support for the E-tick.

Conclusions: Although successful implementation of EHRs can be facilitated by strong user engagement and co-design, outer setting factors such as governance, funding, and policy alignment can pose significant threats to sustainability. This underscores the importance of effective synergy between top-down and bottom-up processes for successful implementation.

Introduction

Overview

Electronic health records (EHRs) hold the promise of improving service delivery, monitoring and evaluation of health interventions, and record-keeping for public health [1]. As more countries work towards universal health coverage, leveraging digital health tools like EHRs becomes more important for enhancing service delivery and improving quality of care [2,3]. The World Health Organization's global digital health strategy emphasizes the need for accelerated adoption of EHRs to achieve health goals [4]. However, EHR implementation in many middle-income countries remains slow due to financial and technological challenges [5].

XSL•FO
RenderX

Implementing EHRs is an evolving process that requires adaptive and context-specific policies to meet ever-changing needs [6], and a clear vision to move from pilot to scaled implementation [2]. In some high-income countries where implementation has occurred [7], a "top-down" approach has typically been used, where systems are preconfigured, and users must adapt. Although this offers coordination and central oversight, it can limit flexibility. In contrast, bottom-up approaches emphasize co-design with end users and adaptation to local workflows, which often enhances usability and adoption [8]. Research suggests that successful EHR implementation in complex health systems requires balancing national coordination with local innovation, as this allows centralized oversight, while engaging local health communities and tailoring systems to user needs [8,9].

South Africa has made policy advances, such as the National Digital Health Strategy (NDHS) (2019 - 2024) [10], with considerable resources as a middle-income country and sufficient technical expertise, but progress toward a national EHR has been slow. This is because policy direction and technical capacity are sometimes impeded by systemic and political barriers. Within this context, most primary health care facilities continue to rely on manual paper-based systems, which are labor-intensive and prone to errors in data collection [11,12]. However, bottom-up efforts have been made to improve data quality and accuracy. These include Tier.net, an electronic record system used with patients living with HIV and tuberculosis, and the electronic tick register (E-tick), the electronic record system we studied. The E-tick is a digital version of the tick register, a book in each health care facility for recording patient attendance and care delivered. In this paper, we use the Consolidated Framework for Implementation Research (CFIR) to explore an attempted implementation of the E-tick, a system conceptually similar to an EHR, examining how its implementation stalled despite a consultative approach in its implementation.

Background

Digital Health Policy in South Africa

As a middle-income country, South Africa has made policy strides in line with the global developments, which should facilitate the adoption of EHRs, such as the National Health Act 61 of 2003 and the NDHS (2019 - 2024) [10,13]. The Health Act outlines the role of the National Department of Health in coordinating health information systems across national, provincial, and district levels [10]. Although policy direction is set at the national level, the federal system means that provinces can independently determine their own health care spending. Therefore, implementation largely occurs at provincial and district levels, with each maintaining its own health information systems within the national framework. This provincial autonomy has contributed to fragmentation, as different provinces and regions develop EHR systems through separate procurement processes [14]. This fragmentation is further compounded by a political economy of procurement, in which tenders are prone to corruption, mismanagement, and the absence of oversight structures [15]. These factors directly affect which innovations are funded, how resources are distributed, and whether systems can successfully reach scale, as funding decisions often prioritize large-scale centralized systems.

South Africa uses 2 health information systems in the public sector: the Health Patient Registration System (HPRS) and the District Health Information Software (DHIS; developed through a collaboration between the University of the Western Cape and the University of Oslo), jointly developed by the University of the Western Cape and the University of Oslo [16]. The HPRS is a manual patient registry that records patient contact details as well as legal identification numbers, while the DHIS is an electronic system used to collect aggregated data on services provided to patients in public health facilities [17]. The DHIS data is first collected manually, then captured into the DHIS software, where it is submitted to the district, provincial, and national health departments. The method used to record primary health care data is a tick register, a manual paper-based system where clinicians mark or tick off the services provided in a large logbook with columns for dates and types of services offered (antenatal care, vaccinations, or chronic disease management). However, this process can be arduous, time-consuming, and prone to many recording errors. Studies evaluating the DHIS have confirmed persistent data gaps, citing poor documentation, manual entry under heavy workloads, and errors as major contributors to discrepancies [18].

South African Health System

South Africa plans to implement a National Health Insurance fund to facilitate better purchasing decisions through more formal contracting relationships rather than the historical allocation of budgets by provinces [19]. In this case, EHRs are key in monitoring patient outcomes and assessing the value of care purchased. Although most provinces have had some type of operational EHR system in public hospitals [20], there is no national EHR at the primary care level, and different architectures still pose a challenge to their integration for nationally coordinated use [21].

Provincial health departments in South Africa are often run by political appointees, who work under directives from their affiliated political party. This has led to pervasive corruption in the country's health system, which has been reported at various levels of government [22]. For example, 150 million rand awarded to a communications company during the COVID pandemic was misappropriated, and the health minister was suspended as a result [23]. In another case, the provincial chief financial officer who exposed a 1-billion-rand tender fraud was assassinated [24]. Such cases illustrate how poor financial management systems and political appointments enable corruption, which acts as an impediment to the public trust in the health system [25]. For digital health innovations, such dynamics increase the risk that systems are chosen for political or financial interests rather than their impact or merit, which affects the health department's ability to work with other stakeholders, or source funds for large-scale projects, including projects to implement EHRs. Moreover, the absence of countermeasures such as accountability and transparency makes it difficult to implement large-scale projects like EHRs.

XSL•FO
RenderX

The E-Tick System

An electronic version of the paper-based tick register (E-tick) was developed and piloted in 3 public health care facilities in the Ekurhuleni district between 2017 and 2021. Clinicians record services provided directly into the digital system on a patient's record, which also allows facility managers to monitor daily activities such as headcount and services offered. Although this is not a full EHR, the system can be expanded to include diagnosis and lab results and to integrate with other systems that are currently used in public health facilities. Against this backdrop, the E-tick system sought to provide an alternative that could improve data accuracy at the facility level while feeding directly into the existing provincial and national reporting systems. However, such progress is dependent on not only user adoption factors but also broader contextual dynamics [26]. Thus, by situating the E-tick in relation to both micro-level realities and macro-level policy and political economy, we aim to provide a more holistic understanding of why grassroots digital health interventions may stall or fail.

Consolidated Framework for Implementation Research (CFIR)

Implementation research seeks to understand why some implementation efforts succeed and others do not, and the role of the context [27]. To explore the key factors affecting implementation in our case study, we used the CFIR, which integrates existing theories of implementation and behavior change into a unified framework [28]. The CFIR is a meta-theoretical tool with standardized constructs to examine enablers and barriers to implementation across different stages (preimplementation, during implementation, and postimplementation) [29].

The CFIR was developed through a review of published theories and reports on factors influencing implementation [30]. Hence, its strength lies in its broad applicability and potential for generalizability, which are useful for informing practice across diverse settings. The framework has 5 broad domains (Table 1), which include: innovation domain, inner setting domain, outer setting domain, individuals domain, and the implementation process domain, which together capture multilevel determinants of implementation [31]. Due to the framework's flexibility, researchers can tailor it to specific interventions and contexts [32], and it has been widely adopted in research, applied across different research designs, and cited in over 300 published articles [29]. Recent updates have been made to the framework, using responses from authors who used the framework, leading to refined construct names and definitions to make them more encompassing [31]. In this paper, we draw on the updated CFIR to guide both our analysis and reporting of findings.

Table . Consolidated Framework for Implementation Research (CFIR) domains by Damschroder et al [28].

CFIR domains	Definition
Innovation	• The "thing" being implemented, such as a new treatment, program, or service. • Key factors that affect innovation include its source, evidence base, advantages over existing practices, adaptability, trialability, complexity, design, and cost.
Individuals	• The roles and characteristics of people involved in innovation. • Key roles include high-level leaders, mid-level leaders, opinion leaders, facilitators, and implementation teams who guide and support the innovation. • It also highlights innovation deliverers and recipients.
Inner setting	• The environment where an innovation is implemented, such as a hospital or school. • Key elements include structural characteristics like physical and IT infrastructure, work organization, and staffing levels.
Outer setting	• The broader context or setting within which an organization or project operates, such as a hospital system or school district. • Factors influencing implementation in the Outer Setting include large-scale disruptions, local attitudes, socioeconomic conditions, external partnerships, and regulatory policies.
Implementation process	• The activities and strategies to introduce and sustain an innovation. • Key components include forming teams to collaborate on tasks, assessing the needs of both innovation deliverers and recipients, and evaluating the context to identify barriers and facilitators. • Planning, tailoring strategies, engaging participants, testing small-scale changes, and reflecting on outcomes are critical steps.

Methods

This study adopted a qualitative design to explore the perceptions and experiences of external stakeholders, senior health managers, implementers, and end users of the E-tick system.

Participants and Sampling

We recruited a total of 38 participants, categorized into three groups: (1) managers and stakeholders, (2) implementation team, and (3) end users. The senior health managers and external stakeholders category included decision makers and higher-level people who were not directly involved in the system's implementation but provided insights into the context and the decisions impacting it. The implementation team comprised individuals who were responsible for initiating and deploying the system and introducing it to the users, while the end user team consisted of the clinicians and managers from 3 recipient facilities. Participants from the managers and stakeholders, as well as the implementation team, were purposively selected through referrals from key individuals and recruited via email. For end users, convenience sampling was used, with the researcher recruiting available users with the aid of gatekeepers during facility visits. Our sample intentionally included stakeholders from multiple levels of the health system to minimize elite bias, ensuring that the perspectives of senior health managers were balanced with those of frontline users and mid-level implementers. Below is a summary table of the participants in this study (Table 2).

Table . Study participants (N=38).

Category and roles	Count (n)
Senior managers and stakeholders	
National, provincial and district health managers	7
Parastatal staff	2
NGO[a] managers and staff	4
Academics	2
Private sector managers	2
Implementers	
Originators	2
IT Technician	1
Data capturers	3
End users	
Facility managers	3
Administrative officer	1
Nurses and midwives	9
Admin clerks	2

[a]NGO: Non-Governmental Organization.

Data Collection and Management

Data collection took place between November 2021 and June 2022, which was after the E-tick project had stalled. Thus, participants, particularly implementers and end users, reflected retrospectively on the system's development, piloting, and discontinuation. Due to COVID-19 health restrictions at the time, some of the interviews with senior health managers and the implementation team were conducted via web using video conferencing software. Interviews with end users were conducted in person in health care facilities during work hours and were conducted primarily in English, which is the standard working language in the facilities. However, participants were free to use local language terms or expressions, which were translated during transcription to preserve meaning.

Different semistructured interview guides were used for the 3 categories of participants. For the managers, we inquired about the broader digital health policy landscape, existing health information systems, government readiness, and feasibility for EHR implementation and the necessary next steps to advance EHR adoption in South Africa. For the implementation team and end users, the interview guides covered topics on the purpose and origins of the E-tick, its piloting rollout, experiences with implementation and daily use, training and support, perceived benefits and challenges, and overall recommendations for improvement. Interviews varied in length, ranging from 10 to 64 minutes. Shorter interviews (under 20 min) were mostly with busy frontline staff, including clerks and clinicians during clinic hours, who provided concise but relevant insights into system use. Longer interviews were with senior health managers with authority over policy alignment, resource allocation, and procurement processes, and implementers who facilitated implementation in the 3 health facilities. Despite these differences, data saturation was reached across stakeholder groups, as no new themes emerged in later interviews. All interviews were audio recorded, and recordings were stored in

XSL•FO
RenderX

a password-protected computer to ensure privacy. Audio recordings were transcribed using transcription software and checked for accuracy, and transcripts were anonymized by removing participant-identifying information.

Data Analysis

The first author led the coding, followed by regular debriefing meetings with coauthors, who are also academic supervisors, to review coding and theme development, which strengthened reliability. In this case, coauthors read all the transcripts, and discrepancies were discussed until consensus was reached. The interview transcripts were coded using NVivo qualitative analysis software (QSR International). Through this process, emergent issues were identified and used to develop the themes, following a 6-step thematic analysis process [33]. An inductive approach guided the thematic analysis, with broad topics derived from the interview guide, leading to the 4 stages of implementation reported in this study (Purpose and origins, Initial development, Piloting and expansion, and Halt). The accounts from the two originators formed the foundation, providing the background story and backbone of the implementation narrative, whose detailed recollections provided a chronological anchor for mapping implementation processes. These accounts were not taken at face value, but were supplemented by other participants' accounts, which were used to triangulate and integrate the information into a cohesive story.

After coding, the CFIR was applied to the analysis, linking the framework's 5 domains to the implementation process as reported in the study's findings (Table 3) [31]. The CFIR framework guided our analysis and reporting of findings. In this case, CFIR constructs were operationalized as sensitizing concepts to guide coding, with data excerpts being coded against relevant constructs, while leaving space for inductive subthemes to emerge. Thus, the analysis combined deductive coding (using CFIR constructs) with inductive coding to capture novel themes. Multiple coders reviewed transcripts, with regular team discussions to minimize confirmation bias.

Table . Implementation stages and applied Consolidated Framework for Implementation Research (CFIR) domains.

Stages of implementation	Description	Applied CFIR domains
Origins and purpose of the system (2015 - 2017)	Conception of E-tick[a] by system originators; designed to digitize the existing tick register and reduce errors.	• Innovation • Individuals • Inner setting • Outer setting
Initial development (2017 - 2019)	Early technical build and adaptation of the system, involving stakeholder input and limited resource mobilization.	• Individuals • Inner setting • Outer setting • Implementation process
Piloting (2019 - 2020)	Deployment of E-tick system in 3 health facilities.	• Individuals • Inner setting • Implementation process
Halt (2021)	Expansion beyond pilot sites stalled due to barriers to scale up and institutionalization.	• Inner setting • Outer setting

[a]E-tick: electronic tick register.

Ethical Considerations

Ethics approval for this study was granted by the University of the Witwatersrand Medical Human Research Ethics Committee (M210213). Additional permissions were obtained from the Ekurhuleni district research committee and the Gauteng Provincial Department of Health (GP_202106_035). The study was conducted in accordance with local, institutional, and national regulations governing research involving human participants, as well as the principles of the Declaration of Helsinki. All participants provided written informed consent prior to participation. The study purpose, procedures, potential risks, benefits, and participants' rights, including the right to withdraw at any time without penalty, were explained before consent was obtained. Participant privacy and confidentiality were maintained as interviews were conducted in private settings, and no identifying information was included in transcripts. All data were anonymized, securely stored on password-protected devices, and were only accessible to the research team. Participants did not receive any compensation for their participation.

Results

Overview

This section presents the findings, which are ordered according to the domains of the CFIR: innovation, inner setting, individual characteristics, implementation process, and outer setting. This structure allows us to highlight how factors at multiple levels and stages of implementation shaped the processes, outcomes, and ultimately the stalling of the E-tick system. To illustrate the distribution of themes across the framework, Multimedia Appendix 1 provides a summary of implementation stages, CFIR domains and applicable constructs, thematic findings, and illustrative quotes.

Origins and Purpose of the E-Tick: Innovation and Individuals Domains (2015-2017)

Identifying the Problem

The development and implementation of the E-tick was initiated and led by a senior district manager and supported by a senior technician who was employed by the funder, labeled as Originators 1 and 2. The senior manager explained the rationale behind the project:

> *Annually, the National Department of Health audits our data for accuracy, and we've always had poor audit reports. The biggest problem was the quality of the data. That's why we started the E-tick, to improve the data quality.* [Originator 1]

The source of poor data quality was traced back to the tick register: "The data was very poorly filled into the tick register, the services provided not counted properly." (Originator 1). This was the stage where most errors occurred: "The data issues started in the consultation room, and then the counting and the transferring of the data into the DHIS accounted for about eighty percent of the mistakes." (Originator 1). Some clinicians echoed these remarks as one shared: "The purpose was to reduce workload and be able to say, reduce patients' waiting time by doing away with pen and paper and to be able to keep our records digitally, which makes it easier to keep them." (Nurse 12 – AR).

The second originator further describes how decision makers often overlook the importance of effective data collection processes:

> *The problem in South Africa is that the people who decide where the funding goes don't take data management records management seriously. They want this wealth of data so they put in these big paper registers, but they don't look at the process it takes to get that data.* [Originator 2]

This includes having too many registers:

> *We had twenty-seven different registers, like the antenatal register for a mother and child, and a chronic disease register for HIV. The problem was that while completing all the registers, users were creating their own registers because some information was missing.* [Originator 1]

Nurses similarly described the burden, with one stating:

> *So with the E-tick it was one less writing system… our patients were registered, all the follow up visits are registered, and… it gave a clear history of the patient.* [Nurse 13 – MM]

Finding the Solution

Against this backdrop, the idea of the E-tick began with an invitation to a staff development project to discuss potential solutions to data quality problems:

> *We received an invitation because we already recognized a problem with data quality in our tick registers. They proposed several ways to enhance the system, involving different levels of information. While some suggestions were overly complex and resembled an Electronic Health System.* [Originator 1]

Eventually, the originators decided to make use of an Excel-based E-tick system:

> *The organization that developed the District Health Information System …had an Electronic Tick Register and we thought we can use that to improve the data quality. But the system was just an excel sheet.* [Originator 1]

Thus, the originators built on the Excel-based system:

> *We decided to improve the front end, the user interface for the clients. That's how we developed the E-tick. It was basically to collect the data electronically and to be able to feed it directly into the DHIS, in a way that is easy for the nurses in the consultation rooms.*
>
> *[Originator 1]*

End users confirmed that the system was simpler and helpful. One nurse explained:

> *It was user friendly. If only we would use E-tick only… we will definitely be perfect.* [Nurse 10 – AR]

Another shared:

> *And it was also user friendly. It wasn't like I'm talking from somebody that's not very computer literate, basically… it made it very easy, accessible.* [Nurse 13 – MM]

Initial Development of E-Tick System: Inner Setting and Individual Domains (2017-2019)

Stakeholder Engagement

The first originator approached a nonprofit organization for funding to get the project off the ground: "After our experience, we approached organization X for financial assistance and shared our ideas with them, as [they were already] our long-term funding partner deeply involved in data collection" (Originator 1). After the funders agreed, this was followed by meetings with software developers for planning: "Once the funders agreed, we met with [software] developers to explore system development possibilities, discussed utilizing the HPRS as our registration system." (Originator 1). It was at this point that the second originator, who worked for the funding organization, became involved. Together, the two originators represented 2 groups of stakeholders, one with the Department of Health and all staff at recipient facilities, and the other with the funding organization and developers:

> *[Originator 1] was very good on the clinician side and I was very good on the software side. I had been working with my team [funders] for many years before we started the E-tick, and I developed many systems with them.* [Originator 2]

As an iterative process, the originators worked closely between clinicians and developers:

XSL•FO
RenderX

> *In a normal software development cycle, you scope your business requirements, hand it over to the team, and they will go develop what they think you want and then return to show it to you. We took a different approach. We were involved in the development, sitting with them every step of the way instead of waiting for weeks for changes. This worked extremely well.* [Originator 2]

Several clinicians further confirmed this engagement, with one manager explaining:

> *The first early step was that we had meetings which included facility managers, other stakeholders and our partner [funder], to explain to us what wants to be introduced, which is when we were first given the idea of the E-tick and what it's supposed to do.* [Administrative officer 19 – RK]

The originators then selected the facilities for piloting involving managers in the process: "We used random selection and cluster sampling, through a session with all operational clinic managers, who actively participated in this process." (Originator 1). A manager from one of the facilities described their involvement: "We were called to a district meeting, and this was pitched, the intention was discussed with us... So the facilities that were going to be pilots were selected." (Assistant Director 17 – RK).

System Development

After selecting the facilities for piloting, the system was taken to the recipient facilities as one clinician recalls:

> *They called us for like a mini meeting to inform us about E-tick and told us that we were one of the only clinics currently using it, and they were piloting to see if it's going to work.* [Nurse 10 – AR]

In the meetings, one of the goals was to find ways to streamline the patient consultation:

> *We focused on what made it easy for clinicians to help the patients without them waiting too long. But a bonus that came out of the system is that the system was also able to retrieve a patient's entire history.* [Originator 2]

The clinicians provided feedback:

> *The clinicians had great ideas. The first time we had the screens ready, we took it back to the clinicians and asked them if this is what they wanted, they approved it and gave suggestions for changes, which we did.* [Originator 2]

Several engagements were made with the provincial Department of Health to gain support and input on issues such as data storage:

> *When we began the pilot, we engaged the Provincial office and kept them informed about the program. A provincial manager suggested storing the data on provincial servers instead. However, they weren't prepared to proceed at that time.* [Originator 1]

To ensure this was possible later, the developers ensured the system was compliant:

> *We looked at the Departments of Health security and ICT standards, we worked with the Department of Health ICT team as well, and their data team.* [Originator 2]

However, this did not go as planned, as the data center was not ready in time:

> *The idea was to eventually transfer the system and its data to the department's data center once it was established. However, when we developed it, there was no data center for us to put it in, and we had complied with all the national standards for the developing systems.* [Originator 2]

Piloting and Expansion: Inner Setting and Implementation Process Domains (2019-2020)

Planning and Configuration

In all 3 chosen facilities, the originators conducted an infrastructural assessment before beginning the pilot:

> *We had to check that all computers were working, and that they all had network. The developers didn't want to have a local server for each clinic because it's too complicated. So they changed the system to an online system that worked with the cloud.* [Originator 1]

Some of the existing infrastructure was from the Department of Health:

> *We only had to get the computers for the Provincial clinics. So that already made life much easier. Because every clinic, every clinician had a computer, or most of them.* [Originator 1]

A technician from the health department was involved in configuring them:

> *My role was to check infrastructure, to see if it's there. But they also installed some private infrastructure because of some policies with our network which would require a lot of approvals before we can run it.* [IT Technician]

This was further supplemented by the funding to improve the infrastructure:

> *They [funders] assisted us and made sure that each room had a network cable. Sometimes there were no plugs, so they put in the plugs. They put in the routers.* [Originator 1]

The planning and configurations also informed decisions on devices that were to be used:

> *We wanted to see what the nurses and the clinicians felt more comfortable with, the tablets or the desktops. Due to a lack of space in some consultation rooms, which were too small to put a big desktop, it was easier to mount a tablet onto the wall.* [Originator 2]

Training and Learning

A comprehensive user training was provided in recipient facilities, which was tailored for specific roles:

XSL•FO
RenderX

> *There were different training categories, because the roles were different like, clerks, clinicians and so on. It was [also] not just one training, it was several; this was because the facility was working on shifts, so they had to accommodate everyone. During rollout, there was another in-service training just to remind the staff.* [Nurse 17 – RK]

Moreover, the training was supplemented by regular visits for support and monitoring:

> *Then we had regular visits from [the originator], often enough for us to deal with whatever issues we were having on the system.* [Nurse 2 – MM]

The training was simple and accommodated varying levels of skills:

> *Some people could not use computers, but it was made as basic as possible to include those that are not computer literate.* [Nurse 17 – RK]

However, some users' competency and reactions to the training were influenced by age:

> *For the young ones, it was easy for them. For the old ones, it was a problem because they wanted to understand what they were ticking as they were pressing.* [Data capturer - 1]

In response, the originators sought assistance from data capturers, acting as an immediate source of help:

> *We had person in each clinic who would be there all day long. So for the first day or two they would sit with them [older users] when they completed it, until they became comfortable with it.* [Originator 1]

Support and Feedback Channels

To supplement the training, the originators had different people involved to provide support to end users, including IT technicians:

> *We provided desktop support, we were the first line of support. My role firstly was on all applications and IT projects running within the district.* [IT Technician]

While data capturers were already involved, especially in the early stages, admin people also assisted with various tasks:

> *We also had three admin people, one for each clinic that assisted in the clinic to help people with the training, setting up the system and checking that the computers are all working.* [Originator 1]

The originators also established communication channels to receive feedback from users:

> *We had a little book for users to report issues and to add anything, and an E-tick admin person was there. I also got information from data capturers and I would also go and check on everybody and they would give me feedback. We would report back to them monthly, usually.* [Originator 1]

Perceived Benefits of System Use

End users reported several benefits of the system, with some sharing how it improved continuity of care:

> *At times you find that the client may have been seen previously but the file could not be found. But if the client's details were captured on the previous visit, you could see it in the E-tick. So it helped with continuation of care.* [Nurse 11 – AR]

For other users, such as clerks, this reduced patient waiting times:

> *It also reduced the waiting period for the patient, because the first thing that we do is to register the patient and create a folder on the E-tick system. It's easier to use than retrieving the manual files, searching the files in the cabinets. When you're using an E-tick, you just search on the system.* [Admin Clerk 8 – AR]

Facility managers also found operational benefits, such as quicker service delivery:

> *The benefits were that the patient consultation times were shortened. It was a little bit faster. That was the best advantage that I've seen from the E-tick.* [Operations Manager 18 – RK]

Some users shared that the system improved data quality and access to it:

> *It improved the reporting of data. We had very reliable, consistent, and accurate data, at all times of the day.* [Administrative officer 19 – RK]

For some, the system enabled the monitoring of the clinic's performance:

> *We are able to evaluate ourselves on the number of patients that we are seeing. When our stats are sent to the DHIS, they can see that we are really performing.* [Nurse 4 – MM]

Perceived Challenges of System Use

Users reported several challenges with using the system, including the simultaneous use of the system with the manual:

> *To be brutal, they [users] were against it at first. They did not understand why we're implementing extra work for them.* [Administrative officer 19 – RK]

For some participants, the early days before mastering the system were difficult:

> *If you're not used to it yet, it takes time to get used to anything, especially if you're overloaded with a lot of patients.* [Nurse 14 – MM]

In some cases, short staffing led nurses to do administrative work, as one nurse shared:

> *I think it was mostly shortage of staff, sometimes I had to enter a new patient into the E-tick as a nurse, which would waste time and to delay the queue. You'd end up having to turn some patients back. So it needs us to be well staffed.* [Nurse 12 – AR]

XSL•FO
RenderX

In response, the originators designated roles for receptionists, clerks, and data capturers as the first point of contact for patient registrations.

There were concerns about the hardware and infrastructure that already existed in the facilities: "The [DOH's] ICT equipment was very outdated. Some of the computers are so old and they haven't been updated." (Originator 1 – R). Some users had challenges with the network infrastructure:

> *Our network system was failing us a lot. You'd be prepared to start the day and notice that you have no network.* [Nurse 12 – AR]

In response to this challenge, a back capture function was introduced, which allowed information to be captured into the system at a later stage. In one site, hardware was frequently stolen:

> *First disadvantage was theft. I'd say more than more than 70% of the tablets disappeared. All the rooms that had extension cords, but in less than two weeks, all the rooms had no extension cords. They also stole the chargers.* [Administrative officer 19 – RK]

In one clinic, the piloting coincided with ongoing protests by nurses:

> *When we were trying to start the system, the nurses and others would be outside complaining about the conditions in the clinic [a protest organized by unions]. Most of the nurses were not working. There were other issues in the clinic. I think they saw the E-tick as another thing that was worth protesting about, because it increased their workload.* [Originator 1 – R]

Halt and Barriers to Scale Up and Institutionalization: Outer Setting Domain (2021)

Changing Developers

Despite its relative success in implementation, several complications affected the continued use and development of the system. One of the complications came when there was a change in the software development company:

> *Originally [funders] were working with [a software developing company], who were helping with developing district programs. They were taken over by [another company] so the people that worked on our system were taken off the project, and a new team took over the development.* [Originator 1 – R]

This affected further developments:

> *We needed to update the system to make sure it's fine. Then it got stuck in that development phase because of the new developers that we have.* [Originator 1 – R]

Some of the previous work was undone by the new developers:

> *There were a lot of upgrades to the system, such as integration with the DHIS. But they removed some of the functionalities that were working well in the process. We were never happy with the final products that we got from them.* [Originator 1 – R]

Funding Cuts

The change of developers brought higher costs:

> *They [funders] agreed to pay for the additional development, but the new developers came with a lot of red tape and were quite expensive. The funding got cut and they could only give us a small amount to continue with the development.* [Originator 1 – R]

Moreover, the funders were eventually withdrawn from operating in the health district:

> *They [funders] moved out of the district, because their funding got canceled completely. So what's happening with their funding will affect our funding.* [Originator 1 – R]

This had an impact on keeping the system operational:

> *So because it's not open source, it was built on the Microsoft platform and the cost to keep it running is high. It's also web based so no offline capability, and we need constantly running servers.* [Originator 2 – T]

Thus, the system needed new funders:

> *We're looking for partners to fund the service, license costs and the implementation in facilities. To date, we haven't found anyone, so it's been put to sleep.* [Originator 2 – T]

Provincial and District Support

The originators had buy-in from district officials, who were in support of the system:

> *I had meetings with my chief director, and my director, and they are still very keen. The clinics are still very keen… So the buy-in is there, even after two to three years, but the funding is not there.* [Originator 1 – R]

However, the provincial health office's priority was to develop a new system, as the department technician explained:

> *Currently the department is rolling out an HIS platform where all other applications will be layered under and integrated into.* [IT Technician]

He further explained how locally developed systems were not as prioritized:

> *There were some contrasting and opposing views. The system was started from scratch but the department in most cases doesn't want that. They want to go on the market and buy something on the shelf. I don't think approvals were going to be granted.* [IT Technician]

The participant further mentions how the IT staff are often not seen as essential to the role of delivering care:

> *Sometimes different services compete for resources. They will say it's essential when it's a clinic, a doctor*

XSL•FO
RenderX

> *or medication, and then we [IT personnel] come last.* [IT Technician]

The originators also expressed their frustration with navigating such terrain:

> *So this is where we are stuck now. I think what is important to me is how difficult it is to roll out a system within the Department of Health, in the politics, the corruption and the agendas of people. It makes the story very complicated because we developed it the bottom up, seeing the need, with the buy-in from the district, and from all the role players.* [Originator 1 – R]

Broader Context (Outer Setting Domain)

Senior managers and external stakeholders shared insights into the Department of Health's challenges in implementing EHRs in South Africa. One manager notes how implementation requires a joint and collaborative effort of various stakeholders:

> *I think it's a complex sociotechnical project to do which requires many different role players and expertise and costs, which needs high level support from the National Department of Health which has been lacking.* [NPO manager]

The provincial health departments hold most of the decision-making power in digital health spending:

> *The national office can come up with guidelines and frameworks and ask for reports but the actual spending on health information systems is done at provincial.* [NPO manager]

In this case, the provincial health department had decided to prioritize an off-the-shelf system:

> *There is a provincial initiative and anything new that comes in has to talk to this one, there should be interoperability…I saw it [E-tick], it works. I tried to support it but we didn't get provincial support from the CIO.* [Provincial manager]

However, NGOs have been supporting and implementing local efforts to build systems (such as E-tick) in health care facilities:

> *NGOs are doing better than the districts and the provincial health in terms of implementing efficient systems. Most efficient systems are systems that have been introduced by NGO's instead of our provincial department.* [Provincial IT technician]

Some participants raised a concern over political appointments in key decision-making positions:

> *I don't believe that we have the right people in government with the right industry experience. They are just given the title and suddenly, they now have to make decisions. I think it's very wrong and it sets them up for failure.* [NGO Technician]

A health department technician added:

> *Most of our activities are driven by politicians while our head of department has his own strategies. We get our mandate from politicians.* [DoH Technician]

As a result, some decisions are made with bias:

> *There are bureaucratic officials in Department of Health national, provincial and local. If they do not like you and your project, they will say you have to go through SETA [a parastatal] which is extraordinarily slow, not particularly technically competent, and staggeringly expensive.* [NPO manager]

Moreover, one academic shared their experience with the Department of Health's reluctance:

> *I think there's not sufficient trust on the part of Government certainly in my experience. They are not coming to partner with us. In fact, they're pushing us away. We only get close when we work with NGO's and so on. The Government definitely keeps us at arms-length.* [Health Academic]

Corruption and inefficiencies have also created barriers, with the tender system being one of the issues:

> *It [corruption] is part of the tender system in South Africa, unfortunately the tender system is open to abuse.* [Provincial health manager - IT]

Moreover, past corruption scandals have tainted the reputation of the Department of Health:

> *The perception is that you can't trust the National Department any longer to do anything. No one is going to give the National Department a big pot of money to run a tender until it can show that it's got systems and people in place who can do it without squandering the money.* [National health manager]

This mistrust has also led to a reluctance to work within the department:

> *Now people are reluctant to work for the department for several reasons. They fear being embroiled in controversy and putting their personal integrity at stake.* [National health manager]

Discussions

Principal Findings

The E-tick system, an innovation, was developed to address the issue of poor data quality stemming from errors in data collection, which were common with the use of paper-based registers. The implementation process involved an iterative co-design process with input from all involved individuals, including end users and stakeholders, to ensure users' needs were met and to streamline the data entry process while supporting scalability and integration with other systems. Despite the system's successful piloting and user adoption in the inner setting, the outer setting posed challenges in funding, change of developers, and lack of support from the provincial health government, leading to the implementation stalling. Using the CFIR, we explored the interaction of different elements, actors, and stakeholders and how they facilitated or impeded implementation. As such, we organize this discussion using CFIR domains, highlighting both facilitators and barriers.

XSL•FO
RenderX

Innovation

Poor data quality is a problem that commonly affects routine monitoring of health outcomes [34]. The E-tick system had a clear relative advantage over paper-based registers to improve data quality and reporting, as errors that frequently compromised data quality and routine reporting were minimized, and users perceived the system as more streamlined than paper-based manual registers. At a national scale, this aligns with South Africa's policies that promote the digitization of record keeping and the establishment of a national EHR [10,35], a crucial component for strategic purchasing and health monitoring. The E-tick's co-design process enhanced usability and fostered buy-in, which is critical in adoption [36], yet innovation alone was insufficient to ensure sustainability.

Individuals

At the level of individuals, the originators showed strong commitment by providing vision, technical expertise, and persistence in driving the implementation of the E-tick system. Leadership practices are known to impact staff motivation, especially when they take a participatory approach [37,38]. Their leadership was instrumental in mobilizing resources, persuading managers and funders to support the system's adoption, acting as champions along with data capturers. Research shows how champions are crucial in promoting technology adoption through building enthusiasm and providing peer support [39]. End users also improved confidence in using the system as a result, especially after undergoing training, which sustained motivation during the pilot. However, while the successful adoption of the E-tick was due to the contribution of many actors, including external stakeholders, individuals in the inner setting were more affected by decisions in the outer setting. This reflects a broader challenge in digital health implementation in South Africa, that for locally developed systems to succeed, appropriate actors must be in place to provide leadership, vision, and sustained support, within an enabling environment that fosters continuity and long-term success [37,40].

Inner Setting

Within the inner setting, several facilitators supported early implementation, such as the co-design process and extensive user training. The originators successfully engaged a wide range of stakeholders, including senior managers and funders, which was pivotal in overcoming initial financial and political barriers. Involving end users was also crucial in enhancing the system's usability and promoting buy-in, an important aspect when ensuring effective user adoption [41,42]. Moreover, users' recognition of the system's value in improving data quality reinforced their motivation to adopt the system. Studies in other low- to middle-income countries show that organizational commitment is a critical success factor to sustain user motivation during piloting phases [43]. However, the sustained use of the E-tick required stable infrastructure, which often posed challenges for many users in the form of interrupted internet connectivity and power cuts. This mirrors challenges reported in other LMICs, where infrastructural fragilities, such as poor internet connectivity and unstable power supply, are common challenges to EHR adoption [44]. Moreover, without dedicated budgets to overcome these challenges, such as the use of mobile internet devices and backup power solutions, this creates uncertainty about sustained use.

Implementation Process

The implementation process revealed a mix of strengths and gaps, which were closely linked to the role of individuals and the inner setting. A key strength was the iterative co-design approach, which ensured that the system was not only technically functional but also responsive to user needs and compatible with existing workflows. Participatory design and user engagement are widely recognized in implementation science as best practice, as they enhance user ownership, adaptability, and long-term adoption, especially as most implementation efforts fail due to user resistance [45,46]. Thus, involving both clinicians and managers at early stages of the implementation process helped to align the E-tick system with user realities, reducing resistance to change. However, this process was undermined by a lack of a long-term financing mechanism and failed provincial support, despite the demonstrated proof of concept at the pilot phase. Therefore, while the implementation process was well executed, the system lacked the institutional anchoring and support for long-term use, a critical success factor of digital health efforts [47].

Outer Setting

We found that the most significant challenges were encountered in the outer setting, particularly the withdrawal of financial support, the change of developers, and the lack of support from the provincial health government due to its lack of capacity. Studies show that one of the main challenges to the initiation of digital health initiatives, including EHRs in South Africa, has been the poor governance and lack of political will [48,49]. For instance, the appointment of people without the required skills and competence has led to a chain of events that affect institutions such as the Gauteng provincial health department [50]. As a result, corruption has eroded the public's trust in the government. These issues are not isolated but rather reflective of the entrenched political economy dynamics that routinely affect digital health innovations in South Africa. Political appointments, who are put in place because they are easily manipulated, often make decisions driven by political interests rather than professional judgment, leading to the political control of government institutions and their spending [51]. As such, patronage networks often produce politically aligned rather than skilled appointments. This leaves room for corruption, irregular spending, fraud, and poor oversight to mitigate them, with procurement processes being vulnerable to perverse incentives, with contracts awarded to less qualified but politically connected vendors. Although efforts have been made to uncover large-scale corruption in South Africa, the necessary mechanisms have not yet been put in place to deal with the challenges [52,53]. Perverse incentives undermine sustainability as officials face pressure to launch new initiatives instead of sustaining existing ones to ensure full expenditure of budgets.

The administrative fragmentation can be seen as a product of South Africa's federal system, which means provinces can develop their own health information systems (bottom-up) or acquire them through separate procurement processes

XSL•FO
RenderX

(top-down) [8]. In this case, despite the provincial government's preference for a top-down approach by opting for an off-the-shelf system over the E-tick, they were unable to implement the former. High-income countries such as the United Kingdom, the United States, and Australia have taken top-down, bottom-up, and middle-out approaches, respectively, with varying outcomes [54]. Bottom-up approaches often build on existing systems, such as the E-tick, using interoperability standards to integrate them across facilities. In contrast, top-down approaches replace local systems with a centralized EHR, but this can be too complex, limiting flexibility and local adaptability, as in the case of the United Kingdom [55]. Therefore, our analysis shows that a single centralized model is not necessarily more effective, as lessons from these experiences, including Australia, suggest that a middle-out approach is more effective, as this blends both by offering central guidance while allowing for local systems to gradually align with national plans [56].

Implementing EHRs requires significant investment, vision, robust management systems, and strong oversight to sustain them, making effective leadership essential for success. Strong leadership plays an important role in guiding decision making, mobilizing the right expertise, and establishing mechanisms to prevent corruption, which increases the likelihood of successful implementation, particularly for large-scale EHRs [57]. Middle-income countries like South Africa and China have the capacity to finance and support EHR adoption, but such efforts can be undermined by corruption and poor governance [49,58]. In some cases, poor leadership and governance stand as significant barriers to achieving universal health coverage and strengthening health systems [59].

Implications for Policy and Practice

Our findings highlight several implications for policy and practice. One of them is the strengthening of accountability in health systems through transparent procurement systems and independent oversight to neutralize the effects of corruption and political patronage. In such cases, procurement frameworks could include pilot-to-scale pathways, where bottom-up innovations such as the E-tick could be formally assessed against national priorities and considered for integration with provincial and national systems. These steps could create a more enabling environment for similar innovations to scale sustainably. Moreover, while the E-tick system was locally hosted, it also incorporated cloud functionality, aligning with the cloud-based EHR architectures promoted in both the NDHS and the national data and cloud policy of South Africa [10,60]. Such policies can be leveraged to mitigate barriers such as reliance on facility servers or hardware failures, challenges already observed with the E-tick, which hold important lessons for similar middle-income country contexts.

Our findings also carry implications for digital health equity, a concept that examines how structural inequities shape the successes and challenges of digital health interventions [61]. In South Africa's dual health system, where private-sector facilities often have better infrastructure and resources than the public sector, grassroots innovations like E-tick are left to face compounded challenges, especially when implemented in low-resource contexts [62]. The stalled scale-up reflects not only outer system or structural barriers by the government but also the broader inequities in digital infrastructure, institutional support, and resourcing across the country's health system [63].

Limitations

Our study incorporates perspectives from a diverse range of stakeholders, including higher-level managers, decision makers, academics, and end users from recipient facilities. This diversity helped in capturing nuanced perspectives from different positions within the system and in closing information gaps through triangulation. A limitation of our study is that data collection from the implementation team, especially clinicians, occurred over a year after the system had halted. As a result, some participants struggled to accurately recall past events, while others had moved to different jobs by the time of data collection. As a result, formal member checking with participants was not possible due to staff turnover and the discontinuation of the E-tick project. However, we validated emerging findings through iterative review with coauthors who included experts in South African health systems and originators who led the implementation from the beginning and had contextual expertise.

Conclusions

In conclusion, the E-tick system is a valuable innovation that was developed from the ground up with user input. While the system showed promise, its long-term sustainability was undermined by external factors such as funding cuts and poor support, political appointments, and corruption, which led to the unwillingness of provincial officials to support local initiatives such as the E-tick. Such bureaucratic inefficiencies also affected the capacity to move forward with another system. This study demonstrates that without alignment to broader factors such as governance, corruption, and skilled leadership, innovative systems such as the E-tick will struggle to be implemented.

Acknowledgments

We would like to thank the study participants for generously sharing their time and experiences. We also acknowledge the support of the implementation team and the provincial and district health authorities for facilitating access to study sites.

Abstract

Background: When used correctly, electronic medical records (EMRs) can support clinical decision-making, provide information for research, facilitate coordination of care, reduce medical errors, and generate patient health summaries. Studies have reported large differences in the quality of EMR data.

Objective: Our study aimed to develop an evidence-based set of electronically extractable quality indicators (QIs) approved by expert consensus to assess the good use of EMRs by general practitioners (GPs) from a medical perspective.

Methods: The RAND-modified Delphi method was used in this study. The TRIP and MEDLINE databases were searched, and a selection of recommendations was filtered using the specific, measurable, assignable, realistic, and time-bound principles. The panel comprised 12 GPs and 6 EMR developers. The selected recommendations were transformed into QIs as percentages.

Results: A combined list of 20 indicators and 30 recommendations was created from 9 guidelines and 4 review articles. After the consensus round, 20 (100%) indicators and 20 (67%) recommendations were approved by the panel. All 20 recommendations were transformed into QIs. Most (16, 40%) QIs evaluated the completeness and adequacy of the problem list.

Conclusions: This study provided a set of 40 EMR-extractable QIs for the correct use of EMRs in primary care. These QIs can be used to map the completeness of EMRs by setting up an audit and feedback system, and to develop specific (computer-based) training for GPs.

KEYWORDS

electronic medical records; primary care; quality assessment; Delphi method; electronic audit and feedback

Introduction

With the advancement of digital technologies, electronic medical records (EMRs) have become the preferred method for recording, storing, and retrieving medical information [1]. The National Alliance for Health Information Technology defined the EMR as “an electronic record of health-related information on an individual that can be created, gathered, managed and consulted by authorised clinicians and staff within one health care organisation” [2,3]. Several studies have shown that the correct use of EMRs may improve the quality and efficiency of care and reduce mortality [4-6]. When used correctly, EMRs can support clinical decision-making (eg, monitoring medication safety) [7-9], facilitate care coordination, reduce medical errors,

XSL•FO
RenderX

and provide information for research [1,10]. EMR data can also be used to generate patient health summaries (PHSs). The PHS is a minimum set of clinically relevant data that can be transferred to other health care workers to support the continuity of care and deliver safe and high-quality care to patients [11,12].

Unfortunately, an observational analysis conducted by the Vlaams Agentschap Zorg en Gezondheid, based on approximately 2000 general practitioners' (GPs) consultations during weekends and holidays in Belgium between 2019 and 2020, revealed that only 32% of patients had a PHS. Several studies have shown that the amount of encoded data registered in EMRs is low (eg, the completeness of height and weight is <76%) [13-16]. Hamade et al [17] suggested that targeting EMR data quality or the use of EMR functions may significantly improve EMR use.

However, there remains a gap in knowledge regarding how to improve the correct use of EMRs [17]. Recently, Ngugi et al [18] developed and validated a set of indicators for the use of EMRs, focusing on the implementation of the EMR, in low- and middle-income countries. There are some guidelines on the good use of EMRs, but none are up to date [19,20]. Appropriate EMR training programs for health care workers and students can improve the use of EMRs; however, an exhaustive list of learning points is lacking [2,21]. Electronic audit and feedback (eA&F) can also be used to improve the correct use of the EMR and, more particularly, the quality of the data stored in the EMR [22]. Ivers et al [23] defined eA&F as "an electronic summary of the clinical performance of health care over a specified period of time aimed at providing information to health professionals to allow them to assess and adjust their performance." To this end, a validated set of quality indicators (QIs) is used. QIs are measurable items that refer to the structures, processes, and outcomes of care [24]. An evidence-based list of QIs, approved by expert consensus, could help develop appropriate training programs and eA&F interventions to improve EMR use [17,25,26]. This study aimed to develop an evidence-based set of electronically extractable QIs approved by expert consensus to assess the good use of EMRs by GPs from a medical perspective.

Methods

Study Design

The RAND-modified Delphi method was used to develop QIs for the use of EMRs from January 2024 to December 2024 based on the method used by Van den Bulck et al [27-29]. The process included the following: (1) development of a questionnaire based on recommendations and existing QIs from evidence-based guidelines and (2) rating procedure by an expert panel in 3 rounds, namely individual written questionnaire, online consensus meeting, and final appraisal.

Selection of Recommendations and Existing QIs

The TRIP database and MEDLINE were searched for guidelines and indicator sets using the following search terms: "Electronic medical records" AND ("Primary Health Care" OR "Primary Care" OR "General Practice") AND ("Standard of Care" OR "guideline" OR "recommendation" OR "quality indicator" OR "quality of health care" OR "quality of care"). The search was also extended to Google Scholar (accessed on April 2, 2024). The sources were selected by the primary researcher using the criteria specified in Textbox 1. Sources were not filtered based on the quality of the methodology because of the limited methodological information in any of the sources found in the first search. An exhaustive list of all indicators and recommendations relevant to EMR quality was compiled. For inclusion, indicators and recommendations were filtered using the specific, measurable, acceptable, realistic, and time-bound (SMART) principle [27-29]. A QI is defined by Grypdonck et al as "a measurable tool to assess the quality of care, including outcome-, process- and patient-oriented indicators" [30]. For recommendations, the following definition provided by the World Health Organization was used: "Recommendations are statements designed to help end-users make informed decisions on whether, when and how to undertake specific actions such as clinical interventions, diagnostic tests or public health measures, to achieve the best possible individual or collective health outcomes" [31]. Screening was performed by 2 independent researchers: a GP (primary researcher) and a methodologist. If there was a difference in the results for an indicator or recommendation between the 2 researchers, they discussed it until a consensus was reached. All remaining items (indicators and recommendations) were then categorized into topics according to the organization of the PHS in Belgium as explained by Domus Medica [19], and comparable with categories defined by Jabaaij et al [13] in the EMR scan for general practitioners: completeness and adequacy of the problem list, encoded registration in the EMR, completeness and actuality of medication list, risk factors and drug monitoring, patient identification and contact information, vaccination status, and patients' choices.

Textbox 1. Selection criteria used to filter articles in the literature.

Inclusion criteria

- Language: English, Dutch, or French
- Evaluation level: microlevel (evaluation at the patient level)
- Source age: indicator sets—any age; recommendations—maximum 10 years
- Target population: primary care providers

Exclusion criteria

- Language: other than English, Dutch, or French
- Evaluation level: mesolevel or macrolevel (regional, national, or other)
- Source age: recommendations published more than 10 years ago
- Target population: hospital physicians

Panel Selection

GPs and EMR developers were invited to participate in the panel via email. Using a purposive sampling technique, priority was given to representing all involved parties at the regional (Flanders, Wallonia, and Brussels) and occupational levels (solo GPs, GPs in group practices, programmers, and academic personnel). The final panel consisted of 18 participants: 11 (61%) Flemish-speaking participants and 7 (39%) French-speaking participants. There were 12 GPs (recently retired: n=1, 6%; worked in a community health center: n=1, 6%; had an individual practice: n=2, 11%; and worked in a group practice: n=8, 44%) and 6 (33%) EMR developers from different EMRs. They were provided with information about the aims and methodology of this study.

Written Questionnaire Round

Completion

An online LimeSurvey questionnaire was presented to a multidisciplinary expert panel (from August 2024 to November 2024) [32]. Each participant was asked to score each item for their capability to measure the quality of EMR use in primary care on a 9-point Likert scale (1=lowest score; 9=highest score). They were asked to base their assessment on the extractability of the indicator or recommendation from the EMR and its possible positive impact on the quality of care. Panel members could also label an item as “not assessable.” At the end of each topic, they were asked to give the top 5 (prioritization) of the items. If a topic did not contain enough items to create the top 5, participants were asked to order half of the indicators in the top X. Finally, all participants could write remarks and add new indicators.

Analysis

The results of the online survey were analyzed using a Node.js (OpenJS Foundation) script to subdivide each item into 3 categories: high, uncertain, or low potential as a QI [33]. The script generated a report for each participant with their responses, a general overview of the calculated parameters (Table 1), and a category based on these parameters (Table 2).

Table 1. Defined parameters to score each quality indicator and recommendation [28].

Parameter	Calculation
Total number of responses	N responses
Likert score	
For each score, the total number of responses	N responses for score
Median Likert score	Median Likert score of all responses
Highest ratings (%)	N responses with a score ≥7 divided by the total number of responses
Prioritization (top %)	Sum of the individual top X scores (eg, first place=score 3, second place=score 2, third place=score 1, and items not ranked in the top 3=score 0) divided by the maximum possible score (N responses × highest possible top score)

XSL•FO
RenderX

Table 2. Selection criteria for indicators and recommendations [28].

Criterion	Selection[a]	Discussion[a]	No selection[a]
Likert score: median	≥7	Any	Any
Likert score: distribution	≥70% with score ≥7	≥30% with score <3	Other
Prioritization (top %)	≥20%	≥1%	<1%

[a]Indicators and recommendations must fulfill all criteria, not only some, to be categorized as either "selection," "discussion," or "no selection."

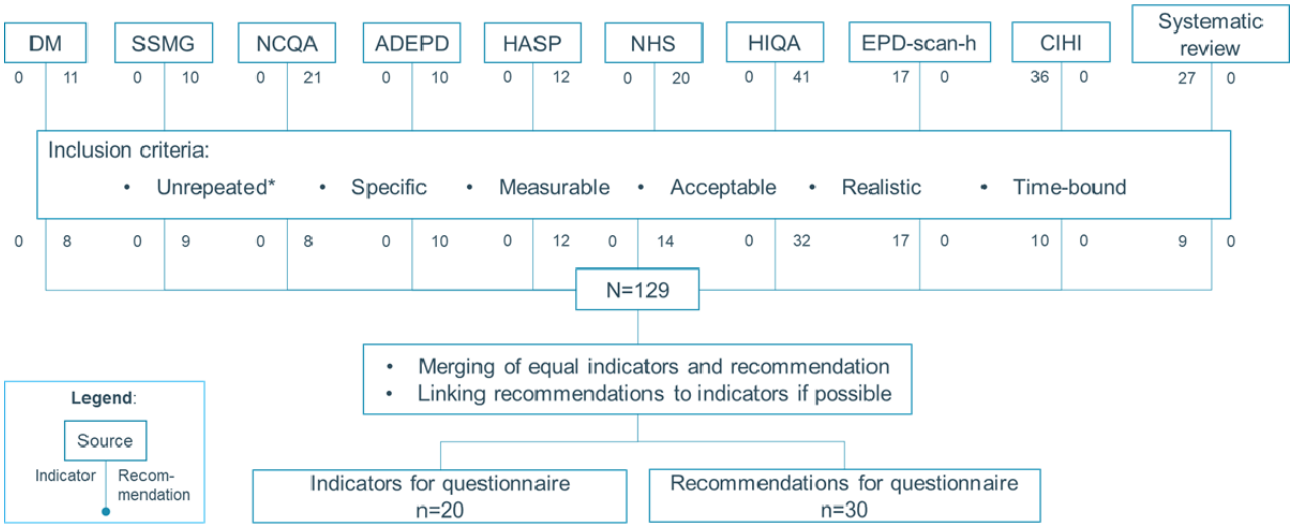
Consensus Meeting Round

Each panel member received an individual feedback report 2 weeks before the consensus meeting. It also included new recommendations and comments. The report contained all items with a color code representing their potential to reach a consensus (Multimedia Appendix 1).

An online consensus meeting was held using Microsoft Teams [34]. To improve the efficiency of the consensus meeting, focus was given to the items categorized as "uncertain," together with the newly added indicators proposed by the panelists. Items with high potential were automatically selected for the final selection unless panel members requested a decision-making discussion. Items with low potential were excluded from the final selection unless the panel members requested deliberation.

All accepted indicators and recommendations were adjusted to the conclusions of the consensus meeting and conformed to the SMART criteria [27-29]. The recommendations were transformed into QIs as percentages. The final report was sent to the panel members for final acceptance in Dutch and French. The final indicator set was translated into English by the researchers.

Ethical Considerations



This study was approved on June 25, 2024, by the Social and Societal Ethics Committee of KU Leuven (G-2024-8020-R2(AMD)). The project was also vetted and approved by KU Leuven's Privacy and Ethics platform in view of the principles and obligations laid down in the General Data Protection Regulation of the European Parliament and the Council of 27 April 2016 [35]. Participants were asked to digitally sign an informed consent form before participation. All data were pseudonymized after the written questionnaire round using a unique identifier. Personal information was separated from other research data in a second file with password protection. The personal data was used to provide the participants the feedback report, to invite them for the consensus meeting round, and to approve the final report. All personal information was deleted after the study was finished. No compensation was provided to the participants.

Results

Extraction of QI and Recommendations

A total of 4 review articles listed QIs for the use of EMRs, containing 27 QIs [13,15,36-38]. Nine guidelines contained 53 QIs and 125 recommendations [11,19,20,39-42]. Where possible, duplicate items were removed, and indicators were linked to similar recommendations in the guidelines. This resulted in a combined list of 20 QIs and 30 recommendations (Figure 1 [11,13,15,19,20,36-42]; Multimedia Appendices 2-4).

Figure 1. Overview of the recommendation and indicator extraction. *Unique: repetitive recommendations were removed. ADEPD: NHG-Richtlijn Adequate dossiervorming met het elektronisch patiëntdossier; CIHI: Canadian Institute for Health Information; DM: Domus Medica; HASP: NHG Richtlijn Informatie-uitwisseling tussen huisarts en medisch specialist; HIQA: Health Information and Quality Authority; NCQA: National Committee for Quality Assurance; NHS: National Health Service; SSMG: Société Scientifique de Médecine Générale [11,14,16,20,21,38-44].

XSL•FO
RenderX

Questionnaire Round

All panel members (18/18, 100%) completed the questionnaire. On the basis of these categories, out of 50 items, 21 (42%) were selected, 27 (54%) required further discussion, and 2 (4%) were excluded.

Consensus Round

Of the 18 panel members, 13 (72%) were present for the consensus meeting—9 (50%) GPs and 4 (22%) EMR developers—8 (44%) of whom were Flemish speaking and 5 (28%) French speaking. In the panel round, none of the preselected indicators (n=7) or recommendations (n=14) were discarded. Of the 10 indicators labeled as "discussion," 7 (70%) were selected, and 1 (10%) indicator was further divided into 7 specific indicators (Multimedia Appendix 1; indicator 3). Of the 17 recommendations labeled as "discussion," 6 (35%) were selected. This resulted in a list of 20 indicators and 20 recommendations (Multimedia Appendix 1). During the consensus meeting, some items that were not yet extractable were included because the panel members felt that their clinical importance should prompt EMR providers to adapt their software.

Final Evaluation

The 20 recommendations were transformed into QIs and added to the 20 other QIs, resulting in 16 (40%) QIs regarding the completeness and adequacy of the problem list, 4 (10%) QIs regarding encoded registration in the EMR, 3 (8%) QIs regarding the completeness and actuality of the medication list, 6 (15%) QIs regarding risk factors and drug monitoring, 4 (10%) QIs regarding patient identification and contact information, 3 (8%) QIs regarding vaccination status, and 4 (10%) QIs regarding patient choices (Textbox 2; Multimedia Appendix 5). All panel members present in the consensus meeting (13/13, 100%) approved the final report.

XSL•FO
RenderX

Textbox 2. Quality indicators for the good use of electronic medical records (EMRs) in primary care.

Topic 1: completeness and adequacy of the problem list

1.1 The mean of active problem items listed on a patient's problem list

1.2 Percentage of items on the problem list that are linked to an encoded diagnosis

1.3 Percentage of patients with medication for thyroid disease in their medication list with an encoded diagnosis of thyroid disease on the problem list

1.4 Percentage of patients with medication for epilepsy in their medication list with an encoded diagnosis of epilepsy on the problem list

1.5 Percentage of patients with medication for Parkinson disease in their medication list with an encoded diagnosis of Parkinson disease on the problem list

1.6 Percentage of patients with medication for depression in their medication list with an encoded diagnosis of depression on the problem list

1.7 Percentage of patients with medication for cardiovascular disease in their medication list with an encoded diagnosis of cardiovascular disease on the problem list

1.8 Percentage of patients with medication for asthma or chronic obstructive pulmonary disease in their medication list with an encoded diagnosis of asthma or chronic obstructive pulmonary disease on the problem list

1.9 Percentage of patients with medication for diabetes in their medication list with an encoded diagnosis of diabetes on the problem list

1.10 Percentage of encoded items in the problem list with an additional description or comment

1.11 Percentage of encoded items in the problem list for which the estimated or actual date of onset has been registered

1.12 Percentage of inactive items on the problem list for which the estimated or actual date the condition was resolved has been registered

1.13 Percentage of surgeries and other procedures that have been registered as an encoded item

1.14 Percentage of surgeries and other procedures in the patient history that have been linked to the related episode of care

1.15 Percentage of surgeries and other procedures in the patient's history with an additional description or comment

1.16 Percentage of surgeries and other procedures in the patient summary for which the date and/or time on which the procedure was or is intended to be performed is registered

Topic 2: encoded registration in the EMR

2.1 The mean number of subcontacts created per contact during the observation period

2.2 Percentage of subcontacts during the observation period connected with an episode of care

2.3 Percentage of subcontacts (registered as consultation, home visit, or teleconsultation) with a subjective, objective, evaluation, and planning item

2.4 The number of patients with a global medical record in the practice with changes in the status of tasks (procedures or actions) over the total number of patients with a global medical record in the practice

Topic 3: completeness and actuality of the medication list

3.1 Percentage of medications on the medication list labeled as *active* that are no longer active

3.2 Percentage of active medications on the medication list that are linked to a health condition on the problem list

3.3 Percentage of active medications on the medication list for which the dosage and treatment regimen are complete

Topic 4: risk factors and drug monitoring

4.1 Percentage of patients with at least 1 registration for a drug allergy or intolerance

4.2 Percentage of patients with a registration for a risk factor; risk factors include clinical information that is imperative to know so that the life or health of the patient is not threatened, for example, prophylaxis for adrenal crisis (Addison disease), endocarditis, bleeding disorders, endoprosthesis, patients who are immunocompromised, (functional) asplenia, thrombosis, or particularly resistant microorganisms

4.3 Percentage of patients with at least 1 encoded registration for a physical examination (weight, height, blood pressure, and pulse)

4.4 Percentage of patients with at least 1 registration of an item for social history

4.5 Percentage of patients aged 12 years and older for whom there is at least 1 notation concerning the use of cigarettes, alcohol, and substances

4.6 Percentage of patients with at least 1 registration of an item for family medical history

Topic 5: patient identification and contact information

5.1 Percentage of patients with a registration for hospital preference

5.2 Percentage of patients with at least 1 registration of contact information for a contact person, caregiver, or person designated as representative

5.3 Percentage of patients with at least 1 registration of a health care professional in their care team

XSL•FO
RenderX

5.4 Percentage of patients with at least 1 registration for address, email, employer, home and work phone, marital status, registration status on patient platform (eg, Helena [43]), or cohousing people and animals

Topic 6: vaccination status

6.1 Percentage of patients aged 7 years and older who have a registration for all the recommended primary childhood vaccines

6.2 Percentage of patients aged 65 years and older who have a registration for a yearly influenza vaccine

6.3 Percentage of vaccinations for which the date the vaccination was administered is registered

Topic 7: patient choices

7.1 Percentage of patients with a registration of treatment preferences: euthanasia request or refusal for intubation, resuscitation, organ donation, vaccination, or blood transfusion

7.2 Percentage of patients with at least 1 contact with a subjective, objective, evaluation, or planning item linked to an encoded diagnosis regarding treatment preferences or end-of-life care

7.3 Percentage of patients with at least 1 registration of a goal for personalized care (goal-oriented care)

7.4 Percentage of patients with at least 1 registration regarding preferences for preventive health care

Discussion

Principal Findings and Comparison With Prior Work

This study used the RAND-modified Delphi method to validate a set of 40 QIs for the correct use of EMRs by GPs based on the indicators and recommendations found in the literature. These indicators are (potentially) EMR extractable and evaluate key aspects of EMR use by GPs: completeness and adequacy of the problem list, encoded registration, completeness and actuality of the medication list, risk factors and drug monitoring, patient identification and contact information, vaccination status, and patient choices. Using the SMART principle, we ensured that the QIs could be evaluated in clinical practice [27-29,44-46].

Previously, Jabaaij et al [38] developed the EMR scan for general practitioners in the Netherlands to evaluate EMR use. However, the method they used to define QIs was unclear. Ngugi et al [18] developed and validated a set of indicators for the use of EMRs in low- and middle-income countries. Their QIs mostly evaluated the general use of the EMRs (eg, indicator 7, "% of required data elements contained in EHRs"). Our study focuses on how data are registered and encoded in EMRs, focusing on which data are registered [18]. Other indicator sets were either outdated (aged >20 years) [36], focused on clinical performance instead of use of the EMR [15], or evaluated EMR use on the mesolevel or macrolevel instead of the microlevel [37]. Hamade et al [17] noted that while there are many studies on the implementation of EMR, there is a scarcity of studies on its use.

Most of the selected indicators evaluated the completeness and adequacy of the problem list. The problem list provides important information for decision-making [47]. Our indicators are primarily process indicators because they focus on the process of EMR registration (ie, use). However, these QIs cannot be directly linked to patient outcomes. Process indicators are useful for quality assessment. They are more sensitive to differences in quality than outcome measures and are easier to interpret [48]. Recent literature shows an interest in eA&F [22,29], dashboard interface features to support reflection on practice ("barometers") [27-29], and computer-based decision support in primary care [49]. The quality of data in EMRs impacts the effectiveness of these systems. Several studies have shown that improving data quality may improve the quality and efficiency of care and reduce mortality [4-6]. Unfortunately, data show that physicians spend approximately two-thirds of their work time interacting with EMRs in their offices. This administrative burden negatively impacts clinicians' wellness, leading to an increased chance of burnout. Recently, the interest in the use of artificial intelligence for analyzing data, identifying hidden information, identifying risks, and providing suggestions for diagnosis has increased rapidly. This can greatly facilitate the process for GPs to easily improve data quality without spending more time entering data in the EMR and less time interacting with patients [50]. GPs should not need to adapt their working habits to the capabilities of their medical software; rather, EMRs should be adapted to the needs of GPs to facilitate the correct registration of data [51]. An important lever to encourage EMR developers to align their software more closely with clinicians' data entry and retrieval needs lies in regulatory frameworks, such as homologation. This is a certification procedure to evaluate the mandatory standards and certification requirements that EMRs must fulfill to be approved for use within the health care system [52]. By embedding QIs derived through expert consensus, such as those developed in this study, into these frameworks, regulators can create explicit performance benchmarks that EMRs must meet. This alignment incentivizes developers to design functionalities that facilitate accurate, complete, and efficient data capture and reporting by clinicians [50].

Strengths and Limitations

Our panel included members working in all parts of Belgium and in all types of practices, giving it broad support. Because our panel included health professionals and EMR developers, we were able to define clinically relevant indicators that considered the technical requirements for extractability. During the consensus meeting, the EMR developers emphasized that these indicators could possibly stimulate GPs to use the features they have already developed more extensively. We are convinced that their opinion was a valuable addition to the panel. EMR developers were the most capable of assessing whether a QI could be automatically extracted from the EHR data. However, we cannot exclude a potential bias caused by their

XSL•FO
RenderX

inclusion (eg, the ease or cost of addressing a recommended QI outweighing the importance of making that QI available from a public health perspective). The scarcity of literature on the initial set of QIs and recommendations is a double-edged sword for our study. On the one hand, it limits the strengths of the initial set of QIs and recommendations because none of our sources used a systematic approach to evaluate the validity of their QIs and recommendations, had a well-explained methodology [13,15,36-38], or could be evaluated using the Appraisal of Guidelines for Research and Evaluation II method [11,19,20,39-42]. On the other hand, this allowed us to conduct a broad and general search on the topic, which could increase its universal applicability. There are many differences between countries in terms of how and which data are registered [11,19,20,39-42]. We attempted to generalize the QIs and recommendations as much as possible. However, adaptation to the local context is necessary. Another important limitation is that some indicators are not currently extractable. However, as mentioned earlier, these indicators reflect aspects of clinical practice that are important enough to warrant adaptation of EMRs to include this information.

Future Research Directions

This set of indicators is important for future research on EMR use. Developing a list of QIs is the first step in implementing a strategy and realizing a quality loop. The next essential step is to conduct practice testing for operational validity [29]. These results can be used to create an eA&F system [22,23]. This set of QIs can also be used to develop specific (computer based) training for GPs based on a set of learning goals [2]. It should be noted that our QIs can be used for the correct use of EMRs but cannot be used to quantify the quality of care provided by GPs. Further research is necessary to evaluate whether the correct use of the EMR, as proposed in this set of QIs, also affects the quality of care provided to patients and its possible effect on the data in the PHS.

Conclusions

This study provided a set of 40 EMR-extractable QIs for the correct use of EMRs in primary care based on international guidelines and approved by GPs and EMR developers. These QIs can be used as a framework to measure and improve the quality and completeness of EMRs in primary care.

Acknowledgments

The authors would like to thank all the participating panel members for the many hours they spent in this study.

Funding

This study was conducted by UZ Leuven and KU Leuven at the request of Rijksinstituut voor ziekte- en invaliditeitsverzekering–Institut national d’assurance maladie-invalidité and funded by Rijksinstituut voor ziekte- en invaliditeitsverzekering–Institut national d’assurance maladie-invalidité as part of a national project to improve medical care in Belgium.

Data Availability

The datasets generated or analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

RP conducted the literature search and organized each step of the Delphi procedure as part of his PhD project. LM assisted during each step of the Delphi procedure. SVdB oversaw the whole process and helped to draft the manuscript. BV and WR supervised the entire process from the beginning to the end and helped draft the manuscript. MDJ and BF were part of the panel during the Delphi procedure and helped draft the final manuscript. All the authors have read and approved the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: A rapidly aging population led to an increase in the number of patients with chronic diseases and polypharmacy. Although investigations on the appropriate number of drugs for older patients have been conducted, there is a shortage of studies on polypharmacy criteria in older inpatients from multiple institutions.

Objective: The aim of this study was to examine the patterns of polypharmacy and determine the criteria for the number of drugs defining polypharmacy in the geriatric inpatient population.

Methods: Electronic health records of 4 medical institutions for patients aged 65 years and older hospitalized between January 1, 2012, and December 31, 2020, were analyzed for the study. The maximum number of drugs prescribed was obtained for each patient and, along with a literature review, was used to determine the appropriate polypharmacy level for our population.

Results: We suggest a 4-level polypharmacy category system consisting of nonpolypharmacy, polypharmacy, major polypharmacy, and excessive polypharmacy based on a review of international guidelines and polypharmacy literature. Application of this system to our study population showed that the major polypharmacy category (use of 10-19 concurrent drugs) was an appropriate threshold for polypharmacy in hospitalized patients versus the traditional threshold of 5 or more concurrent drugs. The tendency of our study population to have a higher disease and drug count supports this threshold. Frequently prescribed therapeutic subgroups in this category were antibacterials for systemic use, anesthetics, and cardiac therapy.

XSL•FO
RenderX

Conclusions: This study proposes a polypharmacy categorization system for older inpatients, which differs from the common definition of the concomitant prescription of 5 or more drugs. The older population tends to have severe conditions including those requiring major surgeries; therefore, a drug count corresponding to the definition of major polypharmacy is appropriate.

Introduction

South Korea is reported to have the highest rate of aging among the Organisation for Economic Cooperation and Development countries, where 8.2 of 51.8 (15.7%) million people in 2020 were aged 65 years or older [1]. The prevalence of chronic diseases in this population was found to be 8481 of 10,097 (84%) individuals aged 65 years or older, making it highly likely that the cost of health care is increasing [2]. This requires close review and consideration of effective measures to prevent and treat chronic diseases and adverse events from polypharmacy.

With the increase in lifespan and aging population in South Korea, patients commonly have multiple concomitant diseases. Consequently, patients visit 1 or more health care institutions and are prescribed medications that expose them to polypharmacy [3]. In 2006, Intercontinental Marketing Statistics Korea found that an average of 4.16 medications were prescribed per health care appointment, which was the highest among the 10 countries studied [2]. A study using the South Korean health claims data of 2016-2019 reported that in 2016, a total of 1548 of 47,631 (3.3%) individuals aged 45 years or older experienced polypharmacy, defined as the use of 10 or more medications for at least 60 days, and this rate increased gradually up to 2019, where 2012 of 48,249 (4.2%) individuals aged 45 years or older were on polypharmacy [4]. To ensure that older adult patients receive appropriate drug therapy, the Korean Health Insurance Review & Assessment Service launched the Drug Utilization Review program. This provides real-time assessment of inappropriate patient drug therapy, including the use of duplicative drug ingredients or drugs of different therapeutic classes, inappropriate drugs for older adults, or drugs not to be used in combination [5].

Considering that older adults have decreased physiological functions and often have several chronic diseases, they are at a higher risk of polypharmacy and hospitalization. The use of at least 5-6 drugs is a definition widely used for polypharmacy in the ambulatory population, and several studies report 25% or more older adults on polypharmacy [2,6-9]. However, this definition may not be practical for the hospitalized older adult population, as this demographic tends to receive more treatments for multiple diseases. Previously reported definitions of polypharmacy in the geriatric hospitalized population were the prescription of 5-9 medications and that of hyper-polypharmacy were 10 or more medications [10,11]. There were also cases of using 5 or more drugs as the definition of polypharmacy for hospitalized patients [12,13]. Although definitions of polypharmacy applicable to older hospitalized patients exist, most studies use single-institution prescription data, making the findings difficult to generalize. Studies from multiple institutions are needed to determine and apply definitions of polypharmacy in the geriatric inpatient population.

Previous studies have used various data sources and methods to define polypharmacy. Data sources included health insurance claims, electronic medical records, spontaneous adverse drug event (ADE) reports, and surveys. The methods used to define polypharmacy include simple numeric definitions, numeric definitions with terms of duration in a therapy or health care setting, and nonnumeric descriptive definitions [14]. Definitions of polypharmacy are diverse due to differing patient age, underlying disease, and disease severity. Accordingly, it is necessary to review the existing definitions of polypharmacy to understand the categories used in various clinical settings and to apply the most appropriate method when assessing the status of polypharmacy in the study population.

Kim et al [2] reported that approximately 6.30 million patients aged 65 years or older in South Korea were prescribed drugs for at least 90 days during 2018, and among this population, 2.64 (41.9%) million were prescribed 5 or more drugs, and 0.77 (13.9%) million were prescribed 10 or more drugs. Cresswell et al [15] reported an increased risk of ADEs with a higher number of prescribed drugs. The older adults were especially at risk of serious long-term outcomes, including death and disability, from these ADEs [15]. Ensuring safer therapy for this population is important. Hanlon et al [16] found that in 167 adults aged 65 years and older, ADEs occurred in 58 (35%), and the most frequent ADEs were gastrointestinal disorders. This was followed by ADEs of the nervous, respiratory, endocrine, skin, and subcutaneous systems [16]. Among the 58 patients who had an ADE, 49 (84%) patients required medical care: 37 (63%) were examined by a physician, 7 (11%) were hospitalized, and 5 (10%) visited the emergency room [16]. Mabuchi et al [17] compared the number of drugs used in patients with a spontaneous ADE report to the overall patient population in Japan using real-world data. In both populations, the number of drugs used increased with age [17].

This study used anonymized electronic health record (EHR) data converted to the Observational Medical Outcomes Partnership (OMOP) Common Data Model (CDM) format, a standardized data structure that accommodates retrospective observational studies [18]. The OMOP CDM data content is generated by extracting EHR data recorded during patient care, removing personal identifiable information, transforming the data into a standardized structure, and mapping hospital-specific terms to standardized, controlled vocabularies. Each CDM in the 4 institutions included patient demographic, condition, measurement, procedure, and drug prescription information [19]. Overall, we examined the characteristics and patterns of polypharmacy in older hospitalized adults across 4 health care

XSL•FO
RenderX

institutions (presented as medical institutions A-D) and created a polypharmacy categorization system for this population. Specifically, for each polypharmacy category, we characterized the drugs and drug classes prescribed to the population of interest and examined their drug use patterns.

Methods

Study Participants and Observation Period

EHR data of 4 medical institutions converted to the OMOP CDM format were used to analyze polypharmacy patterns. The study participants were patients aged 20 years or older hospitalized at one of these 4 institutions between January 1, 2012, and December 31, 2020. The number of patients aged 20 years or older who visited the medical institutions in the study period ranged from 494,875 to 3,349,795. The number of hospitalized patients, hospitalization events, hospitalized patients aged 60 years and older, and the number of drug classes prescribed to the overall hospitalized patients are presented in Table 1.

To extract study participants, we consulted clinicians from medical departments who frequently encountered polypharmacy. The patient visit types were restricted to inpatients. The earliest date of patient admission was the patient study entry date; if the discharge date of this admission and the admission date of the next admission were within 30 days, the 2 admissions were treated as a single continuous admission period. To investigate the status of discharge drug use, drug exposure data from the outpatient setting were followed up for 7 days after patient discharge. For example, if the patient had 2 admission episodes, the total admission period would be the sum of the duration of admission 1 in days, 7 days after discharge from admission 1, the duration of admission 2 in days, and 7 days after discharge from admission 2 (Figure 1).

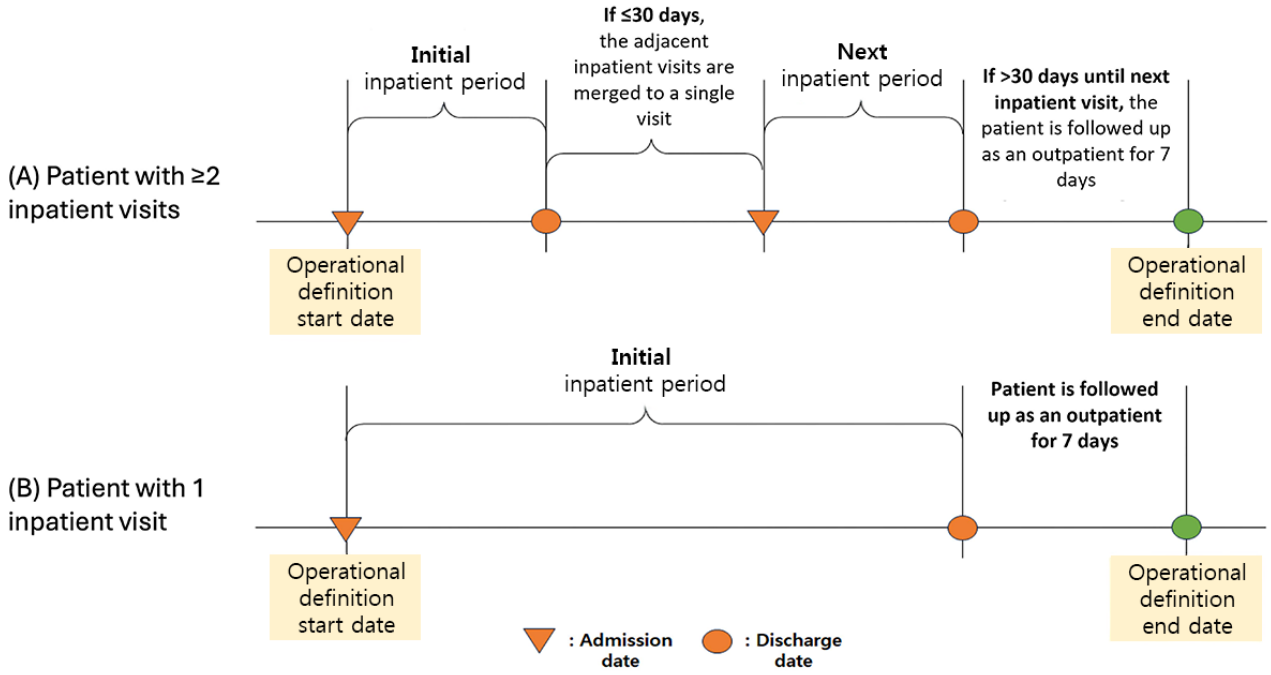

Table 1. Patient characteristics by medical institution.

	Medical institution A	Medical institution B	Medical institution C	Medical institution D
Patients, n (%)	602,483 (100)	1,944,140 (100)	3,349,795 (100)	494,875 (100)
Hospitalized patients, n (%)	169,931 (20.2)	405,956 (20.9)	419,460 (12.5)	128,700 (26)
Hospitalization events, n (%)	315,624 (100)	1,092,936 (100)	871,764 (100)	212,489 (100)
Older hospitalized adults aged ≥60 years, n (%)	48,512 (8.1)	166,071 (8.5)	113,573 (3.4)	33,997 (6.9)
Drug therapeutic subgroups (WHO[a] ATC[b] second-level codes [20]) prescribed, distinct n (%)	79 (84)	86 (91.5)	72 (76.6)	81 (81.2)

Polypharmacy Level

This study examined the distribution of patients by polypharmacy level for each medical institution. The polypharmacy levels increase by the number of concomitant drugs prescribed to the patient. The cutoff values for concomitant drug counts in each polypharmacy level were determined based on internationally recommended thresholds and existing literature on polypharmacy in older adults. The World Health Organization (WHO) and several countries defined the use of 5 or more drugs as polypharmacy [1,14]. WHO differentiates between appropriate and inappropriate polypharmacy by defining appropriate polypharmacy as evidence-based, personalized medication prescribing and inappropriate polypharmacy as irrational, excessive prescribing [21]. It emphasizes the importance of reducing inappropriate polypharmacy by continuously ensuring the appropriate, rational use of medications [21]. The European Geriatric Medicine Society states that polypharmacy patients should be closely managed through medication reviews to prevent inappropriate polypharmacy [22]. The National Institute for Health and Care Excellence recommends monitoring the benefits and harms of each drug taken by adults using 15 or more regular medications [23].

Masnoon et al [14] used concurrent drug counts, admission duration, and treatment duration to define polypharmacy, and Young et al [24] determined the category of polypharmacy by the number of concomitant drugs and the presence of high-risk drugs in the patient's drug regimen. Studies on hospitalized, older patients used polypharmacy levels other than the widespread definition of 5 or more drugs [25-27]. An investigation of the physical performance of hospitalized older patients defined polypharmacy as the use of 10 or more drugs during hospital stay [26]. A study analyzing risk factors of increased hospital stay in older adults defined polypharmacy as the concomitant use of 5 to 9 drugs and excessive polypharmacy as 10 or more drugs [25]. The polypharmacy definition for nursing home patients as well as older populations in general was also 5-9 concurrent drugs, and that of excessive polypharmacy was 10 or more concurrent drugs [27-29]. Kim et al [30] divided polypharmacy into 3 levels: concomitant use of 6 or more drugs as polypharmacy, 11 or more drugs as major polypharmacy, and 21 or more drugs as excessive polypharmacy [30].

Based on WHO recommendations and the literature search mentioned earlier, we suggested a polypharmacy categorization method to detect regimens, including an excessive number of drugs, with an aim to assist in detecting inappropriate polypharmacy (Table 2). Polypharmacy was defined as concomitant prescription of 5 or more drugs, which is consistent with the widespread definition [14] and based on previous studies on polypharmacy in older adults. The next severe polypharmacy level, which was major polypharmacy, was defined as the prescription of 10-19 drugs. This threshold was used, as it was commonly used in the older patient population [25-29]. The most severe polypharmacy level, excessive polypharmacy, was defined as the prescription of 20 or more drugs based on a previous study of polypharmacy use among older adults [30].

Table 2. Definition of polypharmacy based on the number of concomitant drugs.

Concomitant drugs, n	Polypharmacy category
<5	Nonpolypharmacy
5-9	Polypharmacy
10-19	Major polypharmacy
≥20	Excessive polypharmacy

Data Preprocessing and Data Analysis Environment

Preprocessing of the medical institution data was performed by converting the EHR to the OMOP CDM (version 5.3.1) format. We used the following inpatient data extracted from the CDM tables: person, drug_exposure, and visit_occurrence. The data for each CDM table were extracted for the years 2012-2020. Using drug_exposure OMOP CDM data, the severity of polypharmacy and drug use patterns in the patients were analyzed. Based on clinical professional consultation, the study patients were divided into those with 1 admission and those with 2 or more admissions. The operational definition of continuous admission was applied to the data of patients with multiple admissions within 30 days to obtain the final admission counts. Drug exposure data in the outpatient setting for 7 days after follow-up were extracted for each patient. We extracted the drug exposure data for all patients during their observation period and for each day of drug exposure and counted the number of drug ingredients exposed to the patient. The date of the maximum number of dispensed drug ingredients was determined. If the patient was exposed to this maximum number of drug ingredients for multiple days, the date closest to admission was used as the date of the maximum drug ingredient count. The drug ingredient count on that date was used to determine the patient's polypharmacy level. To perform the drug ingredient mapping process, we excluded patients without at least 7 days of drug exposure data after discharge.

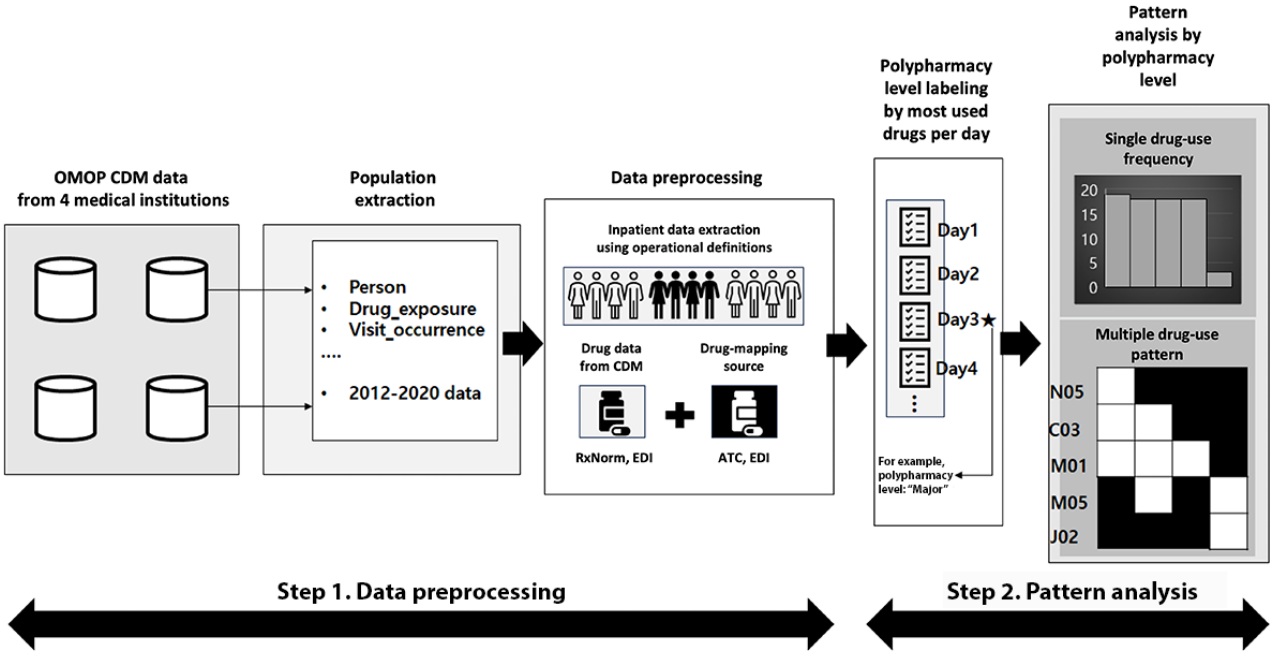
Data processing and analyses were performed using R (version 4.1.3; R Foundation for Statistical Computing). Specifically, CDM data access, extraction, and conversion into variables were performed using R packages *RpostgreSql* (version 0.7-8) [31] and *sqldf* (version 0.4-11) [32]. R packages used for data preprocessing were *dplyr* (version 0.8.3) [33] and *data.table* (version 1.12.2) [34], and that used for descriptive analyses was *moonBook* (version 0.3.1) [35]. The *ggplot2* (version 3.2.1) [36] R package was used for data visualization. Medical institute A used 16 GB RAM in the Windows operating system (OS), medical institutes B and C used 64 GB RAM in the Windows

XSL•FO
RenderX

OS, and medical institute D used 128 GB RAM in the Windows OS.

Polypharmacy Pattern Analysis

For each patient, we mapped the WHO Anatomical Therapeutic Chemical (ATC) code to each drug exposure event in the OMOP CDM. Medical institutions A, C, and D assigned WHO ATC codes to drugs in the OMOP CDM using electronic data interchange (EDI) codes. This is possible because the EDI codes are loaded into the institutional CDM. Mapping the WHO ATC codes to EDI codes required a file with code information for drugs distributed in South Korea provided by the Korea Pharmaceutical Information Service [37]. Korea Pharmaceutical Information Service, operated by the Health Insurance Review & Assessment Service, assigns WHO ATC codes to drugs approved in South Korea. The code information file includes EDI, WHO ATC, and drug ingredient codes for each drug approved; therefore, assigning WHO ATC and drug ingredients to each drug in the OMOP CDM was possible. Traditional Korean medications and drugs without WHO-ATC, EDI, and drug ingredient codes were excluded from the mapping process.



Medical institution B did not have EDI codes available in the OMOP CDM; therefore, a different approach was used to assign WHO ATC codes to the drug concept IDs. This institution maps the WHO ATC code to each drug in the CDM drug_exposure table using the concept and concept_ancestor tables. If the drug_concept_id in the drug_exposure table was a descendant_concept_id of an ancestor_concept_id indicating a fifth-level WHO ATC code, then the concept_id and WHO ATC codes were mapped to the drug_concept_id. The concept table was used to determine if the ancestor_concept_id was a WHO ATC code, and the concept_ancestor table was used to determine if drug_concept_id was a descendant_concept_id of a WHO ATC code.

The maximum daily drug ingredient count was used to determine the polypharmacy level. A maximum drug ingredient count of less than 5 drugs was considered nonpolypharmacy, 5-9 drug ingredients as polypharmacy, 10-19 drug ingredients as major polypharmacy, and 20 drug ingredients or more as excessive polypharmacy.

Demographic characteristics were analyzed using the processed CDM data. The characteristics examined included the total number of inpatients and their admissions, patient age, precautionary drug use, proportion of older adults, admission duration, and drug ingredient exposure distribution for the years 2012-2020.

We performed single and combination drug class pattern analyses using the second ATC level as the unit for the drug class. This level was selected, as it represents clinically meaningful therapeutic groups, allowing the comparison of prescribing trends across multiple health care institutions. We excluded drugs in the ATC second-level B05 (blood substitutes and perfusion solutions) for the analyses, as these drugs have a low risk of interacting with other drugs, have little clinical significance, and are used in the majority of inpatients. [38]. The drug use patterns were visualized using the *ggplot2* R package. Single-drug class use patterns were analyzed by determining the number of patients using each drug class at least once. Combination drug class patterns were analyzed by first determining the date of the highest number of drugs prescribed for each patient and examining the drug classes used on that date. The workflow of the study is depicted in Figure 2.

Ethical Considerations

The study was conducted in accordance with the Declaration of Helsinki and approved by the institutional review board of Konyang University Hospital (protocol code: KYUH2022-07-015-001, approved on September 21, 2022), Asan Medical Center (protocol code: 2022-0342, approved on October 21, 2022), Seoul National University Hospital (protocol code: E-2209-069-1358, approved on September 20, 2022), and Chungbuk University Hospital (protocol code: CBNUH2022-09-030, approved on October 18, 2022). Patient consent was waived, as the data were collected during the routine care of physicians and removed of personally identifiable information, therefore eliminating the risk of compromising patient privacy. There was no direct contact with any patients during the course of this study, and no compensation was provided to the participants.

Results

Polypharmacy Levels and Their Drug Use Patterns

The mean maximum daily drug counts in older adults aged 60-69, 70-79, and ≥80 years were highest in patients admitted to medical institution B followed by medical institution A. Duration of admission increased with higher age range in medical institution C. In all institutions except for institution A, the average hospitalization period of the population aged 70 years or older was longer than the population aged 60-69 years (Table 3).

Table 3. Multi-institutional maximum daily number of drugs prescribed and duration of hospitalization in older adults.

Age group (years)	Medical institution A		Medical institution B		Medical institution C		Medical institution D

Older Adult Polypharmacy Levels Based on Multi-Institutional CDM Data

The level of polypharmacy with the most patients was major polypharmacy in medical institutions A, C, and D, while for medical institution B, this was excessive polypharmacy (Table 4).

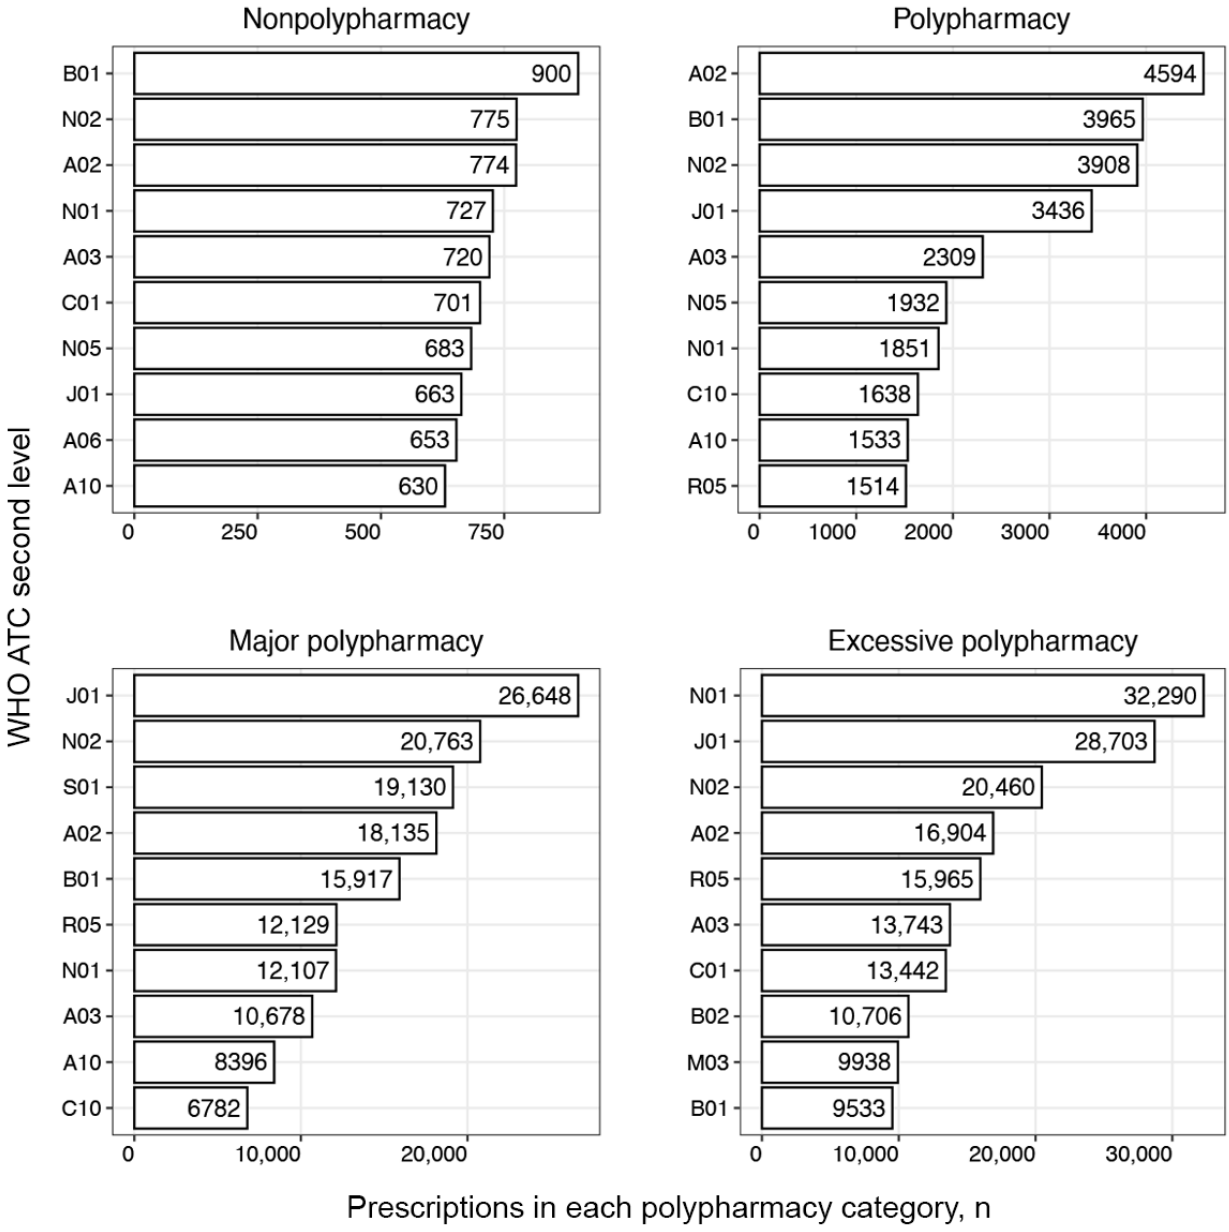
Multi-Institute CDM-Based Polypharmacy Pattern

The pattern of polypharmacy in the older adults was analyzed based on the use of single or combinations of drug therapeutic subgroups (WHO ATC second-level codes). The older population was defined as adults aged 65 years and older, based on the population grouping method of the National Statistical Office of Korea [1].

Single Drug Use Patterns

We examined frequently prescribed drug therapeutic subgroups using second-level WHO ATC codes as the subgroup unit. The 10 most frequently prescribed subgroups for each medical institution are presented in Figures 3-6. The horizontal axis represents the number of prescriptions for drugs included in the therapeutic subgroup specified on the vertical axis. According to the 10 most frequently prescribed therapeutic subgroups, the number of prescriptions tended to increase with higher levels of polypharmacy in all medical institutions, excluding institution C. The highest prescription frequency in this institution was observed at the major polypharmacy level.

For medical institution A, the antithrombotics (B01) therapeutic subgroup was frequently prescribed in patients in the nonpolypharmacy and polypharmacy levels compared to other levels and antibacterials for systemic use (J01) for the major and excessive polypharmacy levels. Notably, drugs in the anesthetic (N01) subgroup were most frequently prescribed to patients with excessive polypharmacy (Figure 3).



In medical institution B, patients in all polypharmacy levels except the excessive level were most frequently prescribed analgesics (N02). The most frequently prescribed therapeutic subgroups for patients with excessive polypharmacy included mineral supplements (A12) and antianemic preparations (B03). Patients in all polypharmacy levels were frequently prescribed antibacterial agents for systemic use (J01) and drugs for acid-related disorders (A02). Patients in the major polypharmacy level were frequently prescribed cardiac therapy (C01) and drugs for constipation (A06; Figure 4).

In medical institution C, the analgesic (N02) therapeutic subgroup was prescribed most frequently to patients in all polypharmacy levels. Cough and cold preparations (R05) were relatively frequently prescribed to patients in the nonpolypharmacy level, and lipid-modifying drugs (C10) and antithrombotics (B01) to patients in the polypharmacy level. Anesthetics (N01) were prescribed more frequently to patients in major and excessive polypharmacy levels than to those in other polypharmacy levels (Figure 5).

In medical institution D, antibacterials for systemic use (J01) and analgesics (N02) were prescribed frequently to patients across all polypharmacy levels. Drugs for acid-related disorders (A02) were frequently prescribed to patients in all polypharmacy levels, excluding the excessive level, whereas antihemorrhagics (B02) and anesthetics (N01) were most frequently prescribed to patients in the excessive level (Figure 6).

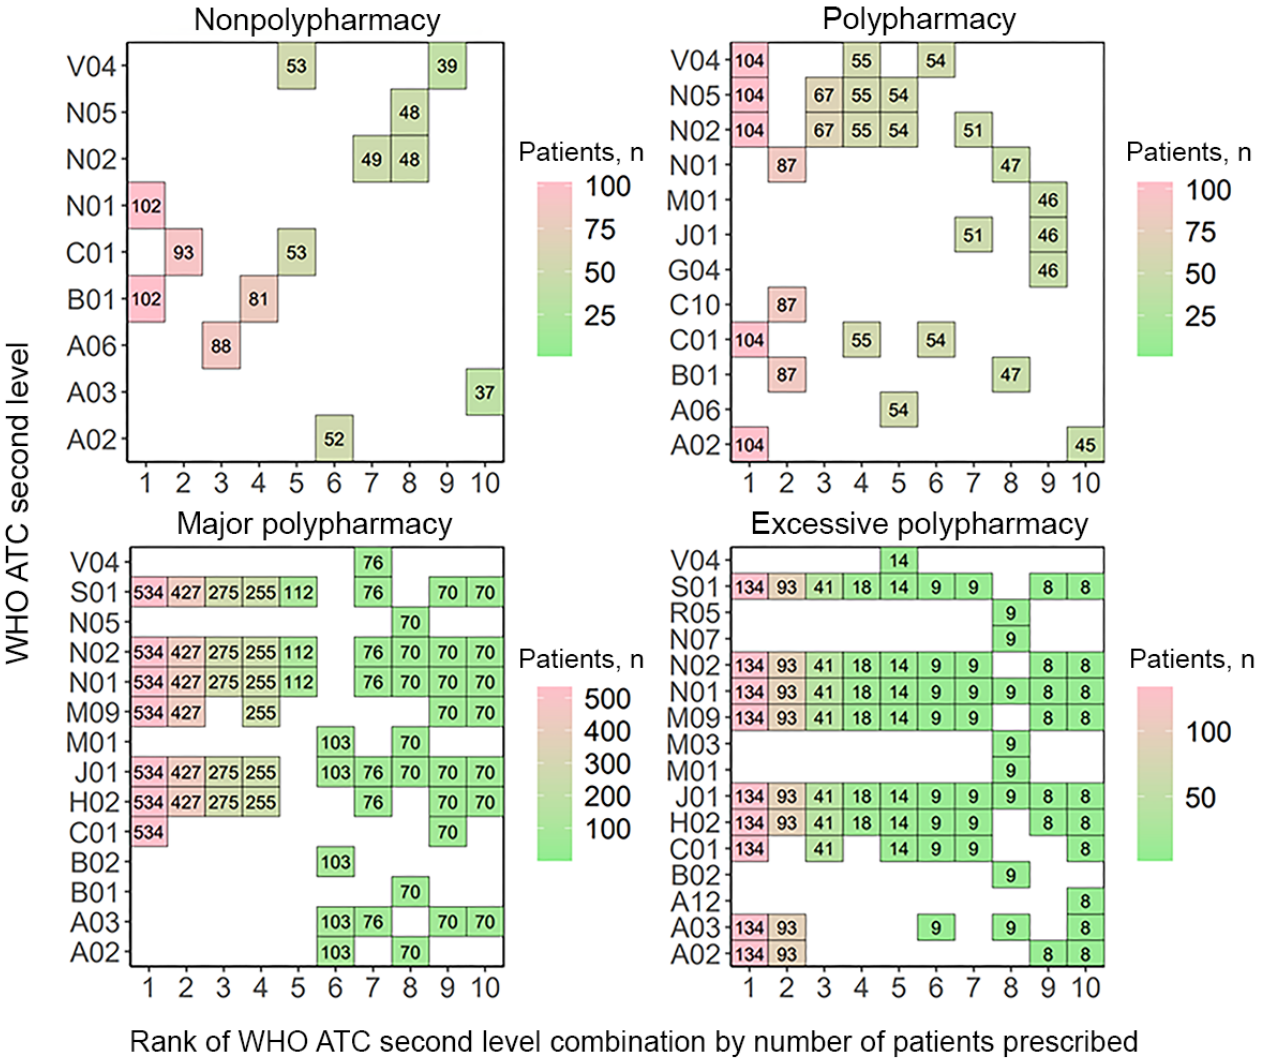
Concomitant Drug Use Patterns

Following the examination of single therapeutic subgroup patterns, concomitantly used therapeutic subgroups were analyzed to determine the trends in combination drug use in patients with polypharmacy. At medical institution A, the most frequently prescribed therapeutic subgroup combination for patients of the nonpolypharmacy level was B01 and N01. For patients in the polypharmacy level, A02-C01-N02-N05-V04 was the most frequently prescribed combination. Patients in the major polypharmacy level were most frequently prescribed with the therapeutic subgroup combination C01-H02-J01-M09-N01-N02-S01, while patients in the excessive polypharmacy group were most frequently prescribed the combination A02-A03-C01-H02-J01-M09-N01-N02-S01 (Figure 7). The full names for each of the therapeutic subgroups denoted as WHO ATC second-level codes are in Multimedia Appendix 1.

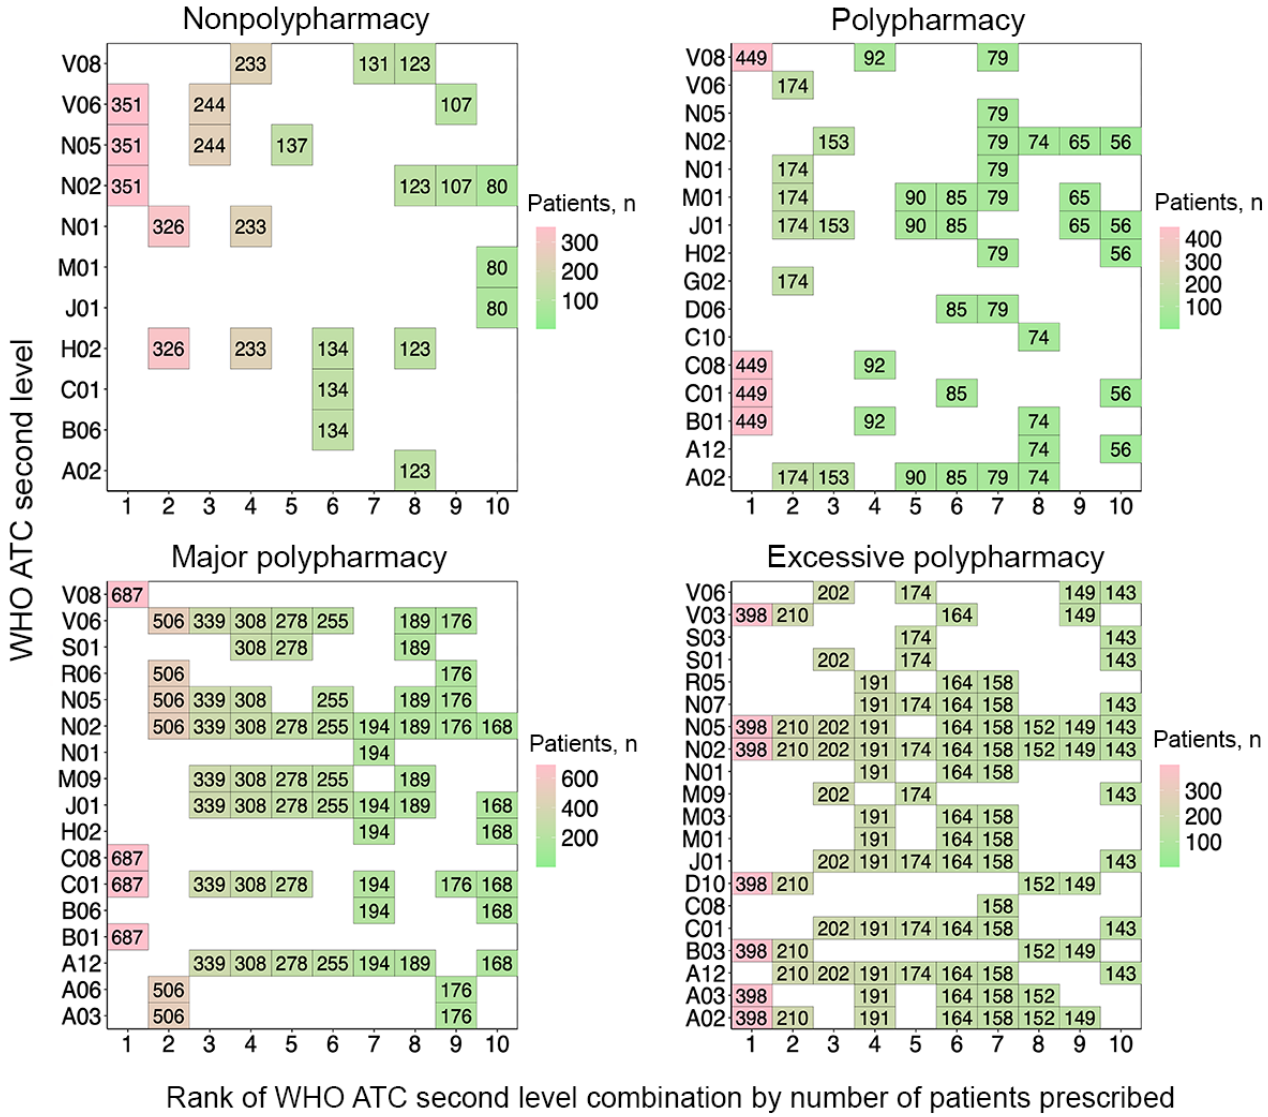
Results for medical institution B showed that patients in the nonpolypharmacy level were most frequently prescribed therapeutic subgroup combination N02-N05-V06, followed by combination H02-N01. The most frequent combination prescribed to patients at the polypharmacy level was B01-C01-C08-V08, followed by A02-G02-J01-M01-N01-V06 and A02-J01-N02. Patients in the major polypharmacy level were also most frequently prescribed the combination B01-C01-C08-V08. The second most frequently prescribed



XSL•FO
RenderX

combination at this level was A03-A06-N02-N05-R06-V06, and the third was A12-C01-J01-M09-N02-N05-V06. The most frequently prescribed subgroup combination for patients in the excessive polypharmacy level was A02-A03-B03-D10-N02-N05-V03, followed by A02-A12-B03-D10-N02-N05-V03 and A12-C01-J01-M09-N02-N05-S01-V06 (Figure 8).

In medical institution C, the 3 most frequent therapeutic subgroup combinations prescribed to patients at the nonpolypharmacy level each involved 1 subgroup: R05, N02, and J01. Patients in the polypharmacy level were most frequently prescribed therapeutic subgroup combination A03-M01-N01-S01. The most frequent subgroup combination prescribed for patients in the major polypharmacy level was A03-C01-M01-N01-S01, followed by A03-M01-N01-S01 and A02-A03-C01-N02-N05-V03. Patients in the excessive polypharmacy level were prescribed A02-A04-C01-J01-M03-N01-N02-R03-R05 most frequently. The second frequent combination was the same as the most frequent combination with the addition of subgroups A03 and A07. The third most frequent combination matched the second, excluding subgroup A02 (Figure 9).



In medical institution D, patients in the nonpolypharmacy level were prescribed therapeutic subgroup J01 most frequently, followed by individual subgroups A02, N02, and A06. Patients in the polypharmacy level were mostly prescribed the combination J01-N01-N02. Those in major polypharmacy level were prescribed B06-C01-H02-J01-N01-N02-S01, followed by J01-N02-R05-R06 and A02-J01-M01-N01-N05. Patients in the excessive polypharmacy level were prescribed combination A03-A04-B02-J01-M01-M03-N01-N02-N07-R05 most frequently, and the second and third most frequent combinations involved the addition of subgroup R03 and the removal of subgroup M01, respectively (Figure 10).

Discussion

Principal Findings

This study used EHR data converted to the OMOP CDM from 4 medical institutions for geriatric inpatients aged 65 years and older admitted over 9 years. Our study is the first to collect the EHR of patients and retrospectively study polypharmacy patterns over multiple institutions to determine a polypharmacy threshold in hospitalized older patients. The authors used data from 2 of the largest hospitals in the South Korean metropolitan area and 2 hospitals in the regional area to represent patients from distinct settings.

The use of OMOP CDM in all 4 study settings allowed the use of similar programming languages and software, thereby increasing the efficiency of the study. Although there were differences in the specific columns customized for each institution, the uniformity of the basic OMOP CDM tables and columns across institutions allowed for the distribution of a single analysis code customized for each institution, and the collection of analysis resulted in a standardized format.

We offer a possible definition of polypharmacy in hospitalized older adults. This was obtained by consulting clinical professionals to define the inpatient observation periods and reviewing previous studies [25,26,30] to determine the time point of drug exposure for polypharmacy level determination. We filtered out drugs that did not contribute to adverse events from polypharmacy (eg, WHO ATC code B05 and its lower-level codes), which improved the quality of our data.

The 4 health care institutions (A, B, C, and D) included in this study showed distinct differences in patient scale, proportion of older patients, sex and age distribution, and medication use patterns. Institution C had the largest patient population with 3,349,795 patients and demonstrated high proportions of older patients and excessive polypharmacy levels. Institution B had the next highest patient population with 1,944,140 patients and the highest number of hospitalization events with 1,092,936 events. This trend reflects that institutions located in metropolitan, urban settings had a higher patient population size and hospitalization event count than their rural counterparts. Institution A, despite having a relatively smaller scale with 602,483 patients, was characterized by the highest average

XSL•FO
RenderX

number of medications per age group and the longest hospital stays.

In terms of sex distribution, institution A showed higher male ratios in patients aged 5-60 years, but female patients were more prevalent in those aged 70 years and older. Institution C displayed higher female ratios in patients in their 50s and 80s or older, while male patients were more common in the 60- to 70-year age group. Institution D exhibited a unique pattern with higher female ratios in patients aged 80 years and older and higher male ratios in those aged 5-70 years. Overall, the proportion of female patients tended to increase in the older population, with sex ratios varying across institutions and age groups.

A tendency was observed for hospital length of stay to increase with advancing age across all institutions. Regarding polypharmacy prescriptions, institution B demonstrated the highest "excessive polypharmacy level" ratio across all age groups.

Comparison to Prior Work

The pattern of drug use among inpatients in the 4 medical institutions showed that patients in the major or excessive polypharmacy levels were most prevalent. This trend is consistent with the results of previous studies reporting 5-10 drugs or more as the polypharmacy threshold. A study using nationwide health care claims data found that hospital admission was significantly associated with polypharmacy (use of 5 or more drugs) and hyper-polypharmacy (use of 10 or more drugs) [39]. Another study reported an increase from 5.6 drugs taken per patient on average at admission to 7.6 drugs at discharge [40]. Considering that the number of drugs prescribed tended to increase during hospital admission, the use of 10-19 or more drugs (major polypharmacy or higher) as the threshold for inpatient polypharmacy was considered appropriate. All data were obtained and analyzed within the securely blocked environment of each medical institution.

The mean number of drugs used in medical institution B was higher than that used in other institutions by 3-10 drugs. The prescription frequency of drugs in the cardiac therapy (C01) WHO ATC therapeutic subgroups tended to increase with the severity of polypharmacy in all medical institutions, and the anti-inflammatory and antirheumatic product (M01) therapeutic subgroups increased across all institutions, excluding institution B. These results correspond with those of a study in which hypertension, osteoarthritis, and rheumatoid arthritis were reported to be prevalent in older individuals aged 65 years or older [41].

The patterns of concomitant therapeutic subgroups differed among the medical institutions. In the major polypharmacy category, medical institution A patients were frequently prescribed ophthalmologicals (WHO ATC second-level code S01), along with other therapeutic subgroups. This drug class has been consistently used in most prescribed combinations of therapeutic subgroups. Medical institution B prescribed drugs in various therapeutic categories including acid-related disorders (A02), functional gastrointestinal disorders (A03), antianemic preparations (B03), antithrombotics (B01), and cardiac therapies (C01) to patients in the major and excessive polypharmacy levels. Medical institution C, which had the highest number of study patients, prescribed drugs for WHO ATC second-level functional gastrointestinal disorders (A03), anti-inflammatory and antirheumatic products (M01), and ophthalmologicals (S01). These drug classes were in the 1-3 highest rank of concomitant drugs prescribed.

Distinct polypharmacy patterns in the polypharmacy group were that patients in all 4 institutions were more frequently prescribed lipid-modifying agents (C10), and in 3 institutions, antidiabetics (A10) were more frequently prescribed, compared to other polypharmacy groups (Figures 3-6). This reflects the increased prevalence of chronic diseases in the older population and their demand for multiple medications to treat the disease [42]. Furthermore, the result is consistent with a finding that older patients with diabetes have a high prevalence of polypharmacy, as these patients commonly have multiple concomitant diseases including cardiovascular, renal, and respiratory disorders [43]. The higher prescription frequencies of ophthalmic agents (S01) and anti-inflammatory and analgesic drugs (M01) observed in institution C reflect that this institution is highly specialized in ophthalmology or rheumatology. The major polypharmacy group was frequently prescribed cough and cold preparations (R05) compared to other polypharmacy groups (Figures 3-6). This trend was consistent with results of a previous study, which reported patients on 5 or more drugs having an odds ratio of 3.18 and 6 or more drugs having an odds ratio of 4.57 to receive prescriptions for cough and cold drugs [44].

Distinctive polypharmacy patterns observed in the excessive polypharmacy group were that cardiac drugs (C01) were frequently prescribed in all 4 institutions (Figures 3-6). This observation suggests that patients in the excessive polypharmacy group may have a higher burden of cardiovascular diseases or more severe cardiac comorbidities requiring complex medication regimens [45]. The frequent prescription of cardiac drugs in this group indicates that managing heart-related conditions—such as heart failure, arrhythmia, or ischemic heart disease—contributes substantially to the overall medication load. This reflects that the patients in the excessive polypharmacy group are clinically more fragile, thus requiring multiple medications for symptom control, prevention of complications, and comorbidity management. This group was also frequently prescribed functional gastrointestinal disorder drugs (A03), antihemorrhagics (B02), and muscle relaxants (M03; Figures 7-10). The reason for the high prevalence of antihemorrhagics prescribing indicates frequent surgeries or procedures in this population [46,47]. Muscle relaxants were found to be frequently prescribed in older polypharmacy patients and coprescribed with opioids [48]. This medication was shown to increase the risk of adverse outcomes including all-cause and cardiovascular mortality, warranting enhanced monitoring of drug therapy [48]. Gastrointestinal drugs may be used for the gastric protection caused by polypharmacy or due to the decreased physiological function of the gastrointestinal system [49].

Although each institution had a distinctive pattern, we observed that drugs related to surgeries, including those needed after the operation (eg, WHO ATC second-level codes C01, H02, J01,

XSL•FO
RenderX

N01, and N02), were commonly prescribed across institutions (Figures 7-10). This reflects the trend from 2011 to 2015, where 3,146,452 of 8,497,443 (37%) surgeries were performed in patients aged 65 years or older, and the surgeries were for high-risk conditions, such as glaucoma [50]. We observed that older inpatients frequently underwent surgeries and were prescribed several drugs during admission for these procedures. The high frequency of antibacterials (WHO ATC second-level code J01), anesthetics (N01), and analgesics (N02) in all polypharmacy levels in the older population reflects the complex clinical conditions of hospitalized older patients, who often require management of infections, surgeries or procedures, and pain control [51]. This population has a high prevalence of osteoarthritis, fractures, and cancer-related pain, increasing the risk of anesthetic and analgesic use [52].

Limitations

This study has several limitations. First, we included 4 medical institutions, which restricts the generalizability of the study results to the institutions of interest. Second, drugs without a mapped WHO ATC code were excluded; therefore, the prevalence of polypharmacy might have been underestimated. Third, we analyzed the pattern of polypharmacy using the second-level ATC code; thus, polypharmacy patterns at the ingredient level were not determined. Fourth, although we examined outpatient drug prescriptions up to 7 days after discharge, polypharmacy use in older outpatients was not comprehensively analyzed. This is a topic of interest for future studies. Fifth, we did not assess the appropriateness of polypharmacy based on linking prescribed drugs and their indications. Although an estimate of the drug-indication linkage is possible, the precise linkage is challenging, as the indications for the drugs were not explicitly recorded in the OMOP CDM database. Finally, the tables used for the analyses did not include the note table, which includes clinical results or interpretations in free-text format, and is a potential resource for detecting polypharmacy.

Conclusions

Based on well-established EHR-based CDM datasets in South Korea, we suggest a polypharmacy definition for older inpatients that is different from the commonly used definition of the concurrent prescription of 5 or more drugs. This is because, based on the severity of the patients' condition and the treatment they require, which includes major surgeries, the number of concomitant drugs used was higher than the commonly used definition of polypharmacy in the majority of patients in this study. Therefore, we suggest that 10 or more drugs is a more suitable definition of polypharmacy for geriatric inpatients. As the geriatric population increases, evaluating the appropriateness of existing polypharmacy definitions and serious outcomes of polypharmacy in this population, including renal failure, falls, and fractures, is necessary for future studies.

Abstract

Background: The expanding use of multisource real-world electronic health record (EHR) and claims data offers major opportunities for research, drug discovery, and clinical decision support. While standards such as Logical Observation Identifiers Names and Codes (LOINC) can ensure semantic interoperability for laboratory observations, clinical documents, and other clinical terms, properly assigning these concepts remains a challenge. Studies show that 6% to 19% of laboratory tests cannot be accurately mapped to LOINC. Existing systems try to address this challenge but often depend on source data strings and other input features that may be absent, null, or incorrect. This underscores the need for a scalable approach to correct LOINC code assignments, standardize units, and ensure data integrity across multisource laboratory data.

Objective: This paper presents a universally applicable framework that identifies and corrects observable errors in quantitative laboratory results coded to LOINC and the Systematized Nomenclature of Medicine for the unit of measure without relying on raw source data strings. The process seeks to improve the accuracy, conformance, consistency, and completeness of laboratory data while maintaining complete provenance.

Methods: The proposed framework uses a 2-step process. First, LOINC codes are corrected using the associated unit of measure. Second, units are adjusted or populated to match a preferred unit for that LOINC code. In both steps, the quantitative result is checked against a predefined acceptable range to determine validity. The process is driven by 3 knowledge tables. The framework is applied to datasets derived from the ConcertAI database of approximately 10 million patients with cancer, evaluating improvements in LOINC code–unit conformance and unit completeness. Analyses are performed on 4 independently LOINC-coded datasets: the full ConcertAI dataset and 3 high-volume diverse subsets grouped by data source or EHR vendor.

Results: A total of 428 LOINC codes were observed across 6.34 billion records in the ConcertAI database. All 4 datasets were processed using the proposed framework. Before applying the framework, 73.1% (4,634,610,173/6,337,101,453) of records in the ConcertAI dataset had correctly assigned units based on the laboratory reasonable range table; after application, this increased to 99.7% (6,322,375,200/6,341,230,213). Similar improvements were observed across the 3 EHR-specific datasets, increasing from 78.5% (691,315,390/880,250,137) to 99.8% (879,626,472/881,157,852; source 1), 71.4% (2,132,455,936/2,985,465,124) to 99.8% (2,982,319,644/2,988,173,959; source 2), and 63.3% (2,936,710,502/4,640,432,294) to 99.6% (4,618,714,114/4,638,862,412; source 3). Unit completeness also improved substantially, increasing from 92.7% (5,879,071,858/6,341,230,213) to 99.8% (6,331,923,060/6,341,230,213) in the ConcertAI dataset and from 92.5% (814,867,241/881,157,852) to 100% (880,816,133/881,157,852), 94.4% (2,822,107,252/2,988,173,959) to 99.9% (2,986,624,027/2,988,173,959), and 91.7% (4,254,054,966/4,638,862,412) to 99.8% (4,632,935,919/4,638,862,412) in sources 1 to 3, respectively.

Conclusions: Laboratory data quality is crucial in oncology systems for therapy selection, monitoring, and disease progression assessment. This proposed solution is a first-of-its-kind, system-agnostic, and scalable normalization process that addresses key gaps in laboratory data quality across multiple dimensions.

Introduction

Background: Real-World Data in Health Care

Multisourced, comprehensive patient health data have seen a recent rise in prominence and utility in supporting research, drug discovery, pharmacovigilance, and clinical decision support [1]. These real-world data (RWD) are collected for individual patient care and reimbursement in often unconnected systems such as electronic health records (EHRs) and claims clearing houses [2]. Secondary use of RWD holds immense potential for improving health due to its volume, variety, and ubiquity [3].

The different source systems producing RWD bring individual challenges and opportunities, and it is often necessary to stitch together disparate sources to cover a complete patient journey [3]. For instance, medical claims may contain procedures and tests performed on a patient and their associated costs, but the results of those tests are only present in the EHR [4].

Data Quality and Semantic Interoperability Challenges

The path to a usable RWD dataset is fraught with challenges [2]. Errors can arise from any system or actor that generates, transmits, transforms, or persists the data during its lifetime [5]. Errors can be discernible from patterns observed in the data or can be hidden from downstream users when information is lost [6]. Information loss can result in incorrectness or missingness of variables, records, tables, or complete data sources [7]. Monitoring and minimizing information loss is a critical requirement of an RWD pipeline.

Semantic interoperability (SI), or the ability to ensure the same meaning and interpretation of data shared between systems [8], is a well-established and ongoing challenge in RWD [5]. It can manifest as redundant representations of the same concept, such as one EHR using the *International Classification of Diseases, 10th Revision, Clinical Modification*, and another using the Systematized Nomenclature of Medicine (SNOMED) to represent the same disease. Use of data standards and common ontologies can alleviate SI challenges but can also introduce errors if used incorrectly [5], which can commonly occur when a concept is assigned to a string by either a human or machine [9]. As health care data systems continue to evolve, the importance of SI is underscored by the increasing adoption of standards such as Fast Healthcare Interoperability Resources (FHIR) [10] with its associated code system bindings supported by the Food and Drug Administration, which are designed to ensure consistent data interpretation and improve interoperability across systems. Even FHIR-based representations may fall short in fully addressing semantic mismatches, particularly for complex domains such as laboratory data, in which variability in coding, units, and local conventions persists despite standardization efforts [11].

Laboratory Data and Logical Observation Identifiers Names and Codes Mapping Challenges

Laboratory result data are both valuable and particularly challenging in RWD [9]. To address SI, laboratory data primarily rely on codes from the Logical Observation Identifiers Names and Codes (LOINC) code system [12,13]. LOINC is the dominant global coding system for laboratory concepts but also extends to a broader range of clinical terms, including clinical questions and documents [12-15]. LOINC consists of concepts that have 6 attributes each. These include the analyte tested, how it is observed, the duration of observation, and the sample type that the observation is performed on [13]. Precoordinating that much information into a single concept makes it convenient for transmission by reducing the potential for misinterpretation but also makes it difficult to use when mapping to LOINC [14,15]. The complete information for LOINC mapping is rarely present in a single string, column, or record [15]. Relevant information may be spread across one or more fields in a record or laboratory information system, such as the observation's display string (eg, glucose), the data type of the result (numeric or categorical), the unit of measure (mass over volume or molarity), the associated order name or panel name (complete blood count or urinalysis), the associated sample (urine or blood), the device or equipment used to make the observation (urine dipstick or continuous glucose monitor), or other observations that occurred as part of the same panel of tests (Is the patient fasting?). Despite the abundance of resources, accurately translating these fields to the correct LOINC code remains a challenge.

This semantic and translational complexity means that laboratory results in RWD can frequently present with errors introduced during terminology binding to LOINC [16]. Prior studies have shown that LOINC codes could not be assigned for 6% to 19% of laboratory tests due to incomplete or incorrect information [17]. Systems have been proposed to reduce this error by coding via automated means in RWD [9,16,18] and clinical trial data [19]. These algorithms rely on source data strings and other input features that may be absent, null, or observably incorrect.

Unit of Measure and Normalization Challenges

The diversity of information required for LOINC mapping increases the likelihood of mapping difficulty [20] and significant information loss. If a result's unit of measure is absent or recorded in the wrong place or the associated panel name, order name, or sample type is missing from the data, it can mean insufficient information to properly assign the LOINC code [15]. Contextually appropriate filling in of absent units of measure has been shown to be effective in a system that extracts logical expressions from clinical trial inclusion criteria pertaining to quantitative laboratory results but not within RWD [21].

XSL•FO
RenderX

A laboratory result may present with a correct concept code, but it is possible to represent the same result using multiple scales (g or mg), and certain units are used interchangeably between sources (mg per day or mg per 24 hours). Unit normalization is necessary to ensure comparable results during data analysis and aggregation, and the variety of representation, the missingness, and the level of incorrectness can all lead to loss of utility of RWD. Even with a correct LOINC code, missing or inconsistent units have been shown to affect as much as 14% of laboratory records in some systems [22,23]. Mechanisms to normalize synonymous units exist, but these techniques do not handle situations in which the unit is incomplete, incorrect, or completely absent [24].

Proposed Framework and Objective: Correcting Quantitative Laboratory Results

In this paper, we present a framework to identify and correct observable errors in quantitative laboratory results that have already been coded to LOINC for the observation and SNOMED for the unit of measure without reliance on source data strings. This 2-step process first adjusts the LOINC code by using information contained in the associated unit of measure. Next, we use the quantitative result to inform whether we can safely populate a missing unit of measure or correct an erroneous unit of measure. Finally, all synonymous or related units are normalized to a single preselected unit for each LOINC code. We characterize the prevalence of these errors and then use this framework to correct laboratory results in a multisource RWD pipeline of oncology patient data from EHRs, laboratory information systems, and medical claims.

Methods

This section outlines the data collection and study design used to develop this framework.

Data Collection

Laboratory result data were extracted from the ConcertAI database, a US-based, deidentified, patient-level dataset from approximately 10 million patients with cancer aged ≥18 years during the period from 2015 to 2025. The data used in this study were sourced from EHRs, including oncology practices, hospitals, and academic medical centers. To evaluate the framework, we analyzed 4 laboratory datasets: the full ConcertAI database and 3 subsets corresponding to the individual EHR sources (represented as source 1, source 2, and source 3) that transmitted data to ConcertAI. These 3 subsets were selected because they were the top contributors of laboratory data by volume and represented a broad diversity of laboratory tests. Specifically, the ConcertAI database accounted for 6.34 billion records, source 1 included 880 million records, source 2 included 2.98 billion records, and source 3 included 4.64 billion records.

Data were contributed by multiple clinical sites and laboratories across the United States, representing a diverse group of care settings. Each dataset was standardized using LOINC codes for laboratory observations and SNOMED codes for units of measure. For records from the full ConcertAI database, LOINC codification was performed using ConcertAI's internal system; for EHR or data source–derived subsets, the LOINC codes that were delivered with those data were used. Only records with a numeric value were used in this study. All datasets used ConcertAI's unit codification that maps unit strings to SNOMED.

System Design

The laboratory correction framework was applied after standardization to LOINC and SNOMED. The laboratory correction system relies on 3 knowledge tables that have been manually created after careful examination of the ConcertAI laboratory data, as outlined below. Their role in supporting the logical framework is discussed later in this section. Below, we provide the formal definitions of these tables, including their constituent fields and primary keys. The procedures used to create each table and the column definitions are documented in Multimedia Appendix 1.

The LOINC conversion map (LCM) relates a LOINC concept and unit concept that are incongruous to a new LOINC code that is compatible with the unit of measure. The table structure incorporates the following computable fields: "old_loinc_code," "old_loinc_display," "old_loinc_system," "unit_code," "unit_display," "unit_system," "new_loinc_code," "new_loinc_display," and "new_loinc_system." The primary key for the table is defined as the composite of "old_loinc_code" and "unit_code." Examples are shown in Table 1, which has been formatted for readability. The complete computable version is available in Multimedia Appendix 1 and in the accompanying GitHub repository to support transparency and reproducibility.

Table 1. Logical Observation Identifiers Names and Codes (LOINC) conversion map.

LOINC code	Unit (SNOMED[a])	Corrected LOINC code
Platelets (#/volume) in blood (26515-7)	fL (258775009)	Platelet (entitic mean volume) in blood (28542-9)
Glucose (mass/volume) in blood (26515-7)	mEq/L (258865000)	Glucose (moles/volume) in blood (15074-8)
Glucose (mass/volume) in blood (26515-7)	mmol/L (258813002)	Glucose (moles/volume) in blood (15074-8)
Kappa light chains (mass/volume) in serum or plasma (11050-2)	Percentage (118582008)	Kappa lymphocytes/lymphocytes in blood (17096-9)

[a]SNOMED: Systematized Nomenclature of Medicine.

The reasonable range map defines metadata about a single LOINC code, including its assigned correct unit of measure, a minimum and maximum value that the laboratory test can reasonably take, and the mean and median of records with that LOINC code and unit across all 4 datasets. The correct unit of measure for each LOINC code was determined using the

XSL•FO
RenderX

"example_unit" supplied in the official LOINC distribution. These units were mapped to the corresponding SNOMED codes. For LOINC codes that listed more than one example unit, we examined the empirical distribution of units observed in our dataset and selected the unit with the highest frequency. This made the choice of the correct unit data driven and ensured that the process could be consistently reproduced in any system. If Unified Code for Units of Measure (UCUM) units are preferred, LOINC also provides "example_ucum_units," which can be incorporated similarly. Minimum and maximum reasonable values for each LOINC code were defined by estimating the empirical distribution of the data through quantiles of 0.005, 0.025, 0.16, 0.5 (median), 0.84, 0.975, and 0.995. The range was set at or near the highest and lowest of those quantiles, providing broad yet data-anchored thresholds for plausibility checking.

This knowledge table includes the following computable fields: "loinc_code, loinc_name," "unit_code," "unit_name," "min_reasonable," "max_reasonable," "mean," and "median." The primary key for this table is the "loinc_code." A readability-optimized version is shown in Table 2, whereas the complete computable version is provided in Multimedia Appendix 1 and the GitHub repository.

Table 2. Reasonable range map.

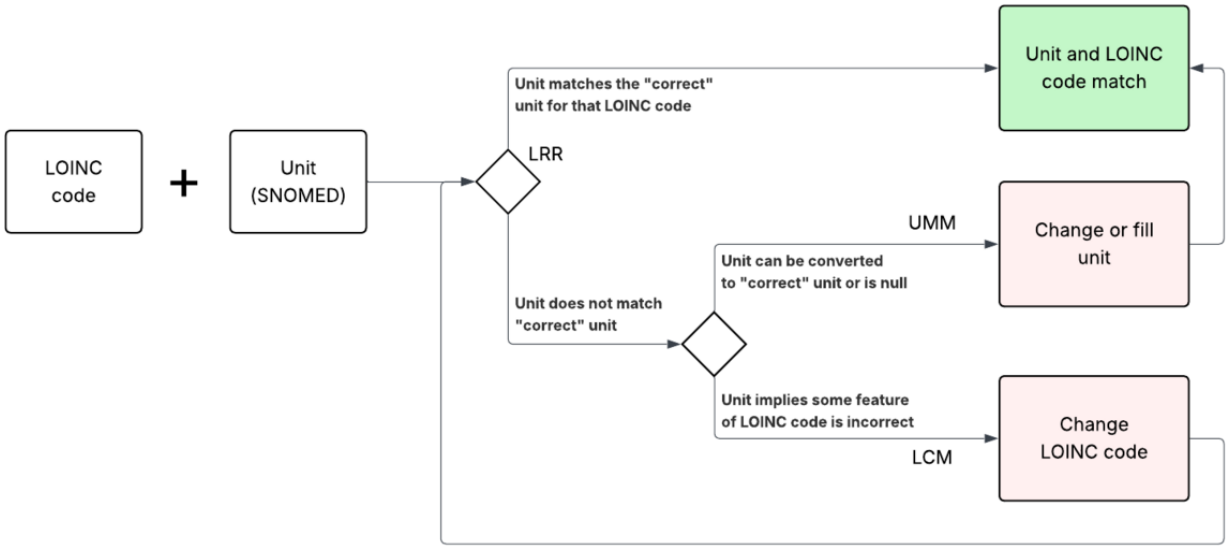
LOINC[a] code	Unit (SNOMED[b])	Reasonable range	Median	Mean
Platelets (#/volume) in blood (26515-7)	×10(3)/mcL (1287856009)	1-800	223.5	215.0
Glucose (mass/volume) in blood (2339-0)	mg/dL (258797006)	40-400	138.8	121
Kappa light chains (mass/volume) in serum or plasma (11050-2)	mg/L (258796002)	0.1-5000	68.7	25.9

[a]LOINC: Logical Observation Identifiers Names and Codes.

[b]SNOMED: Systematized Nomenclature of Medicine.

The unit multiplier map relates a correct unit to a synonymous, convertible, or incorrect unit along with a multiplier value, an additive scalar value, and a description of the relationship between the 2 units (eg, incorrect, synonym, or convertible). The scalar value is only used for temperature conversions. An empty "incorrect unit" represents a null unit field and is used to populate absent units. This knowledge table includes the following computable fields: "incorrect_unit_code," "incorrect_unit_name," "correct_unit_code," "correct_unit_name," "multiplier," "scalar_constant," and "multiplier_type." The primary key is the composite of "incorrect_unit_code," "correct_unit_code," and "multiplier_type." A readability-optimized version is shown in Table 3, with the full computable version available in Multimedia Appendix 1 and the GitHub repository.

Table 3. Unit multiplier map.



Incorrect unit (SNOMED[a])	Correct unit (SNOMED)	Multiplier	Scalar	Multiplier type (description)
<null>	×10(3)/mcL (1287856009)	1	0	"nullfill" (unit absent)
10*9/L (277288007)	×10(3)/mcL (1287856009)	1	0	"synonym"
cells/µL (258878000)	×10(3)/mcL (1287856009)	0.001	0	"unit_conversion" (convertible unit)
cells/µL (258878000)	×10(3)/mcL (1287856009)	1	0	"unit_typo" (known unit error)
g/dL (258795003)	mg/dL (258797006)	1000	0	"unit_conversion" (convertible unit)
g/dL (258795003)	mg/dL (258797006)	1	0	"unit_typo" (known unit error)
g/L (258794004)	mg/dL (258797006)	1	0	"unit_conversion" (convertible unit)

[a]SNOMED: Systematized Nomenclature of Medicine.

The framework logic is shown in Figure 1. Conformance to the selected "correct" unit is checked against the laboratory reasonable range (LRR) table entry. If the unit does not conform, the LCM provides a better LOINC code if one is known for the unit that is present in the record. In the second transformation, the unit is altered according to the unit multiplier map, normalized if it is a synonym, converted using a multiplier value, or swapped for the correct unit if it is a known error pattern or absent altogether. For example, the LOINC code 1920-8 (glucose [mass/volume] in blood) has the correct unit "mg/dL." If a record with this LOINC code has the unit "mmol/L," the LOINC code is changed using the LCM to 15074-8 (glucose [moles/volume] in blood). The process is only 2 steps, although not all records require both. Records may begin with LOINC code–unit conformance and skip the process altogether. Some require only LOINC conversion, some require only unit normalization, and many require LOINC conversion and then unit normalization.

XSL•FO
RenderX

Figure 1. Framework logic and knowledge table use. LCM: Logical Observation Identifiers Names and Codes (LOINC) conversion map; LRR: laboratory reasonable range; SNOMED: Systematized Nomenclature of Medicine; UMM: unit multiplier map.

Each of these transformations only proceeds when the record's result value falls within the reasonable range associated with the LOINC code–unit pair that would appear in the transformed record. These ranges were selected using known correct data and designed to capture most possible values in that laboratory's value distribution.

In rare instances, the system must select between 2 possible transformations for the same record. This might occur in the situation visible in rows 5 and 6 in Table 3 when trying to convert from g/dL to mg/dL. We identified a common error in many records in which a unit's prefix was absent. A g/dL unit might be a simple data entry error at the source, or it may, in fact, require conversion by multiplying the result by 1000. The system uses the reasonable ranges to determine which of these 2 situations is more likely. If the reasonable ranges are not disparate enough to discern which transformation is required, proximity to the median of the target LOINC code–unit's distribution is compared. The transformation resulting in a record closer to that median is selected. If the compared laboratory results have medians of 0, distance from the mean is used.

To evaluate the success of each transformation, the value distribution of the output for any individual transformation was compared with the value distribution of known correct data with that LOINC code–unit pair. If the distribution of the numeric result of the transformed data matched that of known correct data, it was considered successful. If the distribution did not match, the discrepancy was investigated. These investigations led to the discovery of common error patterns that could then be accounted for in the next iteration by adding to the 3 knowledge tables.

To summarize, the precedence of the rules described above is as follows:

1. LRR conformance check—if the LOINC code–unit pair conforms to the LRR table, no transformation is applied.
2. LOINC conversion (LCM)—if the unit is incompatible with the LOINC code, the framework first selects the appropriate LOINC code.
3. Unit normalization or conversion (unit multiplier map)—after the LOINC code is finalized, unit normalization or conversion is applied.
4. Range validation—a transformation is only accepted if the resulting value falls within the target LOINC code's reasonable range.
5. Conflict resolution—when more than one unit transformation falls within the reasonable range, the system resolves this by checking proximity to the median of the known correct distribution or proximity to the mean when the distribution median is 0.

A few examples of LOINC code–unit incongruencies and framework processing are outlined in Multimedia Appendix 1.

Provenance is maintained within each transformed record in an attribute that acts as a ledger of each transformation that alters that record. This attribute is an array of objects that includes a descriptive string that details what features of the record were adjusted and what features were used to justify that adjustment for human readability. For computability, "object" includes the adjusted attribute names and preadjustment values for those attributes, ensuring transparency to downstream users and reversibility if necessary.

A summary of the steps for this framework is illustrated in Figure 2.

Figure 3 shows an example of LOINC code–unit pairs before transformation, each step of the transformation, and the final output after transformation.

Ethical Considerations

This study used retrospective, deidentified data collected for clinical purposes. All data were fully anonymized before analysis, and unique patient identifiers were removed. Analysis of deidentified secondary data does not constitute human subjects research and does not require formal review or approval by an institutional review board, and thus, no institutional review board approval number was sought. Because only deidentified data were used, informed consent from individual patients was not required. Privacy and confidentiality were maintained throughout the study in accordance with all applicable regulations.

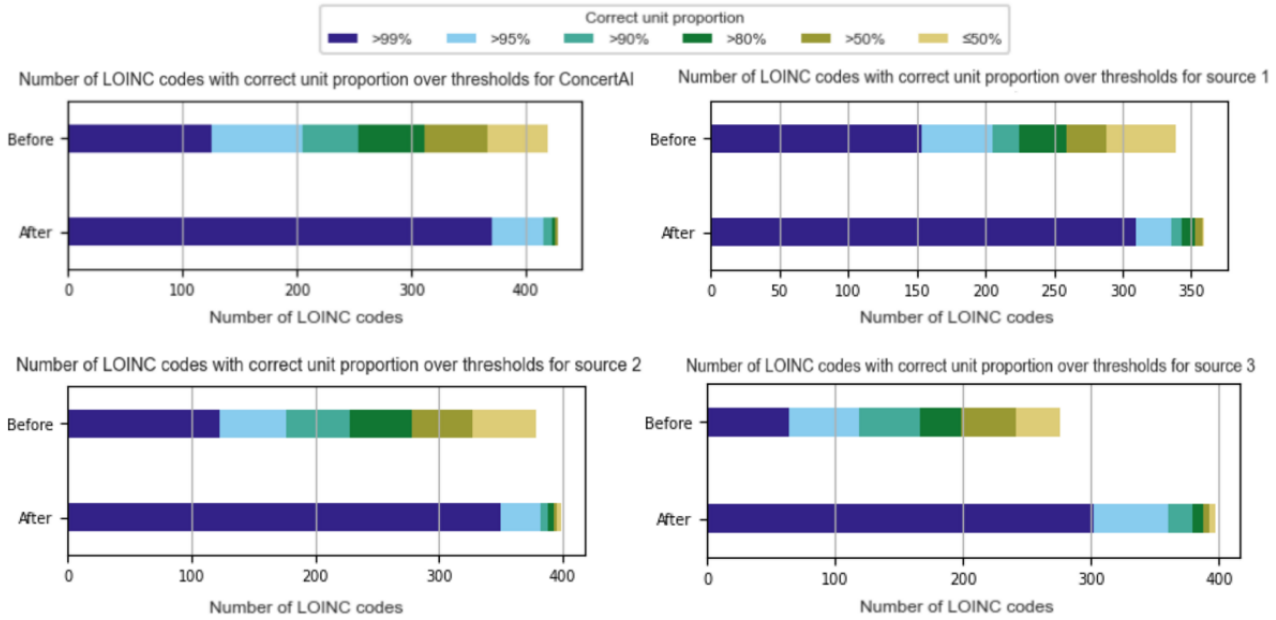
Results

Dataset Collection: Overview and LOINC Coverage

All 4 sets of laboratory data underwent the LOINC code and unit correction process, and the proportion of records exhibiting each LOINC code–unit pattern was calculated both before and after the framework execution. A total of 428 LOINC codes were included in this study, chosen based on their prevalence in the ConcertAI database. Not all datasets contained all 428 LOINC codes. These LOINC codes accounted for 6.34 billion records in the ConcertAI database and 880 million, 2.98 billion, and 4.64 billion records in the source-specific datasets from sources 1, 2, and 3, respectively.

System Design

Impact of Framework on Unit Correction



Before the application of the framework, 73.1% (4,634,610,173/6,337,101,453) records in the ConcertAI dataset with these LOINC codes had the correct unit as assigned by the LRR table. Following the application, this increased to 99.7% (6,322,375,200/6,341,230,213) of records. A similar trend was observed in each of the EHR-specific datasets: 78.5% (691,315,390/880,250,137) to 99.8% (879,626,472/881,157,852), 71.4% (2,132,455,936/2,985,465,124) to 99.8% (2,982,319,644/2,988,173,959), and 63.3% (2,936,710,502/4,640,432,294) to 99.6% (4,618,714,114/4,638,862,412) for sources 1, 2, and 3, respectively. The system increased the completion rate of units, defined as the proportion of records with nonmissing units, from 92.7% (5,879,071,858/6,341,230,213) to 99.8% (6,331,923,060/6,341,230,213) in the ConcertAI dataset and similarly in the other 3 datasets: 92.5% (814,867,241/881,157,852) to 100.0% (880,816,133/881,157,852), 94.4% (2,822,107,252/2,988,173,959) to 99.9% (2,986,624,027/2,988,173,959), and 91.7% (4,254,054,966/4,638,862,412) to 99.9% (4,632,935,919/4,638,862,412) for sources 1, 2, and 3, respectively. Because the framework assigns validated units to previously missing values, improvements in the correct unit rate reflect both corrections to misassigned units and the assignment of correct units to previously missing entries. As a result, the correct unit and completion rate metrics are related but not redundant: the correct unit rate captures accuracy among all populated units, whereas the completion rate captures overall presence of any unit.

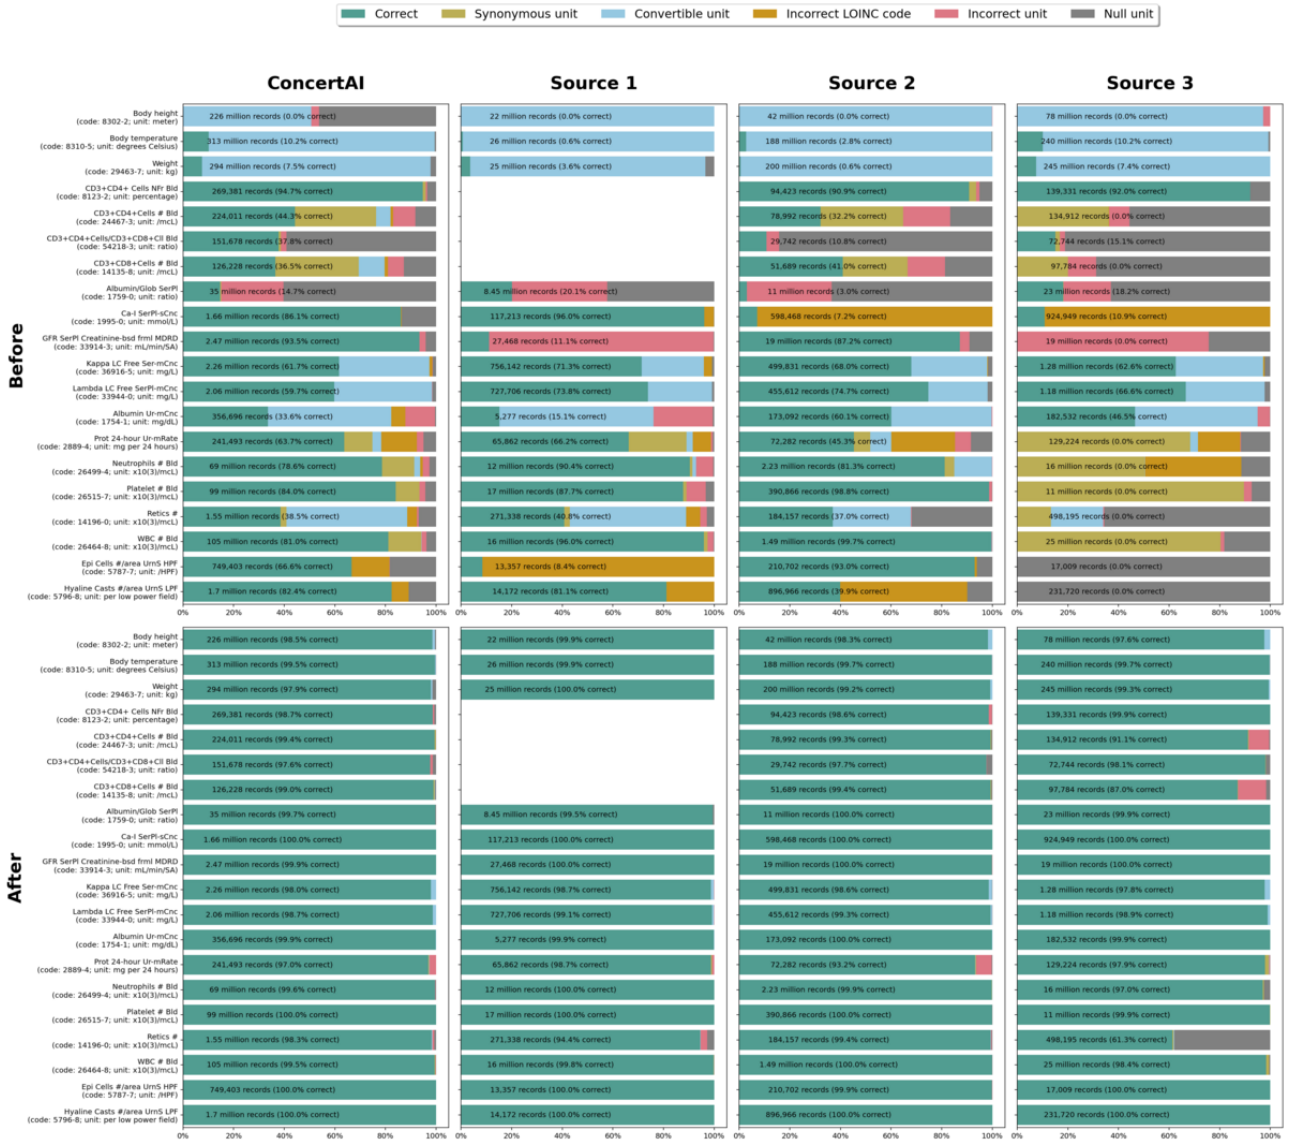
LOINC-Level Quality Threshold

Not all LOINC codes start with the same degree of incorrectness. To evaluate the proportion of LOINC codes that reached specific data quality thresholds before and after framework application, records with each LOINC code were evaluated for unit correctness, and the number of LOINC codes passing certain unit correctness proportion thresholds was counted. These counts for each dataset are shown in Figure 4. Of the 428 LOINC codes, the number meeting the 99% threshold of unit correctness in the full ConcertAI dataset increased from 125 (29.2%) to 370 (86.4%). Similar improvements were observed across the 3 source datasets, which contained different total proportions of evaluated LOINC codes: 83.9% (359/428) of LOINC codes in source 1, a total of 93.2% (399/428) of LOINC codes in source 2, and 88.6% (379/428) of LOINC codes in source 3. In source 1, the proportion meeting the 99% threshold increased from 42.9% (154/359) to 86.4% (310/359); in source 2, it increased from 30.8% (123/399) to 87.7% (350/399); and in source 3, it increased from 16.9% (64/379) to 79.7% (302/379).

XSL•FO
RenderX

Figure 4. Number of Logical Observation Identifiers Names and Codes (LOINC)–coded records meeting unit correctness thresholds.

Illustrative Subset Analysis



To provide a more detailed view of the framework's impact, Figure 5 presents a closer look at 20 specific LOINC codes. These codes were selected for their varied domains and types of incongruencies in the starting data.

Records with each of these 20 LOINC codes had their unit classified as correct, synonymous to correct, absent, or incorrect. Incorrect units were subclassified as incorrect and suggestive of a LOINC change, incorrect but convertible to the correct unit through a multiplier, or incorrect but not convertible. These unit categories represent the types of errors that this system is designed to correct. The proportions in each category were calculated before and after the framework application and are shown in Figure 5 for each system.

A detailed report showing the proportion of correctness for each LOINC code across all 4 datasets before and after the framework application is available in Multimedia Appendix 2.

Discussion

Principal Findings

The proposed normalization framework significantly improved LOINC code–unit congruence and unit absentia across all evaluated datasets, demonstrating generalizability to any clinical data system using standard medical terminologies for observation and unit representation. The method improved LOINC code–unit congruence overall in the ConcertAI laboratory dataset from 73.1% (4,634,610,173/6,337,101,453) to 99.7% (6,322,375,200/6,341,230,213), with similar trends in the other 3 data sources. The method and knowledge tables were developed using the ConcertAI data and applied to these independent datasets to demonstrate generalizability. To the best of our knowledge, this framework is the first of its kind to address 2 key gaps: the absence of a system-agnostic process for cleaning multisource laboratory data for secondary use [18] and an approach tailored to RWD. RWD, where data quality is both challenging [25] and critical to data usability, may lack source-specific semantics such as the local observation concept display name. This would impede the use of a standardization process designed to take advantage of those strings [18].

Mechanism of Framework

The process, driven by 3 small, shareable knowledge tables, uses the observation concept (LOINC), the unit concept (SNOMED), and the numeric result as input. It first adjusts the LOINC code if the unit suggests a better LOINC code. It then normalizes the unit to a predetermined preferred unit for that LOINC code by filling null units, converting related units, or correcting units with overt errors. All transformations only proceed when the numeric result aligns with the predetermined distribution for the target LOINC code–unit pair. This “reasonable range” constraint addresses a shortcoming in existing proposed methodologies [19,21] that handle units without consideration of the numeric result. This range can be used to flag records that fall outside the reasonable distribution for exclusion from analysis or closer review.

XSL•FO
RenderX

Impact on Data Quality Dimensions

Ensuring that laboratory values fall within a reasonable distribution contributes to accuracy, or the degree to which the data represent the true value of what is intended to be measured, and plausibility, 2 prominent dimensions [25] of RWD quality. The results demonstrate improvements across a number of established quality dimensions [25] other than accuracy and plausibility, including conformance, consistency, completeness, and provenance [25-29]. The technique primarily addresses conformance to the approved LOINC code–unit pair set by the LRR table and consistency of semantic representation regardless of data source. Completeness is improved by populating the unit when null. This contextually appropriate population of absent units has not been addressed in prior studies of similar techniques [19,21].

Data Provenance

Data provenance is recognized as critical metadata for systems transmitting, storing, or using health data [30]. Records in RWD pipelines may undergo many transformations on their path to integration into a single dataset, and these transformations must all be tracked to enable error correction and improve trustworthiness with downstream consumers. Data provenance has been defined in many ways [31], and there are established specifications for recording provenance in health care data, such as the FHIR Provenance resource [32] based on the World Wide Web Consortium provenance specification [33]. Establishing the best method for provenance tracking within a system requires an assessment of the stakeholders for those data. The stakeholders for the transformations described in this paper were internal data analysts, informaticists, and quality assurance engineers. Provenance is maintained within each transformed record in an attribute that acts as a ledger of each transformation that altered that record. This attribute is an array of structures that include a descriptive, human-readable string detailing the transformation, as well as the altered attributes and preadjustment values that those attributes took. By consulting this array, transformations are fully reversible, original values are preserved, and a complete audit trail is available to support transparency and verification by downstream users.

Clinical and Research Relevance

Laboratory data quality and usability are critical in systems handling oncology data, where these results are used to select and monitor therapies and assess disease severity and progression [34]. LOINC code–unit incongruence, unit absentia, and lack of unit standardization put an undue burden on any analyst or application attempting to use laboratory data for clinical decision support, retrospective studies, or clinical trial eligibility [35,36]. Improving unit completeness at the source is challenging because units are often inconsistently documented or transmitted in EHR systems [37,38]. Potential upstream improvements could include enforcing unit capture at the point of entry, not allowing free-text entry of units, ensuring consistent transmission in Health Level Seven and FHIR messages, or applying unit standardization at the health system level before data export. However, such approaches depend on local workflows and vendor configurations and cannot be guaranteed for multisource RWD. Consequently, postcodification harmonization frameworks such as the one described in this paper provide a practical and reproducible solution. The technique outlined in this paper presents a minimal set of logical steps to correct these problems within the pipeline of a multisourced data system handling RWD. Enforcing semantic consistency between LOINC and unit improves data usability [24] but can also foster better data exchange [39] between systems by reducing semantic differences. Ultimately, this framework ensures that laboratory data are both accurate and complete, enabling faster data-driven decisions that can enhance patient care, data exchange, clinical trials, and RWD analysis.

Limitations and Future Work

The technique is presently limited by its capacity to correct the body system, which will reduce effectiveness for laboratory tests in which the potential body systems are relatively evenly distributed and share similar units when tested in either sample type. Information related to the body system can be present in the observation name but also in the panel name, the order name, discretely in another attribute in the laboratory result, or in other observations related to the result in question. Efforts are currently underway to evolve the process by incorporating panel or order-related information. The choice of SNOMED for unit may have been less ideal than UCUM [40,41], which is more flexible and more closely aligned with LOINC [42], which suggests a UCUM unit for some of its concepts. The FHIR [43] and Interoperability Standards Platform [44] also suggest that UCUM be used to represent units. However, the framework is easily adaptable by simply replacing the SNOMED codes used in the knowledge tables with UCUM codes without requiring any further changes in script. In addition, the steps described in this paper specifically address quantitative LOINC codes and require modification to be applicable to qualitative scale–type LOINC codes. Another limitation is that the creation of the knowledge tables requires clinical and terminologist expertise to recognize errors and prepare the tables, as well as a large dataset to prepare laboratory value distributions. This framework is designed for secondary use in RWD, where inconsistencies, missing values, and heterogeneous coding practices complicate analysis, and is not intended for integration into direct point-of-care clinical decision-making. Therefore, its use does not pose any direct safety risk to patients. The harmonization of LOINC code–unit combinations and the potential flagging of outlier values can influence downstream analyses such as cohort definitions or outlier detection. It enables data analysts to use laboratory data that would otherwise have required a significant time investment to clean. The primary aim of these corrections is to reduce inconsistencies and facilitate reliable data aggregation for secondary research purposes. Future work will focus on integrating the framework with emerging technologies such as artificial intelligence.

Practical Implementation

To support practical implementation, we have released a starter kit supporting normalization of 146 LOINC codes from blood or serum, covering the “Hematology and cell counts” class and “Chemistry” glucose codes. It has 3 knowledge tables and an accompanying Python script available via a public GitHub repository [45]. The knowledge tables incorporate LOINC and

XSL•FO
RenderX

SNOMED, which are maintained in multiple languages, allowing the tables to be used with datasets in different linguistic contexts. The numeric values in the tables are language independent and do not require conversion, supporting their generalizability to different languages. The Python script executing the rules takes FHIR Observation resources as input, and 6 example resources are provided.

Currently, the framework leverages SNOMED codes for units. However, the design is adaptable: implementers preferring UCUM codes can replace SNOMED codes with UCUM codes in the tables without any modification to the transformation script, allowing for seamless adoption of alternative unit standards. This flexibility ensures that the framework can be applied in diverse institutional or research contexts with minimal overhead.

A key component of the framework is its structured provenance tracking, which records all transformations applied to each laboratory record in a way that allows the original data to be reconstructed if needed. For each modification, information such as the applied rule, details of the transformation, which fields were changed, the original values, and the reference values used in the conversion is systematically captured. Collectively, these elements enable full traceability, providing a clear lineage from the transformed value back to the original measurement. This approach not only supports reproducibility and auditing but also ensures transparency, allowing researchers and data analysts to confidently interpret and validate the standardized data while retaining the ability to recover the source information.

By combining reproducible tables, adaptable unit standards, and robust provenance tracking, the framework provides a practical pathway for implementing consistent laboratory data harmonization in diverse settings while maintaining the transparency and traceability of each transformation.

Conclusions

As the demand for multisourced RWD datasets grows, ensuring data quality and semantic consistency becomes increasingly vital. Persistent challenges regarding SI in laboratory data continue to limit the full potential of these data assets. Common issues include missing or incorrect units and misassigned LOINC codes, all of which can hinder integration and analysis. This framework addresses these challenges by systematically identifying and correcting discrepancies in quantitative laboratory data and has been shown to improve unit accuracy to above 99% for all evaluated datasets. It enables scalable, system-agnostic normalization of laboratory data, addressing critical gaps in several data quality dimensions. By improving laboratory data quality at the foundational level, it strengthens the reliability of RWD for data analysis, insight generation, and utility in software applications.

Acknowledgments

The authors would like to express their sincere gratitude to the ConcertAI reviewers Sheenu Chandwani, Jannette Hanna, Jennifer Rider, and Jocelyn Benson for their constructive feedback and insightful comments, which greatly enhanced the quality of this paper.

Abstract

Background: Inflammation plays a pivotal role in the progression of diabetes and its cardiovascular complications, particularly acute myocardial infarction (AMI). Patients with AMI often face high mortality and morbidity, making accurate prognosis crucial for clinical decision-making and outcome improvement.

Objective: This study aims to develop and validate a stacked predictive model using inflammation-related indices to predict 3-year all-cause mortality among patients with severe diabetes who experience acute myocardial infarction (AMI), aiming to improve patient prognosis.

Methods: We included 833 patients with severe diabetes combined with AMI from the Medical Information Mart for Intensive Care IV (MIMIC-IV) database (training/test cohort) and 166 cases from Zhongnan Hospital, China (external validation cohort with 3-year follow-up). A total of 5 inflammation-related indices (lymphocyte-to-monocyte ratio [LMR], neutrophil-to-lymphocyte ratio [NLR], neutrophil-to-platelet ratio [NPR], platelet-to-lymphocyte ratio [PLR], prognostic inflammatory value [PIV]) were analyzed for their association with mortality using Cox proportional hazards models. Kaplan-Meier curves and restricted cubic spline analysis explored survival probabilities and dose-response relationships. A stacked predictive model incorporating these indices was constructed, and its performance was evaluated using the area under the curve.

Results: LMR was a protective factor (hazard ratio [HR] 0.44, 95% CI 0.25-0.77; P<.001), while NLR (HR 1.78, 95% CI 1.19-2.65; P=.004) and PIV (HR 1.59, 95% CI 1.09-2.30; P=.01) were associated with increased mortality risk. Kaplan-Meier analysis showed mortality increased with decreasing LMR quartiles and increasing NLR, NPR, PLR, and PIV quartiles. Restricted cubic spline confirmed that decreasing LMR and increasing NLR, NPR, PLR, and PIV were associated with higher adverse event risk. The predictive model achieved an area under the curve of 0.803 (95% CI 0.736-0.871) in internal testing and 0.781 (95% CI 0.704-0.858) in the external validation cohort.

Conclusions: The stacked predictive model serves as a robust tool for predicting 3-year outcomes in patients with diabetes combined with AMI. Its reliance on routine, low-cost indices highlights its economic viability and potential for widespread clinical implementation, particularly for optimizing resource allocation in resource-limited settings. However, considering the single-center

XSL•FO
RenderX

nature of the derivation data, future multicenter validation is essential to verify the model's generalizability across different health care systems before establishing it as a standard policy for risk stratification.

(JMIR Med Inform 2026;14:e83328) doi:10.2196/83328

KEYWORDS

3-year mortality; acute myocardial infarction; diabetes; inflammation-related indices; machine learning; prognosis

Introduction

Diabetes and its complications represent a growing global health challenge, affecting an increasing number of individuals worldwide. According to the International Diabetes Federation, an estimated 537 million individuals were living with diabetes in 2021, and this number is projected to 1.31 billion by 2050, underscoring the urgent need for effective prevention and management strategies [1].

Type 2 diabetes is characterized by systemic inflammation, driven by complex crosstalk between immune cells and β-cells, which plays a pivotal role in disease progression [2]. Importantly, inflammation not only contributes to the pathogenesis of diabetes itself but also plays a critical role in the development of its complications, including cardiovascular diseases (CVDs) such as atherosclerosis and acute myocardial infarction (AMI) [3-5].

CVD remains one of the leading causes of mortality in patients with diabetes, with AMI being one of the most devastating complications [6]. Patients with diabetes not only exhibit a higher incidence of AMI but also experience worse prognoses compared to individuals without diabetes [7]. Hyperglycemia has been implicated in these outcomes by promoting oxidative stress, endothelial dysfunction, and proinflammatory processes, including M1 macrophage polarization and enhanced monocyte adhesion to activated endothelial cells [8]. These inflammatory changes disrupt vascular homeostasis and contribute to microvascular damage [8]. Long-term prognosis in high-risk patients with diabetes combined with AMI plays a critical role in guiding clinical decision-making and improving outcomes. Prognostic studies provide valuable tools for identifying high-risk patients, enabling timely and targeted interventions to reduce mortality and improve survival rates.

Given the pivotal role of inflammation in both diabetes and AMI, there is growing interest in inflammatory markers as prognostic tools. Markers such as the lymphocyte-to-monocyte ratio (LMR), neutrophil-to-platelet ratio (NPR), platelet-to-lymphocyte ratio (PLR), neutrophil-to-lymphocyte ratio (NLR), and prognostic inflammatory value (PIV) have been widely used to reflect systemic inflammation and predict outcomes in CVDs and cancers [9-12]. Importantly, these indices derived from complete blood count (CBC) inherit its advantages of being stable, cost-effective, and widely accessible, making them potentially applicable for routine clinical use and large-scale prognostic studies. However, whether these inflammatory markers could be used for predicting clinical outcomes of patients with diabetes combined with AMI remains unclear. To address this gap, we leveraged data from the Medical Information Mart for Intensive Care IV (MIMIC-IV) database and the Department of Critical Care Medicine, Zhongnan Hospital of Wuhan University, China, to systematically compare and evaluate the prognostic utility of LMR, NPR, PLR, NLR, and PIV in predicting long-term mortality risk and clinical outcomes in this vulnerable population.

Methods

Ethical Considerations

This study adheres to the principles declared in the Declaration of Helsinki and STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guidelines and was approved by the Medical Ethics Committee of Zhongnan Hospital of Wuhan University (approval: 2020009). The Institutional Review Board of Beth Israel Deaconess Medical Center (BIDMC) granted a waiver of informed consent and approved the sharing of research resources. The authors obtained access to the MIMIC-IV database (certificate number: 65461627).

Source of Data

This study conducted a retrospective analysis using the large, publicly available intensive care database MIMIC-IV (version 3.0).

For external validation, data were obtained from Zhongnan Hospital of Wuhan University, China. This cohort included 166 patients admitted between January 1, 2021, and June 30, 2022. The final follow-up for outcome ascertainment was completed on July 22, 2025, by hospital record review and telephone interviews. During this period, 56 mortality events were recorded.

Case Inclusion and Exclusion Criteria

Patients diagnosed with both diabetes and AMI were included in this study. Patient identification was based on diagnostic codes from the *ICD-9* (*International Classification of Diseases, Ninth Revision*), and the *ICD-10* (*International Statistical Classification of Diseases, Tenth Revision*). AMI and diabetes mellitus were identified using *ICD-9* and *ICD-10* codes.

The exclusion criteria were as follows: (1) age <18 years; (2) an intensive care unit (ICU) stay of <24 hours; (3) multiple admissions, with only data from the first hospitalization included; and (4) missing data on lymphocyte, monocyte, neutrophil, or platelet count levels.

Data Extraction

The *psql* tool of PostgreSQL was used to extract the data. Laboratory variables were extracted from the first result recorded within 24 hours of ICU admission. Features with a missing data rate exceeding 30% were excluded, while multiple

XSL•FO
RenderX

imputation was applied to those with a missing data rate below 30%. Missing data were handled using multiple imputation by chained equations. We used the predictive mean matching method with 5 imputations (m=5) and set the random seed to 1 for reproducibility. All predictor variables were included in the imputation model.

The LMR was calculated as lymphocyte count (10^9/L) / monocyte count (10^9/L), NPR as neutrophil count (10^9/L) / platelet count (10^9/L), the PLR as platelet count (10^9/L) / lymphocyte count (10^9/L), the NLR as neutrophil count (10^9/L) / lymphocyte count (10^9/L), and the PIV as lymphocyte count (10^9/L) × platelet count (10^9/L) × monocyte count (10^9/L)/ lymphocyte count (10^9/L) [10-12].

Time-Zero Alignment

All predictor variables (including CBC components and inflammatory indices) were extracted as the first recorded value on admission to prevent any look-ahead bias. To ensure transportability, this identical protocol—using the admission baseline—was applied to the external validation cohort.

Outcomes

The start date of follow-up was defined as the date of hospital admission, and the study outcome was 3-year mortality.

Statistical Analysis

As this study is a retrospective analysis, sample size calculations were not performed. For categorical variables, the chi-square test or Fisher exact test was performed for analysis. Student 2-tailed *t* test and the Wilcoxon rank-sum test were used for continuous variables. Kaplan-Meier (K-M) curves and Cox proportional hazards models were used to determine the relationships between LMR, NPR, PLR, NLR, PIV, and the risk of mortality. In Model 1, adjustments were made for age, gender, BMI. In Model 2, further adjustments were made for age, gender, BMI, troponin T, creatine kinase isoenzymes (CK-MB), insulin, history of revascularization (percutaneous coronary intervention and coronary artery bypass grafting), hyperlipidemia, atrial fibrillation, and stroke. Subgroup analysis was performed to examine the relationship between the continuous inflammation index and 3-year mortality across different subgroups. Restricted cubic spline (RCS) analysis was conducted to explore the associations between the 5 indices and mortality in a dose–response manner.

Feature Selection

The variance inflation factor (VIF) was used to assess multicollinearity among features. Features with a VIF greater than 5 were removed due to concerns about multicollinearity (Table S1 in Multimedia Appendix 1).

To identify the most important features associated with prognosis, the Boruta (version 9.0.0; R packages) algorithm was used. As a robust feature selection method, Boruta identifies all relevant predictors by iteratively comparing the importance of real features with random shadow features. Features marked as important (green) were selected for subsequent machine learning model construction.

Construction and Validation of Predictive Models

To construct the predictive model, the important features were identified using the Boruta algorithm. Subsequently, the dataset was randomly split into a training set (666/833, 80%) and a testing set (176/833, 20%) with a fixed random seed of 123. Machine learning models were then developed using the H2O AutoML platform (version 3.44.0.3) in R (R Foundation for Statistical Computing). The AutoML process was configured with the following hyperparameters: maximum number of models = 200, maximum runtime = 24 hours, and class balancing enabled (balance_classes = TRUE) to address outcome imbalance. Finally, models were ranked based on the area under the curve (AUC), and a stacked ensemble model was generated using the top-performing base models.

Each base model was trained on prognostic outcomes derived from the training data, and prognostic scores for each patient were calculated and scaled to a range of 0 to 1, with higher scores indicated worse prognosis. An ensemble method was then applied by compiling the top 5 base models, ranked according to their area under the receiver operating characteristic curve, into a matrix of prognostic scores. A second-layer generalized linear model algorithm was then used to create the final model. Five-fold cross-validation was performed during model training to minimize overfitting and ensure the robustness of the results. A probability threshold of .5 was used to classify patients into high- and low-risk groups for the confusion matrix analysis.

Here, 5 inflammation-related indices—LMR, NPR, PLR, NLR, and PIV—were also selected as features for model construction. Separate models were built for each individual feature following the methodology described above. Additionally, a stacked ensemble model incorporating all 5 indices was constructed to explore their combined predictive performance.

Results

Baseline Characteristics

Following the inclusion and exclusion criteria, 833 patients with diabetes combined with AMI from the MIMIC-IV database were used as the training and test cohorts, and 166 cases from Zhongnan Hospital of Wuhan University, China, were enrolled as an external validation cohort. Figure 1 illustrates the flow of patient selection for this study.

XSL•FO
RenderX

Figure 1. Patient screening and feature selection. Inclusion and exclusion criteria for patients from the Medical Information Mart for Intensive Care IV (MIMIC-IV) database. AMI: acute myocardial infarction; ICU: intensive care unit.

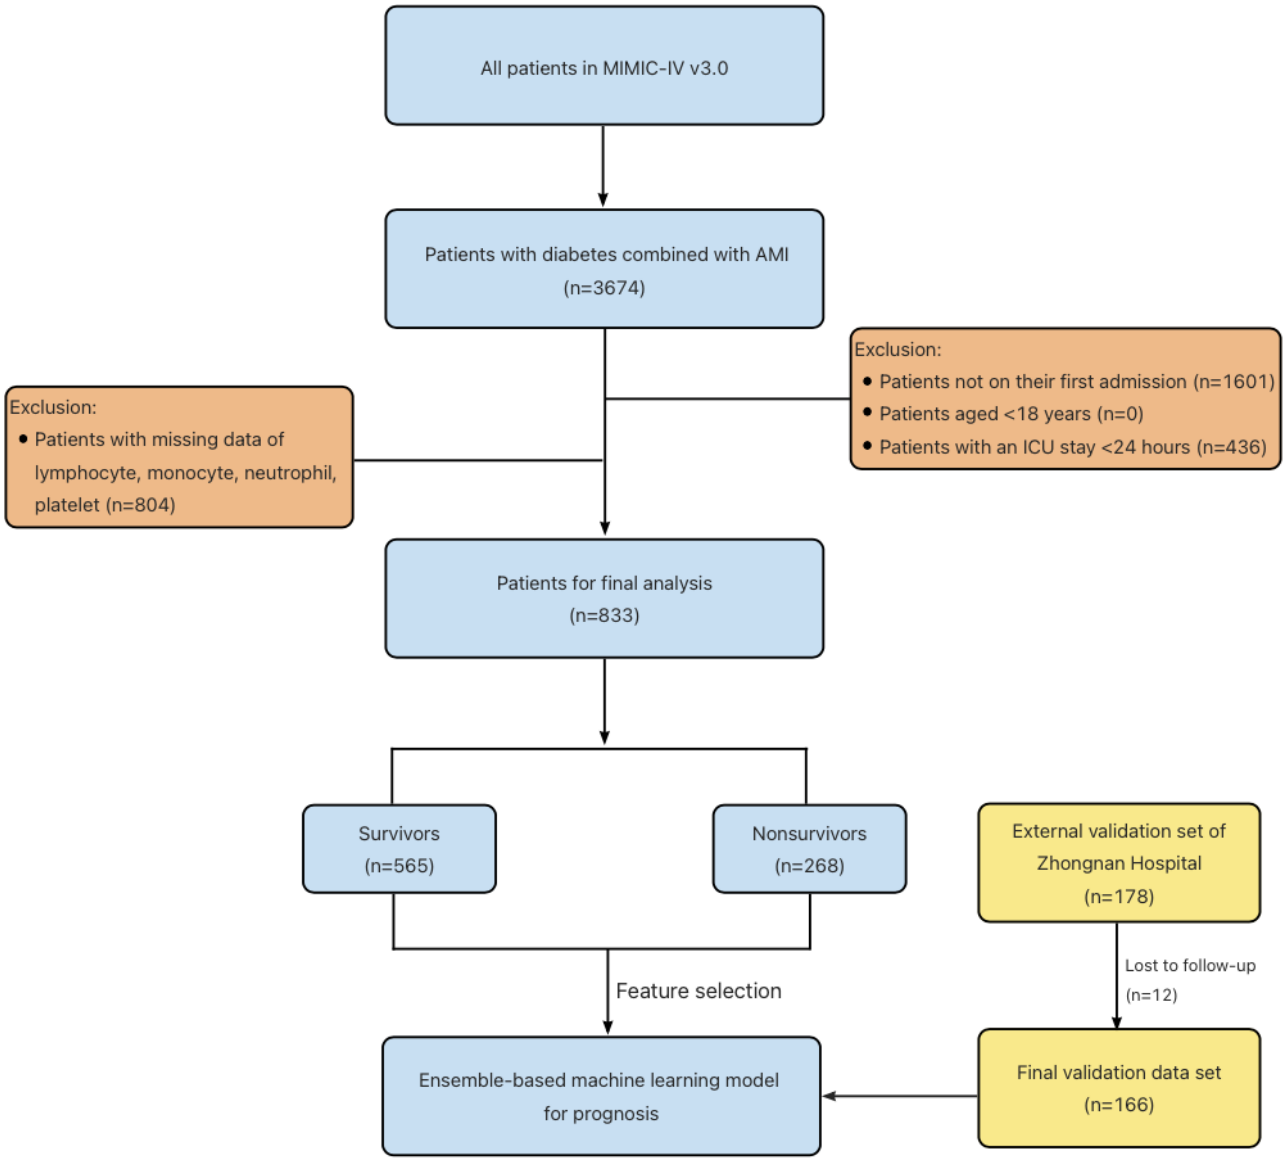

Table 1 provides a detailed comparison of baseline characteristics between survivors and nonsurvivors in the MIMIC-IV cohort (n=833), based on the 3-year mortality outcomes. Overall, the nonsurvivors were older and had a lower proportion of males compared with survivors. Among the comorbidities, the nonsurvivors exhibited significantly higher incidences of stroke, atrial fibrillation, and heart failure. Notably, the proportion of patients undergoing coronary artery bypass grafting was significantly lower in the nonsurvivor group. The nonsurvivors also exhibited significant differences in vital signs, including higher heart rate and respiratory rate, as well as higher diastolic blood pressure. As for laboratory parameters, the nonsurvivors had markedly elevated levels of mean corpuscular volume, red cell distribution width, white blood cells, phosphate, potassium, magnesium, alkaline phosphatase, creatinine, and urea nitrogen, suggesting metabolic and immune disturbance. Furthermore, inflammation-related indices also differed significantly between the 2 groups, with nonsurvivors exhibiting higher levels of NPR, PLR, NLR, and PIV, while LMR was lower. However, there was no significant change in troponin T or CK-MB between the survivors and nonsurvivors, demonstrating that these 2 markers typically show a significant increase during the acute phase of myocardial infarction and decrease rapidly during the recovery phase. These findings suggest that CBC-derived inflammation-related indices hold promise for predicting long-term prognosis in patients with diabetes combined with AMI.

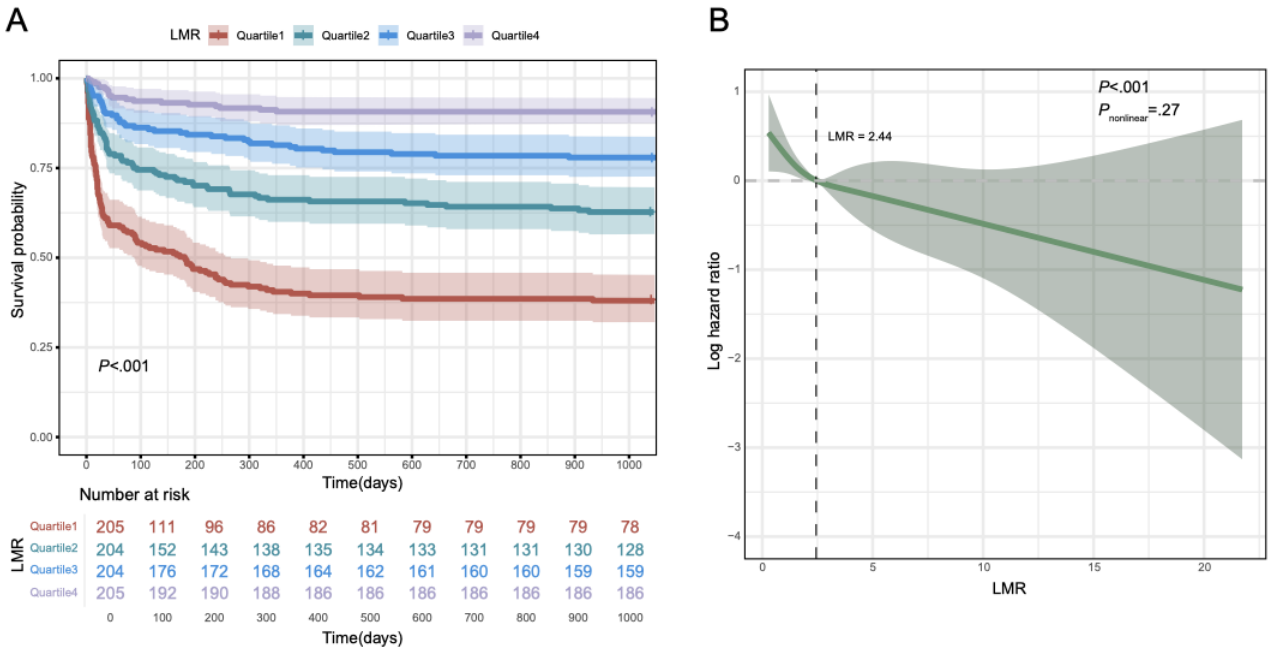
For the external validation cohort (n=166), baseline analysis focused specifically on CBC data and indices in the prognostic model (LMR, NLR, NPR, PIV, and PLR). The detailed comparison between survivors and nonsurvivors based on the 3-year mortality outcomes are presented in Table S2 in Multimedia Appendix 1.

Associations Between the Inflammation-Related Indices and Mortality Risk



Cox proportional hazards analysis identified significant associations between inflammation-related indices (LMR, NPR, PLR, NLR, and PIV) and 3-year mortality risk (Table S3 in Multimedia Appendix 1). LMR was determined to be a protective factor, while NPR, PLR, NLR, and PIV were associated with an increased risk of mortality. These findings underscore the prognostic value of systemic inflammation markers in predicting long-term outcomes in this population.

LMR and Mortality Risk

Patients were stratified into quartiles based on LMR values: quartile 1 (LMR≤1.17; n=205), quartile 2 (1.17<LMR≤2.48; n=204), quartile 3 (2.48<LMR≤4.60; n=204), and quartile 4 (LMR>4.60; n=205). In Cox proportional hazards models, quartiles 2, 3, and 4 were significantly associated with reduced 3-year mortality risk compared to quartile 1, in both unadjusted and adjusted models (Table S3 in Multimedia Appendix 1). K-M survival analysis further demonstrated that patients in quartile 1 had the lowest 3-year survival probability, indicating the detrimental impact of low LMR (Figure 2A). RCS analysis revealed a decreasing trend between LMR and mortality risk, with a critical inflection point at LMR=2.44 (Figure 2B). Below this threshold, lower LMR values were strongly associated with increased mortality risk.

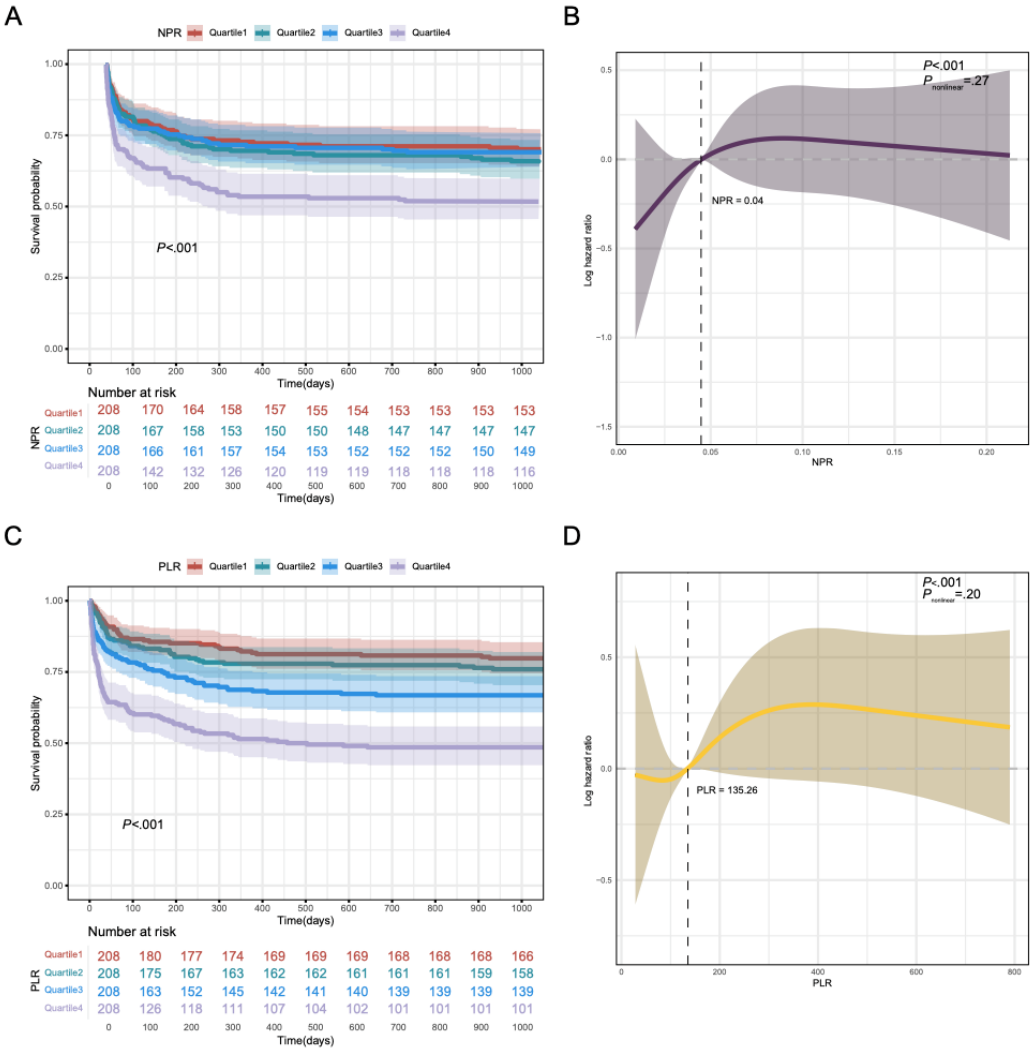
RenderX

Figure 2. Kaplan Meier (K-M) survival analysis curves and restricted cubic spline (RCS) regression analysis of lymphocyte-to-monocyte ratio (LMR) for 3-year mortality. (A) K-M curves of LMR. (B) RCS analysis of LMR.



NPR and Mortality Risk

For NPR, patients were divided into 4 quartiles: quartile 1 (NPR≤0.033), quartile 2 (0.033<NPR≤0.046), quartile 3 (0.046<NPR≤0.064), and quartile 4 (NPR>0.064). In the unadjusted model, higher NPR values were significantly associated with increased mortality risk. However, this association was attenuated and lost statistical significance after adjustment for potential confounders (Table S3 in Multimedia Appendix 1). K-M survival analysis demonstrated that patients in quartile 4 (highest NPR) had the lowest 3-year survival probability compared with other quartiles, underscoring the detrimental impact of elevated NPR values (Figure 3A). RCS analysis revealed a nonlinear trend in the association between NPR and mortality risk, with a potential threshold observed around NPR=0.04. However, the test for nonlinearity did not reach statistical significance ($P_{\text{nonlinearity}}$=.27), suggesting that a linear relationship between these variables cannot be excluded (Figure 3B).

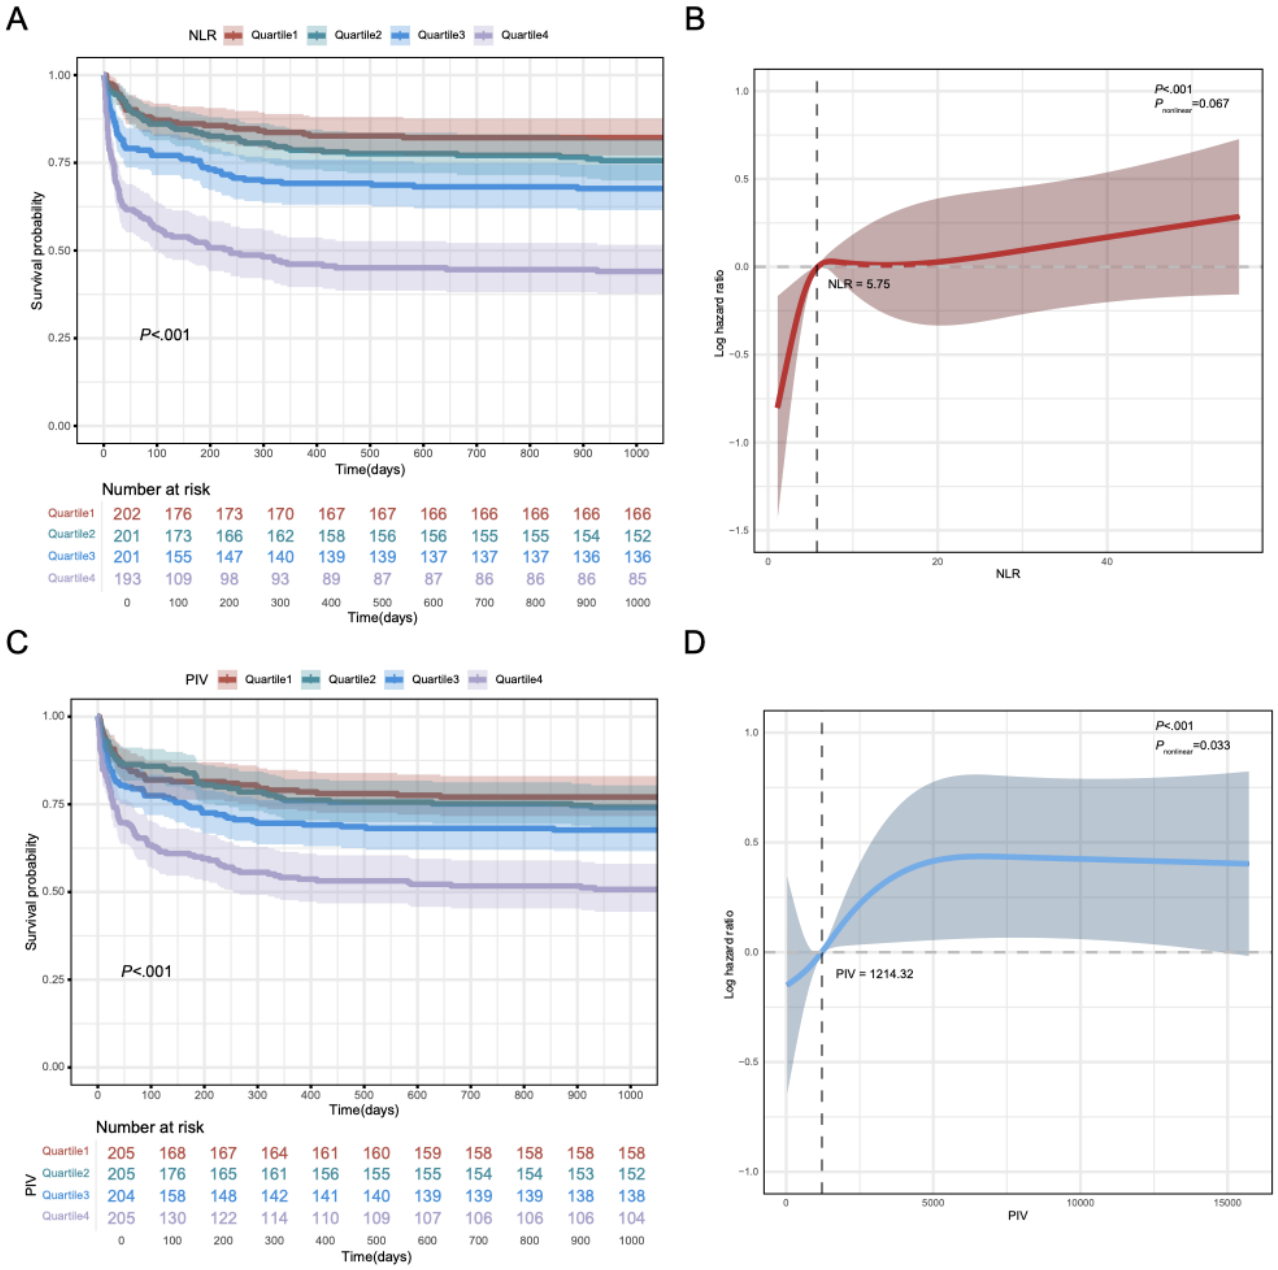
Figure 3. Kaplan-Meier (KM) survival analysis curves and restricted cubic spline (RCS) regression analysis of neutrophil-to-platelet ratio (NPR) and platelet-to-lymphocyte ratio (PLR) for 3-year mortality. (A) K-M curves of NPR. (B) RCS analysis of NPR. (C) K-M curves of PLR. (D) RCS analysis of PLR.

PLR and Mortality Risk



PLR was categorized into quartile 1 (PLR≤83.50), quartile 2 (83.50<PLR≤134.37), quartile 3 (134.37<PLR≤255.65), and quartile 4 (PLR>255.65). In the unadjusted model, higher PLR values were associated with increased mortality risk. However, after adjustment for confounding variables, this association was no longer statistically significant, suggesting potential confounding effects (Table S3 in Multimedia Appendix 1). K-M survival analysis demonstrated that patients in quartile 4 (highest PLR) had the lowest 3-year survival probability, consistent with the hypothesis that elevated PLR reflects a heightened inflammatory state (Figure 3C). RCS analysis indicated that as PLR increased, mortality risk also increased, with a notable value at PLR=135.26 (Figure 3D).

NLR and Mortality Risk

NLR quartiles were defined as follows: quartile 1 (NLR≤3.50), quartile 2 (3.50<NLR≤5.86), quartile 3 (5.86<NLR≤10.62), and quartile 4 (NLR>10.62). In both unadjusted and adjusted Cox proportional hazards models, patients in quartile 4 (highest NLR) exhibited a significantly increased risk of 3-year mortality compared with those in lower quartiles (Table S3 in Multimedia Appendix 1). K-M survival analysis further demonstrated that quartile 4 had the lowest 3-year survival probability, indicating the adverse prognostic impact of elevated NLR (Figure 4A). RCS analysis indicated that lower NLR values were associated with lower mortality risk, whereas higher NLR values significantly increased mortality risk, especially beyond a threshold of 5.75. Although the *P*=.07 suggests the nonlinear relationship was not fully significant, the trend between NLR and mortality risk is noteworthy (Figure 4B).

RenderX

Figure 4. Kaplan-Meier (KM) survival analysis curves and restricted cubic spline (RCS) regression analysis of neutrophil-to-lymphocyte ratio (NLR) and prognostic inflammatory value (PIV) for 3-year mortality. (A) K-M curves of NLR. (B) RCS analysis of NLR. (C) K-M curves of PIV. (D) RCS analysis of PIV.

PIV and Mortality Risk

For PIV, the quartiles were defined as quartile 1 (PIV≤550.46), quartile 2 (550.46<PIV≤1207.40), quartile 3 (1207.40<PIV≤2619.32), and quartile 4 (PIV>2619.32). Similarly, in both unadjusted and adjusted Cox models, quartile 4 (highest PIV) was significantly associated with increased 3-year mortality risk compared with lower quartiles (Table S3 in Multimedia Appendix 1). K-M survival analysis demonstrated that patients in quartile 4 had the lowest 3-year survival probability (Figure 4C), suggesting an association between elevated PIV and poor outcomes. The RCS curve shows that 1214.32 is a risk turning point; beyond this value, risk increased significantly (Figure 4D).

Stratified Analyses

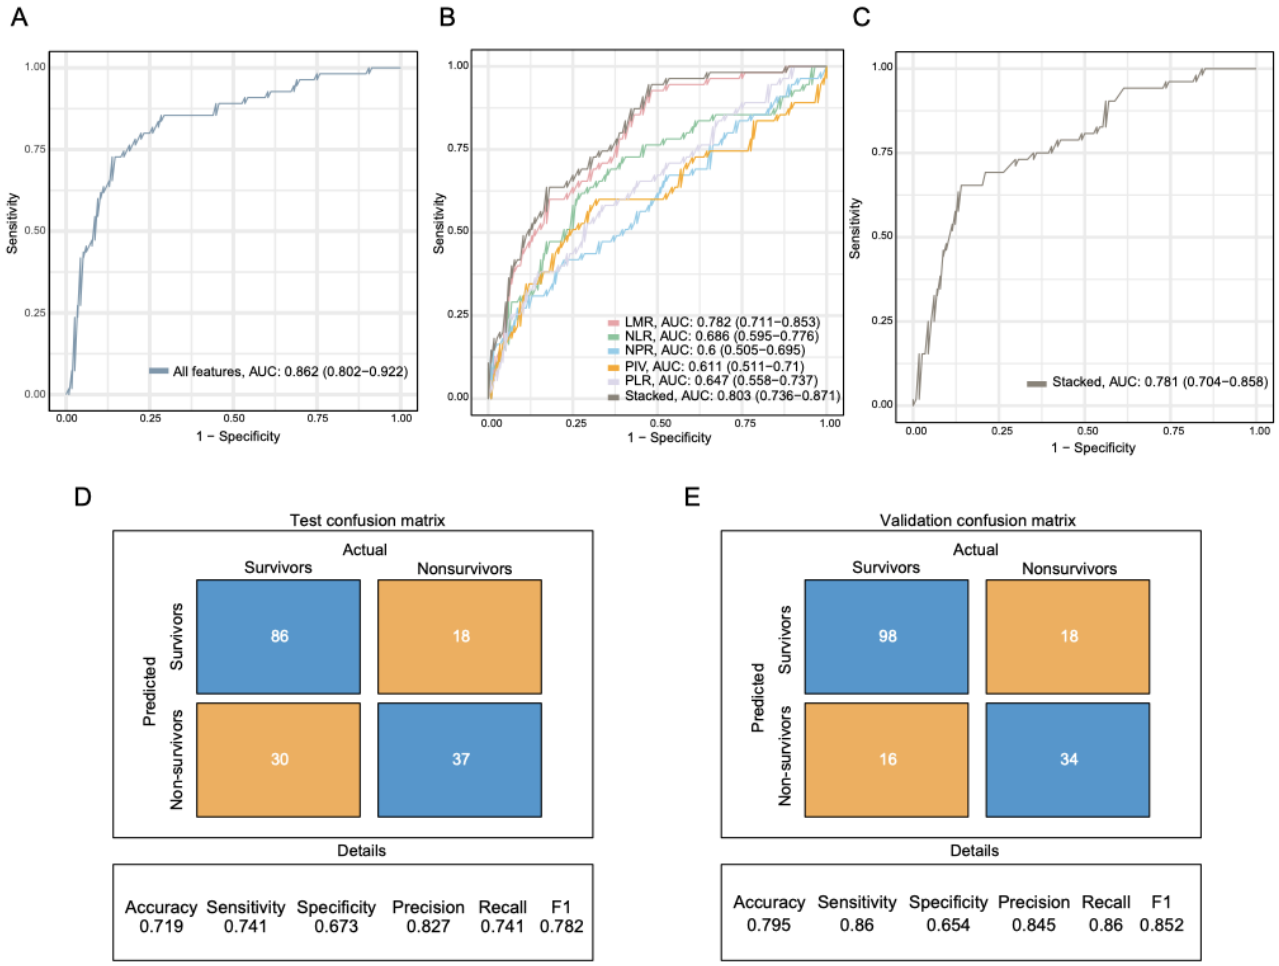
To further explore whether the relationship between inflammation-related indices and 3-year all-cause mortality persists under different conditions, subgroup analyses were conducted based on gender, age, BMI, hypertension, and hyperlipidemia. In the subgroup of patients aged ≥60 years, the hazard ratios (HRs) for all indices related to 3-year all-cause mortality were significant (Figures S1 and S2 in Multimedia Appendix 2). However, in the subgroup of patients aged <60 years, the HRs for NPR, PLR, and PIV did not show statistical significance. Furthermore, the HR for NPR was not statistically significant in the subgroup of patients with BMI<18 kg/m^2 and the subgroup of patients with hypertension. Similarly, the HRs for NPR and PIV were not statistically significant in the

XSL•FO
RenderX

subgroup of patients with BMI>28 kg/m^2 (Figures S1 and S2 in Multimedia Appendix 2).

Feature Selection

Initially, we compared the prognostic performance of individual CBC counts (lymphocyte, monocyte, neutrophil, and platelet counts) with inflammation-related indices using Cox regression models. The C-index values for individual cell counts ranged from 0.62 to 0.68, significantly lower than those of composite indices (0.72-0.79; Figure S3 in Multimedia Appendix 2). This disparity highlights the limited utility of isolated cell counts in capturing systemic inflammatory states. Given that the inflammation-related indices are derived from these individual cell counts, they inherently exhibit a higher degree of collinearity. Therefore, to focus more on the inflammation-related features themselves and minimize the impact of collinearity in the analysis, we excluded the individual immune cell counts before performing the VIF calculation.



We then examined the VIF to detect multicollinearity among variables, and features with a VIF>5 were removed (Table S1 in Multimedia Appendix 1). Subsequently, feature selection was performed using the Boruta algorithm, in which variables in the green area were identified as important features, whereas those in the red area were deemed unimportant (Figure S4 in Multimedia Appendix 2). Both CK-MB and troponin T were classified as unimportant (red box in Figure S4 in Multimedia Appendix 2), corroborating their limited prognostic value observed in baseline and Cox analysis (Table 1 and Figure S3 in Multimedia Appendix 2). This exclusion by the algorithm suggests that, although CK-MB and troponin T are critical for diagnosing acute myocardial injury, their transient elevation may not reflect the chronic inflammatory processes that drive long-term mortality in patients with diabetes combined with AMI.

Development and Validation of an Ensemble Machine Learning Model for Prognostic Prediction

After feature selection, we constructed a stacked model using all the important features, achieving an AUC of 0.862 in the test cohort (Figure 5A). To further explore the effectiveness of inflammation-related indices in predicting mortality risk in patients with diabetes combined with AMI, we built models based on individual inflammation-related indices, with AUCs of 0.782, 0.686, 0.598, 0.611, and 0.648 for LMR, NLR, NPR, PIV, and PLR, respectively, in the test cohort. We also combined these 5 indices into a stacked model, which achieved an AUC of 0.803 in the test cohort (Figure 5B; detailed parameters are shown in Figure 5D). Importantly, this combined inflammation-related indices model demonstrated robust generalizability, achieving an AUC of 0.781 in the external validation cohort (Figure 5C), with its predictive performance detailed in the confusion matrix (Figure 5E).

XSL•FO
RenderX

Figure 5. Receiver operating characteristic (ROC) curves of the machine learning prognostic models. (A) ROC curve for the model constructed using all important features in the test cohort. (B) ROC curves for models based on individual inflammation-related indices (lymphocyte-to-monocyte ratio [LMR], neutrophil-to-lymphocyte ratio [NLR], neutrophil-to-platelet ratio [NPR], prognostic inflammatory value [PIV], platelet-to-lymphocyte ratio [PLR]) and their combined model in the test cohort. (C) ROC curve for the combined inflammation-related indices model in the external validation cohort (area under the curve [AUC]=0.781). (D) Confusion matrix for the combined inflammation-related indices model in the test cohort. (E) Confusion matrix for the combined inflammation-related indices model in the external validation cohort.

Although the combined model performed slightly worse than the model using all important features in the test cohort, it demonstrated comparable and generalizable prognostic ability. The combined inflammation-related indices model may contribute to future prognostic prediction by offering a simplified and cost-effective alternative for clinical applications.

Beyond discrimination, we evaluated the calibration and clinical utility of the model. The calibration plots displayed good agreement between predicted probabilities and observed outcomes, with Brier scores of 0.146 in the validation set and 0.155 in the external cohort (Figure S5 in Multimedia Appendix 2). Furthermore, decision curve analysis (DCA) indicated that the model provided a substantial net benefit over the "treat-all" or "treat-none" strategies across a wide range of threshold probabilities in both cohorts (Figure S5 in Multimedia Appendix 2).

In the external validation cohort, we also evaluated an enhanced model incorporating readily available vitals (age, heart rate, blood pressure, respiration rate). This "Indices + Vitals" model showed marginal improvement (AUC=0.788) and overlapping net benefit curves in DCA (Figure S6 in Multimedia Appendix 2), supporting the use of the 5-index model as a parsimonious stand-alone tool.

We further compared the stacked model with the best-performing single index LMR (Figure S8 in Multimedia Appendix 2). Although the improvements in net reclassification improvement and discrimination improvement were not statistically significant, the stacked model demonstrated superior overall performance. Specifically, it achieved a higher AUC (0.781 vs 0.771 in external validation) and, more importantly, better calibration (Brier score: 0.155 vs 0.183; calibration slope: 1.589 vs 3.147), suggesting that the multi-index approach provides more robust and accurate risk estimates than any single biomarker.

Application of the Model

Using the above model, we developed a web tool to predict the prognosis of patients with diabetes and acute myocardial infarction (Figure S9 in Multimedia Appendix 2). Users can get prediction results by directly inputting features on the web page [13].

Discussion

Overview

To the best of our knowledge, this study is the first to systematically compare 5 inflammation-related indices (LMR, NLR, NPR, PLR, and PIV) derived from CBC in relation to the 3-year mortality risk of patients with diabetes combined with AMI, and to explore their potential application in predicting long-term mortality risk. The findings indicate that inflammation may play a critical role in the long-term prognosis of patients with diabetes combined with AMI. By constructing both single-indicator models and combined predictive models, we demonstrated that these inflammation indices can effectively assess mortality risk while also providing a reference for rapid and straightforward clinical risk assessment methods. Interestingly, adding readily available vital signs to the inflammation-related indices provided limited incremental value in the external cohort, with minimal improvement. This suggests that the 5-index model may offer a streamlined tool for risk stratification (Figure S6 in Multimedia Appendix 2).

From a clinical perspective, the proposed model primarily relies on routine CBC components, which are widely available, rapid, and inexpensive. This accessibility could make the model a potentially useful tool for early risk stratification in settings such as emergency departments and ICUs, potentially helping clinicians to prioritize resource allocation.

The prognostic value of these CBC-derived inflammation-related indices likely stems from the synergistic pathophysiology of diabetes and AMI. The chronic hyperglycemia and insulin resistance unique to patients with diabetes induce low-grade chronic inflammation, which not only exacerbates cardiovascular damage but also drives disease progression through various mechanisms [14]. When AMI occurs, it triggers an acute stress response involving the sympathetic nervous system and the hypothalamic–pituitary–adrenal axis [15]. Both chronic metabolic inflammation and acute ischemic injury leads to a profound dysregulation of hematopoiesis, manifesting as the specific alterations in leukocytes and platelets observed in this study [16].

The elevated risk associated with high NLR, PLR, and PIV can be mechanically explained by the exacerbated proinflammatory and prothrombotic phenotype in patients with diabetes. Hyperglycemia and insulin resistance prime neutrophils to overreact during myocardial ischemia. A critical mechanism linking these cells to poor prognosis is the formation of neutrophil extracellular traps. In a diabetic environment, activated neutrophils release excessive neutrophil extracellular traps, which not only directly damage cardiomyocytes but also serve as a scaffold for platelet aggregation and thrombosis [17,18]. This interaction is particularly detrimental in AMI, as it contributes to microvascular obstruction and extends the infarct size [19]. Furthermore, diabetic platelets exhibit surface protein glycation and increased reactivity, making them more prone to adhering to leukocytes [20]. PIV (the systemic immune-inflammation index), which integrates neutrophils, platelets, and monocytes, essentially captures this extensive interplay between coagulation and inflammation, explaining its strong association with mortality in our cohort of patients with diabetes.

Conversely, the protective role of LMR highlights the importance of adaptive immunity in healing. Lymphocytes, particularly regulatory T cells, are essential for transitioning the immune response from the inflammatory phase to the reparative phase [21]. However, in patients with diabetes complicated by AMI, lymphocytes face dual suppression: chronic oxidative stress from hyperglycemia induces lymphocyte apoptosis, while the acute cortisol surge from AMI causes massive lymphopenia [22,23]. This severe depletion of lymphocytes impairs the containment of the inflammatory storm. Simultaneously, hyperglycemia promotes differentiation of monocytes into the proinflammatory M1 phenotype rather than the reparative M2 phenotype, further delaying scar healing and promoting adverse ventricular remodeling [24,25]. Therefore, a reduced LMR serves as a composite marker indicating an uncontrolled inflammatory response correlating with worse long-term survival.

The elevated levels of NLR, PLR, NPR, and PIV may reflect a proinflammatory state driven by interactions among platelets, neutrophils, and lymphocytes, which could be a critical driver of poor prognosis in patients with diabetes and CVDs. For instance, PIV, as an integrative inflammatory marker, captures the interplay between platelets, neutrophils, and lymphocytes. Studies have shown that elevated PIV levels are associated with worse outcomes in patients with hypertension [20]. Additionally, previous research has demonstrated that high NLR and PLR values are not only independent predictors of in-hospital mortality in patients with heart failure but are also closely associated with the risk of cardiac death [26,27]. Elevated NLR may indicate enhanced proinflammatory neutrophil activity and impaired lymphocyte function, whereas increased PLR may reflect both platelet activation and reduced lymphocyte-mediated immune function. In contrast, NPR primarily reflects the ratio between neutrophils and platelets, and its elevation has been associated with worse outcomes in patients with myocardial infarction with nonobstructive coronary arteries [28].

The protective role of LMR and the risk-associated roles of NLR, NPR, PLR, and PIV further underscore the critical importance of systemic inflammation and immune balance in the prognosis of patients with diabetes combined with AMI. These mechanisms suggest that protective and risk-related inflammatory markers may influence the prognosis of patients with diabetes combined with AMI through distinct pathways, providing a theoretical basis for future research on underlying mechanisms and advancements in diagnostic and therapeutic strategies.

In addition, the findings of this study highlight the significant value of inflammation-related indices in predicting the long-term prognosis of patients with diabetes combined with AMI.

Compared with traditional complex biomarkers or imaging techniques, these inflammation indices are derived from CBC, which is a widely available and affordable diagnostic tool. Furthermore, CBC results are highly stable and reproducible, making them reliable for both research and clinical practice [29]. These advantages highlight their practicality and feasibility

XSL•FO
RenderX

for preliminary prognostic assessment in patients with diabetes combined with AMI. The combined predictive model constructed based on these 5 indices (AUC=0.803) demonstrated a predictive ability comparable to that of the full importance features model (AUC=0.862). Moreover, our DCA confirmed that using this model to guide clinical decisions provides a higher net benefit than default strategies across a wide range of threshold probabilities (Figures 5A and B in Multimedia Appendix 2). By identifying high-risk patients, such prognostic models may facilitate early clinical interventions and potentially improve survival rates.

Limitations

Despite confirming the potential role of inflammation-related indices in predicting the long-term prognosis of patients with diabetes combined with AMI, this study has several limitations.

First, the regulatory mechanisms of inflammation in diabetes and AMI are highly complex, with different types of inflammatory cells potentially exerting bidirectional effects during disease progression. This intricate cellular regulation may not be fully captured by simplified inflammation-related indices.

Second, although 5 commonly used inflammation-related indices were analyzed, other potentially important inflammatory markers (eg, interleukin 6 and tumor necrosis factor α) were not included, which may underestimate the comprehensive impact of inflammation. Additionally, these indices primarily reflect systemic inflammation and may not adequately capture the influence of local immune microenvironments.

Third, a direct comparison with established scoring systems, such as the Global Registry of Acute Coronary Events or the Thrombolysis in Myocardial Infarction score, was not feasible in this study. Critical variables required for these scores—specifically cardiac arrest at admission, Killip classification, and coronary artery stenosis severity—were not systematically recorded or exhibited high levels of missingness in the structured electronic health records of the MIMIC-IV database. Regarding clinical utility, the DCA results suggest that using our model to guide clinical decisions would yield a net benefit over default strategies within a broad threshold range. However, the observed calibration drift in the external validation cohort highlights the heterogeneity between populations (Figures 5A and B in Multimedia Appendix 2). While the model's discriminative power remains robust, this finding emphasizes the necessity of model recalibration to adjust for baseline risk differences before local clinical implementation.

Fourth, the external validation was asymmetrical. While the primary 5-index model was successfully validated externally, we could not validate the full model containing ancillary covariates because these specific variables were not available in the external center's dataset. This limitation restricts the generalizability of the covariate-adjusted analysis to the derivation cohort.

Fifth, while MIMIC-IV provides a large-scale, high-quality dataset, it represents a single-center experience in the United States. Consequently, practice patterns, patient demographics, and admission criteria may differ from those in other institutions or countries, potentially limiting the direct generalizability of our findings. Although external validation was performed to assess transportability, future multicenter prospective studies are widely recommended.

Finally, regarding model transparency, while our model demonstrated excellent calibration in the internal validation, calibration drift was observed in the external validation cohort (Figures 5C and D in Multimedia Appendix 2), showing a tendency to underestimate risk in the new population. This suggests that while the model is effective for risk ranking, it may require recalibration using local data to optimize absolute probability estimates for different clinical settings.

Abstract

Background: Accurate preoperative prediction of renal tumor malignancy is critical for guiding decisions and reducing overtreatment, as a substantial proportion of renal masses prove benign. Although radiology assessments and structured electronic health record (EHR) data are routinely used, many tumor-specific descriptors remain embedded in free-text radiology reports and are underused due to extraction challenges.

Objective: This study aimed to develop and evaluate a multimodal pipeline that integrates structured EHR variables with natural language processing features from computed tomography (CT) radiology reports, including large language model (LLM)–extracted abnormality characteristics and transformer-based report embeddings, to improve malignancy prediction.

Methods: We conducted a retrospective cohort study using University of Florida Health Integrated Data Repository Observational Medical Outcomes Partnership–mapped EHR data from December 2011 to August 2024. Adults with renal tumors were included if they had longitudinal diagnostic documentation consistent with a renal mass and at least 1 preoperative renal CT report; final benign or malignant status served as the outcome. Structured features included demographics, comorbidities, medications, vital signs, and laboratory measurements. From the recent preindex CT report, an on-premises LLM isolated kidney-specific findings and extracted abnormality characteristics. Four locally deployed LLMs were evaluated against manual annotations of 500 reports. Kidney-specific text was encoded using pretrained biomedical transformer models, including radiology Bidirectional Encoder Representations from Transformers (BERT) variants. We evaluated unimodal baselines and multimodal early, middle, and late fusion strategies. Model development used 5-fold cross-validation within the 80% training partition; each fold-specific model was evaluated on the same independent 20% held-out test set, with performance reported as mean and SD across the 5 held-out test evaluations. The primary metric was area under the receiver operating characteristic curve (AUC).

Results: The final cohort included 967 patients (n=712, 73.6% malignant). In extraction evaluation, Qwen2.5-32B achieved 88.3% overall accuracy with a 100% extraction success rate and was selected for downstream feature generation. Among unimodal models, the structured clinical variable model achieved an AUC of 0.758 (SD 0.012), kidney-specific text with radiology BERT achieved an AUC of 0.746 (SD 0.058), and abnormality characteristics alone achieved an AUC of 0.716 (SD 0.015). Multimodal fusion models achieved higher descriptive performance than unimodal models. Early fusion achieved the highest AUC (mean 0.813, SD 0.008), and F_1-score (mean 0.809, SD 0.030), while late fusion achieved an AUC of 0.805 (SD 0.016). Ablation and interpretability analyses suggested complementary predictive information from structured clinical variables and kidney-specific text embeddings.

Conclusions: Integrating unstructured radiology report text with structured EHR variables achieved higher mean predictive performance than unimodal approaches in descriptive comparisons. Multimodal fusion, particularly early fusion incorporating

XSL•FO
RenderX

radiology BERT–derived kidney-specific text embeddings, achieved the strongest discrimination, suggesting potential value of natural language processing–enabled multimodal EHR pipelines for informing preoperative risk stratification.

Introduction

Kidney cancer (KC) is the seventh most common cancer in the United States, with renal cell carcinoma (RCC) accounting for approximately 90% of cases [1,2]. In 2025, a total of 80,980 new RCC cases were estimated, with over 64.7% occurring in males [3]. Early-stage KC is often asymptomatic, and more than half of cases are detected incidentally during abdominal imaging [4]. While surgical resection, partial or radical nephrectomy, remains the primary treatment, nearly 25% of these small tumors prove to be benign postoperatively [5,6]. These unnecessary surgeries expose patients to potential complications without therapeutic benefit, underscoring the urgent need for improved preoperative risk stratification.
